Preface

Experimental Models of Multiple Sclerosis

Multiple Sclerosis (MS) is an enigmatic immune-mediated disease of the central nervous system that affects around 350,000 individuals in the United States. The pathologic hallmarks of this disease are inflammation and demyelination (the destruction of the myelin layer that insulates nerve cell processes, impeding the conduction of neuronal impulses within the brain and spinal cord). The mechanism of demyelination in MS is not completely understood. Immune modulating therapy can delay the progression of MS but there is still no cure for the disease. Thus the development of experimental animal models for MS is among the most powerful tools for studying its pathogenesis and for testing the safety and efficacy of experimental therapies before using these drugs in clinical trials on human patients.

The main experimental models for MS are divided into immune-mediated models or virus-induced models. In immune-mediated models an autoimmune reaction against myelin is induced by the injection of myelin molecules (or portions of it), in combination with immune boosters (Freund's adjuvant). The prototype of this category is EAE, or experimental allergic (or autoimmune) encephalomyelitis. This model uses a variety of experimental animals including mice, rats, rabbits and even primates. The viral models include several ubiquitous animal viruses such as coronaviruses (mouse hepatitis virus) and enteroviruses (Theiler's virus) in mice, visna virus in sheep, and distemper virus in dogs. The virus-induced model systems provide both a substrate for studying the pathogenesis of the disease and a hypothetical mechanism for virus-induced autoimmunity in humans.

In this book we have assembled the different experimental models for MS (both immune-mediated and viral). We have asked MS experts to examine aspects of these experimental models highlighting differences and similarities. Each chapter in this book deals with an element of an MS

model: from individual cellular and molecular CNS factors, to cellular and molecular elements of the immune system. Thus the reader is able to read parallel chapters that deal with the same factor in different model systems. The reader of the book will be able to summarize and integrate the different disease components and highlight the common features and the differences that exist in the different model systems. We realize that a book of such magnitude cannot keep pace with all the new knowledge of immunology (in particular new cytokines being discovered), but it offers a conceptual framework. We hope that this book will improve our understanding of the mechanism of demyelination and the pathogenesis of MS. The analysis of common features in the various experimental models of demyelination may also stimulate the development of new ideas about prevention of demyelination and ultimately the treatment of MS.

EXPERIMENTAL ALLERGIC (AUTOIMMUNE) ENCEPHALOMYELITIS (EAE)

Chapter A1

EAE: HISTORY, CLINICAL SIGNS, AND DISEASE COURSE

J. William Lindsey, MD
Department of Neurology, University of Texas Health Science Center at Houston, Houston, Texas, USA

Abstract: EAE is a useful animal model of autoimmune disease of the central nervous system. In this chapter we discuss the history of EAE, including the original description of the model and the subsequent major developments, and then describe the usual clinical signs and disease course.

Key words: experimental autoimmune encephalomyelitis, encephalitogen, adoptive transfer, active EAE, history, relapses, transgenic models

1. INTRODUCTION

Experimental allergic encephalomyelitis (EAE) is an animal model of autoimmune disease of the central nervous system (CNS). It resembles multiple sclerosis (MS) in many respects, and is used in the laboratory investigation of MS. EAE also serves as a model for the study of organ specific autoimmune diseases in general. EAE was first described over 50 years ago, and it has been a popular and frequently used model. A Medline search of the term identifies more than 5000 citations, with more than 2500 references since 1990. In this chapter, we will review the history of EAE and describe the general features of the model, including the usual clinical signs and disease course.

2. HISTORY

As mentioned in the introduction, there has been an enormous amount of work done in EAE over the last 50 years. In this section, we will briefly summarize the major developments in the field. These include the early studies that led to the establishment of the model, the extensive work done on various antigens, the development of adoptive transfer disease, the development of relapsing EAE, and recent work with EAE in transgenic mice.

2.1 Early Studies

The earliest attempts at producing EAE were efforts to understand the pathogenesis of post rabies vaccination encephalomyelitis. Pasteur's rabies vaccine consisted of a suspension of dessicated spinal cords from rabbits infected with rabies. After a series of injections, occasional patients developed an encephalomyelitis which was distinct from rabies. Early investigators were able to induce a similar encephalomyelitis in rabbits or monkeys by administering repeated injections of neural tissue, thus demonstrating that post rabies vaccine encephalomyelitis probably resulted from the unintentional induction of an autoimmune response against neural antigens [1-3].

In these early experiments the incidence of disease was low, and induction of disease required multiple injections over a period of many weeks. The introduction of complete Freund's adjuvant (CFA) made induction of EAE much simpler and more reliable. CFA consists of a mixture of mineral oil and *Mycobacterium* made into an emulsion with the antigen, and injecting antigen in CFA usually induces a vigorous and prolonged immune response against the antigen. Several investigators were quick to appreciate the usefulness of this technique. In 1946, Kabat et al published a preliminary report of the induction of EAE in 3 of 4 monkeys using three weekly injections of rabbit brain emulsion in Freund's adjuvant [4]. This was followed rapidly by more definitive reports of similar results in monkeys, rabbits, and guinea pigs [5-8]. In each case the majority of animals developed neurologic deficits after one or a few injections of neural tissue in Freund's adjuvant, and the onset of disease occurred three to four weeks after the first injection. EAE was subsequently induced in many other species, including dogs, cats, rats, mice, sheep, goats, pigs, chickens, and pigeons.

Attempts to induce EAE in mice with antigen in CFA were initially unsuccessful. Olitsky and Yager reported on EAE in mice two years later

[9]. The majority of mice developed neurologic symptoms after three to five injections of brain tissue in CFA. The symptoms began about three weeks after the first injection. They noted that their two strains of mice differed substantially in susceptibility to EAE, and future studies verified that susceptibility to EAE varies widely between strains. Subsequently, Lee and Olitsky demonstrated that pertussis vaccine given as a separate injection in addition to antigen in CFA increased the incidence of disease [10]. Munoz and coworkers found that the active ingredient in pertussis vaccine was the toxin, and purified pertussis toxin is now routinely used as an additional adjuvant to induce EAE in mice [11].

2.2 Identification of encephalitogens

The experiments described above were done with homogenate or extract of CNS tissue as the antigen. An early focus of EAE research was identifying the encephalitogenic component of the homogenate. The encephalitogen was present in white matter or myelin rather than gray matter, and appeared to be protein rather than lipid. At the time, there was much controversy over whether brain homogenate contained one or multiple encephalitogens, and over which of the partially purified mixtures prepared with the limited methods available was the relevant encephalitogen. In retrospect, it appears that both of major structural proteins of myelin, myelin basic protein (MBP) and proteolipid protein (PLP), were demonstrated to be encephalitogenic at an early date [12-14].

Subsequent work with MBP demonstrated that the intact protein was not required to induce EAE. Specific fragments of MBP generated by pepsin or trypsin digestion of the whole molecule were encephalitogenic. And in 1970 Eylar et al. induced EAE with a 9 amino acid synthetic peptide corresponding to part of the sequence of MBP [15]. This peptide was as active on a molar basis as the intact molecule. Since then, multiple T cell epitopes for MBP, PLP, and other encephalitogenic proteins have been reported, and synthetic peptides comprising encephalitogenic T cell epitopes are now a standard reagent for inducing EAE.

Recently many other myelin proteins or peptides based on myelin proteins have been demonstrated to be encephalitogenic. Other encephalitogenic myelin proteins include myelin oligodendrocyte glycoprotein (MOG), myelin-associated oligodendrocytic basic protein, and oligodendrocyte specific protein [16-20]. MOG is particularly interesting since it induces relapsing EAE with extensive demyelination. Non-myelin proteins, such as S100β and glial fibrillary acidic protein (GFAP) also cause EAE, but the distribution of the lesions is different than that seen with myelin proteins [21, 22]. Not all CNS proteins will induce EAE. The

myelin protein 2',3'-cyclic nucleotide 3'-phosphodiesterase and the stress protein alphaB crystallin did not induce EAE [19, 23].

2.3 Adoptive or passive EAE

The results discussed above have all been in active EAE, where the disease is induced by injection of CNS antigen in adjuvant. In this model, the induction phase and the effector phase of EAE occur in the same animal. In the induction phase, autoreactive cells are activated and multiply in peripheral lymph nodes in response to the injection of antigen and adjuvant. In the effector phase, the activated autoreactive cells migrate to the CNS and cause autoimmune damage and clinical signs. Another model of EAE is passive or transferred or adoptive disease. In passive EAE, the autoreactive cells specific for CNS antigens are generated in one group of animals, and disease is induced in a second group of animals by transfer of these autoreactive cells. In this way, one can study the effector phase in isolation from the induction phase.

Transfer of disease from EAE induced animals to naïve animals was first achieved by Paterson in 1960 using an elegant experimental design to overcome the difficulty of using outbred experimental animals [24]. Subsequent investigators refined this model by using inbred animals to avoid histocompatibility problems and by stimulating the donor cells *in vitro* with either mitogen or antigen to increase their encephalitogenic activity [25-27]. CNS antigen-specific T cell lines or clones maintained for prolonged periods *in vitro* can be used instead of freshly harvested lymph node cells [28]. Passive or transferred EAE is a very reproducible model of EAE since the variability of the induction phase is eliminated.

2.4 Relapsing EAE

Active or passive EAE is usually an acute, monophasic process similar to the human diseases acute disseminated encephalomyelitis or acute transverse myelitis. Investigators interested in multiple sclerosis would prefer a model with relapsing or progressive symptoms to more closely mimic the course of MS, and methods to produce such a model have been described. The induction of relapsing instead of acute EAE depends on the strain of animal, the antigen used, and the induction regimen. A relapsing course has been described in both active and passive EAE, and different regimens have been reported to reliably produce relapsing rather than acute disease [29, 30]. The tendency to relapse varies between strains of mice [31].

2.5 Transgenic models of EAE

The EAE model continues to develop as new methods and techniques become available. One recent development is the use of transgenic mice. Two types of transgenic mice have been constructed for the study of EAE. The first type is T cell receptor (TCR) transgenic mice. These mice express a receptor specific for MBP on all or most of their T lymphocytes [32, 33]. These mice may develop EAE following injection with adjuvant alone, and mice not maintained in sterile pathogen-free environments may develop spontaneous cases of EAE. A second type of transgenic mice was engineered to express a viral protein in oligodendrocytes [34]. Subsequent systemic infection with the corresponding virus resulted in autoimmune CNS damage.

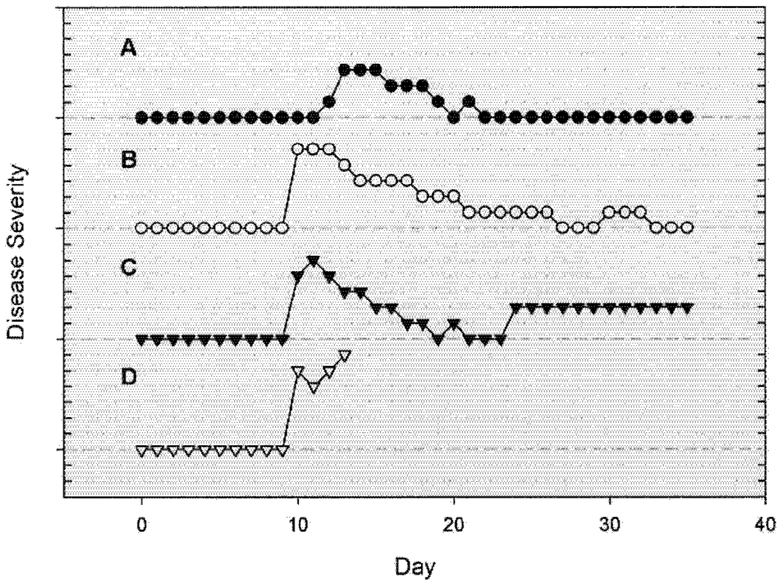

Figure A1-1. Clinical course of EAE. Representative examples of EAE in SJL mice injected with spinal cord homogenate in CFA and pertussis (see reference 35 for detailed methods). Mice were rated daily for severity of EAE using the scale in Table 1-1. Time in days is on the abscissa, with the day of injection as day 0. Severity of disease is on the ordinate. Mouse A developed monophasic EAE starting on day 12 and resolving by day 23. Mouse B had more severe disease. Mouse C recovered from the initial bout of disease, and then relapsed and had a chronic deficit. Mouse D had severe EAE with rapid onset and died on day 13.

3. CLINICAL SIGNS AND DISEASE COURSE

The clinical signs and disease course of EAE vary depending on the strain and species of animal, the inciting neural antigen, the adjuvants, and the timing and dose of antigen and adjuvant. We will describe EAE induced in SJL mice by spinal cord homogenate with mycobacteria and pertussis toxin as adjuvants as a typical example [35]. The first sign is usually ruffled fur and weight loss. One or two days later the animal develops an ascending paralysis. This begins with loss of tail tone and progresses to hind limb weakness and sometimes forelimb weakness. Severely affected mice develop quadriparesis and labored respiration and may die from the disease. The weakness starts about 14 days after injection and worsens over 1 to 4 days. In mice which recover, the symptoms last about 7 days, and relapses after recovery are rare. The clinical course of EAE in representative individual mice is depicted in Figure 1-1.

Severity of disease is rated on an ordinal scale. The scale we use is given in Table 1-1 [31, 35]; other investigators use similar scales with different number of stages or different definitions of stages. We titrate the dose of antigen to minimize the number of mice with stage 5 or 6 disease. Proper veterinary care of severely affected mice is essential.

Table A1-1. Clinical rating scale for EAE

Stage	Clinical deficit
0	no deficits
1	limp tail or slowed righting response
2	limp tail and slowed righting response
3	hind limb weakness with abnormal gait
4	hind limb paralysis, mobile using forelimbs
5	hind limb paralysis, forelimb weakness, mobility impaired
6	moribund

The ascending paralysis described above is typical in mice, rats, and guinea pigs. Other species have different clinical courses. Rabbits may have ataxia and gait difficulties, while monkeys may have visual loss, cranial nerve deficits, and ataxia in addition to paralysis.

The acute, monophasic clinical course described above is typical for EAE in rodents. Other disease courses are seen, including a hyperacute form and relapsing or chronic forms of disease. The hyperacute form of disease is characterized by a short latent period between injection and symptom onset and a fulminant course with a high mortality. Chronic or relapsing disease has been described with particular strains of animals and with particular induction regimens.

ACKNOWLEDGEMENTS

Work in our laboratory has been supported in part by the Clayton Foundation for Research and the National Multiple Sclerosis Society.

Chapter A2

INDUCTION OF EAE

Eli Ben-Chetrit and Stefan Brocke
Department of Pathology, Hebrew University Hadassah Medical School, P.O.Box 12272, 91120 Jerusalem, Israel

Abstract: Experimental autoimmune encephalomyelitis (EAE) can be induced by two principal approaches. The first is based on direct immunization with autoantigen in combination with different types of adjuvant. The second approach of inducing EAE consists in adoptive transfer of activated T cells that are specific for myelin-associated autoantigens of the central nervous system (CNS). This chapter presents an overview of some useful strategies and protocols by which EAE can be induced, and discusses the pros and cons of various approaches.

Key words: Experimental autoimmune encephalomyelitis, active immunization, adoptive transfer, adjuvant, myelin antigens

1. INTRODUCTION

Methods of inducing experimental autoimmune encephalomyelitis (EAE) have come a long way since initial observations that postvaccinal encephalomyelitis is caused by spinal cord contaminants of rabies vaccine preparations rather than by the inactivated virus itself (1, 2). There are many species susceptible to EAE induction, including mice (3), rats (4), guinea pigs (5), pigs (6) and non-human primates (7). In addition, a human version of accidental EAE, 'human EAE', has been described (8, 9).

In 1949, Olitsky and Yager described the induction of experimental disseminated encephalomyelitis in white mice, thus establishing mouse EAE as a model for autoimmune inflammatory diseases of the central nervous system (CNS) (3). EAE in the mouse shares some clinical features with the human disease multiple sclerosis (MS), most prominently paresis/paralysis and ataxia. Depending on the model chosen, EAE can take an acute, a chronic, and/or relapsing-remitting course. Inadvertently induced 'human

EAE' took a course with striking resemblance to a rare form of MS, acute MS (8, 9). Sensitization with myelin antigens often results in perivenous encephalomyelitis and in some cases, depending on the animal model, in histopathologic changes similar to those seen in MS (9).

There is ample evidence that susceptibility of different animal strains to EAE is linked to MHC class II determinants (10, 11), although non-MHC genes also influence disease expression. Thus, murine EAE can be considered a useful model for some aspects of MS (12).

There are several strategies to induce EAE in animals. EAE can be induced by immunization of animals with mouse spinal cord homogenate (MSCH) or isolated myelin proteins and peptides. Alternatively, EAE is generated by adoptive transfer of lymphocytes that have been activated for myelin antigens *in vivo* and/or *in vitro* (11). Both immunized animals as well as mice expressing a transgenic T cell receptor specific for myelin basic protein (MBP) or other myelin antigens can function as a source of T cells suitable for adoptive transfer (13, 14, 15).

Several immunodominant epitopes of myelin components have been characterized, and peptides representing epitopes of MBP, proteolipid protein (PLP), or myelin oligodendrocyte glycoprotein (MOG) are widely used for the induction of EAE. (10, 16-20). As mentioned, the encephalitogenicity of myelin-derived peptides is dependent on the expression of particular MHC class II antigens in the appropriate mouse strain. Thus, induction of disease using PLP peptide $PLP_{139-151}$, MBP peptide MBP_{87-99} or MOG peptide MOG_{92-106} is suitable in SJL (I-A^s) mice. The N-terminal peptide MBP_{Ac1-11} or MBP_{87-99} are suitable in (PL X SJL)F_1 mice. MOG_{35-55} is routinely used to induce EAE in C57BL/6 mice.

Of note, the human MOG-derived peptide MOG_{97-108}, which has a high binding affinity for the (human) HLA-DR4 MHC class II allele, induces severe EAE in HLA-DR4 transgenic mice (21).

In a recent study, inoculation of myelin-associated oligodendrocytic basic protein and one of its derived peptides, $MOBP_{37-60}$, were reported to produce severe clinical and histopathologic signs of EAE in SJL mice (22). Moreover, the encephalitogenic potential of synthetic peptides of myelin-associated glycoprotein (peptide MAG_{97-112}) and oligodendrocyte-specific glycoprotein (peptide OSP_{57-72}) has recently been demonstrated in ABH (H-$2A^{g7}$) and SJL mice, respectively, (23).

EAE in the rat is typically an acute paralytic disease from which most animals spontaneously recover. However, also chronic models have recently been described (24). Dominant MBP epitopes in Lewis rats are MBP_{68-86} (25, 26), MBP_{73-86} and MBP_{87-99} derived from guinea pig myelin as well as rat MBP_{73-86} (27). MAG has also been used in the induction of EAE in Lewis

rats. In DA rats, MBP_{63-81}, MBP_{79-99}, $MBP_{101-120}$ or $MBP_{142-167}$ can be used for induction of EAE (28). DA rats are also susceptible to PLP-induced EAE.

Recently, EAE was induced in the swine by minipig spinal cord homogenate inoculation. The minipigs presented a monophasic course of disease with spontaneous improvement (6).

Weir et al. demonstrated induction of EAE by transferring bone-marrow-derived dendritic cells presenting MOG_{35-35} into naïve C57BL/6 mice (29).

Finally, rabies vaccination in humans has been reported to result in sensitization against neural antigens and lead to acute perivenous encephalomyelitis clinically and histopatholigically indistinguishable from some types of EAE in animals or even MS-like lesions (8, 9). Such complications, however, have been very rare.

2. EAE INDUCED BY IMMUNIZATION (ACTIVE EAE) OR BY ADOPTIVE T CELL TRANSFER (PASSIVE EAE, AT-EAE)

2.1 Overview

Active EAE enables the study of both immunization and effector phases in experimental demyelinating disease. Typical immunization protocols require the emulsification of encephalitogens in complete Freund's adjuvant (CFA) containing inactivated mycobacteria such as *Mycobacterium tuberculosis* strain H37RA. Both reagents are obtainable from suppliers such as BD-DIFCO. Antigen concentrations and protocols used for immunizations vary widely between groups and should be adjusted to each laboratory's own conditions.

Direct immunization may complicate the interpretation of experimental data on EAE induction and expression. Due to the severe long-term inflammation caused by the use of CFA, some of the observed effects could be attributed to the mode of immunization rather than to the pathogenic process of inflammation and demyelination in the CNS. The induction of active EAE in some rat and mouse models is significantly enhanced by the administration of heat-killed whole organisms of *Bordetella pertussis* (30, 31) or their derived toxin, pertussis toxin (PTX) (32).

EAE can be induced by transferring sensitized lymph node cells (LNCs) from mice or rats that have been immunized with MSCH, MBP, PLP or other CNS antigens (33-36). Induction of EAE by cell transfer allows the separate study of the effector phase of the disease without the influence of

immunization and inflammation outside the CNS. More importantly, the prime mediators of this type of disease, myelin antigen-specific T cells, can be studied in detail *in vitro* by standard immunological techniques such as proliferation assays for the determination of antigen specificity, surface marker analysis by flow cytometry, cyto- and chemokine measurements, and T cell receptor sequencing. *In vitro* analysis of enriched or cloned antigen-specific autoreactive T cells is essential for our understanding of cellular and molecular properties associated with demyelinating disease. In transfer protocols, cells can either be directly transferred after dissection of draining lymph nodes of immunized donor animals or be cultured for various time periods with the appropriate antigen to enrich autoreactive cells.

We describe methods that are routinely used in the laboratory to induce a chronic, often relapsing and remitting paralysis by immunization of mice with $PLP_{139-151}$ or MBP or by adoptive transfer of lymphocytes sensitized to $PLP_{139-151}$ or whole MBP (19, 36, 37).

The method for establishing long-term antigen-specific T cell lines and clones was developed by Kimoto and Fathman in 1980 (38). This technique formed the basis for the induction of autoimmune disease by transferring enriched autoreactive T cell populations. Utilizing this technique, it is possible to establish MBP-speccific T cell lines and clones transferring EAE in rats (39) and mice (40). T cell lines specific for MBP or MBP peptides can be established as described (39). The following method for the generation of T cell lines and clones specific for immunodominant and encephalitogenic MBP peptides can be applied to a variety of antigens and *in vivo* systems (41). Our protocol describes T cell cloning for the N-terminal peptide MBP_{Ac1-11} in PL or (PL x SJL)F1 mice and MBP peptide MBP_{87-99} in (PL x SJL)F1 and SJL mice. In general, this protocol will lead to the isolation of CD4-positive T cell clones with chemotactic activity *in vivo* (41-43). The optimal concentration for each antigen, e.g. protein or peptide, must be determined both for the immunization of mice and for *in vitro* primary cultures of LNCs.

2.2 Antigenic preparations

As mentioned before, a variety of antigens and antigenic peptides have been described as inducing EAE in the appropriate mouse strains (10, 16-18, 40, 44-47). Most antigens used for the induction of active EAE are suitable for the restimulation of T cells *in vitro*. Thus, MBP and many other myelin antigens and their derived peptides are capable of inducing T cells that can be cultured *in vitro* to adoptively transfer EAE.

Synthetic peptides are prepared by continuous flow solid-phase synthesis according to the desired sequences. Peptide purity is examined by high-performance liquid chromatography, and peptide identity is confirmed by amino acid composition analysis. Depending on the sequence, the peptide solution may require some pH adjustments before being dissolved in distilled water or phophate-buffered saline (PBS).

After synthesis and before use, peptides should be lyophilized several times to remove volatile organic compounds. Lyophilized peptides should be stored in the cold in a desiccator until use.

MBP for active immunization and for *in vitro* cell culture can be prepared from guinea pig spinal cords according to the protocol from Deibler *et al.* (48).

2.3 Active EAE

Mice of the appropriate strains at 6 to 12 weeks of age are immunized by s.c. inoculation with 20 to 400 µg of $PLP_{139\text{-}151}$, 400 µg of MBP, or 200 µg of MBP peptide in 0.1 or 0.2 ml of an emulsion of equal volumes of PBS and CFA. To enhance immunization with antigen, killed *Mycobacterium tuberculosis* strain H37RA is added to the emulsion at a concentration of 0.3 to 4 mg/ml. Injection sites are the regions above the shoulder and the flanks (25 to 50 µl at each injection site). In addition, 200 ng of PTX is injected i.p. or i.v. on the day of immunization and 48 h post immunization. The onset of disease lies usually between 7 and 12 days post immunization. Figure 1 demonstrates a typical EAE course when disease is induced according to the active immunization protocol.

Some older protocols calling for s.c. immunization into the footpads or in the tail base in order to induce active EAE are obsolete due to the fact that the local inflammation can interfere with the gait of animals and hence with EAE scoring.

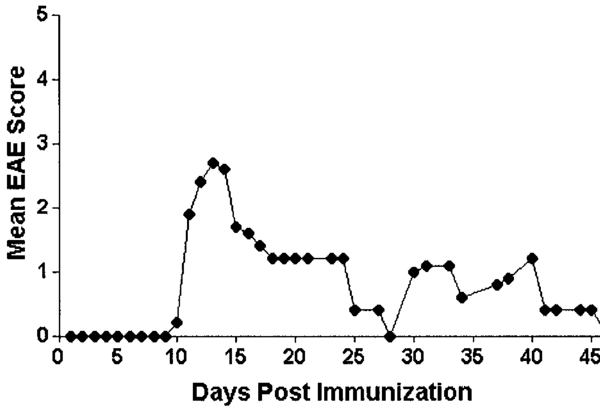

Figure 1. Active EAE. SJL female mice were immunized with $PLP_{139-151}$ in CFA followed by PTX induction and scored daily for clinical signs of disease.

2.4 Generation of PLP- or MBP-specific LNCs

Ten days after immunization, draining lymph nodes are harvested under sterile conditions. The lymph nodes are gently processed and washed through steel mesh until a single-cell suspension is obtained. Cells are then cultured at a concentration of 4 X 10^6 cells/ml for 4 days in RPMI 1640 supplemented with 2 mM glutamine, 100 U/ml penicillin, 100 µg/ml streptomycin, 10% fetal calf serum, and 5–15 10^{-6} M $PLP_{139-151}$. Cultures are set in complete medium as described (36, 37) at 2 ml per well of a 24-well tissue culture plate. The generation of MBP-specific LNCs is performed according to the same technique, except that cells are stimulated with 25 µg/ml MBP.

Isolation and characterization of autoreactive T cell lines and clones

Seven to twelve days after immunization with peptide antigen in an emulsion of PBS and CFA, mice are euthanized, and draining lymph nodes are harvested under sterile conditions. The lymph nodes are gently processed and washed through steel mesh until a single-cell suspension is obtained. Cells (30 X 10^6) are cultured in 5 ml RPMI 1640 supplemented with 2 mM glutamine, 100 U/ml penicillin, 100 mg/ml streptomycin, 5 X 10^{-5} M 2-mercaptoethanol, 10% fetal calf serum, and antigen (5–15 10^{-6} M). After 4

days of incubation, cells are washed and resuspended in 5 ml of the enriched medium as described above without antigen. Depending on cell growth, the cell culture medium can be supplemented with interleukin-2 (IL-2) or 10% (v/v) concanavalin A (Con A) supernatant as a source of IL-2 (and other growth factors) between stimulations. Con A supernatant is prepared from splenocytes of BALB/c mice by incubating 5 X 10^6 cells/ml with 2–5 µg/ml Con A for 24 h. The remaining Con A in the supernatant is removed by stirring it with 2 mg/ml Sephadex G-50 for 1 h. The resulting Con A supernatant is filtered sterile and stored at -70°C until use. T cells are kept in Con A supernatant enriched medium at a concentration of 1 X 10^6 cells/ml and restimulated every 14 days using antigen (5–15 10^{-6} M) presented on irradiated (3000 rad) syngeneic spleen cells at a ratio of 1/5 to 1/50 T cells versus antigen-presenting cells (APCs). T cell clones from the MBP-induced T cell lines are derived by the limiting dilution technique. Cells are diluted in medium and distributed in wells of flat-bottom microtiter plates at a minimal concentration of 0.2 cell/200 µl on 5 X 10^5 irradiated syngeneic splenocytes as APCs. Resulting clones are maintained by techniques described for the lines. T cell lines and clones generated by this protocol are usually characterized by the expression of CD4, VLA-4, and CD44 cell surface markers (Table 1; 49). Cells proliferate well according to their specific antigen and are often quite heterogeneous with regard to their encephalitogenicity and cytokine production (42, 43)

Table 1

Properties of encephalitogenic T cells
CD4 positive
Diverse TCR α/β chain gene usage
High expression of VLA-4
High expression of LFA-1
High expression of CD44
High expression of CD25 (IL-2 receptor α-chain)
Very low or no expression of L-selectin
Production of TNF-α/β
Possible production of IL-4

2.5 Lymphocyte proliferation

Specific recognition of myelin antigens, by sensitized T cells is tested using lymphocyte proliferation assays. Primary proliferative responses of

MBP-specific LNCs are assessed by incubating 2 X 10^5 cells with 100, 50, 25, and 12.5 μg/ml MBP in 200 μl of complete medium per well of a 96-well tissue culture plate. Cultures with no antigen and with 4 μg/ml Con A serve as negative and positive controls, respectively. After 80 h, cultures are pulsed with 1 μCi of [^{3}H]thymidine per well. After 96 h, cells are harvested on glass filters, and radioactivity is determined in a β-counter. All cultures are set up at least in triplicate.

The best time period to examine the proliferation of long-term T cell lines and clones is when the cells are in a resting phase. Thus, 7 to 10 days after antigenic stimulation, cells of T cell lines or clones are tested for their specific proliferative responses to MBP peptides. Ten thousand T cells are cultured in 200 μl in a well of a 96-well tissue culture treated flat-bottom microtiter plate together with 0.5 X 10^6 irradiated (3000 rad) syngeneic spleen cells in the presence of various concentrations of the antigens. A typical concentration range for testing peptide antigens in a proliferation assay includes 0.1, 1, 10, 50, and 100 X 10^{-6} M. At the end of a 48-h incubation period, 1 μCi of [^{3}H]thymidine is added. Twelve hours later, cells are harvested and radioactivity is determined in a β-counter. All cultures are set up at least in triplicate.

2.6 EAE induced by adoptive T cell transfer (passive EAE, AT-EAE)

For AT-EAE, 15 X 10^6 to 50 X 10^6 activated autoreactive LNCs are washed in PBS and injected i.v. or i.p. in 200 to 500 μl PBS into naive (PL X SJL)F_1 or SJL mice 6 to12 weeks of age. The severity of EAE is dependent on the number of MBP-specific cells transferred and can be adjusted accordingly, but precise control of clinical EAE scores is very difficult to achieve.

Additional injections of PTX on the day of transfer and 48 h later have been recommended but may precipitate an exacerbative course of disease or even prevent optimal disease induction. In some cases, whole-body irradiation of mice with 350 rad facilitates the transfer of EAE by weakly encephalitogenic T cell clones.

Figure 2 demonstrates EAE induced by adoptive transfer as described above.

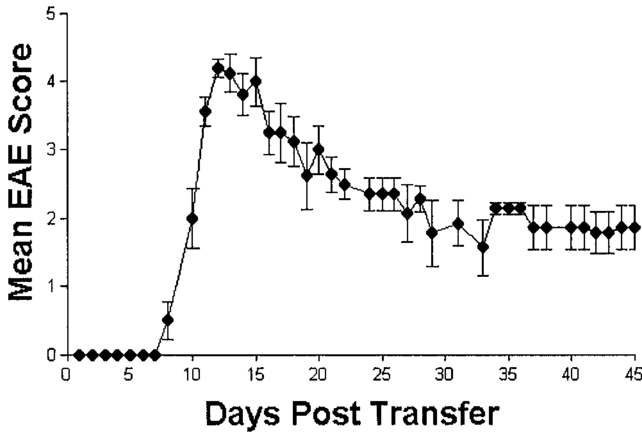

Figure 2. AT-EAE. SJL mice were injected i.p. with 36 X 10^6 LNCs/mouse and clinical disease scores were recorded daily.

3. CLINICAL MANIFESTATION AND EVALUATION OF DISEASE

The clinical and histopathologic signs of EAE can be quantified according to various schemes. We evaluate all animals for clinical signs of EAE using a clinical scoring scale ranging from 0 to 5 presented in table 2. Scoring is performed by an examiner blinded to the experimental protocol and by the same observer throughout the experiment. Mean clinical scores at separate days are calculated by adding the scores of individual mice and dividing the sum by the number of mice in each group.

Table 2

EAE score	Clinical disease
0	No clinical disease
1	Tail weakness
2	Hemi- or paraparesis (incomplete paralysis of one or two hindlimbs)
3	Hemi- or paraplegia (complete paralysis of one or two hindlimbs)
4	Paraplegia with forelimb weakness or paralysis
5	Moribund or dead animals

The onset of actively-induced EAE lies usually between 7 and 12 days post immunization. Maximal clinical severity is often reached between day 9 and day 14, followed by a remitting disease course, although relapses can occur as shown in figure 1. In contrast, transfer of myelin antigen-specific T lymphocytes in the mouse rarely results in a full recovery and tends to leave long-lasting neurological deficits. More severe forms of the disease are associated with an earlier onset, a higher disease incidence, higher disease scores, a slower recovery, and a more synchronized course in the different animals. A significant drop in body weight usually precedes other clinical signs of EAE for about 1 to 2 days. The onset of clinical disease depends on the number and encephalitogenic capacity of the transferred cells.

Disease starts 6 to 12 days after transfer of encephalitogenic cells. Typically, maximal clinical severity is reached between day 8 and day 14 after transfer. Disease course and duration vary according to the animal strain used and the selection cycle of encephalitogenic cells. In primary T cell transfers, a relapsing-remitting disease course over a long time period can be observed, whereas T cell-line- or clone-mediated EAE is characterized by a monophasic disease course with lasting neurological deficits.

3. DISCUSSION

EAE in the mouse is characterized by perivascular inflammatory demyelinating lesions in the CNS and an immunogenetically determined susceptibility. Clinical expression of the disease is obvious by neurological signs and can be easily quantified. The immune system of the mouse is extensively studied, and immune reagents are readily available, making mouse EAE an animal model for the study of some aspects of inflammatory demyelinating disorders of the CNS.

The preparation of T cell lines or clones is obviously much more labor-intensive than mixing myelin antigens in CFA. Why then use passive EAE when active EAE is so much easier? Our laboratories are using routinely passive EAE for several reasons. Passive EAE allows the separate study of immunization and effector events in the pathogenesis of the disease. This procedure avoids local and systemic side effects of adjuvant-based immunizations. Treatment protocols could interfere with the efficacy of autoantigen immunization rather than reflect the effects on the disease process. Finally, cells that mediate EAE *in vivo* are accessible to characterization and treatment *in vitro*. The disadvantage of the approach of

inducing EAE by adoptive transfer is that every culturing process selects for certain properties and deselects others. The outcome of the described process cannot always be well controlled. Culture methods select cells that proliferate efficiently. Experience in EAE shows that T cells that proliferate best are not always the most encephalitogenic cell populations. Thus, any conclusions drawn from experiments that include cell culture procedures bear the potential risk of overgeneralization. This becomes evident when comparing diseases that are induced based on the different methods of culturing cells presented in this paper. However, all EAE models, both active and passive, display a wide variety of different disease courses. A careful matching of the method of choice to induce EAE with the objective of the study under investigation should help to navigate through the various options available to the investigator.

Chapter A3

HISTOPATHOLOGY OF EAE

Michael J. Day
Department of Pathology & Microbiology, School of Veterinary Science, University of Bristol, Langford BS40 5DU, UK

Abstract: This chapter reviews the histological structure of the normal central nervous system and the basic pathology of inflammation and demyelination of this tissue. An outline of the pathogenesis of experimental autoimmune encephalomyelitis (EAE) is given and pathology of multiple sclerosis is reviewed. The limitations of EAE as a model for multiple sclerosis are discussed. The approach to histopathological assessment of the lesions of EAE is outlined, including collection and processing of appropriate samples and a review of grading systems that have been used to quantify the histopathological changes. The specific histopathological features of EAE are described with reference to selected model systems including the SJL/J, C57Bl/6 and NOD mouse, the Lewis rat, rhesus monkey and marmoset.

Key words: EAE, multiple sclerosis, histopathology, inflammation, demyelination

1. BASIC MICROANATOMY OF THE CENTRAL NERVOUS SYSTEM

The central nervous system (CNS) comprises the brain, spinal cord, optic nerve and retina; the latter structures considered embryological extensions of the brain. Within the CNS, the broadest structural division is into the myelinated axons of the white matter tracts, and the collections of neuronal bodies, glial cells and surrounding neuropil that comprise the gray matter.

The basic cellular unit of the CNS is the neuron. The neuronal cell body typically receives input from the dendrites that emanate from the cell body, and transmits output along a single axon through the axonal

telodendritic branches to the dendrites of other neurons. The terminal bulbs of the telodendritic branches store neurotransmitter substances that are released into the synapse. Most synapses are axo-dendritic or axo-somatic, but a range of other possible interneuronal contacts may be made. A single multipolar neuron may receive many thousands of synaptic inputs.

The smaller neuroglial cells produce structural and functional support to the neuroaxonal units, and are the predominant population in CNS tissue. The largest glial cells are the astrocytes that have numerous processes containing glial fibrils. The length and degree of branching of these processes is greater for the fibrous astrocytes of the white matter, than for the protoplasmic astrocytes of the gray matter. Adjacent astrocytes are linked to each other by gap junctions, and astrocyte processes terminate in end feet that are in close association with vascular endothelium and may induce the formation of inter-endothelial tight junctions, forming the basis of the 'blood-brain-barrier' (Couraud 1998). Astrocytes have a range of functions including provision of structural support and insulation for synapses, acting as an energy (glucose) source and acting to inhibit synaptic activity by taking up neurotransmitters. Astrocytes may be induced to express MHC class II and other co-stimulatory molecules (B7 and CD40) and are capable of antigen presentation to T lymphocytes *in vitro* (Dong and Benveniste 2001). Astrocytes may also have a role in down-regulation of CNS immune responses.

By contrast, oligodendrocytes are less branched cells that do not have gap junctions. White matter oligodendrocytes form the multilayered myelin sheath that surrounds and insulates the axon, and one oligodendrocyte may provide myelination for multiple axons (Baumann and Pham-Dinh, 2001). There are areas of unmyelinated axon (nodes of Ranvier) that form at the junction of myelin sheath produced by adjacent oligodendrocytes (internodes). The electrical insulation provided by myelin means that action potentials 'jump' between nodes which increases the speed of signal conduction relative to that which would occur in an unmyelinated axon. The function of gray matter oligodendrocytes is not defined, but they are arranged as 'satellite' cells to neurons and may be involved in neuronal homeostasis.

Microglia are relatively small glial cells with more sparse distribution in the neuropil. During CNS inflammation, microglia become phagocytic and capable of antigen presentation, and therefore act in similar fashion to infiltrating blood-derived macrophages to which they are likely related (Stoll and Jander 1999; Smith 2001). In demyelinating diseases these phagocytic cells accumulate intracellular lipid, appearing as 'gitter cells' with a foamy cytoplasm.

The ciliated ependymal cells form the lining to the ventricular spaces and modified ependyma line the choroid plexus and produce the cerebrospinal fluid (CSF) of the brain.

2. BASIC CNS HISTOPATHOLOGY

The pathogenesis of the lesions of experimental autoimmune encephalomyelitis (EAE) is complex but involves two basic processes of inflammation and demyelination. The generic features of these changes will be described in this section, and the specific pathology that characterises EAE is discussed subsequently.

2.1 Inflammation

The characteristic CNS inflammatory lesion in diseases such as EAE is the 'perivascular cuff' – an accumulation of leukocytes in the perivascular space, involving vessels of the neuropil, meninges or choroid plexus. This accumulation of leukocytes involves the processes of leukocyte margination, molecular interactions with endothelia, breakdown of the blood-brain barrier and active egress of leukocytes from the bloodstream to the perivascular space in response to chemokine signalling (Ransohoff 1999; Boztug et al., 2002). The role of matrix metalloproteinases in disruption of the basal lamina of the blood-brain-barrier has recently been appreciated (Rosenberg 2002). These processes must be distinguished from primary vascular pathology (vasculitis). The nature of the leukocytes within the cuff may vary, and the inflammation may therefore range from neutrophilic to pyogranulomatous to lymphoplasmacytic. Additionally, resident pericytes and local microglial cells may form part of the cuff population. Perivascular cuffing may be accompanied by gliosis of adjacent parenchyma – an increased prominence of glial cells (astrocytes, oligodendrocytes or microglia) due to proliferation or cellular hypertrophy. In some models of EAE there may be resolution of the inflammatory lesion associated with a period of clinical remission. In the resolution of T lymphocyte-mediated inflammatory lesions, it has been suggested that there is Fas-Fas ligand-mediated apoptosis of the infiltrating lymphoid cells and macrophages, with subsequent phagocytosis of the apoptotic cells by microglia (Ouallet et al., 1999; Zipp 2000; Chan et al., 2001).

2.2 Demyelination

The destruction of a normal myelin sheath resulting in an unsheathed ('naked') axon is primary demyelination, and characteristic of multiple sclerosis (MS) and some models of EAE. By contrast, secondary demyelination involves primary axonal degeneration with resulting loss of

the myelin sheath that cannot be maintained in the absence of the axon. In primary demyelination, there may however be eventual axonal damage following a prolonged period of demyelination (Pivneva et al., 1999).

In MS and EAE the target of the disease process is therefore the oligodendrocyte-myelin unit. Demyelination is unlikely to be directly mediated by lymphocytes, but may involve a range of effectors including lymphocyte and macrophage-derived cytokines, oxygen radicals, nitric oxide, matrix metalloproteinases, antibody, complement and phagocytic cells including macrophages and microglia (Smith 1999; Kieseier et al., 1999). Proliferating glial cells will infiltrate the area of demyelination. In the absence of effective remyelination, axonal degeneration will occur and this forms the basis for the progressive clinical nature of these diseases. Failure of remyelination reflects oligodendrocyte apoptosis and failure to renew oligodendrocytes from progenitor cells (Nait-Oumesmar et al., 2000).

3. EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

EAE is an experimentally induced, T cell-mediated inflammatory disease of the CNS that has been most widely studied in primates, mice, rats, rabbits and Guinea pigs as a model of organ-specific autoimmune disease. The disease is characterised by a mixed inflammatory infiltration of the CNS and varying degrees of accompanying demyelination, which underlie the typical clinical signs. The clinical course of EAE may be acute and monophasic or polyphasic with a chronic, relapsing and remitting time course. The clinical course and specific pathology are dependent on the genetic strain, age and sex of animal used, and the method of disease induction.

EAE can be actively induced by immunisation with crude brain or spinal cord homogenates, whole myelin, isolated myelin antigens such as myelin basic protein (MBP), proteolipid protein (PLP) or myelin oligodendrocyte glycoprotein (MOG) or by synthetic peptides constituting defined T cell epitopes of these antigens. These immunogens are administered with adjuvant; for example most murine models of EAE use a combination of complete Freund's adjuvant (CFA) and *Bordetella pertussis* (entire organisms or, more recently, toxin). EAE may also be passively induced by the adoptive transfer of various cell populations including lymph node or spleen cells from donors with actively induce EAE. These donor cells are generally activated by *in vitro* stimulation with encephalitogen before transfer. Disease may be similarly induced by encephalitogen-specific T cell lines or clones, or peptide-loaded antigen presenting cells.

EAE has also been studied in genetically modified experimental animals, for example those with targeted gene disruption, or mice transgenic for an encephalitogen-specific T cell receptor. Several studies have shown that cross-reactive viral peptides are capable of inducing clinical EAE with characteristic CNS lesions in susceptible animals (Ufret-Vincenty et al., 1998).

T cells, in particular $CD4^+$ T lymphocytes, play a pivotal role in the induction of EAE as demonstrated by various adoptive transfer and blocking studies. Later in the disease process other cell types are considered to play an important role in the full expression of the disease. It is thought that the autoreactive T cells are activated in the periphery, proliferate in peripheral lymphoid tissue and then migrate into the CNS. They gain entry having up-regulated various cell surface adhesion molecules such as LFA-1 and VLA-4; the ligands of these molecules, ICAM-1 and VCAM-1, show increased expression on CNS endothelial cells as inflammation develops. Local stimulation of T cells by microglia or astrocytes is likely to occur (Aloisi et al., 2000). The autoreactive T cells involved in EAE pathogenesis are most likely to be of the IFNγ producing Th1 subset, although it has been shown that Th2 cells may mediate pathology when transferred to immunodeficient recipients. A role for B lymphocytes and antibody in some models is also proposed (Lyons et al., 2002).

A number of EAE models show a monophasic disease course, suggesting that immune regulation may mediate recovery from disease. Numerous mechanisms have been investigated to account for this observation, but current emphasis is placed on regulatory populations of T lymphocyte, particularly $CD4^+CD25^+$ T cells, and on the regulatory cytokine IL-10 that is produced by these cells.

3.1 EAE as a model of MS

Multiple Sclerosis is a chronic inflammatory and demyelinating disease of the CNS, the histopathology of which shows marked heterogeneity between individuals (Hickey 1999). There is no clear correlation between lesion histopathology and clinical presentation, which may be broadly categorised as chronic relapsing-remitting or primary progressive in nature. Most studies of the histopathology of MS have been performed with chronic lesional material, but there is also heterogeneity in acute lesions, suggesting that MS may have multiple aetiologies and pathogenic mechanisms (Luchinetti et al., 2000). In classical MS, several broad 'stages' of the plaque lesion have been described. In an acute plaque there is a marked infiltration of T lymphocytes and macrophages, accompanied by endothelial activation, oedema, myelin swelling and

oligodendrocyte loss. In chronic-active plaques lymphocytes are located both perivascularly and at (or just beyond) the advancing edge of the zone of demyelination. There is active demyelination with prominent foamy macrophages, and some axonal damage. Oligodendrocyte loss and astrocytosis are additional features. The chronic-inactive plaque has reduced inflammatory infiltration with persistent perivascular cuffs of lymphocytes, macrophages and plasma cells. There is sharp demarcation at the margin of the lesion with normal myelinated tissue. Within the plaque there is gliosis, reduced oligodendrocytes and axonal loss (Hickey 1999). An important feature of at least some forms of acute MS lesions is remyelination, however as disease progresses the ability to remyelinate clearly fails and this likely relates to loss of oligodendrocytes by apoptosis with failure of proliferation of oligodendrocyte progenitors (Luchinetti et al., 2000; Ransohoff et al., 2002). Additionally, a role for primary axonal loss in the pathogenesis of MS has been proposed (Anthony et al., 2000).

The exact aetiology of MS is unknown, although a role for T-cells is suggested by histopathological analysis of MS lesions, and this has been more specifically suggested to reflect a role for $CD4^+$ T cells by extrapolation from EAE. Again, by analogy with EAE, and in view of the localisation of MS lesions to the white matter, it has been assumed that the lymphocyte populations involved in MS respond to myelin antigens. In this context, T lymphocyte responses to MBP, PLP, MOG and myelin associated glycoprotein (MAG) have been demonstrated. A role for B lymphocytes and antibody in MS pathogenesis is suggested by the finding of increased CNS and cerebrospinal fluid (CSF) levels of immunoglobulin, and intralesional deposition of IgG in MS patients.

Although EAE has been widely employed as an experimental model of MS, it remains imperfect model system. One major limitation is that EAE is artificially induced rather than spontaneously occurring, hence it has limited use in determining the primary triggers in MS pathogenesis. It has been proposed that MS may be triggered by exposure to microbial (particularly viral) antigens cross-reactive to myelin (Weiner and Selkoe, 2002). An additional limitation is that the majority of EAE models show very little, if any, demyelination within the CNS and have an acute, monophasic course with spontaneous recovery. This contrasts with the chronic, progressive nature of MS, and the demyelination that is a feature of the human disease. Several EAE models have been developed in which the CNS lesions more closely approximate those of MS. For example, EAE induced in C57Bl/6 mice with MOG_{35-55} (see below) or that generated in Biozzi AB/H mice with spinal cord homogenate (Baker et al., 1990) is characterised by demyelination. The later model also displays a relapsing-remitting, chronic time course.

4. HISTOPATHOLOGY OF EAE

It is beyond the scope of the present review to describe the histopathological changes that occur in every reported model of EAE, however the pathology described in selected models will be summarised below. The general approach to routine histopathological assessment of EAE involves the collection of brain and spinal cord into 10% neutral buffered formalin, although the use of other fixative solutions (e.g. 75% ethanol, 25% glacial acetic acid) has been reported. In larger animal species, dissection of brain and spinal cord is less complex than for mice. For murine brain samples, the entire skull may be fixed and hemisectioned, allowing two halves of the brain to be freed from the cranial cavity. Murine spinal cord is best removed from the vertebral canal by applying pressure with a saline-filled 10ml syringe and blunt ended 20-gauge needle. Alternatively, a variety of protocols for perfusion of entire animals with fixative under anaesthesia have been described.

Fixed tissues are embedded in paraffin wax. Brain tissue obtained from mice as described above is best embedded for longitudinal sectioning; spinal cord may be embedded for either (or both) longitudinal or transverse sectioning. Serial sections may be stained with haematoxylin and eosin for assessment of inflammation and inflammatory cell populations, Luxol fast blue to assess demyelination and Bielschowksy silver staining to assess axonal pathology (Figure 3-1).

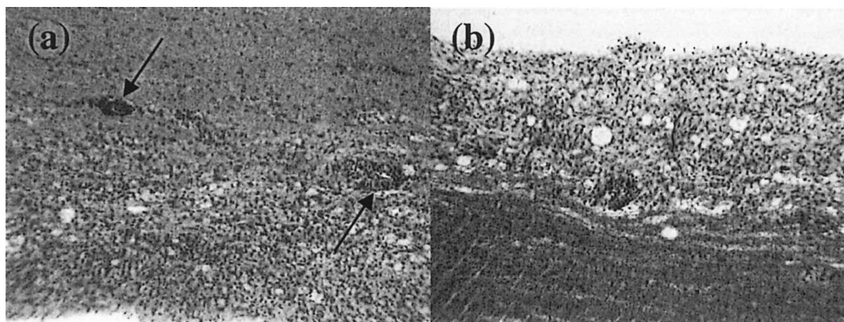

Figure 3-1. Serial longitudinal sections of spinal cord from a C57Bl/6 mouse with MOG induced EAE. (a) In the haematoxylin-eosin-stained section there is an intense mononuclear inflammatory infiltration of the peripheral white matter, with two perivascular cuffs at the margin of the affected area (arrows). (b) In the Luxol fast blue stained section the extent of the demyelination of this area of peripheral spinal cord white matter can be seen relative to the normally myelinated deeper tissue.

Immunohistochemical methodology has been widely applied to investigate the expression of specific molecules associated with EAE

lesions. Some immunohistochemical techniques may be applied to formalin-fixed tissue, but most will require frozen sections (Figure 3-2). Transmission electron microscopic studies of EAE lesions have also been reported, and such investigations will generally require collection of samples into glutaraldehyde for specialised embedding and processing protocols. Thin sections (one micron) stained with toluidine blue may be prepared from tissue samples post-fixed in 1% osmium tetroxide and epoxy resin-embedded for electron microscopy. Such thin sections are often used to evaluate the pathological features of EAE.

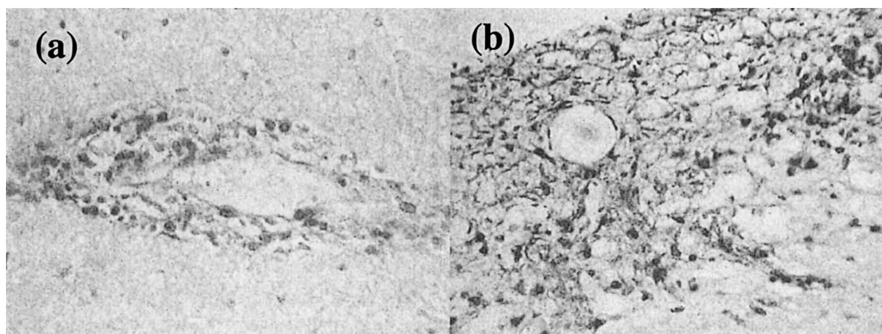

Figure 3-2. Immunohistochemical labelling of sections of spinal cord from a C57Bl/6 mouse with MOG induced EAE. These are formalin fixed, paraffin wax-embedded tissues that have been labelled for expression of CD3 using a cross-reactive polyclonal rabbit anti-human CD3 antiserum in an avidin-biotin immunohistochemical technique. (a) Shows T lymphocytes within a perivascular cuff in affected spinal cord white matter. (b) Shows an area of peripheral spinal cord white matter demyelination, throughout which are scattered individual T lymphocytes.

In general, some form of scoring of the histopathological lesions will be performed, but as the pathology in each model system varies, there is no consensus grading system. Inflammation and demyelination may be scored separately. An example of one scoring system applied to EAE lesions is given in Table 3-1.

Table 3-1. Example of scoring system for EAE histopathology (disease induced in SJL/J mice by adoptive transfer of encephalitogenic T cells)

Inflammation

0	no inflammatory cells
1	a few scattered inflammatory cells
2	organisation of inflammatory infiltrates into perivascular cuffs
3	extensive perivascular cuffing with extension into adjacent subarachnoid space and CNS parenchyma
4	extensive perivascular cuffing with increasing subarachnoid and parenchymal inflammation

Demyelination

0	no demyelination
1	a few, scattered naked axons
2	small groups of naked axons
3	large groups of naked axons
4	confluent foci of demyelination
5	widespread demyelination

Racke et al., 1995

Other means of quantifying lesions are to determine the mean number of discrete lesions within serial longitudinal sections of segments of spinal cord (O'Brien et al., 1999) or specific area of tissue in mm^2 (Furlan et al., 1999). Similarly, demyelination may be measured in a standard region of CNS tissue (Linginton et al., 1988), or expressed as the percentage of a defined area in mm^2 that is demyelinated (Furlan et al., 1999). In a further approach to measuring demyelination, sections of spinal cord were immunolabelled using monoclonal antibody to PLP, and captured digital images were used to assess the proportion of demyelinated tissue using image analysis software (Tuohy et al., 1999).

4.1 EAE in SJL/J mice

An early study reported detailed features of the kinetics of the histological and ultrastructural pathology induced in eight week old, female SJL/J mice following two subcutaneous injections of spinal cord homogenate in CFA (but without *Bordetella pertussis*) (Brown et al., 1982). In this model mice displayed clinical signs of EAE between days 14 and 18 post induction (PI), and had up to three episodes of disease relapse when monitored to 6 months PI. Lesions were reported in the optic nerve, medulla or pons, spinal cord, cerebellum and cerebral cortex, with the former three areas most severely affected.

The initial period of disease was characterised histologically by a mixed neutrophilic and lymphocytic meningitis and perivascular infiltration of these cells into the peripheral white matter. The inflammatory response was accompanied by local petechial haemorrhage, demyelination and macrophage phagocytosis of myelin, and the presence of naked axons. These latter changes only occurred in areas with inflammatory change. Mice sampled at the end of the period of initial disease (day 20 PI) had a reduced neutrophilic component to the inflammation, fewer haemorrhages and evidence of astrocyte proliferation.

By day 25 PI the inflammatory infiltrate had diminished but white matter damage was more extensive. There was gliosis, prominent

phagocytic cells, naked axons and myelin debris with early evidence of remyelination. Plasma cells appeared within the meningeal lesions. Similar changes were observed at day 30 PI, however in addition to these chronic lesions, these mice had small acute lesions (as described before day 20) despite the fact that they were in clinical remission.

At the time of clinical relapse, mice also displayed a mixture of acute and chronic lesions with the latter dominating. The chronic lesions had minimal inflammation, but gliosis and naked axons were more prominent with some evidence of focal remyelination. The CNS of mice sampled after multiple episodes of clinical relapse had similar, but more extensive chronic white matter lesions with small acute lesions. There was no greater degree of remyelination in the chronic lesions at this time.

Disease may also be induced in the SJL/J mouse by administration of other encephalitogens (e.g. $PLP_{139-151}$, MBP_{84-104}), or by the passive transfer of encephalitogenic T cells. For example, transfer of a $CD4^{+}$ T cell line specific for peptide 139-151 of PLP induces a chronic relapsing disease with multifocal areas of lymphocyte and macrophage inflammation and associated demyelination in spinal cord peripheral white matter. When the cell line was preactivated in the presence of TGFβ, extensive areas of demyelination extending to the central gray matter were observed at day 70 after adoptive transfer (Weinberg et al., 1992). An example of a histological grading system applied to $PLP_{139-151}$ induced EAE in SJL/J mice is given in Table 3-2. F1 mice derived from crosses of a number of other strains with the SJL/J mouse have also been used in studies of EAE.

Table 3-2. Histological Grading of Inflammation in $PLP_{139-151}$ induced EAE in SJL/J mice

0	absence of infiltrates
1	small, rare perivascular infiltrates
2	small, numerous perivascular infiltrates
3	numerous perivascular lesions and parenchymal infiltration
4	severe confluent lesions

Langer-Gould et al., 2002

4.2 EAE in C57Bl/6 mice

Monophasic EAE has been induced in mice of the C57Bl/6 strain by immunisation with MOG peptide 35-55 in CFA, followed by intraperitoneal injections of pertussis toxin on days 0 and 2 of the induction protocol. The peak of clinical disease occurs on day 14 after induction. Histologically, this form of EAE is characterised by multifocal, coalescing areas of mononuclear inflammatory infiltration of peripheral white matter of spinal cord (sometimes involving perivascular cuffs in gray matter), with associated local demyelination. The infiltrates include macrophages, B

lymphocytes and both $\alpha\beta$ and $\gamma\delta$ T lymphocytes (Spahn et al., 1999). Small clusters of neutrophils may occasionally be present. When inflammation and demyelination are graded, the peak of the inflammatory response occurs two days after the peak of clinical disease, and peak demyelination occurs several days after the maximal inflammatory response (Figure 3-3).

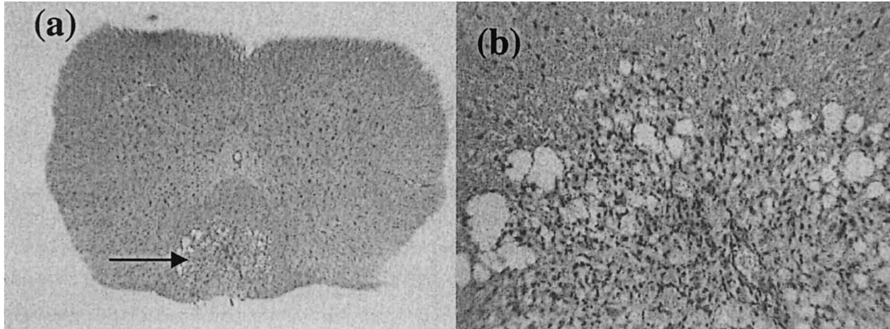

Figure 3-3. Sections of spinal cord from a C57Bl/6 mouse with MOG induced EAE-stained by haematoxylin-eosin. (a) There is an intense inflammatory and demyelinating lesion within the ventral white matter of the cord (arrowed). (b) Higher power view of the margin of this lesion with unaffected white matter, shows extensive macrophage-dominated inflammation.

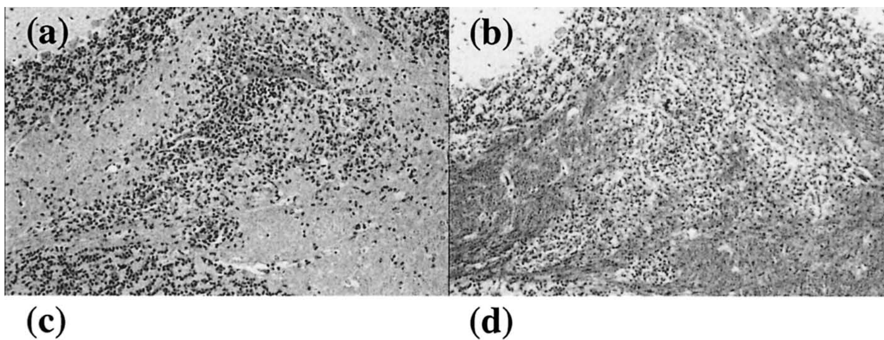
Pathology also occurs in the brain, where there is evidence of meningitis, and perivascular cuffing with mixed mononuclear cells that occurs predominantly in the white matter of the cerebellum, and in the underlying hind brain area (Figure 3-4). The inflammation and demyelination in this model resolve, and when mice recover from clinical disease there is virtually complete resolution of the histopathological changes (Massey et al., 2002).



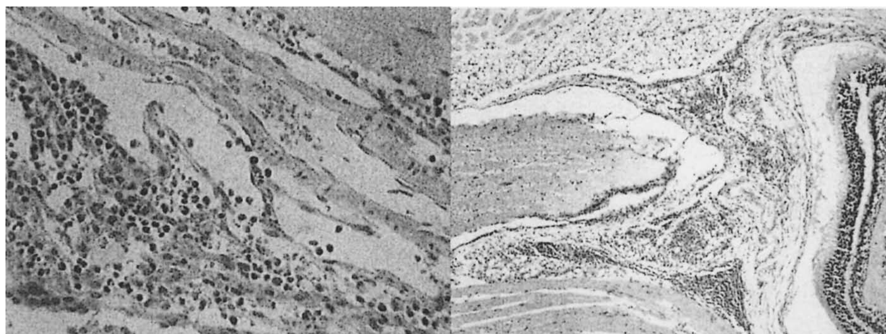


Figure 3-4. Tissues from C57Bl/6 mice with MOG induced EAE stained by haematoxylin and eosin (a, c and d) and Luxol fast blue (b). (a) High power view of cerebellar white matter showing a prominent area of perivascular cuffing with mononuclear inflammatory cells, with extension of the lesion into the parenchyma. (b) This serial section shows that demyelination is restricted to the area occupied by the inflammatory infiltrate, with uninflamed parenchyma showing normal staining reaction. (c) Section through the meninges, showing a mixed inflammatory infiltration throughout the meningeal layers. (d) Section through the retina, optic disc and optic nerve. There is an intense inflammatory infiltration surrounding the optic nerve (perineuritis). This comprises chiefly neutrophils and there are scattered neutrophils within the optic nerve tissue.

A chronic, sustained form of disease may be induced by subcutaneous injection with MOG_{33-55} in CFA on day 0, followed by intravenous pertussis toxin on days 0 and 2, and a booster injection of MOG_{33-55} in CFA on day 7. The pathology of this form of disease is similar to that described above, with extensive diffuse infiltration by mixed macrophages, T and B lymphocytes into the CNS white matter (extending to gray matter) accompanied by demyelination (Suen et al., 1997). A more severe clinical form of EAE is induced in IL-$10^{-/-}$ C57Bl/6 mice immunised with MOG_{35-55} in CFA and pertussis toxin on days 0 and 2. These IL-$10^{-/-}$ C57Bl/6 mice also develop EAE and severe inflammatory lesions when pertussis is not administered (wild-type mice develop minimal disease) (Bettelli et al., 1998).

The C57Bl/6 MOG EAE model has recently been used to demonstrate the effect of $CD4^{+}CD25^{+}$ regulatory cells in this disease. When these T regulatory cells were harvested from the lymph nodes of naïve C57bl/6 mice and adoptively transferred to naïve recipients three days before induction of EAE, there was significant protection from both disease and pathological change in CNS (Kohm et al., 2002). The transferred T reg cells appeared not to enter the CNS, but to localise to the spleen and lymph nodes of the recipient mice.

4.3 EAE in the NOD mouse

A recently reported model of EAE has been used to investigate the clinical relationship between type I diabetes mellitus and multiple sclerosis (Winer et al., 2001). When diabetes-prone NOD (nonobese diabetic) mice over eight weeks of age are simply injected twice with pertussis toxin (in the absence of encephalitogen or CFA), they develop an acute onset malaise within 7 days. Most animals recover from this within 4-7 days, however a proportion die or develop clinical signs of EAE (primary, progressive monophasic disease). A proportion of recovered female mice will develop relapsing disease between days 15-90, but the severity and outcome of this is variable.

The brains of mice with acute onset malaise show small, multifocal, mononuclear cell perivascular cuffs in cortex and brainstem, with inflammation of the margin of the fourth ventricle. The lesions of mice with acute, progressive monophasic disease were more extensive and involved hippocampus, thalamus, cerebellum, brain stem, meninges and ventricles. This form of disease was demyelinating, with plaques present in cerebellar and brain stem white matter. Female mice with relapsing disease had similar pathology to that described for the phase of acute malaise, although the perivascular cuffing was more prominent.

4.4 EAE in the Lewis rat

EAE may be induced in Lewis strain rats by subcutaneous administration of Guinea pig MBP, or encephalitogenic peptide (amino acids 70-86) derived from this protein, in CFA (actively induced disease). These rats develop an acute monophasic clinical disease that resolves spontaneously within 5 days of onset. Recovered animals do not relapse and become refractory to further attempts to induce the disease. The disease is T cell dependent, and may also be induced in naïve recipients by adoptive transfer of spleen or lymph node cells from affected animals, or by administration of MBP-specific T cell lines or clones (passively induced disease). Spontaneous recovery from disease and subsequent refractoriness to disease reinduction has been associated with elevation in the concentration of serum antibody specific for MBP, endogenous corticosterone production, elevated circulating reactive nitrogen intermediates and a range of immunoregulatory events. Adoptive transfer of lymphocytes from recovered rats is reported to protect recipients from the active induction of EAE by immunisation with MBP in CFA, but cannot prevent EAE induced by adoptive transfer of effector cells. Relapsing disease can be induced by a number of protocols including administration of immunosuppressive agents such as cyclophosphamide (Minagawa et al., 1987) or cyclosporin (Polman et al., 1988).

In Lewis rats sacrificed 13 days after induction of disease by injection of MBP in CFA (at the peak of disease), there are perivascular infiltrations of inflammatory cells within both white and gray matter. There is however, no evidence of demyelination of CNS axons although there may be demyelination within the spinal roots. Spinal cords immunostained for expression of MBP display loss of staining only in the areas occupied by inflammatory cells (Sternberger et al., 1989). Demyelinating disease has been induced in Lewis rats by intraperitoneal injection of monoclonal antibody specific for MOG, given eight days after immunisation with MBP in CFA (Schluesener et al., 1988), or at the time of onset of passively induced disease (Linington et al., 1988), providing further evidence for synergy between T cell and antibody-mediated mechanisms in demyelinating disease.

A grading system for the histological lesions observed at the peak of actively induced disease has been described (Table 3-3). In Lewis rats recovered from monophasic disease and sacrificed on day 50 PI, there are residual small perivascular aggregates of T cells and macrophages within brain white matter (Polman et al., 1988).

Table 3-3. Histological grading system for lesions of actively induced EAE in Lewis Rats

0	normal
1	meningeal hypercellularity or one perivascular cuff with a non-invasive margin per high power field
2	meningeal hypercellularity and one perivascular cuff per high power field, or two to three perivascular cuffs per field without meningeal hypercellularity
3	inflammatory cells extending from cuffs into CNS parenchyma
4	diffuse inflammation in either white or gray matter
5	inflammation extending throughout entire tissue section with or without primary demyelination

(Lyman et al., 1989)

Pathological changes have also been assessed in the spinal cord of Lewis rats, five days after adoptive transfer of splenocytes obtained from MBP primed rats and restimulated *in vitro* with MBP before transfer. Such rats develop clinical disease, and have oedema and marked perivascular infiltration of spinal cord white and gray matter and meninges by macrophages and $CD4^+$ and $CD8^+$ T lymphocytes (Sedgwick et al., 1987). These central lesions are non-demyelinating although lymphocytes have been observed within the myelin sheaths (Blakemore et al., 1989). The infiltrates were much reduced when rats were treated with anti-CD4 antibody by daily intravenous injection following adoptive transfer. Studies in this model have suggested that the majority of infiltrating leukocytes are unrelated to the disease *per se* and may be present as a secondary response to tissue damage (Sedgwick et al., 1987; Sedgwick 1988). Following

spontaneous recovery from passively induced disease the inflammatory infiltrates regress, and spinal cords are largely normal by 10 days post transfer (Blakemore et al., 1989). The kinetics of infiltration of adoptively transferred lymphocytes versus recipient cells has been examined in a chimeric model. Adoptively transferred cells dominate the preclinical inflammatory lesions, but during clinical disease large numbers of recipient T cells and macrophages infiltrate the parenchyma. During recovery, the residual T cells are primarily of donor origin (Matsumoto and Fujiwara, 1988). Donor T cells isolated from the recipient spinal cord produce higher levels of Th1 cytokines than recipient cells recruited to the same site (Weinberg et al., 1994).

4.4 EAE in rhesus monkeys and marmosets

EAE has been induced in a range of primate species including Cynomolgus monkeys (*Macaca fascicularis*), rhesus monkeys (*Macaca mulatta*), owl monkeys (*Aotus spp.*), squirrel monkeys (*Saimiri spp.*) and the common marmoset (*Callithrix jacchus*).

In rhesus monkeys an hyperacute form of EAE develops within weeks of immunisation with the recombinant human N-terminal extracellular Ig-like domain of MOG in CFA ('t Hart et al., 2000). This disease has a short clinical course, with death occurring in days, however when monkeys are given immunosuppressive therapy the disease becomes relapsing and remitting in nature. The pathological features of the hyperacute disease are extensive areas of necrosis with a neutrophilic inflammation and resultant loss of myelin and axonal structure. Although the number of infiltrating T lymphocytes is low, myelin-specific T cells are involved in the pathogenesis of this disease.

In marmosets, relapsing-remitting or primary progressive EAE has been induced by immunisation with myelin or myelin derivatives (particularly MOG) in CFA ('t Hart et al., 2000). EAE may also be induced by co-transfer of myelin-specific $CD4^+$ T lymphocytes and anti-myelin antibody (but not by T lymphocytes alone), providing good evidence in this model for a pathogenic role for B lymphocytes. Lesions develop in white matter with varying degrees of inflammation (with numerous macrophages and T lymphocytes), demyelination and remyelination, and axonal damage ('t Hart et al., 1998). Areas of demyelination are associated with local deposition of MOG-specific IgG (Raine et al., 1999). Relative to the pathology in rhesus monkeys however, there is preservation of much axonal structure. Small perivascular foci will eventually coalesce to form large demyelinating lesions. The extent of the inflammatory component of the

lesions is exacerbated when disease is induced by concurrent intravenous injection of *Bordetella pertussis* with the myelin/CFA protocol.

ACKNOWLEDGEMENTS

The histopathological images used in this chapter were prepared by the author whilst grading tissues provided from experiments performed in the laboratory of Professor D.C. Wraith, Department of Pathology and Microbiology, University of Bristol.

Chapter A4

NEUROANTIGENS IN EAE

Myelin genes, proteins and non-protein antigens

James Garbern

Department of Neurology and Center for Molecular Medicine and Genetics, Wayne State University School of Medicine

Abstract: This chapter reviews briefly the biology of myelin and describes the major CNS myelin proteins, the potential neuroantigens in EAE. The genetics of the principal myelin proteins are also discussed. Myelin glycolipids with potential role in CNS demyelinating disease and the enzymes involved in their synthesis are also reviewed.

Key words: Proteolipid protein (PLP, PLP1); myelin basic protein (MBP); 2',3'-cyclic nucleotide 3' phosphodiesterase (CNPase); oligodendrocyte specific protein (OSP); myelin associated glycoprotein (MAG); myelin-oligodendrocyte glycoprotein (MOG); ceramide galactosyltransferase (CGT); Oligodendrocyte myelin glycoprotein (OMgp); Myelin-associated oligodendrocyte basic protein (MOBP); Nogo; Nogo receptor; ganglioside; sulfatide; cerebroside

1. INTRODUCTION

Efficient conduction of neural signals along the axons of higher vertebrates occurs by the saltatory propagation of action potentials between narrow specializations of axonal membrane called nodes of Ranvier. Voltage regulated ion channels are clustered at the nodes and mediate the ionic currents that constitute the action potential. Between adjacent nodes the axon is ensheathed by spirally wound membranous sheets that define the myelinated internode. Myelin is composed primarily of lipids and proteins [for excellent comprehensive review see 1]. The complex composition of myelin offers many known and potential antigens that can induce autoimmune responses that will be reviewed in other chapters. In this

chapter I review the composition and properties of central nervous system (CNS) myelin.

2. THE CELL BIOLOGY OF MYELIN

The composition of myelin is best appreciated in a cellular context. CNS myelin is formed by oligodendrocytes, which elaborate multiple processes that ravel around the axon. At the point of axonal contact the glial membrane loops around the axon, forming the inner mesaxon. As the membranous sheet winds around the axon, most of the cytoplasm is extruded, allowing tight apposition of the adjacent membrane faces to form compact myelin. At regular intervals around successive wraps of myelin the compaction is interrupted by zones of non-compact myelin that form the incisures (or clefts) of Schmidt-Lanterman. These incisures may serve as conduits for small molecules to pass radially across the myelin sheath rather than having to diffuse circumferentially around the cytoplasmic space of the myelin leaflet [2].

The successive edges of each loop of the myelin sheet each contact the axon and are known as paranodal loops. The zone where these paranodal loops contact the axon is called the paranode, and marks a zone of separation of the voltage-gated sodium channels at the node from the voltage gated potassium channel enriched region known as the juxtaparanode. The paranodal loops are bridged to the axon by specialized, electron dense adhesions called septate-like junctions that form diffusion barriers between the periaxonal space and the interlamellar and periaxonal spaces of the internode [4, 5]. These junctions and a network of juxtamembranous filamentous proteins help to maintain the precise partitioning of the various ionic channels of the nodal region [reviewed in 6].

Although the classic view is that myelin and the subjacent internodal membrane are electically inert, myelin provides a relatively low electrical resistance pathway through which current can pass (probably through the septate-like junctions and Schmidt-Lanterman clefts) between the internodal axolemma and extracellular space that is essential for setting the nodal resting potential and also facilitates repolarization of the nodal membrane through dispersal of the charge carried into the axon by nodal sodium channels along the internodal axolemma and generating the depolarizing afterpotential [7, 8].

3. THE BIOCHEMISTRY OF MYELIN

The analysis of myelin composition was facilitated by development of methods to isolate myelin-enriched preparations. Myelin was isolated from the brain using a series of centrifugation steps, including a sucrose gradient flotation that resulted in great enrichment of myelin fragments that could be identified electron microscopically. The composition of myelin prepared in this way reveals that it makes up 40 to 50 % of the dry weight of the brain, and is about two thirds lipid and one third protein. With the advent of newer, especially genetic methodologies, proteins and lipids have been characterized through their association with specific hereditary diseases or cellular properties and localization.

Myelin is essentially highly enriched cell membrane, with a dry weight composition of about two thirds lipid and one third protein [9]. While the conventional view of myelin as a passive electrical insulator is still prevalent, it is now becoming clear that there is a more active role for myelin, and/or other oligodendroglia functions, in the development and maintenance of axonal properties. The presence of oligodendrocytes, and quite possibly axonal contact with them is critical for the formation and spacing of the nodes of Ranvier. As discussed in more detail below, oligodendroglia are necessary for maintaining the long term integrity of axons, demonstrating the existence of important axo-glial signaling pathways.

3.1 Myelin lipids and their synthetic enzymes

3.1.1 Myelin lipids

The composition of myelin is similar with that of cellular membranes with respect to its enrichment in lipids [10]. While there are no known myelin-specific lipids, the distribution of lipids in myelin is distinct from that of other cell membranes. The major lipid in myelin is free cholesterol, which comprises about 30 % of total lipid by dry weight. Cholesterol esters are not found in normal mature myelin. Phospholipids are collectively the most abundant lipids in CNS myelin, constituting about 40 – 45 % of total lipid by dry weight. Most brain phospholipids are derivatives of phosphatidic acid (diacylated glycerol-3-phosphate). Plasmalogens are lipids where an aliphatic alcohol is ether-linked rather than acyl-linked to the glycerol backbone.

Glycerophospholipid classes are defined by the nature of the compound linked at the third position of the glycerol backbone. These compounds are short-chain, polar alcohols phosphodiester-linked to phosphatidic acid. The most abundant of these glycerophospholipids in adult human brain are phosphatidyl ethanolamine, phosphatidylcholine (lecithin), phosphatidylserine and phosphatidylinositides. The phosphoinositides include phosphatidylinositol and its phosphorylated derivatives that are quantitatively minor phospholipids but are important role in signal transduction.

Sphingolipids are distinguished by the substitution of sphingosine, a long chain aminodiol, for the glycerol backbone used by glycerophospholipids. Ceramides are sphingolipids where the amino group of sphingosine is N-acylated with long-chain fatty acid. The first carbon of ceramide is linked to different head groups to form various subclasses of sphingolipids. Sphingomyelin is the phosphodiester of ceramide and choline. Most glycolipids in brain consist of ceramide linked at the first carbon with different mono- or polysaccharides. The major glycolipid of mammalian CNS myelin is galactocerebroside (Gal-C), in which galactose is β-glycosidically linked to ceramide. Gal-C constitutes about 16% of total adult human brain lipid. Sulfatide constitutes about 6% of brain lipid and is formed from galactocerebroside esterified to sulfate at the 3' position of galactose. Other sugars including glucose, (to form glucocerebroside; Cer-Glc), N-acetylglucosamine, N-acetylgalactosamine, fucose and others, are conjugated to cerebroside to form other brain glycolipids. Sialic acid, N-acetyl-neuraminic acid (NANA), is an important N-acylated, nine-carbon amino sugar that is linked to glycolipids to form gangliosides. Gangliosides are acidic in nature because of the presence of a free carboxyl group. Gangliosides are present in a variety of brain regions as well as in other tissues, and are usually classified according to the number of sialic acid residues in the molecule and their relative migration rates on thin-layer chromatograms.

Although they make up a very small proportion of total myelin lipid, gangliosides play a critical role in the nervous system. Mice that are deficient in GM2/GD2 synthase, a key enzyme needed for synthesis of complex gangliosides, can only express the simple gangliosides GM3 and GD3 and have decreased central myelination and develop Wallerian degeneration [11]. In addition, complex gangliosides, such as GD1a and GT1b, are inhibitors of neural regeneration probably through their properties as ligands for myelin associated glycoprotein (see below) [12].

3.1.2 Myelin lipid synthetic enzymes

It is likely that the program of myelination coordinates not only the expression of myelin proteins, but also the synthesis of myelin lipids. Expression of enzymes key for the synthesis of these lipids is maximal during the peak of myelination. For example, expression of UDP-galactose:ceramide galactosyltransferase (CGT), which is essential for the synthesis of galactocerebroside and sulfatide, follows the same pattern as do structural proteins in myelin. [13-15]. There is evidence that some lipids are selectively complexed with myelin proteins for processing and ultimate insertion into the plasmalemma [16-18].

Knockout mouse technology has significantly added to our understanding and appreciation of the roles of myelin lipids in overall function and structure of the CNS. CGT knockout mice are completely deficient in galactolipids, and develop tremors and weakness before dying at about 3 months of age [19-21]. These mice have abnormal paranodal ultrastructure, most notably poor or absent apposition of the paranodal loops with the axon. Septate-like junctions fail to form, resulting in loss of compartmentation separating the voltage gated sodium channels at the node from the potassium channels normally restricted to the juxtaparanodal regions. In addition, while sodium channels remain confined to the nodes, paranodal proteins such as Caspr, and the potassium channels normally restricted to the juxtaparanode are more diffusely spread along the axonal membrane. Similarly, mice deficient for sulfatide synthesis due to knockout of the ceramide sulfotransferase (CST) gene also develop similar abnormalities of the paranodal apparatus as do mice deficient for both sulfatide and galactocerebroside [22, 23]. Thus, the lipid component of myelin plays a critical role in higher order structure of not only the myelin sheath, but also of more complex structures and molecular organization of the critical nodal and surrounding regions. Loss of this segregation these channels causes impaired conduction of action potentials.

Emerging evidence supports a role for aspartoacylase (N-acetylaspartate amidohydrolase; aminoacylase II) (Figure 1) in the synthesis of myelin lipids. This enzyme catalyzes the hydrolysis of N-acetylaspartate (NAA) into acetate and aspartate [24, 25]. Although NAA is one of the most abundant compounds in the CNS, its function has not been conclusively established. However, several observations suggest that it does play an important role in myelination. These include: 1) the expression of aspartoacylase, NAA and of aspartate N-acetyltransferase (ANAT: the synthetic enzyme for NAA) all rise in concert with the classical myelin proteins, 2) apparent deficiency of NAA results in leukodystrophy [26], 3) mutations affecting the

aspartoacylase gene cause the fatal leukodystrophy Canavan disease [27], 4) NAA injected into rodent brains is incorporated into myelin lipids [28], 5) aspartoacylase mRNA is expressed specifically in oligodendrocytes [29, 30], 6) aspartoacylase itself is expressed in oligodendrocytes [31] and figure 1, and 7) NAA injected into the eye can be transported through the optic nerve and then incorporated into myelin [32]. The interpretation of NAA levels measured by magnetic resonance spectroscopy will be greatly impacted by elucidation of the role of NAA in nervous system function [33].

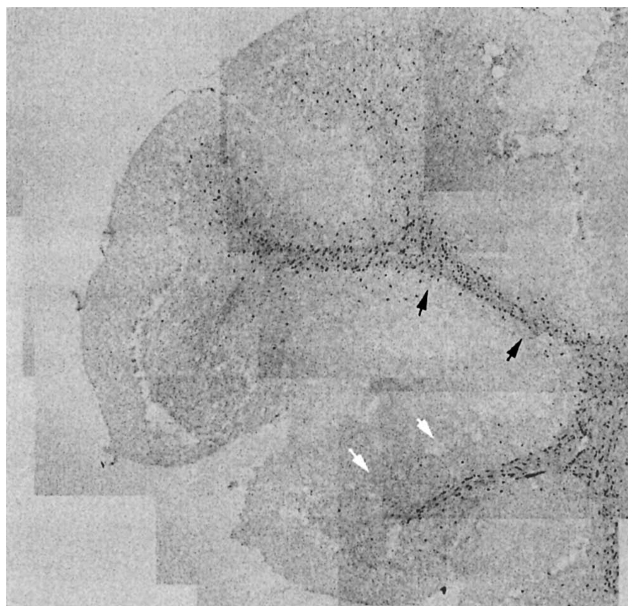

Figure 1. Immunocytochemistry of aspartoacylase in 1-month mouse cerebellum. Note the staining in the white matter tracts (black arrows), but not in Purkinje cells (white arrowheads). Distinct cellular staining is confined to the white matter.

3.2 Myelin proteins

Sodium dodecyl sulfate polyacrylamide gel electrophoretic analysis of myelin proteins reveals a complex composition with several prominent bands that have now been characterized.

3.2.1 Proteolipid protein 1 (PLP1; lipophilin) and DM20

The major protein in CNS myelin is a highly lipophilic protein now designated proteolipid protein 1, to distinguish it from the structurally similar gut-specific protein, proteolipid protein 2 [34]. PLP1 constitutes half

the protein in CNS myelin, or roughly one sixth the dry weight of myelin [35-37]. It is one of several brain antigens that can elicit EAE. PLP1 has the unusual property of being soluble in chloroform/methanol, a solvent mixture used to extract lipids from other cellular compounds. Its unusually strong lipid association led to its alternate designation of lipophilin [reviewed in 38]. PLP1 is a transmembrane protein with four membrane-spanning domains [39-41]. Synthesized as a preprotein with 277 residues, the initiation methionine is cleaved generating the mature protein of 29,869

MAJOR CNS MYELIN PROTEINS

Protein	Abundance	Localization	Gene	Chromosome	Disease(s)	Mouse mutant(s)	Null phenotype	Proposed function(s)
Proteolipid protein	50%	Compact myelin	PLP1	Xq22.2	PMD/SPG2	jimpy; jp	Late progressive weakness, axonal degeneration	Intralamellar adhesion
Myelin basic protein	~30%	Major dense line	MBP	18q22-ter	None reported	shiverer; shi	Dysmyelination, tremors, seizures, abnormal axo-glial junctions	Myelin compaction
Myelin-associated oligodendrocyte basic protein	~20% *	Compact myelin	MOBP	3p22-21	None reported		Normal phenotype	
Oligodendrocyte specific protein	7 %	Intralamellar tight junctions	CLDN11	3q26.2-26.3	None reported		Late hindlimb weakness; normal myelination; absent interlamellar tight junctions	Interlamellar tight junction component
2',3'-cyclic nueleotide phosphodiesterase	4%	Major dense line	CNP1	17q21	None reported		Late progressive weakness, ataxia and seizures; Axonal degeneration	Axo-glial signaling
Myelin-associated glycoprotein	1%	Inner mesaxon	MAG	19q13.1	None reported		Late onset weakness; redundant myelin; oligodendrogliopathy; peripheral axonopathy	Axo-glial signaling; inhibits axon regeneration
Myelin oligodendrocyte glycoprotein	<1%	Outer myelin sheath	MOG	6p21.3	None reported			
Connexin 32	<1%	Non-compact myelin	GJB1	Xq13.1	CMTX1		Peripheral neuropathy; mild CNS dysmyelination	
Oligodendrocyte myelin glycoprotein	<1%	Paranodal myelin	OMgp	17q11.2	None reported			Inhibits axonal regeneration

*Estimate based on mRNA expression relative to other myelin protein genes.

daltons with 276 residues, highly enriched in hydrophobic amino acids. Both the amino and carboxyl termini lie within the cytoplasm, as does an intracellular loop that is enriched in charged residues.

The primary structure of PLP1 is remarkably highly conserved, and is identical in humans, mice and rats. As described in more detail subsequently, the *PLP1* gene undergoes alternative splicing, generating an additional product, DM20, that lacks 35 residues (the PLP1-specific domain) that lie within the cytoplasmic loop of PLP1. Although DM20 appears during embryonic development and is about equivalent in level to that of PLP1 in Schwann cells, PLP1 predominates in mature CNS myelin, where it is about 10 fold more abundant than DM20 [42]. During development, PLP1 expression peaks in concert with other major myelin proteins, and depends upon contact with axons [43].

PLP1 is covalently modified after its synthesis. and several cysteine residues are acylated by fatty acids that probably anchor the protein to the plasma membrane [44-46](figure 2). Proteolytic cleavage may also occur in a physiologically regulated manner to release a peptide with mitogenic properties on astrocytes as well as on oligodendrocyte precursors [47].

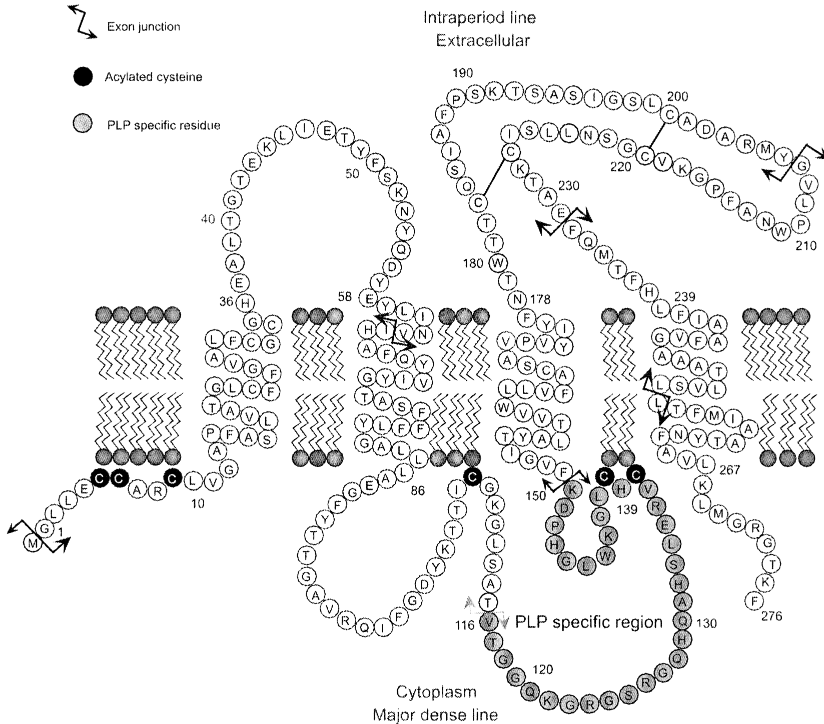

Figure 2. Proteolipid protein 1 structure. PLP1 is predicted to have four transmembrane domains, and both the amino and carboxy-termini in the cytoplamic compartment. A 35-amino acid long domain shaded in blue represents the PLP1-specific region of the protein. Cysteine residues that are predicted to be acylated are shaded in black.

Although studied for over 40 years, the function of PLP1 remains poorly understood. The topology of PLP1 and its abundance in myelin lead to speculation that it must act as an adhesion protein, locking together adjacent membrane leaflets in compact myelin. With the advent of knockout technology, it has been possible to generate *Plp1*[1]-deficient mice. Surprisingly, compact myelin forms in these animals and only subtle ultrastructural abnormalities were seen [48, 49]. Thus, oligodendrocyte development doesn not require PLP1 or DM20, and the process of myelin compaction must depend upon other myelin components. The slight 'loosening' of myelin lamellae does support an adhesive role for PLP1, but the presence of compact myelin in these knockout animals suggests that

[1] By convention, nomenclature for a murine gene or protein requires only the first letter be capitalized, whereas that for the human gene or protein abbreviation requires all letters be capitalized. In addition, the protein name is indicated by normal font, whereas the gene is indicated by italicized characters.

other factors are also important for adhesion of myelin leaflets. The expression of other myelin proteins, such as MBP, is not altered when PLP1 is absent. This indicates that PLP1 is not required for the expression of other myelin proteins, and that there is not an obvious compensatory change in other myelin proteins that accounts for the surprisingly mild null phenotype.

Other PLP1 functions have been proposed, including ion channel and glial mitogenic factor [reviewed in 50]. The *Plp1* knockout studies, however, provide conclusive proof that this protein is necessary for axonal survival. Griffiths and colleagues made the surprising observation that Plp1 deficient mice, which are behaviorally normal until about 15 months of age, clinically deteriorate due to the degeneration of axons [51]. Similar findings were noted in human patients that have null mutations of the *PLP1* gene [52]. Thus, the integrity of the nervous system depends upon the synergistic relationships between axons and glia. PLP1 is also necessary for peripheral nerve function since PLP1-deficient patients develop demyelinating peripheral neuropathy, even though PLP1 and DM20 constitute only a very small fraction of peripheral nervous system myelin [53].

3.2.1.1 Proteolipid protein 1 genetics

The *PLP1* gene lies on the X chromosome band Xq22.2 [54]. It is approximately 20 Kbp in length and contains seven exons [55]. The longest open reading frame of the *PLP1* mRNA has 277 codons. Because the initiation methionine is cleaved during processing of the protein, by convention the numbering of amino acid residues as well as corresponding codons begins with the glycine that immediately follows the initiation methionine.

Alternative usage of a splice site in exon three of the *PLP1* gene generates a shorter transcript that encodes DM20, also a tetraspan protein, but that lacks 35 amino acids from the cytoplasmic loop [56]. DM20 is similar in sequence to the M6A and M6B proteins, which are expressed in neurons or in both neurons and oligodendrocytes, respectively [57].

Many mutations affecting the *PLP1* gene have been discovered that cause clinical syndromes ranging from 'pure' spastic paraplegia (SPG2) to severe Pelizaeus-Merzbacher disease [reviewed in 58]. Mutations occur in all regions of the protein, unfortunately providing little insight into the biological functions of this still enigmatic protein. The most common mutation causing Pelizaeus-Merzbacher disease is complete duplication of the *PLP1* gene, suggesting that precise regulation of PLP1 expression is important for myelination and oligodendrocyte health.

3.2.2 Myelin basic protein (MBP)

The second most abundant protein in CNS myelin, and the first identified EAE inducing antigen, is myelin basic protein (MBP) [59]. Although a myelin protein, constituting about 30 % of myelin protein mass, MBP is not a transmembrane protein. MBP is a hydrophilic protein with a highly basic isoelectric point, and is probably tightly associated with lipids and/or other myelin proteins, where it lies in the thin cytoplasmic space between cell membrane leaflets that constitutes the ultrastructural feature known as the major dense line of compact myelin [60].

MBP is actually a family of related proteins. The *MBP* gene undergoes a complex pattern of alternative splicing, generating 4 major products with molecular masses of 21.5 (encoded by the seven main exons), 20.2 (lacking exon 5), 18.5 (lacking exon 2) and 17.2 (lacking exons 2 and 5) kDa. In mice there are five MBP variants, with molecular masses of 21.5 (all 7 exons), 18.5 (lacking exon 2), 17.2 (lacking exons 2 and 5), 17.0 (lacking exon 6), and 14.0 (lacking exons 2 and 6) kDa [61, 62]. Other splice variants occur but are present at very low levels. These different forms are developmentally regulated, and in the adult brain the 18.5 and 17.2 kDa forms predominate, constituting about 95 % of the MBP. Why the different MBP forms exist is not clear, however, the exon 2 containing transcripts are expressed early during development and the encoded MBP variants can be transported into the nucleus, suggesting a transcription regulatory role for MBP [63]. All these isoforms are not needed for myelin compaction and maintenance, per se, since mice that express only the 14 kDa form can form normal myelin [64].

Campagnoni and colleagues discovered that the *MBP* gene is part of a much larger gene which they named *Golli-mbp* (gene expressed in the oligodendrocyte lineage) [65]. The *Golli-mbp* gene includes three additional exons spanning 73 Kbp that lie 5' of the classical *MBP* gene, and contains a transcription unit of 179 Kbp in humans, compared to 45 Kbp for the classical *MBP* gene. The expression of the *Golli-mbp* gene is complex and includes several alternatively spliced transcripts, including some that are found outside of the nervous system, including thymus, where it could potentially play a role as an autoantigen [65].

Although studied for many years, the role of MBP in myelin formation is not well understood. It is thought to be involved in compaction of myelin and is clearly part of the major dense line of compact myelin. Post-translational modification, such as methylation and citrullination, of MBP may facilitate compaction and interactions with other proteins or oligodendryocyte components [66-69].

3.2.2.1 *MBP* genetics

Mutations of the human *MBP* gene have not been identified as yet. There are individuals that have deletion of the long arm of chromosome 18, where the *MBP* gene lies. Patients with the 18q- syndrome have mild to severe cognitive and behavioral impairment and MRI abnormalities that suggest this gene is haploinsufficient in humans (i.e. only one copy of the gene is not enough for normal neurologic function) [70-72].

Although there are no known pathologically significant *MBP* mutations in man, there are at least three rodent *Mbp* gene mutations that cause dysmyelination. The best characterized of these is the autosomal recessive *shiverer* (shi) mutation in mice that results from deletion of part of the *Mbp* gene containing exons 3 – 7 [73-76]. Heterozygous (shi/+) mice are normal and have morphologically normal myelin. *shi* mice have a severe neurologic syndrome characterized by ataxia and tremor that begins at about 2 weeks of age followed by development of tonic seizures at about 2 to 3 months of age and they usually die by 4 to 5 months of age. Morphologically, shi myelin sheaths are thinner than normal myelin sheaths and lack the major dense line. Similar phenotypes occur in the myelin deficient (shi^{mld}) and Long Evans shaker rats, caused by inverted partial duplication of the *Mbp* gene [77] and by transposon insertion into intron 3 [78], respectively. Although Mbp is present in relatively large amounts in peripheral nerve myelin, peripheral nerve function as well as myelin ultrastructure, including the major dense line, is normal [79]. It has been speculated that the major protein of PNS myelin, myelin protein zero (MPZ) not only acts as an interlamellar adhesion protein, but also acts, through its intracellular domain, to promote myelin compaction and participate in the formation of the major dense line.

Mbp mutations most likely act as functional nulls. No Mbp protein is detectable in *shi* myelin, whereas other myelin proteins are present, although with alteration in some of the myelin protein levels. For example, Plp levels are reduced, but the level of 2',3'-cyclic nucleotide phosphodiesterase is not affected. The level of some lipids, such as gangliosides, is altered in *shi* mice [80]. Abnormal paranodal junctions and localization of ion channels occurs in *shi* mice, demonstrating that lack of MBP results in significant disruption of axo-glial organization as well as myelin and probably contribute to the clinical phenotype [81]. Brady et al. observed that *shi* mice have abnormal axonal cytoskeletal organization and axonal transport demonstrating the importance of normal glial interactions for establishing and maintaining axonal structure and function [82].

Interestingly, the phenotype of the *shi/shi*;jp/Y mutation (i.e. mice deficient for Mbp and with a severe mutation of the *Plp* gene) is less severe

than that of either single mutation and suggests that Plp and Mbp functionally interact consistent with in vitro studies [80, 83].

3.2.3 2',3'-cyclic nucleotide phosphodiesterase (CNPase)

CNPase constitutes about 5 % of CNS myelin protein [84-86]. Although *in vitro* this protein catalyzes the hydrolysis of 2',3'-cyclic nucleotides to 2'-nucleotides, whether this enzymatic activity is active *in vivo* is not known. CNPase is one of the so-called Wolfgram proteins, and on SDS gels consists of two proteins of about 46 and 48 kDa that result from differential utilization of translation initiation sites. Both proteins are isoprenylated at their carboxy termini and are acylated, facilitating their association with membranes, although they are cytosolic proteins. The larger isoform especially is phosphorylated. Immunohistochemical studies have demonstrated that this protein is confined to non-compacted regions of myelin, such as the clefts of Schmidt-Lanterman, the paranodal loops and the inner mesaxon [87]. Expression of the two protein forms is differentially regulated during development, with only the larger protein expressed in oligodendrocyte precursors [88]. As with structural myelin proteins such as MBP and PLP, expression of CNPase by oligodendrocytes is dependent upon contact with axons [43].

The precise role of CNPase in myelin is unclear. CNPase knockout mice have ultrastructurally normal myelin, including compact myelin [89]. These mice have normal motor performance and behavior until about 4 months of age, but subsequently develop progressive motor weakness, ataxia and seizures, followed by death between about 7 to 11 months. Pathologically the most prominent abnormality is widespread axonal degeneration, characterized by axonal swellings filled with vesicles, mitochondria and cytoskeletal proteins, and reduction in axon numbers. These findings are similar to those seen in both mice and humans with *PLP1* null mutations. Thus, CNPase as well as PLP1 are essential for maintaining axonal integrity, further demonstrating the importance of the dynamic interaction between axons and their ensheathing oligodendrocytes.

3.3 Myelin associated glycoprotein (MAG)

Myelin contains several glycoproteins, the best studied of which is myelin associated glycoprotein [90, 91]. MAG comprises about 1% of CNS myelin and is actually comprised of two related proteins of 72 (large or L-MAG) and 67 (small or S-MAG) kDa molecular mass that are both products of alternative splicing of the MAG gene. Both are heavily N-glycosylated,

with approximately 30 % of their mature mass constituted of carbohydrate. MAG is a membrane protein, with a single transmembrane domain, and five immunoglobulin (Ig) domains, the first of which has an RGD (Arginine-glycine-aspartate) motif characteristic of integrin-mediated cell adhesion molecules. The oligosaccharides in MAG are heterogeneous and complex, most being negatively charged due to sialic acid or sulfate groups, and include the L2/HNK-1 carbohydrate epitope.

The structure and localization of MAG is therefore consistent with it playing a role in axo-glial signaling. MAG is located in the inner mesaxon at the point of axo-glial contact. In the CNS, MAG is found only in the periaxonal oligodendroglial membrane, however, in the PNS it is also localized at other non-compacted areas of myelin, i.e. paranodal loops, Schmidt-Lanterman clefts and the outer mesaxons. There are no known mutations in the human MAG gene, but experimentally created MAG-null mice provide clear evidence that MAG mediates important signaling functions between axons and myelinating glia, both in the CNS and PNS [92, 93]. Mice deficient in both S-MAG and L-MAG have a delay in myelination, and later develop cognitive and locomotor deficits. Mice have a normal to near normal lifespan. Pathologically the most striking abnormalities in the CNS are aberrant myelin loops and redundant myelin sheaths, and later develop dying back oligodendrogliopathy [94]. This implicates MAG as a mediator of an axonal signal that exerts a trophic effect on oligodendrocytes.

The strong evidence that a significant cause of disability in patients with multiple sclerosis results from axonal degeneration has placed great importance on studies of neural regeneration [reviewed in 95]. MAG has been shown to have axonal growth-inhibitory effects in postnatal animals after injury [96]. The current evidence favors a complex set of interactions with the oligodendrocyte proteins MAG, Nogo66, and Oligodendrocyte-Myelin glycoprotein (OMgp, see below) interacting with the axonal Nogo receptor (NgR) and p75 neurotrophin receptor on lipid rafts containing complex gangliosides to activate the small GTPase Rho, which then leads to axonal growth inhibition. Nogo, originally identified by the Schwab group as an inhibitor of axonal regrowth, encodes three splice variants, Nogo-A, -B, and –C. Of these evidence from selective knockout of splice variants supports Nogo-A in particular as important in preventing axonal regrowth. However, not all lines of Nogo – deficient mice show the predicted improvement in neuronal regeneration [97-101]. Therefore, understanding the roles of other factors that inhibit regeneration, compensatory and genetic background factors will still be needed before we can develop effective approaches for neural regeneration.

3.4 Oligodendrocyte specific protein (OSP; aka Claudin-11)

OSP was originally found through a molecular strategy to isolate novel oligodendrocyte specific genes [102]. It is a 22 kDa protein that is a member of the tetraspanin and claudin families of transmembrane proteins and comprises about 7 % of CNS myelin protein, making it the third most abundant myelin protein. Mice that are deficient in OSP develop tremors at about two weeks of age but that later improves, followed by adult onset hindlimb paresis and male sterility. There is not a readily apparent deficiency of myelin in these animals, however with specific antibodies, and ultrastructural studies it has been found that OSP forms intracellular tight junctions at sites of apposition of noncompact myelin regions. In addition, it is also necessary for formation of tight junctions in Sertoli cells [103].

3.5 Myelin oligodendrocyte protein (MOG)

MOG is a minor component of CNS myelin that was originally identified through its ability to act as a brain antigen [104]. It is a glycoprotein of 26 to 28 kDa that is like MAG a member of the Ig superfamily of proteins [105, 106]. The *MAG* gene lies within the HLA gene complex on chromosome 6 [107]. It contains complex oligosaccharides, including the L2/HNK-1 epitope. It has a single Ig domain and probably has a single transmembrane domain. Its expression is restricted to the outer surface of myelin sheaths and oligodendrocytes, suggesting that it may function in mediating signals between the oligodendrocytes and the extracellular space [108]. Both T and B cell-mediated immune responses can be experimentally generated by MOG [109, 110]. Thus far, no naturally occurring or experimentally-generated mutations of MOG have been reported in any species.

3.6 Connexin 32 (Cx32; Gap junction β 1)

The gap junction-forming protein connexin 32 is a quantitatively minor component of CNS myelin, where it forms heterologous gap junctions between oligodendrocytes and astrocytes (Cx32 on oligodendrocyte side, and Cx26, Cx30 and Cx43 [111, 112]. The function of these gap junctions was uncertain since patients with mutations in Cx32 classically develop only peripheral neuropathy. In addition, Cx32 null mice only manifest a peripheral nervous system phenotype [113]. Recent reports demonstrate that these gap junctions do have functional significance since some patients with X-linked Charcot-Marie-Tooth disease develop deafness and transient CNS

white matter abnormalities associated with bulbar palsy and quadriparesis [114-117].

3.7 The paranodal junction proteins (septate-like junctions)

Paranodal axo-glial junctions or septate-like junctions are specializations of critical importance to the normal electrophysiological function of myelinated axons [reviewed in 6, 118, 119, 120]. The proteins at these junctions not only interact to form intercellular junctions linking the axonal paranodal membrane to the paranodal myelin loops, but also interact with intracellular proteins to anchor the junctional complex to the cytoskeleton and to segregate ion channels and other proteins to the appropriate spatial domains. The expression of these junction proteins during development is critical to the formation of the nodal region. The best characterized components of septate-like junctions are axonal proteins, and include contactin, Caspr (contactin-associated protein; aka paranodin), and Caspr2, which are collectively also referred to as NCP proteins (neurexin, caspr and paranodin). Recently at least one of the glial receptors for the Caspr/paranodin complex was found to be neurofascin 155 (NF155) [5]. NF155 is encoded by the neurofascin gene, which also encodes additional proteins whose transcripts result from alternative splicing of the gene [121, 122]. NF155 is an ankyrin-bound transmembrane protein of the Ig superfamily related closely to the L1 cell adhesion molecule.

3.8 Other proteins

Myelin-associated oligodendrocyte basic protein (MOBP) is a small, basic protein present in compact myelin, where they probably associate with MBP [123, 124]. At least three splice variants exist, generating polypeptides of 8.2, 9.7 and 11.7 kDa. There are no human MOBP gene mutations reported, however, recently the murine gene has been knocked out. Mobp-deficient mice have no neurologic phenotype and have morphologically normal myelin [125].

Oligodendrocyte-myelin glycoprotein (OMgp) is a glycoprotein of 120 kDa localized to the paranodal areas. It contains the L2/HNK-1 epitope. This protein is implicated as an inhibitor of axonal regeneration, probably acting as a co-ligand for the Nogo receptor (see discussion in section 3.3).

Oligodendrocytes, as do other cells, express a variety of ion channels and ion transporters, but these have not been studied directly with respect to their possible roles in the etiology of EAE or MS. Interestingly, knockout of one

potassium channel gene, the weak inwardly rectifying channel (Kir4.1) results in a severe syndrome characterized by tremor by 2 weeks and quadriparesis with death by about 3 weeks of age [126]. Pathologically the white matter is altered by spongiform change and axonal swellings, reminiscent of Canavan disease pathology.

4. CONCLUSIONS

It is now clear that in addition to their likely roles in the formation, compaction and maintenance of myelin, myelin proteins and lipids are also critical for maintaining the ionic environment of the axon, and for the long term stability of axonal structure. The understanding of disease pathogenesis and development of more effective therapeutic strategies for multiple sclerosis must take into account the basic properties and functions of these oligodendrocyte components, as well as their potential as autoantigens in initiating EAE, and possible MS.

Chapter A5

ADJUVANTS IN EAE

Cris S Constantinescu and Brendan A Hilliard
Division of Clinical Neurology, University of Nottingham, UK and Depertment of Molecular and Celluar Engineering, University of Pennsylvania, Philadelphia, USA

Abstract: Adjuvants enhance autoantigens' immunogenicity and play a major role in the induction of EAE. Complete Freund's adjuvant (CFA) is the key adjuvant for cell-mediated immunity, including EAE. An additional adjuvant, pertussis toxin, is necessary for active EAE in mice. The mechanisms of action of adjuvants are multiple, but important actions are stimulation of proinflammatory cytokines and costimulatory molecules.

Key words:
adjuvant, experimental autoimmune encephalomyelitis, complete/incomplete Freund's adjuvant, pertussis toxin, immunopotentiation

The term *(immunological) adjuvant* refers to an agent that can potentiate an immune reaction (immunopotentiation). *Adjuvanticity* is the efficacy of an immunological adjuvant to enhance immunogenicity of an antigen. The final mode of presentation of the immunogen and adjuvant combination is called adjuvant formulation.

Adjuvants have been extensively investigated for vaccine development. Currently numerous synthetic adjuvants are being tested for vaccines and for effective immunization protocols for generation of antibodies. However, most of the traditional adjuvants are of bacterial origin. It is not surprising that bacteria and bacterial products have high adjuvanticity as infectious agents are strong stimuli for immunological defense. Freund's discovery that killed bacteria suspended in mineral oil enhanced antibody production [1] led to the use of antigen-adjuvant combination emulsified in oil. The oil may play the dual role of having adjuvant activity and acting as a depot for the antigen.

After this important discovery, Kabat [2] successfully and more reliably induced EAE in rhesus monkeys using the complete Freund's adjuvant.

Subsequently in efforts to induce EAE more reliably in mice, the ancillary adjuvant, *Bordetella pertussis* vaccine [3] was used. Subsequent studies have identified pertussis toxin as the component responsible for the adjuvanticity and currently many protocols use intravenous or intraperitoneal injection of killed *B. pertussis*, *pertussis* toxin, or the *pertussis* vaccine.

A large number of synthetic materials or bacterial products have been shown to have adjuvant properties.

Adjuvants	Examples	Immunological effects
Depot forming	Water/oil emulsions, e.g., CFA	Antigen persistence, stronger memory T cell response
Macrophage activating	Muramyl dipeptide (MDP), LPS, CpG bacterial DNA, CFA *C. parvum*, etc.	Enhanced cytokine production by macrophages, Costimulation, MHC expression
Inert materials	Alum, latex, acrylic	Antigen persistence and aggregation
T/B cell activating	PPD, polyA:polyU, LPS	Provide T cell help/enhance B cell function
Surface active	Saponins, lysolecithin, Quil A, liposomes	Antigen aggregation, facilitate antigen presentation

The general mechanism of action of adjuvants is an enhancement of antigen presenting cell (APC) function including increased MHC and costimulatory molecule expression and enhanced expression of relevant cytokines such as IL-1 and IL-12 for adjuvants of cell mediated immune responses and IL-4 for humoral immune responses. Another quality of adjuvants should be that of ensuring persistence of an antigen at the relevant sites. This is accomplished by the use of antigen depots such as oils.

Complete Freund's Adjuvant has all of these properties. It has been widely used in EAE, where its roles are multiple. CFA is an adjuvant preparation of killed mycobacteria, most commonly *M. tuberculosis*, in a water and oil emulsion. The emulsion without mycobacteria is called incomplete Freund's adjuvant (IFA). CFA has been shown to induce preferentially a cell mediated immune reaction, although it is also often used as an adjuvant for generation of antibodies and for humoral immune reactions. Through *Mycobacterium*, a strong inducer of IL-12, it is

preferentially inducing Th1 responses [4]. The ability to induce Th1 responses to myelin antigen is considered to be a major correlate of the adjuvanticity of CFA and it is due to the mycobacterial component, immunization with antigen in IFA fails to induce EAE and appears to be tolerogenic [5]. The tolerogenicity of antigen in IFA is not due to the lack of an immune response, but to the development of a Th2-type response, in contrast to the CFA-associated Th1 response. This phenomenon occurs in a variety of cell mediated experimental autoimmune diseases including EAE [6] and across a spectrum of MHC backgrounds, indicating that the Th1/Th2 dichotomy is more likely a function of the adjuvant (infectious v. non-infectious) rather than of the animal's genetic background [7]. Moreover, IFA was shown to have a direct inhibitory effect on EAE: when administered intraperitoneally it inhibited EAE in various strains of mice. The effect was due to a down-regulation of antigen and mitogen-specific T cell proliferation. The CNS infiltrating cells expressed reduced cytokines, chemokines and chemokine receptors [8].

In addition to its role as an immunization adjuvant enhancing Th1 responses, activating the macrophages, ensuring antigen persistence and facilitating recruitment of memory T cells, *Mycobacterium* in CFA preparation may also have an important role in increasing the blood brain barrier permeability [9]. This process may be due to antibodies to a mannan component of the bacteria [10]. The CFA-induced increased permeability to various proteins of the blood brain barrier by itself does not result in reactive gliosis or microglia activation as shown by Rabchevsky et al [11].

The presence of Mycobacteria in an emulsion form has been considered important for the adjuvanticity of CFA and of many other adjuvants. Finer emulsions have stronger adjuvant effect as shown by Maata et al, who succeded in inducing EAE in otherwise resistant mice by ultrasound emulsification of the antigen-adjuvant mixture. However, Levine (S Levine et al) have shown that, in susceptible rats, immunization in the absence of an adjuvant water-oil emulsion still results in EAE.

Pertussis

Induction of active EAE in mice is greatly facilitated by Pertussis toxin. Pertussis toxin is an important virulence factor for Bordetella pertussis, the agent causing whooping cough. The toxin is a hexamer and its α subunit is a adenosine diphosphate (ADP)-ribosyl transferase which interferes with signal transduction by ribosylating the α subunit of trimeric G_i proteins, while the β subunit binds to cell surface receptors. The mechanisms of facilitation of EAE induction by pertussis toxin are complex. A histamine-sensitizing factor has been extracted from B. pertussis. The susceptibility to EAE in mice was shown to be in large part dependent of the MHC and the histamine sensitization genes. The adjuvant effects of pertussis toxin have

been attributed to an increased vascular permeability of the brain and spinal cord. This is mediated by vasoactive amines and is controlled by an autosomal locus, *Bhps* (Bordetella pertussis-induced histamine sensitization). Recently, this locus has been identified as the histamine H_1 receptor.

Other mechanisms are also likely to be implicated in the ancillary adjuvant effects of pertussis toxin in EAE. One such mechanism is the stimulation of Th1 responses. Pertussis induces IL-12, which in turn activates Th1 responses [12]. This is due to a stimulatory effect on both macrophages and dendritic cells [13]. However, IL-12 alone is probably not sufficient as IL-12 as an adjuvant, although effective in vaccination for infectious disease models [14], was insufficient for modification of resistance (although it can increase disease severity) in several autoimmune disease models in mice (Constantinescu et al, unpublished observations); [15-17].

The adjuvant effect of pertussis, however, appears to involve both Th1 and Th2 immune responses [18] which are both enhanced by it. However, in the context of EAE, it appears, as expected, that the Th1 effect is more important. In studies showing that co-administered pertussis toxin overcomes the tolerogenic effect of IFA in proteolipid protein (PLP)139-151-induced EAE, both Th1 and Th2 PLP139-151-reactive Th1 and Th2 cells were generated but Th2 cells were neither protective nor pathogenic [19].

The expansion and stimulation of CD4+ T cells may be mediated through effects on macrophages and other APC and on T cells.

There is evidence that both the vascular and the immunologic effects of pertussis toxin (the increased vascular permeability and stimulation of encephalitogenic cells) are mediated through the histamine H_1 receptor. Indeed Pedotti et all have recently shown that encephalitogenic T cells express more H1 receptor and less H2 receptor than Th2 cells. Moreover H1 antagonists suppress EAE [20].

Like CFA, pertussis can overcome genetic resistance to EAE [21]. The adjuvant effects of pertussis toxin have have been shown in other autoimmune diseases, where pertussis overcomes resistance to disease. These include experimental autoimmune orchitis [22] uveitis [13], and neuritis [15]. Although generally known as an ancillary adjuvant for mouse autoimmune disease, pertussis has had adjuvant effects in rat EAE. These effects were shown to be associated with increased costimulation, TNF, and nitric oxide synthase. Pertussis can induce a hyperacute EAE in susceptible Lewis rats [23]and can overcome resistance in typically resistant rat strains [24, 25]. Recently, we have also shown that pertussis toxin as an ancillary adjuvant with CFA induced reproducible experimental autoimmune myositis in rats after immunization with skeletal muscle myosin [26].

Protective effect of adjuvant pre-treatment

Although pertussis toxin and CFA are used as adjuvants, pre-treatment prior to immunization for EAE results in protection from EAE. The mechanisms are unclear and it has been suggested that they may be different between CFA and pertussis. [27]. For the latter, it requires native, not genetically inactivated toxin [28]. The protective effect may be through interfering with TCR signaling. The effect was not present on preformed encephalitogenic T cells and it has been suggested that the inhibition is through affecting the development of encephalitogenic cells. For CFA, it has been shown that the effect is due to the PPD component of M. tuberculosis.

Recently it has been shown that cholera toxin, like pertussis toxin a member of the bacterial ADP-ribosylating exotoxins, also has potent adjuvant activity for mucosal immune responses, a property that may be useful in vaccine design. It preferentially induces a Th2-type response. Mucosal (e.g., nasal) administration of cholera toxin results in suppression of EAE via inhibition of IL-12 and IFN-γ production in the CNS [29-31]. Coupling of cholera toxin with the autoantigen followed by mucosal administration also inhibits EAE, by reducing the autoantigen (myelin basic protein, proteolipid protein peptide)-specific delayed-type hypersensitivity and inflammatory infiltration in the spinal cord. It has been shown that the adjuvanticity of cholera toxin is due to the A subunit and is dependent on ADP ribosylation [32]. On the other hand, the tolerizing effect is induced through the B subunit, possibly via induction of IL-10. The mechanism may be similar for pertussis toxin as well. These findings show that bacterial toxins adjuvants can have, in certain circumstances, immunomodulatory effects.

Other adjuvants

Muramyl dipeptide (N-acetyl-muramyl L-alanyl D-isoglutamine) is a bacteria-derived substance widely used as immunostimulator/adjuvant. has been used in an experimental model of MS in guinea pigs displaying acute demyelination and inflammatory infiltrates similar to those of "classical" EAE [33, 34].

Lysolecithin not only can induce demyelination by itself but it can also act as an adjuvant and enhance myelin-induced EAE [35].

Lipid-bound neuroantigen (MBP, extracted using a non-ionic detergent that preserves its binding to myelin lipids also has an adjuvant effect in Lewis rats, where it induced more demyelination than lipid-free MBP.

Intense emulsification by **sonication** in adjuvant emulsion prior to immunization induces EAE in reputedly resistant mice (BALB/c) indicating that it may be the physical state of the neuroantigen that has the major influence on the development of the autoimmune response [36].

Alum adjuvant is thought to favor Th2 responses. This property has been used in experiments in which animals with EAE were immunized with soluble MHC class II molecules. The immunization elicited an antibody

response thus blocking the TCR-MHC interaction. A phase I clinical trial using alum as an adjuvant for immunization with peptides derived from HLA-DR resulted in increased production of anti-HLA-DR antibodies and was well tolerated.

Alum was also used as an adjuvant and compared with IFA in an attempt to generate antibodies against myelin-associated inhibitors of axonal regeneration after experimental spinal cord injury. Although the SJL/J mice used are susceptible to EAE, the mice did not get EAE when immunized with alum. The implications are important, because alum can be used in humans. Interestingly, however, aluminium (tin) has been shown also to have an adjuvant effect in EAE along with a number of other particulate materials (see below) [37].

Schiff base-forming drugs are potent adjuvants for cell-mediated immune responses. Their immunopotentiating ability is mediated through enhancement of costimulation through B7.1 and B7.2 molecules and by preferentially inducing Th1 responses [38, 39]. To date no studies using these adjuvants in EAE are known, but the mechanisms of actions of these drugs are very relevant for the pathogenesis of EAE and are potentially useful adjuvants for the future.

Particulate materials (carbonyl iron, silicon and silica powders etc) inoculated either at the same time or (for some, like silicon and silica powder) prior to the immunization with adjuvants. The mechanism appears to be an increase in antigen persistence [37, 40]. Moreover, carbonyl iron, when used as adjuvant together with rat spinal cord tissue, is capable of inducing EAE in reputedly EAE-resistant Brown Norway (BN) rats. The augmentation of EAE was attributed to an increase in the absorption of the antigen [41].

Live attenuated vaccines also enhance the severity of EAE, having an adjuvant effect. Caspary has shown that the distemper vaccine, the BCG and the measles vaccines all enhanced EAE [42].

The search for alternatives to CFA, an adjuvant that causes pain, is important not only for EAE but also for generation of antibodies. Several additional adjuvants have been tested for their ability to induce monoclonal antibodies in mice with some, such as GERBU adjuvant producing titers of antibodies similar to Freund's adjuvant and poly(A).poly(U) producing lower titers but showing higher fusion efficiency [43]. These findings, however, have not been extrapolated to EAE, where CFA remains the strongest adjuvant. It is hoped, however, that less pain-producing adjuvants will become available.

In conclusion, a variety of adjuvants have been used for induction of EAE. The adjuvant effect appears to be in significant part through cytokine immunity induction, in particular Th1 cytokines associated with cell mediated immunity and also through stimulation of costimulatory molecules.

Chapter A6

THE ROLE OF ASTROCYTES IN AUTOIMMUNE DISEASE OF THE CENTRAL NERVOUS SYSTEM

Olaf Stüve and Scott S. Zamvil
Department of Neurology, University of California, San Francisco, CA 94143, USA

Abstract: Astrocytes are the most abundant glial cell population in the central nervous system (CNS). In the healthy brain and spinal cord, the major function of astrocytes includes the formation and maintenance of the blood brain barrier (BBB), and the supply of structural support and nourishment to neurons. This article will discuss the role of astrocytes in multiple sclerosis (MS) and other inflammatory autoimmune diseases of the CNS. We will address the capacity of astrocytes to serve as immunocompetent cells, their role in major histocompatibility complex (MHC) class II restricted antigen (Ag) presentation, and their ability to express costimulatory molecules. We will also discuss astrocytes as the major CNS producers of several chemokines and cytokines, and their relevance to neurological disease.

Key words:
astrocytes, antigen presentation, major histocompatibility complex, co-stimulatory molecules

Multiple sclerosis (MS) is a chronic inflammatory demyelinating disease of the CNS of unknown etiology, causing relapsing and progressive neurological disabilities (1-3). It is the most common and clinically important demyelinating disease in humans. Worldwide, it is estimated that at least 1.1 million people have physician-diagnosed MS (3, 4). The disease course can be separated into two-stages (5-8). While MS often starts with a relapsing-remitting (RR) disease course, an estimated 50% of patients RR-MS will convert to a secondary progressive (SP) clinical course within 10 years of disease onset. Pathologically, inflammation is a characteristic feature accompanying demyelination in early MS. Remyelination can occur during the early phase when initial damage may be reversible. Activated $CD4^{+}$ T cells, which recognize CNS autoantigen (Ag) in association with

major histocompatibility complex (MHC) class II molecules, have been implicated in the inflammatory stages of MS.

The four types of glia in the central nervous system (CNS) can be divided into microglia and macroglia, which include astrocytes, ependymal cells, and oligodendrocytes. Astrocytes are the most abundant glial cell population in the brain and spinal cord. In fact, they outnumber neurons by 10-50 : 1. Using gold chloride- mercury bichloride staining technique at the end of the 19th century, Drs. Santiago Ramon y Cajal and Camillo Golgi first demonstrated the contributions of astrocytes to degeneration and regeneration of the CNS, a discovery that was awarded with the Nobel prize in 1906. The importance of astrocytes for homeostasis and immune function of the central nervous system (CNS) has relatively recently become a topic of scientific interest.

Astrocytes are easily identified by their star-shaped appearance. In the fully developed adult brain, astrocytes are intimately associated with blood vessels by wrapping their fine processes around the abluminal vascular surface. The interaction between astrocytes and endothelial cells occurs through soluble factors, and seems bidirectional: The induction of tight junctions between endothelial cells is thought be triggered by astocytes, whereas endothelial cells may play a crucial role in regulating the maturation of astrocytes (9). Thus, astrocytes play a crucial role in forming and maintaining the blood brain barrier (BBB), and shielding the CNS from blood-derived pathogens (10). Some data indicate that astrocytes express MHC class II molecules (11-14) and can serve as antigen presenting cells (APC) to $CD4^+$ T cells during the initial inflammatory phase of MS. However, astrocytes may also have a neuroprotective role: Not only do they communicate with neurons through the release of the amino acid glutamate, more importantly they prevent neuronal death from excess release of glutamate during ischemia or inflammation (15). Astrocytes also regulate the extracellular pH and potassium concentration. Physical support for neurons and other CNS cells is provided by the astrocytes through the formation of extracellular matrix (ECM), which also serves to isolate synapses and limits the dispersion of neurotransmitters (15). Astrocytes have an important role in CNS scar formation. After CNS injury or cell death, astrocytes quickly respond with upregulation of glial fibrillary acidic protein (GFAP), which is associated with astrogliosis (16, 17). Increased tissue repair and turnover is then triggered through the astocytic production of ECM, proteases, protease inhibitors, trophic factors, and cytokines (18-23). Around sites of mechanical injury, astrocytes become hypertrophic, and extend numerous fine processes around each other. The scar consists of tightly packed, hyperfilamentous astrocytes, bound together by tight and gap junctions.

The role of astrocytes in the formation of the BBB, in glutamate homeostasis, and scar formation in the CNS make these glial cells important

participants and potential targets of therapeutic interventions in inflammatory diseases of the brain and the spinal cord, including MS. Here, we review investigations that address the role of astrocytes as antigen presenting cells (APC), and specifically their role in major histocompatibility complex (MHC) class II restricted antigen (Ag) presentation. Various costimulatory pathways and the release of inflammatory mediators by astrocytes during CNS autoimmune disease will also be discussed.

The role of astrocytes in MHC class II restricted antigen presentation

Experimental autoimmune encephalomyelitis (EAE) is a CNS inflammatory demyelinating disease that serves as a model for multiple sclerosis (MS) and other organ-specific autoimmune diseases (1, 24). EAE is primarily mediated by $CD4^+$ T lymphocytes that recognize CNS self-Ag's in the context of MHC class II molecules expressed on the surface of APC (1, 24). Ag presentation may be required at different stages of EAE pathogenesis. Peripheral (outside the CNS) activation facilitates T cell entry into the CNS (25, 26). Recent investigations further indicate that Ag processing by resident CNS APC is required for MHC class II-restricted Ag presentation within the CNS (27, 28). While the healthy brain and spinal cord are almost devoid of MHC class II molecules, it has been proposed that both, astrocytes and microglia, may participate in Ag presentation and $CD4^+$ T cell activation through IFNγ-inducible upregulation of MHC class II during inflammatory CNS conditions like MS (29-33). Specifically, interferon (IFN)γ a proinflammatory cytokine that is thought to have a key role in the pathogenesis of MS (34), is required for induction of class II MHC molecules on so called "nonprofessional APC". While the role of microglia as APC for MHC class II-restricted Ag presentation in CNS inflammatory disease was established (32, 33), the role of astrocytes remains controversial.(33, 35) MHC class II molecules have been detected on astrocytes within inflammatory lesions of MS (11, 14) and EAE (12, 13), suggesting that these nonprofessional APC may participate in Ag presentation to $CD4^+$ T cells in vivo (12, 13). IFNγ-activated astrocytes upregulate MHC class II and MHC class I molecules in vitro, and can present antigen to $CD4^+$ T cells or $CD8^+$ T cells, respectively (30, 36-38).

T cells that express the accessory surface molecule CD4 are capable of recognizing and binding linear peptide antigen (Ag) in the context of the MHC class II (*Figure 1*). This high-affinity cell-cell interaction is termed the "immunological synapse" (39-41). MHC class II expression is regulated mainly on a transcriptional level (42-45). Three *cis*-acting elements in the

promoter region of the MHC class II gene, namely W, X, and Y boxes, constitute the major transcriptional control elements. Numerous DNA binding proteins bind to these cis-acting sequences, which are essential but not sufficient to initiate transcription. In contrast to MHC class I, the expression of MHC class II is not ubiquitous. The MHC class II transactivator (CIITA), a transcriptional co-activator, is the essential molecule that directs IFNγ-inducible MHC class II expression in nonprofessional APC and constitutive MHC class II expression in professional APC (*Figure 2*) (46, 47).

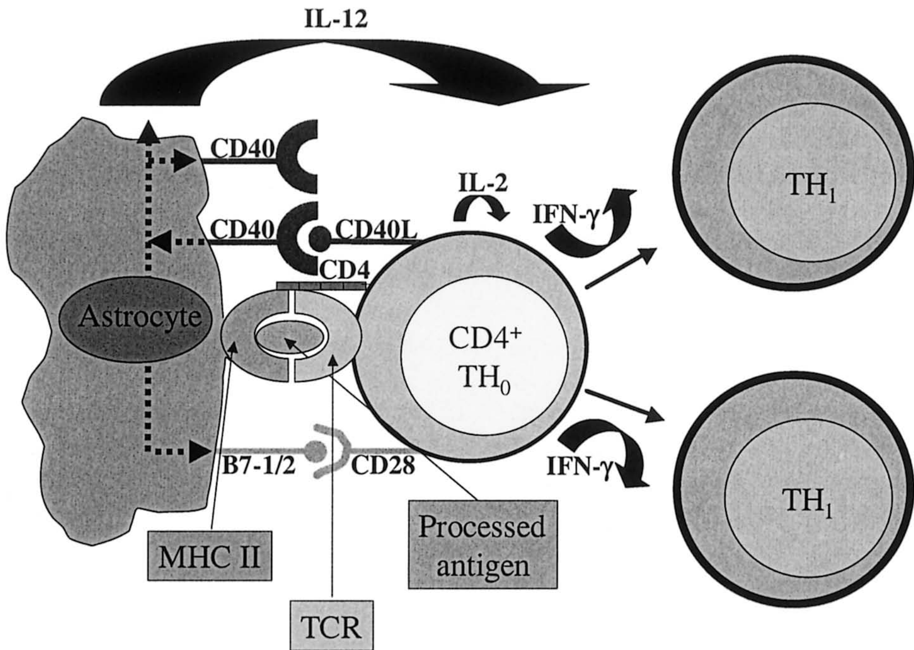

Figure 1: In order for antigen (Ag) presentation in the context of major histocompatibility complex (MHC) class II to occur, some absolute requirements have to be met. An MHC class II heterodimer on the cell surface of an antigen presenting cell (APC) contain and antigen binding groove, which can load a linear peptides that are typically 13-20 amino acids in length. A T cell can bind to Ag within the MHC class II binding groove with its T cell receptor. Only T cells that express the accessory surface molecule CD4 are capable of recognizing and binding linear peptide antigen (Ag) in the context of the MHC class II. Ag-activated T cells express CD40 ligand (CD40L), which engages to the costimulatory molecule CD40 on the cell surface of APC. Cross linking of CD40 and CD40L enhances expression of other costimulatory molecules on APC's, namely B7-1 (CD80), and B7-2 (CD86). Furthermore, engagement of CD40 leads to secretion of the cytokine IL-12, which induces the differentiation of naïve Th0 cells to effector $CD4^+$ Th1 cells. These Th1 cells secrete increased amounts of proinflammatory cytokines like interferon (IFN)-γ and IL-2. INF- γ is required for induction of class II MHC molecules on nonprofessional antigen presenting cells (APC), including astrocytes. Some studies suggest that IFN-γ also causes astrocytes to upregulate expression of B7 (B7-1 and B7-2) molecules, which are required for CD28 T cell costimulation. Thus, in cell-mediated immunity, cross-activation occurs between APC

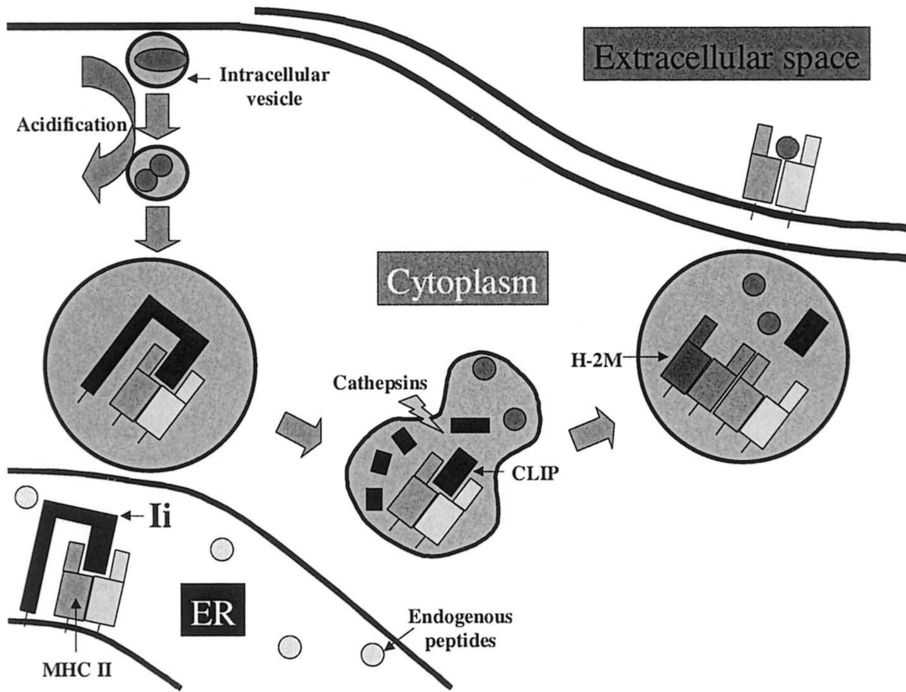

Figure 2: The endocytic compartment. Exogenous protein antigen (Ag) is taken up into an antigen presenting cell (APC) by endocytosis and broken down into peptide through acidification and proteolysis. The major histocompatibility complex (MHC) class II heterodimer is assembled in the endoplasmatic reticulum (ER) and then stabilized by the invariant chain (Ii). Within the ER, the Ii initially is a trimer that can bind three MHC class two heterodimers (not shown). The Ii blocks the MHC class II Ag binding groove, in order to prevent endogenous peptides in the ER from binding. Subsequently, the Ii targets the delivery of MHC class II dimers to the endosomal compartment, where it modulates proteolytic enzymes. Cathepsins are a group of cystein and aspartyl proteases that play a key role in the endosomal degradation of Ag and Ii. The last component of the Ii that remains bound to the MHC class II binding groove is named CLIP. The MHC class II like molecule (H-2M) catalyzes the release of CLIP and low stability peptides from the MHC class II Ag binding groove, and stabilizes empty MHC class II until high affinity peptide can be loaded. H-2M cannot bind Ag itself, and it is not expressed on the cell surface. Peptide loaded into the MHC class II binding groove can now be transported to the cell surface and presented to $CD4^+$ T cells.

Despite the fact that the genes encoding CIITA and MHC class II are located on different chromosomes in humans (chromosome 16 and 6, respectively), these molecules are developmentally coexpressed. CIITA interacts with transcription factors that are bound to the MHC class II promoter. In addition to regulation of MHC class II, CIITA also directs expression of invariant chain (Ii) and the MHC class II like molecule, HLA-DM (47), two molecules involved in MHC class II maturation and Ag presentation through the endocytic processing pathway (*Figure 3*) (48). Although considered the "master regulator" of the endocytic pathway (49), RNA message for MHC class II has been demonstrated in CIITA-deficient mice in secondary lymphoid tissue (50), and in some strains there was even residual expression of MHC class II protein in the thymus (51, 52), spleen (52), and lymph node cells (LNC) (52).

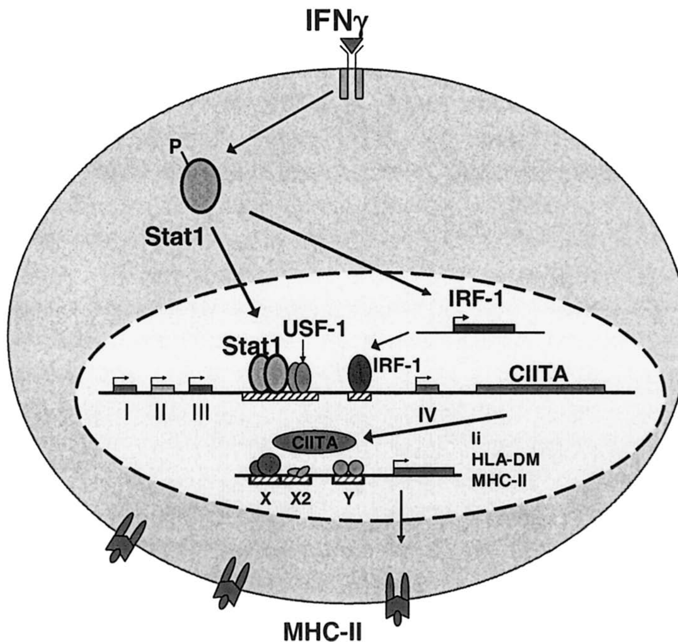

Figure 3: The major histocompatibility complex (MHC) class II transactivator (CIITA), a transcriptional co-activator, is the key molecule that directs interferon-gamma (IFNγ)-inducible MHC class II expression in nonprofessional antigen presenting cells (APC) and constitutive MHC class II expression in professional APC. CIITA expression is controlled at the level of transcription by differential activation of multiple nonhomologous promoters. CIITA promoter, pIV, which contains a GAS site, E-box, and IRF element, directs IFNγ-inducible CIITA expression in non-professional APC. It has been demonstrated that statins decrease IFNγ inducible MHC class II surface expression through inhibition of CIITA pIV.

CIITA expression is controlled at the level of transcription in a tissue-specific manner by differential activation of multiple nonhomologous promoters (53). Originally, it was observed that two CIITA promoter elements, promoter (p) I and pIII, directed constitutive CIITA expression in dendritic cells and B cells, respectively (53). Another CIITA promoter, pIV, which contains a GAS site, E-box, and IRF element (53, 54), directs IFN□-inducible CIITA, Ii, and H-2M expression in non-professional APC, including IFN-□-activated astrocytes (*Figure 3*) (35, 55, 56). While the impact of CIITA on processing and presentation of native Ag's appears cell-type dependent (57), it was demonstrated that activated astrocytes are capable of processing and presenting native Ag to MHC class II-restricted $CD4^+$ T cells in vitro (35).

Two recent studies reported that CIITA-deficient mice are resistant to clinical or histologic EAE induced by active immunization or by adoptive transfer of wild-type encephalitogenic class II-restricted $CD4^+$ T cells, and that CNS class II expression is not detectable in these animals (28, 58). Thus, MHC class II-restricted CNS Ag presentation is clearly CIITA-dependent. To further investigate the role of MHC class II-restricted Ag presentation by astrocytes in CNS autoimmunity, one group of investigators used the GFAP promoter to direct CIITA expression in astrocytes (58). Astrocytes transfected with CIITA constitutively upregulated cell surface MHC class II molecules, Ii and H-2M. The in vivo relevance of constitutive MHC class II expression on astrocytes was examined by generating GFAP-CIITA transgenic (Tg) mice using the same human GFAP promoter construct (59) used for transfection of astrocytes (58). While astrocytes in GFAP-CIITA Tg mice expressed cell surface class II molecules, these animals did not develop spontaneous CNS inflammation and, in comparison to control mice, there was no significant difference in EAE onset or clinical severity (58). These findings may partly be explained by the fact that CIITA-transfected astrocytes did not upregulate cathepsin (Cat) S, a cystein protease that may be required for processing of myelin basic protein (MBP) (60). Significant differences in histologic EAE were also not observed, although some astrocytes within EAE lesions did express MHC class II molecules in the GFAP-CIITA transgenic animals. Thus, by taking it to the extreme, these investigators demonstrated that constitutive overexpression of MHC class II molecules in astrocytes did not promote EAE, indicating that astrocytes may not play a significant role in CNS MHC class II restricted Ag presentation. Furthermore, like others (61), they did not detect MHC class II molecules on astrocytes in wild-type mice with CNS EAE.

Role of astrocytes in costimulation

While binding of the TCR to the MHC class II molecule is an absolute requirement for class II restricted Ag presentation, and commonly referred to as "signal one", a second signal is required for the activation of naïve, unactivated T cells (39, 40) (*Figure 1*). Ag-activated T cells express CD40 ligand (CD40L), which engages to the costimulatory molecule CD40 on APC cell surface. Cross linking of CD40 and CD40L enhances expression of other costimulatory molecules on APC's, namely B7-1 (CD80), and B7-2 (CD86), which are required for CD28-mediated T cell costimulation. Furthermore, engagement of CD40 leads to secretion of the cytokine IL-12, which induces the differentiation of naïve Th0 cells to effector $CD4^+$ Th1 cells. These Th1 cells secrete increased amounts of proinflammatory cytokines like interferon (IFN)-γ and IL-2.

CD 40 has not been demonstrated on astrocytes in vivo in adult human CNS tissue (62). Fetal human astrocytes express CD40 mRNA and protein constitutively. CD 40 expression can further be was upregulated by various inflammatory mediators, including LPS, IFN-γ, TNF-α, or IL-1β (63). The reports regarding CD 40 expression on murine astrocytes are controversial: While CD40 expression on astrocytes was detected by Tan et al. (64), this observation could not be confirmed by three other groups of investigators (33, 65, 66).

The evidence regarding B7 expression on astrocytes is no less confusing. No constitutive or IFN-γ-inducible expression of B7-1 or B7-2 was detected on human astrocytes in vitro (67) or in MS CNS tissue (68, 69). Reports regarding the expression of B7-1 and B7-2 on murine astrocytes have been conflicting: While Aloisi et al. could detect neither one of these costimulatory molecules on astrocytes after IFN-γ stimulation in vitro (33), expression of B7-1 and B7-2 molecules on astrocytes was demonstrated by Nikcevich et al. (70). However, Soos et al. showed that B7-2, but not B7-1, was upregulated in response to IFN-γ stimulation on primary and transformed murine astrocytes in short-term cultures (seven days), whereas in long-term cultures, both B7-1 and B7-2 were upregulated (65). Interestingly, short-term cultures of astrocytes that expressed B7-2, but not B7-1, promoted Th2 differentiation of naive Th0 cells (65). There has also been controversy with regard to determining B-7 in EAE tissue: Cross et al. did not detect either B7-1 or B7-2 in EAE lesions of different mouse strains (71), whereas Issazedeh et al. detected B7-2 expression on astrocytes during acute EAE, while B7-1 was detected on astrocytes during disease remission (72).

T cells also engage APC through binding of the lymphocyte function-associated antigen (LFA)-1 to the very late activation adhesion molecules of the immunoglobulin superfamily, intercellular adhesion

molecule (ICAM)-1. LFA-1 is considered one of the most important integrins for lymphocyte activation, and the activation of naïve T lymphocytes can be completely abrogated with antibodies to this molecule (73). Interestingly, LFA-1 has been identified on the surface of inflammatory cells in perivascular MS lesions (74-78). Furthermore, it has been demonstrated that the expression of its ligand, ICAM-1, on the cell surface of human astrocytes can be enhanced by proinflammatory cytokines (79), and that ICAM-1 is present within MS lesions and surrounding adjacent white matter beyond the lesion edge (76). Constitutive ICAM-1 expression is strongly enhanced by TNF-α and IL-1β, and less so by IFN-β (80, 81). There is accumulating data which demonstrate that activated astrocytes can express a number of other adhesion molecules, including VCAM-1, E-selectin, and LFA-3, which is a ligand for LFA-2 on leukocytes, and known to participate in T cell activation (76, 82). It is thus reasonable to propose that glial cell expression of adhesion molecules in an inflammatory environment may contribute to T cell activation and antigen presentation (78, 82-84).

Conflicting observations regarding the capability of astrocytes to express costimulatory molecules certainly need further clarification. The absence of "signal two" could render astrocytes as incompetent APC, which may promote anergy and apoptosis rather than activation of naïve T cells. The requirement for costimulation in CNS inflammation was recently demonstrated in GFAP-CIITA transgenic mice that constitutively expressed MHC class II surface molecules, Ii, and H-2M, but did not upregulate costimulatory molecules or increase EAE susceptibility (58).

Expression of inflammatory mediators by astrocytes

The extravasation of leukocytes represents one of the pathological hallmarks of several inflammatory CNS diseases, including MS (85). There is ample evidence that the progression of this demyelinating disease is associated with an inflammatory reaction that involves activated lymphocytes, macrophages, and endogenous glial cells (85).

The migration of T cell from the blood into the CNS is a complex, multi-step event (86, 87). Chemoactive cytokines, also known as "chemokines", facilitate the migration of leukocytes into the CNS. Chemokines are produced by a wide spectrum of cell types relevant in EAE and MS, including astrocytes. Their secretion can be induced exogenously through cell-cell contact or bacterial cell wall components like lipopolysaccharide (LPS), the HIV-1 Tat protein, and by proinflammatory cytokines such as TNF-α, IFNγ, TGF-β, and the binding of Fas ligand to its receptor (88-94). Chemokines are currently categorized into four subfamilies, based on their three-dimensional structure (92). The β-chemokines contain two adjacent cysteine moieties (CC). Monocyte chemotactic protein (MCP)-1 is one member of the CC chemokine family that is mainly produced by astrocytes during CNS inflammation, and that binds exclusively to the chemokine receptor CCR2, which is expressed on activated T cells and macrophages (95). Chemokines from several subfamilies have recently been identified that selectively recruit T cell and monocytes into the CNS, and their secretion has been associated with clinical disease activity in EAE (96). MCP-1 appears to play an important, differential role in the pathogenesis of this archetypical CNS autoimmune disease (97), and in one study, monoclonal antibodies directed against MCP-1 significantly reduced the severity of the relapsing form of EAE (98). LNC from primed CCR-2-deficient mice showed decreased Ag-specific proliferative responses and secretion of IFN-γ (99, 100). The importance of MCP-1 in EAE pathogenesis was further underscored by the observation that both, MCP-1-deficient mice (101), and CCR2-deficient mice (99, 102) are resistant to EAE. These results underscore the key role of astrocytes in the recruitment of activated T cells into the brain and spinal cord during CNS autoimmune disease.

Astrocytes respond to and produce proinflammatory cytokines. Th1 $CD4^+$ T cells produce proinflammatory cytokines including IFNγ and TNFα, which lead to astrocyte activation. In EAE, Th1 T cells are strongly associated with clinical disease (103). Specifically, it has been demonstrated in several species that Th1 cytokines are upregulated during acute disease and relapses, but not during clinical remission (104, 105). In plaques from MS patients, immunohistochemical in situ analysis showed the presence of the Th1 cytokine TNF-α (106, 107). Furthermore, in another study TNFα was detected in chronic MS lesions, but not in other neurological diseases

(107). The major sources of TNF-α in the CNS are astrocytes and activated macrophages (108), and in an autocrine loop, activated macrophages in turn increase their cell surface expression of TNF receptors (109). A variety of cytokines, including IFN-γ and TNFα induce the production of nitric oxide (NO) and oxygen radicals by astrocytes (110, 111). NO is a vascular and neuronal messenger abundantly present in the CNS, which is produced by inducible NO synthase (iNOS). In acute MS lesions, intense reactivity for iNOS mRNA and protein was detected in reactive astrocytes throughout the lesion and in adjacent normal appearing white matter (112). Staining of macrophages and other inflammatory cell infiltrates detected iNOS also in acute MS lesions. In chronic MS lesions, reactive astrocytes were positive for iNOS at the lesion edge (112).

However, there is also substantial evidence indicating that astrocytes may serve to downregulate proinflammatory CNS responses (113): Astrocytes produce a number of immunosuppressive cytokines, including TGF-β (29), IL-10 (114, 115), IFNα (116), and IFNβ (117). One study demonstrated that astrocyte supernatants suppressed Ag-specific T cell proliferation (113). Furthermore, it has been demonstrated that astrocytes can promote naïve Th0 cells to differentiate into Th2 cells (65). Thus, while some data support the notion of astrocytes as producers of inflammatory mediators in CNS autoimmune disease, these observations are contradicted by reports of their beneficial effects during CNS inflammation. A better understanding of astrocyte function, specifically of the temporal expression of proinflammatory and anti-inflammatory mediators, is required for therapeutic interventions to reach their full benefit.

Conclusion

The role of astrocytes as APC in CNS autoimmune disease, and particular their role in MHC class II restricted Ag presentation, has been controversial. In vitro, IFNγ-activated astrocytes upregulate MHC class II molecules and can present antigen to $CD4^+$ T cells. While MHC class II molecules have been detected on astrocytes within inflammatory lesions of MS and EAE in some studies, these findings have not consistently been reproduced. A recent report demonstrated that while CIITA-directed MHC class II expression was required for EAE induction, CIITA-directed constitutive overexpression of MHC class II molecules on astrocytes did not increase EAE susceptibility. These results indicate that astrocytes do not have a prominent role as APC in MHC class II-restricted Ag presentation during acute EAE.

Astrocytes express a number of costimulatory cell surface molecules and ligands for costimulatory molecules on leukocytes. Their biological significance in CNS autoimmune diseases remains uncertain and requires further investigation, which should involve more recently discovered costimulatory pathways. Similarly, the contribution of several inflammatory mediators secreted by astrocytes, including that of chemokines, proinflammatory cytokines, and nitric oxide, in the initiation and continuance of CNS inflammation needs to be determined. In comparison to microglia, current data indicate that astrocytes have a more significant role in downregulating CNS inflammatory responses.

Chapter A7

ROLE OF MICROGLIA AND MACROPHAGES IN EAE

Gennadij Raivich and Richard Banati
Perinatal Brain Repair Centre, Dept Obstetrics and Gynaecology, Dept Anatomy, University College London, UK and Molecular Neuropsychiatry Laboratory, Department of Neuropathology, Charing Cross Hospital, Imperial College School of Medicine, London, UK

Abstract: Microglia and macrophages are related cell types that play an important role in the pathogenesis of MS and EAE. This chapters reviews the role of these cells in the normal brain and their contribution to inflammatory demyelinating disease, including their role in antigen presentation, co-stimulation, and production of cytokines and other inflammatory mediators

Key words: experimental autoimmune encephalomyelitis, macrophages, microglia, inflammation, antigen presentation, perivascular, parenchymal, meningeal

The microglia, a brain-resident, non-neuronal cell and the blood-derived or haematogenous macrophage represent two related cell types involved in key events in the development of pathology in Multiple Sclerosis and its autoimmune animal model, the Experimental Allergic Encephalomyelitis. Microglia and macrophages fulfil a variety of different functions, but they are also recognized for their ability to act as a particularly fine sensor of brain pathology. Both cell types are rapidly activated and recruited to sites of infection, neurodegeneration, stroke, autoimmune inflammatory models such as EAE and its presumptive human counterpart, multiple sclerosis. Microglia and macrophages are stimulated by a variety of cytokines, neurotransmitters, modulators and putative neurotoxins, extracellular matrix molecules and proteases present in the inflamed central nervous system. Moreover, both cell types are plastic in their morphology and cellular identity. The presence of dying cells and cell debris will cause a transformation of phagocytic microglia into a detached, rounded and migratory or amoeba-like (amoeboid) macrophage (Streit et al., 1988; Bohatschek et al., 2001). This also works in reverse: surrounded by a CNS environment, non-phagocytic macrophages freshly recruited from the blood stream will gradually develop

branched processes and transform into ramified microglia (Flugel et al., 2001, Bohatschek et al., 2001).

Activated microglia and macrophages synthesise a cornucopia of different cytokines, trophic factors, ECM components and neurotransmitter-like molecules that could exert a positive or damaging effect on the adjacent cells. They also interact with other cells of the immune system, particularly T-cells, which are recruited to the sites of CNS inflammation. Both in vitro and in vivo evidence also suggests that they may act as competent presenters of antigen, inducing and regulating the intensity of T-cell mediated inflammation and tissue injury. The aim of the current chapter will be to provide an overview on the different, related types of microglia and macrophages in the normal brain, describe their cellular and molecular response in EAE and multiple sclerosis and finally focus on their direct contribution to neuropathology in autoimmune demyelinating disease.

1. MICROGLIA AND MACROPHAGES IN THE NORMAL BRAIN

The normal central nervous system consists of several different non-neuronal cell populations that are related to monocytes and macrophages in the bone marrow and peripheral tissues, based on the presence of specific cellular differentiation markers such as the aMb2 integrin (CD11b/CD18), IgG receptors (CD16/CD32), IBA1 and so on. The brain microglia comprise the largest component, located inside the neural parenchyma. In the normal resting state, they are highly ramified cells, with extensive branches that can cover spaces of 30-50 μm in diameter. These resting microglia are territorial, in that their cell bodies or branches are rarely seen to adhere to one another, unlike white matter oligodendrocytes contacting one another like pearls on a string (Suzuki and Raisman, 1992) or protoplasmic astrocytes with extensive cell process to process contacts at astrocyte boundaries which allow the spread of intracellular ions and other small molecules from one astrocyte to the next (Nedergaard, 1994; Bushong, 2002).

The perivascular macrophages are located in between the blood vessel endothelia, occasional perithelial cells and the basal membrane that separates the blood vessel from the surrounding neural parenchyma, the Robin-Virchow space. Perivascular macrophages are typically slender elongated cells (elongated in the direction of the blood vessel axis) with broad but short processes that sometimes go around the blood vessel. Most perivascular macrophages are located around small to moderate blood vessels inside the central nervous system. Unlike the microglia, they do not show the elaborate

ramified structure typical of resting microglia, which could be due to spatial constraints, but also to a molecular and cellular micro-environment, different from that of neural parenchyma. These differences also extend to molecular markers, such as MHC2, cyclo-oxygenase or scavenger receptors, found on normal perivascular macrophages but not in resting microglia (Linnehan et al., 1999), and the paucity of the aMb2 integrin (Angelov et al., 1992).

The meningeal macrophages, a third group, are large and rounded cells located between meningeal epithelial cells and the basal membranes surrounding glia limitans, the astroglial lining encasing neural parenchyma. Immunohistochemically, meningeal macrophages are more closely related to perivascular macrophages, macrophages in chorio-epithelial and ventricular epithelial tissue and less to the highly ramified, resting microglia inside neural parenchyma. On the whole, the basal membranes of vessels meninges, ventricular and chorioepithelium, mark an anatomical border between two brain macrophage subpopulations: the ramified microglia inside the neural parenchyma that lacks intrinsic basal membranes, and perivascular, meningeal, ventricular or chorioepthelial cells sitting on the external side of the surrounding basal membranes.

Some publications also use the term "perivascular microglia", but the term is confusing, controversially defined, and frequently misleading. It is often used it as a synonym for rounded or process-poor perivascular macrophages (Linnehan et al., 1999; Stoll and Jander, 1999), even though these cells look very different from the ramified microglia. In others, it is used to denote microglia in the neural parenchyma with processes that contact blood vessels from the inside (Owens et al., 1998). Since each microglial cell covers a relatively large territory of well vascularized tissue, up to 50-70 μm in diameter, some contact is probably unavoidable, and labelling a microglial cell "perivascular", like that shown in figure 1C can simply reflect a particularly prominent process attached to a vessel co-stained by the same molecular marker.

Despite this clear anatomical partition, between microglia and macrophages, there is clearly at least some exchange between and plasticity in the individual compartments. Perivascular macrophages are gradually replenished by a pool of circulating monocytes, with a half-life of 1-2 months. A small population of macrophages migrate through basal membrane into neural parenchyma, to differentiate into ramified microglia, a process enhanced in different forms of neuropathology (Streit et al., 1989; Priller et al., 2001), including EAE (Fluegel et al., 2001). Resident microglia in the adult brain are themselves descendents of 2 waves of macrophage infiltration into neural parenchyma – a very early one, from the surrounding mesodermal tissue (Navascues et al., 1995; Cossmann et al., 1997; Kurz and Christ, 1998), then as a second wave, as "fountains of microglia" in CNS white matter during axonal pruning in the late fetus/newborn (Rio-Hortega cf Brockhaus et al., 1996), but this is followed by rapid differentiation,

arborisation and quiescence, turning into the resting, ramified phenotype. However, the same resident microglia can be rapidly activated by a host of different pathologies, lose branching and transform into amoeboid macrophages. Some debris-laden transformed microglia also appear to migrate from neural parenchyma into the perivascular, Robin-Virchow space, where they can stay for a very long time (Kosel et al., 1997), which could set the scene for an interaction with T-cells homing onto perivascular macrophages (Walter et al., 2001).

2. CELLULAR AND MOLECULAR RESPONSE IN EAE AND MS

The rapid recruitment of blood-borne monocytes, the activation of resident microglia and perivascular macrophages, together with the recruitment of T-cells, are among the most consistent changes observed in multiple sclerosis and its autoimmune animal models of experimental allergic encephalomyelitis (McCombe et al., 1994; Bruck et al., 1995; Ford et al., 1995; Li et al., 1996). Microglia display strong proliferative activity, particularly at the early active sites of demyelination (Matsumoto et al., 1992, Schonrock et al., 1998), and avid upregulation in their mitogen receptors, that is tuned down in later stages of the disease (Hulkower et al., 1993; Werner et al., 2002). Compared to neighbouring T-cells, microglia/macrophages show relatively little apoptosis (Nguyen et al., 1994; Smith et al., 1996; Bonetti et al., 1997) and much more proliferative activity (Ogmori et al., 1992). Interestingly, almost all of our knowledge of changes affecting brain microglia/macrophages in the human disease come from the post mortem analysis of the terminal stage, unlike the EAE models which allow to explore pathology at different phases of the disease - from the early preclinical stage, to onset of neurological symptoms, paralysis and remission, including the second and following bouts of the disease process in the relapsing forms of the EAE.

Recent increase in the use of diagnostic brain biopsies (Bruck et al., 1995; Lucchinetti et al., 2000), but particularly the introduction of the positron-emitting [^{11}C]-PK11195 in combination with positron emission tomography (PET) scanning has begun to change this situation. In brain tissue, the PK1195 binding site is highly selective for microglia and macrophages, it is rapidly activated in even in moderate forms of brain pathology (Stephenson et al., 1995; Banati et al., 1997) and can be used map the spatial pattern of microglial activation in multiple sclerosis (Banati et al., 1999; Cagnin et al., 2001). Compared with magnetic resonance imaging with or without Gadolinium, the PET-based technique shows a higher sensitivity with respect to identifying white mater regions at risk and provides a good

correlation with disease process and appearance of neurological deficit (Banati et al., 2000). These recent human data underscore the importance of brain macrophage activation as a diagnostic tool, to identify the localization and disease activity in multiple sclerosis.

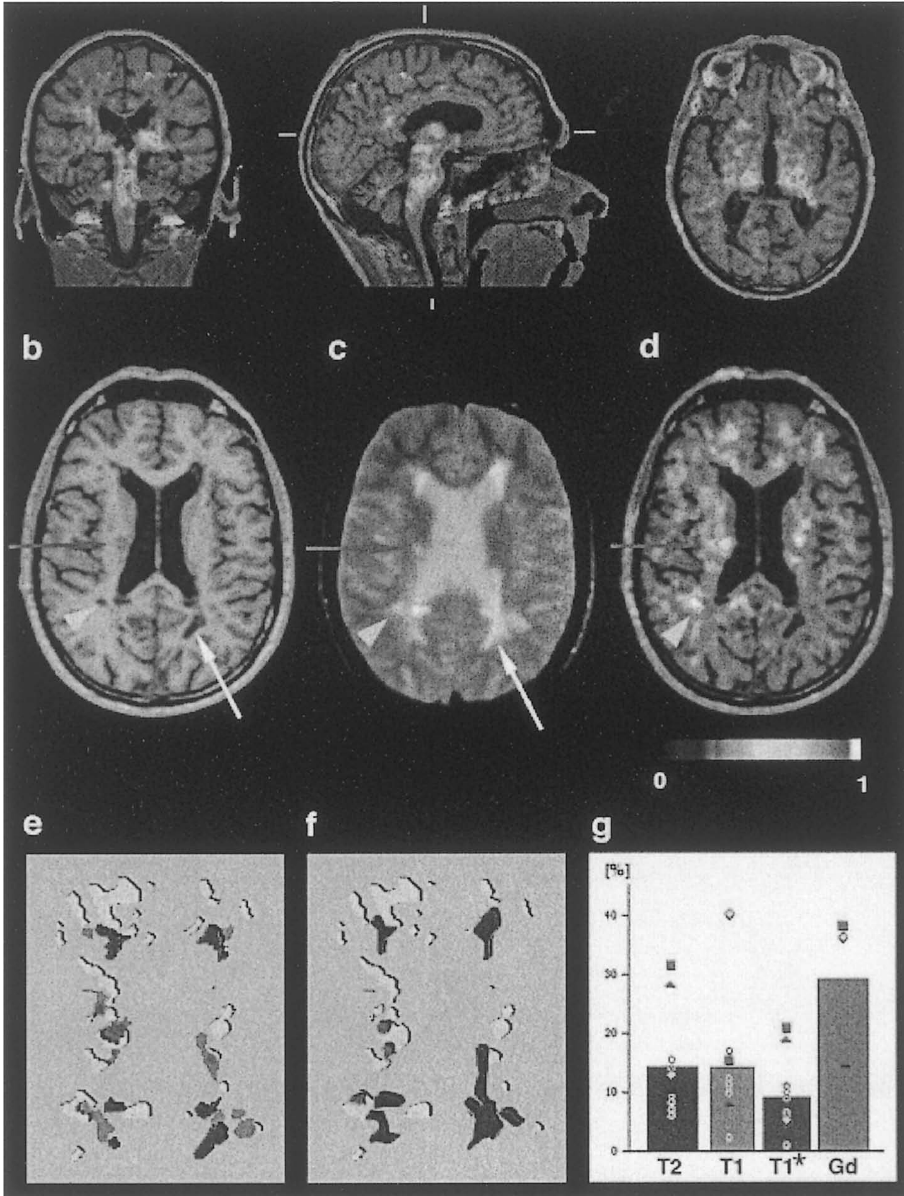

Figure 1. Detection of microglial activation in human patients with muliple sclerosis using positron emission tomography (PET) with [11C](R)-PK11195, combined with nuclear magnetic resonance imaging (MRI). All images follow the radiological convention, i.e. the left side of the image corresponds to subject's right side. (A) Three orthogonal views of

[11C](R)-PK11195 images co-registered and overlaid on the MRI of Patient 9, showing spinothalamic tract-associated [11C](R)-PK11195 signals extending through the brainstem and pons into the thalamus. (B-D) T1-weighted (B) and T2-weighted (C) MRI and [11C](R)-PK11195 PET (overlaid onto T1-weighted MRI) (D) of Patient 9 show lesions in all different spin-echo MRI sequences that partially overlap with areas of significantly increased [11C](R)-PK11195 binding (red arrow). The white arrow points to a `black hole' in an area that appears strongly hypointense in the T1-weighted MRI and has little binding of [11C](R)-PK11195. Note, however, that a similar black hole (yellow arrowhead) adjacent to the right occipital horn of the lateral ventricle shows significant [11C](R)-PK11195 binding. (E-F) Demonstration of the definition of the MRI lesion load masks in Patient 9 (purple, T1-weighted MRI lesions excluding black holes; blue, black hole only; green, gadolinium-enhancing areas; dark grey (in F), T2-weighted MRI lesions; red, areas of overlap between significantly increased [11C](R)-PK11195 binding and MRI-defined areas of pathology); yellow, areas of increased [11C](R)-PK11195 binding and no overlap with any MRI-defined pathology. (G) Average percentage volume of the MRI-defined lesions overlapping with increased [11C](R)-PK11195 binding. The red square represents Patient 8 and the red triangle Patient 6, who were both in relapse at the time of the scans. The yellow diamond represents Patient 9, who had secondary progressive multiple sclerosis. T1*, black holes. Reproduced from Banati et al., Brain. 123:2321-37, 2000.

On the biochemical level, macrophage and microglial activity in MS and EAE is associated with a strong upregulation of molecules involved in antigen presentation, myelin and tissue breakdown, production of reactive oxygen substances. They also synthesize components of the complement cascade, cytokines, growth factors and neurotrophins, chemotactic molecules, excitotoxins and apoptosis-inducing substances, and their receptors. These molecules, reviewed in the following paragraphs, as well as in more detail in the preceding and following chapters of this book, are involved in inducing and regulating the level of macrophage activation, interaction with encephalitogenic lymphocytes, mediating damage to myelin, axons and oligodendrocytes, as well as inducing the repair of the injured white matter.

ANTIGEN PRESENTATION

Major Histocompatibility Complex. T cells are known to recognize their specific antigen when associated to the class I or class II molecules of the major histocompatibility complex, abbreviated as MHC1 and MHC2 (for a review see Zinkernagel and Doherty, 1997). This recognition is aided by the binding of T-cell accessory molecules CD4 and CD8, expressed by the T-helper (mainly CD4+) and the T-suppressor/cytotoxic (mainly CD8+) lymphocytes, to their respective MHC2 or MHC1 ligands (Fleury et al., 1991; Miceli and Parnes, 1991). Despite the strong MHC class-selectiveness in the presentation of specific antigen – MHC1 for the endogenous (cytoplasmic) and MHC2 for the exogenous (phagocytosed) antigen, recent studies point to the existence of alternative and highly effective pathways for the presentation of exogenous antigen via MHC1 (Reimann et al., 1994;

Larsson et al., 2001). In addition, non-classical MHC1-like molecules such as CD1 can also present antigen, particularly glycolipids, to the CD8+ as well as to the CD4-CD8- (double null) T-lymphocytes (Sugita et al., 1998).

The rapid upregulation in the major histocompatibility complex antigens were amongst the first set of molecular changes described in multiple sclerosis as well as in different forms of experimental allergic encephalomyelitis using immunohistochemical techniques. Here, the upregulation of MHC2 was clearly restricted to reactive microglia, macrophages and blood-borne leukocytes, neighbouring GFAP+ astrocytes were MHC2 negative (Konno et al., 1989; Boyle and McGeer, 1990). Unlike MHC2, CD1 expression was not found on parenchymal macrophages or microglia, but rather on perivascular leukocytes and particularly, on the GMCSF+, hypertrophic astrocytes surrounding MS plaques (Battistini et al., 1996). Interestingly, the absence of overlap between MHC2 and CD1b suggests a high level of cell type selectivity in the presentation of MHC2 and CD1b-dependent antigens (Cipriani et al., 2003).

Up to now, most reports on antigen presentation and EAE have concentrated on MHC2, leading to the common assumption that only CD4+ lymphocytes are encephalitogenic. However, studies using beta2-microglobulin-deficient mice do show that MHC1 is involved in mediating EAE elicited by adoptively transferred, encephalitogenic CD8+ T-cells (Sun et al., 2001). This effect is direct and not mediated by some indirectly stimulated host CD4+ lymphocytes, a point demonstrated using the RAG1-/, immunodeficient mice (Sun et al., 2001). In the majority of cases, antigen presentation by CD1+ cells appears to inhibit EAE (Lider et al., 2001; Miyamoto et al., 2001), although this depends on the cytokine requirements of the specific form of EAE (Jahng et al., 2001). In the case of MHC2, most initial reports tended to emphasize that microglial expression of MHC2 may present antigen to encephalitogenic T-cells, needed to initiate or promote the inflammatory and demyelinating process (Hayes et al., 1987; McGeer et al., 1988). More recent studies have focused on their counter-regulatory and immunosuppressive properties. EAE-inducing effects are now attributed to perivascular macrophages.

Studies by Hickey and Kimura using bone marrow chimaeras clearly show that MHC2 expression by perivascular macrophages is sufficient for antigen presentation and onset of severe EAE, following the transfer of encephalitogenic CD4+ T-cells (Hickey and Kimura, 1988). On the other hand, high level of microglial MHC2 corresponds with resistance to EAE in different strains of rats (Sedgwick et al., 1993; Klyushnenkova et al., 1997). Exposure to microglial MHC2 also appears to induce T cell apoptosis, unlike the perivascular macrophages that promote T-cell survival (Ford et al., 1996; Klyushenkova et al., 1997). Presentation of antigen to non-encephalitogenic T-cells appears to play an important part in preventing excessive autoimmunity. Thus, adoptive transfer of encephalitogenic T-cells in mice

with severe combined autoimmunity (scid) leads to a much more severe and recurrent form of EAE compared with immunocompetent mice (Jones et al., 1999). The particularly strong and profuse upregulation of MHC2 on parenchymal microglia during early remission (Konno et al., 1989; McCombe et al., 1992) thus appears to make an important contribution in strengthening the immunosuppressive action of microglial MHC2.

Accessory Molecules. In addition to processed antigen embedded in MHC, effective antigen presentation requires the presence of co-stimulatory or accessory molecules on the surface of the antigen presenting cell, engaging their receptor counterparts on the T-lymphocyte. These accessory molecules belong to several different families of cell surface glycoproteins including B7, CD40, ICAM1-3 and the aXb2 integrin. aXb2 is a cell type-specific marker of professional, antigen-presenting cells (APC) also known as dendritic cells (Brocker et al., 1997; Suter et al., 2000).

MS is associated with a strong upregulation of CD40 (Gerritse et al., 1996; Laman et al., 1998; Weinberg et al., 1999) and B7.1 on the perivascular macrophages and microglia (Williams et al., 1994; De Simone et al., 1995). Inhibition or neutralization of CD40 and B7.1 prevented induction of EAE (Kuchroo et al., 1995; Gerritse et al., 1995; Weinberg et al., 1999; Becher et al., 2001). In the case of B7.1 this effect depended on the presence of IL4 (Kuchroo et al., 1995). Resting microglia already express moderate levels of B7.2 (Dangond et al., 1997), and its inhibition may enhance the severity of EAE (Kuchroo et al., 1995). Interestingly, combined inactivation of B7.1 and B7.2 strongly reduced the pathology and severity of neurological symptoms in adoptively transferred EAE (Chang et al., 1999). Both systems, CD40 and B7, appear to complement each other. Combined inactivation of the B7 receptor CD28, and inhibition of CD40 leads to a particularly strong resistance to the induction of EAE (Grivin et al., 2002).

Activated and phagocytic brain-resident microglia do express co-stimulatory molecules such as ICAM1-3, aXb2 or B7.2 in a variety of pathological conditions (Bo et al., 1996; Werner et al., 1998, Bohatschek et al., 1999; Kloss et al., 1999). However, most studies concur that the majority of the accessory molecule-positive cells in MS and EAE that present antigen to T-lymphocytes are hematogenous in origin and concentrated in the perivascular infiltrates (Williams et al., 1994; De Simone et al., 1995; Gerritse et al., 1996; Laman et al., 1998; Weinberg et al., 1999). Adoptive transfer of encephalitogenic T-cells strongly enhances the influx of bone marrow-precursors of dendritic cells to the site of CNS inflammation. Moreover, these newly recruited dendritic cells, with the appropriate MHC molecules, are fully sufficient to induce inflammation and myelin destruction in mice following adoptive transfer of rat bone marrow and rat encephalitogenic T-cells (Subramanian et al., 2001). This point is also

underscored by recent study using bone marrow chimaeras between the CD40 wild type (CD40+/+) and CD40 null (CD40-/-) animals, with the latter normally resistant to EAE (Becher et al., 2001). Replacement of the CD40+/+ bone marrow with that from a CD40-/- animal, turning perivascular macrophages and newly recruited dendritic cells to CD40-/-, while retaining CD40+/+ microglia, prevents the appearance of EAE in almost all animals. On the other hand, the transfer of CD40+/+ bone marrow to the irradiated, CD40-/- host, causes an almost complete recovery of EAE susceptibility in the host, with just a minor delay (+20%) and reduction in the maximal severity of clinical symptoms (-25%), compared to normal, CD40+/+ animals receiving a CD40+/+ bone marrow transplant (Becher et al., 2001).

CYTOKINES

Perivascular cuff macrophages, parenchymal macrophages and microglia show a strong upregulation for a long list of inflammation-associated, soluble cytokines, including interleukin-1/IL1 (Bauer et al., 1993), interleukin-10/IL10 (Jander et al., 1998; Hulshoff et al., 2002), transforming growth factor beta-1 (Kiefer et al., 1998; De Groot et al., 1999), macrophage-colony stimulating factor/MCSF (Hulkower et al., 1993; Werner et al., 2002), granulocyte-macrophage colony-stimulating factor (GMCSF), interleukin-12 (IL12) and tumour necrosis factor-alpha/TNFa (Hulkower et al., 1993; Renno et al., 1995; Bitsch et al., 1998; Laman et al., 1998; Fischer and Reichmann, 2001). There is also an upregulation of related cell surface molecules such as FAS and FAS-ligand (FasL), which are members of the TNF superfamily (Ouallet et al., 1999). Interestingly, expression is frequently focused to specific and different subpopulations of macrophages and microglia (Bitsch et al., 2000; Juedes et al., 2000). For example, the aMb2-positive microglia/macrophages expressing the dendritic cell marker aXb2 integrin secrete high amounts of IL12, while those negative for aXb2 produce GMCSF and TNFa (Fischer and Reichmann, 2001).

A subpopulation of these macrophage-produced cytokines and related molecules, such as IL10, TGFb1, or FasL has been shown to inhibit or prevent EAE (Rott et al., 19994; Stevens et al., 1994; Zhu et al., 2002; see also Wyss-Coray et al., 1997). However, a majority have a strong disease-promoting activity (Waldburger et al., 1996; Taupin et al., 1997; Marusic et l., 2002). Neutralization of TNF-alpha (Selmaj et al., 1991; Korner et al., 1997), IL1 (Jacobs et al., 1991), IL12 (Leonard et al., 1995) with antibodies or soluble receptors suppresses EAE. Genetic deletion of IL1R1, GMCSF, TNFa or IL12p40 has a similar effect, conferring resistance to EAE (Schiffenbauer et al., 2000; McQualter et al., 2001; Matejuk et al., 2002; Murphy et al., 2002; Gran et al., 2002; see however Liu et al., 1998).

Moreover, studies using bone marrow chimaeras between TNFa+/+ and TNFa-/- mice show that it is the TNFa which is produced by blood-borne leukocytes that plays a decisive role in the onset and severity of EAE (Murphy et al., 2002).

Importantly, moderate overexpression of TNFa or IL12, using the astrocyte GFAP promoter (Stalder et al., 1998; Pagenstecher et al., 2000) has been shown to lead to CNS inflammation and neurological disease. In the case of TNF, it causes overt demyelination and axonal damage very similar to that observed in EAE and MS. The fact that this demyelination is also observed in TNFa-overexpressing scid mice lacking T and B-cells (Stalder et al., 1998) strongly suggests that these cytokines not only promote the initial immune response, but also appear to play a crucial in the final steps following antigen recognition, that actually cause the brain pathology and neurological dysfunction.

CHEMOKINES

The activated macrophages and microglia produce a variety of chemotactic molecules including members of the chemokine family, but also many other chemoattractant factors such as secretoneurin (Storch et al., 1996), leukocyte chemotactic factor/LCF (Schluesener et al., 1996), endothelial-monocyte-activating polypeptide II (Schluesener et al., 1997) and chemotactic peptide-10/CP10 (Deininger et al., 1999). Amongst the chemokines, there is a strong increase in the macrophage chemotactic protein/MCP1 (Hulkower et al., 1993; Simpson et al., 1998, Jee et al., 2001), monocyte inflammatory protein 1 alpha/MIP1a (Balashov et al., 1999), neurotactin or fractalkine/CX3CL1 (Pan et al., 1997), TCA3 (Murphy et al., 2002), CCL19 and the macrophage-derived chemokine/CCL22 (Columba-Cabezas et al., 2002, 2003), which act as chemotactic ligands for macrophages, T-lymphocytes or both. There is also an upregulation for a list of macrophage chemokine receptors, such as CCR1, the receptor for MIP1a (Rottman et al., 2000; Trebst et al., 2001), CCR2, CCR3 and CCR5 (Simpson et al., 2000), CCR8 (Trebst et al., 2003), CXCR4 and CX3CR1 (Jiang et al., 1998), and the receptors for IL8 and N-formyl-Met-Leu-Phe/FMLP, particularly on foamy, phagocytic macrophages (Muller-Ladner et al., 1996).

Many of these macrophage-derived chemokines are produced by hematogenous macrophages, invading the inflamed CNS (Miyagishi et al., 1997; Sorensen et al., 1999; Matejuk et al., 2002) and are controlled by inflammation–associated cytokines such as TNF (Matejuk et al., 2002; Murphy et al., 2002). Studies using genetically deficient animals and/or neutralizing antibodies also show that the chemoattractive molecules play an important role in the pathology of EAE. Transgenic deletion of CCR1, the receptor for MIP1a, CCR2, the receptor for MCP1, or CCR8, the receptor

for TCA3, strongly reduce the susceptibility, onset and severity of EAE (Rottman et al., 2000; Huang et al., 2001; Murphy et al., 2002). A similar inhibitory effect is also observed with the antibody inactivation of MCP1 (Karpus et al., 1995). That these molecules are produced in the brain has suggested that brain-resident cells, particularly microglia, may also play a role in the induction of EAE (Murphy et al., 2002). However, this point is contentious and needs to be confirmed, using bone marrow chimaeras. The fact that many of these chemokines and chemokine receptors are located on blood-borne macrophages, particularly in perivascular cuffs, could argue against a major contribution by microglia.

REACTIVE OXYGEN SPECIES AND SIGNALLING ENZYMES

Acute inflammatory diseases such as EAE and multiple sclerosis are associated with strongly augmented production of reactive oxygen species (ROS), particularly by activated brain macrophages (Ruuls et al., 1995). Brain macrophages show increased deposition of iron (LeVine, 1997), myeloperoxidase (Nagra et al., 1997) and inducible NO synthase/iNOS in multiple sclerosis (Bagasra et al., 1995; De Groot et al., 1997) and in EAE (Van Dam et al., 1995; Tran et al., 1997). Similar upregulation is also observed in viral models of CNS demyelination, e.g. with Theiler's murine encephalomyelitis virus (Oleszak et al., 1997). In combination with peroxide radicals the synthesis of NO will lead to the formation of peroxynitrite, which is toxic for oligodendrocytes (Mitrosic et al., 1996). In vitro, oxidative stress causes macrophages to become toxic (Bartnik et al., 2000), and scavengers of ROS or their precursors such as uric acid or catalase are known to inhibit EAE (Ruuls et al., 1995; Kean et al., 2000).

Nonetheless, brain macrophages also produce a string of molecules that reduce oxidative stress. Perivascular macrophages, and to lesser extent microglia, show high levels manganese superoxide dismutase in EAE (Qi et al., 1997). Expression of metallothioneins 1&2/MT1&2 (Espejo et al., 2001) reduces the high susceptibility to EAE, shown in the MT1&2-/- mice (Penkowa et al., 2001). Multiple sclerosis and EAE also cause increased macrophage synthesis of stress protein heme oxygenase-1 (HO1) that produces CO (Emerson and LeVine, 2000; Schluesener and Seid, 2000), the inducer of cGMP-synthesizing enzyme guanyl cyclase (Brune and Ullrich, 1987). This increased HO1 degrades the pro-oxidant heme groups, but also reduces the availability of the NADPH cytochrome P450 reductase that is needed for the production of superoxide (Emerson and LeVine, 2000). Inducers of HO1 such as hemin, reduce the severity, and HO1 inhibitors enhance the severity of EAE (Liu et al., 2001).

Macrophage iNOS and NO synthesis and their effects in EAE have been a focus or particular attention. In most cases, early pharmacological inhibition of nitric oxide synthase has been shown to reduce EAE (Cross et

al., 1994; Brenner et al., see however Ruuls et al., 1996). Late application interferes with the recovery process and enhances relapsing activity (Okuda et al., 1998; O'Brien et al., 2001). Interestingly, NO production by brain microglia and macrophages strongly inhibits T-cell proliferation (Juedes and Ruddle, 2001).

The importance of this point was illustrated by studies in the interferon gamma receptor deficient (IFNgR-/-) mice, that are normally unable to recover following the induction of EAE, and die from severe demyelinating illness (Willenborg et al., 1999). In vitro analysis showed that supernatants from IFNgR+/+ macrophages inhibit the proliferation of encephalitogenic T-cells while IFNgR-/- macrophages lack this ability. Moreover, the inhibitory effects of IFNgR+/+ macrophages could be suppressed by an inhibitor of iNOS, underscoring the importance of NO in regulating the T-cell response. Interestingly, bone marrow chimaeras between IFNgR+/+ and IFNgR-/- show that the presence of IFNg receptors on just one, blood-borne or brain resident component, was sufficient to prevent the normally lethal outcome following the induction of EAE in IFNgR-/- mice (Willenborg et al., 1999).

FUNCTIONAL ROLE

Both brain–derived microglia and blood borne macrophages are crucially involved in many consecutive stages of autoimmune demyelination in experimental allergic encephalomyelitis and multiple sclerosis. They play an important role as antigen-presenting cells in the initial demonstration of antigen (Hickey and Kimura, 1988; Jones et al., 1999), and secondary recruitment of T-cells, granulocytes and macrophages (Huitinga et al., 1995). They also produce a long list of potentially damaging substances, including reactive oxygen species, NO and peroxynitrite, TNFa, interleukin-1b and excitotoxins (see above). As a case in point, interleukin 1b has been shown to activate mixed glial cell cultures to produce glutamate agonist neurotoxins that cause oligodendroglial cell death (Takahashi et al., 2003). MS-associated inflammation leads to a strong increase in glutamate receptors on axons in the centre of CNS lesions and on neighboring, reactive astrocytes (Geurts et al., 2003), which could predispose them to damage by the glial-derived excitotoxins. Axonal damage is particularly intense at early disease stages of MS (Kuhlmann et al., 2002), which could correspond to particularly intense microglial activation (Bitsch et al., 2002). Microglia and macrophages are also the chief debris-removing cells that eliminate damaged myelin, resulting in the widespread loss of axonal covering the CNS white matter. Last, but not least, microglia and macrophages appear to play a decisive role in the induction of remission, as well as resistance to the induction of the disease (Konno et al., 1989; McCombe et al., 1992; Willenborg et al., 1999).

A key question raised with the respect to microglia and macrophages is the relative contribution of blood-derived versus brain resident cell populations to the overall pathology during the process of autoimmune destruction of myelin. This question is particularly appropriate, since activated, and particularly phagocytic microglia share most of molecular markers with the blood-borne macrophages that enter the damaged brain (Streit et al., 1988; Bruck et al., 1995; Raivich et al., 1999). Most studies concur that blood-derived macrophages are crucial in the induction of EAE. Removal of bone marrow monocyte precursors and circulating macrophages with clodronate reduces the parenchymal influx of new macrophages, interferes with lymphocyte recruitment and microglial proliferation (Bauer et al., 1995; Plofriet et al., 2002). The same macrophage depleting treatment also blocks adoptively transferred EAE (Huitinga et al., 1995; Tran et al., 1998). Similar, disease-abolishing results were also obtained in bone marrow chimaeras, when bone marrow-derived macrophages (but not microglia) lacked the appropriate MHC antigens, accessory molecules (CD40) or cytokines such as TNFa that promote demyelinating disease (Hickey and Kimura, 1988; Stalder et al., 1998; Subramanian et al., 2001; Becher et al., 2001; Murphy et al., 2002), underscoring the significance of blood derived macrophages.

Nonetheless, there are several lines of evidence that begin to shed light on the importance of brain resident microglia at different stages of the demyelinating disease. The initiation of the autoimmune response is an important case in point. For example, the acute transfer of rat encephalitogenic T-lymphocytes and appropriate antigen presenting cells (APC) to scid mice causes a delay phase of approximately 8 days before the onset of EAE (Subramanian et al., 2001), pointing to the importance of local APC in the early initial stages. This point is underscored by the very rapid microglial response to the adoptive transfer of EAE, in this case the induction of microglial amyloid precursor protein, within 24 hours after the infusion of encephalitogenic T-cells in animals with the appropriate MHC antigens (Banati et al., 1995). Studies using bone marrow chimaeras also show that microglia are much more effective removers of myelin than blood-derived macrophages (Rinner et al., 1995). Finally, brain-resident microglia also play a decisive role in limiting the extent of demyelination, preventing lethal outcome and inducing disease remission (Konno et al., 1989; McCombe et al., 1992; Willenborg et al., 1999). Here, new insights into the function and molecular signals of macrophages and microglia, their interaction with each other, as well as with T-lymphocytes, axons and myelin-producing oligodendroglia, could pave the way to introducing new and more effective therapies to the human demyelinating disease.

Chapter A8

THE NEURON AND AXON IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Nikos Evangelou and Cris S Constantinescu
Division of Clinical Neurology, University of Nottingham, UK

Abstract: Neuronal and axonal loss and damage are increasingly recognized major pathological features of MS that correlate with disability. Correspondingly, in EAE, these processes are being investigated in great detail. This chapters discusses the present knowledge of axonal and neuronal pathology in MS and details the relevant studies in EAE, that may form the basis to future neuroprotective/regenerative approaches to MS.

Key words: EAE, MS, axon, neuron, magnetic resonance imaging, atrophy

The importance of axonal dysfunction and axonal loss in Multiple Sclerosis (MS) has been at the centre of the pathological debate over the last decade. Since 1995 the number of publications listed in Medline related to "MS AND myelin" has increased by 30%, whereas articles on "MS AND axon*" increased by 300%. Equally, it is not surprising that more importance is also given to the extent of axonal involvement in the EAE models.

The first part of this review will examine the evidence of axonal involvement in MS, and the second part will focus to studies of axons in the EAE models.

1.1 History of axonal loss

Axonal injury has been recognized since the first descriptions of MS pathology. Neuropathologists usually refer to Charcot when describing the hallmarks of MS pathology, e.g. inflammation, demyelination, and <u>relative</u> preservation of axons. In the historical review on axonal loss in MS, Kornek

and Lassmann [1] suggest that it is Marburg in 1906, who emphasized the term "relative" as he found more axons were lost than generally believed. Charcot clearly described demyelinated axons showing increased diameters, large axonal swellings and admitted that, due to methodic limitations, the presence of axonal degeneration could not be definitively excluded. Fromann provided a detailed description of axonal pathologic changes in the lesions of MS. He noticed that lesion formation not only led to the disruption of the myelin sheath, but also to the appearance of axonal transections. Quantifying the degree of axonal loss came several decades later. Putnam in 1936 found an "unmistakable decrease in number" of axons in 13 out of 35 plaques and in 18 they were "absent or the number was so far decreased that some high power fields were devoid of them". Greenfield and King produced conflicting results: in a series of 125 plaques from 13 cases they found that less than 10 percent showed "severe destruction," meaning a reduction in number to one-fifth or one-seventh.

2. AXONAL LOSS IN MS

2.1 In demyelinated lesions in MS

MS is primarily a demyelinating disease of the central nervous system. Evidence of axonal loss derives indirectly from imaging studies and directly from pathological specimens. Magnetisation transfer imaging (MTI) is a MRI technique that can measure water content in its relation to macromolecules [2]. The MTI signal reflects protons bound to tissue (particularly myelin) and can therefore provide an index of tissue destruction. It is described as a ratio – the lower the ratio, the more destructive the lesion. A moderately strong correlation coefficient has been demonstrated between the MT ratio and disability[3]. Hypointense T1 lesions with decreased MTR are also associated with tissue destruction and axonal loss and are frequently found in MS patients [4, 5].

A number of studies have used Magnetic Resonance Spectroscopy (MRS) techniques in the last decade. MRS techniques permit inferences about chemical changes in tissues. N-acetylaspartate (NAA) is found exclusively or perdominantly in neurons and the NAA peak was found to be low both in lesions [6] and in the NAWM [7] in MS. Brain proton MR spectroscopy in patients with MS has demonstrated substantially reduced NAA/Cr ratios within both chronic [8, 9] and acute [6, 10] lesions.

Pathological studies have found that axonal damage was more evidently found with acute lesions associated with inflammatory activity [11, 12]. On average axonal loss of 59-82% was observed in demyelinated plaques [13].

2.2 Normal appearing white matter in MS

The term Normal Appearing White Matter (NAWM) is a technical MRI definition and was initially used to describe the white matter volume on T2-weighted images outside of areas of abnormally high white matter signal intensity. An increasing amount of evidence suggests that the white matter outside demyelinated lesions is abnormal mainly due to loss of axons.

2.2.1 Atrophy

Whereas late stages of chronic MS have long been recognised to be associated with brain atrophy, more recent quantitative MRI studies have demonstrated that large white mater volume changes occur even early in the progression of the disease. Losseff and colleagues have shown that the relative atrophy of the spinal cord at the level of C3 correlates with the degree of disability [14]. In addition, they described a measurable progressive change in the cross-sectional area of the spinal cord at C3 with time. Just as for the spinal cord, it was found that MS patients show measurable atrophy of brain white matter with time. Although lesion formation resulting in tissue destruction certainly can contribute to volume loss, the degree of atrophy is out of proportion to the relatively small lesion volumes suggesting pathological processes outside lesions being involved.

2.2.2 Magnetic Resonance Spectroscopy shows evidence for diffuse axonal injury in NAWM in MS

Proton magnetic resonance spectroscopy (MRS) provides a unique tool for *in vivo* evaluation of biochemical changes associated with brain pathology. In MRS, information on the resonance frequencies of protons observed in the tissue is preserved. This allows analysis of the relative spatial distributions and concentrations of small molecules. Water-suppressed localised ^{1}H spectroscopy yields spectra dominated by resonances of N-acetyl aspartate (NAA), Creatine (Cr)/Phosphocreatine (PCr) and Choline (Cho). NAA is exclusively or, at least, predominantly localized within neurons in the mature brain [15, 16] and is therefore used as a marker of axonal density and integrity. Conventionally in brain MR spectroscopy NAA has been quantified in relation to the magnitude of the Cr, the concentration of which is believed to vary little.

Irreversible decreases in the relative NAA concentrations in lesions must reflect axonal volume loss (i.e., either a decrease in the number of axons or in their aggregate cross sectional area). Reversible changes are likely to signify axonal dysfunction [17] The possibility that significant biochemical changes occur outside of areas of focal inflammation (i.e. within the NAWM), was highlighted by the finding that reductions in the NAA/Cr ratio from a large volume of interest within the brain were relatively independent of T2-hyperintense lesion volumes and could be found with even very large voxels that included relatively small lesions volumes [18]. Later studies directly demonstrated reduced NAA/Cr adjacent to [6] or even distant from lesions in regions of the brain containing only NAWM [19]. The reduction in the NAA/Cr ratio within the NAWM was shown to be more marked in patients with secondary progressive than relapsing-remitting MS [20].

The reduced NAA/Cr ratio or reduction in absolute NAA signal within the NAWM could arise from reduced axonal density, reduction in axonal NAA concentration with axons or altered relaxation times. Early studies suggested that relaxation time changes are unlikely to be great enough to have a large effect on the NAA/Cr ratio [9]. Decreases in neuronal NAA concentration occur in response to an acute inflammatory insult and can be reversible [6, 17]. Hence, a reduction in the NAA signal within large areas of the macroscopically NAWM in patients who have not suffered a recent relapse most likely reflects chronic changes in axonal morphology or density.

2.2.3 Axonal loss in NAWM

Few studies have investigated the NAWM with pathological methods. In an acute MS case, axonal changes were reported. By studying the corpus callosum we have shown substantially reduced axonal density and loss of volume in the NAWM. Considering both axonal density and volume measurements in the corpus callosum there is a mean estimated loss of 53 % of the total number of axons in the NAWM of MS brains in our samples [21]. We also demonstrated that the axonal loss in the NAWM is the result of Wallerian and post-synaptic degeneration of axons caused by axonal transection at the site of MS lesions.

2.3 Axonal damage is the likely morphological substrate of clinical disability

As mentioned, the association between axonal pathology and clinical disability was first discussed by Charcot. The volume of hypointense lesions (black holes) [22] and the extent of brain atrophy, both considered a marker of axonal loss, correlate with the degree of disability [23].

The significance of those MR abnormalities is strengthened by studies that have found strong correlations between the NAWM changes and clinical disability. Possibly, these MRI abnormalities of the NAWM may reflect the cumulative damage from MS lesions, which appears to occur both early in the disease, as well as later, in the secondary progressive phase.

The earliest MR spectroscopic studies reported that large voxel MRS measurements of brain NAA were lower in patients with higher disability scores than those with lower disability scores [8]. Fu and colleagues later co-registered MRSI with conventional images in which the lesions had been segmented in order to define independently the relationship between axonal injury in lesions or NAWM and progression of disability [7]. They found a correlation between decreases in NAA in the NAWM and the progression of disability. It is notable that a similar correlation was not found between NAA decreases in lesions and disability. While work of Davie *et al* had noted the correlation between overall axonal injury in lesions and disability [24], measurement of NAA in the aggregate lesion load is difficult and may not be as sensitive to change over time as changes in the NAWM. Longitudinal follow-up of the same RR and SP MS patient cohort followed by Fu *et al* demonstrated a strong correlation between the progression of disability and decreases in relative NAA concentrations in a large central volume of WM.

2.4 Pathological methods for detecting axonal loss

MR techniques are only indirectly reflecting axonal dysfunction and are unable to differentiate between acute and longstanding axonal damage.

One of the reasons the axonal element of MS has been given little attention until recently is possibly the ease of identifying demyelinated

plaques using conventional pathological stains compared to the less striking pictures of axonal stains.

A number of techniques can be used to study axonal damage. While with the use of electron microscopy the number and size of axons can be measured accurately, this method is complicated by technical difficulties. The best images are acquired when the brain tissues are frozen immediately following the death of the patient, and as most MS patients do not die in hospital, pathological material is difficult to obtain. The use of the EM and the fixation techniques also require considerable expertise for good quality results. The availability of EM remains another limiting factor.

Silver-based methods (Bodian, Fink-Heimer, Nauta) are the choice of most neuropathology laboratories. Silver-based stains require good fixation of tissue. Modifications of those stains take advantage of the higher affinity of degenerating axoplasm for binding silver.

Most immunocytochemical techniques use antibodies to differentiate neurofilament components (NF70, NF150 and NF200) present in axons. Both silver-based and neurofilament methods visualise mainly the largest of the axons. Quantitative comparative studies examining what percentage of myelinated or unmyelinated axons are visualised using those techniques have not been conducted.

Another immunocytochemical technique involves the use of Amyloid Precursor Protein (APP). APP is a membrane glycoprotein and a normal constituent of neuronal cells. Normally APP is transported in an anterograde direction and is not visualised in healthy axons. If the transport is interrupted either due to axonal transection or possibly due to local dysfunction, APP accumulates in the proximal axonal ends and can be visualised by standard immunohistochemistry in formalin-fixed tissue as APP-positive spheroids. Therefore, beta APP has been suggested to be the immunocytochemical marker of choice for the detection of injured axons. This method was first used in traumatic brain injuries and found to be more sensitive than silver stains. As it has been demonstrated in fatal head injuries, APP stains damaged axons within 2 hours after injury and remains detectable in axons and bulbs for 10 to 14 days. With a survival time longer than 2 weeks, beta APP reactivity disappears from the injured axons as well as from bulbs. Beta APP therefore may serve as a marker for early axonal damage, while more advanced stages of axonal degeneration may not be detected by this method. In MS, APP has been found to be significantly expressed throughout acute lesions and at the border of active chronic lesions.

3. AXONAL LOSS IN EAE

3.1 *Axonal dysfunction vs. axonal loss*

Using magnetic resonance spectroscopy, larger reductions of NAA have been demonstrated than could have been expected by plain axonal loss. The main proposed explanation relies on the existence of significant axonal dysfunction without leading ultimately to neuronal death. Pathologically proven axonal loss probably represents the extreme part of the spectrum of axonal dysfunction. In MS autopsies a reduced number of cortical synapses were found in paralysed compared to ambulatory patients [25].
There is supporting EAE evidence derived from a study of the anatomy and function of the optic nerve in guinea pigs. The axonal density was analysed, but also orthograde transport was studied following tritiated leucine injection into the vitreous by autoradiographic analysis of silver grain counts. The extent of reduction in radioactivity in acute EAE (74%) was significantly more than the axonal loss (16%) [26].

3.2 *Axonal damage in different EAE models*

EAE offers the possibility of providing detailed pathological correlation for the MRI technique used to assess axonal loss and dysfunction [27].

A number of EAE models have been to study axons. These include murine EAE induced by MBP or PLP- specific cell lines and clones [28-32]. Guinea pigs [26], and marmoset [33]. Amongst the different models MOG-induced EAE shows that, the highest incidence of acute axonal injury during active demyelination lead to a pronounced reduction of axonal density in all stages of demyelination [31]. The SWXJ mice, which have been used to study axonal loss in EAE, when immunized with PLP develop relapsing remitting chronic EAE that is very similar in its clinical course to MS. The mice have initial relapses and a late plateau of sustained functional disability [34, 35]. In most of those models a CNS antigen, usually myelin or a myelin protein peptide, was used to induce specific immune responses mimicking MS. A different approach was employed by Newman who used heat-killed bacillus Calmette-Guerin in a rodent mode in a two-staged approach. Initially a brain injection was given. At a second stage, after the blood brain barrier damage had healed, a subcutaneous injection of the bacilli induced CNS immune activation that resulted in axonal damage [36]. The mechanism

of axonal damage by the attracted macrophages is not yet clear, although release of cytokines or matrix mettaloproteinases have been implicated.

3.3 Axonal selectivity

Recent studies have suggested that smaller axons may be preferentially injured in MS [37, 38] We have also shown size-specific neuronal changes in the visual pathways [39]. Size-dependent differences in susceptibility could be a consequence of differences in surface area-to-volume ratio (e.g., if a non-specific, diffusible toxin such as NO is responsible) or other factors, such as the particular metabolic or antigenic characteristics of the different classes of cells. Confirming size-dependent correlations with injury throughout the CNS, for neurons and axons, would help to suggest candidate toxic factors.

Examining spinal cord axons immunostained for tyrosine hydroxylase, serotonin and substance P, differences were found in the degree of axonal damage in the paraplegic phase in guinea pig EAE. The small diameter thinly myelinated or unmyelinated axons that course the spinal cord for long distances are more vulnerable to damage. Substance P containing fibres in the dorsal horns did not exhibit any changes, possibly because of their small intraspinal course [40].

3.4 Timing of abnormalities

The axonal and neuronal abnormalities seem to correlate with the degree of demyelination and the functional recovery following the induction of EAE. As in MS, actively demyelinating lesions have many swollen and distorted axons, seen with Bielschowsky silver stain and immunohistochemistry for APP protein, whereas in inactive lesions and shadow plaques axonal spheroids are found only occasionally [31]. Early active lesions demonstrate higher levels of bAPP [31] as well as non-phosphorylated neurofilaments (SMI-32 positive) [33] compared to late active lesions. In the paraplegic phase of EAE in rats, grossly distorted axons are seen with accompanying grey matter abnormalities. Even by the first day of recovery, those changes are less prominent. Within the next 2 weeks, both the grey matter and the axons became increasing more normal in appearance [41].

In clinical relapses in EAE Lewis rats, the somatosensory evoked potentials was reduced in amplitude and prolonged in latency, presumably due to both demyelination and axonal dysfunction. In well-established remission, there was residual conduction failure, which can be mainly accounted for by axonal degeneration [42]. Most MS remyelinating lesions (shadow plaques) do not show significant demyelinating activity, and equally show very little acute axonal dysfunction by measuring betaAPP levels. This is in contrast to EAE where recurrent demyelination in the plaque is common, which may explain the high incidence of axonal bAPP reactivity [31].

3.5 Molecular changes within neurons

Molecular changes have been observed in CNS neurons both in EAE and in post mortem MS material. In a chronic relapsing EAE mouse model that consistently displays cerebellar lesions, Sensory Neuron-Specific (SNS) sodium channels were detected, which are not present in the cerebellum of control mice. Similarly, SNS expression was detected in Purkinje cells in MS tissues from patients that exhibited cerebellar deficits, but not in the controls. The up regulation of some sodium channels could be due to neurotrophic factors, altered electrical activity, or demyelination *per se* [43].

Abnormal localization of N-type calcium channel has been implicated as a mechanism of axonal degeneration. Prominent axonal transport of a pore-forming subunit of N-type voltage-gated calcium channel has been observed in actively demyelinated axons in MS and MOG induced EAE. The subunit is thought to then integrate in the axonal membrane of the injured axon, possibly causing influx of calcium with activation of proteases and degradation of the cytoskeleton [44]. Calpain is a proteinase, found to be expressed at clinical peaks of EAE in spinal cord microglia of Lewis rats, possibly being one of the causes of degeneration of the axonal cytoskeleton, as its activity is increased by free intracellular [45].

3.6 Cytotoxic cells and axonal damage

What causes this profound axonal damage is unclear. Acute axonal pathology correlates with the presence of macrophages in a Lewis rat EAE model [31]. Direct attack of the neurons by cytotoxic cells is a possibility. Cytotoxic cell precursors recognize antigens on the surface of cells in association with MHC class I molecules. Both neurons and axons in MS can express MHC I rendering them vulnerable to CD8 –mediated cytotoxicity.

Myelin specific CD8 T cells induced clinically and histopathologically severe EAE and these cells can directly cause neuronal and axonal damage [46, 47].

3.7 Agents associated with axonal damage

The severity of inflammation and the degree of axonal damage are positively correlated in both in MS and EAE. Several mediators of inflammation were investigated as primary causes of axonal damage.

Nitric oxide is produced in high concentration by macrophages and possibly by other CNS cells at sites of inflammation. The inducible form of NOS can produce much larger quantities of NO for protracted periods. Inducible NOS has been detected in MS plaques [48] and in the CNS of EAE [49]. The NO levels in the CNS of animals with EAE are reported to be up to 30 times greater than in the control animals. In an in vivo study, Smith has shown that axons operating at physiological frequencies are prone to nitric oxide mediated damage [50].

Other inflammatory mediators and cytokines may also act via induction or enhancement of NO. When relapses of the EAE were induced by intraperitoneal administration of IL-12 in Lewis rats, axonal death was observed in association with iNOS and tPA immunostaining throughout the gray and white matter. These agents might act either directly or indirectly by activating microglia and macrophages leading to axonal damage [51].

Perforin may be the principal mediator of axonal damage caused by cytotoxic T cells [47].

Glutamate neurotoxicity may be implicated in axonal damage and its blockade may be beneficial in EAE [52].

Trophic factors are important for the normal functioning of the complex glial-axon interaction. Ciliary neurotrophic factor (CNTF) has been demonstrated to be an important surviving factor for both neuronal and oligodendroglial populations. Disruption of the CNTF gene results in motor neuron degeneration. A CNTF mutation was detected in a group of MS patients with earlier onset and more severe course than those with at least one functional allele [53]. In EAE induced by MOG CNTF- deficient mice caused histologically a severe oligodendrogliopathy with prominent secondary axonal dystrophy and transection. This resulted clinically in earlier onset disease, with a significantly prolonged recovery phase [54]. In conclusion, lack of trophic factors seems to be associated with more severe axonal damage. Whether pharmacologically providing an excess of

neurotrophic stimulation will lead to less severe disease remains to be tested. Ruffini [55] delivered basic fibroblastic growth factor in mouse by genetically modified herpes virus vector that led to improvement of the clinical course of chronic EAE.

3.8 Correlation with disability

Although the degree of axonal abnormalities observed depends on the different model of EAE, the extent of the axonal involvement in a given EAE model seems to correlate with the degree of clinical severity of the disease. Examining the spinal cord of paraplegic EAE guinea pigs showed abnormalities in axons that were more pronounced, compared to rats that eventually recovered from the illness [41].

With quantitative immunohistochemical methods examining the spinal cord in chronic EAE neurological disability has been correlated with inflammation and axonal loss. Whereas inflammation was the principal determinant of reversible neurological disability during the acute EAE, the fixed neurological deficits correlated with axon loss, that in turn correlated with the number of symptomatic attacks [35].

3.9 Therapeutic interventions

A number of agents that modulate inflammation in EAE can lead to protection of axons. Prazosin an alpha 1- adrenergic antagonist prevented monoaminergic axonal damage in the spinal cord of EAE rats [56]. When recombinant HSV expressing IL-4 a Th2 cytokine, was injected intracranially in the BALB/c model of mice EAE it prevented massive leucocyte infiltration resulting in protection of both the myelin and the axons [57].

Memantine, an NMDA receptor antagonist ameliorates neurological deficits in Lewis rats with EAE. As this was not found to be due to dampened CNS inflammation a direct effect on NMDA receptors had been

postulated, suggesting that this might be an easy neuronal target for modulation during neuroinflammation [58, 59].

Similarly, the phosphodiesterase IV inhibitor roliparm was proven an effective anti-inflammatory agent in EAE, possibly because glutamate-induced cytotoxicity can be prevented by cyclic AMP elevating agents [60]. Studies in progressive MS with pentoxifylline, another phosphodiesterase inhibitor, did not show a significant effect [61]. As relapse frequency and MRI activity were the end point of the study, one wonders if the anti-inflammatory effect of those agents is less important than the effect on glutamate toxicity.

Cannabinoids are currently under investigation in MS especially for control of fatigue, tremor, spasticity and bladder dysfunction. Cannabinoids have bee successful in the control of spasticity in EAE [62]. Cannabinoid receptors are expressed in the CNS, and in vitro studies cannabinoids suppress nitric oxide production in neurons [63] and so possibly protect neurons from NMDA-induced neurotoxicity. There are suggestions that cannabinoids may have a neuroprotective role [64].

3.10 Immune modulation and protective autoimmunity

The degree of neuronal survival following CNS insult is influenced by immune mediated mechanisms. Kipnis *et al* [65] showed that the survival of retinal ganglion cells in adult mice, after a variety of insults to the optic nerve or the vitreous, is influenced by the susceptibility status to EAE of the animal. T cells reactive against neural antigens but nonencephalitogenic may enhance recovery. Animals with EAE resistance had 60 % more surviving neurons than normal animals. Furthermore, an unrelated injury to the spinal cord prior to the retinal ganglion cell insult led to increased survival of retinal neurons. Survival was dependent upon the generation of a protective T cell response, suggesting T-cell dependent protection mechanisms as potential target for neuroprotective therapy.

Chapter A9

ENDOTHELIAL CELLS AND ADHESION MOLECULES IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Jeri-Anne Lyons and Anne H. Cross
Department of Neurology and Neurosurgery, Washington University, Saint Louis, MO USA

Abstract: Under normal circumstances, entry of immune system cells into the central nervous system (CNS) is restricted by the blood-CNS barrier. However, with activation, cells of the immune system undergo changes that allow for an immune response within the CNS. The animal model, experimental autoimmune encephalomyelitis (EAE), is an important tool by which to investigate these processes. Using EAE, it has been shown that the establishment of an immune response in the CNS involves activation not only of the infiltrating inflammatory cells, but also of the CNS endothelial cells. Receptor-ligand interactions between CNS-EC and invading immune cells involved in EAE are multi-factorial. Particularly critical interactions occur between cell surface selectins on leukocytes and addressins on CNS-EC, and between integrins on leukocytes and their ligands on CNS-EC and other CNS cells. These interactions are good targets for potential therapies of MS, the human disease for which EAE is a model.

Key words: EAE, Endothelial Cells, Adhesion Molecules

1. INTRODUCTION

Experimental Autoimmune Encephalomyelitis (EAE) is an autoimmune demyelinating disease of the central nervous system (CNS) that results from the infiltration of neuroantigen-specific T cells into the CNS. These T cells in turn initiate a cell- and humoral-mediated inflammatory response that leads to the destruction of the myelin sheath, resulting in histopathology and clinical signs similar to those observed in multiple sclerosis.

Under normal circumstances, entry of immune system cells (e.g. T cells, B cells, monocytes, polymorphonuclear cells--PMNs) into the CNS is

restricted by the blood-CNS or blood-brain barrier (BBB; discussed elsewhere in this volume). However, upon cell activation, T cells of any antigen specificity are able to cross the BBB and enter the CNS. During immune surveillance, only those T cells specific for neuroantigen remain for an extended period of time (1). Although unproven, it is presumed that cellular activation enhances migration across the BBB by cell types other than T cells as well.

With immune activation, blood vessel endothelial cells (EC) and antigen-specific T cells undergo morphologic and phenotypic changes, allowing for the migration of T cells from the peripheral blood into tissues at the site of an immune response. These processes of cell activation and migration have been the subjects of much investigation. In many ways, migration of T cells across the BBB into the CNS is similar to T cell migration into other anatomic sites. However, there are differences unique to the CNS. Here we will discuss the role of CNS-EC and the adhesion molecules involved in the immunopathogenesis of EAE.

2. INFLAMMATORY CELL MIGRATION IN EAE

EAE lesions are comprised of T cells, monocytes/macrophages, occasional B cells and plasma cells, and reactive glial cells. During early clinical EAE, PMNs are also observed. Migration of inflammatory cells from the peripheral circulation into the CNS is normally highly restricted.

2.1 T Cell migration

Migration of inflammatory cells from blood into tissues is a multi-step process (2; Figure 1). While this model was first derived from studies of monocyte and neutrophil migration, most of the current data, especially as it pertains to migration of cells across the BBB, comes from studies of T cell migration. Activated lymphocytes are far better able to adhere to EC and to migrate across them than are resting T cells. Upon interaction with antigen (Ag), T cells express active forms of a variety of cell surface molecules including chemokine receptors and adhesion molecules. Similarly, chemokine and adhesion molecule expression is induced in EC at the site of an inflammatory response. Expression is induced by cytokines produced by inflammatory cells. Invading inflammatory cells and intrinsic CNS cells at the site of the immune response produce chemokines, small negatively charged chemoattractant molecules (reviewed elsewhere in this volume), which bind to receptors expressed by inflammatory cells. Chemokines also interact with extracellular matrix via electrostactic interactions to form a

chemoattractant gradient to attract inflammatory cells to the site. CNS-EC may also express chemokine receptors, to aid in formation of a chemoattractant gradient (3). This gradient attracts cells bearing specific chemokine receptors to the site. As T cells approach the target site, they loosely adhere to the EC in an interaction referred to as "tethering", typically mediated by interaction of selectin molecules on T cells with their addressin receptors on EC. This interaction slows the velocity of the T cells and induces the "rolling" stage of cell migration, which is mediated by interaction of selectin and integrin molecules on T cells with their addressin and immunoglobulin superfamily receptors on endothelial cells. "Rolling" is followed by "firm adhesion" (integrin-mediated), and subsequent transmigration of the T cell across the EC barrier. The secretion of matrix metalloproteinases by invading inflammatory cells aids transmigration across the EC layer and into the extracellular matrix.

2.2 B cells and polymorphonuclear cells

Although less is known regarding the molecular mechanisms used by B cells and PMNs to access the CNS, it is widely believed that they are similar to mechanisms used by T cells (4). However, evidence suggests that for PMNs different receptor-ligand interactions are involved in rolling and firm adhesion. (5-6; section 4.2.3)

	Chemotaxis	Tethering	Rolling	Firm Adhesion	Transmigration
T cells	Chemokine Receptors	Selectins	Selectins, Integrins	Integrins	Matrix Metalloproteinases
Endothelial Cells	Chemokines	Addressins	Addressins, Ig Superfamily	Ig Superfamily	
(Examples)	(MIP1α, RANTES, IP-10)	(L-selectin CD34, Glycam-1)	(LFA-1/ICAM-1 VLA-4/VCAM-1)	(LFA-1/ICAM-1 VLA-4/VCAM-1)	(MMP-2, MMP-9)

Figure A9-1. T cell migration across an endothelial cell layer

3. ROLE OF CNS ENDOTHELIAL CELLS IN EAE

3.1 Properties of CNS endothelial cells (CNS-EC)

The primary blood-CNS barrier is due to specialized properties of CNS-EC. Studies using tracer molecules point to the endothelial tight junctions, which involve cell membrane fusion between adjacent EC, as the primary barrier (7). CNS-EC are unique among EC in that they display little to no pinocytosis, a paucity of caveolae, reduced vesicle content, high mitochondrial content and a high electrical resistance. The luminal surface of CNS-EC is negatively charged (8), typical of EC throughout the body. The negative charge is believed secondary to localization of sialic groups and sulfated glycosaminoglycans at the luminal EC membrane (9).

Leukocyte recruitment into the CNS is not typical of that of any other body tissues, where recruitment of cells to a site of injury is rapid and often extensive. Nonetheless, during EAE, cells of the immune system locate the target CNS and penetrate the blood-brain barrier. Several studies have indicated that lymphocytes penetrate CNS-EC directly, during which time these same EC continue to display intact tight junctions with the adjacent EC

(8, 10). This phenomenon has also been reported in non-CNS tissues (11). Non-lymphocytic cells such as PMNs and monocytes do appear to invade the CNS by moving between the EC.

BBB breakdown is an early event in EAE, during which the blood-CNS barrier becomes opened at the level of both capillaries and venules at the sites of inflammation (8, 12). Gaps between EC are observed. Increased vesicular transport occurs (12). Such vascular leakage can be induced by leukotrienes, vasoactive amines and cytokines. For example, IL-1β injected into the rabbit vitreous induces both acute and chronic inflammatory changes associated with altered blood-retinal barrier that occur within 6hr of injection and persist for 2 weeks or more (13).

Under normal circumstances and in contrast to systemic EC, lymphocytes do not constitutively adhere to CNS-EC in culture (14). Preincubation of rodent and human CNS-EC with Interferon-gamma (IFNγ) and Tumor Necrosis Factor (TNF) α, and in some cases IL-1, increases the retention of lymphocytes on cultured CNS-EC monolayers (15). Direct injection of either TNFα or IFNγ into rodent spinal cords leads to accumulation of mononuclear cells in perivenular cuffs, presumably due largely to the effects of these cytokines upon the CNS-EC (see section 3.2, below; 16).

Effects of cytokines on EC integrity are dramatically demonstrated by the vascular leak syndrome induced by systemic IL-2 administration (17). This syndrome is associated with the upregulation of E-selectin, ICAM-1 and HLA-DQ on peripheral postcapillary venular endothelium. In animal models injection of IL-2, as well as other cytokines such as IL-6, into the circulation increases BBB permeability (18-19). IL-2 also activates lymphocytes to display enhanced motility, adherence to, and migration across EC *in vitro* (20). Elevated serum IL-2 levels are found in MS patients (21), and are reported to correlate with disease activity and increased BBB permeability (22). Thus, circulating cytokines such as IL-2 may act directly or indirectly on cells of the BBB to increase permeability and enhance CNS inflammation.

EAE is the primary animal model for MS. As in EAE, MS lesions are perivenular and the microvascular EC display upregulated expression of adhesion related molecules (23-25). Several studies of MS patients have shown that BBB breakdown as detected by gadolinium enhancement on MRI, is an initial event in the development of both permanent and transient MS lesions (26).

3.2 Morphologic changes in CNS-EC that support cellular transmigration

Clearly, endothelial cells are not passive bystanders in the process of transmigration of cells across the blood CNS barrier. We and others have reported that CNS-EC associated with early EAE lesions display an altered, "activated" morphology at both light and electron microscopic levels (8, 27). These "activated" CNS-EC appear plumper, possess increased content of mitochondria and rough endoplasmic reticulum, and display frond-like appendages, which can be observed to contact adherent cells, at times appearing to "capture" circulating cells (14; Figure 2). This appearance is distinct from the smooth, flat appearance of CNS-ECs of normal mice.

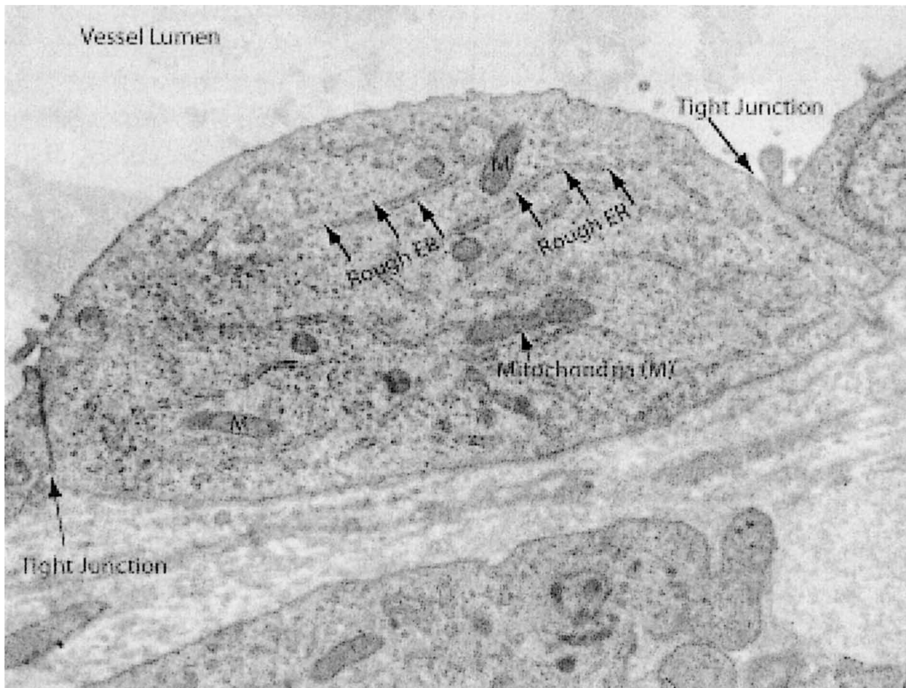

Figure A9-2. Electron micrograph of CNS-EC during acute EAE induced by passive transfer of myelin basic protein sensitized lymph node cells in SJL mouse. Typical of CNS-EC observed at sites of inflammation during acute EAE, this cell is plumper than normal with increased amounts of rough endoplasmic reticulum (rough ER) and mitochondria (M). The EC nucleus is out of the plane of section. Tight junctions with the adjacent EC, characteristic of the BBB, are noted at either side (long arrows). X 20,000. [See Ref. 10 for methods.]

Exposure to cytokines such as TNFα and IFNγ induces the expression of ICAM-1 and other adhesion related molecules by CNS-EC, as well as LFA-

1 by leukocytes. The interaction of ICAM-1 on CNS-EC with LFA-1 expressed by leukocytes leads to signal transduction events that alter EC morphology and function. (28). Upon ligation by LFA-1, the cytoplasmic domain of ICAM-1 interacts with α-actinin (29) and with the actin-binding protein and p60Src substrate, cortactin, leading to its tyrosine phosphorylation (28).The activation of actin-associated proteins and the subsequent cytoskeletal rearrangements induced with ICAM-1 ligation suggest a role for these interactions in the observed morphologic changes of CNS-EC (30).

3.3 Inflammatory mediators expressed by CNS-EC

3.3.1 Chemokine production by CNS-EC

CNS-EC elaborate a number of inflammatory mediators upon activation, including chemokines, cytokines, and vasoactive amines. At sites of EAE lesions, CNS-EC produce chemokines, such as MCP-1 (31). Cultured human brain ECs are reported to produce several chemokines, including IL-8, MCP-1, IP-10, MIP1β, and RANTES (32-33). Expression of these chemokines can be induced by cytokines such as TNFα, IFNγ, IL-1β (32-33). Chemokines are concentrated at the luminal and basal surfaces of CNS-EC via binding to glycosaminoglycans and chemokine receptors (33-34).

3.3.2 Cytokine production by CNS-EC

Both pro-inflammatory (e.g., IL-1α, IL-6, TNFα, GM-CSF) and regulatory cytokines (e.g., IFNβ and TGFβ1 & 2) are among the molecules reported to be secreted by CNS-EC. Production of cytokines by CNS-EC is regulated by glial cell-derived soluble cytokines, including IL-1β, IL-12, TNFα, IL-10 and TGFβ (35).

3.3.3 MHC & costimulatory molecule expression

The cell responsible for initial presentation of antigen to encephalitogenic T cells in EAE (and possibly MS) is unknown. CNS-EC remain a contender, as do astrocytes, but most evidence favors perivascular microglia. Based upon what is known regarding antigen presentation to CD4 T cells, the CNS antigen presenting cells must express MHC II and costimulatory molecules (B7-1, B7-2).

Although CNS-EC do not constitutively express MHC II, they can be induced to do so, and IFNγ is especially potent in this role. Early on, Sobel et

al. showed expression of MHC on CNS-EC during EAE (36). Human and mouse CNS-EC have also been shown to express B7 costimulatory molecules when stimulated with IFNγ *in vitro* (37-38), but this has been difficult to demonstrate on EAE-affected CNS tissues immediately ex vivo (39). Several independent groups have each observed that CNS-ECs do not support primary antigen-induced T cell proliferation, even upon stimulation with cytokines such as IFNγ (40-42). Furthermore, mouse CNS-EC produce 6-KPGF1α, a stable product of prostaglandin GI_2 (PGI_2) that directly inhibits lymphocyte proliferation to antigen. Exogenous macrophages or recombinant IL-1 induce murine CNS-EC to produce PGI_2 in a dose dependent manner. Thus, CNS-EC may actively inhibit the response to antigen by T cells at the BBB by production of 6-KPGF1α (43).

4. ROLE OF ADHESION MOLECULES IN EAE

4.1 Selectins and Addressins

The initial step of transmigration of inflammatory cells across an endothelial cell barrier is "tethering" of activated cells to activated endothelial cells via the interaction of selectin molecules with addressin molecules (44). These molecules can also mediate the subsequent rolling of T cells along the endothelial cell surface. This adhesion of cells to vascular endothelium is a long-recognized process termed "pavementing" by Cohnheim in the late 1800's (45; Figure 3).

The three members of the selectin family include L-selectin (CD62L, found on all leukocytes), P-Selectin (CD62P, found on platelets and endothelial cells), and E-Selectin (CD62E, found on endothelial cells). Selectins are transmembrane glycoproteins with intra- and extra-cellular domains that bind carbohydrate ligands via a calcium-dependent lectin domain. The intracellular domains of the selectins are structurally distinct from each other, but highly conserved between species for a given selectin, suggesting specific effector functions following the ligation of the particular selectin molecules. The extracellular domain is composed of a calcium-dependent lectin domain, an epidermal growth factor (EGF)-like domain, and a series of short consensus repeats (SCR) with homology to complement-binding proteins (reviewed in 46). The extracellular domains of the selectins differ primarily in the number of SCR present. The EGF-like and lectin-binding domains of L-, P-, and E-selectin are quite similar, suggesting that the molecules interact with similar, if not overlapping, ligands (47).

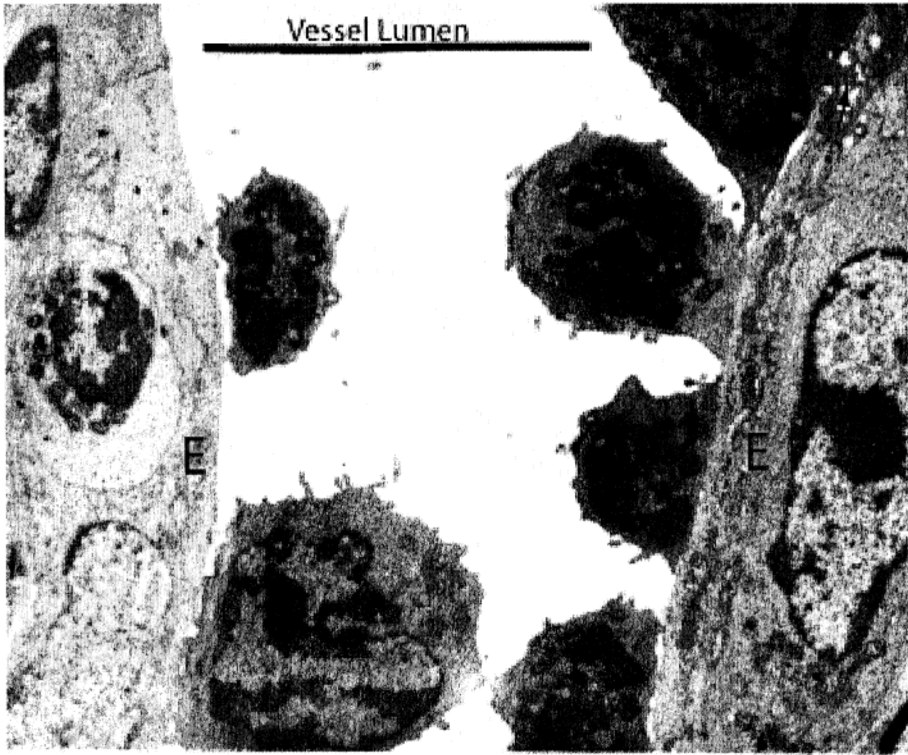

Figure A9-3. "Pavementing" is demonstrating in this electron micrograph taken from a well-perfused SJL mouse less than 24 hr following clinical onset of passively transferred EAE. Mononuclear cells line the luminal aspect of this small venule. Note the tiny finger-like projections of the lymphocytes contacting the endothelium (arrow upper right). At higher magnifications, clathrin coated pits are observed at these contact points. X 10,000

Early reports suggested a role for selectin molecules and their addressin receptors in EAE. Naparstek et al. were perhaps the first to recognize the importance of these molecules in the development of EAE (48). These investigators observed strong binding of neuroantigen-specific T cells to the lectin, peanut agglutinin (PNA) upon activation, suggesting that T cell activation induced expression of lectin receptors. Furthermore, about 75% of activated neuroantigen-specific T cells acquired the lectin binding, and this correlated strongly with ability to transfer EAE to naïve recipients.

Selectins are known to interact with sialylated mucin-like receptors on EC and other leukocytes, and these sialyl moieties are required for receptor-ligand interaction (discussed below). In a second study, pretreatment of CD4+ lymphocytes with sialidase prior to injection into MBP-primed Lewis rats led to a significant reduction in the accumulation of these cells in the

CNS of animals, compared to injection of untreated cells. Circulating levels of treated and untreated cells were similar. Daily injections of sialidase delayed the onset of clinical and histologic EAE in a passive transfer model (49).

4.1.1 L-selectin

The role of L-selectin in the initial stages of lymphocyte migration across most endothelial barriers is accepted (reviewed in 50). However, a function for L-selectin in migration across the BBB remains controversial. It has been suggested that the adhesion molecule phenotype of T cells in the inflamed CNS differs from the phenotype of T cells at other inflammatory sites, including a lack of L-selectin expression by CNS inflammatory T cells by flow cytometric methods (51). Separate studies in a mouse model of EAE did identify L-selectin^{pos} cells in the CNS by histologic observation. These L-selectin^{pos} cells were noted first prior to clinical onset, beginning 8d following immunization with CNS homogenate (52). L-selectin^{pos} cell numbers increased through d18 and then declined with remission of signs. However, injection of anti-L-selectin monoclonal antibodies (mAb) had no effect on disease course or severity in this model or in a peptide-induced mouse EAE model (53). Moreover, L-selectin was not detected on T cell lines and clones used for adoptive transfer. Taken together these observations suggest that L-selectin is not necessary for migration of T cells into the CNS.

In contrast, in a model of MBP-induced EAE in the Lewis rat treatment with either a mAb to L-selectin or F(ab'$_2$) fragments of the mAb suppressed actively induced disease. Passively transferred disease was also mildly suppressed. Histological examination demonstrated a marked reduction in CNS inflammatory cell infiltration. T cell numbers were decreased in the draining lymph nodes and spleens in treated animals (54). Thus, suppression of EAE may have been due to insufficient trafficking of T cells to peripheral lymphoid organs leading to insufficient priming of encephalitogenic T cells, rather than defects in migration into the CNS.

The conflicting results on the effect of anti-L-selectin mAb on EAE induction could be due to differences in the EAE models employed. Differences in the detection of L-selectin^{pos} cells between systems could be a reflection of the different methods of tissue isolation and detection, as it has been shown that L-selectin expression can be altered by various isolation techniques (55-56). Alternatively, it is known that L-selectin is shed readily upon cell activation (reviewed in 50). Thus, differences in the detection of cell surface L-selectin may be related to time-points chosen for observation.

Recent data has suggested a novel role for L-selection expression by CNS-infiltrating macrophages in EAE pathogenesis (57). Mice expressing an MBP-specific T cell receptor (MBP-TCR) transgene were made deficient for L-selectin to study the role of the latter molecule in EAE pathogenesis. L-selectin^{neg} MBP-TCR mice were not susceptible to clinical EAE following immunization with the encephalitogenic MBP_{Ac1-11} peptide. Histologic examination of CNS tissue revealed the presence of typical inflammatory infiltrates but a lack of demyelination in L-selectin^{neg} mice. Moreover, while inflammatory cells were present, they were localized to the perivascular space and did not enter the CNS parenchyma as was observed in L-selectin^{pos} mice. Passive transfer of L-selectin^{pos}, but not L-selectin^{neg}, macrophages resulted in myelin destruction and clinical EAE in L-selectin^{neg} mice, indicating a critical role for L-selectin expression by macrophages in the effector phase of disease. Interestingly, while L-selectin^{pos} macrophages did enter the parenchyma of L-selectin^{neg} mice with EAE, the endogenous L-selectin^{neg} T cells remained in the perivascular space, suggesting a role of L-selectin in the final step of transmigration of cells across the parenchymal basement membrane into the CNS tissue.

4.1.2 P-selectin

The role of P-selectin in EAE remains controversial. P-selectin can be induced on mouse CNS-EC by inflammatory cytokines (TNFα, IL-1β, IFNγ) *in vitro* (58). However, P-selectin could not be detected on CNS-EC *in vivo* by immunohistologic methods, although expression was detected on EC outside the CNS. In addition, administration of anti-P-selectin Ab had no effect on immune cell infiltration of the CNS or actively induced EAE in a mouse model of disease. Interestingly, induction of P- (and E-) selectin on primary CNS-EC *in vitro* was inhibited by astrocyte culture-derived supernatants, suggesting that active inhibition by the CNS microenvironment of adhesion molecule expression may play a role in maintenance of the BBB.

More recent studies have supported a role for P-selectin in EAE induction (59-62). Utilizing a passive transfer model and looking at early time-points (2h and 24h) post transfer (p.t.), Carrithers et al. (59) demonstrated a role for P-selectin in the earliest recruitment of T cells into the CNS. Mice received MBP-specific T cells labeled with a fluorescent dye, and frozen sections of CNS tissue were prepared at various times p.t. Ag-specific T cells were detected in the CNS 2h p.t., and these numbers were increased at 24h. Characterization of adhesion molecules in the CNS revealed expression of ICAM and VCAM (discussed below) beginning at 24h. P-selectin expression was detected 2h p.t. in the choroid plexus and

meninges, but was undetectable at 48h. Thus, expression of P-selectin in the CNS coincided with Ag-specific T cell infiltration of the CNS at early time-points post adoptive transfer. Furthermore, the early migration of T cells into the CNS was inhibited by treatment with Ab recognizing P-selectin, but not $\alpha 4$ integrin (VLA-4, discussed below). These studies suggest a role for P-selectin in the migration of "pioneer" T cells (i.e., those T cells that will initiate the EAE-inducing inflammatory response) into the CNS.

Data from a rat model of EAE further support a role for P-selectin in the inflammatory infiltration of the CNS (61). Immunization of PVG rats deficient for complement component 6 (C6) with neuroantigen resulted in less severe clinical EAE than in control ($C6^{pos}$) animals. T cell and macrophage infiltration in the spinal cords of $C6^{neg}$ rats was also less than that observed in $C6^{pos}$ animals. Immunohistochemistry of CNS tissues revealed a decrease in ICAM-1 expression by EC and infiltrating cells and a lack of P-selectin on vascular endothelium in $C6^{neg}$ rats, suggesting a role for these adhesion molecules in immune cell infiltration of the CNS. Cytokine-induced activation of EC renders EC susceptible to complement activation (63). Thus, an effect of complement activation on activated EC at the site of inflammation may upregulate adhesion molecule expression and further compromise the BBB, leading to amplification of the immune infiltrate into the CNS.

Two independent groups employing intravital microscopy techniques have further defined a role for P-selectin in lymphocyte recruitment across the BBB (60, 62). Kerfoot and Kubes (62) utilized intravital microscopy to study leukocyte rolling and adhesion during the course of actively induced EAE in mice. Both rolling and adhesion were observed 2d prior to onset of clinical signs and remained elevated for 2 weeks before returning to normal levels by 5 weeks post onset of clinical signs. Expression of P-selectin in EAE-primed mice closely followed this profile. Furthermore, while anti-$\alpha 4$ integrin (discussed below) Ab were able to partially block the rolling and adhesion of leukocytes, especially at later time-points, co-treatment with anti-$\alpha 4$ and anti-P-selectin blocked all remaining rolling at all time-points. A role for P-selectin-mediated adhesion in regulation of $\alpha 4$ integrin-mediated adhesions was suggested by the finding that anti-P-selectin treatment lead to a complete block of leukocyte rolling and a 70% reduction in adhesion. In a separate study employing a similar technique, Piccio et al. (60) demonstrated that treatment with Ab recognizing P-selectin was able to block almost 100% of tethering and rolling of neuroantigen-specific T cells in their model. Co-treatment with antibodies recognizing P- and E-selectin had a similar effect, and treatment with anti-E-selectin alone blocked rolling by 77%, suggesting that both P- and E-selectin are important to primary adhesion events in the

CNS. Interestingly, treatment of mice with anti-L-selectin had no effect on Ag-activated lymphocyte rolling (see Section 4.1.1).

Although neutrophils are not a component of the chronic EAE lesion, these cells can be found in the CNS at the first signs of clinical disease. Recently, the role of selectins in the migration of neutrophils across the BBB was investigated in a rat system (64). It is known that injection of IL1-β into the CNS of juvenile rats leads to the accumulation of neutrophils at the site of the injection. This accumulation leads to further breakdown of the BBB (65). Bernardes-Silva et al. (64) demonstrated that the stereotactic injection of IL-1β into brains of juvenile rats resulted in the expression of E-selectin and P-selectin on CNS vessels by immunohistochemistry. Depletion of neutrophils prior to IL-1β treatment had little effect on E-selectin expression, but resulted in significantly lower expression of P-selectin, indicating that neutrophil recruitment may play an important role in the upregulation of P-selectin in this model. The functional importance of P-selectin to neutrophil migration across the BBB was demonstrated by the inhibitory effect of anti-P-selectin Ab, but not anti-E-selectin, on the accumulation of neutrophils in the CNS of treated rats. Thus, P-selectin may function in the migration of neutrophils into the CNS, which may in turn be important to the further compromise of the BBB and recruitment of inflammatory cells into the CNS.

4.1.3 E-selectin

The role of E-selectin in EAE has received little attention. E-selectin has been observed on CNS-EC in MS lesions (26). Induction of expression on cultured human astrocytes by TNFα and on mouse CNS-EC by TNFα, IL-1β, or IFNγ *in vitro* has been reported (58, 66). However, E-selectin expression by CNS-EC could not be detected *in vivo*, and administration of anti-E-selectin did not affect infiltration of inflammatory cells across the BBB or the development of EAE (58). As discussed above, more recent studies have suggested a role for E-selectin in immune cell migration across the BBB (60).

4.1.4 Ligands of selectin molecules ("Addressins")

The selectin molecules interact with their ligands through the N-terminal lectin domain. Consistent with this, most of the identified ligands of selectins are mucin-like molecules with carbohydrate modifications, including sialylation, fucosylation, and carbohydrate sulfation, necessary for receptor interaction (reviewed in 67). Such ligands, originally termed "Peripheral Node Addressins--PNAd", include GlyCAM-1, CD34, MadCAM-1, sialyl

Lewis x (sLe^x), and PSGL-1 (46, 68-71). More recently, other non-mucin ligands for selectins, including heparin, have been identified (72).

4.1.4.1 Addressins in EAE

Early studies by Cannella et al. noted expression of high endothelial cell (HEV) addressins localized to the CNS during periods of active inflammation in a mouse model of EAE (73). More recently, encephalitogenic T cells mediating EAE and inflammatory cells present in the CNS during active disease were shown to express ligands for P-selectin and, to a lesser extent, E-selectin (51, 58). These investigators used fluorescent selectin-Ig fusion proteins to identify cells expressing selectin ligands by flow cytometry but did not establish the identity of the ligands expressed.

Pertinent to EAE and MS, a CNS-specific ligand for L-selectin has been identified. Using a mouse L-selectin-Ig fusion protein, this ligand was shown to be localized to CNS white matter and, more specifically, to the myelin sheath of CNS axons (74). This ligand was not apparent in PNS myelin (75). The identity of this ligand has yet to be determined.

Of the identified selectin ligands, a role for PSGL-1 in EAE has been specifically addressed (60). Mice were pretreated with LPS or TNF to activate endothelial cells followed by the passive transfer of fluorescently labeled T cells specific for neuroantigen. The migration of cells was followed by invtravital microscopy. The neuroantigen specific T cells were observed to roll and arrest activated endothelium, whereas no such behavior was observed in untreated animals. Furthermore, the percentage of neuroantigen-specific T cells rolling along the vascular endothelium was significantly higher than for unactivated peripheral lymph node cells. The rolling behavior was nearly completely inhibited in the presence of anti-PSGL-1 Ab, but not antibody recognizing L-selectin, indicating a role for PSGL-1 and P/E selectin in the early stages of T cell migration across CNS-EC.

A role for MAdCAM-1 in EAE has also been investigated (76-77). MAdCAM-1 is relevant not only as a ligand for the selectins but also as a ligand for alpha4beta7 integrin (discussed below). Expression of MAdCAM-1 was induced on choroid plexus epithelial cells, but not endothelial cells, in a mouse model of EAE. Expression could be induced on choroid plexus epithelial cells *in vitro* following incubation with proinflammatory cytokines (TNFα, IFNγ, LPS), and MAdCAM-mediated adhesion of lymphocytes using *in vitro* binding assays with frozen tissue was demonstrated (76). It was subsequently shown that anti-MAdCAM-1 antibody, administered in the presence or absence of anti-VCAM-1 and anti-ICAM-1 led to rapid

remission of clinical signs when given early in disease progression, although combinatorial therapy was more efficient. Anti-MAdCAM-1 alone or in combination with anti-VCAM-1 and anti-ICAM-1 had no effect on remission when given later in disease (77).

4.1.5 Non-adhesion related functions of selectins

Although selectins are predominantly thought of as adhesion molecules, selectin-ligand interaction results in signal transduction in the selectin-expressing cells as evidenced by increases in intracellular calcium (reviewed in 46). Ligation of L-selectin or E-selectin on neutrophils results in aggregation, augmentation of the respiratory burst, oxygen radical production, and upregulation of Mac-1 expression (78-84). Similar activation of monocytes is noted following P-selectin/PSGL-1 interaction, including secretion of chemokines and cytokines involved in inflammation (85-87). Further activation of T cell transmigration results from L-selectin-mediated activation of beta1 and beta2 integrins and increased adhesion to fibronectin (88-89).

4.2 Integrins and their Immunoglobulin Superfamily receptors

4.2.1 Integrin / Ig Superfamily member interactions

Activated T cells and other leukocytes express the integrins, LFA-1 and VLA-4. These molecules are ligands for the Ig-superfamily molecules, ICAM-1 and –2, and VCAM-1, respectively. Interaction of these receptor-ligand pairs is believed to be critical in T cell adherence to CNS-EC. Resting cultured brain ECs constitutively express low levels of ICAM-1, and minimal VCAM-1 (90). In response to inflammatory cytokines such as IFNγ and TNFα, expression of ICAM-1 and VCAM-1 by cultured rodent and human CNS-EC is greatly enhanced (91-92).

4.2.2 Role of ICAM-1 interactions with LFA-1 in EAE

To determine the function of the integrins and their Ig superfamily member receptors in EAE, studies using mAb directed against these molecules were performed. Archelos et al. reported that either intact or $F(Ab)_2$ fractions of a purified antibody to ICAM-1 inhibited actively induced EAE in guinea pigs (93). Inflammatory infiltration of the CNS was greatly

reduced. In contrast, the anti-ICAM-1 treatment had minimal effect upon adoptively transferred EAE. Proliferation to antigen was suppressed in T cells derived from anti-ICAM-1-treated animals. Another study of anti-ICAM-1 in a mouse model of adoptively transferred EAE using MBP-sensitized cells had similar results, with minimally decreased severity in anti-ICAM-1-treated mice (94). EAE induction in ICAM-1-deficient mice revealed decreased proliferation and Th1 cytokine production in response to antigen in the mutant mice, but unexpectedly EAE was worse in the ICAM-1 deficient mice (95). These studies suggest that ICAM-1 plays a more important role in the induction phase of EAE than in the adherence and transendothelial migration of leukocytes.

4.2.3 Role of α4β1 and αEβ7 integrins in EAE and MS

Several groups have studied the role of α4β1 integrins (VLA-4) in EAE. Yednock et al. found that binding of rat and human mononuclear cells to EAE affected vessels *in vitro* was inhibited by pretreatment of the mononuclear cells with antibody directed toward α4 integrin (96). Moreover, *in vivo* administration of anti-α4 integrin prevented CNS inflammatory cell infiltration and clinical signs of EAE in a dose-dependent manner. Members of this same group later showed that treatment with antibody against α4β1integrin markedly reduced the clinical and pathologic features of EAE in the Hartley guinea pig. Perhaps more significantly, they found that treatment after clinical onset led to rapid recovery (97). Another group of investigators reported that surface expression of α4β1 integrins by Th1 T cells was a critical feature in determining encephalitogenicity. In the latter study of T cell clones and lines directed against MBP peptide Ac1-16, expression of α4β1 integrins correlated with encephalitogenicity, whereas antigen-specific proliferation and production of cytokines IL-2, IFNγ, LT or TNF did not (98).

The β7 subfamily of integrins has two members, α4β7 and αEβ7. Both are expressed solely by leukocytes. The ligand for α4β7 is MAdCAM-1, identified by the antibody MECA89. This molecule is upregulated on CNS-EC with the morphology of high endothelial venular EC during EAE (73). αEβ7 is expressed by intraepithelial lymphocytes and interacts with E-cadherin on gut-associated lymphoid tissue. Expression of E-cadherin can be induced on cultured CNS-EC. Treatment with an antibody directed against β7 integrins leads to remission of established chronic EAE induced with myelin oligodendrocyte glycoprotein (MOG). This remission is even more dramatic when anti-β7 and anti-α4 antibodies are administered together. Mice deficient for β7 integrins display attenuated EAE (99). These findings strongly implicate the interaction of β7 integrins on leukocytes with their

ligands expressed by activated CNS-EC, or perhaps other cells, in the pathogenesis of EAE.

The interaction of α4 integrins with their ligands appears critical to multiple sclerosis disease activity. Early phase trials have shown that treatment of MS patients with a humanized monoclonal antibody against α4 integrins (natalizumab) decreases the number of MS lesions on MRI (100). A multi-center Phase III trial of this drug in MS patients is currently underway.

4.2.4 PECAM-1 in EAE

At least one member of the Ig superfamily appears to play a key role in the maintenance of the BBB. Platelet/endothelial cell adhesion molecule-1 (PECAM-1, CD31) is a member of the Ig superfamily of transmembrane proteins and is expressed on EC, platelets, PMNs and subsets of lymphocytes. In systemic organs, expression of PECAM-1 by EC and PMNs is important for neutrophil transmigration into tissues.

Ligation of PECAM-1 expressed by leukocytes mediates signal transduction events culminating in the expression of β1 and β2 integrins of increased affinity. This would be expected to increase adhesion of leukocytes, enhancing inflammation. However, inhibiting PECAM-1 with antibodies does not alter the course of EAE in the rat (101). More unexpectedly, PECAM-1 deficient mice display earlier onset of clinical EAE, with earlier CNS infiltration by inflammatory cells and with exaggerated CNS vascular permeability compared to wild-type mice. *In vitro*, T cell migration across artificial BBB made from PECAM-1^{neg} EC is enhanced, with PECAM-1^{neg} EC displaying increased susceptibility to histamine-induced permeability. Thus, PECAM-1 appears critical to maintaining BBB integrity in the setting of inflammation or histamine challenge (102).

4.3 Other adhesion-related molecules

Data exist for the role of adhesion molecules that are not members of the above families in EAE.

4.3.1 Leukosialin (CD43)

Leukosialin is a conformationally-extended single-chain leukocyte glycoprotein that binds to ICAM-1 (103). It is expressed by all leukocytes, including T cells, macrophages, neutrophils, and a subpopulation of B cells.

Leukosialin/ICAM-1 interaction leads to intracellular signaling in the leukosialin-expressing cell that synergizes with TCR/CD3 signaling resulting in T cell activation (104). Immunohistochemical analysis of leukosialin^{pos} cells over the course of actively induced EAE in mice revealed their infiltration beginning approximately 8 days post immunization, reaching peak levels at days 11-18 and persisting at peak levels through 28 days post immunization. These cells were noted adhering to the lateral ventricular choroid plexus, in periventricular loci in the hippocampus and in perivascular locations near the optic tract. Injection of Ab directed against leukosialin during the onset of EAE resulted in a trend towards more severe clinical EAE, suggesting inhibition of regulatory mechanisms in disease (52).

4.3.2 Laminins

Laminins are heterotrimeric glycoproteins that form a major functional component of all basement membranes. At least 12 isoforms exist, and expression can be regulated by proinflammatory cytokines (105). It is known that laminins 8 and 10 are expressed in endothelial basement membranes, and laminins 1 and 2 are expressed by blood vessels in the CNS, but not in other locations (106-108).

Larger blood vessels in the CNS are associated with at least two basement membranes--an endothelial basement membrane and an astroglial basement membrane (109). The astroglial basement membrane and the meningeal epithelial basement membrane together form the "parenchymal basement membrane", which defines the border to the brain parenchyma. The perivascular space, where inflammatory infiltrates accumulate during EAE, is defined by the endothelial and parenchymal basement membranes. Thus, in order to penetrate the brain parenchyma, inflammatory immune cells must penetrate two physiologically distinct basement membranes. That cell migration across the two distinct basement membranes is not mechanistically identical is suggested by EAE experiments in macrophage-depleted mice in which infiltrates are trapped in the perivascular space, failing to enter the brain parenchyma (110). Similar localization of cells to the perivascular space is also noted with EAE experiments in TNF-deficient mice (111).

The role of laminins in directing T cell migration across the BBB and into the brain parenchyma was investigated in actively induced EAE (112). Using immunofluorescent staining of tissue sections, localization of laminins 8 and 10 to the endothelial basement membrane and laminins 1 and 2 to the parenchymal basement membrane was observed. Inflammatory cell migration across the endothelial basement membrane took place in areas

where only laminin 8 was expressed, suggesting that laminin 10 is somehow restrictive to cell migration, perhaps through high affinity interaction with T cells. Using neuroantigen-specific T cell lines, activation-dependent integrin-mediated interactions of T cells with laminin 8 and laminin 10 were demonstrated. Penetration of the parenchymal basement membrane was characterized by expression of both laminins 1 and 2 in the absence of smooth muscle actin. However, no physical interaction between activated T cells with either of these lectins was demonstrated.

4.3.3 CD44 (Pgp-1)

CD44 is a family of cell surface proteoglycans thought to function as adhesion molecules. Observed roles include binding to extracellular matrix, cell migration, lymphocyte development, tumor cell metastasis, and lymphocyte homing (113-115). CD44 has been shown to interact with extracellular matrix proteins, including hyaluronate, chrondroitin sulfate, collagen, fibronectin, and laminin (116-120). More recently, CD44 has been shown to function as a receptor for L- and E-selectin (121-122).

CD44 has been shown to mediate tethering and rolling under conditions of physiologic flow (115, 123). A role for CD44 in cell migration across the BBB is suggested by experiments in the EAE model (53, 124). In a passive transfer model of disease, pre-coating encephalitogenic T cells with anti-CD44 prior to transfer reduced cell infiltration into the CNS by half when compared to uncoated cells. Furthermore, mice treated with anti-CD44 antibody failed to develop inflammatory lesions in the brain, and EAE was inhibited in a dose-dependent manner by anti-CD44 antibody (53). Similar results were obtained by Brennan et al. (124), who further showed that amelioration of disease was due to antibody-induced shedding of CD44 by encephalitogenic T cells. While trafficking of T cells to the CNS was inhibited, trafficking to the lymph nodes was unaffected in Ab treated mice, suggesting that CD44 is specifically involved in the trafficking of Ag-primed cells to sites of inflammation.

4.3.4 MECA-325

MECA-325 defines a marker of high endothelial venules (HEV) in lymphoid tissue of mice and is associated with cell transmigration. The identity of the moiety defined by MECA-325, or its exact function is unknown. Expression of the MECA-325 epitope correlated with disease signs in a relapsing-remitting model of EAE in SJL mice induced by passive transfer of myelin basic protein-sensitized lymphocytes (73). MECA-325

was expressed on CNS venules 24-48 hr prior to initial signs of murine EAE, and at higher levels during acute clinical disease. Normal SJL CNS vascular cells did not express MECA-325 *in situ*. Expression decreased to preclinical levels during remission and rose again during relapses. This expression profile was similar to that of molecules also thought to be involved in EAE pathogenesis (ICAM-1 and MHC II), which fluctuated similarly on and around vascular cells during EAE.

4.4 Cytokine regulation of adhesion molecule expression and BBB permeability

4.4.1 Regulation by Th2 cells

It is thought that Th1 cytokines (i.e., IFNγ, TNFα) are necessary and responsible for the induction of EAE, while Th2 cytokines (IL-4, IL-10) are protective for disease. Transfer of Th2 neuroantigen specific T cells, either with transfer of encephalitogenic (Th1) neuroantigen specific T cells or with active immunization with neuroantigen, ameliorates EAE (125-126). Organotypic entorhinal-hippocampal slice cultures were used to study the mechanism by which Th2 cells are protective for EAE (127). By culturing tissue slices with Th1 or Th2 cells specific for neuroantigen, it was demonstrated that both cell types could invade the parenchyma and interact with microglia. However, only Th1 cells induced the expression of ICAM-1 by microglia. Furthermore, Th2 cells were able to inhibit and reverse the induction of ICAM-1 by Th1 cells, suggesting that Th2 cells may protect against EAE in part by affecting migration of inflammatory cells across the BBB.

4.4.2 Effects of Interferon beta on adhesion molecule expression in EAE

Interferon beta (IFNβ) is of established benefit in relapsing-remitting MS, decreasing relapse rate, MRI activity and accumulation of disability. IFNβ also decreases clinical and pathologic manifestations of EAE (128). The mechanisms by which IFNβ acts are unknown, however in a rat model of EAE, a marked reduction in expression of ICAM-1 and VCAM-1 by CNS-EC was noted, accompanied by decreased mononuclear cell infiltration of the CNS (129). Cultured CNS-EC upregulate ICAM-1 and VCAM-1 upon exposure to proinflammatory cytokines and this upregulation can be inhibited in a dose-dependent manner by co-incubation with IFNβ. IFNβ has a number of other effects that may benefit MS, including the diminution of MMP secretion by T cells (130).

5. CONCLUSION

The BBB represents a specialized barrier to inflammatory cells. Migration across the BBB is highly regulated, preventing migration of immune cells during normal circumstances. However, in certain diseases this barrier is breached. The EAE model provides a valuable tool for studying immune cell migration into the CNS and is proving useful in the development of therapies to counteract human CNS inflammation.

ACKNOWLEDGMENTS

We thank Dr. Jen Stark for critical reading of the manuscript and dedicate this chapter to the memory of our colleague, Dr. John L. Trotter. The electron micrographs were taken while AHC was a post-doctoral fellow in the laboratory of Dr. Cedric S. Raine at Albert Einstein College of Medicine. Supported by the National MS Society USA.

Chapter A10

GENETICS OF EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS

David Baker
Department of Neuroinflammation, Institute of Neurology, University College, London, UK

Abstract: The identification of genetic factors that control the pathogenetic pathways of autoimmune neuroinflammation and degeneration may provide targets for new therapeutic strategies in human diseases, such as multiple sclerosis. This is not easily accomplished as significant heterogeneity exists and such genetic dissection may more easily be performed using inbred rodent strains, where the genetic heterogeneity is avoided and variation in the environmental influences is minimized. Chronic relapsing experimental autoimmune encephalomyelitis (EAE) exhibits some histopathological features typical of multiple sclerosis and provides a tool to systemically identify genetic influences controlling susceptibility through genome scanning and selective breeding of congenic animals harbouring disease-related loci. As with MS, susceptibility is controlled by expression of certain major histocompatibility complex allotypes, which in EAE is in response to induction with certain myelin antigens. Both are complex polygenic diseases where disease traits are controlled by a number of polymorphic genes which individually exhibiting modest effect on disease course. A number of as yet largely unknown genes, cluster in certain regions that are sometimes shared between different strain combinations and are also shared by other inflammatory diseases, as they are uncovered the biology understood they may open avenues to treatment.

Key words: EAE, MS, immunogenetics, susceptibility, major histocompatibility complex, polygenic disease

Multiple Sclerosis- a disease with a predisposing genetic susceptibility

Multiple sclerosis (MS) is the major demyelinating disease of the central nervous system (CNS) affecting about 2-3 million people worldwide, however the distribution of MS is geographically restricted and indicates some influence of both environmental factor(s) and genetic background of the affected individuals. (Compston & Coles 2002). Disease is most prevalent in temperate regions inhabited by descendents of northern

Europeans (Hogancamp *et al.* 1997, Compston & Coles 2002) and indicates some genetic aetiology most notable there is evidence of familial aggregation of MS and increased risks to siblings. This is evidenced by higher risk to monozygotic twins (25-30% concordance), dizygotic twins and non-twin siblings (2-5% concordance) compared to adoptees from non-affected parents (<0.2% concordance) which reflects the recurrence risk in the general population. MS sibling pairs tend to cluster by age of onset, rather than year of onset, and there is no detectable effect of shared environment on MS susceptibility in first-degree non-biological relatives (spouses, adoptees). Furthermore there is racial clustering of MS cases, particularly evidenced relative lack of MS in native African black people resident in high risk white regions and suggestive correlations between certain polymorphic genetic loci. (Ebers *et al.* 1995. Compston & Sawcer 2002). Disease in MS exhibits many different clinical and histopathological phenotypes that may change as disease progresses (Olerup *et al.* 1989, Lublin & Reingold 1996, Kira *et al.*1996, Lucchinetti *et al.* 1996, Thorpe *et al.* 1996. Thompson *et al* 1996, Confavreux *et al.* 2000, Compston & Coles 2002, Bjartmar *et al.*, 2003). The disease may have different aetiologies or represent abroad a spectrum of disease and this heterogeneity makes it difficult to analysed the genetic components of MS. Whilst the precise aetiology is unknown, it is thought that once disease is triggered, that MS represents an autoimmune disease (Compston & Coles 2002). Whilst there are no other non-human animals that spontaneously develop a disease identical to MS, elements of MS can be mimicked in experimental allergic encephalomyelitis (EAE), which is an induced autoimmune disease of the CNS (Brocke *et al.* 1994, Wekerle *et al.* 1994). Just as MS exhibits many clinical phenotypes that include benign disease, which is relatively self-limiting, primary progressive disease from onset, relapsing-remitting MS which show periods of neurological deficit with periods of remission that often leads to secondary progressive disease where disease continues unabated. (Compston & Coles 2002), animals species and strains develop a variety of different clinical phenotypes (Raine et al 1980, Brocke *et al.* 1994, Wekerle *et al.* 1994, Brok *et al.* 2001, t'Hart and Amor 2003). In animals disease susceptibility is clearly under genetic control (Levine & Sowlinski 1973, Raine et al 1980) some strains develop hyperacute and often fatal disease (e.g. Hartley strain guinea pigs), others monophasic (e.g. Lewis rats), relapsing (strain 13 guinea pig) or chronic (e.g. Marmosets) disease following induction with CNS myelin. As similar pathological events appear to occur in EAE and MS, its animal model may be used to tease out some of the genetic checkpoints that control different disease traits.

Most adult-onset autoimmune diseases exhibit a female bias (2:1 in MS. Duquette et al.1992), yet pregnancy is associated with disease quiescence to a level not generally matched by currently available pharmaceutical agents

(Homo-Delarche *et al.*1991, Jansson & Holmdahl 1998). Although females exhibit higher incidence of relapsing remitting disease, males with later onset disease more often develop primary progressive disease which is more neurodegenerative (Compston & Coles 2002, Bjartmar et al 2003), this may suggest that differences in genetic background create physiological differences that can withstand varying degrees of insult. However, once a threshold is exceeded, both primary and secondary progressive disease can develop at similar rates, suggesting that these phenotypes are different poles of the same disease process (Confavreux *et al.* 2000). It is well recognized that sex-hormones can influence a great number of immune parameters (Homo-Delarche *et al.*1991, Jansson & Holmdahl 1998). This is also reflected by sex differences (typically females are more susceptible than males) to susceptibility to the development of CNS autoimmunity in EAE (Baker *et al.* 1995, Bebo *et al.*, 1998,1999). The penetrance of disease expression varies between different experimental paradigms and strain combinations and this influences clinical outcome. (Dalal et al.,1997, Jansson & Holmdahl 1998, Bebo et al.,1998,1999).

1.1 Myelin and the Major Histocompatibility complex in susceptibility to CNS autoimmunity

In MS the major pathological feature is demyelination and the loss of oligodendrocytes (Lucchinetti *et al.* 1996, Compston & Coles 2002). That EAE develops CNS autoimmunity following sensitization with CNS myelin, suggests that it could be a major target in MS. Myelin contains a number of proteins where proteolipid protein (PLP. ~50% of CNS myelin) and myelin basic protein (MBP. ~30% of myelin protein) are major constituents. Due to the water solubility and ease of purification, early studies concentrated on MBP as a candidate autoantigen along with whole spinal cord homogenates (Fritz *et al.* 1985). The prototypical susceptible EAE strains were SJL ($H\text{-}2^s$ haplotype), SWR ($H\text{-}2^q$), PL and more recently ABH mice (Levine & Sowinski 1973, Baker *et al.* 1990), whilst C57BL/6 ($H\text{-}2^b$) and BALB/c ($H\text{-}2^d$) were classically considered resistant (Levine & Sowinski 1973, Raine *et al.* 1980). Using mice congenic for the major histocompatibility complex (MHC), termed H-2 in the mouse, it could be demonstrated that MBP-induced disease was restricted by the MHC class II, notably H-2A, gene products, however there are exceptions such as B10.S ($H\text{-}2^s$) and B10.Q ($H\text{-}2^s$. Fritz *et al.* **Table 1**). Furthermore as time has passed novel encephalitogenic antigens have been described that include the CNS-restricted myelin proteins: proteolipid protein (PLP, Tuohy *et al.* 1988) and myelin oligodendrocyte glycoprotein (MOG) in particular (Amor *et al.* 1994, Mendel *et al.* 1995), but includes other myelin antigens such as myelin

associated glycoprotein (MAG), myelin oligodendrocyte specific protein (OSP) and non-myelin antigens (Kojima *et al.* 1994, Morris-Downes *et al.* 2002, Furlan *et al.* 2002). Here *H2* allotypes confer a different set of susceptibilities and peptide-epitope restrictions between inbred strains (Tuohy *et al.* 1988, Abdul-Majid *et al.* 2001, Kjellén *et al.* 2001). Notably C57BL/6 mice, often used for the generation of 'gene-knockout mice" are susceptible to EAE induction with MOG and MOG residues 35-55 peptide (Mendel et al 1995, 1999). Thus although the inducing antigens are varied between strains, animals from virtually all MHC haplotypes of mice can be induced to develop CNS autoimmunity (**Table 1**). Therefore suggests that most mouse strains are susceptible and should no longer be considered as resistant but as low responders to certain disease induction protocols. Indeed mapping studies have indicated that genetic elements from "resistant" strains contribute to susceptibility (Sundvall *et al.* 1994, Teuscher *et al.* 1998, Jirholt *et al.* 2000).

TABLE 1. Susceptibility to myelin antigen induced EAE is genetically controlled

		Inducing Antigen		
Strain	H-2A	MBP	PLP	MOG
C57BL/6	b	-	-	+
BALB/c	d	-	-	-
SJL	s	+	+	+
PL/J	u	+	[+]	[+]
SWR	q	+	+	+
ABH	g7	-	+	+

Different mouse strains actively induced with myelin basic protein (MBP), Proteolipid protein (PLP) and myelin oligodendrocyte glycoprotein (MOG) proteins, and peptides develop different levels of susceptibility, some are relatively resistant (-), others show limited or delayed susceptibilities ([+]) and others develop full susceptibilities (+) to the development of clinical EAE. (Levine & Sowinski 1973, Raine *et al.* 1980, Fritz *et al.* 1985, Tuohy *et al.* 1998, Pagnany *et al.* 2003

Whilst MHC expression is critical for the generation of autoimmunity, there is variability in the background genes of the susceptible MHC haplotypes and this may mask the importance of this restriction (Levine & Sowinski 1973, Fritz *et al.* 1985). Spontaneous EAE can occur in myelin-specific T cell receptor (TCR), transgenic animals that have a high frequency of activated myelin-specific T cells that are capable of entering the CNS (Governman *et al.* 1993, Brabb *et al.* 1997, Kuchroo *et al.* 2002, Bettelli *et al.* 2003), but EAE does not usually occur spontaneously therefore genetics, biology, environment and chance may determine whether spontaneous disease develops in humans. A key issue is likely to be the elements that

activate potentially, autoreactive cells outside the control of normal homeostatic tolerance mechanisms (Governman *et al.* 1993). Many autoimmune diseases in animals use the same induction protocol and it is the nature of the inducing antigen that determines target specificity. Therefore many of the disease processes will be similar between different autoimmune models. It is therefore not surprising that disease loci are mapped to similar regions when different autoimmune diseases are mapped in the same strain combinations, as they are probably involved in the initiation of the conditions that promote (auto)immunity (Dalman *et al.* 1998; Encinas & Kuchroo 2000, Merriman *et al.* 2000, Bergsteinsdottir *et al.* 2000, Becanovi *et al.* 2003).

Although some evidence exists that indicates that polymorphisms in myelin genes such as MBP may be associated with susceptibility in models of MS and a subset of people with MS (Brahic & Bureau 1998, Pihlaja *et al.* 2003), this however, does not appear to be related in the majority of cases (Seboun *et al.* 1999). However, when MBP is naturally catabolised, peptide fragments are created that may not have the necessary chemico-physical properties to form a productive MHC/TCR interaction with many MHC class II antigens. However a major fragment that is generated following MBP cleavage contains the residues MBP 89-101 (Barry *et al.* 1992). This can bind to HLA-DR2 (DRB1*1501–DRB5*0101, DQA1*0102, DQB1*0602) molecules (Li et al. 2000), which are over represented in MS from people of northern Europeans dissent (Barcellos et al., 2003, Hensiek *et al.* 2002) and thus could offer could offer the potential to generate autoimmunity, particularly if the antigen fails to effectively establish thymic tolerance mechanisms (Li *et al.* 2000, Bruno *et al.* 2002). Indeed HLA-DR/DQ transgenic mice of the DR15 haplotype, coupled with transgenic myelin-specific human TCR transgenes spontaneously develop disease (Madden *et al.* 1999). However as immune responses to different myelin antigens can induce the same clinical phenotype it is not surprising that variability of MHC haplotype expression occurs in people with MS, such as DR3/DR4 association observed in Sardinia (Marrosu *et al.* 1997) Furthermore within the human immunological context a significantly greater number of MHC class I and particularly class II molecule variants occur than found in rodents, which allow them to gain protective immunity to pathogens but also offers the, probable evolutionary acceptable, possibility of adult onset autoimmunity. Whilst HLA allotypes form a component of the genetic susceptibility of MS (Haines *et al.* 1996, Sawcer *et al.*1996, Oturai *et al.*1999,) as with EAE disease is clearly polygenic.

Systematic Genome Scans for Eae Susceptibility loci

The search for genes controlling human disease genes continues but the only locus that consistently is associated with MS susceptibility are to genes within the MHC, but no non-HLA region has currently been shown unequivocal linkage in disease and putative susceptibility loci vary between regions, when analyzed by systematic genome scanning of individuals (Ebers *et al* 1996, Haines *et al* 1997, Sawcer *et al* 1996, Kuokkanen *et al* 1997, Chataway *et al* 1998) and in pools of affected individuals (Coraddu *et al.* 2001, Broadley et al 2001, Akesson et al. 2002, Ban *et al.* 2002, Sawcer et al. 2002) and even when stratified for DR2 expression (Coraddu *et al.*1998, Larsen *et al.* 2000, Goedde *et al.*2002). Linkage disequilibrium that occurs frequently in human genetics (certain allotypes of spatially related genes tend to be inherited in one supra haplotype, such as occurs in the MHC) makes it easier to locate disease-related genes, however due to linkage disequilibrium few chromosomal crossover events occur during inheritance, which make it difficult to segregate the disease gene. Each inbred strains essentially represents one individual and by selective breeding to segregate disease traits essentially a simple large family can be generated for mapping purposes within a controlled environment. Whilst it is clear that there are often phenotypic differences between susceptible and resistant strains, these may either represent causal factors or be totally unrelated phenotypes to the disease process, which have been acquired through the 20 generations of sibling mating to generate an inbred strain. Conventional tools such as gene knockout mice, transgenes or any other principle for selective targeting, are not particularly useful for the finding of genetically controlled mechanisms regulating disease, since immense numbers of immunopathological pathways or mediators can be hypothesized to be involved. Microsatellittes are stably inherited polynucleotide repeats that can be amplified using polymerase chain reaction using specific flanking primers. These are present throughout the genome and exhibit allelic differences in the length of the polynucleotide repeat and can be used to track the inheritance of specific chromosomal regions (Todd *et al.* 1991). A search for disease-regulating genes can be done by linkage analysis that requires no preformed hypotheses.

1.2 Non-MHC autosomal susceptibility loci

Induction of EAE in mice often uses co-injection of *Bordetella pertussis* toxin as a co-adjuvant, and an autosomal dominant *B.pertussis histamine sensitivity (Bphs)* was one of the first non-MHC genes shown to be involved in susceptibility to autoimmune diseases and was mapped to the distal of chromosome 6 in (C3H (resistant) x SJL (susceptible) x C3H mice. (Sudweeks *et al.* 1993). Following the generation a panel of interval specific congenic lines to intergress the susceptible gene on the resistant background

in toxin induced vasoactive amine sensitisation controls *Bphs* was recently identified as the histamine H_1 receptor gene (*Hrh1*) and differs in 3 amino acids between the resistant and susceptible strains.(Ma *et al.* 2003). Although the actions of *B.pertussis* toxin are often attributed to permeability and vasoactive effects on blood:brain barrier permeability, the significant leucocytosis (10 fold) is more likely to account for this action. The disruption of *Hrh1* leads to immune deviation of T cell responses characterized by the suppression of IFNγ production and an up-regulation in the production of Th2-related cytokines, a paradigm often shown to inhibit the generation of EAE (Ma *et al.* 2003, Goa *et al.* 2003). Although this represents the first case where a non-MHC gene controlling autoimmunity has been identified, many others require identification.

The majority of mapping studies have used strains where the MHC haplotype is shared by both the susceptible and resistant strains of mice/rats to exclude its influence. Through selective crossing between resistant and susceptible strains and genotypic analysis of affected and unaffected progeny it is possible to systematically scan the whole genome to detect linkage to susceptibility to EAE or related traits (**Table 2-4**). So far a number of loci containing disease-modifying genes have been detected and at present there are over 20 EAE-associated loci (*Eae*) in the rat (**Table 2**) and over 27 loci in the mouse (**Table 3**), whose precise identity are unknown/proven. In the rat, EAE quantitative trait loci have been demonstrated in DA (susceptible) x Brown Norway (BN. resistant), Lewis (susceptible) x BN, and E3 x DA intercrosses induced with whole spinal cord homogenate or with MOG as immunogen in DA x ACI and DA x PVG.1AV1 intercrosses (**Table 2**). Whereas in the mouse, studies have been preformed in B10.RIII (susceptible) x RIII, ABH (susceptible) x NOD, ABH x BALB/c or SJL x B10.S intercrosses following immunization with whole spinal cord homogenates, MBP or PLP peptides with or with *B. pertussis* toxin as co-adjuvant (**Table 3**).

These studies have indicated that disease is a complex polygenic trait of dominant, additive (heterozygotes) and recessive alleles whose products may interact in an epistatic fashion, where the detection of susceptibility loci depends on the presence of another interacting locus. Susceptibility to EAE is typically a dominant phenotype, but with various levels of penetrance of genotypic elements and this varies dramatically depending on the parental strains been analysed (Sundvall et al 1994, Baker et al 1995, Encinas et al 1996, Croxford et al 1997, Butterfield et al 1998). Within any strain combination it appears that a limited number of loci (typically <10-15 depending on the type of trait being analysed) are revealing significant segregation and can be compared to expected Mendelian rates of inheritance

or to expression with the effected and or resistant populations (**Table 2-4**). At a genetic level there is evidence that different disease phenotypes such as acute monophasic, relapsing remitting and chronic disease can be influenced by segregating loci and may also be dependent on the gender of the animal (Butterfield *et al.* 1998, 1999, Karlsson *et al.* 2003. **Table 3**). However clinical course may not be solely explained by genetic variability. Whilst chronic paralytic disease, which is associated with significant neuronal/axonal loss (Wujek *et al.* 2002), often develops in C57BL/6 mice (Mendel *et al.* 1995, Slavin *et al.* 1998). ABH mice often develop relapsing remitting disease and may be considered as evidence of genetic influence (Baker *et al.* 1990). Due to MHC restrictions, different antigens are often uses to induce disease in different strains. However whilst MOG^{35-55} induces chronic disease in C57BL/6, NOD and also ABH mice (Amor *et al.* 1994, Slavin *et al.* 1998, Ichikawa et al. 1999), interesting MOG^{8-22} induces relapsing-remitting disease in ABH mice despite an identical background (Amor *et al.* 1994), unpublished). Likewise although the increased risk of monozygotic twins developing disease clearly indicates a genetic influence, even in twins the disease phenotype may not be concordant. Although there may be other explanations such as antibody isotype responses (Ichikawa et al. 1999), chronic disease in mouse EAE has recently been associated with significant $CD8^+$ MOG-specific T cell activation (Sun *et al.* 2001) compared to classical-remitting EAE, which is clearly $CD4^+$ T cell mediated (O'Neill et al. 1993). There are a number of loci that control the ratio of CD4:CD8 in the mouse that may be linked to EAE susceptibility, such as a locus in the distal part of chromosome 1 (Karlsson *et al.* 2003). Therefore the way the individual may process and present the antigen may determine clinical course, as will lesion location where strategically important lesions can be related to clinical phenotype (Compston & Coles 2002). However genetic background may also contribute to this process such as through influences on lesion location (Butterfield et al 1999, Karlsson et al 2003. **Table 3**).

Initial genome wide mapping studies in (B10.RIII x RIII)F2 indicated a susceptibility locus (*Eae2-m*) proximal portion of chromosome 15 and a second locus *Eae3-m* on chromosome 3. (Sundvall *et al.* 1995). Although the *Eae2* locus (associated with homozygousity of the allele from the RIII-resistant mouse) on mouse chromosome 15 was homologous with a region of human chromosome 5p identified in mapping in MS (Kuokkanen *et al.* 1996, Oturai *et al.* 1999), following backcross to produce *Eae2-m* congenic mice, influence of this locus could not be demonstrated despite replication of the original observations (Jirholt et al 2000). This is indicative that *Eae2-m* is in epistasis (expression of phenotype is dependent on the presence of other unrelated genetic loci), however in crosses of such congenic animals a locus on chromosome 7 was identified. Similarly susceptibility loci could be mapped to two loci on chromosome 7 (*Eae4*, *Eae12*) in mouse myelin

induced (SJL x B10.S)F2 mice, mapping in PLP peptide induced (SJL x B10.S) x B10.S failed to demonstrate evidence of linkage (Encinas et al 1996, Butterfield *et al.* 1998). The major loci controlling EAE susceptibility in (ABH x NOD) x NOD mice was mapped chromosome 7, where disease inheritance was highly penetrant compared to other mouse mapping studies (Sundvall *et al.* 1994, Baker *et al.* 1995, Encinas *et al.* 1996, Butterfield *et al.* 1998). Further analysis of additional microsatellites and susceptible (ABH x NOD) x NOD females (Table 4), strongly support the involvement of in this case dominant ABH alleles near *Eae4-m* (45-51cM), *Eae26-m* (53cM) and *Eae10-m* (10-16cM) in susceptibility and indicate linkage to an additional locus distal to *Eae10-m* cM, consistent will mapping data in (SJL x B10.S)F2 mice. (Butterfield *et al.* 1998. **Table 3**). The importance of these loci has been definitively demonstrated by the generation of *NOD.ABH.Chr7* mice, where at backcross generation N8, a single copy of ABH chromosome 7 loci conferred virtually full susceptibility to disease on the NOD mouse background and indicates that this chromosome may harbor important loci for the control of EAE **(Table 4)**. It is possible that mouse chromosome 7 harbors a cluster of loci controlling elements of EAE, as has been found for the cluster of genes *Idd3*, *Idd10*, *Idd17* and *Idd18* controlling insulin dependent diabetes (Idd) susceptibility in NOD mice (Podlin *et al.* 1997).

In addition to linkage of *Eae3-m* to susceptibility in (B10.RIII x RIII) F2 mice (Sundvall *et al.* 1994), linkage was also detected on chromosome 3 in (SJL x B10.S) x B10.S backcross and in (SJL x B10.S)F2 both for incidence and histological disease (Encinas *et al.* 1996, 2001, Butterfield *et al.* 1998, 2000) suggesting that this may be important locus. However no evidence of linkage was detected in (ABH x NOD) x NOD backcross mice (Baker *et al.* 1995), which suggested that either this gene product was not important in this strain combination or they were not segregating possibly due to identity of the gene product in both strains. This may be supported by observations in diabetes . In NOD mice is diabetes is strong linked to loci on Chromosome 3 in (B6.H-2A^{g7} x NOD) x NOD mice, however the polymorphisms in *Il2* though to be *Idd3* (Lyons *et al.* 2000) and *Fcrg* gene originally (Prins et al 1993) thought to be *Idd10 (*Podolin et al 1997) are identical between ABH and NOD mice as was *Idd1* (H-2Ag7). Furthermore significant linkage was not detected in cyclophosphamide-induced (2 x 200mg/kg day 0 & 14) in diabetic (124/807) (ABH x NOD) x NOD mice (unpublished observations). This suggested that NOD and C57BL mice may differ at these loci and number of congenic mice had been developed for diabetes mapping of *Idd3*, *Idd10*, *Idd17* and *Idd18* of the chromosome region (Lyons et al 2001) and were studied for susceptibility to EAE (Encinas *et al.* 1998). This indicated that the loci for *Eae3* and *Idd3* are in the same 0.15cM interval. Whilst it must be recognized that these may be different but spatially-related loci, this

could represent the same gene product involved in autoimmunity. The interleukin 2 gene (*Il2*) in mice has coding microsatellite repeat allelic variants (Lyons *et al.* 2000) and altered glycosylation (Podolin *et al.* 2000) and is a candidate, indeed *Il2* knockout mice demonstrate spontaneous multi-system autoimmunity (Sadlack *et al.* 1995), further studies in knock-out/knock-in mice will be required to definitively address this. Currently the identity of any gene from genome screens of EAE mapping studies has yet to be identified.

Despite large group sizes of many hundred of animals, which is larger probably than any multiplex family used for mapping in humans, modest levels of significance (P<0.05) are often observed (Baker *et al.* 1995, Encinas *et al.* 1996, Croxford *et al.* 1997, Butterfield *et al.* 1998) and few reach P<0.001, which is substantially less than required for significant linkage for mapping the identity of loci coding monogenic traits. Furthermore within any combination of parental strains a number of loci are found, but often differ between strain combination and mode of inheritance (Jirholt *et al.* 2000). Thus based on even simple inbred systems with a relatively homogeneous phenotype, it indicates the problems faced by similar analysis of mixed samples from an outbred human populations with heterogeneous disease profiles, is immense. This will likely to dilute the ability to identify genes and many thousands will need to be studies to have the power to link major loci and importantly identify genes that confer susceptibility to MS (Ebers *et al* 1996, Haines *et al.* 1996, Sawcer *et al* 1996, Kuokkanen *et al* 1997, Chataway *et al* 1998, Coraddu *et al.* 2001, Broadley et al 2001, Akesson et al. 2002, Ban *et al.* 2002, Sawcer et al. 2002). Some favour the candidate gene approach, possibly due to the increasing availability of markers for typing alleles of known genes however this also means that adequate control populations are available and again is often met with lack of confirmation in studies on other populations of MS patients (Reboul *et al.* 2000, Feakes *et al.* 2000). In contrast to monogenic diseases where emphasis is often placed on identifying mutations, within polygenic disease susceptibility genes are probably part of the normal repertoire of the human population. There is often no need for coding mutations as subtle differences in non-coding elements may influence the level of protein expression within a biochemical/immunological pathway and there may be many different genetic pathways to the phenotype. The evolutionary selective pressures on inbred rodents and outbred humans will not be the same, and therefore different genetic pathways probably also exist between the species, furthermore current models which develop over weeks or maximally months (t'Hart & Amor 2003) may not offer access to all the complexities of pathologies of human disease that develops over years and therefore genetic components of disease may be different. However rodents models do clearly exhibit MHC associations (*Eae 1-m, Eae-1-r*) as found

with human disease (chromosome 6p21) and there are rodent loci (Table 2 & 3) in regions complementary to "hot spots" showing suggestive evidence of linkage to MS such as human chromosomes (Butterfield *et al.* 1998, Olsson *et al.* 2000) such as, 5 p21-p24 (*Eae2-m.* Ebers *et al.*1996, Kuokkanen *et al.* 1996), chromosome 17q12-q25 (*Eae7-m, Eae-12-r.* Sawcer *et al* 1996, Kuokkanen *et al.* 1997, Larsen et al. 2000), 18q12-21 (*Eae18-m, Eae18-r.*Merriman *et al.* 2001), 19q (*Eae12-m*) (Haines *et al.* 1996, Barcellos *et al.* 1997). As genes are identified, rodent studies will undoubtedly play an important role in understanding the biology of the genetic influence.

Table 2. Quantitative Trait Loci identified for susceptibility to EAE in the rat.

Locus	Chromosome	Markers flanking interval	Traits	Ref
Eae1-r	20	D20Rat41-D20Mgh4	Severity	(Bergsteinsdottir et al 2000)
Eae2-r	4	D4Mhh1-D4Mgh14 close to IL-6	Incidence	(Roth *et al.* 1999)
Eae3-r	10	D10Mit 10-D10Mgh10 close IL-4	Incidence	(Roth *et al.* 1999)
Eae4-r	9	D9Rat29-D9Mit6	Incidence	(Dahlman *et al.* 1999a)
Eae5-r	12	D12Mit2-D12Rat2 (recessive)	Severity,relapses	(Bergsteinsdottir et al 2000)
Eae6-r	1	D1Mgh9-D1Mit33 (M recessive)	Severity,duration, weight loss	(Bergsteinsdottir et al 2000)
Eae7-r	1	D1Mit7-D1Mgh12 (M recessive)	Severity,duration, relapses,weight loss	(Bergsteinsdottir et al 2000)
Eae8-r	19	D19Mit9-D19Mit5 (recessive)	Acute disease	(Bergsteinsdottir et al 2000)
Eae9-r	6	D6Mgh3-D6Rat10 (additive)	Weight loss,duration, relapse	(Bergsteinsdottir et al 2000)
Eae10-r	14	D14Mit6-D14Wox11 (recessive)	Weight loss,duration, relapse	(Bergsteinsdottir et al 2000)
Eae11-r	4	D4Wox30-D4Mgh14 (F)	Onset	(Bergsteinsdottir et al 2000)
Eae12-r	10	D10Rat7-D10Rat15	Incidence,	(Dahlman *et al.* 1999b)
Eae13-r	12	D12Rat19-D12Rat23	Incidence	(Dahlman *et al.* 1999b)
Eae14-r	13	D13Rat23	Incidence	(Dahlman *et al.* 1999b)
Eae15-r	18	D18Mgh4-D18Mit9	Incidence	(Dahlman *et al.* 1999b)
Eae16-r	8	D8Rat36-D8Rat11	Chronicity	(Becanovic et al 2003)
Eae17-r	13	D13Rat85-D8Rat64	Severity	(Becanovic et al 2003)
Eae18-r	18	D18Mit9	Demyelination	(Dahlman *et al.* 1999b)
Eaex-r	5	D5Mit10-D5Wox21	Onset	(Bergsteinsdottir et al 2000)
Eaey-r	18	D18Mgh1-D18Wox13	Duration	(Bergsteinsdottir et al 2000)
Eaez-r	18	D18Mit7-D18Wox1	Severity, duration	(Bergsteinsdottir et al 2000)

Microsatellite quantitative trait locus mapping in a number of rat strains and induction techniques suggest linkage in a number of chromosomal regions controlling the development and severity of clinical signs including the development of acute and relapsing disease, demyelination and duration of disease and time of onset and different histological types of lesions (See Becanovic *et al.* 2003 for relative location (proximal or distal) of chromosomal segments). These *Eae-r* loci controlling EAE in the rat bear no relationship of the corresponding mouse *Eae-m* locus

Table 3. Quantitative Trait Loci identified for susceptibility to EAE in the mouse

Locus	Location (cM)		Traits	Reference
Eae1	17	20 (*H2*)	Incidence	(Fritz *et al.* 1985)
Eae2	15	16	Incidence	(Sundvall *et al.* 1995)
Eae3	3	43	Incidence, Acute	(Sundvall *et al.* 1995, Encinas et al. 1996, Butterfield *et al.* 1998)
Eae4	7	50	Incidence, lesion location	(Baker *et al.* 1995, Butterfield *et al.* 1998, 1999)
Eae5	17	21	Incidence	(Croxford et al 1997, Butterfield et al 1998)
Eae6a	11	7	Severity	(Baker *et al.* 1995, Butterfield et al. 1998, Teuscher *et al.* 1999)
Eae6b	11	24	Duration	(Teuscher *et al.* 1999)
Eae7	11	48	Severity, relapsing chronic	(Baker *et al.* 1995, Butterfield et al. 1998. Teuscher *et al.* 1999)
Eae8	2	103	Incidence, Severity, weight	(Baker *et al.* 1995, Butterfield et al 1998)
Eae9	9	35	Incidence, Duration, lesions	(Baker *et al.* 1995, Butterfield et al 1998)
Eae10	3	72	Onset	(Butterfield *et al.* 1998)
Eae11	16	41	Incidence, B lesions (M)	(Baker *et al.* 1995, Butterfield *et al.* 1999)
Eae12	7	6	Incidence, Relapsing Disease(F)	(Baker *et al.* 1995, Butterfield *et al* 1998,1999)
Eae13	13	37	Relapsing (Male)	(Butterfield *et al.* 1999)

Microsatellite quantitative trait locus mapping in a number of mouse strains and induction techniques suggest linkage in a number of chromosomal regions controlling the development and severity of clinical signs including the development of acute and relapsing disease, demyelination and duration of disease and time of onset and the presence and location of histological mononuclear cell infiltration and demyelination and disease associated weight loss. Some of the effects were sex related and seen in only males (M) or females (F). These *Eae-m (*Eae loci of mice*)* loci controlling EAE in the mouse bear no identity relationship of the nomenclature of the rat, although *Eae1* both map to MHC. The chromosomal locations are approximations of the peak location (www.ncbi.org) and the intervals containing the genes are significantly larger.

TABLE 4.
Mouse chromosome 7 harbours dominant susceptibility loci for the development of EAE.

(B) Strain	No. EAE/ total	Group EAE Score ± SEM	Day of Onset ± SD
ABH x ABH	7/7	4.0 ± 0.0	15.1 ± 1.2
NOD x NOD	1/7	0.5 ± 0.5	18.0 ± n/a
NOD.*ABH*^{chr7} x NOD.*ABH*^{chr7}	10/12	3.3 ± 0.4	16.1 ± 1.9
NOD.*ABH*^{chr7} x NOD	8/8	3.6 ± 0.1	16.8 ± 1.9

Following outcross of male ABH x female NOD mice, male (ABH x NOD) F1 were backcrossed with NOD mice and female progeny were selected. EAE was induced following induction with mouse spinal cord homogenate in Freund's adjuvant. **(A)** animals that developed hindlimb paresis or paralysis (grade 3-4 occurs in 25% of the population) were selected for microsatellite analysis and compared to expected mendelian inheritance distribution of the ABH mouse allele (Baker *et al.* 1995). **(B)** Mice were selected for the expression of ABH chromosome 7 (*ABH*^{chr7}) alleles at *D7Nds6, D7Mit211/297 and D7Mit 37/53, D17Mit12* at each generation. Mice expressing the ABH mouse alleles *D6Nds3, D9Nds2, D11Nds29, D13Mit9, D15Mit11* and D18Mit8/Mit9 previously implicated in EAE susceptibility in this strain combination (Baker *et al.* 1995), where excluded. Following a further 7 backcross generations selecting for *ABH*^{chr7} markers mice were intercrossed to produce NOD.*ABH*^{chr7} homozygous congenic mice. Induction of EAE using spinal cord homogenate (Baker *et al.* 1995) demonstrates that chromosome 7 harbours major susceptibility loci that induce clinical disease (Scale 0-4). and that this or these are autosomal dominant genes(Baker *et al.* 1995).

Chapter A11

T LYMPHOCYTES IN EAE

Insights into the development and control of the autoreactive T cell

Kelli Ryan and Stephen M Anderton

Univeristy of Edinburgh, Institute of Cell Animal and Population Biology

Abstract: The EAE lesion is initiated by CD4+ T cells. Although this statement still holds, recent work has shown that CD8+ T cells and possibly γδ T cells can also contribute to pathology. The recovery phase of the disease poses more of a challenge with the potential for various regulatory T cell populations to halt the pathology. We know a good deal about the fine-specificity of T cell recognition of epitopes derived from myelin autoantigens. This, coupled with technological refinements in cellular immunology, is allowing us to ask important questions about the generation and control of the autoreactive T cell repertoire. This information also provides the basis for models of how these cells become activated and for advances in antigen-specific therapeutic intervention.

Key words: T cells; autoimmunity; regulation

1 EAE AS A T CELL-MEDIATED DISEASE

Since Rivers' early experiments in monkeys[1], experimental autoimmune encephalomyelitis (EAE) has become the most widely used inducible model of autoimmunity, serving as a model for multiple sclerosis (MS)[2]. EAE shares some characteristics with MS involving widespread foci of inflammation and demyelination with perivascular infiltration of mononuclear leukocytes[2]. The disease may show a monophasic acute, chronic, or relapsing-remitting course depending on the species or strain studied and the nature of the autoantigen used. Nevertheless, EAE should be viewed as an imperfect model of a diverse human disease. EAE is driven by activation of autoaggressive myelin-specific T cells and provides several

models for the study of various aspects of T cell biology and immune tolerance. The initiation phase of EAE is relatively straightforward, although the precise molecular basis for pathology remains an enigma. However, the many studies that now focus on the regulation of the pathogenic T cells provide a complicated picture of diverse and possibly redundant mechanisms for the control of self–reactivity. The wealth of information on the precise nature of T cell recognition of myelin epitopes now gives a basis for investigation of the breakdown of central tolerance and the generation of the peripheral autoimmune repertoire and for the development of novel therapeutic strategies.

1.1 EAE is driven by CD4+ T cells

The development of delayed type hypersensitivity (DTH) reactions to re-challenge with the inducing antigen provided the first evidence that EAE might have an immunological basis[3]. This report also proposed that the humoral immune response was not relevant to the pathology seen. Subsequent experiments showed that transfer of lymph node cells (and not serum) could elicit the disease in non-immunized recipient rats[4]. Neonatal thymectomy was shown to prevent the development of EAE[5], clearly implicating T cells in driving the disease. But which T cell subset – T helper cells or cytotoxic T cells - was responsible? Transfer of disease in mice was prevented by *in vitro* depletion of CD4+ T helper cells (using an antibody to the Lyt1 marker) prior to transfer[6]. Disease could still be transferred, however, if CD8+ cells were depleted (using anti-Lyt2)[6]. Therefore CD4+ T cells appeared to be responsible for disease, a notion supported by the prevention of disease by the *in vivo* administration of antibodies that depleted CD4+ cells prior to active immunization[7]. In contrast, *in vivo* depletion of CD8+ cells again showed no capacity to prevent disease[8]. The ultimate proof came with the demonstration that EAE developed after the transfer of CD4+ T cell clones specific for a CNS autoantigen. More recently, the crucial role of T cells in EAE has been highlighted by prevention of disease with antibodies that block the costimulatory interactions involved in the initiation and maintenance of the T cell response. Thus, disruption of CD28-CD80/86, CD40-CD154, or OX40-OX40Ligand interactions will inhibit disease[9-13]. In contrast, mice lacking ICOS show more severe disease[14].

Although the activation of CD4+ T cells is central to the induction of EAE, the general view is that the effector cell in EAE is of the macrophage lineage with both the CNS resident microglial cells and infiltrating blood monocytes responsible for tissue destruction and demyelination[15,16]. These cells require instruction from CD4+ T cells in the form of cytokines to

become activated. Antibodies with specificity for CNS autoantigens are also produced during the course of EAE. Whilst these antibodies are not sufficient to initiate the inflammatory lesion in the CNS, they are believed to play a role in the propagation of disease and may be particularly important to the demyelination process through binding to surface components of the myelin sheath[17]. Clearly CD4+ T cell help is also essential for the production of these autoantibodies.

1.2. Identification of myelin autoantigens recognized by T cells

EAE was initially induced using crude preparations of brain or spinal cord tissue. This still remains a very effective antigen for disease induction and its use has advantages in situations when we have no precise information about T cell antigen recognition (when attempting to develop models in previously untested species or strains). Whole myelin is also useful when we wish to provoke a "global" immune response to CNS tissue, for example when we are testing the effects of therapies using individual antigenic epitopes on the entire anti-myelin response[18].

As our understanding of the structure and composition of the myelin sheath has advanced[19-21] our ability to induce EAE with defined CNS autoantigens has developed. Myelin basic protein (MBP) was the first defined CNS autoantigen to be tested[22] and has proved the most reliable antigen for inducing EAE in several species/strains. MBP remains the most widely used antigen, largely because it composes a large fraction (~30%) of the protein content of myelin and is therefore relatively easy to purify (CNS antigens are notoriously difficult to isolate due to the high lipid content of myelin). There are, however, other CNS antigens that are clearly relevant to EAE. Proteolipid protein (PLP)[23] and myelin oligodendrocyte glycoprotein (MOG)[24] are both now commonly used to provoke EAE in appropriate strains of mice. PLP constitutes some 50 % of the protein content of the myelin sheath, whereas MOG makes up less than 1%. Both these antigens are highly hydrophobic and difficult to purify[20,21]. The use of synthetic peptides containing T cell epitopes from PLP[25,26] and MOG[27,28] provide a simpler approach to activating pathogenic T cells. However, immunization with intact antigens does have benefits over the use of individual peptide epitopes to induce EAE. It allows us to study the interaction of one T cell with other T cells or B cells responding to different epitopes within the same antigen. The cloning of the genes encoding MBP[29] and MOG[30] has facilitated the production of large quantities of highly pure antigens to meet this challenge.

1.3 From myelin antigens to synthetic peptides

T cells recognize short (9-15 amino acid) peptide fragments generated from the intracellular proteolytic degradation of antigen (antigen processing) that occurs within antigen presenting cells (APC)[31]. These peptides are then displayed on the surface of the APC bound to major histocompatibility complex (MHC) molecules. CD4+ T cells recognize peptides bound to MHC class II molecules that are (under physiological conditions) only expressed by dendritic cells (DC), B cells and cells of the macrophage lineage. If we know the amino acid sequence of a protein, we can produce synthetic peptides containing the amino acid sequence of a region of interest. Such short peptides can bind directly to MHC class II molecules (without the need for antigen processing) for presentation to T cells. This technology has allowed the definition of several T cell epitopes within MBP[32-34], PLP[25,26] and MOG[27,28]. Since EAE is driven by the activation of CD4+ T cells, immunization simply with peptides containing individual T cell epitopes is sufficient to provoke disease.

The first myelin autoantigen in which an encephalitogenic region was defined was MBP[32,35]. These studies used synthetic peptides to induce EAE in guinea pigs. Remarkably these experiments were performed over three decades ago, before the demonstration of MHC restriction and long before our appreciation of the molecular basis of T cell recognition. Moreover, analog peptides with amino acid substitutions were used to demonstrate the requirement for a single tryptophan for disease development. In essence, these workers were using altered peptide ligands (**APL**) two decades before the term was first coined[36] Subsequent studies used peptides to define encephalitogenic regions of MBP for the rhesus monkey[37] and rat[34,38]. After these reports, it took a further decade to identify encephalitogenic epitopes for the mouse[33,39].

The precise peptide sequences from a given autoantigen that induce disease vary between species and strains depending on the requirements for binding to the MHC haplotype expressed. There do appear, however, to be particular regions that contain epitopes recognized in several species. For example the 80-100 region of MBP contains epitopes recognized by SJL mice and Lewis rats[38-40]. This region is of particular interest as it also contains epitopes recognized by T cells from MS patients[41,42]. This immunodominant region may reflect a dominant cross-species processing activity that generates fragments of this region of MBP for binding to MHC and presentation to T cells.

Today there are several epitopes identified in MBP[33,39], PLP[25,26] and MOG[27,28] that can induce EAE in mice. Initially the mouse strains found to be susceptible to EAE were of the $H\text{-}2^u$or $H\text{-}2^s$ MHC genetic backgrounds[33,39]. These are not common laboratory strains and so these

models remain the preserve of groups that specialize in studying EAE. In recent years, however, this has changed with the identification of peptide 35-55 of MOG as an encephalitogenic epitope in the widely used C567BL/6 (H-2^b) mouse[28]. This has now become the model of choice for many studies, not least because gene knockout and transgenic technologies are well developed in this strain. There has therefore been a rapid expansion in reports on the influence of gene deficiency in EAE without recourse to laborious backcrossing programs.

1.4 Myelin-reactive TCR transgenic mice

The development of transgenic technologies has enabled the generation of mice expressing TCRs specific for myelin antigens. This represents a great advance as it has allowed us to study the activation of naïve autoreactive T cells *in vitro* and *in vivo*. Several different lines of mice have been produced that express TCRs that recognize the acetylated N-terminal epitope of MBP: MBP(Ac1-9)[43-45]. These mice in general do not develop spontaneous encephalomyelitis and disease requires T cell activation following immunization with the Ac1-9 peptide. In some situations maintenance in a dirty environment will provoke disease[44], in other cases giving pertussis toxin alone (without Ac1-9) will suffice[46]. Crossing these TCR transgenic mice with mice that lack recombinase activating gene (RAG) activity, and therefore cannot rearrange endogenous TCRα chains, also leads to an increase in spontaneous encephalomyelitis[43]. This appears to be due to an aberration in immune regulation (see below).

More recently, TCR transgenics specific for PLP(139-151) have been generated that develop severe spontaneous disease[47]. MOG-specific TCR transgenic mice are also now available (V.K. Kuchroo, personal communication). A transgenic line expressing an MBP(85-99)-specific TCR derived from a human T cell clone, together with the human CD4 molecule and the human DR2 class II MHC molecule has been generated[48]. These mice develop encephalomyelitis (with ~4% spontaneous incidence) providing strong evidence that T cells recognizing this region of MBP are important in human MS.

1.5 T cells in the etiology of EAE

Clinical signs of EAE usually develop within two weeks of immunization with myelin antigen. T cells primed in the peripheral lymphoid organs need to migrate into the CNS to establish the EAE lesion. Recent advances have allowed us to track disease-relevant cells. The use of fluorescently labeled multimeric peptide-MHC complexes provides a specific reagent for

identifying T cells bearing antigen-specific TCRs[49]. Such "tetramers" have been developed to bind T cells that recognize MBP(Ac1-9) in association with the A^u class II molecule[50,51]. The frequency of Ac1-9-specific T cells in non-immunized H-2^u mice was below the level of detection. However, by 10 days after immunization with either whole myelin or the Ac1-9 peptide around 0.5% of CD4+ T cells in the draining lymph nodes were found to bind the tetramer[50]. But how many of these cells go on to enter the CNS? This has not yet been addressed using peptide-MHC tetramers. An ELISPOT system has been used to identify PLP-specific cytokine secreting T cells derived from lymphoid organs and CNS[52]. After immunization with the PLP(139-151) peptide, high frequencies of antigen-specific T cells were found in the draining lymph node, spleen and peritoneal cavity immediately prior to onset of clinical signs. At this time-point no cells were detectable in the CNS. Once EAE had developed, however, the CNS showed the highest frequency of 139-151-specific T cells, although this still only accounted for ~20% of the total number of specific cells in the mouse. At later time-points (by 6-10 weeks after immunization) the total number of 139-151-specific T cells had dropped by around ten-fold compared to the peak numbers seen prior to EAE onset. At these later time-points responses to a second PLP epitope, 178-191, were detectable (due to epitope spreading), mainly in the CNS.

In elegant experiments, MBP-specific rat T cell clones were retrovirally engineered to express green fluorescent protein (GFP) so that they could be followed anatomically after transfer to naïve recipients[53,54]. As a control, GFP-expressing cells specific for chicken ovalbumin (OVA) were transferred. MBP-specific (but not OVA-specific) T cells began to accumulate in the spinal cord around 3 days after transfer. In this lag phase between injection and migration the cells populated the peripheral lymphoid organs. Expression of IL-2 receptor and OX40 was reduced whilst expression of the chemokine receptors involved in migration into the tissues was increased. Once in the CNS the T cells regained an activated phenotype. In these experiments the majority of the myelin reactive T cells entered the CNS. This contrasts with the results found after PLP immunization described above, and may reflect differences between transfer systems and active immunization models.

2. CYTOKINES IN EAE

2.1 The effector phase is driven by a Th1 response

The effector cell in EAE appears to be an activated macrophage or microglial cell[16]. Macrophage activation is driven by the production of interferon γ (IFN-γ) and tumor necrosis factor α (TNF-α) from T cells[55]. Effector CD4+ cells have been sub-divided based on the cytokines they secrete upon antigenic or mitogenic stimulation[56]. T helper 1 (Th1) cells produce IFN-γ and TNF-α, whereas Th2 cells produce interleukin 4 (IL-4) and IL-10. The general finding that the CD4+ T cells that transfer EAE fall into the Th1 camp therefore comes as no great surprise. The transfer of myelin-specific T cell clones has shown this most convincingly[57]. The Th1 phenotype was found to be required to induce disease. This most probably explains the requirement to mix the autoantigen in complete Freund's adjuvant (CFA) to induce EAE. CFA is a very aggressive adjuvant that primes strongly for Th1 response due to the presence of heat-killed mycobacteria. In general, the promotion of a Th2 response does not lead to EAE. Immunization with autoantigen in incomplete Freund's adjuvant (IFA), lacking mycobacteria, promotes a Th2 response and fails to induce EAE[58]. Differentiation of naïve T cells into Th1 effector cells is driven by DC production of IL-12[59,60]. Microbially derived danger signals such as bacterial DNA stimulate DC activation and IL-12 production[61,62]. Addition of bacterial CpG DNA to MBP in IFA has recently been shown to substitute for mycobacteria in driving Th1 differentiation and therefore EAE[63,64]. The prevention of disease by *in vivo* administration of a neutralizing antibody to IL-12 has demonstrated the key role of this cytokine initiation of EAE induction[65]. Consistent with this, IL-12 deficient mice are totally resistant to EAE[66].

The key cytokines in progression of disease appear to be the Th1-associated cytokines IL-12, IFN-γ, TNF-α and LT-α. Exposure to T cell-derived IFN-γ leads to upregulation of MHC and costimulatory molecules on CNS APC (microglia and astrocytes)[16,67]. IFN-γ also enhances adhesion molecule expression on endothelial cells thereby facilitating the mononuclear infiltration characteristic of EAE[67]. The role of IFN-γ in EAE, however, is not straightforward. Administration of neutralizing antibodies to IFN-γ can, when given at the right time, increase EAE severity[68,69]. Furthermore, several reports have demonstrated in gene-targeted mice that the absence of IFN-γ or the IFN-γ receptor exacerbates rather than prevents disease[70-72]. Interestingly, antibody blockade of IL-12 prevents EAE in IFN-γ deficient mice, suggesting that EAE pathology is not simply driven by an IL-12-IFN-γ axis[66]. IL-12 clearly must drive other pathogenic processes.

TNF-α and LT-α have cytotoxic effects on oligodendrocytes leading to apoptosis[73,74]. TNF-α also promotes the release of nitric oxide from macrophages leading to further damage of oligodendrocytes and demyelination[75]. TNF-α and LT-α may therefore have a more direct role in

pathology than IFN-γ. Antibody-mediated neutralization of both of these cytokines has been reported to limit EAE severity[76] and LT-α deficient mice develop mild disease[77]. However, other studies using mice that are deficient in TNF-α or both TNF-α and LT-α have found no effect on susceptibility to EAE[78]. Analysis of TNF-$\alpha^{-/-}$ mice is complicated by a failure in peripheral lymphoid organogenesis. Therefore the influence of T cell-derived cytokines on EAE pathology is far from fully understood and probably involves a complex interplay and a significant level of redundancy in function.

It must be noted that the Th1/Th2 paradigm is not totally secure in relation to pathology in EAE. Activation of Th2 cells after disease onset has been shown to exacerbate disease. Immunomodulatory approaches that have expanded Th2 immunity either deliberately (in primates)[79] or unintentionally (in mice)[80] have been found to worsen disease. Furthermore, using a T cell receptor (TCR) transgenic system, MBP-specific Th2 cells have been shown to induce EAE upon transfer to immunocompromized hosts[81]. Th1 and Th2 cells are believed to have the potential to counter regulate the expansion of each other[56]. Establishment of a Th2 response prior to the induction of EAE can prevent disease development[82,83]. There is little evidence, however, that the activation or transfer of a myelin-reactive Th2 population is able to control an established Th1 response and thereby inhibit EAE[84].

2.2 Cytokines controlling EAE remission

Recovery from EAE has been reported to correlate with increased levels of IL-4 and IL-10 mRNA within the CNS[85,86]. Administration of exogenous IL-4 has been found to have some beneficial effect[87] as does the use of myelin-specific T cells transduced with the IL-4 gene to target the CNS[88]. However the use of IL-4 deficient mice has revealed only slight increases in EAE severity[89,90].

In contrast, IL-10 appears to have a dominant role in the regulation of EAE with IL-10 deficient mice suffering a severe non-remitting form of the disease[90,91]. Mice that are transgenic for IL-10 are protected[90,92]. Administration of exogenous IL-10 to treat EAE has proved problematic in rodent models of EAE[93-96]. It appears that the most effective approach requires targeting of the IL-10 to the CNS[94]. This has been achieved either by direct intracranial injection of viral vectors[94] or by transfer of myelin reactive T cells transduced with the IL-10 gene[97]. Both IL-4 and IL-10 are produced by Th2 cells[56]. In fact, the suppressive qualities of IL-10 have been reported to be abrogated by the concurrent administration of IL-4[98].

There is evidence that transforming growth factor β (TGF-β) also plays a regulatory role in EAE since administration TGFβ-blocking antibodies leads to more severe disease[99,100]. Provision of exogenous TGF-β, in contrast,

reduces EAE severity[99,100]. These effects may be through inhibition of T cell expansion and/or a direct inhibition of macrophage activity in the EAE lesion that controls the inflammatory response[101-103].

Nevertheless, the consensus is that IL-10 is a more potent regulator of EAE. This has led to the proposal of a cytokine circuitry involving IL-10 and IL-12 as counter-regulators controlling the progression of the disease[66]. Many cell types produce IL-10[104]. The source of the IL-10 that promotes recovery remains an issue under investigation.

The complexities of cytokine networks in EAE is exemplified by a recent report that administration of DC that had been loaded *in vitro* with the MOG(35-55) peptide in the presence of TNF-α could protect against subsequent attempts to induce EAE[105]. These DC led to the expansion of a MOG-specific CD4+ T cell population that produced IL-10. However, the use of IL-10-blocking antibodies led to only a partial restoration of EAE-susceptibility, suggesting the influence of other factors on protection.

3. NON-CD4+ T CELLS IN EAE

CD4 T cells have been widely accepted as the critical cell in the pathogenesis of EAE and until recently research attention has been focused almost entirely on these cells. However, in the last few years, evidence has emerged supporting a role for conventional CD8+ αβ T cells as well as T cells expressing the γδ TCR.

3.1 CD8+ T cells as effectors in EAE

In the early 1980s it was first reported that both CD4+ and CD8+ T cells are present in CNS lesions of MS patients and mice with EAE[106-109]. However, direct evidence that CD8+ T cells alone can induce EAE has only recently been provided. In 2001, two independent studies demonstrated that CD8+ T cells activated by MHC class I restricted recognition of major myelin antigens can induce EAE when transferred intravenously into normal mice[110,111]. This was accomplished using peptides from either MBP or MOG. Interestingly one of these peptides also contained a previously defined CD4+ T cell epitope[28,110]. Therefore in EAE experiments when we immunize with these peptides we may well be activating CD8+ T cells in addition to CD4+ T cells. Disease produced by MOG-specific CD8+ T cells was more severe than EAE induced by immunization with the MOG peptide in CFA, resulting in massive demyelination and more destructive CNS lesions[110]. EAE resulting from transfer of MBP-specific CD8+ T cells also resulted in severe demyelination, but lesions were confined to the brain[111].

The effector mechanisms of EAE mediated by MBP-specific CD8+ T cells was investigated, specifically the requirements for IFNγ and TNFα. Whilst blocking TNFα appeared to have little effect, administration of an anti-IFNγ antibody *in vivo* significantly reduced severity of disease[111]. This finding contrasts with the CD4+ T cell-mediated models where a genetic deficiency in IFNγ signaling worsens disease[71,72]. Interestingly, in this regard, EAE mediated by CD8+ T cells more closely resembles MS, since administration of both IFNγ and a TNF receptor-Fc fusion protein exacerbates MS[106,112,113]. These CD8+ T cell driven models used transfer of CD8+ T cell lines derived from mice immunized with myelin antigens. They prove that activated CD8+ cells can enter the CNS and initiate pathology without the involvement of CD4+ cells. However, since *in vivo* priming of CD8+ cells usually requires help from CD4+ cells, it remains to be seen whether these pathogenic CD8+ populations can be initially activated *in vivo* in the absence of a CD4+ response.

Whilst these data show CD8+ T cells can have a pathogenic role, other studies have suggested that CD8+ T cells may be a regulatory function promoting recovery from EAE (see below).

3.2 γδ T cells in EAE

Only a handful of studies have addressed the role of γδ T cells in EAE or MS, and these reports give conflicting results. Depending on the method of investigation, some studies find that γδ T cells contribute to disease pathogenesis, others report an inhibitory role, while still others find that γδ cells have no impact whatsoever on the course of disease.

Evidence that γδ T cells have no role in EAE comes from investigations using the Lewis rat and δ-chain deficient mice. In Lewis rats, γδ T cells are absent from the CNS and giving anti-TCRγδ fails to exacerbate EAE[114]. Similarly, the progression and severity of EAE in γδ-deficient mice was found to be no different from control mice[115].

In direct contrast to reports assigning no role for γδ T cells, other studies have found γδ cells in MS plaques and in EAE CNS infiltrates[116-119]. By implication, there may be a role for these cells, but their presence in the target tissue could reflect either a pathogenic or regulatory role. Evidence for a regulatory function comes from *in vivo* γδ depletion experiments that showed exacerbation of EAE. This correlated with an increase in antigen-specific proliferation and elevated IFNγ mRNA at certain phases of EAE[120]. Additionally, IL-4-secreting γδ T cells have been found to increase during onset and peak of the disease[121]. This correlation suggests these cells may contribute to a shift away from a destructive Th1 cytokine profile.

Finally, contrasting evidence also exists showing that γδ T cells can help to promote disease. Recent analysis of surface markers on γδ T cells reveals an activated phenotype that correlates with disease, and these cells produce Th1-like cytokines[122]. More significantly, depletion of γδ T cells has been reported to reduce EAE signs considerably and was accompanied by a decrease in mRNA levels for several pro-inflammatory cytokines, including IFNγ[123]. Reduced expression of certain pro-inflammatory chemokines and chemokine receptors was also reported following *in vivo* depletion[124]. In another study disease was found to be significantly reduced in δ-chain knockout mice compared with controls after either immunization with MOG(35-55) or transfer of a MOG(35-55)-specific αβ T cell line[125]. It is important to note that these mice also display a generalized impairment in their ability to mount an immune response. Nevertheless, together these data indicate that γδ T cells may contribute positively to EAE pathogenesis.

4. REGULATORY CELLS IN EAE

The pathogenesis of EAE therefore is associated with strong Th1 bias in immune-reactivity to myelin antigens, whilst protection is associated with IL-10 production. Since the molecular targets that drive the disease (myelin autoantigens) are constantly available for immune recognition, what mechanisms prevent the pathogenic Th1 response from developing spontaneously? Furthermore, do these same mechanisms re-balance the immune response and promote recovery from EAE? Over the past decade there has been an exponential rise in the study of lymphocytes with the capacity to down-modulate the responses of other potentially pathogenic lymphocytes. The majority of studies have examined the role of regulatory T cells. These cells are currently attracting intense interest and have been the subject of several recent reviews[126-128].

4.1 Spontaneous regulatory T cells.

Experiments using neonatal thymectomy of mice revealed an interesting pathologic outcome. Thymectomy three days after birth (but not at later time points) resulted in the subsequent development of multi-organ immune infiltrations and spontaneous development of high titers of autoantibody[126]. This autoimmunity was proposed to be due to the absence of a suppressive T cell population that exits the thymus at this early time point[129]. Potentially pathogenic autoreactive T cells had already populated the periphery and removal of the regulatory cells by thymectomy prevented their normal control, allowing autoimmunity to develop. Later experiments showed these

regulatory T (Treg) cells to reside in the CD4+CD25+ fraction[130]. Transfer of these cells to thymectomized recipients prevented autoimmunity, whilst their depletion from non-thymectomized mice led to a similar multi-organ pathology.

Experiments using defined CD4+ T cell populations in rats and mice revealed that transfer of purified CD45RB/C^{hi} cells into lymphopenic or immunodeficient hosts resulted in organ-specific autoimmunity (diabetes and thyroiditis)[131] or inflammatory colitis[132]. The co-transfer of CD4+ CD45RB/C^{lo} cells could prevent these conditions[132,133]. These suppressive cells had similar qualities to the CD4+CD25+ Treg cells and the two populations have since been shown to largely (but not totally) overlap[128]. Both populations are described as Treg cells. These cells display an anergic phenotype (they do not proliferate in response to antigenic or mitogenic challenge *in vitro*, unless supplied with exogenous IL-2)[134]. Tregs have a potent capacity to inhibit the activation of other T cells *in vitro* as well as *in vivo*. The *in vitro* activity of CD4+CD25+ Tregs has been reported to require TCR ligation and to be dependent on cell contact, but not IL-10 production[126-128,135]. Other *in vivo* studies, however, have concluded that IL-10 and TGF-β are required for protection from autoimmune pathology[136,137].

The autoimmune manifestations seen in the absence of Tregs in most models do not include encephalomyelitis. However, Treg cells do appear to have an important role in the prevention of spontaneous encephalomyelitis in mice expressing transgenic TCRs recognizing the Ac1-9 epitope of MBP. These mice do not normally develop spontaneous disease. They do, however, when crossed onto a recombinase activating gene (RAG) deficient background[43]. In the RAG-sufficient transgenics a limited amount of endogenous TCRα gene rearrangement can occur and CD4+CD25- from these mice prevent the onset of disease when transferred into RAG-/- recipients[138]. The protective cells were found to express both the transgenic MBP-specific TCR and endogenously rearranged receptor[139]. Thus Treg cells with specificity for MBP can prevent the onset of spontaneous CNS autoimmunity. However this system is far from physiological. More experiments are therefore required to assess the role of Tregs in non-transgenic animals. Also, Tregs clearly do not regulate the initiation of autoimmunity in models such as EAE that are induced by active immunization with autoantigen (if they did, we would not see disease!). Whether they play a role in the recovery phase is unlikely but remains to be investigated fully. However, a recent study has reported that prior transfer of CD4+CD25+ from normal mice conferred significant protection against MOG-induced EAE[140]. Why this should be the case when the recipient mice possess their own Treg cells is something of a puzzle.

4.2 Tr1 cells

T regulatory 1 (Tr1) cells are another regulatory CD4+ T cell population that have been generated experimentally rather than purified as a naturally occurring population[141]. Tr1 cells produce large amounts of IL-10 (in addition to lower levels of IL-4 and IFN-γ)[141]. They have been generated *in vitro* by chronic stimulation in the presence of IL-10[141], or more recently by stimulation in the presence dexamethasone and vitamin D3[142].

Tr1 cells derived from transgenic mice expressing an ovalbumin (OVA)-specific TCR were able to prevent colitis in immunodeficient mice upon oral administration of OVA[141]. Thus these IL-10 producing T cells can prevent onset of spontaneous disease, but can they influence an induced autoimmune disease? Recent data suggest that they can. The transfer of OVA-specific Tr1 cells was found to suppress the development of EAE when OVA was injected intracranially[142]. This provision of antigen in the CNS was presumably essential for the Tr1 cells to exert their effects on pathogenic immune responses taking place within the CNS or in the lymphoid tissue draining the CNS. This is an exciting development, as the generation of myelin-specific Tr1 cells would obviate the need for the intracranial delivery of exogenous antigen.

A recent report suggests the Tr1 cells specific for *Bordetella pertussis* arise naturally during the course of the immune response to the infection[143]. It might be, therefore, that at least some of the effects of IL-10 in promoting the remission of EAE may be provided through the influence of cells of the Tr1 type arising spontaneously as the immune response to the autoantigen develops. At present, however, no evidence that such a cell type arises spontaneously during EAE has been provided. Whether Tr1 cells can be generated *in vivo* by existing or novel immunotherapeutic approaches will be discussed later.

4.3 NKT cells

Natural killer (NK) T cells express surface markers found on both NK cells and αβTCR T cells and have been shown to have regulatory properties in murine models of autoimmunity, particularly diabetes[144]. NKT cells recognize lipid antigens such as α-galactosylceramide (α-GalCer) in association with CD1d[145-147]. This nonpolymorphic MHC class Ib molecule is widely expressed, but is found in high levels on marginal zone B cells and dendritic cells[148,149]. Unlike conventional αβ TCR T cells, NKT cells are able to rapidly produce high levels of IL-4 and IFN-γ upon activation[144]. This IL-4 production has suggested to play a role in driving Th2 responses and thus NKT cells may be important in maintaining balanced immune

responses[144]. This would be consistent with a regulatory function in Th1 driven autoimmune responses. A large proportion of NKT cells express invariant TCR α chains (Vα14Jα281 in mice[150], Vα24JαQ in humans[151]). Levels of Vα14Jα281+ T cells have been found to be reduced in non obese diabetic (NOD) mice[152] and transfer of CD1d restricted cells could prevent spontaneous onset of diabetes[152]. Similar results have been found in diabetic BB rats[153].

Do NKT cells have a regulatory role in EAE? The EAE-prone SJL mouse shows quantitative and qualitative defects in NKT cell function[154]. Although a causative link has not been made in this model, it is interesting to note reported reductions in the numbers of Vα24JαQ T cells in MS lesions[155]. Two recent studies have reported that activation of NKT cells via administration of αGalCer, or a synthetic analog that promoted IL-4, but not IFN-γ production could limit the development of EAE[156,157]. These findings reflected reduced Th1 and increased Th2 responses against myelin autoantigens. Protection was not found in mice deficient in either IL-4 or IL-10[156]. NOD mice transgenic for Vα14Jα281 (that possess large numbers of NKT cells) were found to be partially protected from diabetes without exogenous activation of NKT cells. Activation of NKT cells may therefore provide a future therapeutic approach. The contribution of NKT cells to normal regulation of EAE remains in question, however, since CD1d-/- mice did not develop more severe disease than their CD1d+/+ counterparts[156]. Furthermore, mice transgenic for Vα14Jα281 were also found to be fully susceptible to EAE[156].

4.4 CD8+ T cells as regulators of EAE

Studies with CD8-/- mice crossed onto an $H\text{-}2^u$ background suggest a dual role for CD8+ T cells as both effectors and modulators of EAE since the deficient mice undergo a milder primary course of disease resulting in fewer deaths while later experiencing more spontaneous relapses[158]. The CD8+ T cells appear to act as effectors during the induction of EAE by contributing to the mortality rate, yet help to downmodulate the inflammatory response at the end of the disease course. Lending support to this idea, anti-CD8 depletion *in vivo* rendered mice more susceptible to active re-induction of EAE[159]. Finally, TGF-β producing CD8+ T cells mediate oral tolerance to MBP in rats[160].

Early studies attempting to transfer EAE with T cell lines led to the paradoxical finding that, in certain circumstances, this did not induce disease, but rendered the recipients resistant to subsequent attempts to induce EAE by immunization[161]. This led to the idea of "T-cell vaccination" - variable TCR regions on pathogenic T cells would trigger protective T cells

that would destroy these autoaggressive threats[162]. Subsequently, immunization with the appropriate peptides derived from encephalitogenic TCRs was shown to be sufficient to confer protection[163,164].

In H-2^u mice the majority of MBP(Ac1-9)-specific encephalitogenic CD4+ T cells use the Vβ8.2 gene segment[165]. The expansion of this pathogenic T cell population during EAE has been reported to induce a regulatory CD8+ T cell population specific for the Vβ8.2 chain[166]. These cells can recognize activated Vβ8.2-expressing pathogenic cells through their presentation of Vβ8.2 derived peptides in association with MHC class I leading to their removal via apoptosis. Further complexity is added by the activation of Vβ-specific CD4+ regulatory T cells during EAE (these cells express Vβ14)[167]. The CD4+ and CD8+ regulatory cells recognize distinct TCR-derived epitopes, with the CD4+ cells focusing on the TCR framework 3 region which also appears to be a target for regulation in rat EAE[167,168].

A recent study has reported CD8+ T cells that are activated by Vβ8+ Th1, but not Th2 cells and are restricted by the non-classical MHC class I molecule, Qa-1[169]. These cells downregulated the Th1 response and depletion of CD8 cells skewed the cytokine response to the Th1 phenotype. Cell-cell contact between CD4+ and CD8+ cells was required, but this study did not determine whether the CD8+ cells were killing the CD4+ cells directly.

4.5 B cells as regulators of EAE

So far we have considered the contribution of T cell populations to the induction and control of EAE. But what of B cells? They have the potential to influence the progression of EAE at three levels:- by the production of pathogenic autoantibodies; by acting as APC to enhance activation of autoaggressive T cells; or by having a regulatory function during recovery from disease. There is evidence in support of all of these. Autoantibodies that bind components of the myelin sheath, particularly MOG, can increase disease severity[17,170].

Early experiments in which mice were depleted of B cells using anti-μ antibodies indicated that B cells played an important role in the development of MBP-induced EAE[171]. This involved an enhancement of T cell priming presumably by the B cells acting as APC (although secreted anti-MBP antibodies may also have contributed). The use of genetically B cell deficient μMT mice allowed for a clearer picture to develop. An early report concluded that B cells were not required for the development of EAE after immunization with the MOG(35-55) peptide[172]. A subsequent report reached this same conclusion, but also that B cells were required for EAE development when intact recombinant human MOG protein was used to

immunize[173]. Pathology could be induced in these B cell deficient mice by transfer of serum containing anti-MOG antibodies[174]. However, we have recently shown that μMT mice develop EAE of similar severity after immunization with either the MOG(35-55) peptide or recombinant mouse MOG[175]. The reasons for these contrasting findings remain unclear, but may reflect our use of the true autoantigen (mouse MOG) rather than the xenogeneic human MOG. Both studies used recombinant fragments corresponding to the 121-amino acid extracellular domain of MOG. The mouse and human sequences differ at 11 residues within this region[176]. These differences may be crucial to B cell recognition and hence whether B cells are required as APC.

Janeway's group have reported that μMT mice on the $H\text{-}2^u$ background failed to recover from EAE induced with MBP suggesting a role for B cells as regulators of disease[177]. We found the same effect when using $H\text{-}2^b$ μMT mice immunized with either MOG or the MOG(35-55) peptide[175]. B cell sufficient mice show a peak of disease in the second and third weeks after immunization and then enter the recovery phase. μMT mice, however, show a non-remitting disease course. Transfer of B cells from recovered mice to naïve recipients confers a level of protection against subsequent EAE induction. These B cells were found to produce IL-10 when stimulated *in vitro* with MOG. Interestingly IL-10-/- mice show the same severe non-remitting disease as μMT mice[90,91]. Did this point to a common deficit – a lack of IL-10 production by B cells?

To address this question, we developed a bone marrow chimera technology that allowed us to generate mice in which IL-10 deficiency was restricted only to B cells[175]. These mice also developed the non-remitting form of EAE. This was associated with an uncontrolled anti-MOG Th1 response compared with fully IL-10 sufficient mice. These findings are consistent with the recent report that IL-10 production by B cells is essential to control a model of chronic bowel disease[178]. Furthermore B cell production of IL-10 seems key to their ability to limit the severity of collagen-induced arthritis (C. Mauri, personal communication). Production of IL-10 by B cells may therefore be an essential factor in counteracting the pathogenic T cell function in autoimmune and inflammatory conditions, i.e. B cells have a regulatory function. The precise mechanisms underlying these effects remain to be dissected.

5. STUDIES ON AUTOREACTIVE T CELL DEVELOPMENT AND ACTIVATION

5.1 How do myelin-reactive T cells avoid negative selection?

The cellular and molecular mechanisms of central tolerance – the removal of T cells expressing high affinity TCRs specific for self by negative selection in the thymus – are fairly well understood[179,180]. But how do the T cells that initiate autoimmune damage avoid this central checkpoint? Study of T cell reactivity to several encephalitogenic epitopes is beginning to provide some answers[181].

The simplest explanation would be that the autoreactive T cell does not see the autoantigen during thymic development. However, there is now good evidence that both MBP and PLP are expressed intra-thymically[182,183]. Autoreactivity to PLP seems to be shaped by the form of PLP encountered in the thymus. The PLP(139-151) sequence represents the immunodominant epitope in H-2^s mice[25]. A remarkably high frequency of the resting peripheral T cells of an SJL mouse will respond to this peptide (around 1 in 20,000 T cells)[184]. Why aren't these cells deleted in the thymus?

The gene encoding PLP undergoes alternative splicing producing the DM20 isoform that lacks the 116-150 sequence and therefore the 139-151 epitope[185]. Both full length PLP and DM20 are expressed in the CNS, but DM20 is expressed preferentially in the thymus[184]. The PLP(139-151)-reactive T cells therefore escape negative selection in the thymus because the epitope is absent, or is present at levels that are insufficient to activate the T cell apoptosis pathway. Administration of exogenous PLP139-151 was found to induce negative selection, supporting this conclusion[184]. PLP-deficient C57BL/6 mice mount T cell responses to epitopes contained within DM20 whereas wild type mice do not, indicating that this from of PLP is able to induce tolerance[186]. In this case, the induction of tolerance was localized to the activity of thymic epithelial cells.

In cases where the autoantigen is expressed in the thymus, T cell fate is determined by the strength of the TCR-peptide-MHC interaction with high avidity T cells undergoing negative selection[179,180]. Low avidity interactions fail to trigger T cell death, however. The Ac1-9 peptide of MBP is the immunodominant epitope in H-2^u mice[33]. A remarkable feature of this peptide is that it binds so poorly to the A^u MHC class II molecule that a binding affinity cannot be determined[187,188]. As a consequence the autoreactive T cells that recognize this peptide express very high affinity TCRs[51]. The lysine residue at position 4 of Ac1-9 interacts unfavorably with a hydrophobic pocket within the peptide binding groove of the A^u molecule and accounts for the poor class II binding[188-191]. APL of Ac1-9 in which the lysine residue at position 4 is changed, for example to a tyrosine (Ac1-9[4Tyr]), show greatly enhanced binding to A^u[45,51,192] and hence induce T cell responses *in vitro* at concentrations up to a million times lower than are required when using the wild type Ac1-9.

The wild type version and APL of the Ac1-9 peptide were tested for the ability to induce thymic negative selection in a TCR transgenic mouse (Tg4) with specificity for Ac1-9. Systemic administration of high doses of wild type Ac1-9 failed to induce death of Ac1-9-specific thymocytes. The Ac1-9[4Tyr] APL, however, induced substantial negative selection[45].

These findings are consistent with avidity-based models of thymic selection[193,194]. When the developing Ac1-9-specific thymocytes receive a strong signal through Ac1-9[4Tyr] they die. They avoid this fate, however, when exposed to weak stimulation from the wild type autoantigen. Thus low avidity interactions allow escape from negative selection. A similar mechanism has been proposed to account for the ability of autoaggressive T cells to escape negative selection in NOD mice[195]. Here, the A^{g7} class II molecule is believed to make generally unstable interactions with many peptides.

To stimulate T cell activation the number of peptide-MHC complexes displayed by the APC must reach a threshold level[181]. This in turn is influenced by the ability to release the correct peptide fragment during antigen processing. Analysis of T cell reactivity to the immunodominant MBP(80-100) region in SJL mice has revealed that MBP is probably cleaved after amino acid 94Asn during antigen processing[196]. This is driven by the enzyme asparagine endopeptidase (AEP), which cuts after this Asn residue[197,198]. The MBP(85-99) epitope that is recognized by T cells from MS patients is therefore destroyed by AEP and inhibitors of AEP activity greatly increase the response of these T cells in assays that require antigen processing of native MBP[198]. Thus the action of the AEP enzyme limits the availability of MBP peptide-MHC complexes. Importantly AEP activity was shown in purified thymic DC that induce negative selection[198]. Therefore the ability of MBP(89-99)-specific T cells to avoid negative selection may be linked directly to the action of a single enzyme during antigen processing.

5.2 Promiscuous T cell reactivity: implications for autoimmunity

The old view that each T cell bears a TCR that confers unique specificity for a single peptide-MHC complex has become untenable. Mathematical modeling studies indicate that if this were the case, the shear number of potential pathogen-derived epitopes would leave the immune system, with its limited number of T cells, highly ineffective[199,200]. The answer is simple, TCRs must be able to cross-react with many related but different peptide-MHC complexes. This has been shown clearly in many studies over the past decade since the advent of APL[201,202]. An unavoidable result of this is that a T cell that can mount a desirable response to a pathogen might also be able to respond to an autoantigen.

5.3 Molecular mimicry

TCR cross-reactivity gives the T cell the potential to respond to structurally similar antigenic peptides derived from an infectious agent and self-tissue. Once fully activated in response to infection these cells would have the potential to mount an autoaggressive attack in the organ(s) expressing the cross-reactive self-antigen. This idea of "molecular mimicry"[203] has, over the past decade, become the dominant theory for how autoimmunity arises. Although elegant experimental systems have been devised to provide supportive data[204,205], this remains controversial with limited unequivocal evidence[206,207]. Several studies in EAE have provided data pertinent to this issue.

Database searches have revealed sequence similarities between MBP and various viral peptides. Indeed, human MBP specific T cell clones were able to respond *in vitro* when cultured with peptides corresponding to some of these viral sequences[208]. However, the response pattern of the clones was variable with no viral peptide able to stimulate all clones. Since T cell cross-reactivity has been demonstrated using peptides with minimal similarities, the database approach may not pick out all the relevant microbial peptides[209].

Nevertheless this approach has also been used in EAE. Peptides derived from murine hepatitis virus (MHV) and haemophilus influenzae type B (HAE) could stimulate PLP(139-151)-specific T cells[210]. Whilst immunization with these viral peptides could not provoke EAE directly, it did enhance disease upon subsequent immunization with the PLP peptide. Other studies have reported the development of EAE after immunization with microbial peptides that shared sequence homology with MBP[211-213]. In other studies protection against EAE has been afforded by immunization with viral mimic peptides[214], or after infection with vaccinia virus containing MBP sequences[215]. Studies using immunization are not ideal strategies for analysis of molecular mimicry as the theory depends on infection. Giving a large dose of peptide antigen in CFA is very different from an infection. Also the source of the homologous peptide is not a natural mouse pathogen. Moreover, the use of virus expressing the normal self-sequence does not show molecular mimicry, but molecular identity.

To overcome these criticisms, the HAE sequence that mimics PLP(139-151) was introduced into a non-encephalitogenic mutant strain of Theiller's murine encephalomyelitis virus (TMEV), a natural mouse virus that shows tropism for the CNS. Infection with this virus induced PLP(139-151)-reactive T cell immunity and severe encephalomyelitis[216]. The experiments with TMEV used direct intracranial injection. The CNS inflammatory response associated with this may well play an important role. Since the

molecular mimicry theory does not necessarily require the infection to be in the target organ, it will be interesting to see if the use of murine viruses that are not tropic for the CNS can be used. This has been partially addressed by peripheral infection with mutant TMEV expressing PLP(139-151), which again led to EAE[217].

If molecular mimicry is the dominant factor driving autoimmune responses we are left with some important questions. We all have a large population of self-reactive T cells. We all have infections. Why don't we all develop autoimmune disease? Clearly genetic factors must play a role, but is there any immunological reason?

5.4 Do all autoreactive T cells matter? The threshold for harm.

It is probable that the majority of, if not all, T cells show some degree of self-reactivity[199]. Clearly thymic negative selection cannot be allowed to delete all of these T cells and the threshold for this process seems to be set such that only the T cells with high affinity self-reactive TCRs are removed[179,218]. Therefore we have a peripheral T cell repertoire full of self-reactive cells. How are they controlled? A body of evidence shows that T cells can adjust their threshold for activation so that they become relatively insensitive after sustained exposure to antigen. This can be achieved in two ways:- by the biochemical "tuning" of individual T cells through alterations in their TCR proximal signaling machinery[219-221]; or, within a heterogeneous T cell population, by the activation-induced cell death of those T cells expressing TCRs with high affinity for antigen[181].

Evidence for both these processes has been obtained from the study of responses of encephalitogenic T cells to "superagonist" APL of MBP or PLP peptides. The PLP(139-151) system suggests biochemical tuning *in vitro*[222] whereas the MBP(Ac1-9) model shows that Ac1-9-reactive T cells that bear high affinity TCRs are deleted after immunization with the strong MHC binding Ac1-9[4Tyr] APL[51]. Thus mice do not develop EAE after immunization with superagonist APL. They do however mount T cell responses to the APL, but these T cells use lower affinity TCRs and therefore respond very poorly to wild type Ac1-9. Residual autoreactivity is maintained in this situation, but the T cells cannot initiate EAE because the very high levels of Ac1-9-A^u complexes that are required for their activation cannot be reached in the CNS. So can we determine a threshold of sensitivity for antigen that confers the ability to damage self - that is a "threshold for harm"[196]?

The T cells that induce EAE in the MBP system seem to respond to wild type Ac1-9 *in vitro* at or below a concentration of 1μM[51]. T cells that require concentrations above this seem to be unable to induce EAE. Interestingly,

studies using semi-TCR transgenic systems show that T cells can survive happily in mice expressing their cognate antigen without causing pathology as long as their threshold for activation is above 1μM[223]. Furthermore transfer of resting TCR transgenic T cells into mice expressing transgenic antigen lead to the progressive desensitization of the T cells again leaving them unable to respond to antigen concentrations below 1μM[224]. We can therefore propose a threshold for harm of 1μM. CD4+ T cells generally respond to their cognate antigen at doses of ~0.001μM.

Therefore mechanisms appear to be in place to allow autoreactive T cells to populate the peripheral pool, but to have at least 100 lower sensitivity than "normal" To give this some meaning, *in vitro* studies suggest that 1μM equates to more than one thousand peptide-MHC complexes on the surface of the APC[225-227].

Loss of self-reactivity in response to APL has been shown using PLP-reactive T cells[222,228]. For the 1B6 PLP-reactive TCR transgenic mouse, the wild-type 139-151 peptide behaves as a weak agonist[222]. The Q144 APL (with a W→Q substitution at residue 144) is the full agonist and the L144 APL behaves as a superagonist. Stimulation of 1B6 T cells *in vitro* with the L144 superagonist leads to their desensitization such that they are still able to respond to (higher than normal concentrations of) L144 but can no longer respond to the wild type PLP peptide. This "tuning" of sensitivity was associated with reductions in TCR-proximal phoshorylation and in calcium influx upon TCR stimulation[222]. Therefore after exposure to superagonist these cells that express a self-reactive TCR, are functionally not self-reactive.

Cross-reactive T cells that have been filtered through the selective pressures in the thymus and periphery will see self-antigen with low avidity (i.e. the self peptide is a weak agonist, requiring high doses to induce activation). To mount an effective anti-non-self response, however the cell must have medium-high avidity for the foreign antigen(s). This differential avidity keeps the T cell repertoire as diverse as possible while reserving the ultimate sanction of negative selection (either in the thymus or periphery) as a last resort for T cells expressing high affinity autoreactive TCRs.

5.5 Other factors relevant to autoimmune T cell activation

The "tuning" of T cell activation thresholds would serve to limit the risk of autoimmunity as a result of molecular mimicry as the self antigen would need to be displayed with MHC at unusually high levels to become a target that will interest the T cell. There may be situations when this is achieved probably involving a combination of factors[181]. For example, there is now evidence that the cross-reactive potential of PLP-specific and MBP-specific

T cells is enhanced by increased expression of costimulatory molecules by APC[46,229]. This has been achieved either by transfection of "artificial" APC with high levels of CD80/CD86[229], or by *in vitro* activation of splenic APC[46]. In both cases autoreactive T cells showed a broader response pattern to APL than was observed using "resting" APC with low levels of CD80/CD86 expression.

Alterations in antigen processing upon activation of APC might increase the peptide load available for binding to MHC[230]. This might be the result of enhanced activity of a particular processing enzyme, or the inhibition of enzymes that destroy epitopes. As mentioned above, the AEP enzyme cleaves MBP and destroys the 85-99 epitope and inhibition of AEP improves the ability of 85-99-specific T cells to respond to MBP[198]. Therefore suppression of AEP activity *in vivo* could allow generation of sufficient peptide-MHC complexes to activate the T cell. Interestingly, a parasite-derived inhibitor has recently been described[231]. A possible role for infection could therefore involve release of factors that modulate the activity of enzymes crucial to antigen processing.In addition, there may be a requirement for the natural mechanisms that dampen the T cell's inherent avidity for self to be (perhaps temporarily) subverted.

6. T CELL-DIRECTED PEPTIDE THERAPY OF EAE

Because we know so much about the epitopes recognized by encephalitogenic CD4+ T cells EAE has proved a popular testing ground for peptide-based antigen-specific immunotherapy. This has been approached in two ways: by using peptides corresponding to the wild type sequences, or by using APL based on these sequences[232].

6.1 APL-based approaches

Experiments in the PLP(139-151)-induced model in SJL mice have proved very successful at inhibiting EAE with APL. These studies used APL that were initially identified as TCR antagonists *in vitro* and proved effective blockers of EAE when given at the same time as the wild type PLP peptide[233,234]. It was subsequently found that the most effective APL, rather than simply blocking T cell priming, was inducing PLP-reactive Th2 cells[235,236]. Furthermore, immunization with this APL was able to inhibit EAE induced with different epitopes from PLP, MOG, or MBP via "bystander suppression"[236]. Along similar lines, APL based on the MBP(87-99) sequence have been shown to inhibit EAE in mice and rats[237,238]. This inhibition of disease was reported to be associated with a reduction in MBP-specific TNF-α production and increased production of IL-4.

An alternative approach is to generate superagonist APL that induce apoptosis the autoaggressive T cells. As described earlier, APL of MBP(Ac1-9) behave as superagonists *in vitro*, but do not induce EAE *in vivo*. Instead Ac1-9-specific T cells are deleted after immunization with these APL[51]. Similar induction of apoptosis has been reported using superagonist APL of MBP(87-99)[83]. These approaches probably reflect a similar effect to that seen when high doses of wild-type antigen are given. This leads to activation-induced T cell death and prevention of EAE[239,240].

A note of caution should be added over the use of APL. We identified TCR antagonist APL based on the MBP(Ac1-9) sequence that were effective at blocking *in vitro* responses of Tg4 transgenic cells. However, these TCR antagonist APL were fully capable of inducing EAE when used on their own to immunize non-transgenic H-2^u mice[241]. This was found to be due to the previously unappreciated complexities of the Ac1-9-reactive T cell repertoire that was able to induce EAE. These cells showed subtle differences in antigen fine-specificity so that not all of them responded to APL in the same way. Thus the APL that were TCR antagonists for Tg4 cells behaved as full agonists capable of activating other Ac1-9-reactive T cells *in vivo* leading to EAE.

Subsequent to these findings in the mouse, reports on phase II clinical trials in MS patients using APL based on the MBP(83-99) sequence suggested similar effects[242,243]. At least in one study, administration of the APL was found to boost for Th1 responses that cross-reacted with the wild-type MBP sequences and two of eight patients showed clinical exacerbations[242]. When attempting to predict the results of an APL-based therapy we must therefore consider the variability of autoreactive T cell repertoire in addition to potential adverse effects arising from hyper-reactivity to the APL itself.

6.2 Therapy using native peptide sequences

The use of peptides based on natural sequences recognized by the autoreactive T cells should give more predictable results. These peptides should be able to ligate all the potential autoreactive T cells and, if given in the appropriate way, inactivate them. We have known for sometime that the form in which an antigen is administered has a major bearing on the subsequent immune response[244]. Antigen that is aggregated, or mixed with adjuvant will provoke a response. On the other hand, antigen in monomeric form, in the absence of adjuvant, will lead to a specific state of antigen-unresponsiveness, or tolerance. Thus the systemic administration of peptide antigens via various routes have been shown to inactivate myelin-reactive T cells and inhibit EAE[18,196,245-247].

This ability to switch off autoreactive T cells using soluble peptides has been reported when using peptides derived from MBP[18,245], PLP[18,247,248] and MOG[249](and S.M.A., unpublished observations). Since there are many potential targets for autoimmune T cell attack in MS, how would we be able to treat the disease with a single peptide? Several studies have tried to address this in EAE by administering a single peptide to induce tolerance and then immunizing with complex mixtures of antigens (usually whole myelin) and looking for bystander suppression[232]. T cell reactivity to several epitopes is assessed and bystander suppression appears as a general down-regulation of responses to epitopes other than the one used for tolerance induction. An alternative is to assess bystander suppression in terms of disease. Animals are tolerized to one epitope and immunized with another. If disease is inhibited, bystander suppression is concluded to be at work. Several studies have successfully induced bystander suppression in different EAE models[18,236,247,248].

The induction of bystander suppression may therefore provide attractive future therapies in human autoimmune disorders. But how does the suppression work? Perhaps the most beneficial scenario would be for the tolerance process to boost the natural disease suppressive effects of Treg or Tr1 cells. Recent experiments analyzing T cell tolerance to OVA peptide suggest that this may be possible. A limited number of OVA-specific TCR transgenic cells were adoptively transferred to non-transgenic recipients prior to either intravenous or oral administration of soluble OVA peptide[250]. Subsequent analysis revealed that around 20% of the OVA-specific T cells had converted to the CD4+CD25+ phenotype (such cells were at a much lower frequency in mice that had been immunized with the OVA peptide in CFA). These cells had the typical anergic phenotype of Treg cells and were able to suppress the activation of naïve OVA-specific T cells *in vitro*. This

suppression was independent of IL-10 and presumably involved a cell-contact dependent mechanism.

Similar induction of CD4+CD25+ Treg cells has not, so far, been reported from studies of peptide-induced tolerance in EAE models. Instead, recent data point to the generation of IL-10 producing T cells that would more likely correspond to a regulatory population of the Tr1 type[251]. In our early experiments describing bystander suppression in EAE we were unable to detect any qualitative shift in antigen-specific cytokine production in peptide-treated mice[18]. Thus production of all the cytokines that could be detected in control mice was reduced in the peptide treated mice and IL-10 could not be detected in either group.

Subsequent experiments using the MBP(Ac1-9)-specific Tg4 transgenic mice did reveal production of IL-10, however[251]. Although these mice possess very high numbers of Ac1-9-reactive T cells, they can be rendered resistant to EAE-induction by repeated (five or more) doses of the Ac1-9[4Tyr] APL in soluble form. Analysis of Ac1-9-specific cytokine production revealed that control mice made IL-2, IL-4, IFNγ and low levels of IL-10. In peptide-treated mice, however, production of IL-2, IL-4 and IFNγ were greatly reduced, whereas IL-10 production was greatly increased. This implicated IL-10 in the tolerance process a view supported by experiments that showed administration of neutralizing anti-IL-10 antibodies could block tolerance induction and restore susceptibility of the Tg4 mice to EAE.

Analysis of these IL-10 producing Tg4 cells has revealed a capacity to block activation of naïve Tg4 T cells both *in vitro* and *in vivo*. This inhibition was reversed *in vivo* by administration of anti-IL-10. Importantly, these peptide induced regulatory cells did not reside in the CD25+ Treg population. They could be generated readily from RAG-/- mice and depletion of CD25+ cell did not abrogate their suppressive activity (D.C. Wraith, personal communication). Other recent experiments using the MOG(35-55) model in C57BL/6 mice have revealed a crucial role for IL-10, since IL-10 deficient mice are not protected from EAE by peptide treatment[252].

These data clearly implicate IL-10 as a crucial regulatory cytokine controlling protection from EAE following peptide-induced tolerance induction. This fits with the data showing that IL-10 is probably the most important cytokine in the natural resolution of EAE[90-92]. However, activation of T cells that produce large amounts of TGFβ also provides effective resistance to EAE in studies of oral tolerance[253]. Prior expansion of a myelin-reactive Th2 populations can also limit development of the disease[58,235]. Therefore there is more than one way of eliciting an antigen-specific protective immune response.

Although peptide-induced regulatory T cell populations hold promise as future therapeutic approaches, there is still lot we do not understand. For example, the ability to provoke bystander suppression is dependent on which myelin epitope is used[18]. Furthermore, we are only beginning to appreciate the complexities that arise from the potential ways in which an exogenous peptide can interact with MHC compared with the peptide fragments that are generated through antigen processing of the intact autoantigen[196]. There are therefore considerable challenges remaining to the development of effective and predictable peptide-based strategies for treatment of human autoimmune disorders.

7. CONCLUDING REMARKS

The various models of EAE that are available provide many opportunities for the study of autoreactive T cell development, activation and manipulation. The key to this is our understanding of the epitopes recognized in several myelin autoantigens. The use of transgenic and knockout technologies allows us to dissect the role of individual molecules in the etiology of the disease. EAE is providing insights into the molecular mechanisms that allow autoreactive T cells to avoid negative selection and processes that might control their sensitivity once they reach the periphery. Progress has also been made in developing antigen-specific therapies. The complexities of the immune processes that turn autoreactive T cells on or off are starting to be unraveled. We still have a long way to go, however, and the study of EAE will be central to efforts to meet these future challenges.

Chapter A12

THE ROLE OF COMPLEMENT IN EAE

Johan van Beek and B. Paul Morgan
Department of Medical Biochemistry and Immunology, University of Wales College of Medicine, Cardiff CF14 4XX, United Kingdom

Abstract: The complement system is an essential effector of the humoral and cellular immunity involved in cytolysis and immune/inflammatory responses. Complement participates in host defence against pathogens by triggering the formation of the membrane attack complex. Complement opsonins (C1q, C3b, iC3b) interact with surface complement receptors to promote phagocytosis while complement anaphylatoxins C3a and C5a initiate local pro-inflammatory responses that, ultimately, contribute to the protection and healing of the host. However, activation of complement to an inappropriate extent has been proposed to promote tissue injury. There is now compelling evidence that complement is implicated in the pathogenesis of several neurological disorders including the human demyelinating disease multiple sclerosis and experimental allergic encephalomyelitis (EAE), an animal model that mimics the demyelination seen in multiple sclerosis. Deposition of complement proteins correlates with areas of demyelination and axonal loss observed in EAE and complement inhibition ameliorates disease. However, the precise mechanisms underlying complement-mediated damage are still largely unknown. The recent use of transgenic animals is beginning to shed light on the relative contributions of the different complement activation pathways in the pathogenesis of experimental demyelination. These studies will provide the basis for the development of novel drugs aiming to inhibit complement in the the central nervous system.

Key words: Complement; experimental allergic encephalomyelitis; inflammation; anaphylatoxins; opsonins; membrane attack complex; demyelination; axonal damage; therapy

1. THE COMPLEMENT SYSTEM

1.1 A crucial effector arm of the innate immune response

Functions of the complement system include the recognition and killing of invading pathogens (e.g. bacteria, virus infected cells, parasites) while preserving normal 'self' cells. The complement system also contributes through its activation products to the release of inflammatory mediators, promoting tissue injury at sites of inflammation (1). Having preceded the emergence of adaptive immunity, the complement system has maintained a degree of phylogenic conservation among both invertebrates and mammals, underlying the critical role of complement in tissue homeostasis (2).

The complement system consists of some 30 fluid-phase and cell-membrane associated proteins. Complement can be activated by three distinct routes (Figure 1). The classical pathway (involving C1q, C1r, C1s, C4, C2 and C3 components) is activated primarily by the interaction of C1q with immune complexes (antibody-antigen) but activation can also be achieved after interaction of C1q with non-immune molecules such as DNA, RNA, C-reactive protein, serum amyloid P, bacterial lipopolysaccharides, and some fungal and virus membranes. The initiation of the alernative pathway (involving C3, factor B, factor D, and properdin) does not require the presence of immune complexes and leads to the deposition of C3 fragments on target cells. Mannose-binding lectin (MBL), a lectin homologous to C1q, can recognize carbohydrates such as mannose and N-acetylglucosamine on pathogens and initiate the complement pathway independently of both the classical and alternative activation pathways. MBL is associated with two serine-proteases, mannose-binding lectin-associated serine proteases (MASP)-1 and 2, that, like the C1 complex in the classical pathway, cleaves and C4 and C2 components, leading to the formation of the classical C3 convertase.

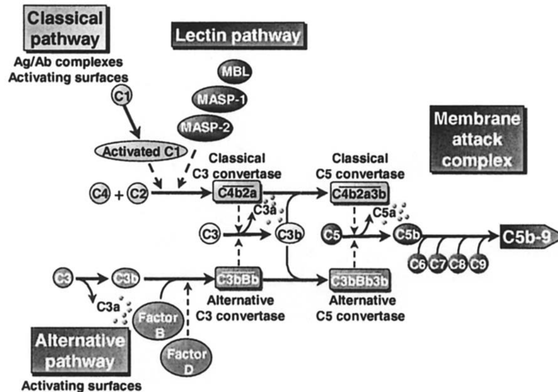

Figure 1. Schematic representation of the complement cascade. The complement system can be activated through the classical, the alternative or the lectin pathway, leading to a common terminal pathway: the cytolytic membrane attack complex. Proteolytic cleavage of components C3 and C5 leads to the release of pro-inflammatory anaphylatoxins C3a and C5a respectively. MBL: mannose-binding lectin; MASP: MBL-associated serine protease.

1.2 Complement receptors involved in phagocytosis

The target pathogen coated with complement opsonins (C1q and C3 activation by-products: C3b, iC3b) is specifically recognised and phagocytosed by macrophages expressing complement receptors (C1qRp (CD93), complement receptor (CR) type 1, 3 and 4). In addition to its role in pathogen clearance, C1q has been shown to play an important role in the clearance of apoptotic cells. C1q binds directly to surface blebs of apoptotic keratinocytes and T cells and there can initiate complement opsonisation (3-5). Moreover, transgenic mice lacking C1q display an impairment in the clearance of apoptotic cells in the kidney, leading to severe glomerulonephritis with immune deposits (6). These obsevations support the hypothesis that C1q serves as an opsonin in the recognition and clearance of apoptotic cells. The transmembrane glycoprotein termed "C1q receptor that enhances phagocytosis" (C1qRp), recently shown to be identical to CD93 (7), has emerged as a defense collagen receptor. Monocytes that have adhered on C1q-coated surfaces display a 4 to 10 fold enhancement of phagocytosis of targets coated with IgG or complement (8). However, the potential involvement of C1q as a ligand for C1qRp/CD93 remains controversial (7) and the cellular and molecular properties of C1qRp/CD93 are yet to be elucidated.

C3, when activated on a cell surface, binds covalently (opsonisation) as C3b and is subsequently cleaved into a very stable fragment iC3b. CR3 (CD11b/CD18) and CR4 (CD11c/CD18) are involved in the phagocytosis process of targets opsonised with C3b and iC3b fragments (9). CR1 (CD35) is also a multifunctional receptor binding to C4b, C3b, iC3b and C1q, and as

such, has been implicated in phagocytic and complement regulatory activities (10).

1.3 The lytic terminal complex and complement regulators

Ultimately, activation of the complement system leads to the formation, through the complement terminal pathway (involving C5, C6, C7, C8 and C9 components), of the membrane attack complex (MAC) which forms a pore in the phosholipid bilayer to lyse the target cell. However, activation of the complement system at inappropriate sites and/or to an inappropriate extent can lead to host tissue damage.

To protect 'self' cells against by-stander lysis, host cells express a battery of regulatory proteins (complement inhibitors) which inhibit either assembly of the C3-cleaving enzymes or the formation of the MAC (11; Figure 2). C1 inhibitor (C1-INH), C4 binding protein (C4bp), factor H, factor I, S protein and clusterin are soluble inhibitors secreted and released in the fluid phase. Membrane-associated complement inhibitors include membrane cofactor protein (MCP, CD46), decay-accelerating factor (DAF, CD55), and CD59. Of note, an inhibitor of complement activation termed "complement receptor related protein y" (Crry) is expressed on rodent, but not human, cell membranes. Crry is broadly distributed and is a functional and structural analog of human DAF and MCP.

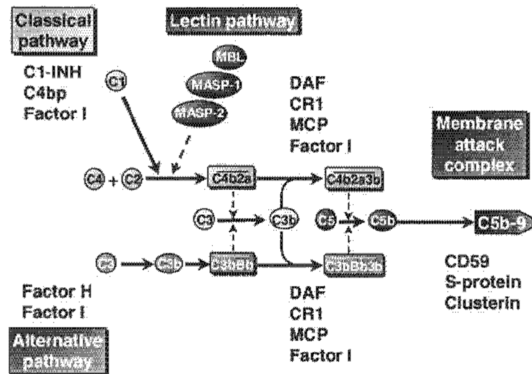

Figure 2. The different pathways of the complement cascade are tightly regulated by membrane-associated (DAF, MCP, CD59, CR1) or soluble (C1-INH, C4bp, Factor I, Factor H, S-protein, clusterin) inhibitors. C1-INH: C1 inhibitor; C4bp: C4 binding protein; DAF: decay-accelerating factor; MCP: membrane cofactor protein; CR1: complement receptor 1.

1.4 Sublytic effects of MAC

Assembly of the MAC is, by definition, involved in cytolytic activities. However, when the number of C5b-9 molecules is limited, cells are able to escape cell death by rapidly eliminating membrane-inserted C5b-9 by endocytosis and membrane shedding (12). When it does not cause death, the MAC is involved in cell stimulation (12, 13). Sublytic levels of C5b-9 have been shown to increase Ca^{2+} influx, to activate phospholipases and protein kinases, and to induce the generation of arachidonic acid-derived inflammatory mediators (14-19). The MAC at sublytic level has also been shown to stimulate endothelial cells to express complement regulatory proteins and to protect against secondary damage (20). Taken together, these data indicate that the MAC at sublytic level could act as a stress signal to activate cells to express increased level of complement inhibitors and protect against subsequent damage.

1.5 Anaphylatoxin receptors

The most potent pro-inflammatory molecules generated upon complement activation are the anaphylatoxins C3a and C5a. C3a and C5a are small polypeptides (~9-10 kDa) that are highly pleiotropic in function and exert their effect at picomolar to nanomolar concentrations (21). C3a and C5a derive from the enzymatic cleavage of C3 and C5 respectively and are involved in the stimulation and chemotaxis of myeloid cells. The functional responses induced by C3a and C5a are mediated through their binding to specific receptors, C3a and C5a receptors (C3aR and C5aR) respectively (21). These receptors are members of the rhodopsin family of seven transmembrane G-protein coupled receptors (22-26).

C5a is an important chemoattractant molecule and stimulates cells to express increased levels of cytokines, chemokines, adhesion molecules and complement components (21). In contrast to the broad pro-inflammatory effects of C5a, the effects of C3a appear to be more selective and rather anti-inflammatory. C3a is chemoattractant but only for mast cells and eosinophils and not for either macrophages or microglia. Recent data indicate that C3a can decrease the production of pro-inflammatory cytokines by LPS-stimulated macrophages and, on the other hand, can induce the production of immunosuppressive cytokines such as IL-10 (21). Furthermore, mice with targeted disruption of C3aR exhibited an enhanced lethality when subjected to endotoxin shock, underlying the potential anti-inflammatory properties of anaphylatoxin C3a (27).

2. COMPLEMENT AND BRAIN INFLAMMATION

2.1 Complement expression by brain cells

In mammals, the liver is the major source of most complement proteins with the exception of C1q, C7 and FD. The brain is separated from the plasma by the blood-brain barrier (BBB), formed by endothelial cells of microvessels, the smooth muscle cells (also called pericytes), and astrocytes. The BBB acts as a molecular sieve and isolates the brain parenchyma from plasma poroteins, including complement components, as well as circulating immunocompetent cells such as lymphocytes, macrophages and natural killer cells. However, transudation of plasma proteins through a damaged BBB can contribute to the deposition of potentially cytotoxic and cytolytic complement components in the brain parenchyma.

In addition, we and others have proposed that brain cells can produce complement proteins to recognize and kill pathogens locally while preserving normal cells in the central nervous system (CNS) (28). Levi-Strauss and Mallat were the first to demonstrate that brain cells can synthesise complement components (29). They showed that cultured rodent astrocyte cell lines and primary cultures of mouse astrocytes produced C3 and FB and that the expression of complement was increased upon stimulation with lipopolysaccharide (LPS). In the last decade, this observation has been extended to include astrocytes, microglia, neurons and oligodendrocytes (30, 31). Cell lines and primary cultures of human origin were used to show that glial and neuronal cells were able to produce most complement proteins, particularly after stimulation with inflammatory cytokines (32-35). In addition, there is now considerable evidence that local expression of complement by resident cells can be dramatically increased in CNS disorders including Alzheimer's disease, brain infection or stroke (36-39). From these studies, it has been proposed that uncontrolled complement activation within the brain parenchyma may contribute to the propagation of the intracerebral inflammatory response and participate in the development of tissue damage.

2.2 Anaphylatoxin receptors in the brain

The expression of C3aR and C5aR was thought to be restricted largely to cells of the myeloid lineage such as macrophages, eosinophils, basophils and mast cells (40-42). However, in recent years, studies have reported

widespread expression of these receptors throughout many tissues and cell types outside the immune system, supporting the view that anaphylatoxins might even exert effects unrelated to inflammation (43-45). If the presence of C3aR and C5aR on microglia was expected given the monocytic origin of these cells, their expression on astrocytes and neurons was not anticipated. The functional significance of the presence of anaphylatoxin receptors on neurons remains ill-defined. Upregulated expression of anaphylatoxin receptors by brain cells has been described in a large variety of CNS disorders, including Alzheimer's disease, brain infection, cerebral trauma and stroke (46-51).

Human astrocyte cell lines stimulated with C5a produce increased amounts of IL-6 while the levels of IL-1, TNF-α and TGF-β remain unchanged (52). Unexpectedly, C5a has been shown to induce apoptosis of the human neuroblastoma cell line TGW (53, 54). Taken together, these data suggest that C5a release during CNS inflammation could contribute to the exacerbation of tissue damage. Interestingly, Heese and colleagues have shown that a human microglial cell line exposed to C3a expressed de novo nerve growth factor (NGF), a molecule involved in neuronal growth and survival (55). These data would support the view that C3a, in contrast to C5a, acts as an anti-inflammatory signal promoting the resolution of the inflammatory process. Unlike C5a, C3a failed to display any effect on apoptosis-mediated neuronal cell death; however, C3a was shown to protect neurons against N-methyl-D-aspartate toxicity, extending its role beyond immune functions (56).

3. COMPLEMENT IN EAE

3.1 Inhibition of complement ameliorates disease

Early work using in vitro models of demyelination demonstrated that the demyelinating component found in sera from animals with experimental allergic encephalomyelitis (EAE), the animal model of multiple sclerosis (MS), was heat labile, a well known characteristic of the complement system (57). The concept that complement activation may contribute to the pathogenesis of demyelinating diseases then developed from key observations in the early 1970s using EAE models. Treatment with cobra venom factor (CVF), which functions as an unregulated C3 convertase, thus activating and depleting C3 and C5 via the alternative pathway, delayed the onset of EAE and reduced demyelination in rodents without affecting cellular infiltration (58-60). Soluble CR1 (sCR1), a potent inhibitor of early

complement activation, was found to inhibit pathology in Lewis rats induced to develop a modified antibody-mediated demyelinating EAE (61). Histologically, there was less inflammation and almost no demyelination or complement deposition in treated rats which were also protected from the paralytic symptoms (Figure 3).

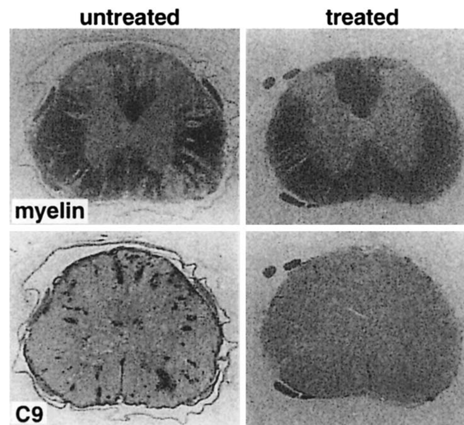

Figure 3. Protective effects of complement inhibition by soluble CR1 (sCR1) in antibody-mediated demylination EAE rats. Rats treated with sCR1 display reduced levels of demyelination and C9 deposition, a maker for the membrane attack complex.

Barnum and colleagues have engineered mice expressing a soluble form of the rodent complement regulator Crry under the control of the glial fibrillary acidic protein (GFAP) promotor to express specifically in the CNS. These mice were protected from MOG peptide-induced EAE, indicating that complement activation plays a critical role in the development of the pathology in this model (62). Studies carried out in C3 gene-targeted mice (C3-/-) have been contradictory. One study reported a protective effect of C3 deficiency. C3-/- mice induced to develop EAE by MOG peptide immunisation displayed reduced levels of disease, inflammation and demyelination, implicating complement in the pathology (63). In contrast, Calida and colleagues found no effect of C3 deficiency on the course of MOG-induced EAE in C3-/- mice (64). The reason for these contradictory results remains unclear but may relate to the genetic backgrounds of the mice studied.

3.2 Complement components are found in EAE lesions

Due to the lack of specific antibodies against rodent complement activation products, the distribution of complement proteins has been studied much less extensively in EAE than in MS. Using an acute antibody-mediated EAE model in the rat, Linington and colleagues demonstrated the presence

of C9, an indicator of MAC deposition, within demyelinating lesions (65). More recently, using EAE in the common marmoset, a model that resembles a chronic MS pathology (66, 67), and EAE in the rhesus monkey, a model that resembles acute disseminated encephalomyelitis (68, 69), we have demonstrated that complement components including C1q and C3b neoepitope are present in foci of inflammatory infiltrate (70; figure 4).

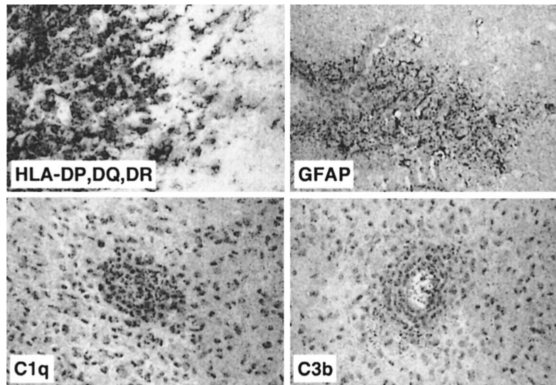

Figure 4. Glial reponses and complement deposition in marmoset EAE. A perivascular demyelinating lesion is diffusely infiltrated by macrophages stained for HLA-DP,DQ,DR. Note the presence of ramified HLA-DP,DQ,DR-positive microglial cells at the edge of the lesion. Reactive astrocytes (antibody to glial fibrillary acidic protein, GFAP) are found in areas surrounding the demyelinating plaque. Complement components C1q and C3b are present in pericocal inflammatory infiltrates.

In line with these findings in EAE models, early observations reported the presence of several activation products of the cytotoxic/cytolytic complement system in the cerebrospinal fluid of multiple sclerosis (71-73). More recently, a correlation of neurological disability and CSF concentration of MAC has been reported (74). Complement activation products have also been localized within the CNS parenchyma of MS patients, providing a strong body of evidence that complement-mediated cell death is prominent in areas of active demyelination in MS (75-77). In these studies, complement activation products such as C3b and C3d, as well as MAC, were found on myelin sheaths and altered myelin within the lesion. Finding deposition of opsonin C3b and C3d in close proximity to disrupted myelin strongly suggests that recognition and uptake, or attempted uptake, of myelin by microglia and/or macrophages is mediated by complement.

3.3 Expression of anaphylatoxin receptors is upregulated in EAE

C3aR and C5aR distribution pattern in EAE has only been documented recently. Expression of the gene encoding C5aR was found to be upregulated in the white matter of EAE rats (78). Cells expressing C5aR were identified as reactive astrocytes, microglia and infiltrating mononuclear cells. In addition, in the spinal cord of affected animals, a subset of motor neurons adjacent to inflammatory infiltrates were found to express C5a mRNA. Interestingly, mice in which the expression of IL-3 is driven by the GFAP promotor display clinical and histopathological features that are relevant for MS (79). In these mice, numerous foci of infitrating cells as well as demyelination were observed, along with a dramatic upregulated expression of C5aR mRNA by glial cells and neurons. In contrast, expression of C3aR on neurons was found to be unchanged during the course of EAE (80). As documented for C5aR, increased expression of C3aR was seen on infiltating mononuclear cells, microglia and astrocytes in both EAE and multiple sclerosis (50, 80).

It is still unclear whether anaphylatoxins drive inflammation in models of EAE. Recent data indicate that the C5aR is not an essential mediator in the induction and progression of EAE. In a study carried out by Reiman and colleagues, C5aR-deficient mice (C5aR-/-) and wild-type mice were induced to develop EAE using a myelin oligodendrocyte glycoprotein (MOG) peptide as the immunogen (81). They found that C5aR-/- mice were fully susceptible to MOG-induced EAE with no difference in disease onset or severity when compared to control mice.

3.4 Mechanisms involved in complement-mediated demyelination in EAE and MS

3.4.1 Is complement activated on myelin in an antibody-dependent manner?

Taken together, data obtained from animal models of MS and the human disease unequivocally implicate complement in the pathology of experimental and clinical demyelination. However, the mechanisms responsible for activating complement and myelinotoxic products of complement on myelin are still uncertain.

Complement activation is classically initiated via C1q interacting with bound immunoglobulin to produce opsonins, anaphylatoxins and MAC. Antibodies against a number of myelin antigens including MOG have been

detected in the blood, cerebrospinal fluid, and affected tissue of MS patients (82, 83), and have been shown to be directly involved in the demyelination process in some models of EAE (83, 84). Interestingly, the demyelinating potential of a given anti-MOG monoclonal antibody in a model of antibody-mediated EAE has been correlated with its ability to fix complement (85). Furthermore, disrupted myelin within active lesions in acute MS is sometimes found to be immunoreactive for IgG and MAC, along with C3d (76, 77, 86). However, the significance of such observations remains uncertain since, in contrast to what observed in EAE, sera from MS patients were found not to be more opsonic for isolated myelin than sera from normal controls (87).

3.4.2 Is complement activated on myelin in an antibody-independent manner?

Physically disrupted myelin itself has been shown to activate spontaneously the complement system via the classical pathway (88, 89). A putative candidate for direct complement binding is MOG, a molecule expressed on the outermost lamellae of myelin and which contains a conserved motif similar to the C1q-binding site of IgG (90). Accordingly, it has been reported that the extracellular domain of MOG can fix C1q in a calcium- and dose-dependent manner (91). Another candidate is 2',3'-cyclic nucleotide 3' phosphodiesterase (CNPase), which has been shown to bind C3 (92). The first observation that oligodendrocytes are themselves extremely susceptible to complement lysis was made by Scolding and colleagues in 1989. They demonstrated that antibody-independent activation occured in vitro on rat oligodendrocyte cell membranes, while O-2A progenitors and astrocytes type I and II remained unaffected (93, 94). In this particular scenario, complement activation was taking place through the classical pathway although the activating molecules were not identified. Further studies have demonstrated that rat oligodendrocytes were lacking CD59, the major inhibitor of lysis, suggesting that their susceptibility to complement-mediated lysis was due in part to their poor ability to control complement activation (85). However, the situation in man appears to be different. Human oligodendrocytes and human oligodendroglioma cell lines were found to express high level of complement regulators, including CD59, and failed to activate spontaneously the complement system (95-97).

3.4.3 An essential role for the MAC in the demyelination process?

Activation of the complement cascade leads to a range of biological outcomes driven either by the generation of anaphylatoxins C3a and C5a,

deposition of complement fragments on cell surfaces, or formation of the cytolytic MAC. The relative contributions of the different pathways in the pathogenesis of experimental and clinical demyelination is still not fully understood.

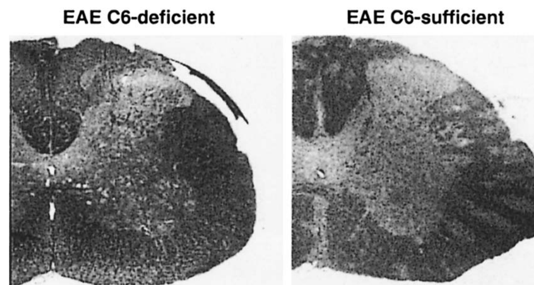

Figure 5. Histological examination of cervical cord sections from C6-deficient and C6-sufficient rats with antibody-mediated demyelination EAE using luxol fast blue/cresyl violet staining. Significant demyelination can be seen in the C6-sufficient rats with EAE, whereas no myelin loss can be seen in the C6-deficient rats.

Although it has been proposed that early components of the complement cascade mediate demyelination via the opsonization of myelin by C3b and C4b and subsequent interaction of these opsonins with complement receptors on microglia/macrophages (98), recent data suggest that the MAC is an essential effector of the demyelination process. Indeed, demyelination was dramatically reduced in C6-deficient rats induced to develop EAE by injection of antibodies to MOG (99; Figure 5). These rats have a normal complement system except that they are unable to form the MAC, suggesting that demyelination in this animal model requires activation of the entire complement cascade, including MAC deposition. This observation also demonstrates that in the absence of MAC deposition, opsonization of myelin and generation of anaphylatoxins C3a and C5a is not sufficient to induce demyelination. Interestingly, sCR1 markedly reduced both demyelination and inflammation in antibody-mediated EAE (61), whereas C6-deficient and C6-sufficient rats had similar degrees of inflammatory infiltrate (99). Because CR1 acts early in the complement cascade, this would suggest that complement anaphylatoxins C3a and C5a drive the inflammatory process in this model but are not responsible for myelin loss. Recent data obtained by inducing EAE in CD59-deficient mice further support the suggestion of a critical role of the MAC in demyelination. CD59

deficiency was shown to markedly exacerbate disease, demyelination and CNS inflammation (100).

3.4.4 A role for complement in axonal damage?

Axonal damage and neuronal injury in multiple sclerosis, first described by Charcot in 1868, have been emphasized recently as hallmarks additional to myelin loss, as evidenced by magnetic resonance imaging (101) and histopathological studies (102, 103). Axonal damage as a consequence of demyelination is also a common observation in rodent (99, 104, 105; Figure 6) and nonhuman primate (106) EAE. Although the exact mechanisms leading to axonal loss are still poorly understood, immunostaining for C9 as an indicator of MAC deposition was found to correlate with areas of axonal damage (99), suggesting a possible role for the cytolytic MAC in this pathological process. However, whether axonal loss is directly mediated by the MAC remains to be ascertained. It is possible that axons, exposed after demyelination, activate complement in an antibody-independent manner. Indeed, human neurons in vitro have the propensity to activate spontaneously the complement system and, consequently, are suceptible to complement-mediated lysis (107). The poor capacity of neurons to control complement activation has been attibuted to the fact that these cells express low levels of complement regulators (107, 108).

Figure 7 summarizes the putative roles of complement activation in inflammation mechanisms, myelin loss and axonal damage.

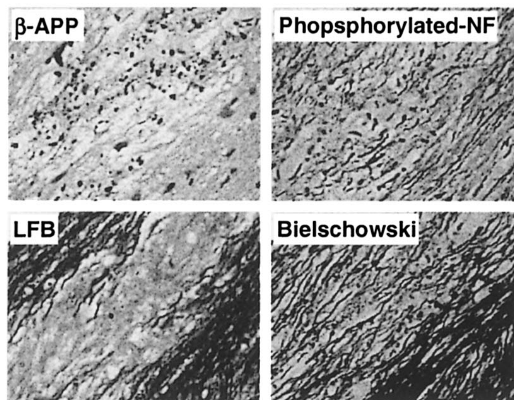

Figure 6. Axonal pathology in antibody-mediated demyelinating EAE rats. Serial transvere sections of spinal cord from EAE rats centered around an inflamed vessel stained for β-APP (β-amyloid precursor protein), phosphorylated-NF (neurofilament), LFB (luxol fast blue), and Bielschowski's silver stain showing axonal fragmentation in the demyelinated area.

3.4.5 Intrinsic neuroprotective mechanisms against complement activation

Although the neurotoxic effects of complement activation are well established in demyelinating diseases, the protective roles of complement regulatory proteins on neurons remain ill-characterized. We found that the complement classical pathway is activated on neurons located in close proximity to inflammatory infiltrates during the course of EAE in the marmoset (70). However, these neurons were found to be relatively spared, suggesting the existence of intrinsic immunoregulatory mechanisms involved in neuronal survival. In response to the insult, these neurons were found to express de novo DAF, a critical regulator of the complement system (70). This observation underlines the ability of neurons to mobilize defense mechanisms to dampen the potentially harmful effects of localised complement activation. In this vein, Stadelmann et al. recently reported that brain-derived neurotrophic factor and its receptor gp145trkB are expressed by neurons within or close to MS lesions, suggesting a role for neurotrophins in neuroprotective mechanisms in demyelinating diseases (109).

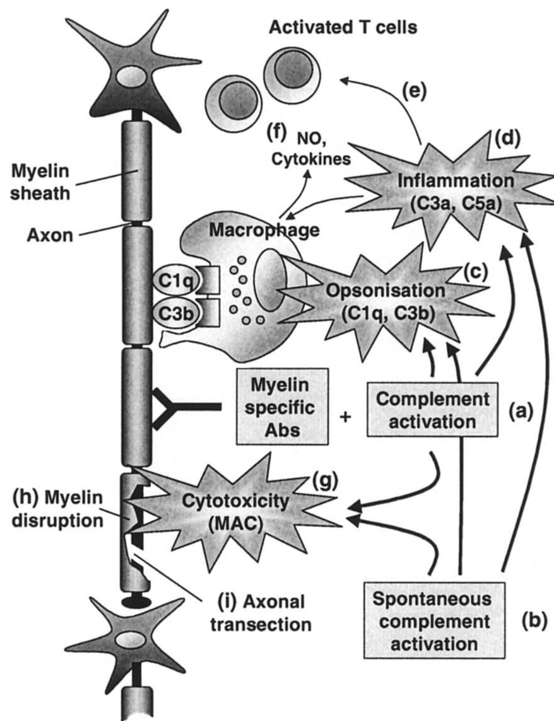

Figure 7. Proposed roles of complement activation in mechanisms leading to demyelination and axonal loss. Complement can be activated on myelin in an antibody-dependent manner (a) or spontaneously (b). Opsonins will decorate myelin sheaths (c), leading to macrophage binding through specific complement receptors. Complement activation can also induce the release of the pro-inflammatory anaphylatoxins (d), which in turn will stimulate inflammatory cells to produce toxic signals (f). Ultimately, the complement cascade culminates in the formation of the lytic membrane attack complex (MAC; (g)), leading to myelin disruption (h) as well as axonal damage (i).

3.4.6 Effects of sublytic assembled MAC on oligodendrocytes

Data indicate that the number of membrane-inserted MAC complexes determines whether complement activation induces or protects from cell death. As an example of their protective role, postmitotic oligodendrocytes exposed to sublytic MAC have been shown to enter cell cycle (110, 111). A novel gene named "response gene to complement" (RGC)-32, induced in rat oligodendrocytes and involved in cell cycle progression, has recently been cloned by differential display and implicated in this phenomenom (112). Moreover, exposure to sublytic MAC has been demonstrated to protect oligodendrocytes from apoptosis induced by serum deprivation (110) or exposure to tumor necrosis factor-α (113). The question of whether sublytic

assembly of the MAC could also modulate the outcome of damage during the course of EAE has been adressed recently. C5-sufficient mice with EAE were found to develop less pronounced levels of inflammation when compared to C5-deficient mice, unable to form the MAC (114). In addition, active remyelination with restoration of tissue integrity was observed in chronic lesions only in C5-sufficient mice (114). Taken together, these data suggest a possible role for the sublytic assembly of MAC in the modulation of tissue inflammation and the initiation of tissue repair in demyelinating diseases.

4. THERAPEUTIC IMPLICATIONS OF COMPLEMENT INVOLVEMENT IN DEMYELINATION

The case for an important role of complement in experimental and clinical demyelination made above has implications for therapeutic strategies to inhibit myelin loss. If drugs can be developed that significantly inhibit complement activation in the CNS then a substantial benefit might be anticipated in demyelinating disease. Complement therapeutics have undergone a mini-revolution over the last decade with the development of agents, based upon the naturally occurring regulators of complement, that efficiently inhibit complement when administered to man or animal (115). As noted earlier, one of these agents, sCR1, has been shown to markedly reduce myelin loss in rodent EAE models (61). None of the current crop of complement therapeutics is suited to treatment of a chronic disease. All are large molecules, active only when administered systemically; all have relatively short half lives and all cause global inhibition of complement with concomitant loss of the protective physiological roles of complement. These shortcomings effectively restrict use to acute disorders. Current research aims to make better complement therapeutics by creating small molecule inhibitors, by targeting complement inhibition to the relevant site in the body or by using a gene therapy approach to the inhibition of complement (116). Again, EAE provides the test-bed for these new approaches. Barnum and colleagues took the ingenious approach of using transgenesis to achieve CNS-specific expression of the powerful rodent regulator Crry. Soluble Crry generated in the CNS rendered the transgenic mouse resistant to disease and demyelination in the EAE model (62). Although transgenesis is not directly applicable to therapy in human disease, the profound effect of local inhibition of complement in the CNS in this model provides a powerful rationale for pursuing more relevant methods for targeting complement regulators to the CNS. The recognition that complement is a major drive to

pathology in EAE models has thus opened a new direction to be explored in the search for effective treatments for human demyelinating diseases.

Chapter A13

B CELLS AND ANTIBODIES IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Xia Lin and Cris S Constantinescu
Division of Clinical Neurology, University of Nottingham, UK

Abstract: EAE is a T cell mediated disease, but increasing evidence shows an important role for B cells and antibodies in its pathogenesis. This also reflects a role for humoral factors in the pathogenesis of multiple sclerosis. The main functions of B cells and antibodies in EAE are discussed.

Key words: EAE, MS, B cells, antibody, Immunoglobulin, antigen presentation, demyelination

B-lymphocytes are the major types of immune cells that mediate antigen-specific humoral immune responses. In the past two decades, the research based on experimental autoimmune encephalomyelitis (EAE) and multiple sclerosis MS has solidified the concept that T-helper cell-driven immune processes are critical for the pathogenesis of MS and MS has been regarded as a T-cell-mediated disease. However, an early support for a role of humoral immunity in the pathogenesis of MS followed Kabat's report on the elevated levels of immunoglobulins in the cerebrospinal fluid (CSF) of patients with this disease[1]. Oligoclonal bands (OCB) (oligoclonal IgG) is present in the CSF of the majority of MS patients and are produced by CNS-resident B cells. Underscoring the utility of the EAE model, both early[2,3] and very recent studies[4] have also been shown in several rodent EAE models and are also present in primate models[5]. In recent years, evidence derived from studies in humans, and in animal models such as knock-out or transgenic mice and autoimmune and virus-induced variants of encephalomyelitis and EAE, has led to a renewed interest in a role for B cells and the humoral immune system in the pathogenesis of MS. Studies show that antibody-dependent effector mechanisms are also involved in the

immunopathogenesis of demyelination[6,7]. It emerges that mutually interacting cellular and humoral immune components may contribute to immune-mediated demyelination in human disorders. In this chapter, a general role of B cells and auto-reactive antibodies in EAE pathogenesis is reviewed.

B cells act as antigen-presenting cells for CD4+ T-cells

In most immune reactions, B and T cells closely co-operate. The important contribution of B cell antigen presentation to T cell activation has been demonstrated in studies in which the absence or depletion of B cells decreases antigen-induced T cell activation[8-10]. It has also been shown in experiments in which B cell presentation of antigen to primed or already activated T cells further stimulates the T cells[11]. In brief, naïve B cells develop into memory B cells with the help of $CD4^+$ T-helper lymphocytes and follicular dendritic cells after an antigen challenge in the secondary lymphoid organs. Memory B cells then can take up antigen via their specific surface receptors (BCR) consisting of the membrane-bound immunoglobulin (mIg) molecule that mediates the binding to antigen, and the mIg associated Ig-α/Ig-β heterodimer [12]that functions as signaling subunits of the BCR. This antigen-induced signaling is modulated by the activity of B-cell co-receptor molecules such as CD19[13]or CD22[14]. The captured antigen is then fragmented by endosomal proteases and presented with MHC-class II molecules to T-cell receptor on corresponding helper T cells. Contact between the antigen-presenting B cell and a specifically primed T cell leads to T-cell activation via engagement of the T-cell receptor and a number of accessory molecules including T-cell costimulatory ligands, such as B7.1 and B7.2 on the antigen-presenting B-cell, and CD28 on the T cell[15,16]. Activation of T cells by B cells is accompanied by secretion of lymphokines and transient expression of new cell surface molecules, particularly the ligand for CD40[17-19]. In this step, B cells are induced to proliferate after contact with the activated T-cell surface[20]. Interaction between CD40 and its ligand on the T-cell surface is essential for this cell-contact-mediated event[18]. Finally, exposure of cell-contact-activated B cells to T-cell-derived lymphokines leads to their differentiation into antibody-secreting cells[20]. This reciprocal activation of T and B cells represents a key immunological event that results in cytokine release, immunoglobulin isotype class swith, somatic hypermutations in the complementarity determining regions, and affinity maturation[21].

Antibodies

The key feature of the humoral immune response is the production of antibodies. Antibodies are immunoglobulins of several classes which play specific roles in the immune response. An important immunoglobulin class

for the pathogenesis of EAE and MS is IgG, but IgM and IgA have also been implicated. IgE is involved in reactions to allergens.

Immunoglobulins consist of heavy and light chains containing the variable (V), diversity (D) and joining (J) regions. The V segments on the heavy and light chains (V_H and V_L, respectively) contain 3 regions that bind the antigen called the complementarity-determining regions (CDR). Each B cells has a specific pair of heavy and light V region, ensuring that each B cell have a single antibody specificity.

Cytokines

B cells can be a source of cytokines, most notably IL-6, IL-10 and IL-12. These cytokines and others potentially produced by B cells play an important role in EAE pathogenesis (see chapter on cytokines).

Self tolerance and mechanism of B-cell autoimmunity

The ability to distinguish between self and foreign antigens is a central feature of immune recognition, allowing immunity to be acquired against foreign organisms while avoiding destructive auto-immunity. Many of the negative selection steps in the generation of B-cell repertoire occur early in the ontogeny of these cells in the bone marrow[22]. However, several additional mechanisms of self-tolerance in the periphery have evolved to prevent B cells from reacting against self-antigen and from producing antibodies that contribute to tissue damage in immune-mediated disorders[23]. These are largely attributable to the degree of Ig receptor engagement and the availability of T cell help[15,21,24,25]. Under certain circumstances, some B cells may escape established tolerance and start to produce autoantibodies that contribute to tissue damage in immune-mediated disorders. The mechanisms that operate in generating B-cell autoimmunity in humans are still obscure. From studies on transgenic and knock-out mice and in vitro investigations, dysregulation at different molecular levels of B-cell function appears to result in B-cell autoimmunity.

Roles of B cells in EAE pathogenesis

There is increasing evidence that antibodies are involved in the development of the demyelinating plaques[26,27]. It is generally accepted that B cells and antobodies, although incapable of initiating EAE, are likely important contributors to the disease process. Possible roles for B cells, plasma cells and antibodies in EAE include: 1). Antigen uptake, processing and presentation that involves B cells acting as APC; 2). Antibody and complement-mediated demyelination 3). Co-stimulation of T-cells; 4). Influence on the cytokine production balance; 5). Potential beneficial immunoregulatory effects of autoantibodies.

B lymphocytes as antigen-presenting cells and as source of antibodies in EAE

Studies both in vitro[28,29] and in vivo[8] show that previously activated T cells can be stimulated to proliferate and differentiate using B cells as APC. An in vivo study has demonstrated that the uptake of antigen through Ig receptor results in B cells having an activated phenotype, i.e. up-regulation of surface B7-2 and MHC class II, and that they are competent APC for naïve $CD4^+$ T cells. Subsequently, the presentation of a foreign soluble protein by APC in the absence of appropriate antigen-presenting B cells was limited, suggesting a major contribution of B cells for T cell priming[8,10]. The role of B cells as APC in EAE is suggested in B cell-depleted mice. Studies have shown that treatment of animals with anti-rat IgM antibody to deplete B cells induces resistance to EAE, suggesting B cells and/or their products were necessary for EAE in Lewis rats[30,31] and in mice[32]. Further studies show that B cells are critical to the induction of EAE, B cell deficient mice being resistant to EAE induced by immunisation with the recombinant form of MOG[33,34]. Transfer of B cells restores the ability of recombinant MOG to induce clinical EAE in B cell deficient mice[34]. A role for B cells in enhancing the priming of autoreactive T cells has also been proposed in EAE induced with myelin basic protein[32]. However, some studies suggest that the importance of B cells in the pathogenesis of MOG-induced EAE is highly dependent on the nature of the MOG, EAE could be induced in the absence of B cells after immunisation with short peptide, but not with the whole protein[33-35] Similarly, Dittel and colleagues failed to find a requirement for B cells in MBP-peptide induced EAE[36]. Thus, the role of B cells in MOG-induced EAE depends on the antigen used for sensitisation. B cells are critical for human and rat MOG protein-induced EAE but are not critical for EAE induced by a short encephalitogenic MOG peptide, where other mechanisms may be operative[33,37].

Autoantibody-mediated demyelination in EAE

The identification of the myelin oligodendrocyte glycoprotein (MOG) as a major target for auto-antibody-mediated demyelination in EAE[38] received interest in the role of antibody in the pathogenesis of MS. It is now apparent that antibody-dependent effector mechanisms are involved in the immunopathgenesis of demyelination[6,7,39]. MOG is a minor component of CNS myelin that is exclusively expressed at the outer surface of the myelin sheath and oligodendrocyte plasma membrane[40]. Sera from animals with chronic EAE injected into the CSF of normal animal induces demyelination[41]. In some animal models that normally show little or no demyelination, such as guinea pigs immunized with MBP without lipids demyelination can be observed following immunisation with both MBP and GALC[42]. Administration of antibody to MOG to rats with EAE converts the

disease to a more severe clinical form and produces more extensive demyelination[43]. Further, study of pathology of MS that examined a large number of samples obtained by biopsy or at autopsy showed that the inflammation was associated with antibody binding to myelin, suggesting an antibody-mediated process producing damage to myelin[44]. These findings are further extended by other reports showing MOG-specific antibodies present in actively demyelinating lesions in MOG-induced marmoset EAE as well as in MS, supporting the role of antibody in myelin damage[7,45]. In humans, elevated levels of anti-MOG antibodies and increased frequencies of anti-MOG antibody IgG-secreting B cells have been demonstrated in the CSF of MS patients[46,47] and in the MS lesions[7,45]. Extensive evidence of the role of autoantibodies in the pathological process of EAE and MS comes from in vitro studies showing demyelination and inhibition of myelination with either sera or immunoglobulin fractions from patients with MS or from animals with EAE in organotypic cultures[48].

B cells express B7-1 and B7-2 and co-stimulate T-cells

The activation of naïve T cells requires not only the recognition of a peptide-MHC complex, but also the interaction of co-stimulatory molecules expressed by antigen presenting B cells. In humans, the number of circulating B cells that express B7.1 are significantly increased during MS exacerbations and reduced with interferon-β treatment[49]. Recent reports have also shown that EAE is markedly reduced in B7.1 and B7.2 deficient mice following adoptive transfer of wild type MOG short peptide activated T cells, suggesting that B7 co-stimulatory molecules, possibly including those expressed by B cells, have a critical role in the effector phase of EAE[50]. Taken together, these studies indicate that B7 ligands on B cells are part of the costimulatory interactions that play a critical role in the initiation of EAE.

Influence of B cells on cytokine balance

Cytokines play a key role in the development and remission of EAE. The inflammatory lesion in the CNS requires a type 1 autoreactive response, producing the pro-inflammatory cytokines interferon-γ and tumour necrosis factor-α. [51]Recovery is associated with production of the type 2 cytokines interleukin 4 (IL-4) and IL-10[52,53]. B cells can regulate immune responses *in vitro* through the production of IL-10[54]. Studies have shown that B cells from normal B6 mice recovered from EAE produced IL-10 when stimulated with the auto-antigen and anti-CD40, while mice with B cells that could not be activated through CD40 or could not synthesise IL-10 suffered severe non-remitting EAE[55]. In addition, transfer of B cells from mice that had recovered from EAE could rescue this defect[55]. These results are consistent

with the previous reports showing that mice do not recover from EAE if they lack B cells[56]or the ability to produce IL-10[57,58]. The effects of B cells in resolving EAE may be attributed to the direct B cell and T cell interaction with B cell antigen presentation favouring Th2 rather than Th1 differentiation[59]. This concept is supported by the previous finding in which targeting auto-antigen to B cells before active induction of EAE leads to protection against disease that correlates with enhanced Th2 responses or with induction of antigen-specific anergy[60,61].

Beneficial role of B cells and immunoglobulins in demyelination

There is evidence that humoral mechanisms may mediate myelin repair. It has shown that administration of either whole antiserum[62] or purified IgG[63,64] directed against unidentified antigens enhances CNS remyelination in the Theiler's virus and EAE models. This property is postulated to be one of the potential explanations for the beneficial effect of intravenous immune globulin in MS.

Antibody-Dependent Cell Mediated Cytotoxicity

Antibody-Dependent Cell Mediated Cytotoxicity is a process whereby specific antibodies contibute to the lysis of cells expressing the cognate antigen. This phenomenon is known to occur in EAE[65] and may explain demyelination and oligodendrocyte loss in autoimmune demyelinating disease.

Opsonization

Myelin phagocytosis occurs during autoimmune demyelination and can be reproduced in *in vitro* models[66]. In MBP-induced, IL-12 enhanced Lewis rat relapsing EAE, MBP-specific IgG1 and IgG2b rise over time and myelin-positive microglia appears increasingly in the CNS[67]. Phagocytosis is enhanced by opsonization with antibodies or complement. Anti-myelin antibodies enhance opsonization and increase the efficiency of myelin phagocytosis, contributing to demyelination.

Complement

A major role of antibodies is to fix complement, which contributes to many beneficial and pathological immune responses. Complement is discussed in a separate chapter.

Conclusion

In conclusion, B cells and antibodies are major components of the immune system that contribute significantly both to the pathogenesis and to the modulation of EAE.

ACKNOWLEDGEMENTS

Dr. Constantinescu's research has been supported in part by the NIH, University of Nottingham, The Stanhope Trust and the Multiple Sclerosis Society of the United Kingdom and Northern Ireland.

Chapter A14

CYTOKINES IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Cris S Constantinescu and David Baker
Division of Clinical Neurology, University of Nottingham, UK and Department of Neuroinflammation, Institute of Neurology, University College, London, UK

Abstract: The cytokine network governing the processes of inflammation, demyelination, relapses and recovery in EAE is very complex. Here we review the major proinflammatory and anti-inflammatory cytokines and their role in EAE, as shown by expression in nervous tissue, production by cells of the immune and nervous system, experiments with exogenous administration, overexpression, antibody neutralization or knockout mice.

Key words: *EAE, cytokines, proinflammatory, anti-inflammatory, Thl/Th2, interleukins, tumor necrosis factor*

Cytokines are soluble proteins that mediate interactions between cells of the immune system and thus regulate immune functions. The term cytokine includes factors produced by lymphocytes (previously named lymphokines), monocytes (monokines) and other cells. The term interleukin (IL) originally denoted cytokines mediating interaction between lymphocytes or monocytes and other lymphocytes but is currently more inclusive and in the current nomenclature most cytokines are interleukins.

Cellular sources of cytokines

The primary cellular sources of cytokines are cells of the immune system, including T and B cells, NK cells, monocytes and macrophages, neutrophils, eosinophils and basophils and mast cells. In addition, other cells in the body produce cytokines, including cells of the central nervous system such as neurons, astrocytes, microglia and oligodendrocytes.

In terms of their effect on the immune responses, cytokines have either predominantly proinflammatory or anti-inflammatory effects. However, there is a great deal of overlap. In experimental autoimmune encephalomyelitis (EAE), the ability of an animal to respond to immunization by producing proinflammatory or anti-inflammatory cytokines correlates with the ability to resist or be susceptible to the development of disease. Numerous cytokine manipulations can influence the ability to develop EAE, its severity and its resolution.

Another classification takes into account the main function of cytokines in the immune system. The haematopoietic cytokines include IL-3, IL-7, IL-9, IL-11 and GM-CSF (granulocyte-macrophage colony stimulating factor). Cytokines involved in innate immunity include type 1 interferons (IFN-1), IL-12 and TNF. Cytokines mediating adaptive (specific immunity) include IL-2, IL-4 and IL-5.

There is extensive redundancy in the cytokine network, and the immune response in EAE is extremely complex. With the continuing discovery of new cytokines, this complexity becomes ever more obvious. The majority of cytokines described to date have been investigated in the context of EAE (and many in the context of MS as well).

The Table lists the main cytokines with main cellular sources and effects

Table I. Cytokines

Cytokine	Main cellular sources	Main cellular targets	Effects	Pro/anti-inflammatory net effect
IL-1	Mono, Mac, astr, mgl	Many cells	Fever, inflammation, tissue injury	pro
IL-2	Mainly T	T, NK	Growth factor, antiapoptotic for T, B	pro
IL-3	T	Immature progenitors	Growth and differentiation	
IL-4	T, baso, ?eos, B	T, B, mast, eos	Th2, IgE, mast, inhibits Th1 and IgG2a switch	anti

IL-5	T	Eos, B, ?T	Eos activation, growth factor for B	anti
IL-6	Mono, fibr, EC, neutr	B cells, hepatocytes	growth factor for B, acute phase protein synthesis	pro
IL-7	Fibr, bone marrow stromal cells	Immature progenitors	Growth and differentiation	
IL-8	EC, Mono	Neutr	Recruitment of neutr	pro
IL-9		T	Growth of T	pro
IL-10	Mono, Mac, T, B, astr, mgl	Mac	Inhibits mac cytokines, MHC, B7	anti
IL-11	Bone marrow stromal cells	Platelets, megakaryo	Megakaryopoiesis	
IL-12	p35 many cells p40 DC, mac, APC	T, NK, B	IFN-gamma production, Th1 development, cytotoxicity	pro
IL-13	Mac, EC	EC, Mac	Induction of adhesion molec, Th2, inhibits mac	anti
IL-15	Mono, Mac	T, NK	NK proliferation, cytotox, Th1	pro
IL-16	T	Eos, T?	Eos recruitment, T	pro?
IL-17	T	Many	Cytokine, adhesion	pro
IL-18	Mac	T, NK	Th1, NK activation	pro
IL-23	Mac, DC	T memory	Th1	pro
TNF-α	Mono, Mac, mast, NK, T, astr, mgl, EC	Many	Activates Mac, NK, IgG2a switch, neutr, adhesion, apoptosis	pro
LT	T	Neutr, EC	Activates EC, neutr	pro
TGF-β	T, Mono, Mac, astr, mgl	T, other cells	Inhibits T activation; inhibits inflammation; promotes fibrosis	anti
IL-27				

APC=antigen presenting cells; astr=astrocytes; baso=basophils; DC=dendritic cells; EC=endothelial cells; eos=eosinophils; fibr=fibroblasts; mac=macrophages; mgl=microglia; mono=monocytes; neutr=neutrophils.

Cytokine receptors

Cytokine receptors are transmembrane proteins capable of signal transduction. There are several families of cytokine receptors. These include:

1. Immunoglobulin superfamily members, for example type I and II IL-1 receptor.
2. Type I family cytokine receptor, characterized by a Trp-Ser-X-Trp-Ser linked to two Cys residues, present in many cytokine receptors including IL-2, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-13, IL-15 and GM-CSF.
3. Type II family cytokine receptor, for example the receptors for IFNs.
4. Type III family cytokine receptor, for example TNF receptor I and II, members of the TNF receptor family.
5. Multichain receptor complexes, for example IL-2, IL-12 and IL-15. The receptor consists of several receptor subunits (some shared with other cytokines), each of which serves different functions.
6. Transmembrane α-helix recptors, for example many chemokine receptors.

Intracellular signaling through the receptors of many cytokines is mediated through the Jak (Janus kinase)/ STAT (signal transducer and activator of transcription) pathways. There are four known Jak and 6 STAT molecules. Different cytokine receptors are associated with different Jak/STAT proteins. Ligand binding results in Jak activation and phosphorylation of Tyr residues. This in turn allows binding of STAT protein. STAT becomes phosphorylated, dissociates from the receptor and dimerizes, and activates gene transcription.

T cell subsets

Two major types of T cells are distinguished based on their cytokine production and their ability to stimulate cell mediated v. humoral immune responses, respectively [1]. Th1 cells produce IL-2, TNFß and IFN-γ and Th2 cells produce IL-4, IL-5, IL-10 and IL-13. In EAE, generally Th1 and other proinflammatory cytokines are associated with disease activity, while Th2 and anti-inflammatory cytokines with recovery, resistance and suppression of EAE. Th1 and Th2 responses are largely reciprocally inhibitory.

The role of cytokines in EAE can be studied in several approaches. The expression of these cytokines at the mRNA and protein levels in the CNS, cerebrospinal fluid (CSF), lymphoid organs and blood during the course of

EAE can be investigated. The effects of exogenous administration of the cytokine on the course of EAE, or in the adoptive transfer models, on the encephalitogenicity of T cells can be studied. Also, the effects of neutralization of the cytokine by antibodies or soluble receptors can be assessed. EAE can be induced in gene-deficient mice or mice transgenic for a cytokine. In addition, pharmacological or biological treatments that specifically inhibit a cytokine or a set of cytokines can be utilized.

Proinflammatory cytokines in EAE

IL-1 is a well-characterized proinflammatory cytokine with multiple effects on EAE. It is largely produced by activated monocytes/macrophages. There are two forms IL-1α and IL-1β, with similar actions and using the same receptors. IL-1β requires processing for activation by IL-1 converting enzyme (ICE or caspase-1). IL-1 is responsible for sickness behaviour (fever, withdrawal, shaking, lassitude, weight loss) associated typically with systemic infections but also with EAE [2]. IL-1 is present in brain [3, 4] and CSF [5] during the induction phase of EAE. Administration of IL-1 enhances disease severity [6] as does exposure of encephalitogenic T cells to IL-1 prior to transfer [7], a process that also inhibits T cell anergy [8]. IL-1 receptor antagonist in EAE successfully prevented or suppressed disease [6, 9, 10], an effect that, however, was not reproduced in an MS trial. Some immunomodulatory drugs such as linomide, which suppress EAE, suppress IL-1 production [11, 12]. Recently it was shown that IL-1 receptor gene deficient mice are resistant to EAE [13].

IL-2 is a pleiotropic cytokine is a key factor for expansion and survival of T cells. Th1 cells produce IL-2 but IL-2 may be produced in early, proliferative stages by T cells that have not differentiated to Th1 or Th2. In Th1 cells, IL-2 production decreases as IFN-γ production increases. Anergic T cells show repressed IL-2 gene expression [14] and costimulation acts in part by stabilizing IL-2 mRNA [15]. IL-2 is expressed together with other proinflammatory cytokines in the CNS during EAE. IL-2 stimulation of encephalitogenic T cells aggravates EAE [16] [17]. Antibody neutralization of IL-2 has had different results in the adoptive transfer and active model. In the former, it effectively blocked disease, while in the latter it had no significant effect. The same divergent results were noted when an anti-IL-2 receptor antibody was utilized [18]. Other therapies targeting the IL-2 receptor IL-2 bearing cells have used immunotoxin such as the chimeric fusion protein between IL-2 and pseudomonas endotoxin, which successfully suppressed EAE [19]. We also have used an IL-2-diphtheria toxin fusion toxin and significantly inhibited EAE in Lewis rats (Rostami et al,

unpublished observations). By increasing susceptibility of IL-2 stimulated T cells to apoptosis induced by high doses of antigen, IL-2 plays a role in this form of peripheral tolerance. On the other hand when supplied exogenously along with high doses of antigen, it exacerbates EAE. Recent small clinical trials of IL-2 receptor antibodies in MS have been promising [20].

IL-3 is a cytokine, which functions as a haematopoietic growth factor for cells of many lineages. It is produced by T cells and mast cells. The role of IL-3 in EAE has not been extensively investigated. IL-3 mRNA is identified in the central nervous system (CNS) of mice along with message for other proinflammatory cytokines at peak of disease and in relapse [21]. Encephalitogenic T cells produce higher amounts of IL-3 along with Th1 cytokines [22]. Moreover, IL-3 stimulation of donor T cells before adoptive transfer enhances their encephalitogenicity [23]. Experimental T-cell receptor-directed immunomodulatory interventions decrease IL-3 production of by encephalitogenic T cells, suggesting a role for IL-3 in disease pathogenesis [24]. Recently IL-3 was shown to stimulate an indirect recall antigen-specific IL-4 response in the spleen and in the blood, but not in lymph nodes of mice, via stimulation of mast cells to produce IL-4 [25].

IL-6 is a pleiotropic cytokine. It is produced by mononuclear phagocytes, T-cells, endothelial cells, astrocytes, fibroblasts, and other cells. It has been shown that astrocytes can also produce IL-6. Inducing stimuli include bacterial lipopolysaccharide (LPS) and IL-1. Although it is a growth factor for B cells, in the context of EAE, the main function of IL-6 is that of a proinflammatory cytokine. IL-6 is expressed in the CNS of mice or rats with EAE during the induction phase [4, 26-29]. Treatment of EAE with antibodies against IL-6 yielded conflicting results. Gijbels at al suppressed EAE using an anti-IL-6 antibody [30]. Interestingly this was not associated with IL-6 neutralization, as the IL-6 levels were actually increased. Willenborg et al, on the other hand, found no effect of anti-IL-6 antibody treatment on EAE [31]. Several studies have shown that IL-6 knockout mice are resistant to EAE [32-34]. This was shown to be due to a deficit in the production of Th1 and Th2 cytokines and in the expression of adhesion molecules. Administration of exogenous IL-6 to the knockout mice in the early stage restored typical EAE. Likewise, administration of the superantigen, staphylococcal enterotoxin, led to development of typical EAE in IL-6-deficient mice, via TNFR1 [35].

IL-7 was originally described as a growth factor for B cells, but more recently, it has been shown that IL-7 plays an important role in the development and function of both T and B cells. Little is known about IL-7 in EAE; however, the studies indicate a proinflammatory function in EAE. IL-7 is expressed in both spleen and lymph nodes of mice with chronic

relapsing EAE [36]. Stimulation of proteolipid protein (PLP)-reactive T cells with IL-7 enhanced proliferation and IL-2 production. Moreover, when transferred to naïve animals, these cells showed significantly enhanced encephalitogenicity [37].

IL-9 has been shown to be co-expressed with many other proinflammatory cytokines in EAE during the acute onset phase [21].

IL-12 was originally discovered as a cytotoxic lymphocyte maturation factor and as a natural killer (NK) cell stimulatory factor. However, its major role is in the development of Th1 responses. IL-12 bridges innate and adaptive immunity and has been involved in numerous normal and pathological immune responses. IL-12 is a disulfide-linked heterodimer with two subunits, p35 and p40 encoded by genes on different chromosomes. The p35 subunit is constitutively expressed at low levels in a variety of cells, while p40 is inducible in a restricted class of cells with antigen presenting function. IL-12 p40 is produced in excess, the ratio being up to 1000. Both subunits are necessary for IL-12 biological activity and IL-12p40 alone may be antagonistic. IL-12 is critical in the differentiation of T helper cells towards the Th1 phenotype. The maintenance of the Th1 responses also requires the synergy of IL-12 and costimulatory interactions between T cells and antigen presenting cells. IL-12 binds its receptor (IL-12Rb1 and IL-12Rb2, the latter being associated with the full-blown Th1 response) and triggers phosphorylation of the STAT-4 signal transduction molecule. STAT-4-deficient mice fail to respond to IL-12 and thus to develop efficient Th1 responses. The major effect of IL-12 on T cells is the stimulation of IFN-gamma production [38]. A solid body of evidence points to EAE and MS being diseases largely mediated by Th1 responses [4, 39-45]. Therefore, since the demonstration of the major role of IL-12 in Th1 responses, its involvement in EAE and MS has been investigated.

Expression of IL-12 in the acute lesions of MS was identified by Windhagen et al [46]. In monophasic EAE, IL-12p40 mRNA was found by *in situ* hybridisation and by RT-PCR in the CNS of Lewis rats only during the initial inflammation period [42, 47]. Jander and Stoll found that, IL-12p35 mRNA did not change throughout the course of EAE. IL-12 mRNA expression was found in the CNS and lymphoid organs in mouse EAE as well [48]. We also detected IL-12p40 mRNA in the CNS of PL/J x SJL/J F1 mice during the initial inflammatory phase and during the relapses. The identity of producing cells is unclear. Microglia, the CNS macrophages, are likely to represent a source of IL-12. We have also shown that astrocytes express IL-12p40 *in vitro* after stimulation with LPS or LPS plus IFN-gamma [49]. Other groups have also detected IL-12p40 mRNA by RT-PCR,

but failed to detect IL-12p35, and postulated that the modulatory actions of astrocytes on immune responses in the CNS may be due to astrocytes production of p40 without p35 [50]. However, in our experiments, we detected mRNA for IL-12p35 in astrocytes from different strains of mice, with our without stimulation with LPS (Constantinescu CS et al, manuscript in preparation).

Neutralization of IL-12 by antibodies has also been investigated in EAE. Anti-IL-12 antibodies (directed against the p40 subunit) prevented or suppressed disease in several models [51-53]. Moreover, the relapses (both spontaneous and superantigen-induced) and progression of disease were also suppressed by anti-IL-12 antibody treatment [52-55]. Agents that are known to suppress IL-12 have also been investigated in EAE. Pentoxifylline and related agents suppress EAE and are known to suppress a number of proinflammatory/Th1 cytokines including IL-12 [56, 57]. Captopril, which suppresses EAE [58] also suppresses proinflammatory cytokines including IL-12 [59]. Curcumin inhibits EAE by interfering with IL-12 signaling [60]. Atorvastatin, a cholesterol-lowering agent, has multiple effects on the immune system, including the ability to inhibit Th1 responses, via reduction in IL-12 production. Atorvastatin successfully blocked EAE [61].

IL-12 signaling is critical for EAE development. This has been demonstrated in STAT-4 deficient mice, which fail to develop robust Th1 responses and are resistant to EAE [62].

Another line of evidence for the role of IL-12 in EAE comes from experiments with exogenous IL-12 administration. Stimulation with IL-12 of antigen-reactive T cells prior to transfer rendered them more encephalitogenic [51, 63]. Administration of IL-12 induces relapses both in Lewis rats [64] and in the mouse model [52]. The mechanisms of induced relapses is unclear, but an upregulation of NO and proteases has been noted [65, 66]. Rats may have multiple relapses following exogenous IL-12, and eventually this leads not only to demyelination but also to axonal loss [65]. More than altering the severity and clinical course of EAE, exogenous IL-12 may also modify susceptibility to EAE. Resistant mice are rendered susceptible to adoptive transfer EAE by treatment of T cells with IL-12 prior to transfer [63]. Moreover, CpG-rich bacterial DNA overcome EAE resistance via IL-12 induction [67]. Experiments with IL-12p40 knockout mice showed that IL-12p40 is essential for EAE development [68]. The role of IL-12p35 is discussed below in the context of IL-23. An important question is: what are the mechanisms of induction of IL-12 in EAE? In addition to induction by bacterial products, induction by the interaction of T cells and antigen presenting cells is obviously important. In this context, the interaction of CD40 and CD40 ligand is probably a critical mechanism. Blockade of this interaction has been shown to suppress EAE and CD40Ligand knockout mice are resistant to EAE [69-71]. We also demonstrated that induction of IL-12 via this interaction plays a significant

role in EAE, because exogenous IL-12 reversed the suppression of EAE achieved by the blockade of the CD40-CD40 ligand [72]. The effects of IL-12 in EAE are also unclear. IL-12 induces IFN-gamma. However, IFN-gamma-deficient mice remain susceptible to EAE [73]. The role of IFN in EAE is discussed in a separate chapter. In IFN-gamma knockout mice, IL-12 neutralization prevented the induction of EAE, suggesting that the role of IL-12 in EAE may involve IFN-gamma-independent actions [68]. One candidate is NO, which is upregulated by IL-12. Other effects of IL-12 may involve the breakdown of tolerance. Exogenous IL-12 reverses both oral [74] and intravenous tolerance [75]. This effect may be more prominent in combination with IL-18 [76]. Also, neutralization of IL-12 facilitates oral tolerance [77].

IL-17 is a recently discovered cytokine with prominent proinflammatory function. IL-17 appears to play a significant role in a variety of inflammatory conditions [78-80]. Its role in EAE has not been amply investigated. It is expressed in EAE in IL-12Rb2 knockout mice during the inflammatory phase of the disease [81].

IL-18 has been identified as a major IFN-gamma inducing factor [82]. It has some similarity to IL-1 and needs processing by caspase 1 (ICE) for biological activity. IL-18 synergizes with IL-12 for many of its actions. The signalling pathways may be different. Both IL-18 and IL-12 may require each other for optimal activity as it has been shown that IL-18 Th1 induction is IL-12-dependent and *vice versa* [83-86]. IL-18 is expressed in the CNS as shown by RT-PCR in parallel to the disease course [47] and in proportion to the inflammatory infiltrate. Neutralizing antibodies against IL-18 suppressed EAE [87].

IL-23. Recently IL-23 was discovered as a cytokine involved in Th1 responses, which stimulates T cell for production of IFN-gamma with preferential effect on memory T cells. IL-23 shares the p40 subunit with IL-12 and has a unique p19 subunit. Producer cells are primarily mononuclear phagocytic cells and dendritic cells. IL-23 shares the IL-12Rb1 and binds another specific receptor. It activates STAT-4, like IL-12 [88]. The discovery of IL-23 led to re-evaluation of the previous work done with IL-12. The neutralizing experiments had used antibodies against IL-12p40 subunit and knockout experiments used IL-12p40 crossed with IL-12p35 knockouts. To determine whether neutralization of IL-12p35 affects EAE, we utilized an antibody against IL-12p35, which had previously been shown to have neutralizing activity and thus inhibit IL-12-induced IFN-gamma *in vitro* and *in vivo*. While ABH mice immunized for EAE treated with anti-IL-12p40 antibodies developed no disease, mice treated with either anti-IL-

12p35 antibodies or control rat IgG developed EAE with the maximal score of 4 (Baker, Constantinescu, Wysocka, unpublished observations) (Figure 1).

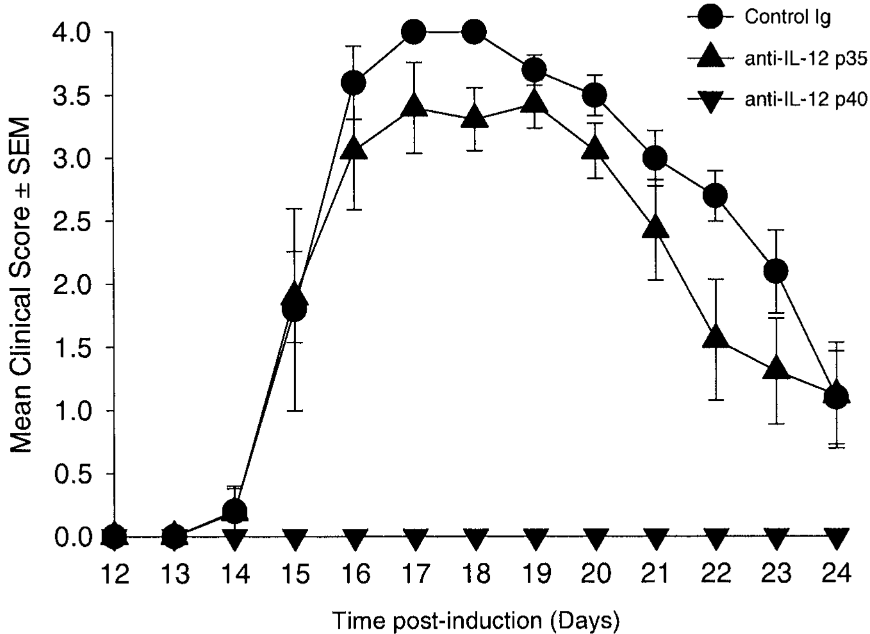

Figure 1. Clinical course of EAE in ABH mice treated with anti-IL-12 p35 or p40 antibodies, showing no suppression of EAE with anti-IL-12 p35 antibodies.

This indicates that in the effects of IL-12 in EAE the p40 subunit is essential. Experiments on knockout mice [89, 90] showed that IL-12p40 knockouts are resistant to MOG-induced EAE while IL-12p35 knockout mice are susceptible. Finally, experiments using the recently generated IL-23p19 knockout mice have confirmed that IL-23p19 is required for EAE development [91]. In these experiments, exogenous IL-12 in IL-12p40 knockout mice did not overcome the resistance to EAE, similar to our own experiments (Gran, Rostami, Constantinescu, unpublished observations). Further work will investigate the relative role of IL-12 and IL-23 in EAE. Experiments with cytokine knockouts are difficult to interpret because of the great redundancy in the cytokine network and the likely development of compensatory mechanisms in the presence of a deleted gene. The evidence from exogenous administration of IL-12 and that from its overexpression in CNS leading to inflammation suggests that IL-12 is, nevertheless important. Immune interventions targeting IL-12p40 are likely to be beneficial in EAE, regardless on the relative proportion of IL-12 and IL-23 they affect.

IL-27. The IL-12 family of cytokines is expanding. IL-27 was discovered as another proinflammatory cytokine with an IL-12p35-like subunit [92]. Its role in EAE has not yet been investigated.

TNF. This is a highly pleiotropic cytokine to which a multitude of effects of relevance to the pathology of EAE ad MS have been attributed. The tumor necrosis factor family of cytokines comprises TNF-α, lymphotoxin (LT)- α (LT) or TNF-β and LT-β. They are encoded by neighbouring genes forming part of the major histocompatibility complex. There are no major differences in the biological activities of TNF-α and lymphotoxin but TNF-α is predominantly produced by monocytes/macrophages (but also other cells including astrocytes and microglia) whereas TNF-β (LT-α) is produced by T cells. LT-β is a membrane protein that can bind LT to form a receptor related to the two TNF receptors (TNF-RI and TNF-RII). TNF (here used collectively for both α and β) is expressed in the CNS in MS [93] and can induce apoptosis in oligodendrocytes with potential resultant demyelination [93]. In EAE, TNF expression parallels the course of the disease [42, 93, 94]. Encephalitogenic T cells produce more TNF than nonencephalitogenic counterparts [43, 44]. Exogenous TNF administration can exacerbate the course of EAE [43, 95, 96], as does its overexpression in the CNS [97]. Moreover, overexpression of TNF-α in the CNS can lead to a spontaneous inflammatory disease with lymphocytic infiltration, gliosis and demyelination [98]. This overexpression can also lead to a primary oligodendrogliopathy with demyelination [99]. Neutralization of TNF by antibodies suppressed adoptive transfer EAE [100]. However, anti-TNF antibodies did not inhibit actively induced EAE in another experiment [101]. Soluble TNF receptor I successfully treated EAE. Moreover, this approach led to significant suppression of disease in mice with established EAE [100, 102]. In addition, a variety of pharmacological agents known to suppress production of TNF have been used successfully to treat EAE, although such agents may also suppress other cytokines and immunologically active molecules [103, 104]. The results from experiments with TNF knockout mice are interesting. In TNF-α and LT double knockouts on 129 x C57BL/6 backgrounds, EAE susceptibility and severity was not changed [105]. However, MOG induced EAE on the 129 x C57BL/6 background was delayed and milder, suggesting a role for TNF in the early inflammatory events [106]. The mice had less demyelination but more inflammatory infiltrates in the CNS than the wild-type littermates. On the other hand, single TNF-α knockouts on 129 or C57BL/6 background develop more severe EAE with enhanced inflammation and demyelination [107]. Investigating the role of the TNF-RI and TNF-RII receptors in the pathogenesis of EAE using knockout mice has revealed that the

susceptibility to EAE depends on TNF-RI (p55). In contrast, TNF-RII deficient mice exhibited more severe disease [106]. In summary, there is variation in the results with TNF knockout mice, which, in part, may be explained by the genetic background and the immunizing antigen used in the experiments. On the other hand, it is likely that the role of the TNF family of cytokine, a pleiotropic set of immune molecules, in EAE, is very complex and not restricted to enhancement of inflammation. For example, TNF is involved in apoptosis, in particular via TNF-RI. Genetic deletion of TNF or TNF-RI enhances survival of lymphocytes and may contribute to the inflammatory damage [108]. Moreover, TNF has multiple direct effects on CNS cells and its genetic absence may have numerous non-immunological consequences, which may influence the course of EAE. For example, TNF may be neuroprotective [109, 110] and it may contribute to synaptic strength [111].

Osteopontin. This proinflammatory molecule has been shown to induce Th1 responses. Osteopontin is expressed in the CNS in several disease states and it was identified in MS lesions by DNA microarray analysis. Because of its marker proinflammatory role, the finding was validated in EAE by assessing susceptibility in osteopontin knockout mice. It was found that osteopontin is required for induction of EAE [112]. This was confirmed in further experiments [113].

Anti-inflammatory cytokines in EAE.

While Th1 cytokines have been associated with EAE induction and severity, Th2 cytokines are associated with remission and suppression of EAE.

IL-4 is the critical cytokine for the development of Th2 responses [114]. IL-4 expression in the CNS has been associated with the remission stage of EAE [40] [94] [115]. Most Th2 cells producing IL-4 are nonencephalitogenic [44, 95, 116-118]. However, all such Th2 cells may not be efficient in their ability to suppress EAE [119]. Exogenous IL-4 administration or delivery by transfected T cells significantly ameliorates EAE [31, 117, 120, 121]. A simultaneous, competing Th2 response not directed against neuroantigens, characterized by high IL-4 (and other Th2 cytokines) production also ameliorates EAE [122, 123]. In addition, experimental immunomodulatory treatments of EAE including the induction of peripheral tolerance or agents such as retinoids are mediated via IL-4. [115, 124, 125]. Similarly, altered peptide ligands and glatiramer acetate induce IL-4 [126-128]. There is also evidence supporting a role for IL-4 in governing the resistance to EAE in mice. Studies using IL-4 knockouts are discussed below. We have shown that MBP-stimulated lymphocytes from relatively genetically resistant strains of mice immunized with mouse spinal

cord homogenate produce IL-4, while those of resistant mice produce IFN-γ. Moreover, *in vivo* neutralization of IL-4 reversed EAE resistance [129]. Experiments with IL-4 knockouts yielded conflicting results. Some investigators showed IL-4 knockouts to have more severe disease [130, 131], and mice deficient in STAT-6, the signal transduction molecule through which IL-4 acts, also had more severe disease [62] while others showed no differences from wild-type mice [68, 132, 133]. These differences may be related to different experimental systems or to compensatory mechanisms with utilization of default pathways triggered by the inactivation of cytokine genes [134]. IL-4 knockout mice do not present a deficit in entering the recovery stage of EAE. The results indicate that, while IL-4 is an important immunoregulatory cytokine in MS, it is not the only factor involved in the downregulation of the immune response in EAE.

IL-5 is a Th2 cytokine produced largely by T cells. Its main role is in eosinophil activation, and it acts as a B cell growth factor as well in mice, but not in humans. Because of the sensitivity of IL-5 assays and the more restricted cellular sources (more literally a Th2 cytokine), IL-5 has been used as a marker for Th2 responses [135]. It has been used in EAE in this context, for the determination of Th1 versus Th2 cytokine expression pattern. In contrast to IL-4, IL-13 and TGF-b (see below), addition of IL-5 to PLP-reactive T cells did not significantly modify their ability to induce transfer EAE [136]. IL-5 appears to be expressed along with other anti-inflammatory cytokines in the CNS in the resolution phase of EAE [40]. Some immunomodulatory treatments beneficial for EAE that suppress Th1 and induce Th2 responses (immune-deviation) either do not affect or enhance IL-5 with other Th2 cytokines [61, 104, 127]. In contrast, other strategies, including those inducing peripheral tolerance by anergy or deletion may downregulate IL-5 along with other Th2 cytokines [137]. Another potential immunomodulatory role of IL-5 in EAE may be the stimulation of CD5+ B cells, which have been attributed a regulatory function in EAE [138].

IL-10 is a thoroughly anti-inflammatory cytokine. It suppresses many proinflammatory cytokines, antigen presentation and NO production [139]. It is produced by T cells with the Th2 phenotype and by macrophages, but other cells including astrocytes and microglia can produce it. IL-10 is also induced by inflammatory stimuli, for example by LPS in endotoxic shock, and by IL-12 [140]. In most studies, IL-10 expression in EAE CNS corresponded to the onset of the recovery phase [4, 42]. Low expression of IL-10 in EAE is associated with a protracted course [29]. IL-10 may participate in a regulatory loop that governs susceptibility versus resistance to EAE [68]. *In vivo* delivery of IL-10 via an IL-10-expressing Vaccinia

vector [31] and adenovirus inhibited EAE. Also, exogenous *in vivo* IL-10 ameliorated EAE in Lewis rats [141]. Nasal administration of IL-10 also was successful in treating EAE in Lewis rats [142]. Immunomodulation of EAE with altered peptide ligands induces Th2 or Th0 nonencephalitogenic and protective cells producing IL-10 [143, 144]. Other therapeutic approaches including peipheral tolerance, IFN-β or –τ and glatiramer acetate (copolymer-1) treatment induce IL-10 [128, 145-148]. IL-10 is also protective against TNF induced relapses of EAE [96]. On the other hand, IL-10 given *in vivo* after transfer of encephalitogenic T cells failed to protect SJL/L mice against EAE and led to slightly more severe disease [149]. Similarly, antibody neutralization of IL-10 in this model immediately after cell transfer enhanced disease, while treatment of donor cells with IL-10 prior to transfer had no effect. These results need to be balanced against those using transgenic and knockout mice. Bettelli et al. showed that transgenic mice overexpressing IL-10 were resistant to EAE while IL-10 knockout mice develop more severe disease [133, 150]. Transfer of transgenic memory T cells overexpressing IL-10 under the control of the activation-inducible promoter of IL-2 both prevented and reversed EAE [151]. In another transgenic model expressing human IL-10 under the control of MHC class II, EAE was successfully prevented despite the development of neuroantigen-reactive T cells, indicating that the inhibitory effect of IL-10 is not on the generation but on the effector mechanisms of Th1 responses [152].

IL-13 is classed under the Th2 cytokines and has many similarities with IL-4 including activation of the STAT-6 signaling pathway. IL-13 is expressed in the CNS in the recovery phase of EAE [115]. It is also expressed in lymph nodes of rats protected from EAE by targeting the autoantigen to B cells [153]. *In vivo* delivery of human IL-13 via an IL-13 expressing vector significantly suppressed MBP-induced EAE. The suppression was not due to a major inhibition of development and responses of T cell reactivity to autoantigen, nor due to a blockade of autoantibodies against MBP. The mechanism involved was an inhibition of macrophage activation [154].

The IL-10 family of cytokines. A whole family of IL-10-related cytokines has been recently discovered, including IL-19, IL-20, IL-22 (IL-10-related T-cell-derived inducible factor or IL-TIF), IL-24 (also known as melanoma differentiation-associated antigen 7 or MDA-7) and IL-26 (AK155) [155]. Their function is not well known and their involvement in EAE has not yet been investigated. Not all of these cytokines may be immunosuppressive/immunomodulatory like IL-10. IL-19 and IL-20, for example, have been implicated in the pathogenic mechanisms of psoriasis, a Th1-mediated autoimmune disease, while IL-22/IL-TIF mediates acute-phase response signals in hepatocytes.

IL-25. Although related to IL-17, IL-25 is an inducer of Th2 responses [156]. Its role in EAE is yet to be determined.

TGF-β. This pleiotropic cytokine has multiple, largely anti-inflammatory, effects on the immune system. TGF-β is produced by T cells, macrophages and many other cells including astrocytes of the brain. TGF-β inhibits T cell activation, down-regulates expression of MHC class II [157, 158] and proinflammatory cytokines and their receptors, and induces T cell apoptosis [159, 160]. TGF-β is expressed in brain during both the acute and chronic phases of EAE [161]. Treatment of neuroantigen-reactive T cells with TGF-β prior to adoptive transfer prevents passive EAE [162, 163]. TGF-β administered systemically suppresses acute and chronic EAE [164-166]. The improvement occurs even when treatment is initiated in established disease. TGF-β also suppresses relapses of EAE [96]. Antibody neutralization of TGF-β enhances the severity of EAE both clinically and histopathologically [161, 167]. TGF-β has been implicated as an important cytokine of regulatory T cells, likely to play an important role in immunoregulation of EAE [168]. A variant of such cells, CD4+ T cells involved in the recovery after the acute phase of EAE in rats, the so-called post-recovery suppressor cells, secrete TGF-β, which down-regulates cytokine production by EAE effector CD4+ T cells [169]. In addition, the hallmark of Th3 cell clones generated by peripheral tolerance is the secretion of TGF-β [170]. The above works strongly support the concept of a prominent immunomodulatory and anti-inflammatory role for TGF-β in EAE. The exact action(s) through which it exerts this role or the sites of action are not known. It is likely that TGF-β operates at multiple levels and possible via multiple mechanisms.

Interferons. These subgroup of cytokines with multiple, important effects on EAE are discussed in another chapter.

Paradoxical effects of cytokines.
The EAE literature contains numerous paradoxes, in particular with respect to effects and mechanisms of actions of cytokines. This underscores the complexity and the redundancy of the cytokine network.

Anti-inflammatory effects of proinflammatory cytokines.
Several proinflammatory/Th1 cytokines have been found to have paradoxical and unexpected anti-inflammatory effects. IFN-γ is discussed in the chapter on interferons in EAE.

IL-1. Administration of IL-1 prior to induction of EAE down-modulates the disease. The mechanism probably involves increasing resting levels of endogenous corticosteroids [171]. **IL-2.** The high-affinity receptor for this cytokine is a putative marker for regulatory T cells. Immunological manipulations in EAE targeting the IL-2R may theoretically impair the function of regulatory T cells and thus enhance disease. In addition, the survival of regulatory T cells in the periphery is dependent upon IL-2, as IL-2 knockouts are deficient in regulatory T cells and are prone to various autoimmune/inflammatory phenomena [172-174]. **TNF.** The experiments with TNF knockout mice are discussed above. Maturation of dendritic cells with TNF led to their development into a tolerogenic population capable of inducing regulatory CD4+IL-10+ T cells [175]. TNF administration rescued TNF knockout mice from severe EAE [107]. These results may be explained in part by the proapoptotic activity of TNF. **IL-6.** Although antibody neutralization of IL-6 suppresses EAE, it does so by enhancing IL-6 levels [30]. **IL-12.** In IL-12p35-deficient mice, there is a significant up-regulation of many proinflammatory cytokines and NO [90]. The mechanisms have not yet been clarified. On the other hand, in vivo administration of IL-12 has enhanced the severity of disease, unlike in experimental autoimmune uveitis (EAU) where IL-12 can have a paradoxically protective role involving IFN-γ, NO and apoptosis [176].
Proinflammatory effects of anti-inflammatory cytokines.
Conversely, some paradoxical effects of Th2/anti-inflammatory cytokines in EAE are also known. **IL-4.** While in many studies neuroantigen-specific Th2 cells are nonencephalitogenic, there are exceptions: IL-4-producing Th2 cells transferred to naïve animals induced EAE-like CNS inflammation [177]. **IL-10.** *In vivo* treatment of SJL/J mice with IL-10 enhanced EAE severity [149]. **TGF-β.** Treatment of encephalitogenic T cells with TGF-β increased the severity of transfer EAE [178]. Moreover, in mice overexpressing in the TGF-β CNS, EAE was more severe [179]. These results may be tentatively explained by the multiple direct effects of TGF-β in the CNS including enhanced gliosis and amyloidogenesis and also by the

possibility that the beneficial effect of in EAE involves the peripheral immune cells before CNS invasion.

In conclusion, many proinflammatory cytokines are involved in the pathogenesis of EAE. Modulation of cytokine production during EAE may provide therapeutic intervention.

Chapter A15

THE ROLE OF INTERFERONS IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Hubertine Heremans & Alfons Billiau
Rega Institute for Medical Research, University of Leuven, Belgium

Abstract: Interferons, despite their common name, comprise a group of cytokines with quite different molecular structures, cellular receptors, biological effects, functions and applications. We here review studies directed at defining the role played by these molecules when they are produced endogenously or administered exogenously in the course of experimental autoimmune encephalomyelitis (EAE), a model disease considered relevant for the pathogenesis of multiple sclerosis (MS).

Studies on the role of Type II interferon, i.e. interferon-γ (IFN-γ), are almost unanimously indicative of a beneficial role, though this is in contrast to clinical observations pertaining to the role of IFN-γ in MS. Possible explanations for this discrepancy are considered in this review.

Interferon-β (IFN-β), one of the Type I interferons, also exerts a beneficial effect in EAE. In this case there is good correspondence with clinical observations, and studies in the animal model have contributed to providing possible explanations for these beneficial effects.

Our review also covers a limited number of studies on the apparently beneficial effect of treatment with another Type I interferon, namely IFN-τ, originally discovered as a pregnancy recognition hormone in sheep.

Keywords interferon, IFN-β (interferon-beta), IFN-γ (interferon-gamma), IFN-τ (inteferon-tau), multiple sclerosis, autoimmune disease, autoimmunity, autoimmune encephalomyelitis.

1. INTRODUCTION

Interferons (IFNs) are major contributors to the first line of antiviral defence. However, soon after their discovery in 1957 as antiviral factors, it became clear that they exert many other important effects on cells and organs. In fact interferons belong to the network of cytokines involved in the control of cellular functions, replication, and the immune response.

Over the years it became clear that interferons represent a large group of different proteins and glycoproteins some of which are products of a multi-gene family, whereas others are the products of separate genes (reviewed by De Maeyer & De Maeyer-Guignard [1]). The current nomenclature for interferons is based on sequence analysis of the IFN genes. Two major interferon superfamilies can be distinguished. Type I IFNs are all derived from the same ancestral gene represented as a cluster on the same chromosome and have sufficient structural homology to act via a common cell surface receptor. They comprise IFN-α, IFN-β, IFN-ω and IFN-τ. Details on the different species of Type I interferons and their cognate cell surface complex have been reviewed [1-3]. Type II interferon or interferon-γ (IFN-γ), originally discovered by Wheelock in 1965 [4] as an antiviral factor, is a lymphokine encoded by a single gene that displays no molecular homology with type I IFN's and uses a receptor on the cell membrane distinct from the common receptor for IFN-α and IFN-β, while sharing some important biological activities with the "classical" interferons. IFN-γ exerts multiple regulatory functions on cells of the immune system distinct from these of IFN-α and IFN-β. To date considerable progress has been made in the knowledge of the IFN receptors, molecular mechanisms of induction and of signal transduction in IFN-activated cells. For references the reader is referred to extensive reviews [2, 5-7].

Another aspect that became clear over the years is that interferons are involved in the pathogenesis of many diseases (reviewed in references [6, 8, 9]). Medical interest in interferons stems from the fact that they represent an important mechanism of nonspecific resistance as well as the specific immune response against a variety of micro-organisms. A deficient function of the sysem is generally believed to be instrumental in increased susceptibility to infection and cancer. Conversely, inappropriately high-level production of IFN-γ is considered to potentially act as a disease-promoting factor in inflammatory and autoimmune diseases such as MS, Crohn's disease, rheumatoid arthritis, myasthenia gravis and others.

Studies on the role of IFN in experimental autoimmune encephalomyelitis (EAE), which are the subject of this review, have made a major contribution to our current knowledge on the latter subject. EAE is a widely used model for multiple sclerosis (MS) which can be induced in

several genetically susceptible rodents and primates by active immunisation with myelin components together with one or several immune adjuvants or by adoptive transfer of encephalitogenic T lymphocytes, T cell lines or T cell clones sensitized to myelin basic protein (MBP) or myelin proteolipid protein (reviewed by Zamvill and Steinman [10] and Martin et al. [11]). The cytokine network plays a central role in initiation and regulation of the disease process. For some cytokines, there is unanimity in literature that they act either as disease promoters (e.g. TNF-α), for others that they downregulate the disease process. IFN-γ is rather exceptional in that both types of effects have been noted.

2. IFN-γ IN EAE

2.1 Effects of IFN-γ relevant to the pathogenesis of EAE

IFN-γ is a cytokine with several immunoregulatory activities (reviewed in ref. [6, 7]) that could in different ways contribute to the pathogenesis of EAE. IFN-γ is known as the most potent inducer of major histocompatibility complex (MHC) antigen expression on a variety of cell types in vitro, including cerebral vascular endothelial cells, astrocytes, and microglia, which in EAE have been shown to play an important role as presenters of central nervous system (CNS) antigen to encephalitogenic T cells (reviewed by [12, 13]). Class I and Class II MHC antigens are barely detectable in the normal CNS. By contrast, in animals with EAE, a marked elevation of these antigen expression mainly on microvascular endothelial cells, but also on infiltrating macrophages and microglia is observed, possibly induced by IFN-γ that is produced by the invading T cells. Following intrathecal injection of IFN-γ, MHC class II antigen expression was found to be increased on perivascular cells and various neuronal cells that do not normally express these proteins at detectable levels [14]. Although class II antigen expression on astrocytes has been conclusively demonstrated in vitro, in vivo studies have yielded conflicting results (see [12] for references). With some exceptions, most studies failed to detect class II antigen-positive astrocytes in the CNS of rats and mice during the disease process. However, class II antigen expression on astrocytes was reported in active MS lesions suggesting that the ability of astrocytes to function as antigen-presenting cells in vivo differs between rodents and humans.

Another activity of IFN-γ consists in influencing production as well as activity of other cytokines (TNF-α, IL-1) (see [5]) and other mediators of

inflammation that play an important role in the pathogenesis of EAE (reviewed by Hartung et al. [15]). This is of particular importance for mediators released by invading MPC, by endothelial cells and by resident astrocytes and microglia. For instance, production of proteases by these cells is thought to be responsible for destruction of myelin (reviewed by Opdenakker & Van Damme [16]. In addition, IFN-γ synergizes with TNF-α that is recognized to exert a disease-promoting effect in EAE, probably by increasing the number of receptors for TNF-α on a variety of different cells [5].

Adhesion to the endothelial cell wall and breakdown of the blood brain barrier are critical steps in regulating the recruitment of activated encephalitogenic T cells and the subsequent influx of additional inflammatory cells (mononuclear and polynuclear phagocytes) from the circulation into the CNS (reviewed in ref. [11, 17]). In vitro IFN-γ causes increased lymphocyte adhesion to microvascular endothelial cells derived from the CNS [18, 19] and may even promote migration through endothelial cell layers in vitro [20]. After intracerebral injection or microinjection of IFN-γ into the lumbosacral spinal cords of normal rats, an influx of lymphocytes and other inflammatory cells into the CNS was noted similar in pattern to that observed in early EAE [14, 21]. A compromised blood-brain barrier may underlie this action of IFN-γ. Morphological and permeability changes on primary cultures of human brain microvessel endothelial cells have been reported [22]. The process of transmigration is governed by adhesion molecules that are reciprocally expressed on endothelial cells and leukocytes (reviewed by Hickey [23]). There have been several reports of fluctuating patterns of elevated levels of the intercellular adhesion molecule-1 (ICAM-1) and vascular cell-adhesion molecule-1 (VCAM-1) on CNS endothelium during EAE and intergrins on leukocytes, corresponding to periods of clinical disease [24-26, 28] (and reviewed by Hartung et al. [17]. IFN-γ is among the cytokines that augment expression of the intercellular adhesion molecule-1 (ICAM-1) on cultured brain microvascular endothelial cells in vitro resulting in increased adhesion of MBP-specific encephalitogenic T cells to these endothelial cells [27, 28] expressing the integrin LFA-1 [29]. The involvement of IFN-γ in the expression of VCAM-1 in vivo has been demonstrated by the observation that anti-IFN-γ antibody treatment inhibits the upregulation of VCAM-1 in a passive-transfer EAE model [30].

As soon as leukocytes have transgressed the endothelial barrier, they encounter chemokines which control their further movement to the target and cause them to release proteases leading to breakdown of myelin. Chemokines, including RANTES, macrophage inflammatory protein (MCP-1) α, macrophage chemoattractant protein-1 (MCP-1), IFN-γ-inducible

protein-10 (IP-10) and chemokine receptors are upregulated in EAE, and their expression has been shown to correlate with disease severity and distribution of inflammatory infiltrates in the CNS (reviewed in ref. [31-33]). Chemokine secretion by endothelial cells and astrocytes is under the regulatory control by cytokines, particularly IFN-γ and TNF-α. The combination of IFN-γ and TNF-α was highly effective in inducing RANTES production *in vitro*: pretreatment with IFN-γ sensitized human glial cells to the induction of RANTES by TNF-α ([34, 35]. IP-10 which is highly expressed in the CNS of mice with an intact IFN-γ gene and EAE, was strikingly absent in IFN-γ knock-out mice. In vitro experiments confirmed that IFN-γ selectively stimulates astrocytes for IP-10 expression [36]. IFN-γ also upregulates MCP-1 gene transcription in vivo [37].

Several lines of evidence suggest that IFN-γ plays a deleterious role in immune-mediated demyelination (reviewed by Popko [38]). IFN-γ may have an indirect effect on the myelination process through the activation of invading MPC and microglial cells e.g. by release of TNF-α and NO [39, 40]. IFN-γ may also exert a direct deleterious effect on oligdendrocytes. Thus, application of IFN-γ to oligodendrocyte cell lines was found to cause molecular and morphological changes, and application to primary oligodendrocyte cultures resulted in apoptotic cell death [41, 42]. Furthermore, transgenic mice expressing IFN-γ in the CNS displayed a reduced myelination, reactive gliosis, macrophage/microglial stimulation, and an increase in MHC class I and class II expression in the CNS [43, 44] as well as increased susceptibility to EAE in mice that are normally resistant to EAE [45]

Finally, IFN-γ facilitates proliferation of the Th1 subset of murine CD4+ cells (see [46]), whereas it has a profound antiproliferative effect on the Th2 subset thereby reducing a key cellular source for IL-4 and IL-10. It has also been shown that IFN-γ blocks production of IL-10 by monocytes [47] and diminishes the ability to produce IL-4 in an immune response (see [46]), thereby reducing or interfering with the anti-inflammatory properties of these cytokines.

Taken together, IFN-γ exerts many effects on MPC, endothelial and resident cells of the CNS that are suggestive for a pro-inflammatory and thus predominantly disease-promoting role in EAE. Many of the pathological effects in the CNS that are observed in EAE and MS, including decreased myelination, increased gliosis, disruption of the blood-brain barrier function, increased MHC expression, stimulation of macrophages/microglial activation (reviewed by Popko [38]) are consistent with the known effects of IFN-γ.

2.2 IFN-γ production in EAE

Proliferation and activity of CNS antigen-specific $CD4^+$ lymphocytes of the Th1 phenotype are assumed to be the driving force in the development of tissue damage in EAE. Most significantly, EAE can be transferred to naïve animals using $CD4^+$ antigen specific Th1 cells isolated from animals suffering from EAE and anti-$CD4^+$ antibodies can inhibit induction of disease [10, 48]. IFN-γ is one of the cytokines produced by these cells after exposure to specific antigens or other stimuli, although in mice the suppressor/cytotoxic CD8+ subset of T cells and NK cells are also able to produce IFN-γ (reviewed by Young and Hardy [7]). In vitro studies have demonstrated that the effector T cells from rats previously challenged with MBP in complete Freunds adjuvant produce IFN-γ when cultured in the presence of the protein. As a contrast, disease suppressing splenic T cells found during the recovery phase of the disease failed to produce IFN-γ and inhibited IFN-γ production when added to challenged effector T cells [49].

Normally these IFN-γ producing cells do not transgress the blood-brain barrier at considerable levels and as such IFN-γ is generally undetectable within the CNS. Nevertheless, in response to infections of the CNS as well as in many immune-demyelinating disorders, CD4+ T cell-traffic across the blood-brain barrier does increase considerably (reviewed in ref. [23, 50]). Before performing their effector functions in the target organ, T cells must recognize Ag presented by antigen-presenting cells in the CNS. It has been shown that both infiltrating macrophages and microglia cells can efficiently present endogenous and exogenous Ags to T cells during the course of MOG-induced EAE, resulting in IFN-γ production [51]. Thus, the CNS-infiltrating CD4+ T-cells are the major source of local IFN-γ, thereby exposing neuronal and glial cells to the pleiotropic effects of IFN-γ. However, IFN-γ may have neuronal origins as well [52]. It should be noted that IFN-γ production by Th1 and NK cells is regulated by IL-12 and IL-18 in a synergistic manner and that the generation of CD4+ Th1 cells depends on the coordinate action of IL-12 and IL-18 with IFN-γ (reviewed in ref. [53-55]). An immunoregulatory role of IL-12 and IL-18 in EAE was demonstrated. IL-12 was found to enhance the in vitro activation of encephalitogenic T cells, and administration of IL-12 following adoptive transfer of PLP-stimulated lymph node cells accelerated, whereas blocking of endogenous IL-12 completely prevented disease progression [56-58]. IL-12 rendered otherwise resistant mice susceptible to EAE [59]. In vitro, neutralizing antibodies to IL-18 reduced T cell production of IFNγ in response to MBP epitopes. Moreover, neutralizing ant-IL-18 antibodies partially protected rats from EAE while shifting the Th1/Th2 balance in

favor of Th2 selection, accompanied by a marked reduction in the production of IFN-γ and TNF-α ([60]).

With sensitive methods, individual IFN-γ-secreting cells could be detected in peripheral lymphoid organs and in the CNS of animals with acute and passively induced EAE [61-68]. The presence of IFN-γ within the CNS paralleled disease severity and occurred predominantly on inflammatory cells, consistent with previous observations correlating disease progression with infiltrations of effector $CD4^+$ T cells, a major source of this cytokine. The highest levels of IFN-γ were observed at the peak of acute disease activity and during relapses [51, 69-71, 71]. IFN-γ levels were very low or absent in recovered and refractory animals. Thus, local IFN-γ production seems to correlate with the disease induction phase. Accordingly, one would tend to postulate that endogenous IFN-γ, produced during EAE, promotes disease, a prediction thas is supported by the various pro-inflammatory effects of IFN-γ (*vide supra*) and the observation that exogenous IFN-γ augments demyelination in rats given anti-myelin/oligodendrocyte glycoprotein antibodies [72]. Moreover, in a single study on patients with MS, systemic treatment with IFN-γ was associated with exacerbated disease symptoms [73-75]. In reality, however, direct and indirect evaluation of the in vivo effects of endogenous IFN-γ in EAE has yielded contradictory results.

2.3 In vivo evidence for the involvement of IFN-γ in EAE

Most of our current knowledge on the role of IFN-γ in EAE stems from experiments employing monoclonal antibodies to neutralize IFN-γ in vivo, and from experiments involving the use of IFN-γ or IFN-γR knock-out mice. In mice, treatment with neutralizing anti-IFN-γ antibodies led to a significant exacerbation of EAE induced by either active immunization or passive transfer and increased mortality even in strains which are relatively resistant to the disease [76-80] (reviewed by Billiau [81]). The disease-enhancing effect was observed only when the antibodies were given early i.e. shortly after immunization or at the time of cell transfer, but not at later times, indicating that the effect of anti-IFN-γ antobody is exerted early in the induction phase of the disease at a stage which follows the appearance of activated CNS-reactive T cells. Also, relapses whether actively induced or occurring spontaneously, are facilitated by administration anti-IFN-γ antibody in the disease-free interval [57]. Studies using both IFN-γ ligand and IFN-γ receptor knock-out mice have been unanimous in reporting that such mice are more sensitive to induction of EAE than their wild-type littermates [82-85]. These data indicate that, although local production of

IFN-γ in the CNS is maximal during the clinically active phases of the disease, the overall role of IFN-γ is to inhibit (limit) EAE contrary to what was expected from a pro-inflammatory and immunostimulatory cytokine. The enhancing effect of anti-IFN-γ is consistent with the observation that, in mice, exogenously administered IFN-γ ameliorated the actively induced EAE reaction and alleviated or delayed disease attacks [57, 76], again suggesting that systemic IFN-γ is protective. This protective role was not observed when EAE was passively transferred [80].

None of these experiments allow dissociating the effects of IFN-γ that is present in the periphery and that produced in the CNS (which may affect EAE pathogenesis in opposite ways). Approaches to deliver the cytokine to the CNS have yielded contradictory results. Local, intraventricular injection of IFN-γ in a rat model for EAE prior to the onset of disease signs failed to affect primary induction of EAE but facilitated relapse induction, suggesting that local IFN-γ promotes disease development [69]. Contradictory to these observations was a result reported by Voorthuis et al. [79], showing no change in disease course following systemic administration, whereas ventricular administration resulted in a complete suppression of symptoms. Intrathecal delivery of an HSV-1-derived vector engineered with the mouse IFN-γ gene protected C57BL/6 mice from chronic progressive EAE induced with myelin oligodendrocyte glycoprotein (MOG) 35-55 [86]. Mice treated before onset of EAE with the IFN-γ-containing vector showed a shorter duration of the disease with full recovery and a significant reduction of neuropathological signs of the disease such as demyelination and axonal loss. Mice treated with the IFN-γ-containing vector within 1 week after EAE onset partially recovered from the disease. In mice, overexpression of IFN-γ in oligodendrocytes, incidence, severity and histopathology of EAE were found similar to those in wild-type controls, but the transgenic mice did develop chronic neurologic deficits, whereas the disease completely resolved in the controls. [43, 45].

2.4 Mechanisms involved

The overall disease-preventing effect of endogenous IFN-γ in murine EAE is suggestive of an immunosuppressive or anti-inflammatory pathway, which supersedes the 'classical' pro-inflammatory, and immunostimulatory pathways. By what mechanism IFN-γ exerts this action in EAE remains unclear. The discrepancy in results coming from the in vivo studies has been rationalized by invoking a differential action of IFN-γ in the periphery and in the CNS [76, 83]. At the local level IFN-γ may promote inflammation, while at the systemic level it may act in an anti-inflammatory fashion. It was proposed that circulating IFN-γ restrains Ag-triggered T lymphocyte

proliferation and may promote apoptosis [83]. Therefore, it is plausible that elimination of IFN-γ from the circulation would have the effect of upregulating autoagressive T cells and worsening the EAE disease process. In contrast, intrathecal IFN-γ is considered likely to activate resident microglia and infiltrating MPCs cumulating in increased tissue injury [83]. This concept is strongly supported by the studies in transgenic mice that expressed IFN-γ in the CNS under control of an oligodendrocyte-specific promoter. [43, 44].

Several studies have documented a role for IFN-γ in the generation and action of MPC-like cells that can suppress proliferative responses of T cells to mitogens (reviewed by Billiau [81]. For instance, it has been shown that T cells from IFN-γ knockout mice display a markedly enhanced in vitro proliferative response to Con A and alloantigens, suggesting a critical role of IFN-γ in suppressing T cell proliferation [87]. Anti-IFN-γ antibody enhanced in vitro proliferation of cloned T cells and of T cell lines specific to myelin proteins [77, 88]. In addition, lymph node and spleen cell cultures derived from either IFN-γ knockout or IFN-γR knockout mice showed enhanced proliferation to Ag restimulation in vitro [84, 85, 89]. More recently, in vivo evidence was presented that IFN-γ downregulates EAE by inhibiting proliferation of activated CD4+ T cells [90]. A possible mechanism of IFN-γ-dependent suppression of T cell proliferation through mononuclear phagocytes is generation of H_2O_2 and prostaglandins, since both catalase and indomethacin can alleviate suppression [91]. IFN-γ also enhances the release of the active form of TGF-β by human mononuclear phagocytes [92]. On the other hand, TGF-β downregulates IFN-γ production by T effector cells [93]. It is therefore tempting to speculate that a feedback regulatory loop exists between IFN-γ and TGF-β, and that neutralizing IFN-γ may prevent TGF-β release.

Another pathway used by suppressor macrophages that can be activated by IFN-γ, is the generation of nitric oxide (NO). NO is considered as one of the major effector pathways in inflammatory demyelination (reviewed by Smith [94]. However, evidence for its role in the pathogenesis of EAE is fraught with internal contradiction. This is well illustrated by studies using selective inhibitors of inducible nitric oxide synthetase (iNOS) (reviewed by Willenborg [95]). These studies showed that iNOS-derived NO can in fact be both deleterious as well as protective in EAE. In general, for both rats and mice, NO-inhibitory treatments targeting passive EAE or the effector phase of actively induced EAE resulted in amelioration of disease, whereas treatments targeting the afferent arm of the response aggravated disease. However, the increased EAE severity in iNOS-knockout mice forms a clear indication of a predominantly protective role for NO [96, 97]. As a possible

mechanism it is suggested that IFN-γ-driven NO production by peripheral MPCs as well as by CNS-resident cells, such as microglia and astrocytes, might downregulate the development of EAE by limiting proliferation of autoreactive cells [51, 95]. MPC-derived NO is recognized as a strong inhibitor of T cell proliferation [98-100]. Inhibition of T cell proliferation in the CNS by NO might account for less severe EAE in wild-type than in IFN-γ knock-out and IFN-γR knockout mice. Consistent with this, peritoneal exudate cells from IFN-γR knock-out mice induced enhanced Ag-specific T cell proliferation compared with wild type mice, apparently because of their reduced production of NO [85]. In addition, T cells from IFN-γ knockout mice demonstrated enhanced in vivo proliferation as measured by BrdU incorporation [90]. APCs in the CNS may also limit the expansion of autoreactive T cells late in disease by downregulation of their MHC class II and costimulatory molecules through NO. [51]. IFN-γ-induced MHC-II expression on macrophages is inhibited by NO in vitro [101].

Another possible down-regulatory mechanism of IFN-γ in EAE is by induction or promotion of apoptosis in T lymphocytes. Many studies have demonstrated apoptosis of infiltrating cells in the CNS of animals with different models of EAE [102-105]. Blockade of IFN-γ inhibits cell death induced in effector cells by TCR linkage in the absence of accessory cells [106]. Furthermore, both in normal and in cultured malignant lympocytes, IFN-γ has been shown to exert contrasting effects, i.e. apoptosis or proliferation, depending on the level of expression of IFN-γ receptors: high level expression is associated with an apoptotic response, low level expression with a proliferative one [107]. Chu et al (2000) [90] noted that during EAE IFN-γ knock-out mice accumulate larger numbers of activated CD4+ T cells in their CNS than wild-type mice. The authors related this to increased proliferation and reduced apoptosis of these cells when exposed to antigen *ex vivo*. A similar situation was found to occur in mycobacterial infection in IFN-γ knock-out and wild type mice, and in this case it appeared that less proliferation and more apoptosis in the IFN-γ-competent mice was not a direct effect of IFN-γ, but was rather mediated by IFN-γ-activated MPCs [108]. On the other hand, by using an HSV-1-derived vector engineered with the mouse IFN-γ gene it has been shown that intrathecal delivery of IFN-γ can protect mice from EAE progression by inducing a fast clearance of encephalitogenic T cells infiltrating the CNS parenchyma via an apoptotic pathway [86].

IFN-γ produced locally in the CNS during EAE may also constitute a feedback control for the efficient clearance of the inflammatory infiltrate in the CNS. A fast and efficient phagocytosis of cells undergoing apoptosis by tissue-specific macrophages may limit direct tissue injury by preventing leakage of harmful (noxious) contents from the dying cells (reviewed in ref.

[109, 110]). Phagocytosis of apoptotic lymphocytes by macrophages, microglia, oligodendrocytes, and astrocytes has been described in histological sections of Lewis rat with EAE [111]. Different pro-inflammatory cytokines, including IFN-γ, have been shown to regulate the uptake of apoptotic cells by human macrophages *in vitro* [112, 113]. Using an *in vitro* phagocytosis assay, Chan et al. [113] demonstrated that pretreatment of microglia cells with IFN-γ led to an enhanced phagocytosis of apoptotic encephalitogenic T cells and to an increase of the proportion of microglial cells ingesting apoptotic cells.

Finally, the effect of IFN-γ on secretion of chemokines implicated in trafficking of leukocytes to the CNS may be involved. It was found that IFN-γ downregulates the induction of IL-8 by IL-1 and IL-2 in monocytes in vitro and may thereby act as a repressor of neutrophil chemotaxis in EAE [114]. In mice with intact IFN-γ response there is a strong up-regulation of the typical T cell and macrophage chemoattractants RANTES, IP-10, MCP-1α and MCP-1, in the CNS during EAE (reviewed in ref. [31, 71, 115]). In mice lacking the IFN-γ gene or the receptor for IFN-γ, MIP-2 and T cell activation gene–3 (TAC-3), both neutrophil-attracting chemokines, were strongly up-regulated, while RANTES and MCP-1 remained undetectable [89]. These mice showed an acute, lethal disease progression compared to limited disease in their wild-type littermates. McColl et al [116] reported that neutrophil depletion inhibits MBP-induced EAE in SJL/J mice and in MOG-induced EAE in IFN-γR knockout mice, suggesting a crucial role for PMN in the pathogensis of this inflammatory disease. Thus, the absence of down-regulation by IFN-γ may lead to a chemokine imbalance and lethal neutrophil invasion.

Taken together, despite many studies the protective effect of IFN-γ on EAE remains enigmatic. Several immunosuppressive effects of IFN-γ have been considered as possible explanations, but there is no clear cut evidence in favor of one of them no more than there is a claer-cut explanation for the contrasting effect of IFN-γ treatment in MS patients [73, 74]. The discrepancy may be due to differences in dosage, treatment schedules or timing. It may be connected to the fact that these patients had already undergone some overt clinical episodes and were in remission at the time of IFN-γ treatment. Further experimentation is required to determine the molecular mechanisms responsible for the seemingly contradictory roles of IFN-γ in EAE and MS.

3. INTERFERON-α AND -β IN EAE

Many different cells can produce type I interferons (IFN-α or -β, or both) during viral infection. IFN-α is a product mainly of monocytes and a subset of immature dendritic cells (reviewed by Liu et al. [117] and Asselin-Paturel et al. [118]. IFN-β can be produced by virtually any cell infected with virus or given another appropiate stimulus. In addition, several growth factors and cytokines have been shown to induce the synthesis of IFN-α and IFN-β (reviewed by De Maeyer & De Maeyer-Guignard [1, 119]). For example IL-2 can induce the production of murine IFN-α,β in mouse bone marrow cells. IFN-γ can also act as an inducer of IFN-α or IFN-β. IFN-α and β are comparable in their actions and interact with the same type I IFN receptor to transduce signals across cell membranes. IFN-α/β are implicated in both normal and neoplastic cell growth regulation and in modulating both innate and adaptive immune responses (reviewed by Brierley & Fish [120]).

3.1 In vivo evidence

Over the past years clinical trials have shown IFN-β to be beneficial in the treatment of relapsing-remitting MS (reviewed by Chofflon [121]). It ameliorates disease activity, reduces relapse frequency, decreases the number of inflammatory CNS lesions, but fails to achieve a satisfactory control of the disease evolution. Clinical trials with IFN-α have given varying results probably because differences in study design (study populations, type, dose and route of IFN-α, length of treatment) and seems to be less effective than IFN-β treatment (e.g. [122-124]).

In animals, many studies have shown that IFN-β can exert a down-regulating effect on the development of EAE. More than 15 years ago both natural and purified IFN-α,β were reported to partially inhibit both the active form of EAE and the adoptively transferred disease in rats when administered during the induction phase of the disease [125-127]. A similar effect was reported to occur in EAE induced in SJL/J mice [76, 128]. In these studies inhibition was obtained by systemic treatment or by adding the interferon to the T cell cultures before transfer. Even a decreased relapse rate was observed [128]. In addition, infection of mice with lactic dehydrogenase virus known to act as an inducer of IFN-α,β had a similar inhibitory effect [76, 129]. Human IFN-β on the contrary had no effect when similarly tested in the rat model, probably due to the known species specificity of interferons [127]. More recently, low doses of orally administered natural IFN-α,β has been shown to suppress clinical relapses and diminished inflammation in a murine model for chronic relapsing EAE [130, 131]. It should be noted that whether or not oral IFN administration can exert systemic effects is a

controversial issue and that the underlying mechanisms, if any, are unknown. IFN-β, given orally, also enhanced the suppressive effects of oral tolerance to MBP and PLP in both rats and mice with EAE [132]. In contrast, studies with intracerebrally injected IFN were inconclusive. Highly purified rat IFN-α,β was not effective in preventing or ameliorating the disease process in rats [133], while natural fibroblast-derived interferon exerted a beneficial effect [127]. This discrepancy may possibly have been due to the fact that the natural rat IFN used was of low purity and may therefore have contained several other effector molecules. Studies using recombinant IFN-β indicated that the timing and length of treatment determines wether IFN-β prevents or aggravates EAE in rats [134, 135]. Recombinant IFN-β effectively prevented acute EAE in rats provided that treatment was continued over a long period of time. Contrastingly, discontinuation of treatment during the induction phase or during the recovery phase led to the rapid onset of EAE with strongly enhanced severity and prolonged duration [135]. Finally, gene therapy by direct injection of IFN-β plasmid DNA–liposome complex into the CNS of mice with established EAE reduced the severity and onset of clinical disease [136].

Studies on the immunoregulatory activity of IFN-α in EAE are limited in number. Small doses of murine natural IFN-α or a cross-species-reactive human recombinant IFN-α, administered orally 3 times a week was found to suppress acute EAE in rats and clinical relapses in mice with CREAE and also to suppress adoptively transferred EAE [130, 137, 138]. Oral administration of IFN-α is superior to equivalent or higher doses of parenteral administration in suppression of clinical relapse in EAE [137, 138].

3.2 Mechanisms involved

The protective effect of IFN-β in EAE may stem from the immunomodulatory and anti-inflammatory properties of this type of interferon (reviewed by Yong et al ([139]). Among these properties is its ability to counteract the production and effects of IFN-γ. IFN-β inhibits IFN-γ secretion by activated lymphocytes. Suppression of EAE relapses by IFN-α,β and recombinant human IFN-α correlated with a decreased Con A stimulated IFN-γ secretion in spleen and lymph node cells [130, 131, 137, 138]. Similarly, Luca et al. [140] showed decreased production of IFN-γ by antigen-specific stimulated spleen and lymph node cells derived from mice with EAE after in vitro treatment with IFN-β. Likewise, IFN-β was shown to limit IFN-γ production by activated lymphocytes from both MS patients and controls [141]. IFN-α/β also antagonizes the effects of IFN-γ on

mononuclear phagocytes. In this respect, IFN-β inhibits IFN-γ-induced class II MHC antigen expression on the surface of antigen presenting cells in vitro, such as macrophages/monocytes, astrocytes and endothelial cells [142-145]. However, IFN-β failed to downregulate basal or IFN-γ-induced MHC class II expression on primary human astrocytes and microglial cells except at high concentrations. Thus, IFN-β lessens the capacity for antigen presentation to T cells and so might be expected to attenuate T-cell response.

Another anti-inflammatory effect of IFN-β is its ability to interfere with the process of recruitment and entry of inflammatory cells into the CNS, events which are regulated by adhesion molecules, cytokines, chemokines and metalloproteinases and are compromised in MS and EAE (reviewed by Brown [146]). Diminishment of clinical signs of EAE in IFN-β-treated mice was found to be associated with a major reduction in the formation of cellular infiltrates in the CNS [128, 134, 147]. IFN-β may directly act on the endothelium by reducing the expression of cytokine-induced (IFN-γ, TNF-α) adhesion molecules, such as ICAM-1 and VCAM-1, as observed in vitro on cerebral and extracerebral vascular endothelial cells and in vivo in rats with acute EAE [144, 145, 147-149]). On the other hand, IFN-β may also influence the interaction of activated leukocytes with brain endothelium [149]. It has been reported that pretreatment of activated leukocytes with IFN-β inhibited their transendothelial migration by down regulation of the expression of the integrins VLA-4 and LFA-1 [144]. In MS-patients treated with IFN-β, VLA-4 expression on selected T cell subsets from blood is also downregulated possibly due to the increased levels of soluble VCAM-1 observed in these patients [150, 151]. Furthermore, IFN-β may antagonize migration of leukocytes through brain vascular endothelium by down-regulating the production and activity of matrix metalloproteinases (MMPs), enzymes implicated in breakdown of the blood-brain barrier, activation and degradation of disease-modifying cytokines and myelin degradation in MS and EAE (review by Yong et al [152, 153]. Indeed, in vitro data have demonstrated that exposing activated T cells to IFN-β resulted in a significant decrease in MMP-9 expression associated with inhibited migratory capacity of T cells [149, 154, 155]. In addition, peripheral blood leukocytes from MS patients treated with IFN-β showed decreased levels of distinct MMP mRNA expression [156-158]. Chemokines that are specifically expressed in EAE tissue at the time of lesion formation (reviewed by Ransohoff [32]) may also be susceptible to IFN-β action and may hence account for reduced infiltration of the CNS by specific subsets of leukocytes. Recently, it was demonstrated that in vitro exposure of stimulated human peripheral blood monocytes to IFN-β differentially affects chemokine production. IFN-β decreased the production by monocytes/macrophages of IL-8, IP-10, MCP-1, MCP-3 and the monokine

induced by IFN-γ (Mig), but not of MIP-1α [159]. In addition, IFN-β has been found to selectively inhibit expression of mRNA for RANTES and MIP-1α and for their receptor, CCR5, on activated peripheral T cells obtained from MS patients [160]. Significantly reduced expression and production of chemokines and the chemokine receptors CCR5 and CXCR3 were found in sera and peripheral blood mononuclear cells from MS patients under IFN-β therapy [159-162]. Data on the regulation of chemokine expression by IFN-α or -β in relevant cell types during EAE are not available. Thus, an important part of the action of IFN-β may be its effect on the complex interaction between adhesion molecules, cytokines, chemokines and MMPs implicated in the blood-brain barrier function.

Autoreactive T cell proliferation in response to antigen presentation is a prominent feature of the induction phase of immune responses. One mechanism of protection by IFN-β may reside in its antiproliferative activity [131, 141], by which it may inhibit the expansion of autoagressive T cells. Mice induced for EAE and fed murine IFN-α or cross-reactive recombinant human IFN-α showed decreased mitogen- and antigen-specific proliferative response of spleen cells ex vivo [130, 131, 137]. Van der Meide et al [135] clearly showed that administration of rIFN-β to EAE rats in the early phase of the disease resulted in a strong (50 to 80%) reduction of encephalitogenic T cells in both spleen and inguinal lymph nodes. Discontinuation of treatment led to a rapid abrogation of the antiproliferative activity of rIFN-β followed by excessive expansion of encephalitogenic T cells, more severe perivascular inflammation in spinal cord tissue relative to control rats. Type I interferons may also serve as growth regulators of astrocytes at sites of reactive gliosis. An antagonistic effect of IFN-α and IFN-β on IFN-γ induced proliferation of human astrocytes in vitro has been reported [163].

Some studies have addressed the question of whether IFN-β could also act by inducing apoptosis. In fact, anti-apoptotic effects of both IFN-α and IFN-β on activated $CD4^+$ and $CD8^+$ T cells have been descibed (reviewed by Akbar et al. [164]), though these findings were not confirmed in more recent studies. Although IFN-β enhanced the expression of the death receptor CD94 (Fas/APO-1) on human antigen-specific T cell lines from MS patients, no clear evidence was found for direct induction of apoptosis as assessed by caspase activity [165]. In adoptively transferred EAE, T cell infiltration was reduced by IFN-β without apparent induction of apoptosis [166].

IFN-β might also redirect cytokine production by immune cells during EAE from a Th1 towards a Th2 profile and this seems to occur in the circulation as well as within the CNS (reviewed by Yong et al. [139]). Thus, IFN-β may lessen tissue damage by inhibiting release of TNF-α and LT by blood mononuclear cells, microglia and infiltrating macrophages [137, 166-

168], molecules reported to be toxic for oligodendrocytes [169, 170] and to be implicated in demyelination [171]. Adoptive transfer of T cells and CD8$^+$ T cells from non-immunized naïve donor mice fed with IFN-α suppressed actively induced EAE in recipients while decreasing TNF-α secretion in these recipients [172].

Alternatively, IFN-β may induce or promote secretion of immunosuppressive cytokines, such as IL-10 or TGF-β. A decreased production of IFN-γ and an increased production of IL-10 and/or TGF-β by T cells from EAE-induced mice treated with IFN-β or IFN-α have been reported [140, 173-175]. Furthermore, PBMC from MS patients treated with IFN-β showed enhanced gene expression of TGF-β and increased secretion of IL-10 [167, 176-178]. Both cytokines can upregulate TIMPs and decrease MMP biosynthesis (reviewed by Yong et al. [152]). IFN-β may also act by modulating the IL-10/IL-12 cytokine circuit in vivo, which has been suggested to control susceptibility to autoimmune disease [179]. McRae et al [180, 181] indicated that IFN-β abrogates Th1 cell differentiation in vitro while inhibiting T cell–dependent CD40-induced production of IL-12 from dendritic cells. In addition, in IFN-β-treated mice the cytokine profile in response to the priming immunogen was significantly skewed toward an increased production of IL-10 and concurrent decreased production of IL-12 [182]. This was accompanied by an aborted development of epitope spreading and disease progression.

Finally, IFN-β may keep in check ongoing immune response by restoring T suppressor cell function. It has been shown that human IFN-β augments suppressor cell activity in MS at least in vitro [183, 184]. A similar positive effect on suppression was reported with IFN-α.

Thus, in EAE and MS IFN-β may curtail immune activation by decreasing T-cell proliferation, by blocking IFN-γ production and by counteracting the peripheral actions of circulating IFN-γ directly, by downregulating the entry of encephalitogenic T cells and MPCs into the CNS and by downregulating the levels of pro-anti-inflammatory and upregulating anti-inflammatory molecules. All these biological activities of IFN-β are likely to act in concert to produce a therapeutic outcome.

4. IFN-TAU IN EAE

Interferon tau (IFN-τ), also called ovine trophoblast protein-1, is a member of the type I IFN family that was originally identified as a pregnancy recognition hormone, constitutively produced in high levels by trophoblast cells in ruminants during a very short period in early pregnancy (reviewed in ref. by [185, 186]). Its major function is to signal receptors in

the endometrium to maintain an appropriate milieu for the embryo. IFN-τ is not induced by viruses or double-stranded RNA, and its production is regulated differently from other Type I interferons. Like IFN-α and IFN-β it possesses antiviral, antiproliferative, and immunomodulatory activities (reviewed by Martal et al. [185]). In contrast to other type I IFNs, IFN-τ does cross species barriers and lacks the toxicity normally associated with high concentrations of these IFNs in vitro as well as in vivo [187]. It has been suggested that differential recognition by IFN-τ of the receptor complex at its N-terminus as well as interaction with different subunits of the type I IFN receptor accounts for its high biologic potency in the absence of associated toxicity [188]. Thus, IFN-τ seems promising as a therapeutic agent in cancer, viral infections and autoimmune diseases as it may be devoid of the adverse side effects associated with high doses of IFN-α and IFN-β.

IFN-τ was explored for its ability to prevent the development of EAE. Ovine IFN-τ was shown to provide protection as effectively as murine IFN-β against development of the acute form of EAE in NZW mice and chronic relapsing form of EAE in SJL/J mice, but without associated toxicity such as weight loss and leukopenia seen with IFN-α and IFN-β [186, 187]. The onset of EAE can be prevented by treating mice with IFN-τ before, during and shortly after immunization with MBP. However, when IFN-τ treatment was discontinued onset of disease was observed within 6-12 days [189]. In addition to protecting against both acute and chronic forms of EAE, parenteral or oral administration of IFN-τ was found to reverse ongoing relapsing EAE in SJL/J mice [190]. A histological evaluation of the CNS of these mice showed a subsiding lymphocyte infiltration and microglial activation. Finally, IFN-τ was also able to prevent superantigen-induced exacerbations of EAE [186, 187].

Evidence for mechanisms by which IFN-τ may prevent EAE include reduced proliferation of T cells specific for the autoantigen MBP [187]. Furthermore, anti-MBP antibody levels and proliferation of B cells in response to MBP were found to be reduced by IFN-τ either in vitro or in vivo in both chronic and acute forms of EAE [190]. Thus, IFN-τ seems to be able to suppress both the humoral and cellular responses in EAE. It has also been reported that amelioration of EAE by INF-τ is associated with induction of suppressor cells and suppressor factors [191]. Suppressor cells of the CD4 phenotype were found to be induced in vitro and in vivo after parenteral or oral administration of IFN-τ. Such IFN-τ-induced suppressor cells were found able to inhibit the MBP-induced proliferation of MBP-sensitized T cells, and injection of these suppressor cells into MBP-immunized NZW mice blocked induction of EAE [191]. In addition, the

CD4$^+$ suppressor cells produced both IL-10 and TGF-β, cytokines previously found to synergistically inhibit activation of MBP-specific T cells derived from EAE mice [191]. It was suggested that the amelioration of superantigen-induced reactivation of EAE seen after treatment with IFN-τ may also be related to induction of suppressor cells [187]. Like other type I interferons, IFN-τ can alter cytokine profiles as evidenced by its ability to reduce production of TNF-α, that has been suggested to be a mediator of EAE [170, 192]. IFN-τ also induces enhanced production of IL-10. Prolonged IFN-τ treatment of mice with EAE was shown to result in production of IL-10 in the circulation [189]. In addition, prevention of EAE by IFN-τ correlated with the induction of IL-10 and a concomitant reduction of the Th1 cytokines IFN-γ, TNF-α and IL-2 by MBP-stimulated spleen and lymph node cells [175]. Another proposed action by which IFN-τ reduces EAE is by interfering with MHC class II expression: IFN-τ was shown to downregulate IFN-γ-induced expression on murine cerebrovascular endothelial cells [193].

The lack of toxicity of IFN-τ and its ability to ameliorate EAE may have important implications for its potential use as an immunotherapy for inflammatory and autoimmune diseases such as MS.

Chapter A16

THE ROLE OF GROWTH FACTORS IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Amy E. Lovett-Racke and Michael K. Racke*
*Department of Neurology and *The Center for Immunology, UT Southwestern Medical Center, Dallas, Texas, USA*

Abstract: This chapter reviews the research done on the role of growth factor in experimental autoimmune encephalomyelitis and demonstrates the increasingly recognized therapeutic potential of growth factors in inflammatory demyelinating disease.

Key words: EAE, growth factors, demyelination, Neurotrophins, insulin-like growth factor-1, glial growth factors, fibroblast growth factors, ciliary neurotrophic factor.

1. INTRODUCTION

The development of tissues, maintenance of homeostasis, and responses to disease and injury are all dependent on effective communication between cells. Cells produce intercellular signaling molecules that provide this function. Peptide hormones, cytokines and growth factors are the three major categories of signaling molecules. This review will focus on the role of growth factors in the inflammatory demyelinating disease, experimental autoimmune encephalomyelitis (EAE). In particular, we will evaluate growth factors that were originally characterized in cells or tissues outside of the immune system. Neurotrophins (NT), insulin-like growth factor-1 (IGF-1), glial growth factors (GGF), fibroblast growth factors (FGF), and ciliary neurotrophic factor (CNTF) are among many growth factors that have recently been studied in EAE. These molecules have the potential to protect

the CNS from damage caused by inflammation, as well as the potential to repair the CNS after damage has occurred. Interestingly, many of these growth factors have been shown to effect the function of lymphocytes and/or be produced by lymphocytes which makes understanding their role in neuroimmune interactions valuable in understanding inflammatory demyelinating diseases, such as EAE and multiple sclerosis (MS).

2. NEUROTROPHINS

Neurotrophins are a family of neurotrophic factors that promote the survival, differentiation and maintenance of neurons. There are currently seven described neurotrophins, nerve growth factor (NGF), brain-derived neurotrophin factor (BDNF), neurotrophin (NT)-3, NT-4, NT-5, NT-6, and NT-7. The biologically active form of these molecules are non-covalent homodimers which interact with two classes of cell surface tyrosine kinase receptors. The high affinity receptors include trkA, trkB and trkC. NGF binds trkA, BDNF and NT-4/5 bind trkB, and NT-3 binds trkC. The low affinity tyrosine kinase receptor, p75, binds all of the neurotrophins with similar affinity, yet with different rate constants. The distribution of these receptors on different populations of neurons in both the central and peripheral nervous system determines the responsiveness of neurons to the various neurotrophins.

Although neurotrophins were originally described because of their effects on neurons, it has become increasely clear that their biological effects extend well beyond the nervous system. Recent studies have clearly shown a bi-directional link between the nervous system and the immune system . In particular, there is significant data illustrating the effects of NGF on both the innate and adaptive arms of the immune system. NGF has been shown to affect mast cells (Aloe 1977, Horigome 1993, Mazurek 1986), basophils (Bischoff 1992, Burgi 1996, Miura 2001), neutrophils (Boyle 1985), granulocytes (Matsuda 1988), and monocytes/macrophages (Matsuda 1988, Chevalier 1994, Ehrhard 1993, Flugel 2001, Kobayashi 2001) . In addition, NGF has been shown to affect the proliferation, differentiation and trk receptor expression by T cells and B cells (Otten 1989, Manning 1985, Thorpe 1987, Kimata 1991, Brodie 1992, Bodie 1994, Ehrhard 1993, Ehrhard 1994, Garacia 2001, Torcia 2001, Bracci-Laudiero 2002). These studies led to interest in the role of neurotrophins in EAE and MS.

Initial studies attempting to elucidate the role of NGF in EAE examined the expression of NGF and its receptors in the CNS during the course of EAE. In the Lewis rat model of EAE, the low affinity NGF

receptor (p75) was found to be dramatically upregulated on the walls of blood vessels and the surrounding neurons in perivascular regions during the acute phase of the disease (Calza 1997, 1998). Nataf's (1998) longitudinal study of p75 expression in the CNS of EAE-affected Lewis rats showed that p75 was first upregulated on the Purkinje cells and later on endothelial and perivascular cells, as well as myelinating cells, suggesting that p75/NGF may play a role in lymphocyte-endothelial cell interaction during EAE. Calza (1997) found that NGF content increased in some areas of the brain, but was decreased in the spinal cord during the peak of inflammation. Further analysis demonstrated that astrocytes and oligodendrocytes in the white matter of EAE-affected brains had an increased expression of NGF (Micera 1998). To determine if NGF was providing a protective effect in EAE, rats were immunized with NGF/CFA twice prior to EAE induction (Micera 2000). This resulted in the production of anti-NGF antibodies capable of binding endogenous NGF. The NGF-immunized rats had more severe disease, more inflammation, and had a reduction of NGF in the CNS, demonstrating the negative effect of NGF deprivation on EAE.

The obvious next step was to determine if administration of NGF might be beneficial in the treatment of EAE. Using a recombinant retrovirus encoding NGF, encephalitogenic T cells were generated that produced high levels of NGF and transferred into Lewis rats (Flugel 2000). Even though these cells maintained a Th1 phenotype, they were unable to induce disease and these rats had very little CNS inflammation. In addition, NGF was shown to upregulate p75 NGF receptor on monocytes and inhibited monocyte migration through TNFα-activated endothelial cells derived from brain vasculature in vitro.

The therapeutic effects of NGF were investigated in a primate model of EAE using the common marmoset (Genain 1997, Villoslada 2000). NGF was administered via continuous intracerebroventricular infusion beginning 7 days after immunization with recombinant MOG/CFA. NGF-treated marmosets had a lower incidence of disease, a delay in disease onset, and a markedly milder clinical course. Histopathological examination of the CNS showed minimal demyelination and inflammation. Both glial and inflammatory cells within the CNS were found to express the p75 and trkA NGF receptors. NGF-treated marmosets had similar lymphoproliferative responses to MOG and similar anti-MOG antibody titers, suggesting that NGF did not interfere with peripheral T and B cell responses. However, cytokine expression in perivascular inflammatory cuffs in NGF-treated primates showed minimal IFNγ and a significant increase in IL-10, suggesting that the phenotype of the infiltrating cells had shifted from Th1 to Th2.

The systemic administration of NGF was evaluated in the B10.PL mouse model of chronic-relapsing EAE (Arredondo 2001). Intraperitoneal injection of NGF during the first two weeks post immunization or adoptive transfer resulted in a delay in disease onset and decreased severity of disease. In vitro stimulation of encephalitogenic T cells with antigen in the presence of NGF did not alter the proliferation, cytokine production or the ability of these cells to transfer disease, suggesting that NGF alone was not capable of altering the phenotype of encephalitogenic T cells. However, when MBP-specific T cells were cultured in the presence of IL-4, NGF gene expression was increased similar to what had previously seen in cultured astrocytes (Brodie 1998). To determine if this was relavant in vivo, NGF levels were measured in splenocytes from mice who were given i.p. administration of antigen which is an immunization protocol that results in Th2 responses. Both NGF and IL-4 were produced by the splenocytes of these mice with a concommitant decrease in IFNγ, demonstrating that NGF production occurs in response to Th2-associated stimuli in vivo. Together, these studies provide several potential mechanisms by which NGF may ameliorate EAE, including inhibiting migration of inflammatory cells across the blood-brain barrier and altering the phenotype of potentially encephalitogenic T cells from Th1 to Th2.

3. CILIARY NEUROTROPHIC FACTOR

Ciliary neurotrophic factor (CNTF) was originally identified as a survival factor for neurons (Alder 1979). Subsequently, it has been shown to promote the differentiation, maturation and survival of oligodendrocytes (Barres 1993 and 1996). This observation led to the investigation of the role of CNTF in EAE. MOG35-55 induced EAE was more severe in CNTF-deficient mice and recovery was poor, but the incidence of disease was similar (Linker 2002). Histopathological analysis of the CNS following EAE induction in CNTF-deficient mice showed a 60% decrease in the number of proliferating oligodendrocyte precursor cells and apoptosis of oligodendrocytes was increased by 50% compared to wild-type mice. CNTF-deficient mice also had more vacuolar degeneration of myelin which is consistent with the loss of oligodendrocytes. Since TNFα had been previously shown to mediate oligodendrocyte apoptosis and loss of myelin, the effect of in vivo administration of anti-TNFα was evaluated in the CNTF-deficient mice. Anti-TNFα treatment did not alter the onset of the disease, but there was significantly less myelin vacuolation and

oligodendrocyte apoptosis. Interestingly, it was recently shown that a null mutation in the CNTF gene is associated with early onset MS with predominantly motor symptoms (Giess 2002). Consistent with the observation in the CNTF-deficient mice, there was no increase in the incidence of MS in CNTF-deficient individuals.

4. GLIAL GROWTH FACTOR

Since oligodendrocytes produce myelin in the CNS, growth factors that stimulate oligodendrocytes are obvious candidates as potential therapies for demyelinating diseases. Glial growth factor (GGF2) has been shown to promote the proliferation and survival of oligodendrocytes (Marchionni 1993, Rutkowski 1995, Canoll 1996, Milner 1997). GGF2 is a member of the neuregulin family of proteins within the epidermal growth factor superfamily (Gassmann 1997). The effect of human recombinant GGF2 on chronic relapsing EAE in mice was investigated (Cannella 1998, Marchionni 1999). Administration of GGF2 to mice during the first ten days after adoptive transfer of encephalitogenic T cells resulted in a delay in disease onset and reduced disease severity. If treatment with GGF2 was begun during the chronic phase of the disease, there was a decrease in the mean clinical score compared to the vehicle-treated mice. In addition, the relapse rate

in these mice was reduced and this was seen even after treatment was terminated. As anticipated, GGF2-treated mice showed more remyelination than control mice and had an increase in gene expression of MBP exon 2 which is only contained in an isoform of MBP produced during myelination. Analysis of cytokine expression in the CNS of GGF2-treated mice showed an increase in IL-4 in mice treated early and an increase in IL-10 in mice treated during the chronic phase of the disease, suggesting the GGF2 may enhance the expression of Th2 (regulatory) cytokines in the CNS.

5. INSULIN-LIKE GROWTH FACTOR-1

Insulin-like growth factor-1 (IGF-1) is a single-chain polypeptide with structural homology to pro-insulin. It is abundant in the circulation and is produced by many tissues, and it regulates the proliferation and

differentiation of many cell types. As reviewed in Folli (1996), IGF-1 has been shown to play a role in CNS development, injury repair, neurodegeneration, as well as a neuromodulator of some higher brain functions. However, it was the ability of IGF-1 to promote the survival of oligodendrocytes and the formation of myelin sheaths in vitro that prompted the investigation of IGF-1 in demyelinating disease (Mozell 1991, Barres 1992, 1993). The potential of IGF-1 to enhance myelin production was confirmed in transgenic mice that overexpressed IGF-1. These mice produced significantly more CNS myelin than wild-type mice (Carson 1993). In situ hybridization analysis of IGF-1 and associated receptors in EAE-affected rats showed that reactive astrocytes produced high levels of IGF1 and oligodendrocytes expressed IGF-1 receptors in areas of lesions (Liu 1994). This observation was also seen in cuprizone-induced demyelination and cryogenic spinal cord injury (Komoly 1992, Yao 1995).

The therapeutic potential of IGF-1 in EAE was first examined in the Lewis rat model. In the initial studies, IGF-1 was administered intravenously at the first signs of tail and hind limb weakness. This resulted in lower maximum clinical deficit scores and a faster recovery than the control animals. IGF-1 treatment appeared to reduce the permeability of the blood-spinal cord barrier as demonstrated by Evans-blue albumin transport. Further analysis illustrated that there were fewer and smaller inflammatory lesions in the spinal cord. Since IGF-1 had previously been shown to enhance myelin formation and promote oligodendrocyte survival in vitro, it seemed possible that IGF-1's therapeutic effects may be due to remyelination and oligodendrocyte proliferation. Following EAE induction in Lewis rats, the gene expression of several myelin proteins was up-regulated, including MBP, PLP and CNPase (Yao 1995). In addition, there appeared to be proliferating oligodendrocyte-like cells in the area of lesions. In the adoptive transfer model of Lewis rat EAE, which has CNS inflammation in the absence of demyelination, IGF-1 treatment decreased disease severity, lesion numbers, lesion areas, and the number of infiltrating cells (Liu 1997). This observation suggested that IGF-1-mediated remyelination was not responsible for the therapeutic effect of IGF-1 in the Lewis rat.

To determine how effective IGF-1 may be on relapsing-remitting demyelinating disease which is more reminiscent of multiple sclerosis, two murine models of EAE were evaluated. Li (1998) adoptively transferred MBP-specific T cells into SJL/J mice and administered IGF-1 on days 7-16 post-transfer. Again, there was a reduction in disease severity, number of lesions and size of lesions. Three-dimensional MR microscopy of placebo-treated mice showed abnormal signal throughout the brain that was not present in the IGF-1-treated mice or the normal control mice, which may

reflect changes in the permeability of cell membranes and/or the blood-brain barrier (Xu 1998).

Since IGF-1 can bind to insulin receptors, as well as IGF-1 receptors, the effect of IGF-1 on EAE in (PLXSJL)F1 mice was analyzed using both free IGF-1 and IGF-1 bound to IGF-1 binding protein-3 (IGF-1/IGFBP3) to determine if the dose of IGF-1 could be optimized without the development of hypoglycemia due to IGF-1 occupation of insulin receptors (Lovett-Racke 1998). Pharmacodynamic studies showed that free IGF-1 could be given at 10 mg/kg/day and IGF-1/IGFPB3 complex given at 100 mg/kg/day, which is equivalent to 20 mg/kg/day free IGF-1, without clinical signs of hypoglycemia. In the initial experiments, IGF-1/IGFBP3 complex was given twice daily during the first three weeks following transfer of encephalitogenic T cells. The disease onset was delayed in a dose-dependent manner, but disease severity was dramatically enhanced in the IGF-1/IGFBP3-treated mice. The histopathology of the CNS of these animals paralleled the clinical picture with minimal inflammation prior to the onset of clinical symptoms followed by increased inflammation, demyelination and axonal degeneration compared to placebo-treated animals. To determine if this increased disease severity was due to IGF-1 being bound to IGFBP3, treatment with free IGF-1 and the complex were compared. Comparison of equimolar amounts of IGF-1 or IGF-1/IGFBP3 administered during the first week post-transfer of encephalitogenic cells showed that free IGF-1 was only mildly beneficial and the complex provided no clinical benefit. When equimolar amount of IGF-1 or IGF-1/IGFBP3 were given at the onset of disease (days 12-20), IGF-1 had a similar disease course as controls and the complex-treated mice had more severe disease. Analysis of adhesion molecule expression within the CNS showed a decrease in ICAM-1 expression in IGF-1 and complex treated mice which may have played a role in the inhibition of inflammation early in the disease. In vitro culture of encephalitogenic T cells with IGF-1/IGFBP3 resulted in increased proliferation of these cells which may explain why disease was exacerbated in mice treated with this complex. In a second study that examined IGF-1 treatment in SJL/J mice, there was only a transient clinical amelioration of disease and a low level of remyelination after IGF-1 treatment during the acute phase (Cannella 2000). During the chronic phase of the disease, there was no evidence of enhanced remyelination or alterations in oligodendrocyte progenitor populations.

The previous studies in rodents showed that timing, dosage, and species may all be critical factors in using IGF-1 as a therapy in inflammatory demyelinating disease. An open-label, crossover study was performed in 7 MS patients to determine the safety and efficacy of recombinant human IGF-

1 (Frank 2002). After 6 months of therapy, there was no significant difference in MRI or clinical measures of disease activity in these patients. The drug was well tolerated, but accumulating data suggest that IGF-1 may not be as beneficial as anticipated in the treatment of inflammatory demyelinating disease.

6. FIBROBLAST GROWTH FACTOR

Like IGF-1, basic fibroblast growth factor (FGF-2) has been shown to stimulate the differentiation of precursor cells to mature oligodendrocytes in vitro (McKinnon 1990). FGF-2 is ubiquitously expressed in the periphery and is expressed by several types of neurons and astrocytes (Grothe 1991, Gomez-Pinilla 1992, Koshinaga 1993, Eckenstein 1994, Follesa 1994, Liu 1994, Reilly 1996). FGF-2 promotes neuronal survival and neurite outgrowth (Walicke 1986, Unsicker 1986). FGF-2 expression in the CNS of EAE-affected Lewis rats was analyzed as a means to assess the potential role of this molecule in inflammatory demyelinating disease (Liu 1998). FGF-2 gene expression was dramatically increased in the spinal cords of EAE-affected rats compared to normal rats. FGF-2 expression was limited to neurons in normal CNS tissue, but was prominent in microglia in the perivascular regions of EAE-affected tissues. Similarly, the FGF-2 receptor (FGFR1) was induced in activated microglia. The expression of FGF-2 on microglia had previously only been seen in vitro (Shimojo 1991, Presta 1995). Liu (1998) gave several potential roles for FGF-2 in EAE. First, it may regulate the activity of microglia in an autocrine manner. Second, it may induce the expression of IGF-1 which may enhance remyelination. Third, it may promote the proliferation of oligodendrocytes in the areas of demyelination. The effect of FGF-2 as a therapy has not yet been published.

7. NEUROPROTECTION BY ENCEPHALITOGENIC T CELLS

Both MS patients and healthy individuals have myelin-reactive T cells in their peripheral blood, suggesting that the presence of these autoreactive T cells is not sufficient to confer susceptibility to MS (Burns 1983, Martin 1990, Zhang 1992, Joshi 1993). It has been shown that the majority of MBP-reactive T cells in MS patients are less dependent on CD28-mediated

costimulation which is more characteristic of memory cells (Lovett-Racke 1998, Scholz 1998). However, several studies have shown that insults to the CNS such as peripheral nerve injury (Olsson 1992 and 1993), cerebrovascular disease (Wang 1992), and viral infection (Miller 1997) can lead to the expansion of myelin-reactive T cells in vivo. These findings have shifted our focus on the role of these cells from the belief that autoreactive T cells should be eliminated during thymic selection to understanding how these cells may become encephalitogenic in only a relatively small percentage of the population. There is increasing evidence to indicate that T cells may actually provide a neuroprotective effect in the event of nerve injury, thus providing a possible explanation why it may be beneficial to maintain a population of myelin-reactive T cells.

To evaluate whether lymphocytes effect the severity of motoneuron loss during nerve injury, Serpe (1999) performed facial nerve transections in severe combined immunodeficient (*scid)* mice and found that these mice had more motoneuron loss than the wild-type controls. Moalem (1999) showed that the protection against neuronal loss following mechanical nerve injury was due specifically to the presence of myelin-reactive T cells. This was demonstrated by showing that the transfer of MBP-specific, but not ovalbumin-specific, T cells protected retinal ganglion cells after optic nerve crush. These studies, as well as the observation that lymphocytes express many growth factors known to affect cells of the CNS, led to the hypothesis that lymphocytes may express molecules that protect neurons from damage. Since it was known that treatment with neurotrophins enhanced neuronal survival after injury, the role of neurotrophins produced by infiltrating lymphocytes following nerve injury was investigated. In rats that were immunized with MBP one day prior to ventral root avulsion, there was a 50% higher survival rate of motoneurons in immunized animals versus controls (Hammarberg 2000). Both BDNF, NT-3 and glial cell line-derived neurotrophic factor were expressed by T and NK cells in the spinal cord. The expression of these neurotrophins was not limited to the encephalitogenic T cells, but was actually higher in the non-specifically recruited T cells. In the optic nerve crush model of nerve injury, it was shown that after local administration of a tyrosine kinase inhibitor known to prevent autophosphorylation of NT receptors, the neuroprotective effect of anti-MBP T cells was diminished (Moalem 2000). These studies suggests that production of neutrophins by CNS infiltrating T cells may limit neuronal damage during injury.

8. CONCLUSION

Theoretically, several of the growth factors previously discussed seem like ideal candidates as therapeutic agents in the treatment of inflammatory demyelinating disease. IGF-1, GGF2, FGF are all capable of influencing the function of oligodendrocytes, which are the myelinating cells of the CNS. Since the myelin sheath appears to be the primary target of inflammatory cells in EAE and MS, these molecules possess the potential to enhance remyelination and oligodendrocyte proliferation. NGF and CNTF are potent neurotrophic factors that promote the survival of neurons. Since it appears that axonal loss following demyelination may be responsible for the permanent deficits seen during the progressive phase of MS, these agents seem like obvious candidates to limit axonal damage. However, these initial studies summarized here using these growth factors as treatments for EAE have demonstrated how vast the effects of these molecules are outside of the nervous system. In particular, these growth factors can have profound effects on immune cells which may alter the encephalitogenicity of lymphocytes in a positive or negative manner. Consequently, it has become increasingly clear that understanding the role that these growth factors play in both the nervous system and immune system are critical in determining how effective they may be as therapies for inflammatory demyelinating disease.

Chapter A17

THE CHEMOKINE SYSTEM IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Andrzej R Glabinski[1] and Richard M. Ransohoff[2]
1) Department of Neurology, Medical University, Lodz, Poland, 2) Department of Neurosciences, Cleveland Clinic Foundation, Cleveland, OH, USA

Abstract: Chemokines chemoattract selected populations of inflammatory cells towards sites of inflammation in a gradient-dependent fashion, and also activate both recruited and resident inflammatory cells. Chemokines act on target cells through G-protein-coupled seven-transmembrane-domain receptors. High expression of several chemokines was found in the CNS during EAE. Cells expressing these chemokines were predominantly astrocytes and macrophages/ microglia. In addition to chemokines, expression of several chemokine receptors was reported in EAE. Amelioration of EAE by anti-chemokine antibodies and studies in knock-out mice confirm the important roles of some chemokines in EAE pathogenesis. In the last several years many reports have been published addressing chemokine expression in multiple sclerosis. These results resemble results obtained earlier in EAE. Taken together, these data suggest that chemokine system may be a promising target for future treatment methods of multiple sclerosis.

Key words: Chemokines, chemokine receptors, experimental autoimmune encephalomyelitis, neuroinflammation, inflammatory cell migration

Experimental autoimmune encephalomyelitis (EAE) is a model autoimmune disease of the central nervous system (CNS) induced in susceptible strains of experimental animals with myelin, myelin proteins or peptides. The classical autoantigens used for EAE induction are myelin basic protein (MBP), proteolipid protein (PLP) and myelin oligodendrocyte glycoprotein (MOG). This model may be induced in appropriate strains of mice, rats, guinea pigs and nonhuman primates including rhesus and marmoset species. The advances made by studying this experimental disease resulted from the observation that the pathology of EAE resembles in some

respects the pathology of the major human demyelinating disease – multiple sclerosis (MS). Typical histopathological hallmarks of the initial phase of both diseases are perivascular mononuclear inflammatory foci disseminated in the CNS. The mechanism of migration of inflammatory cells from blood to the CNS has been studied for many years and it remains incompletely understood. Our knowledge about this process has significantly grown since the observation that chemoattractant cytokines – chemokines may play an important role in inflammatory cells homing to the CNS.

CHEMOKINES AND THEIR RECEPTORS

Chemokines and their receptors are the principal determinants of leukocyte-type and organ specificity within inflammatory foci. Chemokines chemoattract selected populations of inflammatory cells towards sites of inflammation in a gradient-dependent fashion, and also activate both recruited and resident inflammatory cells. The chemokine family can be divided into four separate subfamilies (CXC, CC, C, CXXXC) according to the position of the first two cysteines near the N-terminus. Beyond these differences in structure, there are also functional differences between chemokine subfamilies. The largest subfamilies are CXC and CC chemokines. In CXC chemokines the first two cysteines are separated by one additional amino acid. The CXC subfamily can be further divided into two groups, one with ELR (glutamate-leucine-arginine) motif preceding the first cysteine and another without it. CXC chemokines with ELR are primarily chemoattractant for neutrophils, while several other non-ELR chemokines attract mainly activated lymphocytes and monocytes. SDF-1/CXCL12 is an outlier among chemokines in that it acts towards many non marrow-derived cells in addition to most leukocytes. CC chemokines have the first two cysteines adjacent to one another. They attract principally mononuclear leukocytes. The C subfamily consists of lymphotactin which is a potent T cell chemoattractant. The single member of CXXXC subfamily is fractalkine, a chemokine with three amino acids intervening between the first two cysteines. Fractalkine is the prototype tethered chemokine with a long stalk attached to the cell membrane; CXCL16 also possesses this unusual structure. After cleavage fractalkine may chemoattract mononuclear inflammatory cells [1, 2]. In the last few years several new chemokines were described by independent research teams. They have been known by different names. This complicated chemokine nomenclature. To solve this problem, a consensus meeting at the Keystone Chemokine Conference (Keystone, CO, January 18-23, 1999) proposed a new nomenclature for the chemokines (Table 1).

Table 1. New nomenclature for mouse chemokines (Keystone Chemokine Conference, Keystone, 01.18-23,1999).

Systematic name	**Mouse ligand**	**Receptor(s)**	**Systematic name**	**Mouse ligand**	**Receptor(s)**
CC CHEMOKINE FAMILY			**CXC CHEMOKINE FAMILY**

CCL26	Unknown	Unknown			
CCL27	CTACK, ALP	Unknown			

Chemokines act on target cells through G-protein-coupled seven-transmembrane-domain receptors. They are designated as CXCR, CCR, XCR and CXXXCR. The largest family of chemokine receptors are CCR receptors consisting at present of ten well-characterized members. CXCR family of receptors consists of five receptors described to date (CXCR1-CXCR5). There are only two XCR receptors and one CXXXCR receptor. Classically chemokine receptors are divided into four different subgroups: shared, specific, promiscuous and viral [3]. Most of the chemokine receptors belong to the first group because they bind more than one chemokine ligand. A typical example of this kind of chemokine receptor is CXCR2 that binds as many as seven CXC chemokines with ELR motif. The example of specific receptor is CXCR4 that binds SDF-1/CXCL12. Duffy blood group antigen (DARC) is a promiscuous chemokine-binding molecule (distinct from a receptor), which can bind several chemokines belonging to CXC and CC subfamilies but does not signal. Many viruses including *Cytomegalovirus CMV US28* and *Herpes virus saimiri HSV ECRF3* encode chemokine receptors. The role of virally encoded chemokine receptors is unknown [4].

CHEMOKINES IN EAE

Initial studies describing chemokine expression in EAE were published less than ten years ago [5, 6]. They showed that chemokines MCP-1/CCL2 and IP-10/CXCL10 were transiently upregulated in mouse and rat models. In the mouse model astrocytes were the cellular source of chemokine expression confirmed by colocalization studies using *in situ* hybridization and immunohistochemistry for GFAP [7, 8]. Later other chemokines including RANTES/CCL5, MIP-1α/CCL3, MIP-1β/CCL4, TCA-3/CCL1, IP-10/CXCL10, MCP-1/CCL2, KC/CXCL1-3 and MCP-3/CCL7 were also detected in the spinal cord during passive transfer mouse EAE [9]. Encephalitogenic T cells expressed RANTES/CCL5, MIP-1α/CCL3, MIP-1β/CCL4 and TCA-3/CCL1 in that study [9]. In murine EAE expression of chemokines RANTES/CCL5, MIP-1α/CCL3 and GRO-α/CXCL1 correlated with the intensity of CNS inflammation [10]. Analyzing the kinetics of chemokine gene expression at the beginning of EAE we suggested that chemokines amplify but not initiate invasion of CNS by inflammatory cells from the blood [11]. In chronic relapsing EAE we observed increased expression of MCP-1/CCL2, IP-10/CXCL10, MIP-1α/CCL3, RANTES/CCL5 and GRO-α/CXCL1 at the beginning of spontaneous disease relapse. Chemokines MCP-1/CCL2, IP-10/CXCL10 and GRO-α/CXCL1 were expressed by astrocytes in the vicinity of inflammatory foci,

whereas MIP-1α/CCL3 and RANTES/CCL5 were expressed by inflammatory cells [12]. In variant of EAE in BALBc mice characterized by pronounced neutrophil accumulation upregulation of MIP-1α/CCL3, MIP-2/CXCL2-3 and MCP-1/CCL2 was reported. The main cellular sources of MIP-1α/CCL3 and MIP-2/CXCL2-3 in this model were activated astrocytes. Neutrophils produced MIP-1α/CCL3 and MCP-1/CCL2 [13]. In an EAE model enhanced by focal brain injury (cryolesion) significant upregulation of chemokines MCP-1/CCL2 and MCP-5/CCL12 was observed at the beginning of the disease. Interestingly, expression of RANTES/CCL5, GRO-α/CXCL1 and MIP-1α/CCL3 was not elevated in these animals. These results suggest that MCP-1/CCL2 and MCP-5/CCL12 are selectively involved in enhancement of autoimmune inflammation by focal cortical injury [14].

Recently expression of relatively new chemokines was analyzed in EAE. High expression of C10/CCL6 was found in the CNS during MBP-induced murine EAE. Cells expressing this chemokine were predominantly macrophage/microglia and foamy macrophages present in perivascular cuffs and within the demyelinating lesions [15]. Expression of CXC chemokine I-TAC/CXCL11 was very low early after induction of EAE, but was upregulated at day 14 post-immunization. By day 20, expression of I-TAC/CXCL11 in EAE returned to low baseline levels [16].

CHEMOKINE RECEPTORS IN EAE

In addition to chemokines, expression of several chemokine receptors was reported in EAE. In the first study in acute rat EAE upregulation of CXCR4, CCR2, CCR5, CCR6 and CX3CR1 was observed in the lumbar spinal cords [17]. In chronic-relapsing EAE expression of CXCR2 and CXCR4 was significantly increased in the spinal cord during relapses. It was suggested that CXCR2 is expressed by migrating inflammatory cells, whereas CXCR4 is expressed mainly by CNS parenchymal cells [18]. We also observed upregulation of CC chemokine receptors CCR1, CCR2 and CCR5 during the initial attack and relapse of the same chronic EAE model [19]. CCR5 was expressed by inflammatory cells invading the spinal cord. CC chemokine receptors associated with Th2 T-cells (CCR3 and CCR4) were not detected during the active stages of this model [19].

It was reported recently that CCR6 and its ligand MIP-3α/CCL20 are upregulated in the CNS during EAE. MIP-3α/CCL20 is a potent chemoattractant for dendritic cells, which infiltrate the spinal cord in this model [20]. Moreover, in the rat acute EAE model CXCR3 and all its ligands IP-10/CXCL10, Mig/CXCL9 and I-TAC/CXCL11 were detected in the spinal cord. In the draining lymph nodes only expression of CXCR3, IP-

10/CXCL10 and Mig/CXCL9 was detected [21]. A CC chemokine receptor CCR7 associated with lymph-node trafficking, as well as CXCR3, were found by immunostaining on encephalitogenic T cells isolated from mice with EAE [22]. Immunohistochemistry localized ligands for these receptors, ELC/CCL19 and SLC/CCL21 within inflammatory cuffs in CNS parenchyma. This is the first observation suggesting that these chemokines are also involved in lymphocyte migration to the CNS during EAE, in addition to their documented role in regulation of lymphocyte homing to lymphoid tissue [22].

In acute EAE encephalitogenic CD4+ T cells isolated from the CNS expressed mRNA for chemokine receptors CCR1 – CCR5 [23]. Encephalitogenic T cells isolated from spleens of the same animals did not express CCR1, but expressed other analyzed CC chemokine receptors. Neutralization of the CCR1 ligand, MIP-1α/CCL3 resulted in lower accumulation of encephalitogenic T cells in the CNS [23].

Depletion of gamma-delta T cells reduced expression of CCR1, CCR2, CCR3 and CCR5 at the beginning of EAE. Later levels of CCR2, CCR3 and CCR5 were higher than in control EAE mice. Similarly expression of chemokines RANTES/CCL5, MIP-1α/CCL3, MIP-1β/CCL4, MIP-2/CXCL2-3, MCP-1/CCL2, eotaxin in gamma-delta depleted mice was reduced at the onset of EAE [24]. Levels of CXCR2, CXCR3, CCR1, CCR5 and CCR8 in spinal cords were significantly reduced by protection from EAE with altered peptide ligand (APL). In APL-treated mice CCR3 and CCR4 epitopes were found mostly on lymphocytes supporting the hypothesis that Th1 cells are down-regulated by APL treatment [25].

CHEMOKINES IN GENETICALLY MODIFIED ANIMALS WITH EAE

In interferon gamma knockout (GKO) mice with EAE expression of IP-10/CXCL10 was selectively diminished in the spinal cord. This observation suggests that expression of IP-10/CXCL10 in EAE is induced by IFN-γ [26]. Upregulation of neutrophil-attracting chemokines MIP-2/CXCL2-3 and TCA-3/CCL1 was observed in IFN-γ and IFN-γ receptor-deficient mice. In those models expression of MCP-1/CCL2 and RANTES/CCL5 was undetectable during EAE [27]. Moreover, in the CNS of GKO mice PCR analysis showed very low levels of I-TAC/CXCL11 throughout the time course of the disease, although these mice developed severe EAE [16].

It has been recently demonstrated that chemokine and chemokine receptor expression during EAE follows a distinct pattern in cytokine deficient mice [28]. In TNF-α knockout mice expression of MIP-1α/CCL3

and MIP-2/CXCL2-3 was almost completely absent, while expression of RANTES/CCL5 and IP-10/CXCL10 revealed strong reduction, and the decrease of MCP-1/CCL2 was moderate (50%). IFN-γ deficient mice displayed pronounced reduction of RANTES/CCL5 and IP-10/CXCL10 and moderate decrease in MIP-1α/CCL3, MIP-2/CXCL2-3 and MCP-1/CCL2 [28]. Other analyzed knockout mice (IL-4 and IL-10 KO) showed less remarkable diminution of chemokine expression during EAE. In IL-4 deficient mice only a 50-60% decrease of RANTES/CCL5 and MIP-1α/CCL3 was found, whereas in IL-10 KO mice 50-60% reduction was detected for RANTES/CCL5, IP-10/CXCL10, MIP-1α/CCL3 and MIP-2/CXCL2-3 [28]. In addition to chemokine expression, expression of chemokine receptors was also analyzed in those experiments. Expression of CCR1, CCR2 and CCR5 receptors was diminished in TNF-α and IL-10 knockout mice. Lack of IL-4 or IFN-γ weakly affected expression of these three chemokine receptors [28].

Chemokine and chemokine receptor expression was also analyzed in the CNS of TCR BV8S2 transgenic mice expressing BV8S2 specific for the myelin basic protein (MBP)-NAc1-11 peptide [29]. In the spinal cord of these mice increased expression of chemokines RANTES/CCL5, IP-10/CXCL10 and MCP-1/CCL2 as well as chemokine receptors CCR1, CCR2 and CCR5 was found. This expression correlated with pronounced cellular infiltration of the target organ. Transgenic mice protected from EAE by vaccination with heterologous rat BV8S2 protein showed amelioration of inflammatory infiltrates in the spinal cord. This amelioration correlated with a profoundly reduced expression of chemokines and their cognate receptors in the spinal cords of treated animals [29].

EAE IN ANIMALS WITH GENETICALLY MODIFIED CHEMOKINE SYSTEM

Recently two publications showed that CCR2 plays an important role in the pathogenesis of EAE [30, 31]. Mice without CCR2 did not develop clinical signs of EAE and did not accumulate mononuclear inflammatory cells in the CNS. CCR2 knockout mice failed to upregulate RANTES/CCL5, MCP-1/CCL2, IP-10/CXCL10, CCR1, CCR2 and CCR5 during EAE. In addition, their T cells displayed decreased proliferation in response to autoantigen and lower production of IFN-γ than T cells from control wild-type animals [30]. MOG-specific T cells from CCR2-deficient mice were able to induce passive-transfer EAE but autoimmune T cells from wild-type animals transferred to CCR-2 knockout recipients could not induce EAE

[31]. Complementing these results, CCR2 knockout mice showed impaired recruitment of monocytes and degradation of myelin at the site of a spinal cord contusion injury [32].

C57BL/6 mice lacking CCR2 ligand - MCP-1/CCL2, are also resistant to EAE induction and show impaired recruitment of macrophages to the CNS [33]. Similarly like in CCR2 knockout mice, T cells from MCP-1/CCL2 deficient animals were able to induce passive-transfer EAE in naive recipients, whereas autoimmune T cells from wild-type mice transferred to mice lacking MCP-1/CCL2 did not trigger clinical EAE [33]. Disruption of MCP-1/CCL2 gene in SJL mice produced milder EAE. Expression of MCP-2/CCL8, MCP-3/CCL7 and MCP-5/CCL12 was not upregulated in MCP-1/CCL2 knockout mice with EAE but expression of IFN-γ in CNS and draining lymph nodes was reduced in those animals [33].

CCR1 knockout mice developed less severe EAE [34]. Disease incidence and clinical score were significantly lower than in wild-type controls. Moreover, only expression of IP-10/CXCL10 was elevated in CCR1-deficient mice, whereas in controls expression of IP-10/CXCL10, RANTES/CCL5 and MCP-1/CCL2 was elevated. Lymphocyte proliferation, cytokine production upon stimulation with MOG and cutaneous hypersensitivity were similar in both groups showing that CCR1 knockout mice were not immunosuppressed [34].

Mice with lack of MIP-1α/CCL3 and its receptor CCR5 are fully susceptible to development of acute EAE [35]. Clinical and histopathological signs of EAE in these knockout mice were indistinguishable from those observed in wild-type control animals with EAE. IP-10/CXCL10, RANTES/CCL5, MCP-1/CCL2, MIP-1β/CCL4, MIP-2/CXCL2-3, Lymphotactin/XCL1 and TCA-3/CCL1 gene expression during EAE was similar in MIP-1α/CCL3 deficient mice and in controls. Additionally, comparable Th1 responses were present in the spinal cord of MIP-1α/CCL3 knock-out mice and wild-type animals [35].

TREATMENT OF EAE WITH ANTICHEMOKINE STRATEGY

Initial attempts to treat EAE with anti-chemokine strategies came from Karpus and colleagues. They showed that anti-MIP-1α/CCL3 antibodies prevent development of an initial attack of EAE after adoptive transfer of activated antigen-specific T cells. Moreover, anti-MIP-1α/CCL3 antibodies may also ameliorate ongoing disease [36]. This therapy does not influence the cytokine production by encephalitogenic T cells suggesting that they rather influence inflammatory cell recruitment to the CNS [36]. Later, the same group showed that anti-MCP-1/CCL2 antibodies, which were inert towards initial attacks, could reduce relapses of chronic-relapsing disease,

which were unaffected by anti-MIP-1α/CCL3 [37]. In another study anti-MIP-1β/CCL4 and anti-MCP-1/CCL2 antibodies influenced the onset of EAE and disease severity [38]. Expression of MIP-1β/CCL4 was not detected in the spinal cord of antibody-treated animals, but expression of RANTES/CCL5, MCP-1/CCL2 and MIP-1α/CCL3 was not decreased in these animals. Anti-RANTES/CCL5 and anti-MIP-1α/CCL3 treatment had no significant effect on amelioration of EAE [38].

There are unclear observations regarding treatment of EAE with anti-IP-10/CXCL10 antibodies. In a murine model induced with 139-151 PLP peptide anti-IP-10/CXCL10 polyclonal antibody decreased clinical and histological EAE [39]. In that study anti-IP-10/CXCL10 treatment was shown to decrease accumulation of mononuclear cells in the CNS. Specifically accumulation of encephalitogenic T cells in the spinal cord was diminished. Anti-IP-10/CXCL10 did not influence the peripheral activation of encephalitogenic T cells [39]. Opposite results were reported in acute EAE induced by immunizing rats with guinea pigs brain homogenate [21]. In that model, treatment with neutralizing antibody against IP-10/CXCL10 resulted in exacerbation of EAE with increased migration of T cells to the CNS. In the group treated with anti-IP-10/CXCL10, draining popliteal lymph nodes were smaller, with lower cell number than in the control group. In the spinal cords of these mice, larger numbers of CD4+ infiltrating cells were found [21].

A newer strategy to block chemokine-chemokine receptor interactions was the usage of chemokines with amino-terminal modifications converting agonists to specific antagonists. An example of this type of compound is Met-RANTES/CCL5. However, recent study showed that Met-RANTES/CCL5 is ineffective in prevention and treatment of acute EAE. In a chronic–relapsing model this treatment showed modest amelioration of neurological disability. Histological analysis of treated mice did not show reduction of inflammatory cell accumulation in the CNS [40].

Several other therapeutic strategies of EAE were shown to affect the chemokine system. Oral administration of myelin basic protein (MBP) conjugated to cholera toxin B subunit before the appearance of the first signs of EAE prevented the development of the disease in Lewis rats. This treatment was associated with a significant reduction of inflammation in the CNS. *In situ* hybridization analysis showed evident reduction of MCP-1/CCL2 and RANTES/CCL5 expression in spinal cords of treated animals [41]. Treatment of ongoing EAE with granulocyte-CSF (G-CSF) resulted in significantly reduced expression of chemokines RANTES/CCL5, MIP-1α/CCL3, MIP-1β/CCL4, MCP-1/CCL2 and MIP-2/CXCL2-3 in spinal cords [42]. G-CSF-treated mice displayed reduced recruitment of T cells to the CNS and limited demyelination. G-CSF induced a cytokine imbalance in

periphery characterized by deviation towards a type 2 immune response, with reduced IFN-γ and increased IL-4 levels. Gene therapy of EAE with an HSV vector containing IL-4 gene reduced severity of this disease. Amelioration of EAE was associated with decreased expression of MCP-1/CCL2 and RANTES/CCL5 in the CNS of treated mice [43].

CHEMOKINES AND CHEMOKINE RECEPTORS IN MULTIPLE SCLEROSIS

In the last several years many reports have been published addressing chemokine expression in MS. These results resemble results obtained earlier in EAE. In one of the first studies, expression of RANTES/CCL5 was described in perivascular inflammatory cells [44]. Expression of MCP-1/CCL2 by astrocytes and inflammatory cells was demonstrated in another study. In that study, MIP-1α/CCL3 and MIP-1β/CCL4 were expressed in inflammatory cells in active MS plaques [45]. MCP-1/CCL2, MCP-2/CCL8 and MCP-3/CCL7 were detected in reactive astrocytes and inflammatory cells in acute and chronic MS lesions [46]. Recently hematogenous monocytes expressing CCR1 and CCR5 were found in perivascular cuffs in active MS lesions. In later stages macrophages CCR1-/CCR5+ predominated [47].

In cerebrospinal fluid from MS patients with relapse we found increased levels of IP-10/CXCL10, Mig/CXCL9 and RANTES/CCL5 [48]. IP-10/CXCL10 was detected in all CSF samples from active MS. Cells bearing receptors for IP-10/CXCL10 were localized in MS plaques. CXCR3, the receptor for IP-10/CXCL10, was detected on lymphocytes in perivascular inflammatory cuffs as well as on approximately 90% of T cells from the cerebrospinal fluid of MS patients. CCR5, receptor for RANTES/CCL5 was present on lymphocytes, macrophages and microglial cells in active MS lesions. MCP-1/CCL2, chemokine associated with Th2 responses was significantly reduced in CSF of patients with MS attacks [48]. Balashov and coworkers reported similar findings and additionally demonstrated increased production of IFN-γ by circulating CCR5+ T cells from MS patients [49]. Another group reported decreased levels of MCP-1/CCL2 in CSF in acute MS, whereas IP-10/CXCL10 levels were significantly increased in this group. Therapy of MS with 6-methylprednisolone or IFN-β did not modify the levels of these chemokines [50].

In very small pilot studies, expression of CCR2 and CCR5 on CD4+ cells was significantly higher in MS patients at relapse than in controls and expression of CCR3 and CCR4 (Th2-type receptors) on CD4+ cells was significantly lower in MS patients than in control subjects [51]. Similarly, in the population of CD8+ cells from MS patients at relapse, expression of

CCR5 was higher than in controls, and expression of CCR4 was significantly lower than in control subjects [51]. Similar preliminary results in small groups of patients suggested that treatment of MS with IFN-β reduced RANTES/CCL5 levels in sera and its production by blood mononuclear cells from MS patients [52]. There are formidable technical challenges to performing such studies in human material and these results await confirmation in larger, prospective studies.

CONCLUSIONS

The presented data obtained to date show relationships between expression of some chemokines and disease activity in EAE. Amelioration of EAE by anti-chemokine antibodies and studies in knockout mice confirm the important roles of some chemokines in EAE pathogenesis. Involvement of chemokines in development of CNS autoimmune inflammation is further supported by recent results from MS studies. Taken together, these data suggest that the chemokine system may be a promising target for future treatment methods of MS.

Chapter A18

FREE RADICALS AND EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Sean Murphy
Institute of Cell Signalling, Medical School, QMC, University of Nottingham, UK

Abstract: This chapter reviews the major reactive oxygen and nitrogen species, their generation and their relevance for EAE. The relative contribution of NO and ONOO- species is discussed and the current literature EAE reviewed. The dual nature of free radicals, pathogenic and protective, and the correspondingly conflicting results of therapeutic interventions aimed at diminishing free radicals (in particular reactive nitrogen species), are also discussed in this chapter.

Key words: free radicals, EAE, MS, reactive oxygen species, reactive nitrogen species, peroxynitrite, nitric oxide

Introduction

Inflammation is associated with demyelinating disease in humans. The generation of reactive oxygen (ROS) and nitrogen species (RNS) is increased dramatically in conditions involving inflammation, overwhelming intrinsic anti-oxidant defences, and causing damage to the lipid, protein and nucleic acid constituents of cells and mitochondria. Oligodendrocytes, with little in the way of antioxidant defence and also a high iron content, are particularly sensitive to oxidative and nitrative stress. In addition, reactive species can damage the myelin sheath directly, promoting the attention of macrophages.

Consequently, there has been intense interest in the contribution of free radicals to myelin disorders, summarized recently in a collection of useful reviews (1-4). The tone of their collective conclusions is that, while the neurological deficits associated with demyelination can be ameliorated by reducing ROS, the outcomes of therapies aimed at diminishing RNS are more variable, and often exacerbate disease. The purpose of this chapter is to try and resolve roles for RNS in EAE.

Nitric oxide generation

There are three major isoforms of NO synthase (NOS). While these are products of distinct genes, the cDNAs share 50-60% homology at the nucleotide and amino acid levels (5). Two of these gene products, nitric oxide synthase (NOS)-1 and NOS-3, are constitutively expressed enzymes that are calcium-calmodulin dependent, producing small amounts of NO in response to transient elevations in intracellular calcium level. Both NOS-1 and NOS-3 are catalytically functional only as dimers (head-to-head), exhibit alternative splice products, and display protein- and lipid-interacting domains in their N-terminal regions. To date, the understanding of transcriptional regulation of these isoforms is rudimentary. For NOS-1, first characterized in the nervous system, activators of the gene include mechanical injury, hypoxia, and sex steroids. For NOS-3, responsible for the production of endothelium-derived relaxing factor, transcriptional activation is associated with shear stress, hypoxia, sex steroids and growth factors (6).

The NOS-2 isoform is also active only as a dimer, but functions independently of a rise in intracellular calcium and is capable of producing a large and continuous flux of NO. This isoform is not normally expressed but can be transcriptionally induced in response to proinflammatory cytokines, bacterial endotoxins, hypoxia, and viral coat proteins. Upon activation of the NOS-2 gene, the transcript is very unstable with a $t_{1/2}$ of 2-3 hours. Clearly there are proteins co-induced which are responsible for this RNA instability, as $t_{1/2}$ is prolonged by inhibitors of transcription and also protein synthesis. The relatively large amount of NO generated by NOS-2 over a sustained period has been implicated in various pathologies (7), and also as part of the host response to infectious organisms (8).

The NOS isoforms have similar catalytic domains: a C-terminal reductase (homologous with cytochrome P-450 reductase) exhibiting binding sites for flavins and NADPH, and a N-terminal oxygenase domain which contains bound heme and the site for H4 biopterin. The reductase domain transfers electrons from NADPH to heme. Calmodulin binds just at the N-terminal side of the reductase. The regulation of dimer assembly is of interest, as this leads to functional NOS. The degree to which H_4 biopterin is required depends on the isoform and the cell type in which the enzyme is expressed. Whether arginine and/or heme limits intracellular NOS assembly is still unclear. Certainly, in activated cells, NOS-2 exists as a mixture of dimer and monomer, implying either that dimers are unstable or that assembly is limited. Cell culture studies point to the former. The accumulating NO limits dimerization, perhaps by preventing heme insertion into the protein.

In active MS lesions multiple cell types express NOS-2, and there is abundant evidence for the local generation of NO oxidation products, such

as peroxynitrite (ONOO-) (9). Elevated levels of CSF nitrate (NO_{3-}) correlate with clinical relapse. Calabrese et al. (10) report NOS-2 and NOS activity in the CSF from patients with MS, and detect nitrotyrosine (NT) immunostaining of CSF proteins. There is also evidence for nitrosylation (11). In MS there is greater concordance among monozygotic (30%) that dizygotic (2.5%) twins, and involvement of the NOS genes has been investigated. The NOS-2 gene is situated on the long arm of chromosome 17, which is linked to MS in British and Finnish populations. The NOS-3 gene is on 7q36, a locus for induced arthritis. The NOS-1 gene is on the long arm of chromosome 12, which is linked to MS. Modin et al. (12) investigated five markers within the three NOS genes with regard to MS susceptibility and disease course in 156 affected sib-pairs, and in 96 benign and 96 severe definite MS patients in the Nordic population. However, genetic variation of these genes neither contributes directly to susceptibility to MS, nor does it influence disease severity.

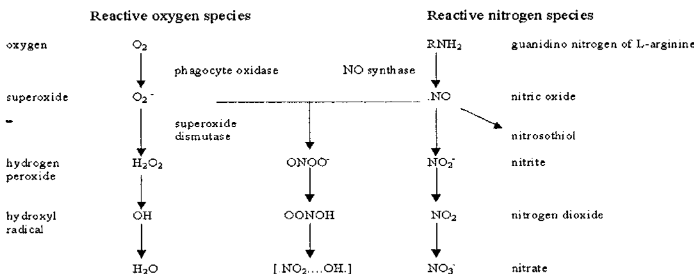
Free radical chemistry

Reactive nitrogen species are oxidation states and adducts of the products of NOS that arise in physiological environments, and include NO-, $.NO_2$, NO_2-, N_2O_3, N_2O_4, S-nitrothiols, ONOO-, and dinitrosyl-iron complexes. Reactive oxygen species are intermediate reduction products of O_2 en route to water, namely, O_2-, H_2O_2 and OH (Figure 1). What follows is a synopsis, and more complete coverage can be found (13, 14).

There are three major classes of pro-oxidant enzymes: NOS, cyclooxygenase (COX) and NADPH oxidase, and myeloperoxidase (MPO). It is estimated that between 2-5% of electron flow in brain mitochondria produces O_2-. This is scavenged by superoxide dismutases (SOD), glutathione peroxidase and catalase. Cellular antioxidants include glutathione, ascorbate, and α-tocopherol.

All eukaryotic cells, as well as simpler organisms, are capable of synthesizing NO (with L-citrulline as the co-product) from the five electron oxidation of L-arginine. The reaction is catalyzed by NOS, which employs components familiar from other enzymes but in novel and somewhat unconventional ways. As a radical, NO reacts rapidly with other species that contain unpaired electrons. In a reaction with O_2, NO can form an

Figure 1 Production of reactive oxygen and nitrogen species. Modified from (8).



intermediate species (N_2O_3?) that efficiently nitrosates thiols and amines. Out-competing SOD, NO reacts with O_2^- to produce $ONOO^-$ which, if protonated, decomposes within seconds to a hydroxyl radical. This $ONOO^-$ reacts rapidly with CO_2 (acting as a catalyst) in a complex manner that produces several short-lived reaction intermediates, such as NO_2 and CO_3^-. These intermediates are probably responsible for many of the reported toxic effects of NO. In the absence of arginine and BH_4, the NOS enzymes can catalyze the production of O_2- and, consequently, H_2O_2 when the O_2- is dismuted by SOD. Therefore, the NOS enzymes can produce ONOO-, and the decomposition of H_2O_2 or ONOO- can lead to the production of HO (15).

Molecular targets for RNS

The chemical alteration of DNA underlies a variety of pathological states. Nitric oxide can potentially damage DNA either through RNS ($ONOO^-$, N_2O_3), the inhibition of DNA repair processes, or by increased production of genotoxic (alkylating) agents. A species such as N_2O_3 causes mutations in cells, chemically altering DNA. Deamination of cytosine, adenine, and guanine results in conversion to uracil, hypoxanthine and xanthine, respectively. As well as modification, NO can form or modulate the activity of carcinogens. Nitrosamines are metabolized to alkylating species which lesion DNA.

The ability to nitrosate and to nitrate key amino acids in proteins (transcriptional regulators, enzymes, receptors) explains many of the actions of RNS, in terms of gene regulation and alterations in cell signalling pathways. Transcription factors, the regulatory proteins that bind to gene promoters and recruit RNA polymerase, display sequences specific for DNA binding and also a transactivation domain. A number of transcriptional activators have been shown to be regulated by NO, either post-translationally through direct modification of the protein, or indirect regulation via alteration in the rate of their own transcription. In so doing, NO can turn off constitutively expressed genes, activate transcriptionally regulated genes, or prevent their activation. The best examples to date are the transcription factors NF-kB and AP-1. Their activation can be blocked by NO and the proteins can also be directly nitrosated, with a reduction in promoter association. These two transcription factors are involved in the regulation of expression of a very large number of genes. Serine substitution of a cysteine residue at the N-terminal region of the p50 NF-kB subunit reduces DNA binding. Specific binding of NF-kB is also inhibited reversibly by NO, and these effects appear to be mediated by nitrosation of the same cysteine residue. There is also good evidence that NO stabilizes the NF-kB inhibitory protein IkBα and activates its transcription, thus inhibiting NF-kB translocation from the cytoplasm to the nucleus. AP-1 is a dimeric complex

of Jun-Jun or Jun-Fos proteins. The key to dimer formation resides in two cysteine residues in the leucine zipper and basic regions of Fos and Jun, and nitrosation of cys 252 in the DNA binding domain decreases AP-1 binding to DNA.

Critical signalling proteins can be influenced by RNS, functioning at the transcriptional and/or post-transcriptional level either as an activator (poly ADP-ribose synthetase, p21ras, sGC) or inhibitor (adenylyl cyclase Type I, protein kinase C, cytochrome P450, nitric oxide synthases, lipoxygenase). The heme protein cyclooxygenase (COX) is inhibited by NO at high concentrations but activated by low concentrations. The mitochondrial respiratory chain is also susceptible. While NO inhibits cytochrome c oxidase (complex IV) in a reaction that is reversible and competitive with oxygen, $ONOO^-$ irreversibly inhibits respiratory complex I-III as glutathione levels decrease. Nitric oxide can have diverse effects on cell fate, initiating or protecting against apoptosis depending on the cell type, NO concentration and redox environment. The family of protein-cleaving enzymes known as caspases are targets for NO, which inhibits their activity in a reversible manner.

Exposing cells to NO, coupled with the use of NOS inhibitors, has revealed complex effects on the production of cytokines. Some members of the caspase family participate in the maturation of cytokines. Precursors of IL-1β and IL-18 are cleaved by caspase-1, and NO reversibly blocks this process, thereby acting as an anti-inflammatory agent. However, NO can be proinflammatory, increasing release of other cytokines such as TNFα and IL-6. Chemokines, small chemoattractant cytokines, can be quite specific in determining the immigration patterns of lymphocytes and macrophages to certain inflammatory regions. There appears to be an interesting cross-talk between NO and chemokines in that the expression of IL-8 and MCP-1 are inhibited by NO, whereas MCP-1 can prevent the expression of NOS-2.

RNS and EAE

It is 10 years since RNS and ROS were first described as products of the inflammatory cells seen in rats with hyperacute EAE (16). Associated with increased pro-inflammatory gene expression in EAE, there is expression of NOS-2 mRNA, protein, and evidence for the generation of RNS. There is also evidence for the formation of NT and nitroso-S-cysteine (11), indicating interaction of RNS with proteins. While tyrosine nitration has been assumed to result from the generation of ONOO-, this view has recently been challenged, and $.NO_2$ is now suggested to be the culprit (17).

In 1999, Willenborg et al. (4) reviewed the 45 papers that had appeared on the role of NO in CNS autoimmune inflammatory disease. Predictably, the first group of publications all concluded that NO contributed to EAE

pathology. This was based on observation that anti-inflammatory steroids block cytokine-mediated NO production and reduce EAE symptoms, NOS inhibitors reduce passively transferred EAE, encephalitogenic T cells cause macrophages to produce NO, and NOS-2 expression correlates with disease severity. However, a study of the therapeutic effects of five different NOS inhibitors in both adoptive transfer and actively induced EAE revealed no protection, and some exacerbation of disease (18). Okuda et al. (19) noted that the inflammatory cells dying in spinal cord lesions of EAE mice were juxtaposed to NOS-2 expressing cells, suggesting that NO was eliminating them. The phosphodiesterase inhibitor, Rolipram, elevated NOS-2 expression in monocytes and ameliorated disease (20). With one of the first NOS-2 selective inhibitors (L-NIL), Gold et al found protection in adoptive EAE and exacerbation of actively induced disease (21). However, the emergence of NOS-2 knockout mice, and the observation that NO is important in recovery and refractoriness to active reinduction, again pointed to the potential protective role of NO in actively induced EAE. Thus, while the majority verdict was to maintain that NO was contributing to disease, by 1999 fully one third of publications were leaning towards NO having a protective role.

It is well known that NO has a number of effects on immune responses, such as the inhibition of macrophage Ia expression, which would have the effect of preventing T cell expansion. This inhibition of T cell proliferation appears to be a specific impairment of Th1, while sparing Th2 cells. Since EAE is a function of Th1 cells, the increase in NO may selectively limit proliferation of the encephalitogenic effector population. In addition, the expression of VCAM and ICAM-1 are downregulated by NO, significantly altering lymphocyte migration. In target tissue, NO can induce both apoptosis and necrosis in T effector cells and protect oligodendrocytes against destruction by lipid peroxidation (1).

So, what are the roles of RNS in EAE? More recent publications have clarified their effects.

ONOO- vs. NO in EAE

The group at Thomas Jefferson University in Philadelphia have long claimed a destructive role for ONOO- in MS and EAE, based on the observation that a natural antioxidant scavenger, uric acid (UA), ameliorates disease. They postulate that the normal levels of UA in humans confers enhanced protection against free radical-mediated cell injury, and that low UA would predispose towards the development of CNS diseases involving ONOO-, which include not only MS but also amyotrophic lateral sclerosis (ALS), Parkinson's and Alzheimer's diseases.

To understand how ONOO- is involved, they examined the effects of UA on blood-brain barrier permeability, and on the accumulation and activity of inflammatory cells in the spinal cord (22). Induction of EAE in female mice was by direct immunization with MBP. They reasoned that, if UA acts solely by inactivating ONOO-, then raising UA levels should not directly affect the activation of inflammatory cells (eg. NOS-2 expression) but would reduce the subsequent inflammation (eg. NT accumulation). In mice that received UA before the onset of clinical signs of EAE there was reduced invasion of inflammatory cells into the CNS and disease prevention. In mice with active EAE, and therefore a compromised blood-brain barrier (BBB), the administration of UA blocked NT, reduced apoptosis in the lesions, and promoted recovery. The UA treatment also reversed the increase in BBB permeability observed in EAE. This action could explain why UA administration prevents the onset of EAE. While UA does not affect the specific T cell proliferative response, the levels of IgG antibodies, or appearance of cells expressing NOS-2 in lymph nodes and peripheral blood of MBP-immunized mice (23), it does reduce the levels of NOS-2 expression in spinal cord (24). This group has also looked at novel ONOO- scavengers, mercaptoethylguanidines, that readily cross the BBB (25). These compounds delayed the onset, and reduced the incidence of MBP-induced EAE. Surprisingly, the scavengers did not alter the severity of disease or overall mortality, but this could be due to the lower efficiency with which these compounds inactivate ONOO-, as compared with UA. Alternatively, it could be because these scavengers also inhibit NOS-2 activity, removing the protective influence of NO. Interestingly, the radical scavenger ascorbic acid (AA) can also block nitration, but does not protect against EAE (26).

There have been concerns raised about the interpretation of the UA effects in EAE, and its role as a ONOO- scavenger. Uric acid causes an inflammatory response in the peritoneum, characterized by neutrophil accumulation, and it is suggested that this could reduce the number of cells available for extravasation. In addition, UA was found to be effective even in EAE induced in IFNγ receptor knockout mice, where very little NO (and therefore ONOO-) is generated (27). However, catalysts specific for the decomposition of ONOO- have recently been developed, and these promote the isomerization of ONOO- to NO_3 without directly affecting NO levels. Mice receiving catalyst displayed less severe clinical disease, and less inflammation and demyelination, but encephalitogenic T cells could still be recovered from catalyst-treated mice (28).

Evidence for beneficial NO and/or against NOS-2 derived NO being harmful

1. The oral administration of L-arginine (the NOS substrate) was found to delay disease onset and to reduce the severity of neurological and histological signs of EAE, and yet there was a significant elevation in CNS nitrite, and decreases in O_2- and H_2O_2 (29).
2. Female PVG rats are resistant to actively-induced EAE, their spleens have more monocytes and fewer RBC than males, and produce more RNS. If splenectomised, these animals are no longer resistant. Immunized intact females do generate EAE effector cells, and are also susceptible to passively transferred disease. Therefore, in actively-induced EAE in these animals, there must be a block at the effector cell expansion phase, or of transmigration into target tissue, and this could be related to the higher RNS levels (30).
3. Mice deficient in glucocorticoid receptors (GR) are resistant to actively induced EAE, because of a reduction in spleen and lymph node cell proliferation. These GR-deficient mice have much higher NO_2 levels, due to unsuppressed NOS expression. When treated with NOS inhibitors, the level of NO_2 decreases, there is increased effector cell proliferation, and mice are now susceptible to EAE. Thus, NO appears to be the immunosuppressant (31).
4. The administration of a low dose of IL-4 prior to immunization improves clinical scores of EAE. The dendritic cell population proliferates, secreting high levels of IFNγ, NO and IL-10, and the NO promotes apoptosis of autoreactive T cells (32).
5. Xu et al. (33) used 3-morpholinosydnonimine (SIN-1) to enhance NO levels during the development of EAE. This compound can release ONOO-, but they found no changes in O_2- or ONOO- formation. Given within the first week following immunization, SIN-1 enhanced IFNγ levels, reduced expression of MHC class II, and augmented apoptosis of blood mononuclear cells. This resulted in less cellular infiltration into the CNS and, therefore, reduced clinical signs of disease.
6. High dose of the specific antigen can induce apoptotic T cell death and so suppress immune responses. Weishaupt et al. (34) looked at levels of TNFα, IFNγ, and NOS-2, and found them highly elevated in this response. Apoptosis of T cells was evident, but a potentially harmful side effect was the observation that oligodendrocytes were also undergoing apoptosis. Interestingly, there still remained a clinical benefit, and this was lost when TNFα activity was neutralized.
7. The injection of mice with staphylococcal enterotoxin B prior to immunization for EAE provides protection against disease, and yet more NOS-2 is evident in the brains of treated animals (35).

8. Mice immunized with complete Freund's adjuvant (CFA) containing mycobacterial extract (which can transcriptionally activate NOS-2) are protected against EAE, but NOS-2 knockout mice are not protected. In the wildtype mice there was augmentation of the IgG1 response, a decrease in IL-6 production by T cells, and a marked decrease in monocyte infiltration into the CNS (36).

Multiple roles for NO in EAE ?

The addition of pertussis toxin (PT) when EAE is triggered worsens the CNS effects. Both NOS-2 and TNFα are increased, over and above the levels seen in animals not receiving PT (37). Pozza et al. (38) showed that a NOS inhibitor, given prior to immunization, caused complete recovery from the acute phase of EAE, and a delayed and milder relapse. The benzoquinoid ansamycins (anti-fungals) induce heat shock proteins, and reduce NOS-2 expression and NO_2 accumulation. Given after immunization, these agents reduce EAE disease onset by >50% (39).

Lewis rats, immunized with MBP-CFA, recover from EAE. They do not relapse, and develop a resistance to further induction. The serum levels of RNS are increased during recovery and, if challenged again with MBP-CFA, increase further. If a NOS inhibitor is given (even in the absence of MBP-CFA), then 100% enter a second episode of disease. This is consistent with NO inhibiting T cell proliferation, adhesion and migration into the CNS. However, this second episode is chronic, with periods of remission and relapse (40). Why is NO unable to prevent relapse? The authors conclude that there is primary disease, limited in time by the production of NO, and then relapsing disease, perhaps as a result of excessive production of RNS.

Conclusions

In their review Willenborg et al. (4) concluded that, for both rats and mice, treatments that target passive EAE, or the effector phase of actively induced EAE, result in amelioration of disease. However, treatments that target the afferent arm of the response lead to the aggravation of pathology. Simply put, an increase in RNS levels in the target tissue is bad, but an increase during immunization is good. Much of the recent data support this notion, and provide a strong hint that it is ONOO-, and not .NO, that causes the tissue damage. If so, then EAE joins a growing list of pathologies in which RNS have causal and protective functions. The trick for therapeutics will be to devise means to eliminate one but preserve the other.

Chapter A19

PROTEASES AND PEPTIDASES IN EAE

M Nicola Woodroofe and Rowena AD Bunning
Biomedical Research Centre, School of Science and Mathematics, Sheffield Hallam University, Howard Street, Sheffield S1 1WB, UK

Abstract: The role of proteases and peptidases in the pathogenesis of EAE has been extensively studied. In particular research has focussed on the matrix metalloproteinase (MMP) family of enzymes as well the plasminogen activator/plasmin system. These enzymes have been proposed to have a number of functional roles in disease pathogenesis including: breakdown of the blood brain barrier and the extracellular matrix, degradation of the myelin sheath with the generation of further encephalitogenic peptides and amplification of the inflammatory process in the CNS, via activation of pro-inflammatory cytokines. The administration of proteolytic enzyme inhibitors to animals with EAE resulting in clinical improvement, has provided further support for the MMP/plasminogen activator/plasmin system in the disease process. The involvement of other enzymes including, myelencephalon specific protease, calpain and dipeptidyl petidase IV in EAE pathogenesis is also discussed.

Key words: metalloproteinases, serine proteases, demyelination, blood brain barrier, inflammation

1. INTRODUCTION

Proteinases and peptidases involved in neuroinflammation can be divided into those with intracellular or extracellular activity. Intracellular proteases, include calpains and caspases and the extracellular proteases, which have been extensively investigated in EAE pathogenesis, consist of two major groups: the serine proteases, plasminogen activators (PAs), including urokinase-type PA (uPA) (EC 3.4.21.73) and tissue type PA (tPA) (EC 3.4.21.68) and plasmin and the matrix metalloproteinases (MMPs)[1,2].

The MMPs are a family of Zn^{2+} dependent endopeptidases, which are capable of degradation of the extracellular matrix (ECM) and have been implicated in the degradation of myelin. This family of at least 25 proteins, includes collagenases, gelatinases, stromelysins and membrane-type MMPs (MT-MMPs), based on their substrate specificity and domain structures, however there is considerable overlap in substrate specificities between sub groups. MMPs are capable of degradation of all protein components of the ECM including collagen, elastin, fibronectin and laminin[3,4,5]. Members of the related ADAMs (A Disintegrin And Metalloproteinase) family of proteins are important sheddases for the release of membrane bound proteins e.g. TNF and its receptor are cleaved by ADAM 10 and 17 (TACE, tumour necrosis factor converting enzyme)[5]. These enzymes are membrane bound and possess an integrin binding, disintegrin domain, which may be important in cell-cell interactions[6]. Another group of ADAMs family proteins, recently identified, are the ADAMTSs, which are secreted proteins possessing one or more thrombospondin motif and no transmembrane or cytoplasmic domains. ADAMs and ADAMTSs have to date not been investigated in EAE.

The activity of these two main families of proteases, PAs and MMPs, is tightly controlled, to prevent any unwanted tissue damage, in a number of ways: the enzymes are synthesised as pro-forms which require proteolytic cleavage to produce the active enzyme; the presence of endogenous inhibitors, PAIs and TIMPs (Tissue Inhibitors of Metalloproteinases) which bind to the enzymes in a 1:1 stoichiometry; regulation of gene transcription, and *de novo* synthesis by secretion. The transcriptional regulation of these enzymes and their inhibitors by chemokines[7] and cytokines via AP1 transcription factors is also critical in chronic inflammation[6]. Thus the resultant activity of these proteolytic enzymes is dependent on their levels within a tissue, the concentration of the endogenous inhibitors at the same site as well as the presence of pro- or anti-inflammatory cytokines.

PAs catalyse the conversion of plasminogen to plasmin (EC 3.4.21.7)[8]. Plasminogen is present in most body fluids and plasmin generated from it has a wide range of substrates including not only fibrin but components of the basal lamina, fibronectin and laminin, tenascin-C, components of the ECM of the brain, tenascin-C, proteoglycans and myelin[9,10,11,12,13,14,15,16]. Thus plasmin may play a role in ECM breakdown as occurs in damage to the blood brain barrier (BBB) and during cell migration in the central nervous system (CNS) parenchyma as well as in myelin breakdown. In addition, plasmin is capable of activating the proforms of several MMPs[17,18,19]. Thus plasmin provides a link between the two systems whereby plasmin is a limiting factor on MMP activation. It can also activate latent transforming growth factor β (TGFβ), reducing inflammation[20].

These proteolytic enzyme systems have been implicated in a number of pathological events during the pathogenesis of EAE including[1,2]:

- Disruption of the BBB via proteolysis of the basement membrane, permitting inflammatory cell migration across the blood brain barrier
- Myelin degradation and generation of further myelin basic protein (MBP) fragments to amplify the immune response
- Disruption of cell-cell or cell-ECM interactions within the CNS parenchyma
- Amplification of inflammation via cytokine processing and activation
- Further cleavage of pro-MMPs into the active enzyme

Paradoxically they have also been reported to play a beneficial role in recovery following an inflammatory insult to the CNS. For example, degradation of the ECM may be required to allow remodelling following CNS injury, migration of phagocytic cells, i.e. microglia and macrophages, within the CNS. To remove cellular debris will require the secretion of MMPs by these cells. Similarly neural cell precursors may require MMPs to aid their migration into the damaged area, to replenish cells damaged as a result of the inflammation and allow axonal elongation, finally they may release growth factors anchored to the ECM, which could then promote repair within the lesion[4].

Here we review the research to date on the role of these proteases and others in the pathogenesis of EAE, as well as summarising evidence which suggests that inhibition of these enzymes is a potential therapeutic strategy in the treatment of CNS inflammation.

Matrix metalloproteinases

The structure of the MMP family of enzymes is similar, each having five protein domains, a classical signal peptide is recognised by the ER docking enzyme and leads to secretion, the pro-peptide domain with a single cysteine sulphydryl group forms the amino terminal part of the secreted protein, the presence of this sulphydryl group determines the latent state of the pro-enzyme. The active enzyme domain, and the zinc-binding domain form the catalytic site. The hemopexin domain is located at the carboxy terminus. In addition, the MT MMPs possess a short chain of hydrophobic amino acids, which anchor the enzymes in this group to the cell membrane. MMP2 (EC 3.4.24.24) and 9 (EC 3.4.24.35) have an extra fibronectin-like domain and MMP9 also has an additional type V collagen domain. Activation of the inactive zymogen to the active enzyme occurs via a cysteine switch mechanism, which involves removal of the cysteine, sulphydryl group and replacement with water[21]. This activation occurs downstream of the proteolytic cleavage of plasminogen by uPA and tPA to plasmin, although MT-MMPs can cleave pro MMP2 to the active form and pro MMP9 has been reported to be cleaved by MMP2[1]. Cytokines modulate

the expression and regulation of MMPs, via expression of proto-oncogenes of the c-*fos* and c-*jun* family which in turn contributes to formation of dimeric forms of AP1 transcription factors that bind to specific promoter sequences which are present in the promoter region of most MMP genes[5]. MMPs in turn can act as sheddases for membrane bound cytokines, their receptors and adhesion molecules. Although, ADAM10 and 17 (TACE) are more effective sheddases for TNFα, a key cytokine in the CNS immune response in EAE[22].

MMPs and EAE

Studies on the expression of MMPs in EAE have included a wide range of different models of the disease, including rat and mouse models induced by active immunisation with myelin antigens, usually MBP, myelin oligodendrocyte glycoprotein (MOG), proteolipid protein (PLP) or spinal cord homogenate as well as passive transfer models using CNS antigen-specific T cells. More recently, genetically modified animals have also provided further information on the role of MMPs in CNS inflammation. For example, mice over expressing cytokines, in particular TNF, in the CNS and mice under expressing MMP9, have been used to elucidate the role of these enzymes in CNS inflammation[23,24].

Reports on the expression of MMPs during the course of EAE are generally in agreement with a dominant role being assigned to MMPs 7 (EC 3.4.24.23) and 9. These enzymes are expressed by both inflammatory cells in perivascular locations as well as by resident glia. However other MMPs including MMPs 1, 3, 10, 12 (EC 3.4.24.7, EC 3.4.24.17, 3.4.24.22 and 3.4.24.65 respectively) and MMP 14 have also been demonstrated in the CNS in EAE[25]. Elevated levels of MMP 9 were found in the cerebrospinal fluid (CSF) of mice with EAE and correlated with clinical disease score[26]. In acute EAE in the Lewis rat, development of clinical disease was associated with a 3 fold increase in MMP activity in the CSF, measured by a coumarin-labelled peptide substrate assay. Using quantitative PCR, mRNA for at least seven MMPs were expressed in normal and EAE spinal cord. However MMP 7, localised to macrophage cells, showed a dramatic increase of over 500 fold in EAE animals compared to normal control animals and the levels remained high during the recovery period. MMP 7 has been shown to degrade MBP and this may be one of the actions of this enzyme in EAE. MMP 9 showed only a moderate, five fold increase, which peaked at disease onset but declined thereafter[27]. In an adoptive transfer model of EAE in Lewis rats, MMPs 7 and 9 increased, 100 fold and ten fold respectively, as assessed by a semi-quantitative competitive reverse transcriptase PCR assay, which was in line with the increasing clinical severity. Also using gelatin zymography, the authors demonstrated that the increase in mRNA was associated with an increase in MMP 9 activity. In contrast to the active disease model, MMP 7 levels declined in the recovery period. Expression

was localised by immunohistochemistry to infiltrating mononuclear cells and to the perivascular space as well as within the parenchyma. The localisation of the protein was predominantly extracellular although the most likely source of the enzyme was reported to be from the infiltrating T cells and macrophages (Figure 1).

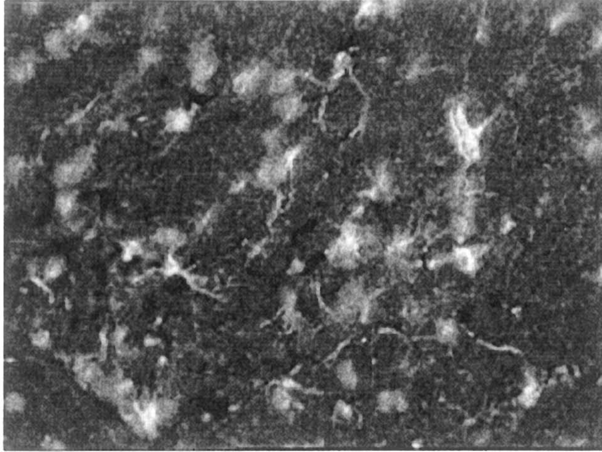
MMP-2

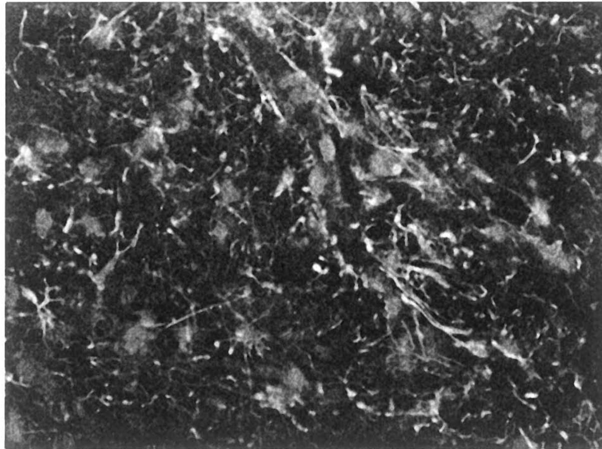
MMP-7

MMP-9

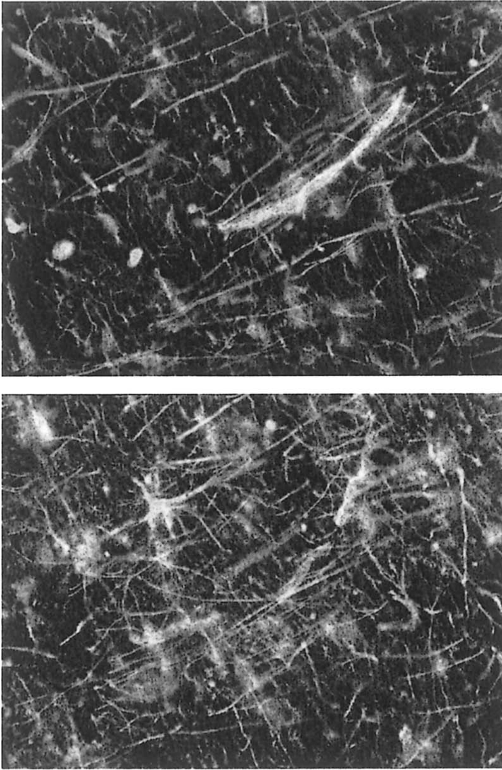
ADAM 17 expression in normal control rat brain parenchyma



ADAM 17 (TACE) expression by perivascular astrocyctes in spinal cord of EAE rats



ADAM 17 expression by endothelial cells and astrocytes within spinal cord of EAE rats.



Frozen sections (10μm) were stained for the various MMPs and ADAM17 using monoclonal primary antibodies with an FITC labelled secondary antibody(green). Sections were counter stained with propidium iodide (red) to demonstrate cell nuclei (magnification x 400). The photographs were kindly provided by Mr Jonnie Plumb, Biomedical Research Centre, Sheffield Hallam University

MMPs 2, 3, 11 and 13 were unchanged during the course of the disease[28]. MMP9 activity is essential for degradation of type IV collagen within the basal lamina that surrounds blood vessels, thus local expression of this enzyme would permit an influx of inflammatory cells into the CNS across a damaged BBB. Sustained production of MMPs throughout the course of chronic EAE may be a key factor in the neuronal loss that occurs in the later stages[5].

The expression of nine different MMPs and three TIMPs was examined in normal SWR mice and mice with EAE. Upregulation of expression of three MMPs, MMP 3, MMP 9 and MMP 12, were the major changes reported[23]. In EAE animals an inverse relationship was seen between MMP expression and TIMP1 expression, the former was localised to leukocytes and possibly microglia, whereas TIMP-1 was restricted to the astrocytes surrounding the inflammatory lesions. The balance between the level of MMPs and TIMPs will determine the outcome of the inflammatory

lesion. TIMPs 2 and 3 levels remained at constitutive levels in the choroid plexus and neurons.

The role of MMPs in induction of EAE in BALB/c mice with spinal cord homogenate, a strain more resistant to induction of EAE, has been assessed[29]. This is a monophasic disease with peak clinical scores at days 10-14. Although mRNA for MMP 9 was undetectable in the CNS in this model, enzyme activity was detected by in situ zymography in the meninges, around blood vessels and in the parenchyma in areas of inflammatory cell accumulation, particularly in the lumbar and cervical spinal cord, which was confirmed by gelatin zymography. MMP 2 was constitutively expressed in both control and EAE mice

Experiments undertaken on the role of MMP 2 in T cell extravasation in EAE demonstrated a role for alpha 4 integrin in the induction of MMP2[30]. This work agreed with the earlier study of Pagenstcher98 highlighting a role for inflammmatory cell production of MMPs, MT1-MMP, MMP 9 and MMP 12 and astrocytic cell production of the endogenous inhibitor TIMP-1. In a more recent study EAE was induced in BALB/c mice using a sonicated preparation of spinal cord homogenate with complete Freund's adjuvant. Both MMP 8 and 9 activity was demonstrated to correlate with disease severity[31]. MMP 8 has not been previously reported in sensitive strains and its expression was co-localised to neutrophil infiltration into the CNS, which is a unique feature of this model, particularly associated with cortex, cerebellum and submeningeal space of the spinal cord. MMP 9 activity was localised to perivascular infiltrates, in agreement with studies on sensitive strains. The source of MMP 9 appeared to be a result of release from stores within leukocytes, since mRNA for the protein was not detected. In contrast, increased TIMP-1 protein and mRNA were expressed by astrocytes in the surrounding tissue in the mice injected with sonicated antigen, possibly serving to prevent excessive tissue destruction by the released MMPs, as reported previously in SWR mice[23].

We are currently undertaking a study of the distribution of ADAM 17 in the spinal cord of Lewis rats with EAE. Preliminary results demonstrate expression of ADAM 17 in astrocytes and endothelial cells in both normal spinal cord and in animals with EAE, at a single time point (Figure 1). Studies are ongoing to examine the expression of the enzyme throughout the disease course as well as the relationship between the expression of TIMP-3 and ADAM 17, the ration of which will ultimately determine the level of ADAM 17 activity.

MMP expression in transgenic mice with EAE

In a comparative study on EAE in SWR mice and mice transgenic for one of the cytokines, IL-3, IL-6 or TNFα linked to a GFAP promoter, there was increased expression of MMP 9, MMP 12 and MMP 3 mRNA with increasing disease score. MMP 12 was expressed by foamy macrophages and lymphocytes in the CNS in mice with EAE. There were striking similarities between the mice over expressing TNF in the CNS and mice with EAE except that MMP 2 was not expressed in EAE animals. The changes in level of mRNA were accompanied by increased enzyme activity and immune reactivity for the proteins and expression was localised to lesional areas and in particular infiltrating leukocytes and microglia[23]. In mice in which the gene for MMP 2 had been inactivated, EAE could still be induced, however in the MMP 9 knock out mouse there was resistance to induction of EAE, compared with age-matched controls. When EAE was actively induced in C57Bl/6 mice less than 4 weeks old, in which the MMP 9 gene had been deleted, the animals were less susceptible to EAE induced by spinal cord homogenate, and the mean disease score was significantly lower than the wild type controls, although this was not the case in adult KO mice[24].

In an analogous experimental approach MBP specific T cells were genetically manipulated in vitro to over-express MMP 2 and injected into PL/J x SJL/J F1 mice, to determine the effect on induction of EAE. An enhanced T cell migration *in vivo* with this T cell line was reported and a hydroxamate inhibitor of MMPs (GM6001 see below), administered daily i.p. from the day of induction of EAE, delayed T cell entry into the CNS parenchyma. However if administered 48 hours post adoptive transfer of T cells, the treatment had no effect on the disease course. Thus, the data obtained using adoptive transfer of T cells over-expressing MMP 2 provides evidence for a role for MMP 2 in the entry of T cells into the CNS. The results of the inhibitor studies in this model suggest that although autoreactive T cell expression of MMP 2 is important for T cell entry into the CNS, expression of MMPs or other enzymes by cells recruited to the inflammatory lesion are important in invasion of the cells into the parenchyma[30].

Inhibition of MMP activity in EAE

There are a number of key reports on the use of synthetic inhibitors of MMPs to ameliorate the signs of EAE, indeed as early as 1982 protease inhibitors have been reported to ameliorate or treat EAE in animals models[32].

GM6001, a hydroxamate inhibitor, suppressed the development of EAE in SJL/J mice and reversed clinical symptoms when administered after disease onset in a dose dependent manner[33]. A reduction in MMP9 activity in the CSF of treated animals was noted. The beneficial effects of the drug were a result of decreased inflammation as a result of a restored BBB in treated animals, rather than any inhibitory effects on demyelination as this was not a feature of this EAE model. Since GM6001 is a broad spectrum inhibitor of MMPs, enzymes other than MMP 9 could be inhibited and these may also play a role in induction and progression of EAE. In a separate study, another hydroxamate inhibitor, Ro31-9790, reduced the severity of clinical signs in both active and passive transfer models of EAE in the Lewis rat, when administered on the day of disease induction or 3 days post induction. However in animals with more severe clinical signs the inhibitor was less effective in controlling the disease[34]. Similarly BB1101, a broad spectrum MMP inhibitor, reduced disease severity in Lewis rats with active EAE[27] and prevented onset of EAE and reversed acute disease in SJL/J mice[35].

Chronic relapsing EAE in SJL/J mice, induced by adoptive transfer, was attenuated following BB1101 administration and this agreed with histological evidence of reduced demyelination and glial scarring in treated animals. There was also a shift in cytokine profiles in these animals from pro-inflammatory, TNF, to anti inflammatory, IL-4, relative to untreated controls. The transcription of FasL was also down regulated by MMP inhibition suggesting a role in prevention of Fas induced cell death which has been proposed as a mechanism for oligodendrocyte death[35]. Fas ligand can be cleaved by MMP 7 resulting in soluble FasL which is a potent inducer of cell death by apoptosis[36]. Thus decreased MMP7 activity would lead to decreased apoptosis mediated via Fas-FasL. However recovery from the acute stage of EAE has been associated with the apoptotic deletion of autoreactive T cells[37]. These apparently contradictory functions of apoptosis in EAE need to be more fully understood before the effects of MMP 7 on the Fas system can be fully elucidated.

D-Penicillamine, an anti-rheumatic drug, was partially effective in treating EAE in SJL mice and in Biozzi AB/H mice. In chronic relapsing EAE in the Biozzi mouse model, treatment attenuated exacerbations even when the drug was administered after disease induction[38]. However, other investigators have questioned whether D-penicillamine is acting as a proteinase inhibitor in this model[35].

The use of Minocycline, a semi-synthetic analogue of tetracycline, has been assessed for its effectiveness in treatment of MOG_{35-55} petide-induced EAE in C57BL/6 mice. Two forms of the disease were induced, mild (peptide alone) and severe (peptide plus pertussis toxin i.p.). The drug was administered daily ip from the day of MOG immunisation. Minocycline was found to delay the onset of the severe form of the disease and increased the time by 6-8 days for animals to become moribund, however treatment did

not prevent the disease. In the milder form of the disease, the drug was effective in reducing the severity throughout the disease course. The beneficial effects of Minocycline were mediated by inhibition of MMP 9, although MMP 2 was also inhibited, the significance of this finding was unclear[39].

An antioxidant, alpha lipoic acid, has been used as a treatment for EAE and it was found to suppress EAE both clinically and histologically as well as being effective in reducing disease severity, following its administration after disease induction. Since the entry of T cells into the CNS was prevented by this treatment it was proposed that the effect was through the inhibitory actions of alpha lipoic acid on MMP9 which was inhibited in a dose dependent manner[40].

Due to the multiple effects of the MMP inhibitors tested to date it is unlikely that a single molecular mechanism will explain their actions in ameliorating or preventing EAE[35]. The beneficial effects of these broad spectrum MMP inhibitors therefore may be a result of preventing transmigration of cells at the BBB, inhibiting demyelination[1] and also reducing the level of active TNFα within the CNS, through inhibition of ADAM17, thus preventing exacerbation of the inflammatory process. It has been shown that TNFα exacerbates EAE and preventing its actions with specific antibodies or soluble receptors is beneficial in treatment of mice with EAE[22].

The PA/Plasmin System

The PA/plasmin system has received much less attention than the MMPs in EAE, despite the interactions between the two systems and the potentially important role of plasmin, generated by plasminogen activation inEAE. Both tPA and uPA are produced as single chain proforms requiring activation to two chain forms by proteolytic cleavage by enzymes such as plasmin or cathepsin B, or in the case of tPA by binding to fibrin[41,42]. These enzymes differ in their extracellular location which influences their function. tPA binds to extracellular components whereas uPA is predominantly cell associated, bound to specific uPA receptors (uPARs)[42,43]. uPA is therefore thought to be involved in processes requiring pericellular proteolysis such as tissue remodelling and cell migration/invasion and tPA in fibrinolysis.

uPARs concentrate uPA on cell surfaces and enable more efficient plasminogen activation when plasminogen is also bound to the cell surface[44,45]. uPAR binding of pro-uPA also enhances its activation[44]. Plasmin generated at cell surfaces in this way is not susceptible to inhibition by its major inhibitor α2-antiplasmin[45]. The receptor binding of uPA may also facilitate other direct catalytic activities such as its ability to degrade fibronectin, activation of hepatocyte growth factor, an activity shared with tPA, and activation of procathepsin B[46,47,48]. Furthermore, uPARs can bind to vitronectin in the ECM promoting cell adhesion and migration[49] and

signalling can occur via uPA receptors by association of receptor molecules with adaptor molecules such as integrins[50,51].

The activity of PAs and plasmin is controlled not only by their production as proenzymes requiring activation but also by the presence of endogenous inhibitors. The major inhibitor of plasmin is α2-antiplasmin and there are three specific inhibitors of PAs, PA inhibitors 1, 2 and 3 (PAI-1, 2 and 3) which bind only the active two chain forms of the enzymes[52].Two less specific inhibitors are the protease nexin and neuroserpin, which inhibit plasmin and thrombin and trypsin respectively, in addition to the Pas[53,54]. PAI-1, in addition to binding to PAs, also binds to vitronectin and can compete with uPARs for vitronectin binding, hence modulating cell adhesion and movement[49,50].

The PA/plasmin system in EAE

An early insight into the role of the PA/plasmin system in EAE was obtained from investigations on the effects of a range of proteinase inhibitors on the development of disease. It was thought that a major source of these enzymes was activated macrophages within the inflammatory lesion[32,55,56]. These studies used an active model of EAE in Lewis rat. Inhibitor treatment was started on day 6 or 7 after induction and continued until around day 16 when the experiments were terminated. In these studies, inhibitors of PA and plasmin, aminomethylcyclohexane carboxylic acid (AMCA), ε-aminocaproic acid (EACA) and ρ-nitrophenylguanidinobenzoate (NPGB) gave protection against EAE in terms of reduction of paralysis and weight loss. Histologically only a slight reduction in infiltration by inflammatory cells was seen in rats treated with AMCA and EACA but the extent of infiltration and the degree of demyelination surrounding these cells was reduced. Interestingly trasylol, an inhibitor of PA and plasmin, exacerbated EAE in both studies. The effects of AMCA have also been investigated in a a passive transfer model of EAE in the Lewis rat. The inhibitor was started on day 2 after cell transfer and continued until the end of the experiment on day 9 or 10. Again clinical signs of EAE were reduced in the treated rats, however cellular infiltrates were still observed. These workers also studied the effect of AMCA on the permeability of the BBB using a double isotope method to study the distribution of ^{125}I and ^{135}I-labelled human serum albumin. They found a reduction in BBB permeability in AMCA treated rats compared with saline treated controls which appeared to be coincident with clincal improvement. They suggested that the BBB barrier permeability was the result of reduced fibrinolysis. Breakdown of fibrin, deposited on endothelial cells of CNS blood vessels as a result of inflammatory processes would, in the absence of AMCA, produce vasoactive peptides which could increase permeability of the BBB.

Effects of D-penicillamine, an inhibitor of MMP9 and tPA and uPA have been investigated in mouse models of acute and chronic relapsing EAE. Penicillamine inhibited disease development and attenuated disease recurrence[38]. It was suggested that penicillamine modulated MMP9 activity directly and indirectly via PA/plasmin mediated activation.

These observations provide circumstantial evidence for the involvement of the PA/plasmin system in the pathogenesis of EAE, however the inhibitors used may not be absolutely specific for PAs and plasmin and could act via other serine proteinases. More recent studies have investigated the induction of components of the PA/plasmin system in EAE. Koh and coworkers studied PA activity in normal rats and the Lewis rat cell transfer model of EAE[57]. Activity was determined using a fibrin slide technique on sections of spinal cord. Fibrin degradation which occurred only in the presence of plasminogen was taken as a measure of PA activity. Normal rats showed PA activity associated with vascular endothelial cells, particularly meningeal endothelial cells. In EAE, PA activity decreased in the early phase of disease, compared to normal rats and remained low during clinical disease and increased with remission. Little or no activity was associated with vessels containing inflammatory cells, however this was suggested to be an artefact resulting from cell binding of PA which limited its diffusion into the fibrin overlay. This drop in PA activity may be the result of:- (1) exhaustion of endothelial cell PA content in the presence of fibrin deposition in blood vessels at lesion sites; (2) release of PAI-2 by infiltrating monocyte-macrophages and (3) stimulation of PAI-1 production by endothelial cells in response to inflammatory cytokines, IL-1 and TNF. It was suggested that rather than promoting demyelination, infiltrating monocyte-macrophages may promote remission by down-regulating fibrinolysis and release of fibrin degradation products, some of which are chemotactic and may contribute to disruption of the BBB.

More recent studies have however shown induction of elements of the PA/pasmin system in EAE. Teesalu et al investigated the expression of tPA, uPA, PAI-1 and uPAR in spinal cord and brain from a BALB/c mouse model of EAE, induced with an emulsion of mouse spinal cord in complete Freund's adjuvant followed by an injection of pertussis toxin 24h later[29]. In situ hybridisation and zymography were used to detect gene expression of these components and PA activity respectively. In situ hybridisation in normal animals indicated little or no transcripts for tPA, uPA, PAI-1 or uPAR. Spinal cords from EAE mice showed tPA transcripts on the edge of the white matter in activated astrocytes. The presence of tPA protein in activated astrocytes was confirmed by immunohistochemistry. PAI-1 transcripts had a similar distribution to tPA and both were also increased in the brainstem and pons. uPA transcripts were undetectable, but uPAR transcripts were present in immune cells in inflammatory lesions. This contrasts with PA activity, determined by in situ zymography, which was

detected in spinal cords, this was weak in control animals but increased in EAE and was present in areas of the dorsal horn, central spinal cord and along the meninges. A slight reduction of activity was noted in the presence of amiloride, an inhibitor of uPA, indicating the presence of both tPA and uPA, though tPA appears the predominant enzyme in this model.

Ahmed and coworkers, using a relapsing remitting model of EAE in Lewis rat, with relapses induced with IL-12, saw an increase in tPA, determined by immunostaining, during the second and third relapse[58]. It was localised to macrophages and activated microglia in inflammatory cuffs and microglia and axons in grey and white matter. Whereas in first relapse animals, tPA was confined to inflammatory cells in cuffs and microglia in the grey matter but not in axons. PAI-levels, also determined by immunostaining, appeared to decrease as tPA increased.

There are a number of speculations about the role of the PA/plasmin system in these latter two models[29,58]. The increase in tPA may be both detrimental and beneficial. tPA/plasmin mediated ECM degradation may lead to damage to the BBB and neuronal damage[36]. Neuronal damage and demyelination is more evident in relapsing remitting models of EAE. tPA is thought to promote neuronal damage by mediating the degradation of laminin, the loss of substratum causing cell death via apoptosis[12,59] and by the activation of microglia via a non-proteolytic mechanism[60]. Activation of protease-activated receptors (PARs) by serine proteinases such as plasmin, leading to astrocyte proliferation and microglial activation may also contribute to tissue damage[61,62,63].

tPA may have beneficial effects via tPA mediated degradation of fibrin deposits in areas of perivascular inflammation. The clearance of fibrin may limit the extent of immune cell infiltration by removing a substrate for immune cell adhesion and invasion[29]. tPA mediated fibrinolysis has also been shown to reduce axonal degeneration and demyelination after damage[64]. Activation of TGF-β by the PA/plasmin system may also be beneficial, reducing the production of NO by microglia which is toxic to microglia and oligodendrocytes[20]. uPA, though less evident in these models of EAE, may contribute to plasmin generation and its consequences. uPARs could promote adhesion and movement of inflammatory cells on perivascular deposits of vitronectin. PAI-1, in addition to modulating PA activity, modulates uPAR mediated cell adhesion to vitronectin.

The evidence available strongly suggests a role for the PA/plasmin system in EAE, though this would appear to differ in different models and is complicated by the range of effects mediated by this system which may exacerbate or alleviate EAE.

Myelencephalon-specific protease

In addition to the PA system proteinases, another trypsin-like serine proteinase, rat myelencephalon-specific protease (MSP), (human homologue, kallikrein 6), has been implicated in demyelination in EAE and MS[65]. MSP is more highly expressed in the CNS compared to other non-neuronal tissues where it is present in neurons and oligodendroglia[66]. In a marmoset model of EAE, MSP was found at lesion sites in infiltrating mononuclear cells where it may be secreted from these cells and activated by proteolysis[65,67].

MSP has a broad substrate specificity including MBP, MOG and ECM components laminin, fibronectin, and collagen[65,67]. In EAE, inflammatory cell MSP may therefore contribute to demyelination and immunogenic peptide production and may facilitate their infiltration into the CNS by degradation of the BBB basal lamina. Addition of MSP to oligodendrocytes in vitro has also been shown to interfere with process formation, reducing formation in immature cells and causing loss of processes in mature cells. Such effects may be detrimental to repair processes[65]. It has been suggested that the predominant CNS distribution of MSP, makes it a good potential therapeutic target for MS, however it requires further characterisation in terms of its regulation.

CALCIUM-ACTIVATED NEUTRAL PROTEINASE

Calcium-activated neutral proteinase (calpain) is another enzyme thought to have a role in the pathogenesis of EAE[68]. Calpain is a cytosolic cysteine endopeptidase, active at neutral pH and with activities against a range of proteins including neurofilament protein, myelin and its own endogenous inhibitor calpastatin[69]. There are two main subclasses of calpain, ubiquitous and tissue specific[70] and it is the ubiquitous subclass which has been implicated in EAE[68,71]. Ubiquitous calpain has microcalpain and millicalpain isoforms (EC 3.4.22.17) so called because they are activated by μM or mM concentrations of calcium respectively.

Calpain level and activity and calpastatin levels were studied in the spinal cords of Lewis rats, 10 – 12 days after induction of EAE by immunisation with guinea pig MBP. Calpain, determined as millicalpain, and calpastatin levels were increased in EAE as was the activity of calpain, determined indirectly by the presence of calpain-specific breakdown products of neurofilament protein and myelin associated glycoprotein. There was no significant increase in mRNA for calpain or calpastatin, suggesting that their regulation was at the post-translational level[68]. In view

of its substrate specificity, calpain is thought to be involved in demyelination and axonal degeneration via breakdown of neurofilaments[72,73]. Increased expression in activated glial and inflammatory cells in EAE support this[71]. Its degradation of MBP is only partial but may lead to the production of immunogenic peptides, exacerbating EAE.

In order to degrade myelin or neurofilaments calpain requires activation by calcium. Activation of either of the calpain isoforms intracellularly would require a calcium influx as intracellular calcium is ~ 100 nM. In EAE this could result from complement fixation at the cell surface or perforin damage[74,75] and would enable intracellular degradation of myelin in the myelin sheath. Alternatively calpain may be secreted and function extracellularly where calcium levels are ~2 mM. Calpain can be secreted from activated macrophages and T cells[76,77,78].

Calpain is also thought to be involved in T cell migration from the spleen to the brain in EAE, promoting disease progression. Calpain activity and levels are increased in spleen T cells and macrophages in developing EAE[79]. However this may not be specific to EAE, but may be a more generalised response to immunisation as it was also seen in rats given complete Freund's adjuvant containing *Mycobacterium tuberculosis* but no MBP. Calpain may facilitate T cell migration by disruption of cytoskeleton/integrin links enabling clustering of LFA-1 and enhanced binding to adhesion molecules[80,81]. This may be important in enabling the passage of T cells across the BBB.

Caspases

Caspases are involved in apoptosis and cytokine activation[82]. Their role in apoptosis is discussed in detail in the chapter by Gold and Chan. Caspase-1 (EC 3.4.22.36) is involved in the activation of IL-1β and was formerly known as IL-1β converting enzyme (ICE). It is therefore a key early component in inflammatory processes. Caspase-1 has been shown to be induced in a mouse model of EAE, induced by immunisation with incomplete Freund's adjuvant supplemented with *Mycobacterium tuberculosis* and MOG peptide 35-55 or spinal cord homogenate[83]. Transcription levels of caspase-1 correlated with the severity of disease and the transcription rates of pro-inflammatory cytokines such as IL-1β and TNFα. The caspase inhibitor, Z-Val-Ala-DL-Asp-fluoromethylketone reduced the incidence of EAE in mice, when administered from the time of immunisation However when administered 7 days post immunisation, it had little therapeutic effect. Caspase-1 null mice showed a reduced severity and susceptibility to induction of EAE. These results indicated the importance of caspase-1 in the early stages of development of EAE[83].

Mast cell proteinases

Early work showed that activated mast cells produced proteinases capable of degrading rat myelin to produce an encephalitogenic peptide. Immunisation of Lewis rats with this peptide or adoptive transfer of T cell lines stimulated with the peptide produced EAE[84]. Mast cells have been localised in MS brain, in normal rat brain and in brain from a Lewis rat model of EAE. In the CNS of EAE rats there was an apparent increase in mucosal-type mast cells fairly late on in the disease process, 13 days post immunisation. This was determined by the mRNA expression and immunoreactivity of rat mast cell protease II (RMCPII) (EC), a marker for this type of mast cell. The RMCPII content of these cells was also increased. These mast cells were localised adjacent to inflamed blood vessels[85]. Mast cells and their proteinases may therefore contribute to EAE via demyelination and the generation of immunogenic peptides.

Peptidases

There have been few studies on the role of peptidases in EAE. Two peptidases implicated in the disease process are angiotensin converting enzyme I (ACE) (EC 3.4.15.1) and dipeptidyl peptidase IV (DPIV)(CD 26) (EC 3.4.14.5). ACE is a membrane bound peptidase which mediates inflammation, participates in T cell activation via its generation of angiotensin II and has effects on the permeability of the BBB[86,87,88,89]. Evidence for the involvement of ACE in EAE comes from a study of the effects of an ACE inhibitor, captopril, in a Lewis rat model of EAE. It was shown that when captopril was administered from the day of immunisation, it reduced both disease severity and the in vitro responsiveness of lymphocytes from captopril treated rats to MBP[90].

DPIV is also a membrane bound peptidase which is present on T cells and is involved in T cell activation and function[91]. It has been investigated in a mouse model of EAE induced by adoptive transfer of lymph node cells from mice immunised with either guinea pig MBP or peptide 139-151 from PLP[92]. The effects of DPIV inhibitor Lys[Z(NO_2)]-pyrrolidide (I40) were studied. When administered from the day of cell transfer a reduced incidence and severity of disease was observed. It was also effective in reducing disease severity if administered following development of clinical signs which agreed with histological evidence of reduced inflammatory lesions and myelin loss. In vitro studies showed a reduction in proliferation and pro-inflammatory cytokine secretion by MBP primed lymph node cells and an increase in TGFβ1 secretion. Thus it was suggested that the effects were mediated by TGFβ1 production, which in turn suppressed disease[93].

Thus DPIV appears to have an important role in the activation and function of T cells in EAE and could constitute an important new therapeutic target.

SUMMARY

The evidence reviewed here provides strong support for an effector function for proteases and peptidases in the pathogenesis of EAE in a range of rodent species using both active and passive disease transfer models as well as relapsing remitting forms. Inhibition of these enzymes has resulted in amelioration or prevention of the disease. Effective inhibition in some cases required administration before disease onset, whereas others were effective when given after disease onset. The PA/plasmin/MMP enzymes have been most specifically identified as the major contributors to the pathological process including increasing the permeability of the BBB, degradation of the myelin sheath resulting in axonal damage, generation of active pro-inflammatory cytokines by cleavage of the pro forms, further propagating inflammation within the CNS and finally generation of further encephalogenic peptides which may promote the autoimmune. However other enzymes such as MSP may provide more specific potential targets for new drug development.

Chapter A20

THE BLOOD-BRAIN BARRIER IN EAE

Britta Engelhardt[1] and Hartwig Wolburg[2]
[1]Theodor-Kocher Institute, Bern, Switzerland and [2]Institute for Pathology, University of Tübingen, Germany

Abstract: The normal function of the blood brain barrier (BBB) is the maintenance of the central nervous system homeostasis. The normal structure, development, differentiation and maintenance (and in particular the role of tight junctions) of the BBB are discussed in this chapter, followed by a description of the pathological changes in the BBB during EAE: leakiness, molecular changes in the tight junctions, the crossing of encephalitogenic T cells and the immunological factors responsible for the BBB breakdown during EAE.

Key words: EAE, cerebrospinal fluid, blood brain barrier, tight junctions, endothelium

1. INTRODUCTION

Homeostasis of the central nervous system (CNS) microenvironment is essential for its normal function and is maintained by the blood-brain barrier (BBB). The BBB is formed by highly specialized capillary endothelial cells, which inhibit transcellular passage of molecules across the barrier by an extremely low pinocytotic activity. The lack of fenestrae and an elaborate network of complex tight junctions (TJ) between the endothelial cells restrict the paracellular diffusion of hydrophilic molecules. On the other hand, in order to meet the high metabolic needs of the CNS tissue, specific transport systems selectively expressed in the capillary brain endothelial cell membranes mediate the directed transport of nutrients into the CNS or of toxic metabolites out of the CNS.

Because of the presence of the BBB, the lack of lymphatic vessels and the absence of classical MHC-positive antigen presenting cells the CNS is considered an immunologically privileged site. In fact, under physiological conditions lymphocyte entry into the healthy CNS across the BBB is kept at a low level. During inflammatory diseases of the CNS such as in multiple sclerosis (MS) or its prototype animal model experimental autoimmune encephalomyelitis (EAE), however, circulating immunocompetent cells readily get access to the CNS. In EAE, $CD4^+$ autoaggressive T cells are activated outside the CNS, migrate across the healthy BBB into the CNS and

start the molecular events leading to inflammation, loss of barrier properties and subsequently edema formation and finally demyelination.

During inflammatory demyelinating diseases the BBB might be considered as performing both, a passive and an active role. Loss of barrier function during EAE might be considered as a passive involvement of the BBB leading to edema formation and exacerbation of the disease. In contrast, the BBB is actively involved in such disease processes as the altered phenotype of BBB endothelium during EAE that is characterized by enhanced expression of traffic signals like adhesion molecules and chemokines leads to enhanced leukocyte traffic into the CNS and consecutively chronic inflammation. In this chapter we will describe the molecular mechanisms involved in altered BBB function during EAE and consider their impact on the initiation and progression of the disease process.

2. THE PHYSIOLOGICAL BLOOD-BRAIN BARRIER

2. 1 History

The discovery of a vascular barrier between blood circulation and the CNS dates back more than 100 years, when in the 1880s Paul Ehrlich and Edwin E. Goldman discovered that upon the injection of protein-bound dyes into the vascular system they were rapidly taken up by all organs with the exception of the brain and spinal cord (Ehrlich, 1904), whereas the very same dyes when injected into the cerebrospinal fluid readily stained neural tissue but were excluded from all the other organs (Goldmann, 1913). Obviously these dyes could not penetrate the wall of CNS blood vessel. The concept of a vascular blood-brain barrier, which also functions as a brain-blood barrier was born. It took an additional 70 years until Reese, Karnovsky and Brightman (Reese and Karnovsky, 1967; Brightman, 1968) localized the barrier ultrastructurally to the capillary endothelial cells within the brain by electron microscopy studies. Following injection into the vasculature or into the CNS, the electron-dense tracer horseradish peroxidase distributed into the intercellular clefts of brain endothelial cells up to the tight junctions (TJs) between the endothelial cells. Thus, the interendothelial TJs were recognized as the morphological correlate of the blood-brain barrier (BBB; Figure 1).

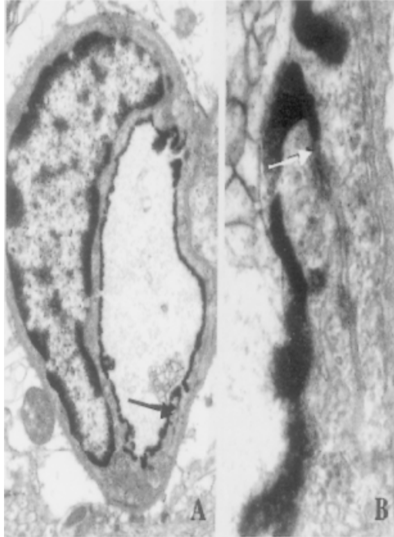

Figure 1:
Ultrastructural localization of the BBB
Diffusion of the electondense tracer lanthanum localizes the BBB to the endothelial TJs
A: Rat brain capillary with lanthanum deposited on the luminal surface of the endothelium. The arrow points out the TJ where diffusion of lanthanum stops. B: higher magnification of the TJs pointed out in A.

2.2 Development, differentiation and maintenance of the BBB

During embryogenesis the development of the brain vascular system begins when angioblasts, which differentiate from the mesoderm, enter the head region and form the perineural vascular plexus that covers the entire surface of the neural tube. From the perineural plexus vascular sprouts invade the proliferating neuroectoderm. This mechanism, whereby new vessels are formed from pre-existing vessels, is called angiogenesis (Risau, 1997). These observations suggested that the embryonic brain produces angiogenic factors that bind to specific receptors expressed on endothelial cells thus leading to migration and proliferation of these cells. To date, the probably most critical of these factors have been characterized largely by analyzing genetically modified mice. By using these mouse models, the essential roles of numerous gene products for blood vessel development and morphogenesis in general including the brain have thus been established. The most prominent examples of genes, the function of which is essential during development already, include VEGF-A and its endothelial tyrosine kinase receptors VEGF-R1 (Flt-1) and -R2 (Flk-1), the receptor tyrosine kinases Tie-1 and Tie-2 as well as the Tie-2 ligands Angiopoietin-1 and -2, components of the TGFβ signalling pathway (such as TGFβ1, ALK-1, endoglin, SMAD5 and SMAD6) and more recently members of the EphB-receptor / ephrinB-ligand family such as EphB4 and ephrinB2 and also select members of the Notch receptor / jagged and delta-like ligand families (for review see Risau 1997; Gale and Yancopoulos 1999; Carmeliet and Collen, 2000; Adams 2002). By virtue of gene targeting technology it has been demonstrated that the VEGF-A ligand and its receptors VEGF-R1 and -R2

are essential for endothelial cell lineage specification, differentiation and blood vessel formation. Based on the spatial and temporal relationship of VEGF and VEGF-R expression during brain angiogenesis, it seems that capillary sprouts originating from the perineural vascular plexus expressing VEGF-R1 and-R2 radially invade into the developing neuroectoderm along a concentration gradient of VEGF, which is highly expressed by cells in the ventricular layer of the developing neuroectoderm (summarized in Engelhardt and Risau, 1995). There is a precise regulation of the timing and pattern formation in brain angiogenesis in mammals with brain angiogenesis being maximal in early post-natal days and downregulated in the adult (Bär, 1980). Obviously, additional signals are required to produce the complex architecture of a mature vascular tree within the CNS. In recent years, two endothelial cell specific receptor tyrosine kinases, Tie-1 and Tie-2 have been identified, the activities of which seem to govern processes that allow for endothelial cell sprouting, remodelling of primitive vascular networks and blood vessel maturation and integrity (Dumont et al., 1994). Tie-2 and at least two of its angiopoietin ligands (Ang-1 and Ang-2; Davis and Yancopoulos, 1999) are involved in the regulation of angiogenic sprouting, vascular remodelling and recruitment of perivascular cells during embryonic development. A common feature of Tie-2 and Ang-1 deficient embryos is a defect in the association of endothelial cells with the underlying extracellular matrix and with perivascular cells. Based on these findings, it has been suggested that Tie-2 signalling could be required for upregulation of factors in endothelial cells that are chemotactic for pericytes and smooth muscle cells leading to the migration of these cells towards the endothelial cell wall and subsequent maturation of the vessels by an increased production of extracellular matrix components elicited by the action of activated TGF-β and other proteins (Folkman and D'Amore, 1996). Amongst these, platelet-derived growth factor (PDGF)-B, a high affinity ligand for the receptor tyrosine kinase PDGF-Rβ present on perivascular mesenchymal cells is produced by endothelial cells during development. PDGF-B has been shown to be involved in vascularization of the brain as disruption of the PDGF-B gene leads to pericyte loss and lethal micoraneurysm formation during late embryogenesis (Lindahl et al., 1997).

Even though many of the molecular components involved in brain angiogenesis have now been identified, their exact mechanisms of action are still not fully understood. Furthermore, as these mechanisms also apply outside the CNS it seems unlikely that they are involved in BBB differentiation. However, the biggest remaining obstacle to the understanding of the roles of those proteins for the development of specific vascular beds is the fact that mutations in their genes invariably lead to lethal phenotpyes during early embryogenesis before BBB differentiation starts. Therefore, meaningful *in vivo* analysis of their possible involvement in BBB differentiation or their contribution during pathological alterations of the BBB has to await the development of more sophisticated genetic models such as conditional and inducible mouse mutants.

In any case, additional molecules specifically expressed in brain endothelial cells have to be involved in the differentiation of the BBB. To date, specific expression of the non-receptor tyrosine kinase *lyn* (Achen et al., 1995) and of gene products encoding P-glycoprotein has been demonstrated early during brain angiogenesis (Qin and Sato, 1995). Whereas the relevance of *lyn* expression during brain angiogenesis remains to be determined, expression of P-glycoprotein is required for the differentiation of the BBB (Schinkel et al., 1994) and seems to ensure the rapid removal of toxic metabolites from the neuroectoderm before the BBB has fully differentiated. In the developing chicken CNS, it has been shown that angiogenic vessels invading the neuroectoderm express N-cadherin between endothelial cells and pericytes. With the onset of barrier differentiation, N-cadherin labelling decreased suggesting that transient N-cadherin expression in endothelial and perivascular cells may represent an initial signal which may be involved in the commitment of early blood vessels to express BBB properties (Gerhardt et al., 1999). Thus establishing of the barrier is accompanied by further changes in the phenotype of the brain endothelial cells such as upregulation of the HT/7-antigen/basigin (Seulberger et al., 1992) or downregulation of the MECA-32 antigen (Hallmann et al., 1995), the mouse homologue of the rat VP-1 (Stan et al., 1999) besides the expression of specific transporters and metabolic pathways can be observed (Pardridge, 1988; Pardridge, 1991). At present, the development of the barrier function of brain capillaries is basically still investigated as done by Paul Ehrlich over 100 years ago by measuring the decreasing permeability for vascular tracers. Although different approaches gave somewhat different results (Wakai and Hirokawa, 1978; Risau, 1991; Stewart, 2000; Dziegielewska et al., 2001) it has become clear that BBB tightness is not just "switched on" at a specific time point during brain angiogenesis but rather that the tightening of the barrier occurs as a gradual process, which is independent from vascular proliferation and begins late during embryogenesis when angiogenesis is not complete (Risau et al., 1986). The molecular mechanisms involved in this process are not understood until today. Based on the elegant transplantation studies of Stewart and Wiley, who were first to show that vessels derived from the coelomic cavity when growing into an ectopic brain transplant gain BBB characteristics (Stewart and Wiley, 1981), it is known that the development of BBB characteristics in endothelial cells is not pre-determined but rather induced by the neuroectoderm.

The question remains, which cell or combination of cell types within the neuroectoderm induces BBB characteristics in endothelium. Astrocytic endfeet are in close proximity to the endothelial cells' plasma membrane and are separated only by the basal lamina. As the astroglial perivascular sheet is a unique feature of CNS capillaries and forms at around the same time as the permeability barrier develops (Phelps, 1972), astrocytes and their precursors have been implicated in the induction of the BBB (Goldstein, 1988). First hints have been provided by Janzer and Raff (Janzer and Raff, 1987), who were the fist to demonstrate that purified astrocytes induce BBB-like

permeability changes in invading endothelial cells *in vivo*. However, as some of the BBB characteristics in brain endothelial cells appear very early and prior to astrocyte differentiation, other cell types might be involved in BBB differentiation in addition to astrocytes. The fully differentiated BBB consists of a complex cellular system of highly specialized endothelial cells, pericytes embedded in the basal membrane, perivascular cells and astrocytic endfeet (Figure 2).

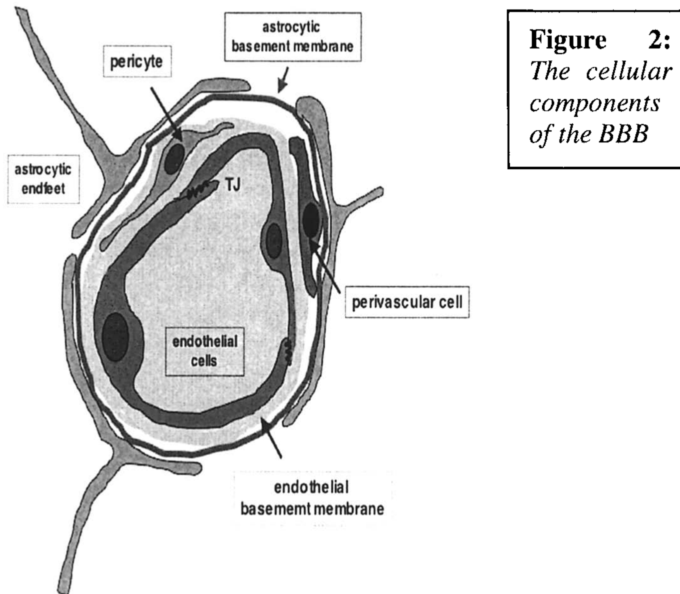

Figure 2: *The cellular components of the BBB*

While the endothelial cells form the barrier proper, the interaction with adjacent cells seems to be a prerequisite for barrier function. Pericytes are found in close association with endothelial cells even at very early stages of development and seem to be more prevalent on neural capillaries than on other capillaries (Simionescu et al., 1988). The function of pericytes *in vivo* has been unclear for a long time (Sims, 1986), but recently it has become evident that they are required for vessel maturation (Lindahl et al., 1997).

The role of the extracellular matrix in the induction and maintenance of the BBB has been insufficiently investigated so far. This may partly be due to the enormous molecular heterogeneity including different laminins, collagens, fibronectin etc. (see below). In particular agrin, a heparan sulfate proteoglycan, was found in the basement membranes of vessels with special barrier properties like those in the brain, thymus and testis, and it has been proposed to be involved in the development of the BBB (Barber and Lieth, 1997). Agrin was first isolated from the electric organ of *Torpedo californica* and identified to be essential for clustering acetylcholine receptors in the postsynaptic membrane of the motor endplate (Nitkin et al., 1987).

Astrocytes have been shown to express agrin *in vivo* and *in vitro*, which is why agrin could serve as a basal membrane factor inducing barrier functions in brain endothelium *in vivo*. Since agrin is linked to the cytoskeleton via dystroglycan and the dystrophin-glycoprotein complex (Blake and Kröger, 2000), it could participate in establishing cellular polarity, which is a characteristic feature of perivascular astrocytes. In any case, it is noteworthy that the extracellular matrix of leaky blood vessels in malignant human brain tumors was found to be devoid of agrin (Rascher et al., 2002). In multiple sclerosis or in EAE, BBB capillaries also become generally permeable leading to edema formation and exacerbation of the disease. These observations suggest that a continuing regulation of BBB maintenance is provided by the tissue microenvironment. Disturbances in the molecular interplay between the CNS microenvironment and the BBB might therefore lead to BBB dysfunction.

Taking these observations together, based on the observations that early during embryogenesis endothelial-neuroectodermal interactions induce a "commitment" in endothelial cells to form a BBB lineage, we have previously proposed two phases of endothelial –neuroectodermal interactions leading to BBB differentiation (Engelhardt and Risau, 1995). This is documented by the early induction of specific genes in those endothelial cells such as *lyn* and P-glycoportein (see above). In a subsequent phase, secondary interactions of "committed" brain endothelial cells with the developing neuroectoderm elements induce further endothelial differentiation, which leads to the fully functional BBB. Whereas the "commitment" of brain endothelial cells to form a BBB remains stable, the second phase might be reversible. Maintenance of a functional BBB thus strictly depends on the permanent interaction of the BBB endothelium with the surrounding cellular and extracellular elements. Molecular changes in the CNS within close proximity of the vascular barrier will thus lead to changes in BBB phenotype and function. Thus immigration of encephalitogenic cells across the BBB during EAE would induce an alteration in the "molecular communication" of the perivascular cells with BBB endothelium and ultimately lead to altered BBB function (see below).

2. 3 In vitro models of the BBB

Further evidence for the necessitiy of continuous signals provided by the CNS microenvironment for brain endothelial cells to maintain barrier properties is provided by *in vitro* observations. When brain endothelial cells are isolated and cultured *in vitro* they rapidly lose many of their BBB characteristics including formation of proper TJs and a permeability barrier, indicating that integrity of the BBB strictly depends on signals provided by the CNS microenvironment (Figure 3).

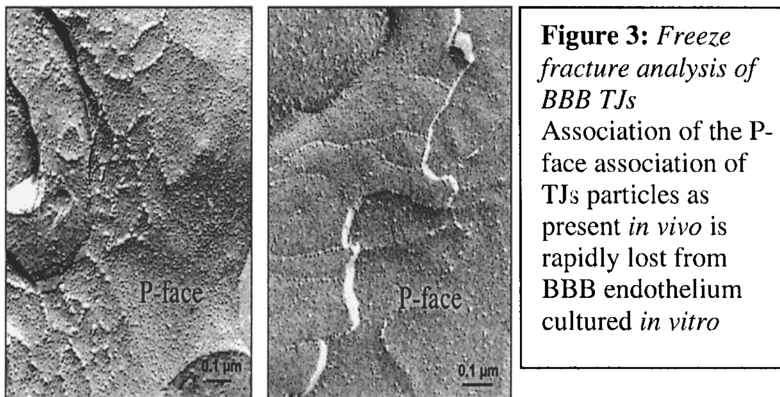

Figure 3: *Freeze fracture analysis of BBB TJs*
Association of the P-face association of TJs particles as present *in vivo* is rapidly lost from BBB endothelium cultured *in vitro*

This is in contrast to epithelial cells, which when cultured *in vitro* still form proper TJs emphasizing that the formation of epithelial TJs is less dependent on extrinsic factors than the formation of endothelial TJs (Kniesel and Wolburg, 2000). This might be due to the fact that the architecture of epithelial and endothelial TJs differ with respect to their spatial and molecular organisation. In endothelial cells components of adherens junctions and TJs can be intermingled along the intercellular cleft, whereas they remain spatially separated in epithelial cells (Schulze and Firth, 1993). Thus, *in vitro* BBB models employing epithelial cells have to be considered as not suitable for the study of BBB characteristics. Also, based on the observations described above, namely that brain endothelial cells become "committed" to form a BBB during emryogenesis, *in vitro* BBB models employing non-cerebral endothelial cells must be considered less appropriate, as these endothelial cells lack expression of genes specifically induced in brain endothelial cells during development.

Several *in vitro* BBB models have been established which utilize the co-culture of cerebral porcine or bovine brain endothelial cells with primary glial cells mimicking the *in vivo* BBB microenvironment (Meresse et al., 1989; Rubin et al., 1991; Wolburg et al., 1994). In most of those models the permeability barrier and high electrical resistance of the cerebral endothelial cells have been extensively characterized. *In vitro* establishment of other biological aspects of BBB endothelium, such as expression of surface markers (i.e. HT7/basigin) (Prat et al., 2001) or transcytosis of LDL or transferrin (Cecchelli et al., 1999) across the cerebral monolayer has, however, been investigated less frequently. In agreement with the literature (reviewed in (Wolburg and Lippoldt, 2002), when employing the *in vitro* BBB model by Cecchelli (Cecchelli et al., 1999) we observed that bovine brain capillary endothelial (BBCE) cells grown in mono-culture *in vitro* did not build a permeability barrier to tracers, whereas co-culture of BBCE cells

with primary glial cells for 10 days induced a tight permeability barrier (Hamm et al. manuscript submitted). In that study, we could demonstrate that removal of glial cells from the co-culture resulted in a modulation of the permeability barrier. Therefore, in this *in vitro* system the permeability barrier of the BBCE cells is directly dependent on humoral factors present in the co-culture only. Modulation of the BBB *in vitro* was due to the opening of the endothelial TJs as demonstrated by the increased permeability to ^{3}H-inulin and ^{14}C-sucrose and most significantly by their opening to horseradish peroxidase at the ultrastructural level. An increase in the number of pinocytotic vesicles leading to increased transendothelial transport of tracers did not occur.

Our observations emphasize that leakiness of the BBB most probably occurs via modulations at the TJ level. To date, no *in vitro* system has yet been established that allowed the induction of TJ complexes between the cultured endothelial cells in such a way that they mimicked barrier properties leading to high electrical resistance measurements as *in vivo*.

In contrast to their compromized usefulness for investigations of the molecular mechanisms involved in barrier formation or barrier breakdown (i.e. the passive involvement of the BBB in EAE pathogeneis), *in vitro* cultured brain endothelial cells or even brain endothelial cell lines have proven to be valuable tools to study traffic signals involved in leukocyte/endothelial interactions *in vitro* (active contribution of the BBB in EAE pathogenesis), which have proven to be valid *in vivo* as well (Greenwood et al., 1995b; Laschinger and Engelhardt, 2000; see below).

2. 4 Tight junctions (TJs) of the BBB

2.4.1 Morphology

Although BBB TJs are unique as they are very sensitive to ambient factors, within ultrathin section electron micrographs their morphology resembles those of epithelial TJs as they appear as a chain of fusion points - "kisses" - of the outer plasma membrane leaflet of adjacent cells (Figure 4). Additionally, TJs between the endothelial cells of the brain microvessel have been analysed by qualitative freeze-fracture electron microscopic studies. TJs function as a seal only if they are continuous and branched. The complex network of TJs between brain endothelial cells is therefore primarily responsible for the paracellular impermeablity and, unlike simple TJs present between endothelial cells elsewhere in the organism, provides a high electrical resistance.

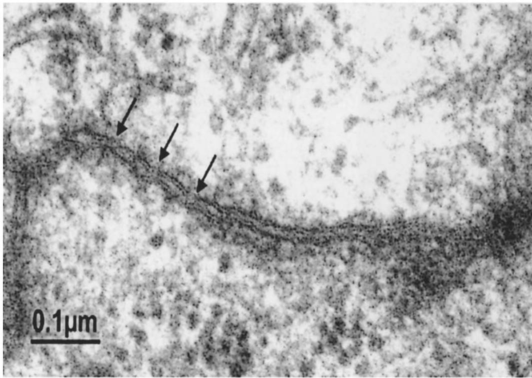

Figure 4: *TJ "kisses" between endothelial cells of the BBB*
Ultrathin section of a BBB TJ. Arrows point to the characteristic kissing points of the outer leaflets of the plasma membranes of adjacent cerebral endothelial cells.

In freeze-fracture electron microscopy studies the BBB TJs have been demonstrated to be more complex than TJs in other endothelial cells in the body appearing as a continuous network of parallel and highly interconnected strands that circumscribe the apex of lateral membranes of adjacent cells (Figure 3; Nagy et al., 1984; Nico et al., 1992). However, it turned out that the complexity of strands is only one feature of the tight junctional network and that the association of the TJ particles with the protoplasmic (P-face) or external leaflet of the membrane (E-face) is another criterion to correlate morphology and physiology of TJs. In the endothelial cells that form the BBB, the association of TJ particles with the P-face is higher than in all other endothelial cells of the entire vasculature of the body. It was shown that the P-face association correlates with the barrier function of the BBB endothelium (Figure 3; (Wolburg et al., 1994). This observation is also consistent with the low P-face association in TJs of peripheral, non-barrier endothelial cells, where the E-face associated tight junctional particles clearly predominate (Mühleisen et al., 1989; Simionescu et al., 1988). It has been hypothesized that there is an important functional role for the P-face association, and thus presumably the cytoplasmic anchoring of the TJ particles, particularly for BBB function (Wolburg et al., 1994). This is further supported by the finding that a molecular component, which was identified to associate with the P-face, claudin-3, is predominantly incorporated into BBB endothelial cell tight junctions (see below).

2.4.2 Molecular composition of BBB TJs

In recent years, several proteins have been identified that are asociated with epithelial and endothelial TJs (Figure 5). This group of TJ associated proteins include cytoplasmic peripheral membrane proteins of the MAGUK

family, such as ZO-1, ZO-2 and ZO-3 (reviewed in Tsukita et al, 1999 and Wolburg and Lippoldt, 2002). These proteins link integral membrane proteins of the TJs to the cytoskeleton. Occludin was the first integral membrane protein found to be exclusively localized within TJs (Furuse et al., 1993). However, mice carrying a null mutation in the occludin gene are viable and develop morphologically normal TJs in most tissues including the brain (Saitou et al., 2000) proving that occludin is not essential for proper TJ formation. In contrast to occludin, the claudins, which exhibit no sequence-homology to occludin, comprise a novel gene-family of integral membrane TJ proteins with more than 20 members to date and have been shown to be sufficient for the formation of TJ strands (Morita et al., 1999a). Transfection of claudin-1 or claudin-3 into fibroblasts lacking TJs, induced P-face associated TJs (Furuse et al., 1999), whereas transfection of fibroblasts with claudin-2 or claudin-5 induced E-face associated TJs in the absence of occludin (Morita et al., 1999c) demonstrating that different claudins induce structurally different TJs. Claudins are not randomly distributed throughout the tissues. Using immunohistochemistry we could demonstrate that besides claudin-5, claudin-3 is localized in endothelial TJs in the CNS of mice and man (Wolburg et al., 2003). Additionally, we and others have shown that occludin and ZO-1 are localized within BBB TJs (Bolton et al., 1998; Wolburg et al., 2003). Furthermore, the Ig supergene family members junctional adhesion molecule (JAM) (Martin-Padura et al., 1998) and the recently discovered endothelial cell-selective adhesion molecule (ESAM) are localized in TJs (Nasdala et al., 2002) of the BBB. Via interaction with ZO-1 these integral membrane proteins interact with the actin cytoskeleton thus providing the molecular link for TJ association with the cytoskeleton. In addition, adherens junctions, which are strongly associated with the cytoskeleton, e.g. via cadherin/catenin interactions seem to be intermingled with TJs at the BBB (Schulze and Firth, 1993).

2.4.3 Molecular composition of adherens junctions and cell-to-cell contacts in BBB endothelium

In cerebral endothelial cells non-occluding adherens junctions are found in close proximity to TJs (Schulze and Firth, 1993), Figure 5). In adherens junctions the endothelial specific integral membrane protein VE-cadherin (Corada et al., 1999), is linked to the cytoskeleton via catenins, which belong to the family of armadillo proteins (Vleminckx and Kemler, 1999). In endothelial cells expression and localization of β-catenin, γ-catenin and $p120^{cas}$ have been described to be crucial for the functional state of adherens junctions (Dejana, 1996).

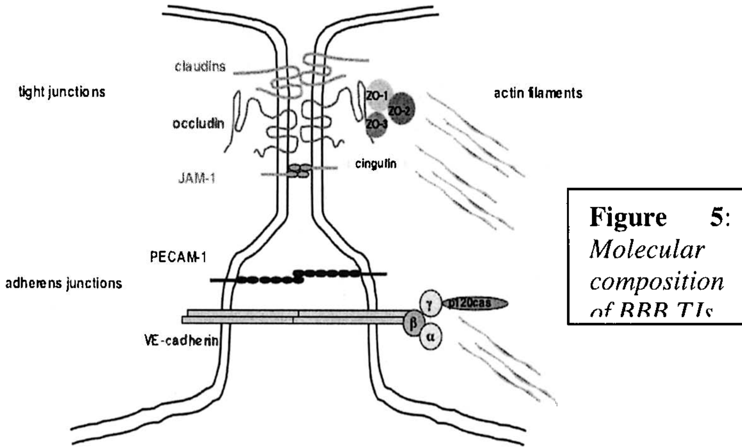

Figure 5: *Molecular composition of BBB TJs*

This is supported by the observation that application of monoclonal antibodies directed against VE-cadherin increase vascular permeability *in vivo* (Corada et al., 2001). Whether VE-cadherin is also required to maintain integrity of the BBB remains to be investigated.

Finally, PECAM-1 has been demonstrated to be localized in endothelial cell contacts outside of either TJs or adherens junctions. In mice deficient for PECAM-1 no defect in BBB integrity has been reported (Duncan et al., 1999).

3. THE BLOOD-BRAIN BARRIER DURING EAE

3.1 BBB leakiness

Breakdown of the BBB was shown to precede symptoms and other MRI signs of new lesion development in MS (Kermode et al., 1990). These findings are modelled in EAE, where the impaired integrity of the BBB has been demonstrated to precede clinical signs of the disease (Claudio et al., 1989). Using several tracers to investigate BBB integrity during EAE, increased transport of sodium, chloride, sucrose and inulin could be demonstrated in different areas of the diseased brain (Juhler, 1988). Studies on the time course of BBB breakdown in rodent models during progress of EAE support a caudal-to-rostral gradient preceeding the progression of the gradient of severity of the inflammatory disease (Butter et al., 1991). However, more recently it was demonstrated that during EAE the cerebellar BBB is dramatically and briefly compromised even before breakdown of the BBB in the spinal cord prior to disease onset (Tonra et al., 2001). Disruption of the BBB during CNS inflammation can lead to the immediate problem of

vasogenic edema and the clinical problems related to this condition. Active lesions are characterized by the perivascular accumulation of serum components such as albumin or fibrin and inflammatory cells (Figure 6).

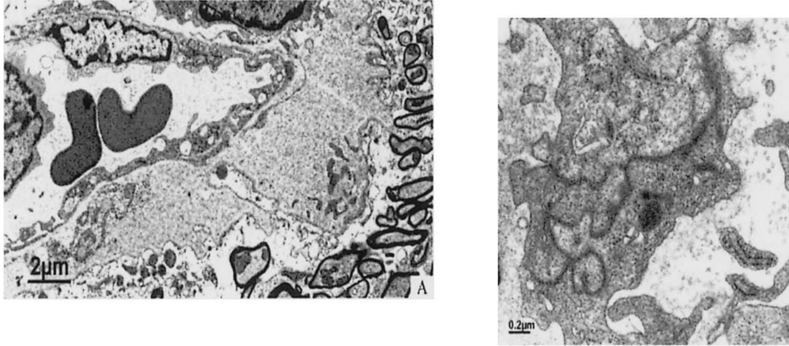

Figure 6: *CNS microvessels during EAE*
A) (left) Leakiness of the BBB during EAE . Upper left: CNS micovessel with erythrocytes, center: perivascular space with massive protein deposits, lower right: myelinated nerve fibers. Note the protrusion of the glia limitans from the left to the right. B) (right) Characteristic "tortured" TJ between cerebral endothelial cells in an inflamed vessel during EAE is shown

Whereas the accumulation of serum components in the perivascular space of CNS microvessels demonstrates that passive diffusion of these proteins can occur across the BBB, at the same time the absence of neutrophils and red blood cells within the CNS suggests that even the impaired BBB still plays an active role in the recruitment of inflammatory cells into the CNS. In EAE, leakiness of the BBB occurs mainly at the level of postcapillary venules, which are surrounded by inflammatory cuffs. CNS postcapillary venules are thin walled and mainly comprised of endothelial cells and function as exchange microvessels, much like capillaries (Fenstermacher et al., 2001). Several observations suggest that these small venules are the microvessels that are most prone to disruption and BBB breakdown. Eventually, leakiness of the BBB is accompanied by the loss of the differentiated phenotype of BBB endothelial cells as supported by the re-expression of the MECA-32 antigen on brain endothelial cell in inflamed vessels surrounded by inflammatory cuffs (Engelhardt et al., 1994).

Leakiness of the BBB could be a result of either TJ opening or enhanced pinocytotic activity of the endothelial cells. Whereas the latter could not be observed by us, in the CNS of mice afflicted with EAE, vessel profiles surrounded by inflammatoty cuffs were characterized by an increase of the luminal surface of postcapillary endothelium and by a complicated and branched course of the tight junctional domains (Figure 6B). This suggests that BBB leakiness mainly occurs via an opening of the BBB TJs. This observation on the ultrastructural level seems to be confirmed by immunocytochemical studies demonstrating that inflamed CNS vessels

exhibit a seemingly disrupted immunostaining for TJ molecules, while staining in the healthy BBB is characterized by straight and continuous patterns (Wolburg et al., 2003).

3. 2 Molecular alterations of BBB TJs during EAE

Using immunohistochemistry, we recently demonstrated that during the clinical disease of EAE the TJ molecule claudin-3 is selectively lost from vessels surrounded by inflammatory cuffs (Wolburg et al., 2003). In contrast to claudin-3, the presence of other TJ molecules like claudin-5, occludin or ZO-1 in cerebral vessels was not affected during EAE. These observations differ from a previous report, where loss of ZO-1 and occludin from cerebral vascular endothelium was observed during CNS inflammation caused by injection of LPS in juvenile rats (Bolton et al., 1998). However, in this study the cellular infiltrate was dominated by neutrophils, which is in contrast to EAE, where the cellular infiltrate is mostly composed of mononuclear cells. Interestingly, only juvenile rats younger than 3 weeks developed LPS induced neutrophil mediated inflammation in the CNS, whereas injection of LPS in older rats did not lead to any CNS inflammation or alterations at the BBB, indicating that maturation of the BBB was not complete at that age. Thus, loss of occludin and ZO-1 from cerebral vessels upon neutrophil recruitment might be specific to the immature BBB. Alternatively, recruitment of different leukocyte populations might differently affect the TJs due to usage of distinct routes of transendothelial migration, i.e. transcellular versus paracellular (Faustmann and Dermietzel, 1985, Greenwood et al., 1994). Interestingly, selective loss of claudin-3 can also be observed in leaky vessels in glioblastoma multiforme in the absence of any inflammation, suggesting that *in vivo* the loss of claudin-3 from BBB TJs correlates with BBB breakdown at these sites and that this is not necessarily dependent on the presence of inflammatory cells (Wolburg et al., 2003). Claudin-3 might therefore be a key component determining the permeability of BBB endothelial TJs *in vivo*. Future studies will have to demonstrate the signals determining the subcellular distribution of claudin-3. Defining these signals might allow to develop new therapeutic strategies to reduce BBB permeability and thus severity of brain edema in CNS diseases.

An alteration of the TJ structure during EAE is further supported by our findings that during EAE the TJ molecules JAM-1 becomes accessible at the luminal surface of BBB endothelium whereas in the healthy CNS JAM-1 is confined to the BBB TJs and cannot be accessed for immunostaining by antibodies injected into the blood-stream (Dehouck and Engelhardt, unpublished observations). In fact, *in vitro* studies demonstrated that stimulation of endothelial cells by pro-inflammatory cytokines will lead to a release of JAM-1 from endothelial TJs and its availability on the endothelial luminal surface, where it can then mediate the binding of highly activated T cells via the integrin LFA-1 (Ostermann et al., 2002). These observations suggest, that during inflammation, TJ proteins such as JAM-1 might be involved in guiding inflammatory cells across the BBB TJs.

3.3 Contribution of endothelial PECAM-1

Platelet/endothelial cell adhesion molecule-1 (PECAM-1, CD31) is a member of the Ig superfamily of transmembrane proteins and is concentrated at cell contact sites in all continuous endothelial cell linings *in vivo* including the endothelial cells of the BBB and is proximal to adherens junctions (Figure 5).

The lack of endothelial PECAM-1 expression in knock-out mice results in an earlier onset of clinical symptoms during EAE, associated with an increased inflammatory cell migration across the BBB (Graesser et al., 2002). Lack of endothelial PECAM-1 was additionally shown to lead to an impaired ability to restore vascular integrity after alteration of the endothelium in PECAM-1 deficient mice or of cultured PECAM-1$^{-/-}$ endothelial cells (Graesser et al., 2002). The resulting increased and prolonged vascular permeability might lead to enhanced transendothelial migration of inflammatory cells and thus early onset of CNS inflammation during EAE. We hypothesized a role for PECAM-1 in the restoration of inter-endothelial junctional integrity following disrupting stimuli, while normal, homeostatic endothelium is not affected. The prolonged vascular permeability in the PECAM-1-deficient mice could be accounted for if PECAM-1 plays a role in re-establishing intact junctions following inflammatory stimuli and transendothelial migration of leukocytes. In turn, disruption of endothelial cell-cell junctions has been shown to facilitate transmigration of leukocytes, which may contribute to a cycle of increased migration and decreased junctional integrity in the PECAM-1-deficient mice. However, the endothelial permeability barrier was eventually restored, showing that the requirement for PECAM-1 at inter-endothelial junctions is not absolute. One might speculate on an involvement of β-catenin, which normally associates with the transmembrane junctional protein VE-cadherin, linking it to cytoskeletal proteins, but can also associate with PECAM-1 (Ilan et al., 2000). When, through certain stimuli, such as inflammation in EAE, junctional disassembly is induced, β–catenin becomes tyrosine-phosphorylated, dissociates from VE-cadherin but associates with PECAM-1 (Ilan et al. 1999). The presence of phosphorylated β-catenin and protein tyrosine phosphatases such as SHP-2 on the same scaffolding molecule may induce the dephosphorylation of β–catenin, allowing it to re-associate with VE-cadherin, thus re-assembling intact adherens junctional complexes (Ilan et al. 1999). Perhaps in the PECAM-1-deficient mice, PECAM-1 cannot act as a reservoir for phosphorylated β-catenin, resulting in an increased cytoplasmic pool of the phosphorylated protein, which cannot readily re-associate with VE-cadherin in the junctional complex. Ultimately, β-catenin may become dephosphorylated by other mechanisms and resume its association with VE-cadherin and other junctional proteins, thus eventually restoring integrity of the endothelial cell layer. Further elucidation of the underlying mechanism(s) by which PECAM-1 modulates vascular integrity will aid in our understanding of the roles PECAM-1 plays during

inflammatory responses. Although this does not discount the possibility that signals mediated via PECAM-1 may contribute to the generation or propagation of the immune response during EAE, the impairment of dynamic vascular junctional integrity is likely to be one of the driving forces in the early EAE phenotype of the PECAM-1-deficient mice.

3.4 Inflammatory mediators/cytokines involved in BBB leakiness during EAE

Inflammatory cytokines play an active part in the mediation of the immune response during EAE. Proinflammatory cytokines such as tumor necrosis factor (TNF)-α, interferon (IFN)-γ, interleukin (IL-1) and IL-6 have been detected in the cerebrospinal fluid of MS patients and in CNS tissue of mice suffering from EAE (Gijbels et al., 1990). These cytokines have been shown to be involved in the immunopathogenesis of EAE and based on *in vitro* studies demonstrating that TNF-α, IL-1 and IL-6 induce increased vascular permeability of tracers across monolayers of endothelial cells (de Vries et al., 1996), it has been suggested that they also impair BBB function *in vivo*. In fact, administration of TNF-α to an *in vitro* model of the BBB resulted in increased paracellular permeability to small tracers and was accompanied by the reorganization of actin filaments within the brain endothelial cells (Deli et al., 1995), supporting the possibility that locally increased levels of TNF-α in the CNS during EAE might directly lead to increased permeability of the BBB. Intravital microscopy studies demonstated that *in vivo* TNF-α increases the permeability of pial microvessels to tracers via a mechanism involving the activation of soluble guanylate cyclase and protein tyrosine kinases (Mayhanm, 2002). Additionally, *in vivo* application of IL-1 was demonstrated to impair barrier properties of the BBB (Blamire et al., 2000).

In addition to locally produced cytokines affecting BBB function, impairment of BBB in EAE was shown to be accompanied by an increased transport of TNF-α from the blood into the CNS by a saturable system (Gutierrez et al., 1993; Pan et al., 1996). Increased transport of TNF-α was observed throughout the CNS, i.e. brain and cervical, thoracic, and lumbar spinal cord with a distinct time course and reversibility (Pan and Kastin, 2001).

Exposure of cerebral endothelial cells to pro-inflammatory cytokines can lead to the release/expression of various products of the arachidonic acid cascade with both vasoactive and pro-inflammatory properties, including prostaglandins, leukotrienes, and platelet-activating factor (PAF) by the BBB endothelial cells themselves leading to changes in local cerebral blood flow and blood rheology, and finally increases in BBB permeability (Stanimirovic and Satoh, 2000). Whereas involvement of these mechanisms and of classical vasoactive mediators such as nitric oxide or endothelin in BBB breakdown is generally accepted, their involvement during MS is not well studied. Recently, VEGF was suggested to be involved in BBB breakdown during EAE/MS (Proescholdt et al., 2002). As described above, VEGF is a major

inducer of angiogenesis, but originally, it was described as vascular permeability factor (Senger et al., 1990). In both acute and chronic MS plaques as well as during EAE, VEGF expression was found to be upregulated in astrocytes in association with inflammatory cuffs (Proescholdt et al., 2002), suggesting that VEGF might exacerbate the inflammatory response in autoimmune diseases of the CNS by inducing focal BBB breakdown. To date, involvement of VEGF in the development of vascular leakage in the CNS has rather been associated with stroke, head injury and high-altitude illness, disorders that are associated with tissue hypoxia. As VEGF gene expression was shown to be upregulated by hypoxia, increased VEGF expression may link hypoxia and vascular leakage in the CNS *in vivo*. Thus it remains to be shown whether hypoxic conditions might occur in inflammatory cuffs during EAE or whether VEGF might be induced by other means.

Last but not least, pro-inflammatroy cytokines lead to the activation of BBB endothelium, which is characterized by the upregulated expression of traffic signals for leukocytes such as adhesion molecules and chemokines that govern inflammatory cell recruitment across the BBB during EAE (see below).

4. RECRUITMENT OF ENCEPHALITOGENIC T CELLS ACROSS THE BBB

4.1 Antigen presentation by BBB endothelium

The question whether BBB endothelium would present antigen has been addressed extensively, when it was still assumed that the BBB is impermeable for lymphocytes. It was thought that "accidental" presentation of myelin-antigens on the luminal surface of the BBB endothelial cells would lead to local activation and thus transmigration of activated T cells across the BBB. In order to present antigen to encephalitogenic $CD4^+$ T cells, endothelial cells must present MHC class II antigens. Although it was repeatedly claimed that during EAE there is induction of MHC class II products on BBB endothelium, demonstration of MHC class II on BBB endothelium at the electron microscopic level *in vivo* was achieved only in the guinea pig model of EAE (Sobel et al., 1987; Wilcox et al., 1989). In contrast, the inducibility of MHC class II products on brain endothelial cells from different species *in vitro* could be demonstrated by several groups by using pure cultures of BBB endothelial cells. Furthermore expression of the costimulatory molecules B7-1 and B7-2 was demonstrated on human brain endothelial cells in an *in vitro* BBB model (Omari and Dorovini-Zis, 2001). Inflammatory mediators such as TNF-α or γ-IFN were shown to induce MHC class II expression on those cultured endothelial cells *in vitro* (Male and Pryce, 1988; Risau et al., 1990). Direct investigation of the antigen-presenting potential of MHC class II-positive brain endothelial cells *in vitro*, however, demonstrated that T cells cocultured with MHC class II positive

mediated by $CD4^+$, MBP-specific T cells in those cultures (Risau et al., 1990; Sedgwick et al., 1990; Wang et al., 1995), which was, however, dependent on the presence of the specific antigen and the appropriate MHC class II molecule. This apparent paradox might be attributed to the production of prostaglandins by brain endothelial cells inhibiting T cell proliferation (McCarron, 1992). More recently it was shown that $CD4^+$ T cell proliferation and cytokine production is inhibited by a factor derived from human brain endothelial cells. Addition of exogenous Il-2 prevented T cell unresponsiveness reinforcing the notion that brain endothelial cells can induce T cell anergy (Prat et al., 2000).

Taken together, based on the observations that T cell blasts can migrate through the BBB endothelium independent of their antigen specificity and MHC-restriction as shown using ovalbumin-specific T cells and bone-marrow chimeras (Hickey et al., 1991) and that traffic signals guiding T cells across the BBB were identified (see below) it is highly unlikely that antigen-presentation is required for T cell migration across the BBB. It might well be though that later during ongoing EAE, when high levels of cytokines and myelin degradation products are present within the inflammatory cuffs, antigen-presentation by brain endothelial cells might contribute to the destruction of the BBB, which is typical for acute EAE and MS (Tsukada et al., 1993).

4. 2 Traffic signals provided by BBB endothelium

In general, lymphocyte recruitment across the vascular wall is regulated by the sequential interaction of different adhesion or signaling molecules on lymphocytes and endothelial cells lining the vessel wall (Butcher et al., 1999). An initial transient contact of the circulating leukocyte with the vascular endothelium, generally mediated by adhesion molecules of the selectin-family and their respective carbohydrate ligands, slows down the leukocyte in the bloodstream. Subsequently, the leukocyte rolls along the vascular wall with greatly reduced velocity. The rolling leukocyte can receive endothelial signals resulting in its firm adhesion to the endothelial surface. These signals are transduced by chemokines via G-protein coupled receptors on the leukocyte surface. Binding of a chemokine to its receptor results in a pertussis toxin sensitive activation of integrins on the leukocyte surface. Only activated integrins mediate the firm adhesion of the leukocytes to the vascular endothelium by binding to their endothelial ligands, which belong to the immunoglobulin (Ig)-superfamily. This ultimately leads to the extravasation of the leukocyte. Successful recruitment of circulating leukocytes into the tissue depends on the productive leukocyte/endothelial interaction during each of these sequential steps.

We and others have investigated the expression of adhesion molecules on CNS endothelium during EAE in the SJL/N mouse by means of *in situ* hybridization and immunohistology and found induction of ICAM-1 and VCAM-1 but not E- and P-selectin on CNS endothelium (Engelhardt et al., 1997; Cannella et al., 1991; Steffen et al., 1994; Wilcox et al., 1990). ICAM-1 and VCAM-1 were shown to mediate adhesion of lymphocytes to inflamed

cerebral vessels on frozen brain sections *in vitro* (Steffen et al., 1994; Yednock et al., 1992). *In vivo* monoclonal antibody inhibition studies confirmed the involvement of VCAM-1 and its ligand α4-integrin but not E- and P-selectin in the pathogenesis of EAE as antibodies directed against VCAM-1 and its ligand α4-integrin but not against E- and P-selectin successfully blocked the development of clinical EAE in the SJL/N mouse (Engelhardt et al., 1997 and 1998). Although we have discounted a role for endothelial selectins in EAE, recent evidence was provided demonstrating that during ongoing EAE P-selectin is involved in leukocyte recruitment at least into the meningeal vessels (Kerfoot and Kubes, 2002). Even though it was previously reported that BBB endothelial cells lack storage of P-selectin in Weibel-Palade bodies (Barkalow et al., 1996), P-selectin was recently implicated in the initial recruitment of activated encephalitogenic T cells into the healthy CNS (Carrithers et al., 2000). These apparently contradictory results can only be investigated by direct observation of leukocyte-endothelial interaction *in vivo.*

In order to gain direct evidence for the molecular mechanisms of leukocyte interaction with the vascular wall within the CNS, observation of the CNS microcirculation by intravital fluorescence microscopy is necessary. This approach is hampered, however, by the protected localization of the brain and spinal cord within the skull and the spinal column, respectively. In order to gain intravital microscopic access to the CNS microcirculation, acute and chronic cranial window preparations have been developed for rodents, which allow observation of the pial and cortical, i.e. CNS grey matter, microcirculation respectively (Uhl et al., 1999; Vajkoczy et al., 2000). In EAE, however, CNS white matter is the battle field of the inflammatory attack with preference of the spinal cord. Therefore, we recently developed a novel spinal cord window preparation, which enabled us to directly visualize CNS white matter microcirculation by intravital fluorescence videomicroscopy (Vajkoczy et al., 2001). We gained direct evidence that T lymphoblast interaction with the BBB is unique due to the lack of rolling. Constitutively expressed VCAM-1 mediates the G-protein independent prompt arrest (capture) of circulating encephalitogenic T cell blasts via α4-integrin to the endothelium of the healthy BBB. Transient capture is followed by G-protein dependent α4-integrin /VCAM-1 mediated adhesion strengthening and subsequent LFA-1 mediated migration of lymphocytes across the BBB into the spinal cord white matter (Vajkoczy et al., 2001, Laschinger et al., 2002). Requirement for α4-integrin in leukocyte interaction with the inflamed BBB during ongoing EAE is maintained as demonstrated by intravital microsocpy of CNS microvessels in the brain (Kerfoot and Kubes, 2002). Furthermore, as recently demonstrated the requirement for α4-integrin in inflammatory cell recruitment across the BBB seems to translate to the mechanisms invoved in inflammatory cell recruitment across the BBB in MS, where therapy using a humanized anti-α4-integrin antibody has proven to be beneficial (von Andrian and Engelhardt, 2003).

A crucial role for chemokines in successful recruitment of encephalitogenic T cells across the BBB is suggested by the requirement for signalling via G-protein coupled, PTX-sensitive receptors on encephalitogenic T cells to firmly arrest on BBB endothelium *in vivo*. We found expression of the lymphoid chemokine "EBV-induced molecule 1 ligand chemokine" (ELC)/CCL19 at the level of the BBB endothelium on a subpopulation of CNS venules and induced expression of the "secondary lymphoid chemokine" (SLC)/CCL21 in inflamed CNS venules during EAE (Alt et al., 2002). Expression of their common receptor CCR7 was detected in a subpopulation of cells present in the perivascular inflammatory cuffs. Encephalitogenic T cells show surface expression of CCR7 and the alternative receptor for CCL21, CXCR3. They chemotax specifically towards both, CCL19 or CCL21 in a concentration dependent and pertussis toxin-sensitive manner, comparable to naive lymphocytes *in vitro*. Additionally, in frozen section assays functional ablation of CCR7 and CXCR3 or blocking CCL19 and CCL21 reduced binding of encephalitogenic T lymphocytes to inflamed venules in the brain. Absence of rolling, the involvement of the lymphoid chemokines CCL19 and CCL21 and the predominant involvement of α4-integrin and VCAM-1 make this T lymphoblast interaction with the BBB unique and suggest that these specific mechanisms operate to limit leukocyte travel to this immunoprivileged site (Figure 7).

Interestingly, although we observed T cell interaction with the vascular wall in CNS capillaries and post-capillary venules, extravasation of encephalitogenic T cells was only observed at the level of post-capillary venules. This is consistent with the observations of the localization of inflammatory cuffs, which characteristically form around the post-capillary venules but not around capillaries, indicating that extravasation of autoagressive T cells and inflammatory cells preferentially occurs at this level. In contrast to peripheral organs, where extravasation of leukocytes takes several minutes, we observed that extravasation of encephalitogenic T cells across the BBB takes several hours (Laschinger et al., 2002; Vajkoczy et al., 2001), supporting the notion that transendothelial migration across the BBB follows unique mechanisms. In this context, it should be noted that initial T cell recruitment across the healthy BBB is not accompanied by BBB leakiness as observed by intravital microscopy (Vajkoczy et al., 2001).

In any case the passageway of leukocytes in transendothelial migration across the BBB is still a matter of debate. The general belief is that outside the CNS leukocytes migrate across the interendothelial junctions. This has been supported by observations that antibodies directed against VE-cadherin accelerate neutrophil recruitment into the inflamed peritoneal cavity of mice (Gotsch et al., 1997). Involvement of the TJ molecule JAM-1 was described in transendothelial migration of monocytes at least *in vitro* (Martin-Padura et al., 1998) and supported by the recent findings that JAM-1 can function as a ligand for LFA-1 on highly activated T cells (Ostermann et al., 2002). Involvement of JAM-1 in leukocyte recruitment into the CNS *in vivo*, however, is still controversial (Del Maschio et al., 1999; Lechner et al.,

2000). It is possible that differences in the usage of passageways across endothelial cells are chosen by different leukocyte subpopulations as suggested by the observation that transendothelial migration of neutrophils and monocytes but not of lymphocytes can be blocked by pre-treatment of endothelial cells with antibodies directed against PECAM-1(Muller et al., 1993; Nakada et al., 2000). The highly specialized BBB might even lead to BBB specifc passageways for leukocyte subpopulations during immunosurveillance and inflammatory disease. It has been suggested previously that leukocyte recruitment across the BBB occurs rather parajunctional than through the TJs (Greenwood et al., 1995a), which is supported by our own observations (Wolburg and Engelhardt, unpublished). Therefore understanding the entire sequence of traffic signals involved in the recruitment of inflammatory cells across the BBB will be necessary to understand CNS inflammation and whether these events will eventually lead to BBB breakdown during EAE.

4. 3 The BBB basement membrane

After their passage across the endothelial cell monolayer forming the BBB inflammatory cells still face the endothelial cell basement membrane and the subjacent glia limitans consisting of astrocytic endfeet and associated basement membrane before entering the CNS parenchyma (Figures 7 and 8).

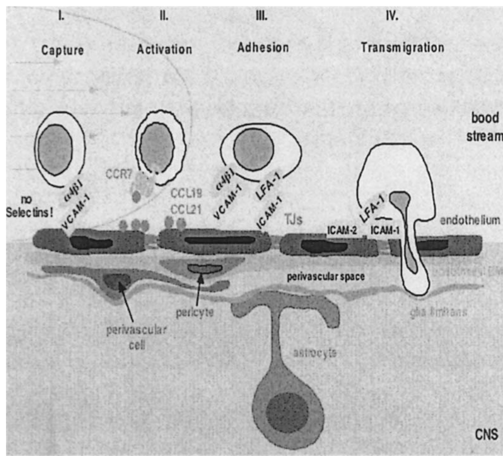

Figure 7: *Multi-step cascade of encephalitogenic T cell recruitment across the BBB during EAE*

During EAE the endothelial cell and astroglial basement membranes clearly define the inner and outer limits of the perivascular space around post-capillary venules, where inflammatory cells accumulate during acute EAE before infiltrating the brain parenchyma (Figure 8). However, the molecular mechanisms involved in T cell penetration of the endothelial cell basement membrane and the process of invasion across the glia limitans have not been investigated in great detail until recently.

basement membrane and the process of invasion across the glia limitans have not been investigated in great detail until recently.

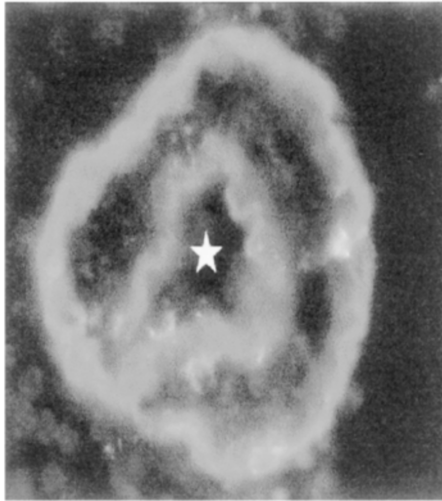

Figure 8: *Basement membranes at the inflamed BBB*
Immunofluorescence staining for laminin of a postcapillary venule surrounded by inflammatory cells in the brain of a mouse afflicted with EAE. Laminin staining marks the borders of the perivascular space with the inner endothelial basement membrane and the outer astrocytic basement membrane. I = vessel lumen.

There is evidence suggesting that these two steps are distinct and independent of one another: In EAE induced in macrophage depleted mice (Tran et al., 1998) or in TNF-α-deficient mice (Korner et al., 1997) the inflammatory infiltrate becomes entrapped in the perivascular space and parenchymal infiltration is prevented, indicating that progression through the astrocytic basement membrane is functionally distinct from endothelial cell basement membrane transmigration.

The major proteins of all basement membranes belong to the laminin family of glycoproteins. Laminins are heterotrimers composed of an α, β and γ chain. Only two isoforms, namely laminin 8 (composed of laminin $\alpha 4$, β_1 and γ_1) and laminin 10 (composed of laminin $\alpha 5$, β_1 and γ_1) are found in endothelial basement membranes of most tissues including the CNS (Sorokin et al., 1994). Blood vessels in the CNS have also been reported to express laminins 1 and 2 (Jucker et al., 1996; Virtanen et al., 2000), which are not detected in blood vessel basement membranes elsewhere. Recently, laminin distribution in blood vessels in the CNS could be clarified by investigating the laminin isoforms of BBB basal membranes during EAE (Sixt et al., 2001). The localization of inflammatory cuffs surrounding post-capillary venules during EAE allowed a clear distinction of endothelial cell and astroglial basement membranes, demonstrating that the endothelial cell basement membrane contains laminins 8 and 10 whereas the astroglial basement membrane contains laminins 1 and 2. In the absence of inflammation the endothelial and astroglial basement membranes lie in such close proximity that at the light microscopic level they may be mistaken for a single structure leading to the mis-conception that laminin 1 and 2 are present in endothelial cell basement membranes.

membrane. Perivascular cuffs were only observed around endothelial cell basement membranes containing laminin 8, while in the presence of laminin 10 no infiltration was detectable. *In vitro*, encephalitogenic T-cells could bind to both laminins 8 and 10 present in the endothelial basement membrane via $\alpha 6\beta_1$-integrin, however, they were unable to bind the laminins 1 and 2 present in the astroglial basment membranes, suggesting that encephalitogenic T cells might not be able to penetrate the astrocytic basement membrane (Sixt et al., 2001). This is supported by previous observations that encephalitogenic T cell blasts injected to induce EAE in naive recipients remain in the perivasular space of CNS venules and do not immigrate into the CNS parenchyma (Cross et al., 1990).

These data suggest that the astrocytic basement membrane breaks down in more advanced stages of the disease process during EAE and is likely to be dependent on the proteolytic activity of matrix metalloproteinases (MMPs). MMPs have been demonstrated to be involved in T-cell entry into and residency in the parenchyma of the CNS, as well as in demyelination (Graesser et al., 1998; Graesser et al., 2000). While protease inhibitors have been shown to reduce the severity or delay the onset of EAE, to date no protease inhibitor has been shown to completely ablate T-cell migration into the perivascular space or the brain parenchyma (Graesser et al., 2000). Until now it was not clear that emigrating T-cells face more than just the subendothelial cell basement membrane. The results of the MMP inhibitor experiments were, therefore, interpreted as reduced transmigration across the endothelial cell basement membrane. However, they can equally well be explained by inhibition of transmigration across the parenchymal basement membrane. It now remains to be determined whether the main targets of MMP activity are components of the endothelial cell or the parenchymal basement membrane.

Investigations of the distribution of the major laminin receptors, $\alpha 6\beta_1$-integrin and α–dystrophin, demonstrated that $\alpha 6\beta_1$-integrin occurs predominantly on the endothelial cells in the brain mediating interactions with the endothelial cell laminins 8 and 10, while α-dystroglycan is expressed on the astrocyte endfeet and probably mediates binding to the parenchymal laminins 1 and 2 (Sixt et al., 2001). It has been shown that during the course of MS, $\alpha 6\beta_1$-integrin is downregulated on the endothelial cells at sites of infiltration (Sobel et al., 1998). *In vitro*, laminin $\alpha 4$ expression was shown to be strongly upregulated in endothelial cells by proinflammatory cytokines such as interleukin-1 (IL-1) (Frieser, 1997), suggesting a role in inflammatory events. Thus, selective upregulation of laminin $\alpha 4$ expression by cytokines such as IL-1 or TNF-α, which have been shown to play a role in EAE, in combination with a high turnover of laminin $\alpha 4$ in endothelial cell basement membrane in the brain may lead to a loosening of the endothelial cell-basement membrane interaction at sites of T-cell infiltration in EAE facilitating the further development of perivascular cuffs during EAE.

5. THE BLOOD-CEREBROSPINAL FLUID BARRIER IN EAE

A role of the choroid plexus in the pathogenesis of EAE or MS , i.e. as an alternative entry site for circulating lymphocytes directly into the CSF, has not been seriously considered before. In the choroid plexus, the epithelium forms the blood-cerebrospinal fluid (CSF) barrier and is responsible for the secretion of the CSF from the blood. The morphological correlate of the blood-CSF barrier are the TJs of choroid plexus epithelium. Interestingly, in EAE the adhesion molecules ICAM-1 and VCAM-1 are upregulated on the choroid plexus epithelium in parallel to their upregulation on BBB endothelium (Steffen et al., 1996). Ultrastructural studies revealed polar localization of ICAM-1, VCAM-1 and MAdCAM-1 on the apical surface of choroid plexus epithelial cells and their complete absence on the fenestrated endothelial cells within the choroid plexus parenchyma (Wolburg et al., 1999). Furthermore, ICAM-1, VCAM-1 and MAdCAM-1 expressed in choroid plexus epithelium mediate binding of lymphocytes via their known ligands (Steffen et al., 1996).

Massive ultrastructural changes can be observed during EAE within the choroid plexus (Engelhardt et al., 2001), however, at the ultrastructural level the TJs seem to remain intact (Wolburg et al., 2001). Choroid plexus epithelial TJs are morphologically unique resembling the TJs of the central myelin sheaths, which are characterized by their parallel and poorly anastomosing strands (Dermietzel et al., 1980). These morphologically unique TJs of CNS myelin sheaths were recently found to be exclusively constituted by oligodendrocyte specific protein/claudin-11 (Morita et al., 1999b). The central role of claudin-11 for the formation of parallel-array TJs was confirmed in the OSP/claudin-11 null mouse (Gow et al., 2000), in which myelin sheaths of oligodendrocytes were shown to be devoid of any TJs. We found that the TJs in the choroid plexus are unique with respect to the presence of claudins as claudin-11 is found to be accompanied by claudin-1 and claudin-2 (Wolburg et al., 2001). A possible role for OSP/claudin-11 in the development of EAE was demonstrated by the induction of the disease in susceptible mice after immunization with OSP/claudin-11 (Stevens et al., 1999) and the demonstration of antibodies directed against OSP/claudin-11 in the CSF of patients suffering from multiple sclerosis (Bronstein et al., 2000). Whereas presence of claudin-11 in the CSF of MS patients is taken as a measure for myelin degradation until the present day, it might well reflect a modulation of the blood-CSF barrier localized at the choroid plexus epithelium.

In addition, as choroid plexus epithelial cells have been found to express MHC class I and II molecules on their surface (for review see (Engelhardt et al., 2001) it will be interesting to see the contribution of this barrier to autoimmune inflammation within the CNS.

6. OUTLOOK

The endothelial cells of the BBB and probably the epithelial cells of the blood-CSF barrier are involved in the pathogenesis of inflammatory

demyelinatingdiseases such as MS or its animal model EAE. Contribution of the BBB can be considered twofold, an active role by guiding inflammatory cells across the BBB and a passive role characterized by breakdown of the BBB.

It has been more than 100 years since the discovery of the BBB. During the last 10 years great progress has been made in understanding the active contribution of the BBB by characterization of the traffic signals involved in leukocyte recruitment into the CNS. In contrast, the molecular mechanisms leading to BBB breakdown are less well understood.

For this purpose it will be mandatory to characterize the mechansims involved in BBB differentiation during development and those involved in maintaining BBB characeristics in endothelial cells in the adult CNS.

7. ACKNOWLEDGEMENTS

We owe special thanks to Karen Wolburg-Buchholz for providing and preparing the figures on the ultrastructure of the BBB. We also thank Urban Deutsch for his devoted discussion of this chapter.

Chapter A21

IMMUNOMODULATION OF EAE: ALTERED PEPTIDE LIGANDS, TOLERANCE, AND TH1/TH2

Brendan Hilliard and Youhai H. Chen
Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA 19104.

Abstract: Experimental autoimmune encephalomyelitis (EAE) is an animal model for human multiple sclerosis (MS). The disease is initiated by myelin-specific T cells, but mediated by cells of both the adaptive and innate immune system. Therefore, strategies targeting either lymphocytes or myeloid cells can be effective in modulating EAE. In this chapter, we will review some of the strategies that have been developed to treat or prevent EAE. Our emphasis will be on those strategies that are still in the developmental stage, but may have the potential to be used in the clinic in the future

Keywords: EAE, tolerance, MS, deletion, anergy, suppression.

Introduction

Studies using experimental models of multiple sclerosis (MS) have revealed important principles of autoimmune demyelination. The presence of self-reactive T cells directed against myelin antigens present in the central nervous system (CNS) is a defining characteristic of experimental autoimmune encephalomyelitis (EAE), the animal model that shares many of the clinical and pathological features of multiple sclerosis. [1-3]. In most experimental models, EAE is induced by priming specific T cells with immunogenic forms of myelin. Myelin antigens can be immunogenic if they are administered with adjuvants such as complete Freunds adjuvant (CFA). The adjuvants stimulate antigen presenting cells and result in the differentiation of autoreactive encephalitogenic T cells, which in most models of EAE are T helper (Th) 1 cells.

The importance of T cells in EAE [reviewed in [4]] was first established by the observations that 1) depleting $CD4^+$ helper T cells [5, 6] led to the suppression of the disease and 2) depleting $CD4^+$ T cells from activated lymph node cultures of myelin basic protein (MBP)-sensitized rats prevented the adoptive transfer of EAE [7, 8].

Helper T cells can be divided into different sub-populations, based on the types of cytokines they secrete [9]. Th1 cells are $CD4^+$ T cells that secrete a distinct set of cytokines including interferon (IFN)-γ, IL-2, and TNF-α. Th2 cells on the other hand secrete IL-4, IL-5 and IL-10. The development of these two classes of helper T cells appears to be mutually antagonistic because the cytokines of one type can downregulate the development of the other [10, 11]. For instance, IL-4 potentiates the development of Th2 responses while suppressing the development of IFN-γ secreting cells [12]. On the other hand, IL-12, which is produced by antigen presenting cells and NK cells and has a major role in the differentiation of IFN-γ secreting Th1 cells, suppresses Th2 cell development [13, 14]. The vast majority of encephalitogenic T cell clones secrete IFN-γ and IL-2 and, thus, are Th1 cells. Enhancing the development of Th1 cells exacerbates the disease [15]. For example, treatment of mice with IL-12 [16-18] or deficiency in IL-4 gene expression in mice [19] potentiates the development of EAE. Anti-IL-12 antibody treatment prevents EAE in mice while anti-IL-4 treatment increases the susceptibility of mice to EAE [15].

During the past decade, many advances have been made in the area of helper T cell activation. It is now clear that for a T cell to become activated, it must receive at least two signals. The first is an antigen specific signal that activates the T cell receptor by a peptide presented in the context of the major histocompatibility complex. The CD4 molecule is also involved in generating this first signal. The CD4 molecule is responsible for binding the major histocompatibility class II molecules on the antigen-presenting cell. The second signal comes from costimulatory receptors and their ligands. The most studied such ligand/receptor pairs are 1) the CD28 receptor and its ligands B7.1 (CD80) and B7.2 (CD86), and 2) the CD40 receptor and its ligand CD154 (CD40L). It has been reported that costimulation through B7.1 may lead to a Th1 bias whereas B7.2 costimulation may give rise to a Th2 type response [20].

In EAE, after the initial activation events, encephalitogenic T cells further undergo a differentiation program to become effector cells in the draining lymph nodes and spleen, and then migrate via the blood vasculature

to the central nervous system. There they leave the blood stream by passing through the vascular endothelium forming the blood brain barrier and enter the CNS tissue. It is at this point that they reencounter antigen-presenting cells harboring specific myelin antigens and execute their effector functions.

EAE, therefore, is a consequence of concerted actions of myelin specific T cells, antigen presenting cells as well as non-specific effector cells such as macrophages and granulocytes [21]. Many antigen specific and non-specific strategies have been explored to treat or prevent EAE, some of which have already been incorporated into treatment regimens for MS patients. In this chapter, we will review some of these strategies. Our emphasis is on those that are still at the experimental stage, but may have the potential to be used in the clinic in the future.

1. Non-specific strategies

1.1 Macrophage-based strategies

Blood-derived macrophages and microglia, the resident macrophage-like cell of the CNS, are believed to be critically involved in the effector phase of EAE and MS. Macrophages phagocytosing myelin in active lesions can be easily detected in the CNS. Macrophages can be directly activated by myelin via CR3 [22]. EAE is suppressed in mice depleted of macrophages following administration of mannosylated liposome-encapsulated dichloromethylene diphosphonate (Cl_2 MDP) [23], which regulates the leukocyte influx to the CNS. In addition to directly phagocytosing myelin, macrophages may damage myelin by producing reactive oxygen species [22, 24]. Aminoquanidine, an inhibitor of nitric oxide synthase [25], suppresses EAE. Similarly, modulating arginine uptake and subsequent NO production by macrophages was effective in suppressing the disease [26].

1.2 Immunoglobulin injection.

Intravenous administration of immunoglobulins from healthy donors can have beneficial effects for patients with autoimmune diseases. It has been reported that normal human serum suppresses the development of EAE [27-31]. The suppression was associated with an inhibition of antigen specific Th1 type cytokine (IFN-γ, IL-2 and TNF-α) production [29, 31] and T cell proliferation [28, 29]. This may be due to the induction of anergy in reactive T cells since the suppression of cytokine secretion could be reversed by IL-2 in vitro [29]. Two reports have shown that Igs have no suppressive

effect on the adoptive transfer of EAE [27, 31]. However, Ig injection at the time of disease onset could be effective [31]. The protective effect may be due to the changes at the TCR-peptide/MHC interface. Activated T cells specific for MBP can bind IgG, presumably through the Fc receptor since binding could be inhibited by soluble Fc molecules [27].

1.3 Bone Marrow Replacement Therapy

Replacement of the 'defective' autoimmune-susceptible immune system with a nondefective autoimmun resistant immmune system represents a rational strategy for the treatment of autoimmune disease. This necessitates the ablation of the immune system of susceptible mice (usually with lethal irradiation) followed by transfer of allogeneic bone marrow from autoimmune-resistant strains autoimmune-susceptible recipient, with the concommitant immunodeficiency and risk of infection shortly after the irradiation and graft versus host disease later. EAE-susceptible animals with bone marrow from resistant animals were resistant to induction of EAE [32-38].

In only two reports susceptible mice remained susceptible to EAE after transfer of bone marrow from resistant strains [39, 40].
Unexpectedly in experiments in rats with arthritis, syngeneic bone marrow replacement therapy was as effective in suppressing disease as allogeneic bone marrow from resistant mice [41]. This surprising result provided a rationale for similar experiments in EAE which recapitulated the results in arthritis. In chronic and relapsing models of EAE, treatment of mice with syngeneic bone marrow transfer at the acute stage of disease was also very effective with complete remission and only rare relapses. Treatment at the chronic stage of disease was however not effective, presumably due to the recalcitrant nature of the preexisting demyelinated lesions in the CNS [42]. In experiments using high dose cyclophosphamide the time of treatment was important, treatment on the 6th day after the first of two immunizing injections one week apart was very effective [43]. Likewise treatment during acute disease was highly effective but treatment on the 9th day after the first immunization did not prevent EAE. The induction of tolerance was proposed as a mechanism in lower dose cyclophosphamide (30% of lethal) followed by sygeneic bone marrow although the evidence was far from conclusive [44, 45]. Even treatment with autologous or pseudoautologous bone marrow could reverse the disease course of EAE although relapses both spontaneous and induced did occur [38, 46, 47]. Treatment with syngeneic bone marrow cells though, had less relapses [36, 37]. This effect has been explained by the possible elimination of residual memory T cells after immune ablation by the 'graft versus-autoimmunity' reaction [48]. This

theory was supported by the finding that myeloablation resulted in the elimination of autoreactive T cells in the CNS [47]. These experiments suggest that bone marrow transfer in human MS patients has the potential to significantly suppress disease. The high risk factors involved in the procedure however, must be very seriously considered.

2. Antigen-specific strategies

Administration of tolerogenic forms of myelin antigens can inhibit the development of EAE in an antigen-specific manner. Because of the relative lack of side effects, this strategy is a very attractive alternative to the currently used therapies for MS. Tolerogenic antigens can be administered intravenously (i.v.), intranasally (i.n.), or orally. Although different mechanisms may be associated with different forms of tolerance induction, the following general mechanisms may operate in most systems [49].

a) Clonal deletion. Clonal deletion is the elimination of antigen specific cells by apoptosis.
b) Clonal anergy. Clonal anergy is the induction of functional hypo-responsiveness to antigens.
c) Active suppression. Active suppression is the induction of an antigen specific population of cells, which in turn antagonise or negatively regulate the antigen specific autoreactive cells. Immune deviation is the conversion of a Th1 type (interferon-γ secretion, delayed type hypersensitivity) response to a Th2 type (IL-4 and IL-10 secretion) response. Since Th2 type response can antagonise the Th1 response, this mode of regulation may also be considered a component of active suppression.

2.1 Mucosal Tolerance

The existence of regulatory mechanisms in the mucosa can restrict the development of unwanted immune responses to common or harmless antigens encountered in the air or food. Exposure of the mucosal surfaces of the intestine or the naso-pharangial mucosa can induce tolerance to antigens. The induction of tolerance to myelin-specific antigens by oral [50-52] and nasal [53-57] route is a powerful and highly specific method to suppress EAE.

2.1.1 Oral Tolerance

The mucosae are the major ports of entry for foreign antigens. More than 100 kilograms of food antigens are processed each year by our gastrointestinal mucosa and an estimated 0.1 to 1% of these (100-1000 grams) are absorbed in un-degraded forms. To meet up with this challenge, more than 60% of our peripheral lymphoid tissue is deployed at the gut mucosa, where it secretes large quantities of IgA with various specificities [58, 59]. Yet, not all foreign antigens are infectious pathogens. In fact, most food antigens are beneficial nutrients that must be tolerated. Therefore, the gut immune system has to differentiate two types of antigens: beneficial dietary antigens and infectious pathogens. Failure to tolerate dietary antigens may lead to intestinal hypersensitivity as exemplified by food-sensitive enteropathies, and failure to expel infectious pathogens may contribute to infections [59, 60].

2.1.1.1 The unique properties of the gut mucosal immune system

Collectively, the gut-associated lymphoid tissue (GALT) makes up the largest lymphoid organ of the body. It consists of a large number of lymphoid follicles scattered throughout the entire intestinal tract. In many areas, the lymphoid follicles aggregate to form lymphoid nodules called Peyer's patches. The Peyer's patch is structurally similar to peripheral lymph node in that it contains separate zones for T and B cells. In the T cell zone of the Peyer's patch, i.e., the interfollicular region (IFR), high endothelial venules (HEL) are present, allowing extravasation of naive T cells to the mucosal lymphoid tissues. The B cell zone is located at the antiluminal side of the Peyer's patch and often exhibits characteristics of secondary follicles with activated B cells forming germinal centers.

However, the Peyer's patch differs from peripheral lymph node in one important aspect: it contains a subepithelial dome (SED) which is separated from the intestinal lumen by only one layer of epithelial cells. Some of the epithelial cells overlaying the Peyer's patch have a dendritic morphology and are called microfold (M) cells. The M cells are specialized epithelial cells which function to directly transfer antigen to underlying antigen-presenting cells (APC) [61, 62]. The APC present in the SED appears to be primarily dendritic cells; macrophages are rarely detected in the SED [63, 64]. The dendritic cell in the SED is the interdigital type but differs from those present in the interfollicular regions of the Peyer's patch or those in the

paracortex of the lymph nodes: they express N418 and 2A1 but not NLDC-145 or M342 [63, 64]. Furthermore, Peyer's patch dendritic cells express 5-10 fold higher levels of MHC class II molecules than splenic dendritic cells [63, 64]. Unlike the T or B cell zones of the Peyer's patch, the SED contains both T and B cells [63-65].

The 'non-lymphoid' compartment of the mucosa is also different from that of most other organs: it contains relatively large number of lymphocytes. In fact, the 'non-lymphoid' compartment of the mucosa is often referred to as the 'diffused gut-associated lymphoid tissue' [59, 61, 62]. It consists of primarily the vili-associated epithelium and the underneath laminar propria. Inside the epithelium, a unique type of lymphocytes called intraepithelial lymphocytes are present; whereas in the laminar propria, T, B lymphocytes as well as plasma cells are abundant [58, 59]. Intraepithelial lymphocytes contain a sub-population of T cells that develop extra-thymically, most probably in intestinal epithelium. These cells express $\gamma\delta$ T cell receptors [66, 67]. Additionally, the epithelial cells of the small intestine express both class I and class II MHC molecules and can present antigen *in vitro* [58, 59].

For the development of mucosal immunity, a naive T cell must accomplish a minimum of four migration steps. First, it must extravasate at the interfollicular region of the Peyer's patch (or scattered lymphoid follicles of the intestine) through HEL. Second, it must become activated in IFR or SED and enter the B cell rich follicle of the Peyer's patch to activate specific B cells. Third, it must leave the Peyer's patch through lymph as memory T cells and re-enter systemic circulation. Finally, it must home to the laminar propria of the gut through specific "homing receptor" (e.g., $\alpha4\beta7$ integrin) [68-70]. Of note is that GALT is a member of the *common mucosal immune system* which serves not only the gastrointestinal tract, but also the bronchus, the lung and the urinary/genital tracts. Lymphocytes activated in the GALT will home not only to the gut but also to other mucosal tissues to effect immune function [69-71]. This is the cellular basis for oral vaccination against infections of non-gastrointestinal origins.

2.1.1.2 Mucosal immunization and tolerization

It is a long-recognized fact that oral administration of antigen can induce both immunity and tolerance. Oral immunization has been extensively exploited for vaccine development and is now being used for preventing a number of devastating diseases including polioviral and

adenoviral infections [59, 72]. Oral tolerance on the other hand has only recently been exploited as a potential therapy for allergies, autoimmune diseases and transplant rejections [73, 74].

The potential application of oral vaccination and oral tolerization in clinical medicine has helped foster the growth of mucosal immunology during the past decades. Studies of the various cellular and molecular components of the mucosal immune system [64, 67, 72, 75-78] have enhanced tremendously our understanding the phenomena of oral immunization and tolerization. Characterization of TH1 and TH2 mucosal responses to various antigens revealed pivotal roles of cytokines in mucosal immunity [76, 79, 80]. Investigation of different pathways of tolerization led to the recognition of the importance of the antigen dosage in mucosal tolerance [74, 81, 82]. However, despite these progresses, an efficient manipulation of mucosal immune system, either for vaccination or for tolerance induction, remains to be a challenging task.

2.1.1.3 Deletion and non-deletion pathways of oral tolerance

Tolerance induced at the mucosa may be mediated by both deletion and non-deletion mechanisms [73, 74, 83, 84]. Although apoptotic cells can not be directly demonstrated in conventional animals (due to the extreme low frequency of antigen reactive cells), a role for deletion has been strongly suggested by the decrease in T cell frequency and by the lack of complete reversibility of the tolerance, especially when high dose antigens were used [85]. Using TcR transgenic animals [84] and conventional animals injected with transgenic T cells [86], we have demonstrated directly that mucosal exposure of antigen induced apoptosis and deletion of specific T cells. Because deletion eliminates specific cells from the system, this pathway of oral tolerance is usually not reversible and therefore the most effective.

However, deletion is not complete either in transgenic mice or conventional animals. In TcR transgenic mice, although more than 50% of transgenic T cells can be deleted in the Peyer's patch after five feedings with high dose ovalbumin (50-500 mg OVA per feeding), only about 20% decrease of transgenic cells was noted in other lymphoid organs [84]. In mice receiving an injection of TcR transgenic cells, deletion induced by high dose antigen may affect only about 50% of the transgenic cells [86] suggesting that non-deletional mechanisms also play important roles in mucosal tolerance. Non-deletion mechanisms of oral tolerance may involve clonal anergy of TH1 cells and immune deviation to TH2 cells. Clonal

anergy is characterized by deficiency in interleukin (IL)-2 production and the reversibility of hypo-responsiveness by IL-2 [74, 81, 87]. By contrast, deviation is characterized by preferential activation of T cells producing TGF-β and TH2 cytokines. The deviated T cells may be not only non-pathogenic but also capable of downregulating TH1 responses through releasing their cytokines [73, 88].

It should be emphasized that deviation pathway leads to tolerance of TH1 but not TH2 cells and that the end result of immune deviation is partial or 'split' tolerance rather than full tolerance; this pathway has been shown to be a result of low dose antigen administration [81, 82, 88]. When high doses of antigens are used, both TH1 and TH2 cells are tolerized, and this may be mediated by deletion and/or anergy pathways [84, 89, 90].

2.1.1.4 Application of mucosal immunity and tolerance for immunotherapy.

Despite the success of polio oral vaccine, effective mucosal vaccines have not yet been developed for most infectious pathogens including human immunodeficiency virus (HIV) and various sexually transmitted microbes which invade the mucosa. Similarly, application of mucosal tolerance for treatment of autoimmune diseases and allergy has just begun to be explored; no clinical trials have yet been conducted successfully in humans, despite the bulk of evidence from animal studies that oral tolerization effectively ameliorates autoimmune diseases and allergies.

Thompson and Staines [91] and Nagler-Anderson et al. [92] initially described suppression of collagen induced arthritis by feeding type II collagen. Weiner's [93] and Whitacre's [74, 94] groups have studied suppression of experimental autoimmune encephalomyelitis by orally administered myelin antigens. Weiner's and others' laboratories have also investigated oral tolerance to suppress anti-viral immunity, allograft rejection (by feeding donor cells or MHC peptide) [95, 96] and autoimmune models of uveitis [83, 97, 98], diabetes [99] and adjuvant arthritis [100]. However, in none of these models, disease protection was complete especially when the antigens were given after the onset of the disease. Similarly, in many of these models, immune tolerance was partial, and preferential activation of certain arms of immunity was documented. Recently, Blanas et al. showed in a TcR transgenic model that oral antigen may exacerbate rather than suppress autoimmune diabetes [101]. Similarly, partial tolerance induced by intravenous antigen may delay the onset but exacerbate late stages of the disease in the marmoset model of autoimmune encephalomyelitis [102].

Using both intact TcR transgenic and adoptive transgenic mouse models, we showed that T cell activation preceded the development of mucosal tolerance [84, 86]. To determine whether blocking T cell activation during mucosal tolerization enhances the tolerance, we performed a series of experiments using B7-blocking agent CTLA4-Ig. This led to our unexpected finding that B7-blockade prevents the development of mucosal tolerance [103]. It is our belief that a thorough understanding of the cellular and molecular mechanisms of mucosal immunity and tolerance is essential for the success of mucosal antigen therapy.

2.1.2 Nasal Tolerance.

Intranasal (i.n.) administration of tolerogenic antigen can suppress responses not only against the tolerogen but also against other related antigens present at the same location. Thus, epitopes found in myelin basic protein can be used to regulate responses directed against other epitopes of the MBP or epitopes of the PLP, another component of the myelin. Bystander suppression of autoreactive T cells by regulatory T cells can be demonstrated following a single dose i.n. administration of autoantigen [53, 54]. The regulatory T cells appear to be short-lived since they could not regulate newly exported T cells from the thymus [54]. In rat, the bystander suppression induced by i.n. MBP was associated with the increased IL-4 and/or TGF-β response and decreased IFN-γ and TNF-α responses [56, 57]. Low doses of myelin antigen was sufficient to prevent the development of EAE whereas higher doses were necessary to suppress disease progression after active immunization. A role for regulatory CD8+ γδ T cells in the airway has also been proposed [104, 105]. CD8+ γδ T cells could suppress the adoptive transfer of diabetes to non-diabetic mice [106].

2.2 Intravenous Tolerance.

Intravenous administration of autoantigen has long been used to suppress EAE [107-109]. Tolerance was shown to be dependent on the presence of the encephalitogenic epitope in the tolerizing antigen. The timing of intravenous antigen can have a significant effect on the efficacy of the treatment. It is the most effective when the antigen is administered at the time of disease onset, or two weeks before active immunization, and the efficacy is reduced both before the time of the onset and after the establishment of the disease [110]. Tolerance induction by high dose i.v. antigen is mediated, at least in part, by the elimination of autoantigen specific T cells [111-113]. However, the induction of regulatory cells in

the spleen may also play a role [114]. In studies utilizing mice containing the transgenic T cell receptor for the encephalitogenic epitope of MBP (which spontaneously develop EAE), the disease course could be reversed by repeated i.v. administration of the antigen. This reversal was accompanied by massive deletion of peripheral and thymic T cells and the anergy of the remaining T cells in the periphery [115]. The lack of adequate activating factors probably plays a role in the tolerance induction, and IL-12 can block the induction of i.v. tolerance [116].

Intravenous administration of antigen-coupled splenocytes also results in specific suppression of EAE whose efficacy is dependent on the dose and timing of the administration [117-119]. Anergy plays an important role in the development of tolerance following this form of i.v. antigen administration [120].

2.3 Altered Peptide Ligands

An altered peptide ligand (APL) is the MHC-binding antigenic peptide modified by susstitution of one or more amino acids to change the MHC or TCR binding characteristics. It can induce tolerance to the original peptide through several mechanisms including partial activation of specific T cells [121, 122] and antagonism at the level of T cell activation [123]. A single TCR can transmit different signals depending on the ligand it encounters [121, 122, 124]. APLs have been used to regulate and modify the nature of the T cell responses to antigens. The induction of anergy in both Th1 [125] and Th2 [126] cells have been accomplished using altered peptide ligands.

A comparison of the response of Th1 and Th2 clones to the same peptide/MHC complex revealed that different amino acid contact residues of the peptide were important for TCR recognition and signaling by different clones. Altered peptide ligand may compete with native antigen peptide for MHC binding to antagonise T cell activation [123]. In addition; APLs can cross-react with native antigen specific T cell clones to induce qualitatively and quantitatively different cytokine responses. Altered peptide ligands, therefore, can be used to regulate or alter immune responses.

There is ample evidence that APL can be used to suppress EAE. Several different mechanisms may be responsible for the suppressive effect. APL with high affinity for the MHC class II molecules can block peptide MHC interaction [127, 128]. Regulatory cells were demonstrated following administration of a proteolipid protein (PLP)-based APL. This APL, when co-injected with the original PLP peptide, could protect mice from clinical

EAE. However, the protected mice and mice immunized with APL alone showed substantial histological EAE [129, 130]. T cells isolated from the CNS of APL treated mice secreted TGF-β and the suppression could be partially blocked by treatment with anti-TGF-β antibody [130].

Superagonists, which are defined as altered peptide ligands with similar or lower MHC binding affinity, induce half-maximal effector responses at 100-fold lower concentrations than the original peptide [131]. An APL consisting of a single amino acid change replacing the lysine residue at position 4 of the MBP Ac1-ll with alanine (Ac1-ll [4Ala]) could bind to MHC II I-A^u with a higher affinity and was a better stimulator in vitro for encephalitogenic T cell clones. However, it prevented EAE when administered in vivo [132] in (PL/JXSJL)F1 mice. Since a related but different APL with no protective effect could bind to I-A^u with similar affinity, MHC blockade was ruled out as a mechanism for the EAE inhibition. Moreover, since the splenocytes from protected mice could not prevent mice from EAE, the generation of a regulatory cell population was likewise ruled out. Further experiments in this model using a superagonist amino acid substitutions at position 4 of the Ac 1-11 peptide Ac1-ll [4Tyr] demonstrated that stimulation with the weakest (original) antigen could expand the high affinity encephalitogenic T cells and cause disease. Ac1-ll [4Tyr] however deleted the high affinity T cells and stimulated a different population of T cells which had a lower affinity TCR [133]. Furthermore, responsive cells remaining after i.v. treatment with Ac1-ll [4Tyr] secreted Th2 type cytokines [134].

The modification of the antigenic peptides can have drawbacks, however. Immunization with an antagonistic APL effective in in vitro testing with a TCR transgenic T cell actually induced EAE in susceptible mice [135]. Recent human trials using APL have yielded unexpected results [136]. It is possible that tolerizing one population of encephalitogenic T cells could activate another. It is, therefore, necessary to carefully investigate the cellular and molecular mechanisms of APL action before it can be successfully applied in humans.

Acknowledgments

Chapter A22

THE ROLE OF COSTIMULATION IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Michael K. Racke*, Robert B. Ratts, Rodney W. Stuart, Caishu Deng and Amy E. Lovett-Racke

*Department of Neurology and *The Center for Immunology, UT Southwestern Medical Center, Dallas, Texas, USA*

Abstract: Experimental allergic encephalomyelitis (EAE) is a T cell-mediated, autoimmune disorder characterized by central nervous system (CNS) inflammation and demyelination, features reminiscent of the human disease, multiple sclerosis (MS). In addition to the signal the encephalitogenic T cell receives through the T cell receptor (TCR), a second signal, termed costimulation, is required for complete T cell activation. The B7 family of cell surface molecules expressed on antigen presenting cells (APC) is capable of providing this second signal to T cells via two receptors, CD28 and CTLA-4. Our studies and those of others have shown that costimulation provided by B7 molecules to its ligand CD28 is important in the initiation of the autoimmune response in EAE. Further, it appears the costimulation provided by B7-1 is important in disease development, while B7-2 may play an important regulatory role. We and others have shown that B7/ CTLA-4 interaction plays a critical role in down-regulating the immune response in EAE. Other costimulatory pathways, such as CD40/CD40L and ICOS and its ligand, also play significant roles in the EAE model.

Previous work has shown that activated T cells and T cells of a memory phenotype are less dependent on costimulation than naive T cells. T cells reactive with myelin components that are involved in the pathogenesis of EAE and possibly MS would be expected to have been activated as part of the disease process. Building upon our prior work in the EAE model, we have tested the hypothesis that myelin-reactive T cells, which are relevant to the pathogenesis of CNS inflammatory demyelination, can be distinguished from naive myelin-reactive T cells by a lack of dependence upon costimulation for activation. It is hoped that therapies targeting costimulation may provide a means of conserving normal immune function whilst eliminating or suppressing autoreactive T cells, providing a more efficient means to treat autoimmune disease.

Key words: EAE, costimulation, second signal, CD28, CTLA-4, B7-1, B7-2, ICOS, memory T cells, multiple sclerosis

Introduction

In the United States, it is estimated that 250,000-350,000 people have physician-diagnosed MS (Anderson et al., 1992). The majority of patients are diagnosed with the disease during their third and fourth decade of life, resulting in many patients having to suffer the effects of this disease for most of their adult life. The cause of MS remains elusive. However, because the disease is characterized by perivascular, mononuclear cell, inflammatory infiltrates and demyelination, features also characteristic of EAE, an autoimmune process is thought to be involved in disease pathogenesis (Martin et al., 1992; Raine, 1984; Arnason, 1983). Interestingly, both MS patients and normal controls have been shown to have T cells reactive to a number of myelin antigens, making it difficult to establish a relationship between myelin reactivity and the presence of disease. Epidemiological studies as well as studies examining identical twins suggest that both genetics and environment, particularly viral infections, may play a role in disease pathogenesis (Martin et al., 1992; Sadovnick and Ebers, 1993; Martyn, 1991). Three drugs have been approved by the FDA for use in the treatment of patients with relapsing and remitting MS (IFNB Multiple Sclerosis Study Group, 1995; Jacobs et al., 1996; Johnson et al., 1995). However, these agents are not a cure for the disease, so the need for the development of better treatment strategies in MS remains.

Relevance of EAE to human MS

There are several animal models which have been used to study MS. In some of these models, disease is induced by viruses such as Theiler's virus (Miller and Karpus, 1994). Of the EAE models, the most commonly studied are those established in the Lewis rat and in several susceptible mouse strains. Our laboratory has used exclusively the murine model for a number of reasons. Many models of murine EAE result in a relapsing/remitting disease, similar to the early phase of most MS patients, while EAE in the Lewis rat is a monophasic illness. In chronic murine EAE, the pathology observed in the white matter is much more reminiscent of the pathology seen in the CNS of patients with MS, showing much more demyelination than the Lewis rat model. With the advent of transgenic and homologous recombination technology, it is becoming increasingly clear that many powerful molecular tools are becoming available to study the immune response in mice in pathological processes such as EAE.

EAE as a model of organ-specific autoimmunity

The understanding of immunological mechanisms involved in autoimmune, inflammatory demyelination has advanced greatly through the investigation of EAE, an animal model of MS which can be induced either by immunization of susceptible animals with components of myelin or adoptive transfer of CD4+ T cells specific for myelin antigens (Martin et al., 1992; Zamvil and Steinman, 1990). It is the adoptive transfer experiments which have clearly established that EAE is a T cell-mediated autoimmune

disease. Studies of various inbred mouse strains demonstrated that their ability to develop EAE following immunization with myelin varied significantly (Fritz and McFarlin, 1989). MHC class II background was initially thought to be the most important factor in conferring susceptibility to EAE, but studies have shown that other genetic loci are also involved in disease susceptibility (Fritz et al., 1985). Another variable in EAE studies has been the antigen used to induce disease. MBP and PLP are the major protein components of myelin and have been most studied as the disease-initiating antigen in EAE, although myelin oligodendrocyte glycoprotein (MOG) is being used increasingly in B6 mice (Martin et al., 1992; Zamvil and Steinman, 1990). Although EAE produced by immune responses against MBP or PLP is T cell mediated, it has also been shown that addition of antibodies to MOG, a minor glycoprotein on the outer surface of the oligodendrocyte, dramatically enhances demyelination in MBP-induced EAE (Linington et al., 1988).

T cell costimulation

The activation and differentiation of T cells require both antigen/MHC recognition and costimulatory signals. The signal conferred by the TCR determines the antigen-specificity of the response. The second signal, termed costimulation, is provided by accessory molecules on the antigen-presenting cell (APC) and appears to be necessary for T cell activation (see Figure 1). There are several receptor-ligand pairs which can provide costimulation. However , the signal provided by the B7 family of cell surface molecules with its receptors on T cells, CD28 and CTLA-4, appears to be the predominant one for T cell activation (June et al., 1994; Jenkins and Johnson, 1993; Bretscher, 1992).

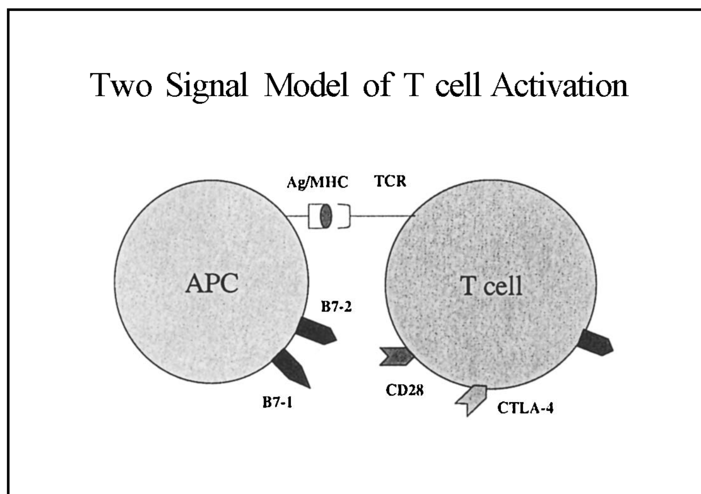

Figure 1. Trimolecular complex (TCR:Ag/MHC) forms signal one, while B7:CD28/CTLA-4 pathway composes important second signal.

At least two members of the B7 family of CD28 ligands have been defined, B7-1 (CD80) and B7-2 (CD86) (Freeman et al., 1993a,b,c; Hathcock et al., 1994;). These molecules, although having modest homology, are each capable of providing costimulation to T cells for proliferation and IL-2 production. It is for this reason that a mouse genetically deficient for B7-1 was still immunocompetent (Freeman et al., 1993a). On the other hand, T cells from a mouse deficient in CD28 could not produce IL-2 after stimulation with the mitogenic lectin Con A, demonstrating that costimulation through this molecule is critical for IL-2 production (Green et al., 1994a).

B7-1 and B7-2 are expressed differentially on various APC and their kinetics of expression and binding also differ (Larsen et al., 1994; Freedman et al., 1991; Linsley et al., 1994). B7-2 is expressed by monocytes constitutively, while B7-1 can be induced on these APC with IFN-γ. B7 is expressed on B cell populations after an activation stimulus; B7-2 is expressed within 6 hours, while B7-1 expression peaks after 48 hours. The expression of B7-1 and B7-2 has also been shown to occur on T cells themselves (Sansom et al., 1993; Azuma et al., 1993). Interestingly, it appears that B7-2 expressed on T cells is unable to interact with CD28, yet is still able to interact with CTLA-4 (Greenfield et al., 1997). Work by our group demonstrated that T cells are the main cell type expressing B7 molecules in the CNS during various stages of EAE (Cross et al., 1999). Thus, as with CD28 and CTLA-4, B7 molecules themselves may be able to either enhance or inhibit immune responses.

Much has been learned about the role of costimulation in immune processes with a soluble fusion protein, CTLA-4Ig, which can prevent the interaction between B7 and CD28 or CTLA-4 (Gimmi et al., 1993). Administration of CTLA-4Ig prevented rat cardiac allograft rejection and pancreatic islet cell xenograft rejection in transplantation models in mice (Lin et al., 1993; Lenschow et al., 1992). In both instances, it appeared the mechanism of suppression involved the induction of antigen-specific tolerance. The costimulation provided by B7 also appears to be important for the development of encephalitogenic effectors and subsequent autoimmunity. Our laboratory has examined the role of B7:CD28/CTLA-4 interactions in the induction of EAE (Perrin et al., 1995a,b; Perrin et al., 1996a; Racke et al., 1995). In the adoptive transfer model of EAE, CTLA-4Ig was able to inhibit the proliferation and IL-2 production of MBP-specific lymph node cells during activation *in vitro*, diminishing the clinical disease observed upon subsequent transfer. Thus, B7-mediated costimulation was found to be an important factor in determining encephalitogenicity of myelin-specific T cells. It is important to note that once activated autoreactive cells had been injected into naive recipients, CTLA-4Ig intervention did not alter the course of disease. This would be consistent with the concept that activated T cells do not require costimulation to perform their effector function.

In active models of EAE, several intriguing observations have been made. Disease induced by immunization with MBP and pertussis toxin (PT)

injection was inhibited by a single injection of CTLA-4Ig (Perrin et al., 1995b). On the other hand, in a model using a two immunization schedule without PT, clinical signs of EAE were enhanced following administration of multiple doses of CTLA-4Ig, yet was inhibited with a single injection 48 hours after the initial administration of encephalitogen (Racke et al., 1995). These paradoxical results suggested that B7 costimulation may also provide a regulatory role during an immune response.

Early studies indicated that CTLA-4 induced a positive costimulatory signal in conjunction with CD28 (Linsley et al., 1992). Evidence generated by our laboratory utilizing the EAE model suggested that the signaling through the CTLA-4 molecule actually mediated a negative regulatory function (Perrin et al., 1996b). In CD28-deficient mice, costimulation provided by B7+ APC did not transduce a positive signal (Green et al., 1994b). Furthermore, a mouse genetically deficient in CTLA-4 has a fatal phenotype secondary to a lymphoproliferative disorder (Tivol et al., 1995; Waterhouse et al., 1995). These studies all suggested that B7 mediated costimulation provided regulatory signals that limited the immune response.

We and others showed that B7-1 provides an important stimulus for the development of encephalitogenic T cells (Perrin et al., 1995a,b; Perrin et al., 1996a; Racke et al., 1995; Kuchroo et al., 1995; Miller et al., 1995). However, we were unable to demonstrate that B7-1 costimulation skewed development to the Th1 phenotype (secreting IFN-γ, IL-2, and LT) or that B7-2 costimulation preferentially resulted in Th2 cells (secreting IL-4-6), as described by Kuchroo et al. (1995). Interestingly, we did make similar observations that anti-B7-1 administration was protective while anti-B7-2 administration exacerbated EAE. Observations using mice deficient in either B7-1 or B7-2 suggests that both molecules can make significant contributions to the production of both IL-4 and IFN-γ. However, neither molecule plays an obligatory role in priming for the production of either effector cytokine (Schweitzer et al., 1997). Furthermore, in the non-obese diabetic mouse, the effect of administration of anti-B7 antibodies was reversed, with anti-B7-1 exacerbating disease and anti-B7-2 blocking the development of disease (Lenschow et al., 1995). However, as noted above, because the B7-2 expressed on T cells appears to be able to interact with CTLA-4, the addition of anti-B7-2 may result in the inhibition of a negative signal to the responding T cells, resulting in the enhanced disease observed in the EAE model. Thus, the role of the B7 family of costimulatory molecules in autoimmune diseases appears to be quite complicated.

Inhibition of the B7/CD28 pathway has been shown to have significant effects in a number of autoimmune models, including EAE. For example, NOD mice deficient in CD28 were totally resistant to the development of EAE (Akdis et al., 2000). However, T cells primed against proteolipid protein (PLP), which were also deficient in CD28, could proliferate and secrete IFN-γ and TNF-α at wild type levels (Howard et al., 1999). Recent studies in the EAE model examining the role of CD28 and B7

molecules have utilized mice generated by homologous recombination which are deficient in these molecules. Initial studies examining susceptibility of B6 mice deficient in CD28 to EAE demonstrated that the T cells from these mice were impaired in their ability to enter the CNS (Perrin et al., 1999; Chitnis et al., 2001). These mice specifically developed a significant picture of meningitis, with clear impairment of T cells to directly enter the CNS parenchyma. Interestingly, studies carried out using B6 mice deficient in both B7-1 and B7-2 demonstrated that these mice were also resistant to the development of MOG-induced EAE (Chang et al., 1999). This impairment was not due solely to impaired priming of MOG-reactive T cells, since wild type T cells transferred to B7-1 and B7-2 deficient mice were still resistant to the development of EAE. Again it appeared the major finding was that these cells could not invade the CNS parenchyma. These observations clearly suggest that CD28:B7 interaction may also play an important role for T cells to enter the CNS itself. In addition, it appears CD28 blockade is most effective in situations where the number of memory T cells for a particular auto-antigen is low, which may not be the case for all situations in autoimmunity.

Costimulation requirements for naive versus memory T cells

The ability of the immune system to respond upon first contact with an antigen is critical for host defense against foreign pathogens. Understanding the requirements for expansion of T cells in the adaptive immune response for a particular antigen is not only important for host defense, but also important in understanding the pathogenesis of autoimmunity. Several functional differences between naive and memory T cells have been delineated. Naive T cells, which have not encountered their antigen since exiting the thymus, express high levels of CD45RA or RB and L-selectin and low levels of CD44. Memory T cells, which have encountered their antigen one or more times, have low expression of CD45RA/B (or high CD45RO in humans), low L-selectin, and high CD44 (Croft et al., 1994).

It has been shown that naive T cells have distinct activation requirements in comparison to memory or activated T cells. For example, MHC-peptide complexes could stimulate primed TCR transgenic T cells, yet this same stimulus resulted in poor activation of those same TCR transgenic T cells when these cells were naive (Sagerstrom et al., 1993). Providing costimulation through CD28 resulted in activation and proliferation of the naive T cells. In addition, memory T cells have been shown to be considerably less dependent on accessory cell costimulation than naive T cells (Croft et al., 1994; Damle et al., 1992). The activation state of myelin-reactive T cells has not been well characterized. Myelin-specific T cells with a mutation in the HPRT gene have been found at a higher frequency in MS patients than normal controls, suggesting that these cells have replicated *in vivo* and had the opportunity to mutate (Allegretta et al., 1990; Trotter et al., 1997). In another study, the frequency of myelin-specific T cells expressing the IL-2 receptor, a marker of activation, was shown to be higher in MS patients (Zhang et al., 1994). Our own studies demonstrated that antigenic stimulation of murine MBP-specific lymph node cells made them much less

dependent on B7-mediated costimulation on subsequent antigenic stimulation *in vitro* (Racke et al., 1995). An important issue is whether costimulation-independent, myelin-reactive T cells in MS patients accumulate over time and whether this accumulation correlates with disease progression. This result will have important consequences with regard to the potential application of interference with costimulatory pathways as a treatment for human autoimmune diseases.

Antigen determinant spreading in EAE and MS

The relapsing-remitting course of disease characteristic of both EAE and MS has suggested the possibility that T cell immunity to new myelin antigens may develop during chronic CNS inflammation and may play a role in subsequent relapses. This phenomenon, termed antigen-determinant or epitope spreading, occurs when T cell immunity has developed to antigens other than that antigen used to initiate the inflammatory response. Work performed in the laboratory of the late Dr. Dale McFarlin was the first to demonstrate that following the induction of EAE to one MBP epitope, T cell responses to another MBP peptide could be observed (McCarron et al., 1990; Lehmann et al., 1992). This process represented what is now known as intramolecular spreading. Later, work by Dr. Anne Cross demonstrated a response developed to PLP after EAE had been initiated by MBP, a phenomenon termed intermolecular epitope spreading (Cross et al., 1993; McRae et al., 1995). Recent studies have demonstrated that administration of Fab fragments that block B7-1 during remission in relapsing /remitting EAE were able to prevent epitope spreading and development of new relapses in EAE (Miller et al., 1995).

Relevance to the therapy of multiple sclerosis

Our studies have addressed the question of whether memory T cells specific for an autoantigen such as MBP have different costimulatory requirements than naive cells specific for the same autoantigen. If we can demonstrate that memory T cells have reduced costimulatory requirements *in vivo*, this would have implications for the development of an immunotherapy targeting the B7:CD28/CTLA-4 pathway. Such an immunotherapy has several attractive features, the greatest being that it might be able to target autoreactive T cells without actually requiring the knowledge of the specific autoreactive antigens.

Our laboratory has performed several studies that have helped define the contribution of the B7:CD28/CTLA-4 pathway in the pathogenesis of EAE (Perrin et al., 1995a,b; Perrin et al., 1996a; Racke et al., 1995; Perrin et al., 1999; Cross et al., 1999; Ratts et al, 1999a,b). It is only much more recently that our laboratory has begun to engage in studies which attempt to characterize the immune response to myelin antigens in patients with MS (Lovett-Racke et al., 1997). The studies we have performed on the pivotal role of costimulation in the EAE model provided the intellectual basis for the experimental approaches we have used to study T cell activation requirements to myelin antigens in patients with MS.

CD28 Costimulation Requirements in MS patients

Myelin-reactive T cells are present in both MS patients and controls (Pette et al., 1990; Martin et al., 1993), indicating that autoreactive T cells can exist in individuals without pathologic consequences. We wished to address whether there was a difference in the costimulatory requirements of MBP-reactive T cells in MS patients versus normal controls. The hypothesis tested was that MS patients would have myelin-reactive T cells that were less dependent on CD28-mediated costimulation because they had an activated or memory phenotype.

We decided to use an approach which would minimize the amount of *in vitro* manipulation, such as that which occurs with T cell cloning, because after repeated *in vitro* stimulation, T cells would have an activated or memory phenotype. Peripheral blood mononuclear cells (PBMC) from MS patients, stroke patients, or controls were plated at a density of 2.5 x 10^5 cells/well in the presence of MBP and either αCD28 or control antibody. In addition, 48 wells without antigen and each antibody were plated. After 6 days in culture with MBP, ^{3}H-methyl-thymidine was added and the cells were harvested on day 7. Positive wells were considered to be those wells with MBP and antibody (either αCD28 or control) that had counts greater than 2 SD above the mean of the control wells and also had a stimulation index greater than 2 (see Lovett-Racke et al., 1998 for details). Figure 2 shows the percentage of the MBP response inhibited by αCD28 in MS patients, stroke patients, and controls.

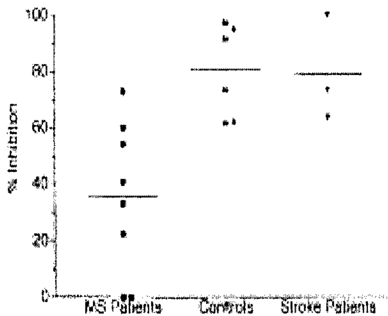

Figure 2. Blockade of CD28-mediated costimulation did not efficiently inhibit proliferation of MBP-reactive T cells in most MS patients. The percent inhibition of the number of positive wells in lymphocyte proliferation assays in the presence of anti-CD28 was determined for the patients and controls who had a response rate >3% with the control antibody. A two-tailed *t* test indicated a significant difference between the MS patients and controls. Reproduced from the Journal of Clinical Investigation, 1998, vol. 101, pp. 725-730 by copyright permission of the American Society for Clinical Investigation.

Approximately 80% of the MBP-specific proliferative response was inhibited in normal controls and stroke patients, while only 35% of the response was inhibited by αCD28 in MS patients (MS vs. control, p=0.0036; MS vs. stroke, p= 0.0317; control vs. stroke, NS). This data suggests that MBP-reactive T cells in MS patients are less dependent on costimulation, a characteristic of activated or memory T cells, than the MBP-reactive T cells in controls or stroke patients. The stroke

patients represent an important control, because presumably after an infarct, macrophages that are recruited to the region of the infarcted tissue would subsequently have the opportunity to present MBP and other myelin antigens to the immune system. It was previously shown that B7-1 is expressed in the inflammatory lesions in the brains of MS patients, but not in cerebral infarcts, making it likely that priming to MBP would occur in MS, but not in stroke (Windhagen et al., 1995). As another control, we have examined the responses to tetanus toxoid (TT) in MS patients and normal controls. As one might expect, since almost everyone has had multiple immunizations to TT, patients and controls make an excellent response to TT that is not inhibited by the addition of αCD28 (Lovett-Racke et al., 1998). One might expect that costimulatory blockade should completely inhibit MBP-specific proliferation in healthy controls and conversely, have no effect on the proliferation of MBP-reactive T cells in MS patients. One explanation for the incomplete inhibition of MBP-reactive T cell proliferation in healthy controls following CD28 blockade may be due to cross-reactivity of MBP-reactive T cells with foreign antigens. Wucherpfennig and Strominger (1995) described MBP-reactive T cells that could proliferate to a variety of antigens derived from common viral pathogens, suggesting that these "MBP-specific" T cells may have been activated *in vivo* in controls in response to an infection and may have never encountered MBP, which is sequestered behind an intact blood-brain barrier. Limiting dilution analysis of MBP and TT-reactive T cells demonstrated that the frequency of MBP-reactive T cells able to respond when CD28 was blocked decreased 4-6 fold in controls, suggesting that these T cells are naive. In contrast, there was no significant difference in the frequency of MBP-reactive T cells with or without αCD28 in MS patients. There was also no difference in the frequency of TT-reactive cells for the controls or MS patients. This is consistent with the hypothesis that memory T cells in humans are less dependent on CD28-mediated costimulation to mount a proliferative response.

Our laboratory has a great deal of experience using CTLA-4Ig to block B7-mediated costimulation in the EAE model. Both CTLA-4Ig and αCD28 give similar responses in their ability to block an MBP-specific response in MS patients (Lovett-Racke et al., 1998). Just as important, CTLA-4Ig behaved similarly with regard to αCD28 in its inability to block the memory proliferative response to TT. Similar results blocking the proliferative response of MBP-specific T cells from normal controls using CTLA-4Ig have been demonstrated by others (Scholz et al., 1998). Thus, using both αCD28 and CTLA-4Ig has allowed us to accurately examine the costimulatory requirements of myelin-reactive T cells in MS patients. Recent work by Markovic-Plese et al. (2001) showed that these costimulation-independent T cells lack CD28 expression, yet can be stimulated to produce high amounts of IFN-γ and upregulate the IL-12Rβ2 chain. The authors hypothesized that these T cells would likely initiate immune responses in the CNS, because they would not require the expression of costimulatory molecules on professional APC.

Costimulation Requirements in EAE

In our prior studies examining costimulation in the EAE model, we have methodically examined the clinical outcome of blocking B7 molecules individually or together using either anti-B7-1 and anti-B7-2 antibodies or CTLA-4Ig (Perrin et al., 1995a,b; Perrin et al., 1996a; Racke et al., 1995; Perrin et al., 1999; Cross et al., 1999; Ratts et al, 1999a,b). Although we have identified certain regimens which appear to reduce clinical signs of EAE and reduce production of relevant inflammatory cytokines, we have never been able to completely eliminate the development of disease. This suggests the possibility that there may be a population of T cells that are B7-costimulation-independent and that these T cells will be able to mediate disease despite costimulatory blockade.

Recently, we performed experiments which demonstrated that blockade of the CD28 signal is actually responsible for reducing clinical disease following costimulatory blockade. MBP-specific LNC activated in the presence of αCD28 Fab (10 μg/ml) make less IL-2 and were less encephalitogenic when subsequently transferred into naive recipients (Perrin et al., 1999). Here again, although the encephalitogenic response was reduced, it was not eliminated, suggesting that there are encephalitogenic T cells which are not dependent on CD28-mediated costimulation. Another important observation was that blockade of CD28 during the first disease episode resulted in significant attenuation of subsequent disease course. However, this observation needs to be considered with recent findings using mice deficient in CD28 (Bachmeier et al., 1996). In an autoimmune myocarditis model, CD28 -/- mice developed autoimmune heart disease, although it was less severe than that observed in heterozygous littermates. After primary immunization with myelin oligodendrocyte glycoprotein, CD28 -/- mice develop experimental autoimmune meningitis (EAM) instead of EAE (Perrin et al., 1999). EAM is characterized by neutrophil-dominated lesions within the leptomeninges and is reminiscent of aseptic meningitis. The different disease phenotypes seen in CD28-/- and CD28 +/+ mice demonstrate the importance of CD28 in T cell differentiation. In addition, breeding of NOD mice to CD28 -/- mice exacerbated autoimmunity, suggesting CD28 plays an important regulatory role in that disease model (Lenschow et al., 1996).

Costimulation dependence of i.v. tolerance.

We have also made some interesting observations with regard to the mechanisms of extrathymic tolerance secondary to high dose i.v. antigen therapy (Critchfield et al., 1994; Racke et al., 1996). The potential use of such a therapy in MS necessitates the need to further elucidate the mechanisms involved in tolerance induction. In our initial studies, we have learned that the Vβ8 transgenic mice, which do not express the Vα2 transgene, are useful in these studies (Ratts et al., 1999a,b). Unlike the Vβ8, Vα2 transgenic mice, these mice do not develop spontaneous EAE, however

100% of these animals develop EAE when immunized with either Ac1-11 or MBP in CFA, and do so without a requirement for pertussis toxin injection. These mice have a precursor frequency of MBP-reactive T cells ranging from 1/80,00-1/200,000 before priming with antigen, which is increased over naive B10.PL mice. LNC isolated from these mice without prior antigen priming can be shown to proliferate to MBP in a standard 4 day proliferation assay, thus we have used the proliferative response and cytokine secretion as a measure of tolerance induction.
Interactions between B7 molecules on antigen presenting cells and CTLA-4 on T cells have been shown to be important in establishing tolerance (Perez et al., 1997). We examined the kinetics of tolerance induction following i.v. administration of myelin basic protein (MBP) Ac1-11 in mice transgenic for a TCR Vβ8.2 gene derived from an encephalitogenic T cell clone specific for MBP Ac1-11 (Ratts e al., 1999a). Examination of the lymph node cell (LNC) response 10 days after antigen administration demonstrated an accentuation of i.v. tolerance induction with anti-CTLA-4 blockade. Anergy was induced in splenocytes by i.v. antigen administration as demonstrated by a decrease in MBP-specific proliferation and IL-2 production, and co-administration of anti-CTLA-4 potentiated this effect. In addition, i.v. antigen plus anti-CTLA-4 and CFA was not encephalitogenic. Interestingly, i.v. tolerance (a single injection) did not inhibit EAE, and anti-CTLA-4 administration did not alter this phenotype. These results suggest that while the majority of MBP-specific T cells are tolerized by i.v. antigen, and that this process is potentiated by anti-CTLA-4 administration, a population of T cells still remain that is quite effective in mediating EAE.

Costimulation dependence of i.p. tolerance.

Evidence suggests that costimulation provided by B7 molecules through CTLA-4 is important in establishing peripheral tolerance, whether by i.v. or i.p. antigen administration (Perez et al., 1997). In another study, we examined the kinetics of tolerance induction and T cell differentiation following i.p. administration of MBP Ac1-11 in mice transgenic for a TCR Vβ8.2 gene derived from an encephalitogenic T cell clone specific for MBP Ac1-11 (Ratts et al., 1999b). Examination of the lymph node cell (LNC) response after antigen administration demonstrated a dependence on CTLA-4 for i.p. tolerance induction. Examination of splenocyte responses suggested that i.p. antigen administration induced a Th2 response, which was potentiated by co-administration of anti-CTLA-4. Interestingly, i.p. tolerance was able to inhibit the induction of experimental autoimmune encephalomyelitis (EAE) and anti-CTLA-4 administration did not alter this phenotype, suggesting that CTLA-4 blockade did not block tolerance induction, but rather potentiated the Th2 phenotype of MBP-specific T cells, which likely was responsible for the inhibition of EAE. Thus, T cell differentiation and the dependence on CTLA-4 for tolerance induction following i.p. antigen administration differs between immune cells in the lymph node and spleen in the EAE model.

Additional Costimulatory Pathways Regulating EAE

While the B7:C28/CTLA-4 pathway has been the best studied in EAE, other pathways have also been investigated. For example, CD40L, a member of the TNF receptor family, is predominantly found on activated T cells, while its ligand CD40, can be found on B cells, dendritic cells, macrophages, astrocytes, and thymic epithelial cells. Professional APC constitutively express the costimulatory molecules CD40 and B7 and both are upregulated when the APC becomes activated (Howard et al., 1999b; Lefrancois et al., 2000; McCormick et al., 1999; van der Eertwegh et al., 1993). In CD4+ T cells, ligation of the TCR results in increased expression of CD40L and its expression is further increased by other costimulatory events. CD40 ligation leads to the upregulation of B7-1 and B7-2 on APC and thereby enhances the ability of APC to activate naïve T cells (Howard et al., 1999b). Thus, CD40L interaction with CD40 is important in T cell activation, particularly in its early stages. Studies conducted in SJL mice examining PLP139-151-induced EAE showed that anti-CD40L antibody could block progression of clinical disease, whether administered at the peak of disease or during disease remission. CNS inflammation was also reduced by anti-CD40L administration (Howard et al., 1999b). Thus, blockade of the CD40/CD40L pathway appears to be a promising method for inhibiting initial T cell activation and subsequent clonal expansion of autoreactive T cells.

Another recently described pathway is that of the inducible costimulator (ICOS) and its ligand B7-H2, which is expressed by B cells in the lymph node and also present in a number of nonlymphoid tissues. CD40 stimulation does not increase B7-H2 expression as it does with B7-1 and B7-2 (Yoshinaga et al., 1999). ICOS shares about 30-40% sequence homology with CD28 and CTLA-4 an dit maps to the same locus, suggesting that it likely arose via gene duplication. ICOS is not constitutively expressed by the T cell, but is upregulated after stimulation, reaching maximal expression in 48 hours (Zhang et al., 1997; Kouki et al., 2000; Barrat et al., 1999; Coyle et al., 2000; Mages et al., 2000). Interestingly, ICOS can be upregulated in the absence of CD28, however IL-2 production is less than if CD28 costimulation also exists (McAdam et al., 2000). ICOS expression does appear to be present constitutively on previously activated T cells, suggesting it may play a more important role in modifying the responses of memory and effector T cells.

Manipulating ICOS in the setting of diseases such as EAE has proven that complexity of ICOS signaling. ICOS blockade dramatically improved the resolution of clinical symptoms in EAE (Sporici et al., 2001), however susceptibility to EAE was greatly enhanced in ICOS-deficient mice (Chen et al., 2001). Hopefully future studies will determine whether targeting this costimulatory pathway will be beneficial in the treatment of human diseases such as MS.

Conclusions

The studies described in this review demonstrate an important role for costimulation in both multiple sclerosis and its animal model EAE. Our current studies of MS patients, which are based on our prior work in the EAE model, will demonstrate whether costimulation-independent, myelin-reactive T cells develop over time with disease progression. More significantly, we will be able to determine whether these T cells have been expanded *in vivo* and will be able to follow the T cell repertoire to myelin antigens over time in MS patients. We feel these studies, initially developed in the EAE model, will provide important information relevant to the pathogenesis of MS and will have implications for the development of immunologically based therapies for this disease.

Chapter A23

EPITOPE SPREADING IN EAE

Andrea E. Edling and Vincent K. Tuohy
Department of Immunology, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH, U.S.A.

Abstract: Intramolecular and intermolecular epitope spreading, the development of immune cells with new reactivities different from the original immunodominant response, plays an important role in the relapses and progression of EAE and has been implicated in the progression of MS. This chapter describes the process of epitope spreading in EAE, its impact on the development on tolerance, and the induction of peptide-specific tolerance and other immune intervention modalities that can prevent epitope spreading and its consequences.

Key words: epitope spreading, EAE, MS, intramolecular, intermolecular, peptide-specific tolerance

Introduction

Experimental allergic encephalomyelitis (EAE) is an inflammatory paralytic central nervous system (CNS) demyelinating autoimmune disease in rodents that serves as a widely used experimental model for studying multiple sclerosis (MS). In several mouse models of EAE a relapsing-remitting disease pattern of disease similar to that of MS develops (1). Studies have demonstrated that EAE is mediated by encephalitogenic $CD4^+$ proinflammatory T cells of the Th1 phenotype (2,3). Data from animal studies show that the autoimmune T cell repertoire is not fixed but changes as disease progresses. Many reports have indicated that the relapse and progression of EAE may be due to the acquisition of emerging T cell responses to new self-antigens during the course of disease. This acquired T cell neoreactivity is commonly referred to as epitope spreading or determinant spreading. Epitope spreading has been observed in both actively induced EAE and passively induced disease. Epitope spreading is typically demonstrated by proliferation, ELISPOT, or delayed type

hypersensitivity (DTH) reactions to self epitopes not involved in initiation of disease. Epitope spreading during EAE has been shown to be a pathogenic process that spontaneously generates encephalitogenic T cells capable of inducing relapses and sustaining autoimmune demyelination. On the other hand the emergence of destructive new autoimmune T cell repertoires serves to provide more potential targets for developing antigen-specific immunotherapies capable of inhibiting or preventing the debilitating effects of chronic inflammatory self-recognition.

EAE Disease Induction in Studying Epitope Spreading

EAE is a useful animal model system in which to study MS because both have many clinical, histopathologic, and immunopathologic similarities. EAE is generally induced in susceptible strains of rodents by immunization with CNS myelin proteins or their disease-inducing peptides, referred to as encephalitogenic determinants. The most common proteins used for inducing EAE include myelin basic protein (MBP;4,5), myelin proteolipid protein (PLP;6,7), and myelin oligodendrocyte glycoprotein (MOG;8). The adoptive transfer of MBP, PLP, or MOG specific $CD4^+$ T cells into naïve recipient mice can also induce acute and relapse-remitting EAE (9-11). Clinical disease symptoms emerge when activated $CD4^+$ T cells enter the central nervous system and recognize the encephalitogenic peptide epitopes presented in the context of major histocompatibility (MHC) class II molecules on CNS antigen presenting cells. Rodents that are susceptible to disease display an acute phase of disease followed at times by several relapsing episodes that are marked by flaccid limb paralysis.

In the SJL/J and (SWRxSJL)F_1 (SWXJ) mouse strains, antigen-induced EAE results in a relapsing-remitting form of disease. A moderate to severe initial acute disease followed by a recovery period characterizes the relapsing-remitting EAE (R-EAE) model. One or more relapses may occur over a period of weeks to months. This R-EAE mouse model system resembles the clinical features of relapsing-remitting MS patients that develop over many years. In both the SJL/J and SWXJ mouse strains the R-EAE animal model is often utilized by investigators to examine epitope spreading because disease can be induced by encephalitogenic epitopes of PLP, MBP and MOG that have been previously identified. In addition, a hierarchy of disease inducing epitopes has been demonstrated in both the SJL/J and SWXJ mouse models of EAE (12,13).

Mouse Models for Examining Epitope Spreading

In SWXJ R-EAE the relapsing-remitting stage of disease often progresses to chronicity, thereby mimicking the clinical features of MS (14).

Immunization of SWXJ mice with either the p139-151, p104-117 or p178-191 peptides of PLP generates an acute disease followed by a relapsing-remitting course of EAE, with each new relapse progressively more severe than the previous (15;Figure 1A). Most SWXJ mice develop a chronic progressive stage of disease several months after EAE onset. Clinically, at this stage the mice exhibit the inability to initiate movement and show a significant loss in body weight. Severe demyelination and perivascular inflammatory foci develop in the CNS, particularly in the spinal cord. SJL/J mice also develop a relapsing-remitting EAE disease, similar to that seen in SWXJ mice and EAE can be induced in SJL/J mice with peptides from several myelin proteins including MBP (16), PLP (17) and MOG (18).

Intramolecular Epitope Spreading during EAE Progression

Intramolecular epitope spreading in EAE was first described in studies by McCarron *et al.* (19) who showed that $(SJLxPL)F_1$ mice develop a new MHC class II-restricted response to MBP during relapse that is not observed during the initial inflammatory immune attack. In this study EAE was induced by adoptive transfer of $I\text{-}A^u$ restricted MBP1-37 specific T cells, whereas responses to the $I\text{-}A^s$ MBP89-169 determinant developed during disease progression.

Other studies by Lehmann and colleagues (20) expanded on these findings by analyzing T cell responses to MBP in the $(SJLxB10.PL)F_1$ mouse strain, which is highly susceptible to EAE. The investigators demonstrated that the specificity of the T cell repertoire in the $(SJLxB10.PL)F_1$ mice was restricted to the MBP1-11 immunodominant priming epitope during the inductive phase of EAE, but broadened to involve responses to the cryptic MBP epitopes p35-47, p81-100, and p121-140 as disease progressed. Most importantly immunization with whole MBP was not required for detection of epitope spreading which occurred even when mice were primed with the immunodominant MBP1-11 epitope. In other mouse strains such as SJL/J and B10.PL and in the Lewis rat EAE model, epitope spreading within the MBP protein has been detected (21, 22). Therefore, determinants of MBP that are cryptic after a primary immunization can become immunogenic during the disease course of EAE.

Intermolecular Epitope Spreading In EAE

Intermolecular epitope spreading in EAE has been described in studies where immune responses specific for the priming CNS myelin autoantigen is associated with the detection of T cell responses specific for other CNS myelin proteins. Intermolecular spreading was first observed by Perry and colleagues (23) who analyzed lymph node T cell proliferative responses and DTH responses to PLP during the course of disease induced by immunization of $(SJLxPL)F_1$ with MBP. The investigators found *in vitro* T

cell responses to PLP at 3 weeks post-immunization, and this response to PLP peaked during the first and second relapses at 5-7 weeks post-immunization.

In additional studies by Cross and colleagues (24), the authors adoptively transferred disease with MBP87-99 primed lymph node cells into naïve recipient mice and analyzed the lymph node and spleen cell reactivity to the encephalitogenic PLP p139-151, as well as to the priming MBP p87-99. Proliferative responses to the PLP 139-151 epitope were observed during the acute and chronic stages of EAE. The pathogenicity of intermolecular spreading was demonstrated by passive transfer of EAE into naïve SJL/J recipient mice with PLP139-151 stimulated spleen cells taken from SJL/J mice that had previously developed EAE by passive induction of EAE with MBP 87-99 stimulated cells. The results suggest that the autoimmune inflammatory CNS destruction mediated by T cells targeted against MBP leads to endogenous self priming to PLP.

Other studies by McRae *et al.* (12) demonstrated PLP intermolecular spreading during EAE induced in SJL/J mice by adoptive transfer of MBP84-104 primed T cells. Responses to the PLP139-151 spreading determinant were detected by proliferation and DTH during the emergence of the first disease relapse.

The Epitope Spreading Cascade

In EAE primary autoreactivity associated with the clinical onset of disease regresses with time and often becomes undetectable during the course of disease. The emergence of secondary immune responses to autoreactive spreading epitopes is detected as disease progresses. Thus, the chronic progression of EAE involves a transition of autoreactivity from the primary initiating self-determinant to a defined cascade of secondary determinants that sustain the CNS inflammation (25).

In the SWXJ mouse strain, when EAE is induced by immunization with either PLP139-151, PLP178-191, or PLP104-117, the order in which new self-determinants are recognized during the course of disease follows a predictable and sequential pattern (13,15). By 12-16 weeks after immunization, responses to the priming determinants regress and are often undetectable by conventional proliferation assays despite the development of chronic progressive disease. This regression of primary autoreactivity occurs both in the periphery and CNS. SWXJ mice immunized with PLP139-151 develop a sequential pattern of neoreactivity that includes initially PLP249-273, MBP87-99 and PLP178-191 at 4, 8, and 12 weeks post-immunization, respectively (Figure 1A,B). After priming with the PLP104-117 determinant, responses to PLP139-151 occur early after EAE onset and are subsequently followed by responsiveness to MBP87-99.

Similarly, immunization PLP178-191 results in the development of responses to PLP139-151 and MBP87-99. This neoreactivity to spreading determinants has been detected up to 12 weeks post-immunization. In contrast to SWXJ mice, immunization of SJL/J mice with PLP139-151 results in a reverse spreading ordering with expansion of the PLP178-191 repertoire occurring before expansion of MBP84-104-specific T cells (12,26,27). The disease course in PLP139-151 or PLP178-191 induced R-EAE results in a moderate to severe acute stage followed by an incomplete remission. Primary relapse usually develops within 3 weeks after remission onset with a severity of disease not substantially greater than the acute phase. Responses to the relapsing PLP178-191 determinant develop after remission from onset of disease in PLP139-151 induced EAE. However, immune responses to the MBP84-104 spreading determinant begin to emerge during the second relapse. In MBP84-104 induced R-EAE in the SJL/J model, the disease is characterized differently. A mild acute stage of disease develops which is followed by complete remission. Approximately 30-40 days following the onset of remission, relapse occurs and an immune response to the immunodominant determinant PLP139-151 can be detected.

Epitope spreading has also been associated with disease progression in MS. Studies have focused on patients with isolated monosymptomatic demyelinating syndromes (IMDS) that have clinical disorders associated with progression to CDMS. In studies analyzing proliferative immune responses to PLP peptides, patients with monocentric monophasic IMDS responded to distinct PLP peptides (28). Responses to these defined PLP epitopes can be detected for more than 1 year (Figure 1C). However, the autoreactivity associated with the onset of symptoms in IMDS patients wanes over time and eventually becomes undetectable as disease progresses. Moreover, there is a shift in the responses to new PLP epitopes that appear to sustain the autoimmune inflammatory disease state. These results indicate that epitope spreading occurs during the development and progression of MS, similar to the epitope spreading cascade that develops during EAE progression.

Figure 1
Edling and Tuohy

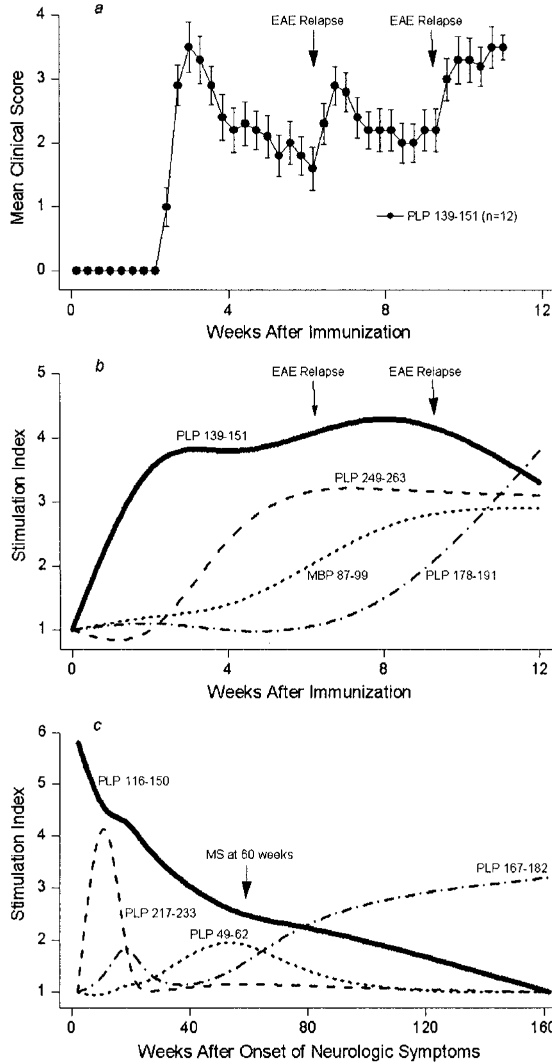

Figure 1. *The Epitope Spreading Cascade Accompanies Progression Of EAE And MS.* (***a***) Immunization of SWXJ mice with PLP 139-151 results in a relapsing-remitting course of EAE that progresses to chronicity. Each relapse is followed by an incomplete recovery that results in a progressive accumulation of neurologic deficit. Similar clinical profiles occur following immunization with PLP 104-117 and PLP 178-191. Error bars show ±SEM. (***b***) A predictable sequential epitope spreading cascade accompanies progression to chronicity in EAE. Induction of EAE

by immunization of SWXJ mice with PLP 139-151 results in a temporally spaced cascade of neoautoreactivity involving PLP 139-151 → PLP 249-273 → MBP 87-99 → PLP 178-191. Similar sequential cascades occur during progression of EAE induced with the encephalitogenic PLP determinants p104-117 and p178-191. It should be noted that EAE progression continues long after responses to the priming p139-151 determinant have peaked. The data are represented as spline curve plots of mean splenocyte proliferative responses of at least three mice tested at each 0, 2, 4, 8, and 12 week time points. (*c*) The progression of MS is accompanied by the decline of primary autoreactivity associated with initial symptoms and by the concurrent emergence of epitope spreading. IMDS patient DL showed progression to CDMS 60 weeks after the initial onset of symptoms. Disease progression involved a sustained neo-autoreactivity to PLP 167-182 accompanied by a decline and eventual disappearance of responses to the PLP 116-150 determinant associated with disease onset. The data are represented as spline curve plots of mean proliferative responses of PBMC on each day tested. (Figure and legend from: Tuohy, V.K., Yu, M., Yin, L., Kawczak, J.A., Johnson, J.M. Epitope Spreading to Self Determinants in Theiler's Murine Encephalomyelitis (TMEV)

TMEV is a murine pathogen in the picornavirus family that results in a persistent infection of CNS APCs. In SJL/J mice a persistent TMEV infection in the CNS produces a chronic progressive inflammatory demyelinating disease clinically similar to chronic progressive EAE, but not to relapsing-remitting disease (29). Demyelination in the TMEV model appears to be immune mediated and initiated by T cells specific for the viral epitopes. Recent studies have shown that epitope spreading of myelin self determinants contributes to the chronic progressive demyelination induced with TMEV.

Immune responses to TMEV epitopes develop at 5-7 days post-infection. However, T cell responses to myelin epitopes do not develop prior to disease onset, but are detected 30-35 days post-viral infection. CNS APCs persistently infected with TMEV present viral epitopes to virus-specific T cells thereby targeting T cell mediated myelin destruction in the CNS. During later stages in TMEV infection, T cell responses to a number of encephalitogenic myelin epitopes can be demonstrated (30,31). At 50-60 days post-infection T cell proliferative and DTH responses can be detected to the immunodominant epitope PLP139-151. T cell responses to several other myelin epitopes develop as the disease progresses. Four weeks after

the detection of PLP139-151 responses, T cell responses to PLP56-70 and MOG92-106 appear followed 2 months later by responses to PLP178-191 and MBP84-104. These data demonstrate a pattern of epitope spreading to myelin proteins during the chronic stages of TMEV induced demyelination.

In the TMEV demyelination model epitope spreading may be viewed as a virus-specific T cell mediated inflammatory response which leads to the activation of resident CNS APCs that process and present endogenous self-epitopes to autoreactive T cells. Thus, Th1 autoreactivity is triggered by the inflammatory response to the viral infection and leads to a chronic autoimmune disease in the CNS by an epitope spreading process.

Epitope Spreading and EAE Disease Progression

It is widely believed that newly acquired autoreactive T cell specificities develop during the course of EAE as a result of chronic tissue inflammation or damage and subsequent presentation of new self epitopes to T cells invading the target organ. Thus, the processing and presentation of newly acquired antigenic determinants lead to the activation of autoreactive T cells specific for spreading epitopes. One question that arises in autoimmunity is whether epitope spreading contributes to disease pathogenesis. This issue has been most difficult to address in human disease.

Evidence indicating a role for intramolecular epitope spreading in the pathogenesis of disease was observed in a PLP139-151-induced RR-EAE SJL/J disease model. T cells responding to the encephalitogenic PLP spreading epitope p178-191 were detected in spleens of PLP139-151-induced EAE mice. Importantly, the epitope spreading splenic PLP178-191 specific T cells demonstrated pathogenic potential by passively transferring disease into naïve SJL/J mice (12).

Vanderlugt *et al.* (32) demonstrated that T cells specific for endogenous myelin epitopes play a major role in the development of EAE relapses. In these studies splenic T cells isolated from SJL/J mice 7 weeks after induction of EAE with MBP84-104 specific T cells were able to transfer disease after *in vitro* activation with either MBP84-104 or the spreading determinant PLP139-151. Moreover, the autoreactive T cells specific for spreading epitopes were found in the CNS of mice before and during the primary disease relapse.

The pathogenicity of T cells responding to spreading determinants was also evaluated by adoptive transfer experiments in SWXJ mice (33). Seven weeks after priming with PLP139-151, spleen cells were activated with the PLP139-151 or MBP87-99 epitope *in vitro* and EAE was passively transferred into naïve SWXJ/J recipient mice. The EAE severity induced by T cells specific for the spreading MBP87-99 was similar to the severity induced by T cells specific for PLP139-151. Therefore, the neoautoreactive T cells were pathogenic and expressed a Th1 proinflammatory cytokine profile, secreting significant levels of IL-2 and IFN-γ.

More recent studies by Targoni et al. (34) demonstrate that throughout the course of EAE, a first stage of effector cells undergoes exhaustion in the CNS and periphery while a second stage of effector cells, developed by epitope spreading, emerges in the CNS. The investigators used enzyme-linked immunospot analysis (ELISPOT) to determine the frequency of the priming PLP139-151 or spreading PLP178-191 specific T cells in the CNS and periphery during disease progression. The frequency of T cells specific for the priming PLP139-151 epitope in the CNS and periphery was high during the onset of paralysis and then declined over time, completely disappearing 70 days after immunization. However, PLP178-191 specific T cells were detected in the CNS, prior to their detection in the periphery during the second episode of paralysis. Thus, the epitope spreading responses were shown to initiate in the targeted CNS tissue rather than in the periphery. Although the primary effector response declined to an undetectable level, mice continued to demonstrate disease progression. Presumably as a consequence of the active spreading repertoire these results confirm previous findings that epitope spreading plays a significant role in the progression of autoimmune disease.

Peptide-Specific Tolerance in the Prevention of Epitope Spreading

Several studies indicate that induction of tolerance to spreading determinants inhibits EAE relapse and progression even when tolerance is induced after onset of disease. Vanderlugt *et al.* (32) showed that pretolerization with relapse associated epitopes 7 days before EAE induction did not have an effect on acute disease, but reduced the relapse rate in both PLP139-151 and MBP84-104 induced R-EAE. Tolerance induction with the relapsing-epitopes was also induced during the remission period following acute disease and resulted in a decrease in relapses.

Similar studies were conducted in the SWXJ mouse model. Mice were tolerized by intravenous injection of the MBP87-99 spreading determinant ten days after onset of EAE induced by immunization with PLP139-151. Mice tolerized to the spreading MBP 87-99 determinant showed consistent improvement in mean clinical score and delayed progression of clinical disease while mice tolerized to the non-spreading PLP104-117 determinant continued their progression to disability. The clinical improvement of MBP 87-99 tolerized mice was accompanied by a corresponding significant inhibition of MBP 87-99 DTH as measured by peptide-specific ear swelling. These studies demonstrate that epitope spreading is not simply an epiphenomenon but rather plays a pathogenic role in the development of relapse and chronic progression of autoimmune disease (33).

Additional Therapeutic Strategies Targeting Epitope Spreading in EAE

It has been shown that progression of EAE may be significantly inhibited when Th2-like T cells specific for priming determinants are adoptively

transferred after onset of disease (35,36). Yin *et al.* (37) examined the efficacy of preemptive targeting of the epitope spreading cascade by adoptive transfer of regulatory T cells after onset of disease. A panel of high IL-10 producing Th2/Tr1-like T cell lines were generated by transfecting primed lymph node cells with a transgene construct designed to produce mouse IL-10 regulated by a mouse IL-2 promoter. The investigators found that after induction of EAE with PLP 139-151, adoptive transfer of MBP 87-99 specific Th2/Tr1-like T cells resulted in a marked and prolonged inhibition of disease progression accompanied by a significant decrease in spinal cord demyelination. The therapeutic effect involved a Tr1 immune deviation of the response to the MBP 87-99 spreading determinant and a bystander inhibition of the recall IFN-γ response to the priming PLP 139-151 immunogen. These results indicate that the clinical course of autoimmune demyelinating disease may be dramatically altered by preemptively creating an immune deviated epitope spreading cascade. However, such deviation may produce cascades involving distinctly different targeted self-antigens as has been shown in the response of NOD mice to beta cell antigens in insulin dependent diabetes mellitus (38).

Another target of therapy for inhibiting epitope spreading in EAE is blockade of B7-1 mediated co-stimulation (26,32). The activation of T cells requires two signals: an antigen-specific signal through the T cell receptor and MHC complex and co-stimulatory signals through the CD28 molecule expressed on T cells, and B7-1 (CD80) expressed on APCs (39,40). B7-1 is upregulated during R-EAE disease progression. When anti-B7-1 F(ab) fragment therapy is administered in SJL/J mice, endogenous self priming and epitope spreading are blocked and clinical relapses and CNS pathology are reduced. The clinical and pathological effects appear to be long lasting, even when treatment is administered late in the disease stage. The mechanisms involved in the inhibition of disease may include anergy induction of T cells specific for relapse associated epitopes. Thus, the co-stimulation antagonist may have a therapeutic application in MS as a result of its ability to prevent endogenous self priming and epitope spreading.

Finally, it is quite possible that the therapeutic effects of IFN-β in MS may substantially be due to inhibition of IL-12 dependent epitope spreading (41). McRae *et al.* (42,43) have shown that IFN-β abrogates Th1 differentiation *in vitro* by inhibiting T cell dependent CD40-induced production of IL-12 from monocyte derived DC, a requirement for priming Th0 → Th1 cells (44,45). We have found that the therapeutic effect of treating SWXJ mice with IFN-β after EAE onset is accompanied by a dramatic inhibition of IL-12 production in *ex vivo* splenocyte responsiveness to the PLP 139-151 immunogen (46). Moreover, this IFN-β induced inhibition of IL-12 is accompanied by a marked failure to develop neoautoreactivity to determinants involved in the epitope spreading cascade. These results support the view that IFN-β inhibits IL-12 dependent

endogenous self-priming *in vivo* resulting in aborted epitope spreading and subsequent inhibition of disease progression.

In summary, epitope spreading is a pathogenic process that leads to relapse and chronic progression of autoimmune disease. During development of autoimmune disease a predictable sequential pattern of epitope spreading emerges. This ordered epitope spreading cascade may provide a basis for targeted peptide-specific immunotherapy after onset of clinical disease in MS.

Chapter A24

APOPTOTIC CELL DEATH IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Apoptosis of effector cells as a safe mechanism in the termination of an autoimmune inflammatory attack

Andrew Chan and Ralf Gold
Department of Neurology, Clinical Research Group for Multiple Sclerosis and Neuroimmunology, Julius-Maximilians University, D-97080 Würzburg, Germany

Abstract: Particularly in the vulnerable CNS with a low capacity for regeneration specialized mechanisms must be active for the fast and gentle elimination of dysregulated autoaggressive immune cells. In EAE, local apoptosis of autoimmune T-cells has been identified as a safe means for the removal of these unwanted cells. T-cell apoptosis *in situ* followed by phagocytic clearance of apoptotic remnants by glia assures a minimum of detrimental bystander damage to the local parenchyma and down-regulates the local inflammatory reaction. The pharmacological augmentation of local apoptosis of inflammatory effector cells might gain therapeutic importance also in human neuroimmunological diseases such as multiple sclerosis.

Key words: T-cell, phagocytosis, Experimental autoimmune neuritis, astrocyte, microglia, glucocorticosteroids, multiple sclerosis

1. INTRODUCTION

Multicellular organisms face the task of safely disposing unwanted cells under physiological and pathological conditions. The active and tightly regulated cell death program during apoptosis is considered to play a major role in the physiological control of cell turnover while at the other end dysregulation of apoptosis has been shown to contribute to the pathogenesis of different autoimmune diseases.

During the last decade the role of apoptosis also in neuroimmunological diseases has been more clearly defined. In EAE and experimental autoimmune neuritis (EAN), especially apoptosis of the pathogenic effector cells has been thoroughly investigated. This review will briefly introduce definitions and detection methods for apoptosis. We will focus on apoptotic cell death of effector T-cells in EAE, proposed mechanisms of T-cell apoptosis, functional consequences and finally its potential therapeutic implications.

1.1 Apoptosis: definition and detection

Apoptosis is a specialized, morphologically and biochemically distinct form of eukaryotic cell death. Introduced in 1972 by Kerr and colleagues, the term apoptosis served to describe a set of morphological features commonly observed during cell death in various tissues and cell types which were different to those observed during necrotic cell death (1). The stereotypic series of cellular changes comprise blebbing of the plasma membrane and condensation of chromatin at the periphery of the nucleus, followed by disintegration of the cell into multiple membrane-enclosed vesicles. In contrast to the lytic processes observed during necrosis, cell death by apoptosis is not associated with secondary inflammatory tissue responses, e.g. towards potentially harmful intracellular contents of the dying cells (2). Thus, apoptosis is considered to provide a safe and gentle cell death mechanism. *In vivo*, apoptosis also appears to be a fast and efficacious mechanism for the elimination of unwanted cells, with completion of the cell death program within 4-5 hrs at least in certain tissues and under defined conditions (3).

As the traditional definitions of apoptosis were mainly based on morphological criteria, electron microscopy served as the gold standard in the detection of apoptosis. Meanwhile, the better understanding of underlying biochemical processes during apoptosis has led to the introduction of an array of detection methods at the molecular level (4,5). For example, intravital internucleosomal DNA-fragmentation which generates fragments of 180 bp and multiples thereof can reliably be detected using TUNEL or *in situ* nick translation techniques. The identification of a set of aspartate-directed cysteine proteases (Caspases) whose activation underly many of the observed morphological changes during apoptosis has further broadened the spectrum of detection methods. Thus, either the activated caspases or their proteolytic cleavage products (e.g. cytokeratin 18, Poly(ADP-Ribose)-Polymerase PARP, APP, actin cleavage products) can be identified. Also specific alterations of the cell membrane (e.g. loss of

phospholipid asymmetry detected with annexin-V) or mitochondrial changes (e.g. cytochrome c release, "permeability transition") serve as the basis for commercially available detection methods for apoptosis. However, many of these detection methods have to be interpreted cautiously (4). For example DNA-fragmentation does not only occur during apoptosis, but also during necrosis. Since different intracellular pathways lead to typical apoptotic features, a combination of different molecular detection methods is feasible. Thus, typical morphological features of apoptosis can also occur in the absence of oligonucleosomal DNA-fragmentation as well as in enucleated cells (6,7).

1.2 T-cell apoptosis in EAE and CNS inflammation

T-cells autoreactive to CNS-antigens such as MBP can also occur in healthy individuals (8,9). Albeit more often in MS-patients, surges of increased frequencies of circulating myelin-reactive T-cells can also be observed in healthy subjects, possibly driven by cross-reactive environmental antigens (10). These activated autoreactive T-cells are capable of entering the CNS-parenchyma and thus have the potential to induce a local immune response when they encounter their specific antigen in the context of appropriate restriction molecules (11,12). Therefore, specialized anatomic barriers such as the blood brain barrier or the absence of lymphatic drainage are not sufficient to prevent immune-mediated damage in the CNS, arguing for other mechanisms in the physiological control of autoreactive inflammatory cells *in situ*. Local apoptosis of pathogenic T-cells has been identified as a major immunological defense mechanism in the "immune-privileged" CNS, leading to an inhibition of inflammation or, once it has encroached, to rapid and non-destructive elimination of the inflammatory infiltrate (review in (13,14).

First reports on cell death by apoptosis in inflammatory brain lesions of Lewis rat EAE were from Pender and colleagues (15). Using morphological criteria the majority of the dying cells appeared to be lymphocytes and oligodendrocytes. Apoptosis of α/β-T-cells was subsequently confirmed by the same group using pre-embedding immunolabelling techniques (16). By combined T-cell immunohistochemistry, molecular labeling techniques and ultrastructural criteria, Schmied and coworkers analyzed T-cell apoptosis in the spinal cord quantitatively during the time course of different rat EAE models (17). Of all apoptotic cells, 64% were identified as T-lymphocytes, mostly expressing the α/β-T cell receptor. While another 9% of the apoptotic cells were classified as oligodendrocytes, apoptosis of macrophages was only

rarely observed. However, a considerable proportion of apoptotic cells could not be identified immunocytochemically, due to the advanced degeneration of the cells.

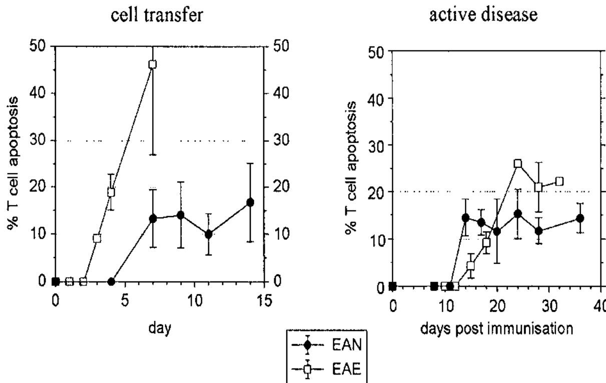

Figure 1. Time course of T-cell apoptosis *in situ*. Apoptosis during the natural course of experimental autoimmune encephalomyelitis (EAE) or neuritis (EAN), passively induced by cell transfer or by active immunization with MBP (EAE) or peripheral nerve myelin (EAN). Ordinate: percentage of apoptotic T-cells (mean +/- SD). Modified after (18).

During Lewis rat cell transfer (AT)-EAE using MBP-specific T-cells the degree of T-cell apoptosis was minimal at early stages on day 4, but peaked at the time of recovery from disease at day 7 with apoptosis rates of up to 49% (figure 1). Also in the active disease model prevalence of T-cell apoptosis *in situ* was highest when animals had recovered from the disease.

Apoptosis of inflammatory cells *in situ* also occurs in chronic relapsing EAE models, especially during clinical relapses (15,19,20,21). In the CNS of adoptively transferred chronic relapsing EAE in SJL/J mice, apoptosis of CD4+ T-cells and microglia/brain macrophages could readily be observed, while oligodendrocytes and astrocytes did not exhibit TUNEL positivity (19).

T-cell apoptosis *in situ* has not only been identified in EAE but also in coronavirus-mediated encephalomyelitis (22). Apoptosis of T-lymphocytes also occurs in inflammatory human brain lesions, most prominently in acute disseminated leukoencephalomyelitis (ADEM) (23), an acute monophasic disease which closely mimics pathological changes of acute EAE. T-cell apoptosis can also be observed in active MS lesions albeit to a lesser extent, possibly due to the chronicity of the disease (24). The similar degree of T-cell apoptosis in the acutely autoimmune inflamed rodent (EAE) and human

CNS (ADEM) (25) with approximately 30% of all invading T-cells undergoing apoptosis highlights the importance of the local apoptotic destruction of inflammatory T-cells in the termination of CNS-inflammation.

In contrast to the high T-cell apoptosis rate observed in the CNS, the PNS and other peripheral tissues appear to have a lower capacity to induce T-cell apoptosis locally. T-cell apoptosis could also be observed in sciatic nerves of Lewis rats with active or AT-EAN (26). Whereas the time course was similar to EAE, the extent of T-cell apoptosis was markedly different: highest levels were also found during recovery, with typical T-cell rates of approximately 10% (figure 1). However, in spite of this lower apoptosis rate, also in the PNS local T-cell apoptosis can be regarded as an efficient mechanism of cell elimination. Thus, given a time frame of 4-5 hrs for the completion of apoptosis, one could assume that up to 50% of an inflammatory infiltrate would be eliminated within 24 hrs.

Negligible degrees of T-cell apoptosis were found in T-cell mediated autoimmune diseases of muscular tissue. T-cell apoptosis was less than 0.5% in CD8-T-cell dominated experimental autoimmune myositis and biopsies of different human myopathies of presumed autoimmune etiology (27,28). Thus, T-cell inflammation in muscle is not cleared by apoptosis *in situ*, which could contribute to the non-self-limiting nature of these diseases. Even in HIV-associated polymyositis and -neuropathy there is virtually no relevant T-cell apoptosis *in situ*, in spite of the pathophysiological relevance of T-cell apoptosis in HIV-infection (29).

Also T-cell infiltrates in the skin do not appear to be eliminated by local apoptosis. In Lewis rat EAE, there was negligible T-cell apoptosis in the dermal tissue adjacent to the sensitization site, despite a heavy T-cell infiltration (17). Furthermore, in skin biopsies of patients with dermatomyositis and lupus erythematosus, T-cell apoptosis was virtually absent (30)(Chan, Gold, unpublished observations).

Given the obvious disparity in T-cell apoptosis between the "immunoprivileged" CNS and other non-immunologically protected sites, tissue-specific local mechanisms must be active in the CNS, that lead to a very efficient apoptotic clearance of pathogenic T-cells.

1.3 Possible mechanisms of T-cell apoptosis in the CNS

An important question in the elucidation of possible mechanisms of T-cell apoptosis concerns the specificity of the dying cells. Thus, apoptosis-inducing mechanisms such as activation induced cell death via triggering of the T-cell receptor would lead to selective cell death only of autoantigen-specific T-cells. In contrast, apoptosis also of non-antigen specific

"bystander" T-cells, secondarily recruited into the lesion, would suggest non-selective mechanisms of apoptosis induction.

To elucidate this further, Pender and colleagues investigated T-cell apoptosis in Lewis rat EAE passively induced with a MBP-specific T-cell clone using the Vβ8.2+ T-cell receptor, which is the predominant T-cell receptor element in MBP-induced Lewis rat EAE (31,32). Apoptosis and T-cell receptor usage was then analyzed in lymphocytes isolated and enriched from spinal cord. The frequency of Vβ8.2+ T-cells was about sevenfold higher in the apoptotic cell population than in the non-apoptotic T-cells. Moreover, using MBP- and ovalbumin-specific T-cells, it appeared that MBP-specific T-cells were readily eliminated from the CNS by apoptosis, while T-cells specific for ovalbumin, an antigen not present in the Lewis rat, survived in the CNS and recirculated to peripheral lymphoid organs. However, these studies could not exclude that also ovalbumin specific T-cells underwent apoptosis in the CNS. Also, altered physicochemical properties of collapsed apoptotic cells could have precluded their quantitative recovery from spinal cord during gradient centrifugation. Moreover, other MBP-reactive T-cell receptor elements besides Vβ8.2, proven to be encephalitogenic were not analyzed in these studies (33,34).

Using T-cells stably expressing specific genomic markers, Lassmann and colleagues could demonstrate that both MBP-specific and ovalbumin-specific T-cells undergo apoptosis in the CNS of EAE-animals (35). In addition, the occurence of T-cell apoptosis during EAE in bone marrow chimeras with different MHC-haplotypes of the resident glial cells and the passively transferred T-cells indicates that T-cell apoptosis is not dependent on antigen-specific mechanisms (35). Thus, both encephalitogenic, antigen-specific T-cells as well as secondarily recruited bystander T-lymphocytes appear to undergo apoptosis *in situ*.

The molecular mechanisms leading to T-cell apoptosis in the CNS *in situ* are as yet incompletely understood (14). *In vivo*, the TNF-receptor-1 (TNFR1)-mediated death pathway appears to play a major role in the induction of T-cell apoptosis in the CNS (36). Thus, in EAE of TNFR1-or TNF/lymphotoxin-deficient mice, local T-cell apoptosis was decreased. TNF-α has been demonstrated to be a potent inducer of T-cell apoptosis (37). Following this line, administration of anti-TNF-α antibody decreases local T-cell apoptosis in EAE of Lewis rats undergoing high-dose antigen-therapy with MBP, where the release of high amounts of TNF-α can be observed *in situ* (38).

T-cell apoptosis in the CNS may also be mediated via the Fas/Fas Ligand (CD95/CD95L)-pathway (review in (14,39)). Thus, one proposed mechanism is the ligation of T-cell CD95 by CD95L expressed by host cells

resident in or secondarily recruited into the CNS (40). In addition, intrathecal infusion of FasL suppresses Lewis rat EAE and augments apoptosis of inflammatory cells *in situ* (41).

Since T-cell apoptosis appears to be tissue specific, resident glial cells might sensitize T-cells towards cell death directly or through soluble factors. Antigen presentation to MBP-specific T-cells by rat microglia results in T-cell apoptosis *in vitro*, which can be prevented by exogenous IL-2 (42).

Also astrocytes, which act as non-professional antigen presenting cells (APC), render T-cells susceptible to apoptosis induced by glucocorticosteroids *in vitro* (43). Glucocorticosteroids markedly increased T-cell apoptosis when added to T-cell astrocyte co-cultures during late T-cell activation stages whereas there was no effect when thymus cells were used as antigen presenters. These results could argue for a scenario, where an infiltrating T-cell is primed for an apoptotic stimulus by a resident non-professional APC, and subsequently undergoes apoptosis under hormonal influences of the microenvironment or systemic changes. However, T-cell apoptosis during recovery from EAE also occurs in the CNS of adrenalectomized animals, arguing for additional mechanisms (44).

Among others, further proposed mechanisms of local CNS T-cell apoptosis comprise the action of reactive oxygen intermediates and nitric oxide, or cell death due to deprivation of growth factors such as IL-2 (45,46). Yet, the precise role of the different putative mechanisms as well as other to date unknown CNS-specific factors in the induction of T-cell apoptosis remain to be elucidated.

1.4 Phagocytosis of apoptotic cells in the central nervous system

The high degree of apoptosis of inflammatory cells in the autoimmune inflamed human and rodent CNS raises the need for an efficient and tightly controlled removal mechanism for these unwanted cells. A key event in the resolution of an inflammatory infiltrate is the nonphlogistic and thus safe phagocytic clearance of dying, yet intact leukocytes undergoing apoptosis (review in (47,48). Apoptosis labels unwanted cells with signals that direct the recognition, uptake and subsequent degradation by tissue-specific phagocytes, thus preventing the spilling of potentially harmful contents and inhibiting secondary immune responses directed towards the dying cells. In addition to the mere clearing of cell remnants, the ingestion of apoptotic cells

also actively elicits phagocyte responses that modulate immune reactions and inflammation.

In Lewis rat EAE, phagocytosis of apoptotic lymphocytes by macrophages/microglia, oligodendrocytes and astrocytes *in situ* has first been described by electron microscopy (49). Using an *in vitro* phagocytosis model, we have further investigated the phagocytosis of apoptotic T-cells by different glial cell elements and its functional consequences (50). Lewis rat microglia efficiently phagocytose specifically apoptotic, encephalitogenic MBP-specific T-cells. This process is differentially regulated by Th1-/Th2-type cytokines (51). The phagocytosis of apoptotic T-cells by Lewis rat microglia is more efficient than by other glial cell elements such as astrocytes. Moreover, phagocytosis of apoptotic T-cells leads to a profound downregulation of microglial immune functions with a suppression of pro-inflammatory cytokines and microglial T-cell activation, thus silencing the microglial phagocyte in the inflammatory context (52). Figure 2 gives a hypothetical model of the phagocytosis of apoptotic T-cells in the CNS.

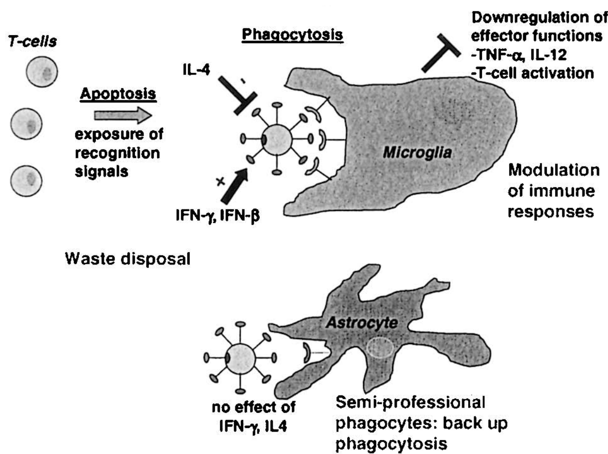

Figure 2. T-cells undergoing apoptosis exhibit specific "eat me" recognition signals for phagocytes. Phagocytosis by microglia is differentially regulated by cytokines ("waste disposal"). The uptake of apoptotic cells leads to a down-regulation of different microglial immune-functions ("modulation of immune responses"). Astrocytes have a lower capacity to phagocytose apoptotic cells and may provide a "backup" mechanism. Modified from (50).

In vitro, rat microglia/brain macrophages have also been demonstrated to phagocytose apoptotic neurons via lectin-, integrin-, and phosphatidylserine-dependent mechanisms (53).

1.5 Induction of T-cell apoptosis by immunotherapy

Current therapeutic approaches in presumably immune-mediated, demyelinating diseases of the CNS such as MS aim at the rapid termination of the inflammatory process, thereby hastening clinical recovery and potentially also preventing subsequent demyelinative and axonal tissue damage (54). Glucocorticosteroids (GS) are potent anti-inflammatory drugs, whose therapeutic efficacy in neuroimmunological diseases has especially been established in immune neuropathies, MS, lupus erythematosus and cerebral vasculitis. Intravenously administered high-dose GS serve as the current mainstay in the therapy of acute MS-relapses(55). GS can mediate their pleiotropic anti-inflammatory effects via different mechanisms, e.g. modulation of cell activation, cytokine expression, secretion of inflammatory mediators, leucocyte migration and the reduction of local edema (56). These effects are mediated via the cytosolic GS-receptor (GSR) and can be blocked by the GSR antagonist RU 468 at low GS concentrations. At higher concentrations, GS appear to induce cell death directly, possibly via non-genomic, physicochemically mediated effects on the plasma membrane (56).

In Lewis rat EAE, iv. methylprednisolone (MP) therapy administered at the clinical disease maximum increased T-cell apoptosis in the spinal cord *in situ* and decreased T-cell infiltration (57). This effect was clearly dose-dependent with a dosage of at least 10 mg/kg body weight MP required to achieve an increase of T-cell apoptosis and a marginal decrease in T-cell infiltration. Higher dosages of 50 mg/kg body weight MP were superior in both respects, and were also effective in mild EAE, in contrast to the lower dosage of MP. The strong apoptosis-promoting effect of GS has also been demonstrated on peripheral blood leukocytes (PBL) of MS-patients (58). After intravenous high-dose corticosteroid treatment, apoptosis of PBLs was markedly augmented in different MS-subgroups, predominantly affecting CD4-positive T cells.

Also in the peripheral nervous system, high-dose GS augment T-cell apoptosis (59). In Lewis rat EAN, a 4-5-fold increase of T-cell apoptosis could be observed in the sciatic nerve after therapeutic administration of GS (10 mg/kg body weight prednisolone). Similar results could be observed in Lewis rat experimental autoimmune myositis (EAM), a model for human idiopathic myosites of presumed autoimmune-inflammatory etiology (27).

Here, a clear increase of apoptotic endomysial T-cells could be demonstrated, with up to 50% of these apoptotic T-cells being CD8-positive. This indicated that glucocorticosteroids also induce CD8-T-cell apoptosis, even in organs where normally T-cell apoptosis does not occur.

The type 1 interferon (IFN) IFN-β, is one of the current mainstays in the immunomodulatory therapy of MS (60). IFN-β appears to affect particularly inflammatory aspects of MS, with a reduction of the relapse rate and positive effects on inflammatory changes observed in MRI scans. In the experimental models, IFN-β has been shown to inhibit progression of relapsing-remitting EAE (61), while early discontinuation of IFN-β led to exacerbation of active EAE (62). While the exact mechanism of action of IFN-β is still unknown, numerous putative mechanisms have been proposed (review in (63)). Whether the therapeutic benefit of IFN-β is also based on the induction of apoptosis in inflammatory cells is still controversially discussed (64,65). In Lewis rat AT-EAE, no major increase of T-cell apoptosis *in situ* could be observed after treatment with IFN-β (66). However, IFN-β clearly increases the phagocytosis of apoptotic, encephalitogenic, MBP-specific T-cells by microglia *in vitro* (Chan, A., Seguin, R., submitted). Thus, theoretically IFN-β could help to engulf and eliminate T-cells driven into apoptosis by other therapeutically used agents, e.g. corticosteroids.

Antigen-specific therapy with CNS or PNS-autoantigens has been shown to be effective in EAE and EAN (67,68). The underlying mechanism appears to involve T-cell receptor reengagement at an appropriate stage of the cell cycle which leads to T-cell apoptosis (69). In Lewis rat cell transfer (AT)-EAE, high dose antigen (guinea pig MBP) therapy not only led to apoptotic cell death of invading T-cells *in situ* but also of resident oligodendrocytes (38). This was accompanied by a profound modulation of the cytokine network with a rapid induction of the Th1-type cytokines TNF-α and IFN-γ as well as inducible nitic oxide synthase. Neutralization of TNF-α *in vivo* led to a decrease in T-cell and oligodendrocyte apoptosis but did not change the beneficial clinical effect of high-dose antigen therapy. This argues for a central role of TNF-α as a mediator of local apoptosis which may have different functional effects. Similar results could also be observed in antigen-specific therapy of Lewis rat AT-EAN using P2-protein (70,71).

Conclusions

Apoptosis of inflammatory effector cells constitutes an effective protective mechanism in the autoimmune-inflamed CNS. Thus, the selective

induction of apoptosis in pathogenic cells is an attractive therapeutic target in neuroimmunological diseases. However, apoptosis of resident CNS cells represents also a major mechanism in the pathogenesis of different neurodegenerative disorders, where selective blockade of apoptotic pathways may be benificial. Therefore, the identification of the molecular, tissue- and cell-specific factors that lead to local apoptosis remain to be elucidated in order to take advantage of this phylogenetically old and important defense mechanism.

Chapter A25

ENVIRONMENTAL INFLUENCES IN EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Cris S Constantinescu
Division of Clinical Neurology, University of Nottingham, UK

Abstract: Environmental factors, in particular infectious agents, are thought to have a major influence on the development and course of MS. Some of these influences are also reflected in the animal model, EAE. In this chapter, the role of infectious agents in the development and course of autoimmunity in EAE is discussed. Other environmental agents including trauma, solar radiation exposure, temperature, stress, toxins, are discussed in terms of their relevance to MS and EAE.

Key words: EAE, MS, infection, autoimmunity, trauma, solar radiation, UV light, temperature, stress, toxins

Introduction

Like several other diseases with an autoimmune mechanism and polygenic susceptibility, including type I diabetes mellitus and rheumatoid arthritis, the most commonly accepted working model of MS development is that it is an autoimmune disease triggered in genetically susceptible individuals by some environmental factor. MS thus arises as a result of an interplay of varying degrees of environmental and genetic factors. Such an interplay is important not only in determining the susceptibility of an individual to the disease but also possibly other aspects of the disease such as severity or course.

Experimental autoimmune encephalomyelitis (EAE) is in many respects the prototypical organ specific, T cell mediated autoimmune disease having provided many clues to the immune mechanisms of MS. As a useful animal model, EAE ideally must reflect some of these environmental influences that play a role in MS. Moreover, EAE being generally induced in strains of

animals, which are very well characterized immunogenetically, the genetic contribution remains equal across the strain or substrain, and the environmental conditions can be varied to provide clues to their contribution to the susceptibility and course of EAE.

Infectious agents

Of the many environmental factors implicated in MS, infectious agents have been most consistently investigated [1]. The possibility that MS is caused by an infectious agent has been entertained since the first detailed clinico-pathological description of MS, and is supported by several lines of evidence. The possibility that, in addition, infectious agents, directly or through their immunological consequences, may modify disease activity is also being increasingly substantiated by studies.

Many infectious agents have been implicated in MS, including spirochetes, bacteria, and viruses (table)

Table 1.

Some infectious agents linked to MS
Adenovirus
Borrellia burgdorferi
Canine distemper virus
Chlamydia pneumoniae
Coronavirus
EBV
Enterovirus
HSV 1, 2, 6, 8
Herpes zoster
HTLV-1 and 2
Measles
Mumps
Papovavirus
Rubella
Simian virus 5
Theiler's encephalomyelitis virus

Some of these infectious agents are linked to MS because of evidence of an increased titer of antibodies against them in the CSF of MS patients, for example measles and herpes zoster, or in their blood, for example EBV. Many, however, are linked to MS because of the existence of spontaneous or experimentally induced demyelination in animal models. These aspects are discussed in detail in the section of this book dedicated to viral models of

demyelination.

However, like in MS, and underscoring the utility of EAE as a model, infectious agents can influence aspects of EAE.

Self-reactive lymphocytes recognizing neuroantigens exist not only in MS patients but also in normal subjects. Moreover, the precursor frequency of these cells does not appear to be higher in MS patients. However, the neuroantigen-reactive T cells from MS patients are in higher state of activation than those of normal subjects [2]. Activated T cells are more capable of crossing the blood brain barrier and there, where they encounter their cognate antigen, they can cause the inflammatory demyelination damage. In relapsing MS, as in relapsing models of EAE, the reactivation of these cells may be a major event in the pathogenesis of relapses.

The role of infectious agents in these situations has been investigated, as it is recognized that infectious events (or immunizations) can trigger MS relapses or the first manifestations of the disease.

Several mechanisms may operate whereby autoreactive T cells can be activated and their action in EAE is discussed below.

Superantigen activation

Superantigens (SAG) are viral or bacterial products capable of activating a large number of T cells bearing the same T cell receptor (TCR)V chain [3]. SAG include several bacterial enterotoxins such as staphylococcal enterotoxin A (SEA) and B (SEB) and have been implicated in several human diseases. SAB bind the Vβ region of the TCR outside the groove normally occupied by the antigenic peptide, and also the MHC class II molecule on the surface of antigen presenting cells. In EAE, and possibly in MS there may be a bias in the Vβ TCR usage in particular in the early stages of the disease, before significant epitope spreading has occurred. SAG activation of neuroantigen-reactive T cells bearing the corresponding TCR may lead to a relapse in EAE. This is indeed the case. SAG SEB, which predominantly binds Vβ TCR in mice has been demonstrated to induce relapses in myelin basic protein (MBP)-induced EAE in PL/J and PL/J x SJL/J F1 mice, whose MBP-reactive T cells predominantly use TCR Vβ8 [4, 5]. Moreover, we confirmed this ability of SEB to induce relapses [6]. In addition, we demonstrated that SEA (which does not bind Vβ8 in mice) also induces significant relapses. Therefore, although it was originally proposed that Vβ8 TCR confers specific tendency for autoimmunity [7], the ability of SAG to reactivate autoimmunity in EAE is not entirely dependent on Vβ8 TCR.

What is the mechanism by which SAG induce relapses? It is known that SAG preferentially activate Th1 cells [8, 9]. It is also known that superantigens induce a variety of proinflammatory cytokines and other

inflammatory mediators. We demonstrated that SAG induce IL-12, the major factor in the development of Th1-type immune responses. Indeed antibodies against IL-12 p40 blocked SAG-induced relapses in PL/J x SJL/J F1 mice. Moreover, IL-12 administration mimicked the effects of SAG, inducing itself relapses [6]. This result was also demonstrated in MBP-induced EAE in Lewis rats [10].

A similar response has been found with TNF. TNF administration induced relapses [11] while administration of neutralizing TNF antibodies partially suppressed relapses [4].

Several anti-inflammatory cytokines including TGF-β, IFN-τ, and IL-10 were capable of suppressing SAG-induced relapses of EAE.

It appears most likely that the mechanism of activation of potentially pathogenic T cells in EAE by superantigens, in addition to activation of a large number of T cells using the same TCR, involves tipping the balance of pro- and anti-inflammatory cytokines toward a more inflammatory environment.

Interestingly, SAG were not only shown to reactivate autoimmunity by inducing relapses in EAE, but also to modify susceptibility to EAE. Interleukin-6 (IL-6) is a proinflammatory cytokine also known to be induced by SAG. Besides IL-12 (p40) it is a proinflammatory cytokine whose deficiency is consistently known to render mice completely resistant to EAE [12, 13]. Administration of SEB to IL-6 knockout mice has overcome their resistance to EAE [14].

These results are highly relevant for MS. It is known that relapses or the initial attack are often preceded by infections. It is also known that SAG can activate human neuroantigen-reactive T cells [15]. This may represent an important mechanism whereby infectious agents can (re)activate MS. Knowledge of this possibility also has implications for the treatment of MS. For example, glatiramer acetate, currently successfully used in the treatment of relapsing remitting MS, promiscuously binds MHC class II inside the peptide binding groove but not requiring antigen processing [16]. Although initially developed as a mimic of MBP, it suppresses not only MBP-induced EAE but also PLP-induced EAE [17]. This promiscuous MHC binding makes it a potentially very useful immunomodulatory treatment, and it was shown to suppress autoimmune uveitis as well [18]. However, while it suppresses antigen-specific T cell proliferative responses in vitro to nominal antigen, it does not suppress SAG-induced responses, suggesting that its blockade of the peptide-binding site in the MHC class II groove, does not affect SAG binding. We have recently confirmed this observation in human SEB-stimulated T cells (Constantinescu C, Robins A et al, unpublished observations).

Molecular mimicry

Another possible activation mechanism for autoreactive T cells with potential to cause or reactivate autoimmunity is molecular mimicry. The concept implies the existence of a structural similarity and an immunological cross-reactivity between self antigens of the host and an infectious agents such as bacteria, viruses, or yeasts, which elicits an immune response, after which T or B cells developed against these agents respond against cross-reactive self-determinants. A most convincing and biologically relevant example of molecular mimicry in human autoimmunity and neuroimmunology is the Guillain-Barre syndrome (GBS) [19]. This is another autoimmune demyelinating disease of the nervous system involving the peripheral nerves. There is convincing evidence for a bacterial etiology in up to 50% of patients. Although typically monophasic, the presentation can be different (for example the various proportions of axonal, myelin, or cranial nerve involvement) and the distribution across age groups in different part of the world can also be different. *Campylobacter jejuni* is a common gastrointestinal pathogen that causes diarrhea. It also, less frequently causes GBS. However, up to two thirds of patients with GBS have serological evidence of a recent *C jejuni* infection. Of these serogroup Penner 19 is overrepresented, while, on the other hand, rarely associated with gastroenteritis. Different serogroups express different lipopolysaccharides (LPS) closely resembling human cell surface glycolipids. Infection with *C jejuni* can thus lead to production of anti-ganglioside antibodies, which cross-react with human glycolipids. The most common such cross-reactive self-antigen is ganglioside GM1. Anti-GM1 antibodies are found in approximately 70% of patients with C. jejuni-associated GBS and in about 30% of patients with GBS but without serological evidence of recent *C jejuni* infection.

Other anti-ganglioside antibodies are associated with specific clinical forms of GBS, for example anti-GQ1b with the Miller Fischer variant with prominent cranial nerve involvement and anti-GalNac-GD1a antibodies with distal motor variant. These antibodies can also be triggered by *C jejuni* as well as other infections.

Other infection can result in GBS, notably *Mycoplasma pneumoniae*. Molecular mimicry may play an important role here as well. It has been shown that *M pneumoniae* triggers anti-GalC antibodies, which, in high titre are associated with a demyelinating GBS. It is important to note here that these glycolipids are also present in abundance in the CNS myelin therefore may represent potential autoantigens in MS and EAE in addition to GBS. Moreover, EAE has been induced by immunization with GalC.

Although a significant component of neuropathology in GBS is antibody and complement mediated, a role for a T cell participation in molecular mimicry involving glycolipids, traditionally considered T-independent

antigens, is likely to exist, and this mechanism likely to be relevant to T cell mediated autoimmunity such as occurs in EAE and MS. It has been shown that GM1 antibody production by B cells of GBS patients is T cell dependent [20]. Moreover, self-glycolipids reactive T cells have bee found both in normal individuals and in patients with MS [21]. In addition, EAE is more severe when the immunogenic brain homogenate contains the glycolipid fraction than when this fraction has been removed [22]. Therefore, a T cell and B cell cross reactive immune response between infectious agent components such as LPS and myelin glycolipids is a conceivable mechanism whereby molecular mimicry generates and activates self-reactive lymphocytes in CNS inflammatory demyelination.

Another important example of molecular mimicry with great relevance to EAE and MS is the hepatitis B virus (HBV). Its polymerase has been found to have sequence homology and antigenic cross-reactivity with an encephalitogenic epitope on MBP. Moreover, immunization of animals with HBV leads to a histologically evident EAE-like inflammatory demyelination [23]. It is thus conceivable that T cells against antigenic determinants of the HBV polymerase recognize cross-reactive MBP epitopes and become self-reactive. Wucherpfennig et al screened viral sequences for potential homology with the peptide predicted to bind MHC class II groove of the commonest MS-associated haplotype, HLA-DR2 (DRB1*1501), and demonstrated that some of these peptides stimulated myelin antigen (MBP)-reactive T cells from patients with MS [24].

Bystander activation

Bystander activation is the mechanism in which T cells are activated by exposure to self-antigen in the situations in which an infection has created an inflammatory environment favorable for the development of Th1 type T cells, or in an evironment which allows the expression of an antigen normally not exposed to the immune system, for example a sequestered antigen. The latter situation is closely linked with the phenomenon of epitope spreading, which is known to occur in EAE and MS, whereby previously unexposed (cryptic) epitopes become exposed during the tissue damage accompanying the initial event [25]. The initial event may be the initial inflammatory demyelinating attack, but also potentially an event with another pathogenesis such as injury, ischemia, or indeed, infection. The latter can be exemplified by the fact that infection with viruses that cause experimental demyelination such as coronavirus or TMEV eventually leads to spreading of the epitope to self-determinants including the known neuroantigens of EAE such as MBP [26].

Another example of bystander activation with a sequestered antigen is that of αB-crystallin. This is a protein belonging to the heat shock protein family. It has been shown that αB-crystallin induces marked T cell responses

in individuals with MS, more prominenent than responses to other neuroantigens such as MBP or PLP [27]. αB-crystallin is normally sequestered, not exposed to the immune system, not being on the surface of oligodendrocytes, but the response against it may develop later in the course of the disease via epitope spreading [28]. Moreover, EBV has been shown to induce expression of B-crystallin in B cells, which then present it in an HLA-DR-restricted fashion [29]. Since serological evidence of EBV exposure is present in nearly 100% of people with MS [30], it is conceivable that a mechanism of activation of neuroantigen (in this case αB-crystallin)-reactive T cells is induction by this virus in the context of a non-sequestered environment.

The creation of an inflammatory environment for bystander activation of autoreactive T cells by infectious agents has been convincingly demonstrated (and it may in great part explained why in some EAE induction models there is need for adjuvants (see chapter on adjuvants in EAE). Mice transgenic for a TCR specific for MBP do not develop EAE when kept in a germ free environment; however, when placed in a germ-containing environment they develop spontaneous EAE [31]. It is known that bacterial products other than SAG are involved in this (re)activation of autoimmune disease. LPS of gram-negative bacteria is an example of such infectious product. It was shown to be involved in the reactivation of experimental arthritis by bacterial overgrowth in the bowel [32]. In EAE, CpG-rich bacterial DNA, which has been shown to have multiple immunostimulating activities largely centered on induction of proinflammatory cytokines, modifies resistance to disease of prototypically resistant mice, rendering them susceptible [33].

A common feature of these bacterial products is their ability to induce proinflammatory cytokines and in particular, IL-12, a key cytokine for the development of Th1 responses, required for EAE. Also adjuvants such as the *Mycobaterium tuberculosis*-based complete Freund's adjuvant (CFA) all induce IL-12 [34, 35].

A plausible working hypothesis, therefore, is that the final common pathway of activation of autoimmunity in EAE (and in MS) by infectious agents is through their effects on proinflammatory cytokines and in particular IL-12 and/or the related IL-23, with which IL-12 shares a subunit. In terms of how this applies to MS, it is likely that not all infections, but those infections preferentially inducing a Th-1-type immune response may trigger or reactivate autoimmunity. In support of this is the fact that the viral sequences found to have homology with HLA-DR2 binding motif capable of activating CNS-reactive T cells from MS patients belong to relatively common human viruses such as EBV [24]. A substantial proportion of people without MS have evidence of EBV exposure. Thus, a large number of HLA-DR2+ individuals would be expected to develop MS if that were the unique requirement for self-reactive T cell activation. The ability to build a

response in which these activated T cells have a Th1 phenotype, which may depend on a combination of host and pathogen factors may represent one of the additional requirements necessary for induction of autoimmunity.

An infectious agent capable of skewing the immune response toward Th2 may conceivably confer the opposite mechanism, protection against Th1 autoimmunity in EAE. It has been shown that coexistent Th2 responses dampen the mangnitude of a Th1 response. This may reflect the finding that the prevalence of asthma and allergic conditions is decreased in MS [36]. Some infections may also have a protective role against autoimmunity. This has been used to explain the increasing rates of autoimmune diseases including MS, paralleled by decreasing rates of infectious diseases in the developed countries [37].

Other possible mechanisms

Conceivably, other mechanisms may contribute to the pathology of EAE. Cytokines potentially induced by infectious agents may have directs effects on the CNS including oligodendrocyte apoptosis or permeabilization of the blood brain barrier.

Trauma

Whether head trauma can trigger the onset of MS or attacks of established MS remains controversial [38, 39]. However, it is known that head trauma can cause a breakdown of the blood brain barrier, thus potentially facilitating the entry of autoreactive T cells in the CNS. Recent experiments in EAE have shown that focal brain injury following the immunization can lead to more severe neuropathology, mediated in part by chemokines [40].

Solar radiation

A well-described feature of the epidemiology of MS is that its prevalence increases with increasing latitude. This holds true for both hemispheres [41]. Although in part this feature can be described on the basis of genetic factors taking into consideration various population migration patterns [42], it strongly suggests that an environmental factor linked to latitude plays a role in the susceptibility to MS. Of all potential factors investigated, the most consistently associated with MS has been the decreased level of exposure to solar radiation [43]. In addition, at the same latitude, there is an inverse altitude gradient, in that the prevalence of MS in mountainous areas is significantly lower than in neighboring regions in industrial valleys [44]. This further supports the concept that sunlight exposure has a protective effect against MS. Sunlight contains ultraviolet and visible light. Both have

the potential to affect MS and EAE.

Ultraviolet light

UV light from sunlight has numerous biological activities including many effects on the immune system. It is therefore used as a therapeutic agent in a number of diseases. It induces apoptosis in several cell types [45]. It also modifies properties of lymphocytes potentially changing the autoreactive cells and rendering them tolerant. Photopheresis, a procedure in which circulating blood cells are exposed extracorporeally to UV light after administration of a photosensitizing agent, and then reintroduced in the circulation, is based on this principle. Although established in cutaneous T cell lymphoma and graft versus host disease, photopheresis has had conflicting results in MS. In an uncontrolled report, two patients with relapsing remitting disease benefited [46], while in a placebo-controlled study in progressive MS it was not beneficial [47]. In EAE, a recent study shows that photopheresis decreases the number of relapses in a relapsing model in rats.

A major role of UV light is in the supply of the Vitamin D. Diet, in particular fish and vitamin D-enriched milk provide only a part of a human's daily requirement of Vitamin D. The majority of this requirement is provided by the Vitamin D synthesis in the skin. Pre-vitamin D3 is synthesized in the skin from 7-dehydrocholesterol in a reaction catalyzed by UV light. It then isomerizes to form Vitamin D3, which is then converted to 25-hydroxy-Vitamin D3in the liver and then to the active 1,25 Dihydroxy-Vitamin D3 (calcitriol) in the kidney.

Goldberg, noting a high prevalence of MS in areas with low solar radiation exposure suggested that this might be related to low vitamin D3, and that this vitamin is important in myelin biosynthesis [43]. There is no evidence for a role of vitamin D3 in myelination, but there is increasing evidence for its multiple roles in regulation of immune functions. It has been shown that vitamin D3 and its biologically active derivatives suppress the major Th1 inducing cytokine, IL-12 [48]. Thus, its deficiency may lead to an enhanced Th1 immune response. The epidemiological evidence suggesting that MS patients may have a vitamin D3 deficiency was confirmed in studies in which 25-hydroxy-vitamin D3 was actually measured in MS patients. These showed a very significant proportion of vitamin D3 deficiency or insufficiency. Moreover, there was evidence of significantly reduced bone mass in women with MS compared to age-matched controls [49].

In EAE, Cantorna et al [50] showed that oral administration of calcitriol

prevented the onset of the disease, and its administration at the first clinical signs of EAE suppressed further progression. In further studies [51] the same group showed that calcitriol also is capable of reversing the clinical signs of disease in mice that already had clinically severe disease.

The mechanisms of action of calcitriol in EAE are not entirely elucidated. However, it is likely that its acts on the balance between pro- and anti-inflammatory (Th1/Th2) cytokines in favor of the latter. Cantorna et al [51] presented evidence that calcitriol induces anti-inflammatory cytokines TGF-β1 and IL-4. On the other hand, another study demonstrating suppression of EAE by vitamin B12 showed that the major mechanism was inhibition of IL-12 [52].

Vitamin D3 is not only effective in EAE. It was also successfully used in other experimental models of autoimmune disease including collagen-induced arthritis (where it was effective in both preventing and suppressing disease), [53] and insulin dependent diabetes mellitus in NOD mice [54]. It also has a beneficial effect in ameliorating the human inflammatory, presumed autoimmune disease, psoriasis [55].

Visible light

A fundamental component of sunlight is, of course, visible light. There is evidence that visible light is also important in MS and EAE. Daylight is also closely linked with the biological clock. One possibility explaining the latitude gradient for MS is that day length may be related to MS prevalence. There is anecdotal evidence of relapses being more frequent in the spring and autumn. The biological clock that maintains daily and seasonal rhythmicity may have an influence on the susceptibility to and manifestations of, autoimmune disease including EAE and MS.

In mammals the central clock is in the suprachiasmatic nucleus (SCN), which sends signals to the pineal gland to produce its hormone, melatonin, in a cyclical fashion. Melatonin feeds back onto the SCN and can modulate the clock cycle [56]. Melatonin can also modulate the body temperature cycle. The body temperature is high during the day, when melatonin levels are low [57].

Melatonin has a number of immune effects, in particular immunostimulatory activities [58]. It enhances production of IFN-γ and appears to favor a Th1 bias of T cells. Interestingly, this action has been shown to be due to the ability of melatonin to induce the major cytokine driving Th1 responses, IL-12 [59]. In a study of diurnal rhythmicity of cytokine production in humans, the analysis of the ratio of IFN-γ to IL-10

indicates that the strongest Th1 bias coincided to the highest levels of melatonin [60]. Removing production of melatonin by pinealectomy can suppress experimental autoimmune disease including collagen-induced arthritis. This has subsequently been demonstrated in EAE as well [61].

The peak production of melatonin is at night and the nadir is during daytime. Visible light suppresses production of melatonin. Thus conceivably increased daylight exposure time may be associated with lower susceptibility to Th1 mediated autoimmunity, in part possible due to decreased melatonin-enhanced Th1 cytokine production. This may explain why the geographic distribution of MS is related to the degree of sunlight exposure.

In experimental models of autoimmune diseases, this has been confirmed: constant light ameliorated experimental arthritis. In addition, exposure of animals with EAE to constant visible light significantly suppressed disease activity [62].

Melatonin can act directly upon cells of the immune system including T and B cells which have been shown to possess melatonin receptors [57]. We have used a melatonin receptor antagonist, Luzindole, injected at nighttime in the dark during peak melatonin production, and significantly suppressed EAE disease activity [63].

These results concur in suggesting that sunlight' visible light spectrum via suppression of melatonin, and UV light spectrum via provision of vitamin D3, and their effects on the immune system may contribute to the susceptibility to and manifestations of EAE and MS.

An additional and opposing aspect of melatonin needs to be considered. By modulation the body temperature clock, it lowers the body temperature. This has led to relief of several temperature-dependent symptoms in demyelinating disease. It is known that increases in body temperature can worsen symptoms of MS, usually in a transient fashion (Uhthoff's phenomenon). Conversely, lowering the body temperature improves symptoms of MS, possibly by improving conduction through demyelinated nerve fibers. This has been shown in human and experimental demyelination. Thus melatonin, which lowers the body temperature, can lead to short term symptomatic relief of MS symptoms. In the long term, however, its immunostimulating, Th1 biasing effects may make this hormone detrimental, and the above evidence of the positive effects of its suppression on EAE supports this.

Although speculative, another aspect of sunlight exposure may be protective against inflammatory demyelination: its ability to stimulate

melanin production. Even within the same latitude, dark skinned individuals are at lower risk of developing MS than light skinned individuals. In EAE, with notable exceptions, susceptible strains are albino, while resistant ones are dark. This may be related to the protective effect of melanin, for example its known ability to scavenge and suppress free radicals.

Stress

Stress can be physical (trauma) or psychological (emotional). This part of the discussion refers to the latter. The role of stress in MS remains controversial. It is very difficult to assess and quantify stress. Many differences in the threshold, degree of perception, and cultural responses to stress between individuals are likely. Stress is so much a part of everyday life that envisioning a stress free environment is difficult in humans. Because of the ubiquity of stress, prospective studies in MS linking disease activity to stressful events are also difficult, and retrospective studies pose problems with controls. As with major physical trauma, major stressful events are most easily remembered, which may bias retrospective studies. However, a study in MS has suggested that stress may have a protective effect. Investigating the frequency of relapses and new onset of MS in Israel during the period of general stress to the whole population of Israel, of the Gulf War, Nisipeanu and Korczyn [64] have shown it to be significantly lower than expected. On the other hand, stress is frequently blamed, usually by patients themselves, for the onset of MS or for an exacerbation in the MS symptoms.

In solving this apparent discrepancy, here again animal models can be very helpful. Although emotional stress in humans is obviously a very complex phenomenon, its simplified direct biological correlate is a strong sympathetic response. The immunological phenomena that ensue are mediated by the presence of both beta2 and alpha2 adrenergic receptors on cells of the immune system. It is thought that Th1 cells possess beta2 receptors and thus are more amenable to immunomodulation via these receptors, while Th2 cells do not. Therefore, creating conditions representing the biological correlate of a stress free environment in an experimental animal can be accomplished by sympathectomy. Chemical sympathectomy can be achieved by using 6-hydroxydopamine hydrobromide, which becomes oxidized in the sympathetic nerve terminals and destroys them resulting in long term sympathectomy in the neonate and temporary axotomy in the adult. The short-term results of either procedure are similar, and consistent with a significant enhancement of immune functions.

This can be reflected in EAE as well. Animals having undergone

permanent or temporary sympathectomy have been shown to exhibit more severe CNS inflammation [65, 66]. In adoptive transfer experiments between sympathectomized and non-sympathectomized mice, it has been shown that donor T cells from sympathectomized animals induce more severe EAE, and when the recipient is sympathectomized, the EAE is also more severe, suggesting that both T cells and APC from sympathectomized animals contribute to the increased severity of EAE [67].

In addition to sympathectomy, experimental situations inducing stress in the animal have been tested for its effect on EAE. These have included maternal deprivation, a swimming test, thermal stress etc. These investigations have consistently shown a protective effect of stress on EAE.

Taken together, these results suggest not only that EAE reflects reliably the relationship between MS and stress, but also that sympathectomy as is reliable as a surrogate for creation of "stress-free" conditions while adrenergic stimulation mimics stress.

This is further confirmed by the fact that beta adrenergic agonists such as terbutaline or isoproterenol mimic stress by inducing similar, suppressive changes in the immune system. These effects were also seen on EAE [68].

After the initial sympathetic stimulation and immune suppression by stress, there appears to be an overshoot of immune stimulation as stress declines or the stressful situation has passed. It has been shown that after exposure of medical students to examination stress with the corresponding immune suppressive effect, there was a hyper-responsiveness in immune functions 4-6 weeks after the examination. It is also possible that chronic stress induces different changes than acute or one-time stressful conditions. This may reconcile the discrepancies between the studies showing a protective effect of stress on EAE and MS and situations in which worsening or onset of MS were attributed to stress.

Diet

Besides the importance of vitamin D3 (with the contribution of diet and sunlight) as discussed above, there are several other associations of diet and MS, which, despite much investigation, remain controversial. The most consistent aspects linking diet and MS are the positive association with the consumption of meats (in particular those preserved by curing or smoking) and the prevalence of MS, and the inverse relationship with the use of fish and vegetable oils rich in polyunsaturated fatty acids. The protective effect of omega-6 and omega-3 fatty acids has been investigated in double blind trials. They appear to decrease the severity of relapses. They reduce production of proinflammatory cytokines and eicosanoids [69]. Similarly,

omega-6 fatty acids have a beneficial effect in EAE. This effect appears to be mediated by enhancing TGF-beta1 and prostaglandin (PG) E2 production [70].

In addition to vitamin D3, retinoids such as vitamin A appear to be important in skewing the immune response toward a Th2, anti-inflammatory type. In experimental animals, a diet poor in vitamin A resulted in an enhanced Th1-type responses and administration of retinoids led to suppression of EAE. The mechanism has been shown to be via suppression of IL-12 and enhancement of IL-4 production. [71-73].

Toxins

Several toxins have been implicated in MS but none have been consistently and definitively demonstrated to have role in MS. The more notable ones have been occupational exposure to Zinc and organic solvents.

With regard to EAE, these have not been studied extensively. However, several toxins have been shown to induce experimental demyelination, and, although not necessarily involved in human demyelinating disease, provide important insights into the pathology or demyelination, the biology of myelin producing cells and the glial and neural response to demyelination. They can also answer important questions regarding mechanisms of remyelination and the use of novel mechanisms to induce or enhance it.

Several toxin-induced demyelinating models exist.

Cuprizone-induced demyelination

The drug Cuprizone (biscyclohexanone, oxaldihydrazone) represents an excellent model fro demyelination [74-78]. When the drug is added to the diet of weanling mice for several weeks or longer, a near-total, primary demyelination of the superior cerebellar peduncle develops. The demyelination is caused by oligodendrocyte degeneration, but there is relative preservation of axons. There is a continuum between myelin degeneration via formation of vacuoles and death of oligodendrocytes. The prevalence of these pathological processes is in part dependent of the concentration of the toxin, suggesting that the demyelination via vacuolation does not represent a specific myelinopathy but rather an dose-dependent oligodendrocyte toxicity. The myelin debris is removed by microglia/macrophages and astrocytes. The relatively preserved axons become invested in glial processes. There is a remarkable glial response to demyelination, characterized by the occurrence of immature glial cells, both of astrocytic and oligodendroglial nature. There is also survival of some of the mature oligodendrocytes.

A great advantage of this model is that it allows the detailed study of the kinetics and mechanisms of remyelination in the CNS.

With the re-institution of a normal, cuprizone-free diet, remyelination begins within a week, and continues until nearly all residual axons are remyelinated. The pattern resembles that of myelination as part of the normal CNS development, with spiral wrapping around axons. Cellular sources of remyelination largely represent residual surviving adult oligodendrocytes and new cells differentiated from immature precursor forms. The possibility of perineuronal satellite cells contributing to remyelination has also been proposed. Like in EAE and MS, remyelination is incomplete: the maximal thickness reached by new myelin sheets is ½ that of normal sheets, and the internodal distance is shortened.

Importantly, recurrent demyelination can be demonstrated in this system. This can be accomplished by repeated exposure to cuprizone. This recurrent demyelination appears to be more protracted and the remyelination potential is more reduced. This is attributed to reduced numbers of surviving oligodendrocytes. The intensity of the glial reaction to the injury is lower compared to the initial reaction, and this may also in part explain the less efficient remyelination. In addition, this model of re-exposure to cuprizone shows that remyelinated axons are not more susceptible to demyelination than axons that have not previously been demyelinated. This finding, if it can be extrapolated to other mechanisms of demyelination, has important implications for EAE and MS.

Ethidium bromide-induced demyelination.

Another model of toxin-induced demyelination is the ethidium bromide exposure model [79]. This is accomplished by the intracisternal injection of ethidium bromide in rats. The toxin induces status spongiosus and oligodendrocyte degeneration. Many axons are demyelinated within 6 days of injection. The myelin debris is phagocytosed largely by microglia/macrophages. Such cells also infiltrate between myelin lamellae. There can be complete oligodendrocyte degeneration in areas of myelin loss.

There is remyelination in this model as well. Remyelinated axons are thinner. In addition, Schwann cells may contribute to remyelination, a feature recognised in some forms of MS with predominanlty myelopathic features in Japan.

There are additional models of toxin-induced demyelination including diphtheria toxin and lysolecithin induced demyelination [80]

Effects of temperature

The effects of temperature on clinical and experimental demyelination have been investigated since the report by Uhthoff of worsening symptoms

of optic neuritis associated with an increased in body temperature caused by physical exertion [81]. It is now recognized that any other mechanisms of elevating the body temperature (even within the normal range, even by as little as 0.5C) can cause an increased perception of symptoms of demyelination (Uhthoff phenomenon), and that such symptoms are not limited to visual disturbances [82].

Conversely, a decrease in body temperature can improve symptoms of demyelination. This has been shown in humans with optic neuritis given ice cream or iced water [83, 84]. Although Uhthoff's phenomenon is not exclusively limited to primary demyelinating conditions, having been reported in giant cell arteritis or brain tumors, the ice test seems to allow distinguishing optic neuritis from other clinically similar conditions, and has been suggested as an auxiliary differential diagnostic tests.

These phenomena have been studies in experimental models of demyelination as well.

Lower temperatures increased conduction while high temperatures impair it . [85-87]

Hyperbaric oxygen

Although hyperbaric oxygen has long been advocated by some authors as a treatment for multiple sclerosis, no convincing evidence from controlled trials has been obtain to support its use. There are anecdotal accounts of symptomatic improvement with hyparbaric oxygen treatment.

Reports in EAE are also somewhat controversial. Theoretically the high pressure provided during hyperbaric treatments can affect the blood brain barrier and increase its permeability, thus potentially facilitating invasion of CNS by myelin-reactive cells. However, an opposite effect on the blood brain barrier has been proposed.

Dysbarism, as occurs in scuba diving accidents, may result in permeabilization of the blood brain barrier and autopsies of fatal cases have shown demyelination in the spinal cord similar to that seen in MS and EAE.

Few studies have investigated the effects of hyperbaric oxygen treatment in EAE. The effects may be dual, and may depend on the timing of the treatment relative to the immunization.

An old study revealed immunosuppressive effects of hyperbaric oxygen, with an associated positive effect on EAE in guinea pigs [88]. These effects depended on the duration of treatment and gas pressure. They, were, however, sustained only briefly after discontinuation of treatment. The immunosuppression was demonstrated by inhibition of cellular reactivity to myelin basic protein and tuberculin.

More recent studies using magnetic resonance (MRI) imaging showed that hyperbaric oxygen treatment does not reduce the disruption of the blood

brain barrier or the cerebral edema seen in EAE [89]. On the contrary, it was shown to increase the blood brain barrier breakdown. When given at the time of immunization as a preventive treatment, it caused amelioration in the clinical course of EAE, but when given 11 days after immunization in attempt to modify EAE, it had no effect [89].

Conclusion

In conclusion, the various environmental influences on MS can be investigated in the animal model, EAE. The mechanisms by which infectious agents can have an impact on MS and autoimmunity in general can be carefully dissected in the EAE model. Other factors such as UV and visible light exposure, stress, temperature, trauma, and their relevance to MS can be explored.

Chapter A26

HORMONAL AND GENDER INFLUENCES ON EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

Christopher Gilmore, Cris S Constantinescu and Caroline C Whitacre*
*Division of Clinical Neurology, University of Nottingham, UK and *Department of Molecular Virology, Immunology and Medical Genetics, Ohio State University, Columbus, OH, USA*

Abstract: This chapter highlights the important interactions between the CNS, the endocrine system and the immune system that influence the course of EAE. In particular, we focus on the bi-directional relationship between the hypothalamic-pituitary-adrenal (HPA) axis and EAE, and the influences of gender and sex hormones on EAE.

Key words: EAE, glucocorticoids, hypothalamic-pituitary-adrenal axis, sex hormones

Experimental autoimmune encephalomyelitis (EAE) is studied as a model for the human demyelinating disease, multiple sclerosis (MS). Nearly all of the therapeutic strategies which have been tried in MS have first been tested in the EAE model system. EAE can be induced in all common laboratory animals by the injection of central nervous system (CNS) myelin proteins and adjuvant or by the transfer of disease-causing activated T lymphocytes. EAE has been studied most intensively using the following animal species/strain and antigen immunization regimens: Lewis rats immunized with myelin basic protein (MBP), DA rats immunized with myelin oligodendrocyte glycoprotein (MOG), SJL (H-2^s) mice immunized with myelin proteolipid protein $(PLP)_{139\text{-}151}$ peptide, B10.PL (H-2^u) mice immunized with MBP, and C57BL/6 (H-2^b) mice immunized with $MOG_{35\text{-}55}$ peptide. In the aforementioned models, EAE is characterized by clinical neurologic signs of ascending hindlimb paralysis and CNS histopathologic changes consisting of demyelination and inflammatory cell infiltration into

the brain and spinal cord. EAE is mediated by CD4+ MHC Class II-restricted Th1 lymphocytes, and IL-2, interferon gamma (INF-γ) and tumor necrosis factor alpha (TNF-α) have been shown to be important contributors to disease pathogenesis. Because EAE is a Th1-mediated disease, the disease course can be dramatically affected by immune modulatory drugs, hormones, cytokine ablation, and other therapies directed at T cells and their products. In this chapter, we review the influences of steroid and sex hormones on the disease course and pathogenesis of EAE.

1. Glucocorticoids

MacPhee et al. observed markedly elevated serum corticosteroid levels in Lewis rats with MBP-induced EAE, with peak levels occurring at the time of maximal clinical disease[1]. The rats started to recover while glucocorticoid levels were still maximal and, as the clinical signs resolved, levels decreased to normal. Corticosteroid levels increased after the appearance of CNS inflammatory changes, but before the onset of paralysis, suggesting endogenous steroid production is not triggered by the stress of the paralytic attack. It is proposed that macrophage production of pro-inflammatory cytokines, such as IL-1β and IL-6, contributes to activation of the HPA axis in EAE[2,3]. Blockade of IL-1 receptors in Lewis rats manifesting MBP-induced EAE reduces corticosteroid levels[2]. IL-1 may stimulate the HPA axis by acting on the anterior pituitary, stimulating adrenocorticotrophic hormone (ACTH) release, or the hypothalamus, stimulating corticotrophin releasing factor (CRF) release[3,4].

1.1 Glucocorticoids modulate the severity of EAE

It has been recognized for over fifty years that ACTH and cortisol can prevent the development of EAE[5]. The importance of endogenous glucocorticoid production in mediating EAE recovery is highlighted by studies on adrenalectomized animals, exogenous glucocorticoid administration, and the pharmacological blockade of the HPA axis[1,6,7]. MacPhee et al. demonstrated that animals adrenalectomized before EAE induction, and treated with exogenous steroids to maintain normal resting corticosterone levels, rapidly developed clinical disease and died[1]. When steroid replacement was adjusted to mimic the levels produced in EAE the disease followed a non-fatal course, while higher steroid levels suppressed clinical disease completely.

Pharmacological blockade of the HPA axis also worsens EAE[6,8]. Reder et al. observed that treatment with RU 486 (a glucocorticoid receptor antagonist),

from the time of immunization with guinea pig spinal cord, amplified the clinical and histological severity of EAE in Lewis rats, while dexamethasone therapy blocked clinical disease[6]. Similarly, Bolton et al. showed RU486 worsened chronic relapsing EAE in Biozzi ABH mice, while dexamethasone suppressed disease[8].

Stefferl et al. observed the corticosteroid response to MOG-induced chronic relapsing EAE in DA rats, characterized by an initial episode of disability, followed by a clinical remission and then a relapse, with chronic progressive disability and death[9]. In the initial phase corticosteroid levels rose markedly and then dropped as the animals entered remission. However, relapse was not accompanied by a second rise in corticosteroid levels, but rather a further decrease as disease progressed. The authors suggest the poor HPA axis response during relapse is due to a combination of reduced production of pro-inflammatory mediators and HPA hypo-responsiveness to these mediators. During relapse, the HPA axis was hypo-responsive to IL-1β (but not to disease-unrelated psychological stress) and IL-1β levels in the spinal cord were reduced in comparison with the initial phase of the disease. Supplementing corticosterone, to maintain steroid levels at those seen during the initial phase of disease, delayed relapse. Sternberg et al. reported that Lewis rats exhibit a deficit in HPA axis responsiveness to inflammatory and other stress mediators which may contribute to a high susceptibility to autoimmune disease[10]. In comparison to the Lewis rat, the PVG rat, which is not susceptible to EAE, mounts a more vigorous response to stress[11]. Adrenalectomy allows EAE induction in some, but not all, resistant rat strains[7,11].

1.2 The influence of restraint stress on EAE

The importance of endogenous glucocorticoids in mediating EAE recovery is supported by work on restraint stress (RST). Levine et al. first demonstrated that stress induced by 3 hours of daily restraint (i.e. by taping down all four limbs), initiated before immunization with spinal cord homogenate, decreased both the incidence and the clinical and histological severity of EAE in the Lewis rat[12]. Dowdell et al. extended these findings to male B10.PL mice which exhibit a relapsing-remitting disease course following immunization with guinea pig MBP[13]. 12 hours of RST dailystarted before disease induction and administered during the active night cycle, reduced the incidence, severity and relapse frequency of EAE. Furthermore, they demonstrated that the HPA axis plays a greater role than the sympathetic nervous system in mediating the protective effects of EAE. Blocking glucocorticoid action with RU 486 and aminoglutethimide (a glucocorticoid synthesis inhibitor) partially reversed the RST-induced suppression of EAE, while nadolol (a β2-adrenergic antagonist) had no

effect. The duration of RST is important. While 9 hours of RST/day suppressed EAE in Lewis rats, 1 hour/day enhanced disease[14].

1.3 Abrupt steroid withdrawal can worsen EAE

Reder et al. demonstrated that abrupt withdrawal of glucocorticoids can exacerbate EAE, using Lewis rats immunized with guinea pig spinal cord[6]. Untreated rats developed EAE 9 to 11 days after immunization and then completely recovered over 7 to 12 days. Animals treated with dexamethasone for 3 weeks from the time of immunization showed no clinical evidence of EAE. However, when the dexamethasone was stopped suddenly (or rapidly reduced over 4 days), rather than being reduced gradually, severe clinical and histological disease was provoked. Interestingly, disease was also provoked when untreated rats, which had recovered spontaneously from EAE, received a 5 day "pulse" of dexamethasone. Clearly this work has potential implications on steroid treatment regimens for Multiple Sclerosis.

1.4 Mechanisms of action of glucocorticoids in EAE

The mechanism of action of glucocorticoids in the amelioration of EAE is unknown. *In vivo*, glucocorticoids are likely to interact with the immune system at a number of levels (for reviews see[15-17]), limiting the generation and trafficking of encephalitogenic cells to the CNS, and by inhibiting the activity of these cells. In EAE encephalitogenic T cells primarily produce Th1 cytokines (IL-2, IFN-γ, TNF), while Th2 cytokines (IL-4, IL-10) help disease recovery. There is *in vitro* evidence that glucocorticoids mediate a Th1 to Th2 shift in cytokine production[16]. *In vivo*, a reduction in both Th1 and Th2 cytokines, rather than a Th2 shift, was observed when RST reduced disease severity in relapsing EAE[13,18].

Steroids may reduce the proliferative capacity of lymphocytes or induce apoptosis of autoreactive T cells[16]. RST and corticosteroid therapy have been shown to reduce T cell numbers in the lymph nodes and spleen of mice with EAE[13]. Smith et al. described T-cell infiltration and apoptosis in spinal cord lesions of Lewis rats with MBP-induced EAE, observing reduced T-cell apoptosis in adrenalectomized rats[19]. In addition, treatment of EAE that is equivalent to the standard glucocorticoid treatment of relapses in Multiple Sclerosis induces T cell apoptosis[20]. Glucocorticoids may also inhibit lymphocyte trafficking to the CNS, by altering endothelial cell expression of adhesion molecules[15]. Recent *in vitro* work has suggested that decreased synthesis of inducible nitric oxide synthase (iNOS) is responsible for mediating dexamethasone-induced protection of rat microglial cells from inflammatory injury[21].

1.5 Neonatal glucocorticoid therapy increases EAE susceptibility in adult rats

Glucocorticoids play an important role in the development of the immune system[16]. Bakker et al. demonstrated that treating Wistar rats with dexamethasone for the first three days of life resulted in an increase in incidence and severity of EAE when rats were immunized with MBP at 8 weeks of age[22]. This was associated with a reduction in corticosteroid response to endotoxin. Neonatal dexamethasone therapy was also shown to reduce endotoxin-induced TNF-α and IL-1β production by macrophages in adult rats, suggesting that a diminished macrophage response contributes to the HPA hypo-reactivity that predisposes to EAE.

2. Gender influences on EAE

Gender-related differences in susceptibility and severity of EAE are well recognised. Many models of EAE parallel multiple sclerosis, where females are more susceptible to disease than males[23,24] and pregnancy is associated with reduced disease activity[25,26]. Increased female susceptibility to EAE has been observed in both active and adoptive models[24,27]. In adoptive EAE gender differences influence both the ability of the donor to generate encephalitogenic T cells and the ability of the recipient to manifest disease[24]. It should be noted that important differences exist between different EAE models, depending on the species, strain and method of disease induction. For example in the Lewis rat males may be more susceptible to disease and less amenable to immunomodulation than females[28]. This may be related to lower production of corticosteroids and higher numbers of immunologically competent cells[28] Seven different mouse strains were evaluated for gender differences in susceptibility to actively induced EAE[29]. In the SJL, females exhibited greater severity regardless of immunizing antigen (PLP or MOG peptides) as did the ASW, both strains on an $H\text{-}2^s$ genetic background. However, male B10.PL and PL/J mice, both $H\text{-}2^u$, showed more severe disease than females. No sex differences were seen in the C57BL/6, NZW or NOD strains[29].

Sex hormones and sex-linked genetic factors are likely to influence gender differences in susceptibility to autoimmune disease[30]. Sex hormones may act directly on androgen or estrogen receptors expressed by immune cells, influencing antigen presentation, cytokine production, homing of immune cells or lymphocyte activation (for review see[31]). Sex hormones may contribute to the female preponderance for autoimmune disease by affecting the T cell balance between Th1 and Th2 cytokine production. Several groups suggest the increased severity of EAE in female mice is associated with increased levels of Th1 cytokines, while males produce higher levels of Th2 cytokines and develop less severe or frequent disease[23,31,32].

2.1 Gender differences in ability to generate encephalitogenic T cells

Using an adoptive transfer model of EAE, Kim et al. demonstrated that lymphocytes derived from male SJL mice following immunization with MBP are less encephalitogenic, with female-derived cells transferring more severe disease[23]. Male-derived cells only induced disease when transferred at higher doses. Similarly, Bebo et al. demonstrated T cells derived from PLP-immunized female SJL mice transferred more severe disease than T cells from male mice[33]. Kim et al. observed that, following immunization with MBP, draining lymph nodes derived from males contained fewer lymphocytes compared to females[23]. Furthermore, the proliferative response of these lymphocytes to MBP and non-MBP stimulation was reduced. Bebo et al., in contrast, found no differences in proliferation between sexes when spleen cells from $PLP_{139-151}$-immunized mice were stimulated with neuro-antigen *in vitro*[33].

Kim et al. suggested that reduced IL-12 during antigen-specific stimulation is central to the decreased encephalitogenicity of MBP-specific T lymphocytes derived from males[23]. When draining lymph node cells from immunized mice were stimulated *in vitro* with MBP, cells from males produced lower levels of IL-12 and IFN-γ. When stimulated with MBP in the presence of exogenous IL-12, lymphocytes from male mice induced more severe disease.

The B10.PL strain provides an interesting comparison to the results observed in the SJL. In the B10.PL immunized with MBP, males exhibit more severe disease than females during the acute disease period[29]. In this strain, male lymph node cells demonstrate a greater proliferative response to MBP than female cells. Moreover, upon stimulation with MBP *in vitro*, male lymphoid cells showed higher levels of IFNγ and TNFα and lower levels of IL-10 than female lymphoid cells.

Several studies have examined the role of androgens in regulating T cell cytokine secretion. Bebo et al. suggest that the presence of androgen in the lymphoid microenvironment during EAE induction alters the development of encephalitogenic T cells, causing a shift towards Th2 cytokine production and contributing to gender differences in EAE susceptibility[33]. Spleen cells, removed from female $PLP_{139-151}$-immunized SJL mice and stimulated *in vitro* with neuro-antigen, secreted increased IFN-γ while male T cells produced increased IL-10. When T cell lines from immunized females were stimulated *in vitro* in the presence of exogenous androgens they secreted less IFN-γ and more IL-10 than untreated cell lines and transferred less severe disease. Interestingly, the Th2 shift induced by androgen therapy was maintained during subsequent stimulations in the absence of androgen. Other work has also reported a bias in autoantigen-specific T cell responses toward the Th2 phenotype in males with EAE. Increased IL-4 and reduced IFN-γ production has been implicated in the mechanism of reduced encephalitogenicity of T

cells derived from SJL male mice following immunization with MBP or $PLP_{139-151}$[27,34].

2.2 Gender differences in the effector phase of EAE

When MBP-specific T cells are transferred adoptively to female and male SJL mice, female recipients show more severe clinical and histological disease[24,32]. Dalal et al. suggested the protective effect of testosterone on EAE is mediated by enhancing IL-10 production by encephalitogenic T cells[32]. MBP-specific T cells derived from spleens of male mice during the effector phase of EAE produced higher levels of IL-10 than female-derived cells. IFN-γ and IL-4 production was not different. Treating females with dihydrotestosterone, initiated before injection of MBP-specific T cells, enhanced IL-10 production and resulted in less severe disease.

2.3 Role of sex hormones in determining gender differences in EAE

2.3. 1. Androgens

The effect of exogenous androgens on enhancing Th2 cytokine production has already been discussed. Hormonal manipulation by castration of male animals provides further evidence of the effect of androgens on disease course. Bebo et al. immunized SJL mice with $PLP_{139-151}$, inducing a monophasic disease in male mice but a relapsing disease in females[31]. However, when males were castrated before immunization, the majority developed relapsing disease. This was associated with increased activated IFN-γ-producing T cells in the spinal cord at relapse. The authors suggest androgens may modify leucocyte migration to the CNS[31].

2.3.2. Estrogens

Pregnancy levels of estrogen are protective against a number of autoimmune disorders including EAE, as will be discussed[30]. It has been proposed that estrus or diestrus levels of 17β-estradiol (E2, the primary hormone of the ovulatory cycle) enhance Th1 immunity and susceptibility to cell-mediated autoimmune diseases, whereas the high levels seen in pregnancy shift the response toward Th2 immunity and protection from cell-mediated pathology[35]. Indeed, *in vitro* studies on human T cell lines have shown a biphasic dose effect of E2, with low doses increasing TNF-α production, and doses approximating those of pregnancy decreasing TNF-α production and increasing IL-10 production[36].

Bebo et al. challenged this hypothesis, demonstrating low dose estrogens can provide protection against EAE in SJL mice immunized with $PLP_{139-151}$[37]. Estrogen therapy with either E2 (at estrus and diestrus levels) or estriol (E3, at sub-pregnancy levels) reduced the clinical and histological severity of

active EAE, with both genders being equally sensitive to estrogen. Furthermore, low dose estrogens (E2 or E3) reduced the capacity of lymphocytes from female mice to transfer EAE, with recipients of splenocytes from estrogen-treated animals showing a delay in onset and reduction in severity of disease. Low dose E2 therapy initiated after the appearance of clinical disease had no effect on disease severity suggesting differentiated effector cells are less sensitive to estrogens.

The protective effects of estrogens are also highlighted by the increased incidence and severity of EAE seen in ovariectomized female mice[29,38,39]. Gender differences in EAE susceptibility appear to be primarily due to the protective effect of testosterone[40]. It should be noted that low-dose E2 therapy has produced disparate results in different mouse strains. For example, Jansson et al. observed no disease amelioration when castrated B10.RIII female mice received E2 at ovulatory cycle doses[38].

The mechanisms by which estrogens inhibit EAE are poorly understood. While high dose estrogen therapy mediates a shift towards Th2 cytokine production[41,42], low dose estrogens can be protective in the absence of such a shift[37,43]. *In vitro*, estrogens alter the function of various immunocompetent cells and estrogen receptors are expressed on a variety of immune cells, including T cells and macrophages[30,44,45]. Recent evidence suggests that the intracellular estrogen receptor alpha (ERα) mediates estrogen-induced disease protection in EAE[42]. ERα-knockout mice were not protected from disease by E3 treatment, while control mice showed reduced disease severity with E3[42]. *In vitro*, estrogen can regulate the expression of endothelial cell adhesion molecules and some groups have suggested that estrogens regulate lymphocyte trafficking to the CNS[39,46]. For example, Matejuk et al. observed that E2-mediated suppression of EAE was accompanied by a dramatic reduction in CNS cellularity and chemokine synthesis[39]. A recent DNA microarray study in BV8S2 transgenic mice immunized with MBP suggests that E2 therapy regulates the expression of a number of genes for several cytokines, chemokines and adhesion molecules[47].

Ito et al. suggested that down-regulation of TNF-α is an important pathway by which estrogens ameliorate EAE[43]. Low dose E2 therapy (five times less than pregnancy levels), initiated before immunization with MOG_{33-55}, suppressed the clinical and histological manifestations of EAE in C57BL/6 female mice. E2 suppressed EAE in IL-4 knockout, IL-10 knockout, and IFN-γ knockout mice to a similar extent, suggesting E2 regulation of EAE occurs independently of inducing changes in these cytokines. The frequency of TNF-α producing cells in the CNS and spleens of estrogen-treated animals was decreased profoundly. Reduced TNF-α production has also

been observed in lymphocytes from MOG_{33-55}-immunized C57BL/6 male mice treated with E3[42].

Sex steroids may also act indirectly via the HPA axis. Suppression of MBP-induced EAE with restraint stress is more pronounced in the female Lewis rat than in the male[18]. The female Lewis rat exhibits higher levels of basal and stress-induced corticosteroid production than males[28]. The presence of an estrogen-response element in the promoter region of the CRH gene further suggests that estrogen-mediated regulation of glucocorticoid production is a mechanism by which estrogens protect mice from EAE[30].

3. Pregnancy

A protective effect of pregnancy on EAE has been reported in acute models of EAE in rats, rabbits and guinea pigs [25,26]. Recently, Langer-Gould et al examined the effect of pregnancy on a relapsing model of $PLP_{139-151}$-induced EAE in SJL mice[50]. Late pregnancy improved disability and protected against relapses in mice with pre-existing EAE, without an associated improvement in CNS inflammatory lesions. They also demonstrated that mice immunized during mid and late pregnancy had a reduced incidence of EAE. We have confirmed these observations and shown that mice immunized during the post-partum period exhibit increased severity of clinical signs and increased EAE relapses. A shift towards humoral (Th2) immunity, which is thought to be beneficial for maintenance of the foetal allograft, has been demonstrated during pregnancy[17]. This shift may explain observations that Th1-mediated diseases, such as multiple sclerosis and rheumatoid arthritis, remit during pregnancy while Th2-mediated conditions, such as systemic lupus erythematatosus, are exacerbated[17].

3.1. Mediators of beneficial effects of pregnancy

Potential candidate hormones responsible for the amelioration of EAE during pregnancy include E3, E2 and progesterone, all of which increase during late pregnancy and can induce Th2 shifts in cytokine secretion *in vitro*[36,48].

3.1.1. Estrogens

Estrogen at pregnancy levels hasbeen shown to decrease the severity of EAE in mice[38]. E3 has profound effects on EAE. Kim et al. demonstrated that E3 decreases the ability of encephalitogenic T cells to induce EAE in non-pregnant SJL/J female mice[41]. E3 therapy at late pregnancy levels, commenced before the adoptive transfer of MBP-specific T cells, reduced the clinical and histological severity of EAE. This was accompanied by a Th2 shift, as evidenced by an increase in MBP-specific antibodies of the IgG1 isotype and increased IL-10 production by MBP-specific T cells

obtained from E3 treated animals. E3 therapy also reduced the severity of EAE after disease induction, when commenced at the onset of clinical signs. Again this was associated with increased IL-10 production during the MBP-specific response. The concept of an E3-induced Th2 shift is also supported by the work of Liu et al. who treated C57BL/6 male mice with pregnancy levels of E3 before immunization with MOG_{33-55}, protecting them from disease[42]. They observed reductions in the pro-inflammatory cytokines TNF-α, IFN-γ and IL-2, and increased levels of the Th2 cytokine IL-5.

E2 has also been shown to have beneficial effects at pregnancy levels. Jansson et al. studied chronic relapsing EAE in female B10.RIII mice induced with MBP_{89-101}[38]. Ovariectomy led to earlier disease onset. High levels of E2 delayed onset, but not incidence or severity, in both castrated and normal female mice. In castrated females pregnancy levels of E3 delayed disease onset for longer than pregnancy levels of E2, suggesting E3 might be more potent. In contrast Bebo et al. detected no difference in the incidence or severity of $PLP_{139-151}$-induced EAE between E2 and E3 treated female mice[37].

3.1. 2. Progestogens

In vitro, progesterone induces a Th1 to Th2 shift in cytokine production[48]. Despite this, progesterone has not been shown to ameliorate disease activity in EAE[41]. Implanting progesterone pellets into non-pregnant SJL/J female mice before the adoptive transfer of MBP-specific T cells had no effect on EAE[41]. However, progesterone has been shown to be neuroprotective and thus in the long term it may also have a beneficial effect on neuronal loss or dysfunction in inflammatory demyelination[49].

3.2 Evidence for another serum factor that suppresses EAE in pregnancy

Not all studies implicate a Th2 shift in ameliorating EAE during pregnancy. Langer-Gould et al. suggest the presence of a transient circulating serum factor in late pregnancy that suppresses T cell activation[50]. T cells derivedfrom mice immunized with neuroantigen during late pregnancy, and stimulated *in vitro* with $PLP_{139-151}$, showed no differences in cytokine secretion profiles or proliferation compared with virgin controls. However, when this stimulation occurred in the presence of sera taken from mice in late pregnancy, proliferation and IL-2 production weredecreased compared with stimulation in the presence of normal mouse sera. Similarly, late pregnancy sera diminished the proliferative response and IL-2 production of auto-reactive cells from virgin controls.

4. Other hormones in EAE

4.1 Prolactin

Riskind et al. demonstrated that female Lewis rats immunized with guinea pig spinal cord homogenate experienced a rise in prolactin levels before the

onset of clinical signs[51]. Prolactin suppression with bromocriptine therapy reduces disease severity in these animals, either when started before immunization, or at the onset of disease[51,52]. Dijkstra et al. also used bromocriptine therapy in a chronic relapsing EAE model. Starting therapy at the onset of the first attack reduced the duration of the second attack[52].

4.2. Thyroid Hormones

Thyroid hormone (T4) has potential application in promoting re-myelination in EAE by recruiting CNS progenitor cells and channelling them into the oligodendrocyte lineage. T4 is required for normal oligodendrocyte maturation and myelination[53]. Calza et al. induced EAE in Lewis rats using guinea pig spinal cord tissue[54]. A large number of proliferating cells and undifferentiated precursors were present in the spinal cords of the animals. T4 treatment, commenced at disease onset, reduced the number of cells expressing proliferation markers and markers for undifferentiated precursors, and up-regulated expression of markers for oligodendrocyte progenitors. This effect of T4 on differentiation of progenitor cells towards the oligodendrocyte lineage was found only in EAE rats and not in controls.

4.3. Growth Hormone-Releasing Hormone (GHRH)

Ikushima et al. recently suggested a role for GHRH in the development of EAE, demonstrating C57BL/6J mice deficient of the GHRH gene were resistant to MOG-induced EAE[55].

5. Conclusion

Interactions between hormones and the immune system are clearly important ina wide variety of immune responses. Sex and steroid hormones exert profound effects on the course and disease progression of EAE. A predominant mechanistic theme of both hormone systems is a Th1 to Th2 shift in cytokine production, but these hormones are likely to exert their effects by multiple mechanisms. Identification of these mechanisms will lead to a greater understanding of autoimmune disease of the CNS.

Chapter A27

EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS IN PRIMATES

Paul A. Smith, Sandra Amor, and Bert A. 't Hart
Biomedical Primate Research Center, Rijswijk, Netherlands

Abstract: Due to their genetic and immunological proximity to humans, the common marmoset, *Callithrix jacchus*, provides an important bridge between rodent-based research and the human disease. Experimental autoimmune encephalomyelitis (EAE) induced in the outbred common marmoset provides a highly reproducible model of multiple sclerosis (MS) phenotypically characterised by neurological deficits, inflammatory lesions of the cerebral white matter and spinal cord, primary demyelination and axonal destruction. A fused placental blood circulation *in utero*, unique amongst monkeys, results in an immune tolerance between chimeric twins which allows adoptive transfer experiments assessing the relative contributions of T- and B-cells to pathogenesis. Overall, the ability to perform serial blood sampling, quantitative magnetic resonance imaging (MRI) and histopathological techniques, which are comparable to the human MS situation, means that the common marmoset EAE model provides an excellent test system for investigating the relationship between neurological deficits and pathological processes and the evaluation of new therapeutics.

Key words: common marmoset, experimental autoimmune encephalomyelitis (EAE), magnetic resonance imaging (MRI), myelin oligodendrocyte glycoprotein (MOG), non-human primate, pre-clinical model

Introduction

In this chapter we review a new non-human primate experimental model of multiple sclerosis (MS) that bridges the experimental data between inbred rodent strains and the disease in humans. The animal model experimental autoimmune encephalomyelitis (EAE) shares many of the clinical and pathological phenotypes of MS. To date, EAE induced in

susceptible inbred rodent strains has highlighted many possible therapeutic candidate molecules although few have translated to clinical efficacy. Clearly the extrapolation of experimental data from genetically homogenous laboratory rodents to the heterologous human population has been hampered by the wide microbiological, genetic and immunological diversity.[1]

Until recently, reproducible non-human primate EAE models were restricted to two macaque species, namely rhesus (*M. mulatta*) and the cynomolgus monkey (*M. fascicularis*). *M. mulatta* appeared to be the most susceptible of the *Macaca* species to disease induced with whole brain homogenate or myelin basic protein. EAE in the rhesus macaque usually followed an acute course with large haemorrhagic/necrotic lesions observed in most animals, these data suggested that the acute pathological event induced a severe inflammatory necrosis rather than selective demyelination.[2] Thus, EAE in the rhesus monkey most resembled the acute fulminant forms of MS, such as post-infectious leuko-encephalomyelitis, rather than the more common chronic MS phenotypes.

1. EAE IN THE COMMON MARMOSET

1.1 The common marmoset

The common marmoset (*Callithrix jacchus*) is a small sized monkey originating from the Atlantic rainforest in north and north-east Brazil (Figure 1). Common marmosets are born as non-identical twins however due to a fused placental blood circulation *in utero* they share a natural bone marrow chimerism, a unique feature among monkeys. Chimeric twins have, in effect, haemopoetic cell systems that are educated in the same thymic environment resulting in a permanent state of mutual allospecific tolerance.

Figure 1: *The common marmoset (Picture*

was a kind gift from Dr. Susanne Rensing, German Primate Centre)

The evolutionary divergence of 65 million years between mice and humans has resulted in several known discrepancies in both the innate and adaptive immunity.[1] In contrast, humans and common marmosets share a high degree of similarity at the level of cytokine mediated T- and B-cell responses,[3] cell surface markers,[4-6] T-cell receptor Vβ repertoire,[7] co-stimulatory molecules,[8] major histocompatibility complex (MHC) class II genes,[9,10] immunoglobulin V_H repertoire,[11] and myelin proteins.[12,13]

1.2 Myelin-induced EAE

Outbred common marmosets immunised with human brain-derived myelin from MS patients, emulsified within Freund's complete adjuvant, were characterised by a clinically and pathologically heterogeneous disease pattern. Despite the outbred population EAE incidence was 100%, with the vast majority of monkeys characterised by a variable number of neurological episodes followed by a chronic-progressive phenotype.[14,15] Whilst chronic-progression to hind-limb paralysis (score 3) resulted in a humane end-point, the time duration between disease onset and non-remitting paralysis varied considerably.

Multiple Sclerosis		Experimental Autoimmune Encephalomyelitis		
		Marmoset	Rhesus	Rodent
Epidemiology				
Population	Outbred	Outbred	Outbred	Inbred
Prevalence/ incidence	1:1000	100%	MOG 100% MBP 60%	100% in susceptible strains
Cause	Unknown	Immunisation	Immunisation	Immunisation
Clinical Course		Relapsing-remitting chronic-progressive	Acute, fulminant	Monophasic, relapsing remitting or chronic progressive
MHC association	HLA-DR2	*Caja-DRB*W1201*	*Manu-DPB1*01*	Strain-dependent
Pathology				
Demyelination	Present	Present	Probable	Present
Inflammation	Focal	Mainly focal	Mainly focal	Focal and diffuse
Remyelination	Present	Present	Present	Strain/model dependent
Axonal pathology	Extensive in acute MS, variable in chronic MS	Present, limited	Strong in all lesions	Strain/model dependent
MRI analysis	Yes	Yes	Yes	Only in rats
Immunology				
Induction	Not testable	Myelin, MBP/PLP, MOG, MOG14-36	Myelin, MBP, MOG, MOG 35-56	Myelin proteins or peptides.
Adoptive Transfer	Not testable	Yes, chimeric twins	Yes, autologous	Yes
B-cell/antibodies	Plasma cells, Ig/C	Plasma cells, Ig/C, anti-MOG ↑ demyelination	Not investigated	Anti-MOG ↑ demyelination
Pre-clinical testing	Limited possibilities	Possible, low quantity of reagents needed	Suboptimal model	Reagents may not be species cross-reactive.

Table 1: Comparison of multiple sclerosis with non-human primate EAE models

Isolated lymphoid organs from necropsied monkeys with chronic neurological progression demonstrated more prominent mononuclear cell (MNC) *in vitro* proliferative responses to the quantitatively minor myelin protein myelin oligodendrocyte glycoprotein (MOG) compared to major myelin proteins, such as proteolipid protein (PLP) and myelin basic protein (MBP).[16] It is pertinent to mention here that all experiments were performed with recombinant protein encompassing the Ig-like extracellular domain of human MOG (amino acids 1-125; rhMOG^{Igd}). Myelin-induced EAE was characterised by active lesions within the brain and spinal cord and immunohistochemical analysis revealed the presence of many macrophages containing myelin degradation products and the expression of activation markers 27E10, MRP14 and CD40. Also, activated T-cells positive for the CD40 ligand protein CD154 were found at these sites, although at lower numbers. Since CD40-CD154 ligation provides one of the important co-stimulatory signals needed for Th1-cell stimulation by antigen presenting cells (APC), it was not surprising that within these cell clusters a variety of immunomodulating molecules were expressed (Figure 2).[17-19]

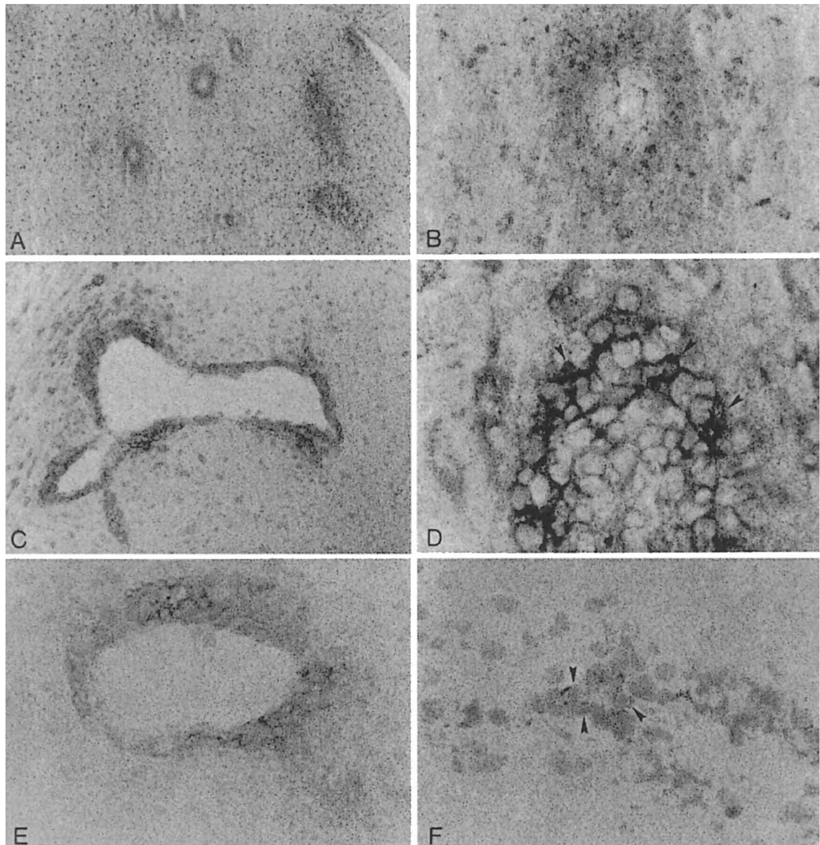

Figure 2: *Expression of accessory molecules and cytokines in marmoset EAE brain. (a) Acid phosphatase (red) expressed by infiltrating macrophages and activated microglia (magnification = x40); (b) Detail of (a), showing extensive perivascular infiltration by macrophages (red)(x200); (c) CD40 (red) expressed on infiltrating mononuclear cells (x100); (d) Doublestaining showing macrophages with cytoplasmic acid phosphatase activity (red) and membrane CD40 expression (blue). Arrowheads indicate examples of macrophages expressing CD40 (x650); (e) CD40L (red) expressed on perivascular mononuclear cells (x200); (f) Scattered CD40L-expressing cells (red) within an infiltrate (x325). Figure reproduced with permission, from ref 17.*

The prevalence of MOG-specific antibodies in areas of myelin disruption suggested a causal relationship between anti-MOG humoral responses and lesion formation.[20] Furthermore, the induction of demyelination and clinical signs in the common marmoset were dependent on the presence of anti-MOG antibodies.[20,21] Fine specificity of anti-MOG antibody responses were characterised by testing necropsy sera against 23-mer peptides encompassing the MOG extracellular Ig-like domain. Robust antibody responses to conformational epitopes within the Ig-like domain of MOG, but minor antibody reactivity to MOG peptides was present following myelin-induced EAE. Occasional responses to recombinant human MBP, PLP (purified from human brain), or αB-crystallin were also observed.

1.3 MOG-induced EAE

To further elucidate the contribution of MOG-specific autoreactivity during EAE common marmosets were immunised with rhMOG^{Igd}. Similar to myelin-induced EAE, rhMOG^{Igd} immunisation resulted in complete susceptibility to chronic-progressive EAE (Figure 3)

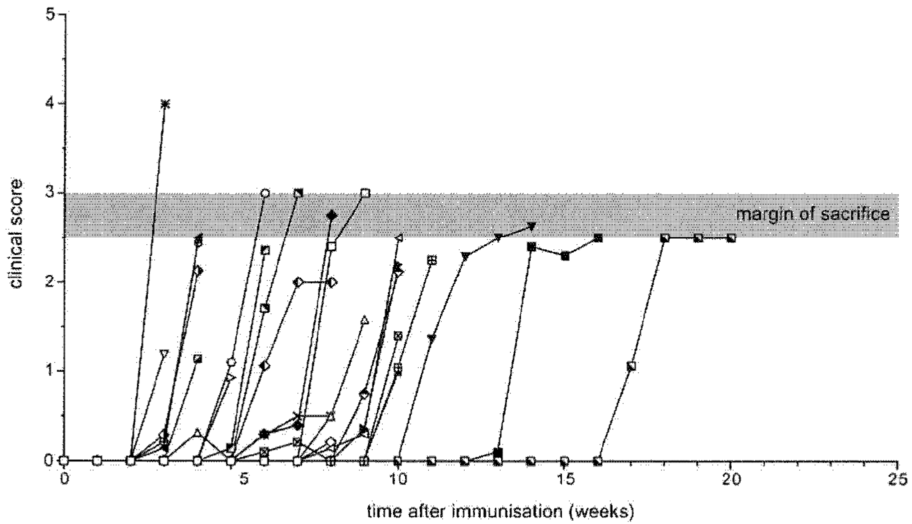

Figure 3: *Clinical heterogeneity in rhMOG-immunised marmosets. Twenty-six marmosets (2-5 years old) were immunised with 100 mg rhMOG in CFA. The clinical scores represent: 0.5=apathy, loss of appetite; 1.0=lethargy, anorexia, flaccid tail; 2.0=ataxia, sensory loss,, blindness; 2.5=incomplete paralysis one-(hemi-) or two-sided (paraparesis); 3.0=complete paralysis hind part of the body (hemi-/paraplegia); 4.0=complete paralysis of whole body (quadriplegia). Figure reproduced with permission, from ref 2.*

This 100% susceptibility within the outbred population was found to map to the monomorphic class II allele *Caja-DRB*W1201*.[9,16] This allele was found to be present in all monkeys from four different outbred populations and the generation of T-cell lines from unrelated animals demonstrated diverse patterns of T-cell reactivities, however the epitope $pMOG_{24-36}$ was common to all. Subsequent MHC isotype blocking and cross-presentation studies revealed that the *Caja-DRB*W1201* was the restriction element for the activation of $CD4^+$ $pMOG_{14-36}$-specific T-cells.[16] This conclusion was further supported by the observation that B-cell lines from the evolutionary ancestor of *Callithrix jacchus*, *Callithrix penicillata*, could present the $pMOG_{14-36}$ peptide in a recognisable fashion, as the *Caja-DRB*W12* locus in this species also contains the *–DRB*W1201* allele. B-cell lines from the more distantly related cotton-top tamarin (*Saguinus oedipus*), which lacks the *Caja-DRB*W1201* homologue, failed to stimulate peptide specific T-cell lines. Importantly, the marmoset *Caja*-DR is equivalent to the human HLA-DR, which has been shown to exert a strong genetic influence on MS susceptibility.[22]

Adoptive transfer of $CD4^+$ $pMOG_{14-36}$ T-cell lines into naïve MHC compatible recipients induced early pathological signs of EAE.[23] Interestingly, $pMOG_{14-36}$ induced EAE was characterised by only mild clinical disease, inflammatory oedema and perivascular infiltrates of MNC but an absence of demyelination. Whilst serum antibodies from $pMOG_{14-36}$ immunised marmosets recognised linear epitopes of MOG they were unable to bind to the protein expressed within a MOG-transfected cell line (unpublished data). The onset of clinical disease following $rhMOG^{Igd}$ immunisation correlated with broadening of the T-cell repertoire to numerous MOG epitopes. No such association could be demonstrated between the presence of autoantibodies and disease onset (unpublished data).

2 MAGNETIC RESONANCE IMAGING

As lesions of both MS and EAE are localised to the CNS *in vivo* characterisation requires the use of non-invasive imaging techniques. To date, the diagnostic imaging modality of choice is magnetic resonance (MR) imaging (MRI).[24,25] The most frequently used imaging parameters are T1-weighting (T1W) with gadolinium-diethylenetriamine-penta-acetic acid (Gd-DTPA) contrast enhancement and T2-weighting (T2W). Inflammatory active demyelinating brain lesions can be visualised following intravenously injected Gd-DTPA extravasation through the disrupted ('leaky') blood-brain barrier (BBB), giving rise to a focal increase of the T1W NMR signal intensity. T2W images reveal alterations in structural alteration of CNS tissues with all lesion stages, from early inflammation to late chronic stages, characterised as hyperintense regions. Quantification of T2W MRI positive lesions equalled those found by pathological analysis and thus T2W can be utilised to discern spatial distribution and total lesion load.[26] Lesions with contrast-induced regional signal enhancement correlated reasonably well with disease activity both in MS[27-30] and EAE.[31] Essentially the same MRI techniques were used for visualisation and initial characterization of brain white matter lesions in the marmoset EAE model.[14,32]

By utilising NMR-spectroscopy (MRS) markers for inflammation, such as lactate, myelin degradation (choline, inositol), or axonal degradation (N-acetyl-aspartate) can be measured in individual lesions. Through a combination of MRI and MRS analysis a reasonable impression of the neuropathological aspect of a lesion can be formed, although very little is still known about the MRI correlates to distinct pathophysiological processes that give rise to lesion formation.

3. PATHOLOGY

Pathological examination of common marmosets with EAE revealed the presence of inflammatory lesions with predilection sites in the cerebral white matter and spinal cord. In contrast, the cerebellum and medulla oblongata remained relatively spared with only occasional perivascular lesions present.[14] Large confluent plaques containing lymphocytes and macrophages were present within the cerebrum. The maturation stage of lesions were assessed using previously published criteria of MS lesions.[33] Based upon the presence of inflammatory T-cells, myelin degradation products in phagocytic macrophages, as well as astrocytic scar formation, all animals presented active as well as inactive lesions. Furthermore, immunoglobulin deposition was present in both active and inactive lesions and this co-localised with complement factor C9 in demyelinating lesions.[14,34] These data suggested that Ig- and complement-dependent mechanisms played an active role in the destruction of myelin sheaths, as described in MS.[35,36] Remyelinated lesions, or shadow plaques due to the presence of very thin LFB-positive myelin sheaths, were observed in inactive, early and late actively demyelinating lesions.

3.1 Axonal damage

In rhMOG-immunised marmosets a substantial lesion load can occasionally be observed within the brain of animals without evidence of neurological dysfunction. A similar discrepancy between clinical and pathological features has also been reported in MS patients.[37] Recent attention has highlighted the significant contribution of axonal pathology to the neurological dysfunction in MS patients, even at early stages of the disease.[38,39] Either staining by conventional silver staining or monoclonal antibodies directed against two markers of early axonal pathology in MS, namely human β-amyloid precursor protein (β-APP) and unphosphorylated neurofiliaments (SMI-32) revealed axonal suffering in demyelinated lesions.[14,40] Early active lesions showed β-APP accumilation and staining with SMI-32. These markers of early axonal pathology (suffering) were absent in late active lesions. Finally, silver staining of old chronic lesions revealed marked axonal destruction.

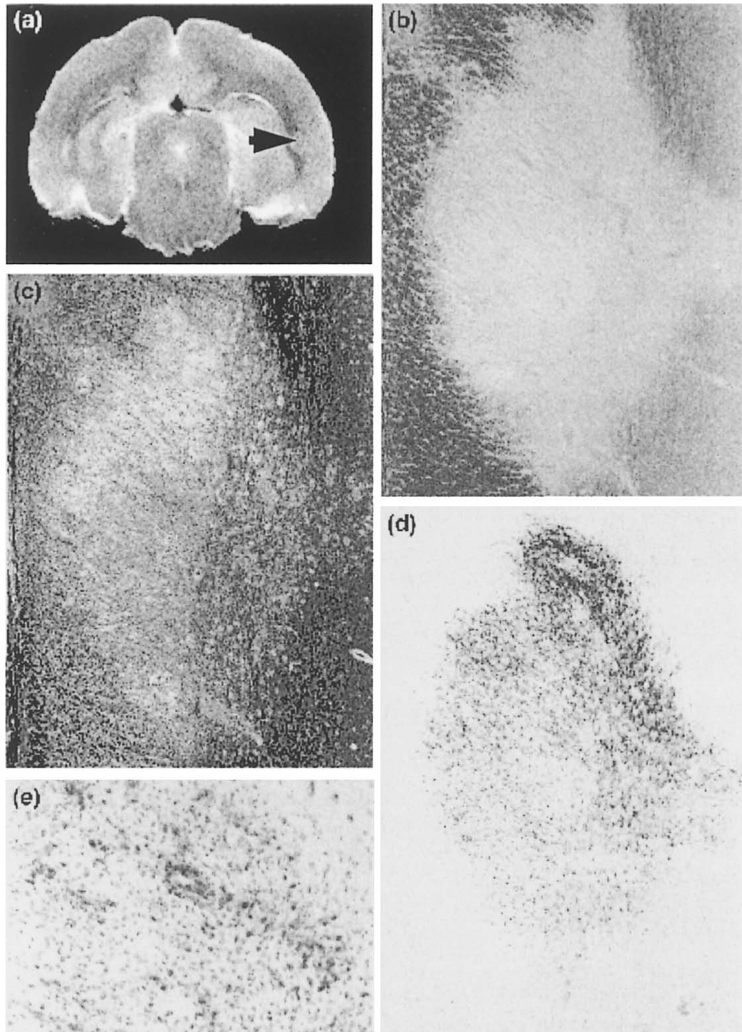

Figure 4: *Histopathology of a magnetic resonance imaging (MRI)-detectable lesion in common marmosets. (a) coronal slice of a T2-weighted MRI recorded post mortem shows at least three MRI-detectable lesions (magnification = x2.5). The lesion indicated with the arrowhead was processed for histology. (b) Klüver-Barrera staining visualises myelin in blue, showing strong demyelination (x99). Within the same lesion axonal conservation was confirmed by Bielschowsky silver impregnation (x 99). The presence of numerous 27E10-positive macrophages (orange) (d) and $CD3^+$ T-cells (brown) (e) classifies the lesion as late-active (x246). Figure reproduced with permission, from ref 14.*

3.2 Pre-clinical model.

As outlined early, the disappointing translation of therapeutic candidate molecules from rodent EAE models to MS have highlighted the necessity to establish model systems with greater genetic and immunological proximity to humans. The common marmoset EAE model facilitates the investigation into the relationship between neurological deficits and pathological processes. The ability to perform serial blood sampling, quantitative MRI and histopathological techniques, which are comparable to the human MS situation, means that the autoimmune common marmoset EAE model provides an excellent test system for new therapeutics.

Previously we have demonstrated the therapeutic potential of a chimeric anti-CD40 antibody (5D12) therapy[41] as well as the protective effect of a fully human anti-IL12p40 antibody (CNTO1275) which neutralised interleukin (IL)-12/23.[18] More recently, these antibodies were shown to suppress the activity and enlargement of existing brain lesions (unpublished data).

4. CONCLUDING REMARKS

Due to their genetic and immunological proximity to humans, non-human primates provide an important bridge between rodent-based research and the human disease. The two most investigated models are EAE in rhesus monkeys and common marmosets. As myelin or myelin antigen-induced EAE in the rhesus monkey resembles acute fulminant forms of MS its pre-clinical value remains limited. However, EAE induced in the common marmoset provides a reproducible model of chronic with several immunological advantages (Table 1). Their small size and relative ease of breeding and handling reduce the amount of therapeutic agent needed. Marmoset MHC typing and TCR characterisation permit epitope specificity to be described in detail. Widespread primary demyelination, the hallmark of MS, occurs in the marmoset CNS. Finally, the immune tolerance among chimeric twins allows adoptive transfer experiments assessing relative contributions of T- and B-cells to pathogenesis.

THEILER'S MURINE ENCEPHALOMYELITIS VIRUS (TMEV) – INDUCED DEMYELINATION

Chapter B1

HISTOPATHOLOGY IN THE THEILER'S VIRUS MODEL OF DEMYELINATION

Ure, D. R. and Rodriguez, M.
Deparments of Neurology and Immunology, Mayo Medical and Graduate School, Rochester, MN

Abstract: The Theiler's virus model shows all the major features of MS pathology - demyelination, inflammation, axonal injury, and remyelination. Extensive qualitative and quantitative characterization of the pathology has provided important insights into disease mechanisms, particularly how they relate to neurological function.

Key words: Theiler's virus, histopathology, demyelination, multiple sclerosis

Among the viral models of MS, one of the best characterized is inflammatory demyelination in the mouse CNS induced by Theiler's murine encephalomyelitis virus (TMEV). A primary reason why the TMEV model is relevant to MS is the similarities in pathology between the two diseases. Both are characterized by inflammation, demyelination, axonal injury, and remyelination to varying degrees. Each of these pathological features varies widely and somewhat independently in the TMEV model, largely as a result of mouse strain. This chapter will focus primarily on the spinal cord pathology in the SJL mouse strain following infection with the Daniel's strain of TMEV. SJL mice develop inflammatory demyelination in the spinal cord and brainstem starting at 3 weeks postinfection (pi). It persists for the life of the mouse, accompanied by extensive axonal injury, minimal remyelination, and progressive accumulation of neurological deficits – a model of chronic, progressive MS. This disease differs in important ways from that induced by the closely related BeAn strain of virus, which includes infected cell types, pathology, and disease course. Dal Canto, Lipton, and colleagues provided many of the early descriptions of TMEV pathology. In the past decade our laboratory has extended these observations, but more importantly we have analyzed each of the major pathological features quantitatively and related them to motor dysfunction.

INFLAMMATORY DEMYELINATION

Inflammation is the earliest pathologic event in spinal cords from infected mice, only slightly preceding demyelination. Inflammation comprises the infiltration of blood-derived cells, particularly T and B lymphocytes and monocytes, and activation of resident microglia and astrocytes. Monocyte-derived macrophages and activated microglia account for over half of the inflammatory cells in spinal cords, as determined by fluorescence activated cell sorting (FACS) of isolated, inflammatory cells. They are nearly indistinguishable from each other morphologically and phenotypically and are widely distributed throughout the white matter where virus persists. T and B lymphocytes, including plasma cells, each account for approximately a quarter of the isolated cells. Within the T cell population, CD4 cells outnumber CD8 cells approximately 3:1. B cells and CD4 cells reside predominantly around blood vessels, forming perivascular cuffs, whereas CD8 cells distribute widely throughout the parenchyma. Meningeal inflammation also is common. The relative abundance of each cell type changes little over the course of disease.

The onset of demyelination coincides with the inflammatory response. Electron and light microscopy of plastic-embedded sections show several characteristics of demyelination in common among all mouse strains. Demyelination and inflammation co-localize to areas of virus expression, as shown by in situ hybridization and immunohistochemistry for TMEV. Demyelination is not obviously centered on blood vessels in chronic disease. Normally myelinated axons often are seen adjacent to perivascular cuffs, suggesting that the perivascular cells do not ubiquitously injure myelin. Demyelinated lesions develop only rostral to the second lumbar level, concentrating in the thoracic cord and secondarily in the cervical cord. Ventral and lateral columns are consistently lesioned, whereas the dorsal column is more variably affected. The ventral-most aspect of the dorsal column is the only area where lesions rarely develop. Demyelination usually begins at the cord periphery, but during advanced disease may extend the entire width of the white matter.

Demyelination first appears as myelin splitting, vesiculation, or thickening of the myelin lamellae associated with axon collapse. Swelling and vesiculation of inner glial loops, the most distal oligodendrocyte processes, also are seen early and support the hypothesis that demyelination represents a dying-back oligodendrogliopathy (1,2). Myelin figures are abundant within phagocytes during early demyelination. Myelin "stripping" by macrophages has been reported (3), but it is not clear whether macrophages initiate attack on completely normal myelin or alternatively that macrophages are responding to molecular changes that target the myelin for degradation. Often early stage lesions have a patchy appearance, in which degenerating myelin, phagocytes, and other inflammatory cells are interspersed among normal axon-myelin profiles. In other lesions myelin degeneration occurs uniformly in a region, which results in demarcation from

normal white matter. In some mouse strains the lesions develop a highly vacuolated, spongiform appearance. Early stage lesions are found at any time postinfection, suggesting that the pathogenic mechanisms responsible for demyelination are ongoing throughout disease.

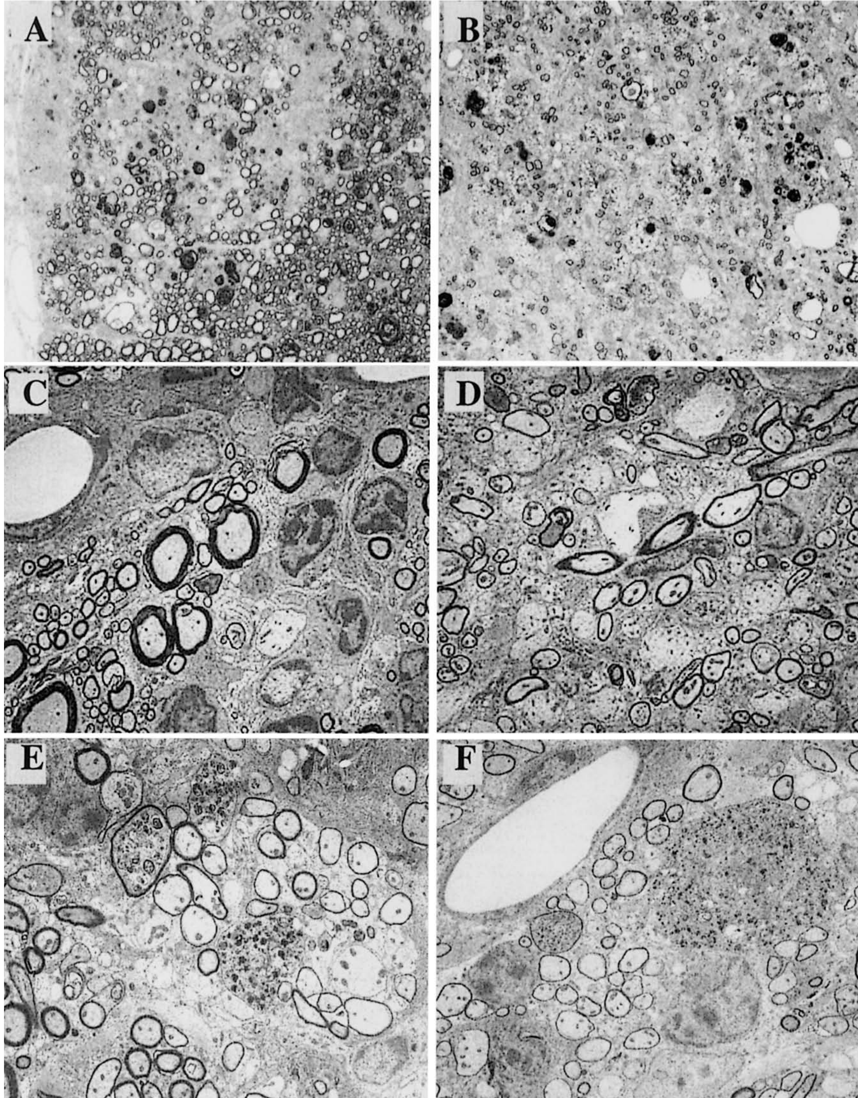

Figure 1. SJL spinal cord lesions. (A) Early stage lesion showing patchy demyelination ; numerous phagocytic cells with myelin debris. (B) Late stage lesion showing inflammati nearly complete demyelination, and many vacuolated cells. (C) Perivascular inflammat with partial preservation of myelin. (D) Chronic demyelination with minimal remyelinati (E) and (F) Axonal injury indicated by large accumulations of abnormal organelles demyelinated, partially remyelinated, and sometimes swollen axons.

Morphometric data indicate that the proportion of white matter with inflammatory demyelination in SJL mice reaches a plateau by 3 months pi,

but the cord continues to atrophy beyond this time (4). Late stage, or chronic lesions take on a "cleaned out" appearance in which the center of the lesion is devoid of myelin figures, being replaced by cells filled with lipid vacuoles. The vacuolated cells are more common in SJL mice than many other strains. Some likely are foamy macrophages and microglia containing end-products of myelin degradation, but others likely are oligodendrocytes (5,6). Inflammatory cells and glia persist in chronic lesions, and axons are either completely demyelinated or remyelinated to varying degrees.

Demyelination is quantified in our lab morphometrically by camera lucida tracings of lesions on a digital tablet (7). Ten cross-sections spanning the second cervical to second lumbar level of each spinal cord are analyzed, and lesion areas are expressed as a percentage of total white matter area (lesion load). Beyond 3 months pi lesions occupy 5-10 % of the total white matter. This percentage seems low, but in fact the proportion of axons that course through lesions at least at some point in the cord is much higher – at least 30%. This value represents the fraction of white matter area that is lesioned in the single cross-section with the most expansive lesions from each cord (8). Lesion tracing also reveals that most lesions extend several millimeters rostro-caudally. This does not necessarily imply that axons completely demyelinated over this distance, as some remyelination occurs. However, the probability is high that conduction in every axon in the lesion is affected at least somewhere along its length.

Myelin degeneration probably occurs in many ways. It may reflect a direct effect of toxic factors such as proteases, cytokines, complement, or free radicals upon the myelin sheath, with sparing of oligodendrocyte cell bodies. A second possibility is secondary dying-back of myelin following a primary insult to the oligodendrocyte cell body. Oligodendrocyte cell bodies show degenerative pathology in lesions, consisting of swelling, vacuolation, and the presence of degenerating, electron-dense organelles. Reductions in proteolipid protein mRNA expression occur well in advance of any morphological change and probably contribute to myelin disruption (9,10). Some demyelination also must be associated with Wallerian degeneration, as axonal loss occurs in chronically diseased mice.

One mechanism of oligodendrocyte death and myelin disruption is direct, virus-induced cytolysis or apoptosis, although its extent in immunocompetent mice is not clear. The Daniel's strain of TMEV kills oligodendrocytes in culture (5,11). It also infects oligodendrocytes in vivo, including cell bodies, inner and outer glial loops, and Schmidt-Lanterman incisures, and colocalizes to degenerating oligodendrocytes (2,12-14). A direct role for virus in causing demyelination is supported by infection of athymic, nude mice, which lack most T lymphocytes. Infected and degenerating oligodendrocytes and demyelination are present in these mice, although the overall extent of demyelination is relatively small (15,16). In T and B lymphocyte-deficient RAG -/- (recombinase activating gene) mice we have not observed demyelination after direct inoculation of the brain or spinal cord, although 3-week survival of these mice may be insufficient to realize the full effects of oligodendrocyte infection. Virus persistence and

neuronal necrosis in the gray matter in nude and RAG-/- mice highlight an important role of the immune system in protecting neurons from infection.

The immune system plays a prominent role in demyelination insofar as many experimental manipulations such as drug or antibody treatment, adoptive cell transfer, or genetic knockout influences pathology and disease course. One nice example is the adoptive transfer of splenocytes into immunodeficient SCID mice, which normally succumb to encephalitis within 3 weeks of infection (17). Transfer of too few cells does not protect against death, and too many cells leads to nearly complete virus clearance and little pathology. However, transfer of intermediate numbers of cells results in virus persistence and demyelination, an independent effect of both CD4 and CD8 lymphocytes. The tenuous balance of TMEV immunity and immunopathology illustrated by this study is the reason why the contributions of specific immune mechanisms are difficult to discern. Manipulations designed to reduce immunopathology also impact antiviral immunity and alter viral pathogenesis. For example, cyclophosphamide depletes T lymphocytes and reduces the extent of demyelination when administered at an early stage of disease (e.g. 1-wk pi) but kills many mice both early and late (e.g. 6-months pi), presumably due to viral recrudescence (18-20). Similarly, antibody-mediated depletion of CD4 cells early in disease and genetic knockout of CD4 also cause high viral titers and mortality. Depletion of CD4 cells late in disease reduces clinical symptoms but does not affect demyelination (20-23).

In mice that normally do not develop demyelination, elimination of Class I MHC activity through genetic knockout of β2microglobulin (β2m-/-) makes them susceptible to demyelination. Interestingly, the converted mice develop CD4-mediated DTH responses and demyelination equivalent to SJL mice but no obvious disease symptoms (8,24-26). On the SJL background β2microglobulin knockout results in more demyelination than in wildtype animals but no greater incidence of disease (27). CD8-/- mice on both resistant and susceptible backgrounds also exhibit increased demyelination compared to wildtype but little or no deficit (23). Virus titers are elevated in β2m-/- and CD8-/- strains (23,27,28). Therefore, both the Class II MHC-CD4 and Class I MHC–CD8 pathways are important in virus control and in turn CNS pathology.

Other treatments that exacerbate pathology in some strains of mice include cobra venom factor, anti-mu antibodies, anti-interferon-gamma (IFNγ) antibodies, and knockout of Vβ loci of the T cell receptor (29,30). These results are consistent with protective, antiviral effects of complement, B lymphocytes, IFNγ, and a diverse T cell repertoire. Other cytokines that reduce demyelination and virus expression early in disease include interleukin-6, tumor necrosis factor-alpha (TNFα), and transforming growth factor-beta2 (TGFβ2) (31-33). In contrast, cyclosporin A and macrophage-depleting agents reduce demyelination, consistent with a deleterious role for interleukin-2 release and macrophage infiltration (34,35). Thus, a wide variety of cells and molecules regulate demyelination in the TMEV model.

AXONAL INJURY

Ultrastructural studies suggest that axons mostly are preserved in MS lesions as compared to other neurological diseases, but axonal injury does occur variably and is more common than previously believed. Likewise, most axons present in TMEV lesions look normal ultrastructurally, although demyelinated axons contain more mitochondria than normally myelinated axons (36). The abundance of mitochondria in lesions implies a mechanism to focally regulate ATP supply and meet the energetic demands of demyelinated axons. Some axons, however, show clear signs of dysfunction or degeneration, including overcrowding of axoplasm with abnormal organelles, darkened axoplasm, and irregular axonal outlines. Degenerating axons are found in all states of myelination – completely demyelinated, remyelinated, or normally myelinated (36). Completely demyelinated axons may be most susceptible to injury by inflammatory cells or secreted factors such as nitric oxide (37,38). Degenerating, remyelinated or normally myelinated axons probably represent Wallerian degeneration following axonal transection in lesions elsewhere in the white matter. Neurofilament immunohistochemistry and Bielschowsky staining also show axonal disruption.

An EM morphometric analysis of 48,827 axons showed that large-diameter axons are preferentially lost in chronically diseased mice (36). A light microscopy procedure that quantified surviving, normally myelinated axons in parts of the white matter that were free of lesions (e.g. lumbar) verified the dropout of large axons, and secondarily medium axons, (7). Axon loss was present at 3 months pi and increased at 7 months pi despite a constant level of demyelination. The loss translated into atrophy of the white matter columns in the cervical and thoracic cord up to 25% compared to uninfected mice (4). Extrapolation of the axon loss from sample images to the entire cord estimated a 23% reduction in axon number and 37% loss in axon area overall (39).

Another method that documents axonal injury is retrograde neuronal labeling with the fluorescent tracer, Fluoro-Gold. Administration of Fluoro-Gold into the lower thoracic cord results in its accumulation within a few days in cell bodies of all descending neurons in the brain that have intact and functional projections to the site of Fluoro-Gold application. In 9-month-infected mice the number of neurons that accumulate tracer is reduced by 60 – 93% compared to uninfected mice, depending on the neuronal population studied (vestibulospinal, reticulospinal, rubrospinal). Vestibulospinal neurons show the largest reduction, consistent with their projection through ventral columns where lesions are most common. Thus, most descending neurons are transected in chronically diseased mice, or their retrograde uptake and/or trafficking mechanisms are completely disrupted somewhere along the axon length (39).

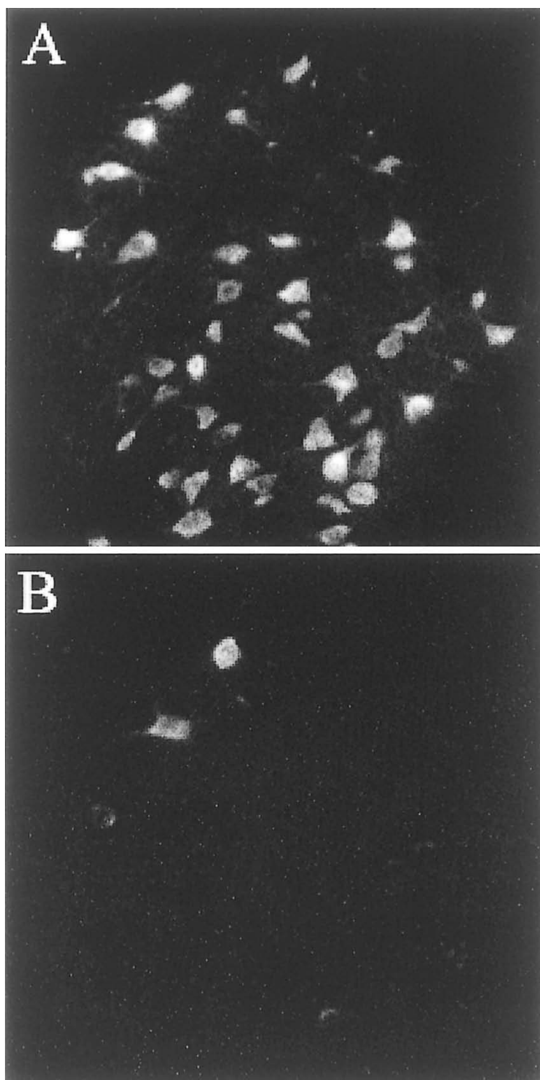

Figure 2. Axonal injury shown by retrograde neuronal labeling of vestibulospinal neurons. (A) Uninfected mouse with many labeled cell bodies in the vestibular nucleus. (B) Chronically infected mouse with few labeled neurons due to axon injury in the spinal cord.

The extent of axonal pathology is the major predictor of neurological deficits in the TMEV model. In most SJL mice neurological deficits become obvious not until beyond the time at which lesion load reaches a plateau. Most informative is the finding that motor dysfunction measured by rotarod assay in chronically diseased mice correlates linearly with all measures of axonal injury - spinal cord atrophy (4), dropout of axons as measured by light and electron microscopy (4,36), reduction in retrograde labeling, and remarkably even the number of degenerating axons in electron micrographs

from single lesions (36). The importance of axon integrity in maintaining normal function also is exemplified in β2m-/- mice, which develop demyelination but no neurological deficits (26). β2m-/- mice develop similar lesion loads, lesion expanses, and lesion distributions as SJL mice, but show more retrograde labeling indicative of axonal preservation (8). This finding has several important implications. First, it indicates that demyelination and axonal loss can occur independently and at different rates. Secondly, it emphasizes that the quality or extent of CNS pathology can not be inferred in all cases from the clinical presentation of disease or lack thereof. Like β2m-/- mice without obvious deficits, people also develop subclinical demyelination (40). Thirdly, the data suggest that CD8 T cells may specifically injure axons, which is supported by the lack of deficits in CD8-/- mice (23) and by axon transection by CD8 cells in a culture model (41). These findings are relevant to MS because CD8 cells are the major type of lymphocyte in many MS lesions and their presence correlates with axonal pathology (42).

REMYELINATION

Remyelination improves impulse conduction (43). It also may protect axons by shielding them from inflammatory insults or by providing trophic support, although this hypothesis has not been thoroughly tested. Remyelination in MS patients occurs sporadically and its regulation is poorly understood. As in MS, remyelination in the TMEV model can be mediated by oligodendrocytes or by Schwann cells that migrate into the injured CNS (44). Remyelination by oligodendrocytes, which is most common in the TMEV model, appears as thin, compacted myelin (45) and usually begins at the edge of lesions adjacent to normal myelin. Schwann cell myelin is thicker than oligodendrocyte myelin, and the Schwann cell body juxtaposes to the axon-myelin unit. Schwann cell remyelination usually begins near the periphery of the cord. Prior to remyelination, lesions show nearly complete demyelination and largely are void of degenerative myelin figures (chronic lesion), implying that catabolism of myelin debris or associated events are necessary for remyelination to proceed. This chronology also supports the conclusion that the thin myelin sheaths indeed represent remyelination rather than partial demyelination. A reduction in inflammation also is prognostic of repair, as the best remyelination occurs in areas with the least inflammation. Astrocytic processes often associate with remyelinated axons.

The extent and timing of spontaneous remyelination varies widely among different mouse strains. SJL mice develop little remyelination even up to 1 year pi. Lymphocytes are partly responsible for the poor repair, especially CD4 cells, as their depletion by antibodies or genetic knockout induces remyelination (20). Depleting lymphocytes for the goal of promoting remyelination is problematic, however, because it also elevates virus expression and kills many mice. In MS, treatment with lymphocyte-depleting antibodies reduces inflammation but either has no effect on clinical disease or increases disability and worsens MRI parameters of neuronal pathology

(46,47). Thus, lymphocytes appear to have both protective and destructive properties in demyelinating diseases. Macrophages and microglia also likely have multiple roles.

Remyelination is inducible in SJL mice not only by immunosuppression but also by treatment with certain antibodies (48,49). The first demonstration of this effect was the treatment of diseased mice with serum or polyclonal antibody generated against spinal cord homogenate (50,51). Many remyelination-promoting antibodies of murine and human origin now have been identified and share certain characteristics. All recognize oligodendrocytes at an intermediate developmental stage and all are polyreactive. Some of the antibodies are polyclonal, for

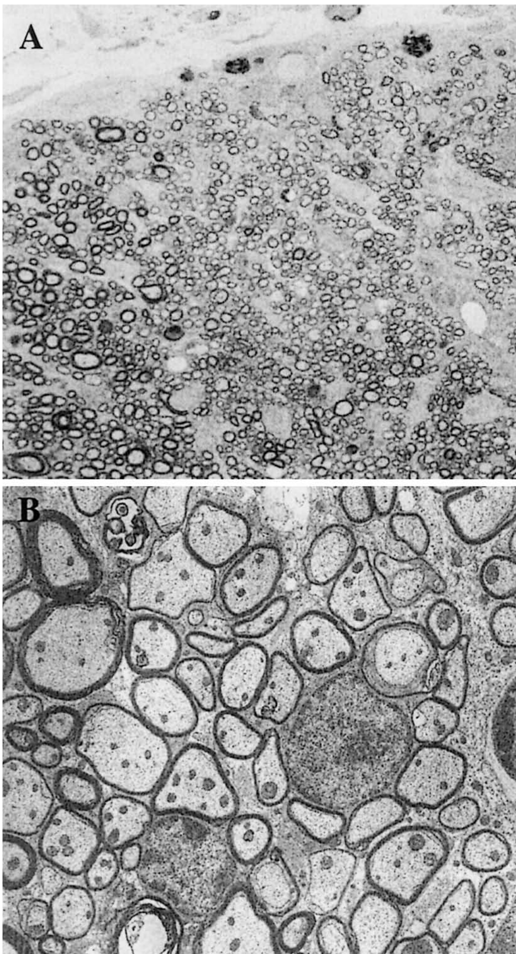

Figure 3. Remyelination induced with oligodendrocyte- reactive antibodies in SJL mice. (A) Light microscopy shows nearly complete lesion repair. (B) Electron microscopy shows oligodendrocytes and thin myelin sheaths around most axons.

example recognizing myelin basic protein or copolymer-1 (52,53), whereas others are monoclonal. Two mechanisms are proposed for their activity. Firstly, binding to oligodendrocytes or their progenitors might trigger proliferation or differentiation directly. In support of this hypothesis we have observed calcium fluxes and changes in phosphorylation in oligodendrocytes

upon antibody binding (54). Secondly, the antibodies might modulate immune mechanisms sufficiently to release the block on remyelination (55). Induced remyelination in SJL mice has not yet shown clinical benefit; combining remyelination with other immunosuppressive treatments may be necessary. In support, PLJ-CD4-/- mice show late remyelination and improvement in motor function (56).

In conclusion, investigation of the pathology of TMEV disease has yielded invaluable clues about disease mechanisms and potential, reparative treatments. Prominent examples include á role of CD8 T cells in neuronal injury, and the potential for antibodies to promote remyelination. The Theiler's model provides a rare opportunity for rigorous quantitation of pathology in a demyelinating disease.

Chapter B2

TMEV AND NEUROANTIGENS: MYELIN GENES AND PROTEINS, MOLECULAR MIMICRY, EPITOPE SPREADING, AND AUTOANTIBODY-MEDIATED REMYELINATION

Ikuo Tsunoda, and Robert S. Fujinami
Department of Neurology, University of Utah School of Medicine, 30 North 1900 East, Salt Lake City, Utah 84132

Abstract: The Theiler's murine encephalomyelitis (TMEV) model has been used to study the interactions of virus, myelin and anti-neuroantigen autoimmunity. TMEV and myelin can interrelate during virus entry and persistence. On virus entry, TMEV might use peripheral myelin P_0 protein as a virus receptor. For persistence, TMEV seems to require myelin functional proteins or structural myelin itself. Here, myelin and oligodendrocyte loss and downregulation of myelin genes would lead to demyelination, but might limit virus spread in the central nervous system. Unlike experimental allergic encephalomyelitis (EAE), a pathogenic role of anti-myelin autoimmunity is unclear in TMEV infection. Anti-myelin autoantibodies have been detected in TMEV infection. Among them, only anti-galactocerebroside (GC) antibody is shown to be myelinotoxic, and has molecular mimicry with TMEV. Myelin-specific T cells play no role in initiation or progression of demyelination in the first two to three months after TMEV infection. However, cellular autoimmunity against several myelin antigens (epitope spreading) can be detected during the late chronic stage. Using the TMEV model, epitope spreading and autoantibody-mediated remyelination have been investigated by recombinant TMEV and anti-neuroantigen (natural) antibodies, respectively

1. INTRODUCTION

1.1 Overview

The Theiler's murine encephalomyelitis virus (TMEV) infection model of multiple sclerosis (MS) has provided excellent paradigms to study the interactions between the virus, myelin and immune system (1-5). In this chapter, we will first review the associations between TMEV and myelin genes and proteins. We will next discuss possible roles of anti-myelin immunity including molecular mimicry and epitope spreading in the pathogenesis of demyelination. Finally, we will introduce two unique model systems using TMEV infection (i) to study the pathogenic role(s) of molecular mimicry and (ii) to explore potential therapeutic agents, remyelination-promoting autoantibodies, in demyelinating diseases. An understanding of the diverse interactions between viruses, myelin and host immune responses to neuroantigens may shed light on the etiology and pathogenesis of MS.

1.2 Theiler's murine encephalomyelitis virus

In 1934, TMEV was isolated by Max Theiler, who was awarded a Nobel Prize for developing the first effective vaccine against yellow fever (6,7). TMEV belongs to the genus *Cardiovirus*, family *Picornaviridae* (2). Picornaviruses are small, nonenveloped negative stranded RNA viruses. Several picornaviruses, such as poliovirus and coxsackievirus, can cause neurological disease in humans (8). However, TMEV infects mice and rats *in vivo* and causes a demyelinating disease only in mice. Thus, TMEV has not been identified as a causative agent in any human disease; its association with dermatomyositis (9) and Vilyuisk encephalomyelitis (10,11) are thus far inconclusive.

The Theiler's original (TO) subgroup, which includes Daniels (DA), BeAn 8386, and WW strains, produces a biphasic disease in susceptible mice inoculated intracerebrally [reviewed in (2)]. During the first week (acute phase), the mice develop an acute polioencephalomyelitis where mice occasionally show clinical signs such as weight loss. Virus antigen is expressed primarily in neurons in the central nervous system (CNS) (12). Subsequently, about one month post infection (p.i.) (chronic phase), the mice show signs of spastic paralysis as a result of demyelination within the white matter of the spinal cord. Areas of demyelination are associated with perivascular infiltration of mononuclear cells (MNC). The disease progresses without evidence of remission, either clinically or pathologically, with the exception of CD-1 mice infected with the WW strain of TMEV

(13). During the chronic phase, viral antigens are expressed within oligodendrocytes (14,15), astrocytes and macrophage/microglia but not in neurons [reviewed in (4)].

TMEV-induced demyelinating disease is one of a few animal models for the progressive forms of MS (16). Although there are many animal models for MS, their clinical courses are either acute monophasic or relapsing-remitting (RR). These animal models are only useful as experimental models for RR-MS. Therefore, the TMEV model is a unique animal model to study the pathogenesis for the other three types of MS: primary progressive (PP)-, secondary progressive (SP)-, and progressive relapsing (PR)-MS (17).

The precise mechanisms of demyelination in TMEV infection are not clear. There are two major hypotheses: (i) direct virus infection of myelin forming cells, i.e. oligodendrocytes, and (ii) immune-mediated mechanisms. Infection with live TMEV is necessary to induce demyelination, since neither ultraviolet-inactivated TMEV nor cDNAs encoding individual TMEV capsid proteins alone cause demyelination (18). Virtually all immune cells, including T cells, B cells and macrophages, have been shown to play important roles [reviewed in (1-4)]. In contrast to experimental allergic encephalomyelitis (EAE) (3) and other virus-induced demyelinating diseases (19), adoptive transfer of uninfected immune cells from TMEV-infected mice does not induce demyelination in the recipient mice (20). In addition, acquired immunity is neither necessary, nor sufficient in some TMEV model systems; TMEV can persistently infect the CNS and induce demyelination in: major histocompatibility complex (MHC) class I-deficient mice (21,22), MHC class II-deficient mice (23), CD4-deficient mice (24), or CD8-deficient mice (24). TMEV also causes demyelination in the spinal cord of moth-eaten mice, lacking protein tyrosine phosphatase SHP-1, as early as five days p.i., when no acquired immune responses are normally generated (25).

2. MYELIN GENES, VIRUS ENTRY, AND VIRUS PERSISTENCE

2.1 Peripheral nerve myelin protein for TMEV entry

During a natural infection, TMEV spreads from mouse to mouse by the oral-fecal route (26,27). In order to cause CNS infection by this route, the virus must get from the alimentary tract into the CNS, either hematogenously or intra-axonally. Since the strains of the TO subgroup of TMEV could be isolated from feces up to 154 days p.i. (28), invasion into

Table 1. Myelin gene, virus entry and virus persistence

Virus Entry	Virus Persistence	
CNS Receptor unknown	TMEV ↓	Host ↓
PNS P_0 protein as a virus receptor?	requires MBP and PLP ← functionally and/or requires myelin itself ← as a structure	downregulates → MBP and PLP mRNA actively or passively and/or → loses oligodendrocyte and myelin (demyelination)
Evidence: *In vitro* assays	Evidence: No virus persistence in shiverer and rumpshaker mice	Evidence: *In situ* hybridization, TUNEL, myelin staining, EM

Abbreviations: CNS, central nervous system; EM, electron microscopy; MBP, myelin basic protein; PLP, myelin proteolipid protein; PNS, peripheral nervous system; TMEV, Theiler's murine encephalomyelitis virus; TUNEL, terminal deoxynucleotidyl trasnferase-mediated dUTP-biotin nick-end labeling.

the CNS via the neural route from a persistent infection in the intestine may be one pathway, as originally suggested by Theiler and Gard (27). Myelin is a multiple lamellar membrane that sheathes axons and facilitates the saltatory conduction of nerve impulses. P_0 protein is a member of the immunoglobulin (Ig) gene superfamily, and constitutes 50% of the total myelin proteins present in the peripheral nervous system (PNS). Using virus overlay and virus binding assays, Libbey *et al* (29) identified P_0 protein as a potential receptor for TMEV (Table 1). They suggested that the use of the P_0 protein in Schwann cells as a receptor may be one mechanism by which TMEV spreads from the gastrointestinal tract to the CNS *in vivo*. In the CNS, TMEV receptors on neurons during the acute phase and on glial cells and macrophages during the chronic phase have not been identified.

2.2 Myelin protein requirement for TMEV persistence

Myelin basic protein (MBP) and myelin proteolipid protein (PLP) are the major component of CNS myelin; many other proteins and glycoproteins are present to a lesser extent. Bihl *et al* (30) demonstrated that myelin gene mutation could affect the persistence of TMEV. Susceptibility/resistance to chronic TMEV infection has been mapped to several loci including one tentatively located in the telomeric region of chromosome 18, close to the myelin basic protein locus (*Mbp* locus) (31,32). To determine if the *Mbp* gene influences viral persistence, Bihl *et al* (30) inoculated DA virus into C3H mice bearing the shiverer (*shi*) mutation, a 20-kb deletion in the gene. Whereas TMEV-infected wild-type C3H +/+ mice had intermediate levels of virus persistence on days 20 and 45 p.i., an increase in viral persistence was detected in heterozygous C3H +/*shi* mice, and no virus persistence was

detected in homozygous C3H *shi/shi* mice. The increased susceptibility of the heterozygous shiverer mice was also seen in (C57BL/6 x C3H +/*shi*) F1 mice (1), although C57BL/6 mice are resistant to TMEV persistence. Furthermore, no viral RNA was detected 20 days after DA virus infection of C3H/101H mice homozygous for a point mutation in the gene coding for PLP (*PLP1*, previously *PLP*), the rumpshaker (*rsh/rsh*) mutation (no data was available in control C3H/101H (+/+) mice, though) (30). In these studies, infection of oligodendrocytes, the presence of demyelination and anti-TMEV immune responses were not tested. The number of oligodendrocytes has been reported to be normal, or even slightly increased in uninfected shiverer and rumpshaker mutant mice, although the myelin is grossly deficient. Therefore, these results suggest that TMEV persistence is linked to myelin and functional alteration, for example, may change the virus's ability to replicate in, or traffic through, the myelin sheath. Although the *MBP* gene or some other *MBP*-linked locus has been suggested to influence susceptibility to MS, other studies have not demonstrated linkage between MS and the *MBP* gene (33,34).

2.3 Myelin gene downregulation in TMEV infection

The genes encoding myelin proteins, such as MBP and PLP, are expressed by oligodendrocytes in the CNS, and their transcripts are markers for activity of maintenance or reproduction of myelin. Yamada *et al* (35) demonstrated the relationship between MBP and PLP mRNAs, viral RNA, and demyelination within the spinal cord during TMEV infection. At four weeks p.i., decreased levels of MBP and PLP mRNAs were associated with the presence of viral RNA and demyelination. By 8 or 12 weeks p.i., however, extensive demyelination was associated with a significant decrease of MBP and PLP mRNAs but not with the presence of viral RNA. These results indicate that a viral infection of white matter in the early phase of TMEV infection leads to demyelination, but that, later in the course of disease, some other mechanism, such as an immunopathologic process, drives extensive demyelination. Subsequent reports by other groups confirmed the decrease in PLP mRNA expression, not only in infected- but also in uninfected-oligodendrocytes in the spinal cord (36-38).

The decrease of MBP and PLP mRNAs in the lesions indicates either a loss of oligodendrocytes or suppression of the myelin metabolism of the oligodendrocyte without cell lysis. The former is supported by the finding of apoptosis of oligodendrocytes in demyelinating lesions in TMEV infection (39). The latter possibility is supported by the fact that some viruses are known to alter the "luxury" or differentiated function of a cell, without disturbance of its vital function, i.e., ability to survive (40). Using electron

microscopy, Rodriguez (15) demonstrated degenerative changes in the most distal processes of oligodendrocytes in TMEV infection. Although this 'dying-back oligodendrogliopathy' has not been directly linked to suppression of myelin metabolism, similar ultrastructural pathology has also been described in MS (41). Also, in the polyomavirus-induced human demyelinating disease, progressive multifocal leukoencephalopathy (PML), JC virus has been reported to cause demyelination not only by the lytic infection of oligodendrocytes, but also via the suppression of myelin gene expression [reviewed in (42)].

Although suppression of MBP and PLP mRNAs as well as demyelination results in neurological functional deficit, this might benefit the host by suppressing viral replication in the CNS. As we discussed in the previous section, persistent viral infection seems to require either functionally or structurally intact myelin. Therefore, suppression of myelin function and loss of myelin (demyelination) might serve a protective role by suppressing virus persistence in TMEV infection (Table 1). Demyelinating diseases might represent the oligodendrocytes' futile attempt to suppress viral replication, which ultimately results in potentially irreversible myelin damage. On the other hand, incomplete suppression of the oligodendrocyte functions might actually benefit the virus, since the heterozygous shiverer (*+/shi*) mutation resulted in an increase in viral persistence in the CNS.

3. HUMORAL AUTOIMMUNE RESPONSES TO MYELIN

3.1 Anti-myelin antibodies in TMEV infection

Damage to CNS tissue liberates CNS antigens into the cerebrospinal fluid (CSF) compartment. MBP can be detected in the CSF of patients with active myelin destruction caused by MS or other processes, such as CNS infarction. Rauch *et al* (43) found MBP in the CSF of 14 of 19 mice infected with DA virus 12 weeks p.i. They also detected serum anti-MBP antibody in 10 of 14 TMEV-infected mice. Welsh *et al* (44) also demonstrated that antibody responses to myelin developed in CBA mice by day 28 after BeAn virus infection and reached a peak between day 42 to 56 p.i. Anti-myelin antibody production was prevented by depletion of $CD4^+$ T cells. However, there was no correlation between the titer of anti-myelin antibodies and the severity of clinical disease.

Using Western blot analysis, Cash *et al* (45) studied the specificity of Ig secreted by B cells isolated from the spinal cord of SJL/J mice infected with DA virus. They found antibodies directed against two unidentified nonviral

proteins with molecular weights of 26 and 28kDa; these were present only in the white matter of infected mice and were not found in purified myelin.

Rodriguez *et al* (46) showed that, like in MS, increased amounts of Ig in the CSF and oligoclonal IgG bands were detected in TMEV-infected mice on day 21 p.i. However, IgG in the serum and CSF was primarily directed at virus antigen rather than at normal myelin components, although rare examples of myelin sheaths positive for IgG were found by immunoelectron microscopy in TMEV-infected mice. On the other hand, Roos *et al* (47) demonstrated that the heterogeneity of anti-TMEV antibody in the CSF was less restricted than oligoclonal IgG bands seen in MS or subacute sclerosing panencephalitis (SSPE). Rodriguez *et al* (46) also showed that complement depletion on day 15 p.i. resulted in exacerbation of demyelination on day 21 p.i. Although the authors suggested no pathogenic role of humoral immunity from this study, the treatment can hamper antibody-mediated clearance of TMEV and day 21 might be too early to assess effector mechanisms in TMEV infection, where overt demyelination is generally seen later.

A direct pathogenic role for anti-MBP antibody in demyelination is unlikely, since anti-MBP antibody has been demonstrated not to be myelinotoxic either *in vivo* or *in vitro* (48). This is in contrast to antibodies against galactocerebroside (GC) or myelin oligodendrocyte glycoprotein (MOG), whose adoptive transfer to mice with EAE exacerbates demyelination (49). Functionally, Barbano and Dal Canto (20) demonstrated that sera from mice infected with TMEV for two to three months did not injure myelinating cultures *in vitro*. This study suggests that there is no myelinotoxic humoral factors in sera from TMEV-infected mice.

Anti-myelin antibody might indirectly affect myelin antigen presentation to class II-restricted T cell by receptor-mediated antigen uptake in TMEV infection (50). Myelin-specific surface Ig can serve to capture myelin antigens on the surface of B cells (51). The B cells could then internalize and present myelin antigen to specific T cells. In addition, professional antigen presenting cells (APCs) could exploit soluble anti-myelin antibody for antigen capture by Fc receptor mediated uptake of myelin-containing immune complexes. This would lead to augmentation of myelin-specific T cell responses, and also might contribute to determinant spreading (see a later section) in TMEV infection, as suggested for other autoimmune diseases (52). The potential beneficial role of anti-neuroantigen antibodies will be discussed in the last section of this chapter.

3.2 Molecular mimicry between TMEV and galactocerebroside

Molecular mimicry between host protein and microorganism has been known for many years. A cross-reacting immune response initially generated against a virus that also reacts with myelin components could lead to demyelination. However, Rauch *et al* (43) found that anti-MBP antibody from TMEV infected mice did not cross-react with TMEV antigens. Lack of cross reaction between MBP and capsid proteins VP1, VP2, and VP3 was also supported by a competition radioimmunoassay with sera from rabbit subcutaneously injected with TMEV capsid proteins (53).

On the other hand, Fujinami *et al* (54) raised a monoclonal antibody (mAb) H8 that reacts with TMEV and GC from spleen cells of BALB/c mice infected with DA virus intracerebrally. GC is a major lipid component of myelin. The mAb H8 reacts with viral capsid protein VP1 and efficiently neutralizes TMEV *in vitro*. Intraneural injection of mAb H8 into the sciatic nerve induced Schwann cell destruction and demyelination (55). When injected intravenously into mice with EAE, mAb H8 increased demyelinating lesions within the spinal cord by ten-fold (56). To determine whether antibodies similar to mAb H8 exist during viral infection, mice were infected with TMEV and sera were collected at various times after infection. Antibodies to GC were detectable ten days p.i. These results suggest that antibody(s) of the H8 type is generated and could contribute to demyelination *in vivo* in TMEV infection.

Interestingly, Fujinami *et al* (57) also demonstrated that another TMEV-neutralizing antibody (H7) could react with VP1 but not with GC. Passive administration of mAb H7 resulted in the clearance of virus and survival of athymic mice. Both H7 and H8 antibodies can neutralize TMEV, yet only H8 is myelinotoxic (Table 2). Further investigation is needed to clarify which immunologic factors, such as T helper cells, favors generation of each type of anti-VP1 antibody *in vivo*. The presence of "myelinotoxic activity" has been demonstrated in the CSF and sera in demyelinating diseases; only GC and MOG are identified as target molecules of demyelinating antibodies of which passive transfer exacerbates, but not initiates, demyelination in the CNS *in vivo* (58). Anti-GC antibody has also been detected in some MS patients (59).

Table 2. Destructive or beneficial autoimmunity in TMEV infection

Effector Mechanism	P.I. Days	Destructive	Beneficial
Molecular mimicry	10 days	Antibody to TMEV cross reacts with GC and exacerbates demyelination	Virus neutralization
Epitope spreading	2-3 months	MBP-, PLP-, MOG-specific T cells induce DTH responses	CNS regeneration
Natural autoantibody	N.E.	Autoantibody binds to CNS antigens	Remyelination

Abbreviations: CNS, central nervous system; DTH, delayed-type hypersensitivity; GC, galactocerebroside; MBP, myelin basic protein; MOG, myelin oligodendrocyte glycoprotein; N.E., not examined in TMEV infection, but detected in SCH-immunized mice; P.I., TMEV post infection; PLP, myelin proteolipid protein; SCH, spinal cord homogenate; TMEV, Theiler's murine encephalomyelitis virus.

4. CELLULAR AUTOIMMUNE RESPONSES TO MYELIN

4.1 Myelin-specific T cell responses play no role in demyelination in the first two to three months after TMEV infection

Epitope spreading (determinant spreading) is defined as the diversification of epitope specificity from the initial dominant epitope-specific immune response to subdominant epitopes [reviewed in (60)]. Epitope spreading can play an active role in the relapse or progression of autoimmune diseases, as was first suggested in EAE by Lehmann *et al* (61). After initial immune-mediated tissue destruction, tissue debris is taken up by macrophages, dendritic cells or B cells, and presented to tissue-specific T cells. Spreading of the specificity of an immune response can be from one epitope to another on the same molecule (intramolecular epitope spreading, for example, from $PLP_{139-151}$ to $PLP_{178-191}$) or from an epitope on one molecule to one on a different molecule (intermolecular epitope spreading, for example, from $PLP_{139-151}$ to MOG_{92-106}) (60).

Although tissue destruction occurs less than one week after TMEV infection, epitope spreading is not observed until two to three months after TMEV infection [reviewed in (62)]. Barbano and Dal Canto (20) demonstrated that spleen cells from TMEV-infected mice did not injure myelinating cultures and did not proliferate in response to MBP or spinal cord homogenate (SCH) *in vitro*. In addition, these spleen cells did not produce disease *in vivo* by adoptive transfer into naïve mice, regardless of whether *in vitro* stimulation was with MBP or SCH. Similarly, Miller *et al* (63,64) demonstrated a lack of delayed-type hypersensitivity (DTH) responses and T cell proliferation against whole MBP and PLP, their encephalitogenic peptides MBP_{91-104} and $PLP_{139-151}$, and SCH in TMEV-infected mice 23, 60, 69, 90 and 127 days p.i.

Comparative studies using the EAE model induced by neuroantigens also demonstrated no pathogenic role of myelin specific T cells during the early chronic phase of TMEV infection. EAE is induced by subcutaneous injection of myelin antigens emulsified with complete Freund's adjuvant (CFA), while emulsification with incomplete Freund's adjuvant (IFA) can induce anergy to myelin antigens, rendering resistance to subsequent EAE induction. Following MBP or SCH emulsified in IFA injection, Lang *et al* (65) injected mice with DA virus or SCH/CFA for EAE induction. They found that pretreatment with myelin antigens/IFA suppressed EAE induction, but not TMEV-induced demyelination at 45 days p.i. Another protocol for neuroantigens-specific tolerance induction that can suppress

EAE also failed to alter the development of TMEV-induced demyelinating disease on day 65 p.i. (64). Similarly, using a treatment regimen reported to suppress EAE, Drescher *et al* (66) demonstrated that oral tolerization with myelin did not alter TMEV-induced demyelination at day 45 p.i., supporting a non-autoimmune mechanism of TMEV-induced demyelination. Although TMEV-infected mice develop demyelinating disease one month after infection and disease progresses continuously from then on, myelin-specific cellular immunity contributes to neither initiation nor progression of demyelinating disease at least for the first two to three months after TMEV infection.

4.2 Epitope spreading during the late chronic phase of TMEV infection

Although TMEV-infected mice develop extensive inflammatory demyelination with progressive disability by two to three months after infection, neurological disease seems to progress for the rest of the life of infected mice. While most studies on TMEV-induced demyelination have used mice infected with TMEV for one to two months p.i., the Miller group has examined the role of epitope spreading in initiating anti-myelin autoimmune responses in SJL/J mice during the late chronic phase of disease, more than two to three months after BeAn strain of TMEV infection (60). As reviewed in the previous section, before three months p.i., TMEV-infected mice develop $CD4^+$ T cells specific for TMEV, but not for neuroantigens. However, the Miller group demonstrated $PLP_{139-151}$-specific T cell proliferation in TMEV-infected mice 87 days, but not 33 days, after infection, and DTH response to $PLP_{139-151}$ was first demonstrable at day 52 (67). Peripheral T-cell responses to myelin epitopes develop during progressive disease in a hierarchical order, beginning with the dominant $PLP_{139-151}$ peptide, but only after the onset of demyelination. As disease progresses, responses to various other less-dominant encephalitogenic myelin epitopes, such as $PLP_{178-191}$, PLP_{56-70} and MOG_{92-106} develop. Although there are some inconsistencies as to the onset date of the anti-neuroantigen specific immune response between the reports by Miller's group, overt anti-myelin immune responses seem to be detectable around three months after TMEV infection, which argues against these responses contributing to myelin damage before this time.

Autoreactivity could be initiated, in part, by the processing of myelin debris and subsequent presentation of myelin epitopes by infiltrating macrophages and resident perivascular cells/microglia in the CNS. Macrophages and microglia harvested from the CNS during the early chronic phase, 40-42 days after TMEV infection, presented viral peptides,

but not myelin peptide (68). However, by 90 days post-infection, CNS APCs presented both viral and myelin epitopes to Th1 and Th2 cell lines and hybridomas specific for TMEV or PLP peptides in the absence of exogenous antigen *in vitro*, indicating these APCs could endogenously process and present both viral and myelin antigens (68,69). Importantly, anti-CD86 (B7-2) antibody predominantly inhibited $PLP_{139-151}$-specific T cell proliferation mediated by endogenous antigen presentation by CNS APCs from TMEV-infected mice (72% inhibition), compared with anti-CD80 (B7-1) (44% inhibition). This is in contrast to CD80 predominance in SJL/J mice with RR-EAE. Therefore, the costimulatory dependence of epitope spreading differs between TMEV infection and RR-EAE. *In vivo* costimulatory blockade of CD28 (ligand for CD80 and 86) on days 0, 2, 4, 6 and 9 after TMEV infection inhibited anti-TMEV immune responses and increased virus persistence, accelerating epitope spreading (70). This CD28 blocking would have been more intriguing, if it had been administered in TMEV-infected mice during the early chronic phase, possibly during the priming period of anti-PLP responses, where the treatment could inhibit epitope spreading without suppression of anti-TMEV immunity.

Most recently, Miller's group demonstrated that the treatment of TMEV-infected mice with an MP4 fusion protein, consisting of PLP and MBP, mildly attenuated disease progression (40-110 days p.i.) and resulted in decreased inflammatory cell infiltration in the CNS (71). Paradoxically, $PLP_{139-151}$-specific splenic T cell proliferative and interferon (IFN)-γ responses were enhanced in the MP4-treated mice, while $PLP_{139-151}$-specific DTH responses were downregulated. In addition, after 120-140 days p.i., MP4-treated mice showed disease severity comparable to control animals. These results indicated that MP4-treatement in TMEV infection did neither induce tolerance via deletion or anergy, nor immune deviation from Th1 to Th2 responses. In contrast, the MP4 treatment completely inhibited both the acute attack and relapse of PLP- and MBP-induced EAE with significant suppression of PLP- and MBP-specific lymphoproliferative responses (72). Administration of MP4 also markedly ameliorates the course of established EAE. These results suggest that the immunological parameters of epitope spreading differ between TMEV infection and EAE.

Another group also demonstrated myelin specific-DTH responses during the late chronic phase (36-48 weeks p.i.), but not during the early chronic phase (4 to 12 weeks p.i.), indicating autoimmune responses do not play a major role in the initiation of demyelination in TMEV infection (73). There was no correlation between clinical score and the strength of the DTH response to myelin autoantigens in mice tested at 36-48 weeks. Therefore, the authors concluded that anti-myelin autoimmunity might be an additional factor that contributes to lesion progression during the late chronic stage,

although autoimmunity to myelin might represent only an epiphenomena, being induced only after damage to myelin produced by other mechanisms.

It is unknown why epitope spreading can be detected only during the late chronic stage of TMEV infection. In addition to virally induced tissue injury and immunomodulation, mouse strain and aging might contribute to epitope spreading in TMEV-infected SJL/J mice. Naïve SJL/J mice have a high frequency of $PLP_{139-151}$ specific T cells, and it increases with age (74,75). Moreover, aged SJL/J mice tend to have immunological abnormalities: a high incidence of reticulum cell sarcoma and paraproteinemia with enlargement of lymph nodes and splenomegaly (76).

A pathological role for epitope spreading is controversial even in EAE (74) and difficult to verify. Epitope spreading might simply reflect release of autoantigens secondary to myelin destruction, and may not have pathogenic significance. However, Dal Canto *et al* (77) showed that lymph node cells harvested from mice 70 days after TMEV infection produced demyelination in organotypic cultures after stimulation with $PLP_{139-152}$ but not after stimulation with whole MBP. The authors suggested that antigen spreading to PLP, but not to MBP, might play an important role in demyelination. It would be intriguing to test whether adoptive transfer of the PLP peptide-stimulated lymphocytes from TMEV-infected mice could cause demyelination in naïve mice *in vivo*, while possible contamination with live transferred virus in cultures and the effect of whole PLP or MBP peptide stimulation of lymph node cells should also be addressed in future experiments. On the other hand, autoimmunity in the CNS, including MBP-specific T cells, has been demonstrated to have a protective or beneficial nature under certain circumstances (78). Therefore, one cannot rule out the possibility that anti-myelin autoimmunity might play a neuroprotective role during the late chronic phase of TMEV infection, a time when severe axonal injury and loss has been demonstrated [reviewed in (5)].

5. TMEV INFECTION AS MODELS TO STUDY MOLECULAR MIMICRY AND REMYELINATION

5.1 Recombinant TMEV as a molecular mimicry model

Using TMEV, Olson *et al* (79) established a virus-induced molecular mimicry model of MS. They engineered a nonpathogenic TMEV (ΔClaI-BeAn) encoding $PLP_{139-151}$. Infection with the $PLP_{139-151}$-encoding TMEV (PLP139-BeAn) led to rapid-onset of paralytic disease within ten days. As early as 14 days p.i., inflammatory demyelinating lesions were detected in

the spinal cord, and $PLP_{139-151}$-specific T cell proliferation and DTH response were detected in the spleen. Similar early-onset disease with anti-PLP responses was also observed in mice infected with a TMEV encoding altered peptide ligand (APL) of $PLP_{139-151}$ with an amino acid substitution at the T cell receptor contact residue (H147A PLP139-BeAn). $PLP_{139-151}$-specific T cells, but not TMEV-specific T cells, from PLP139-BeAn-infected mice transferred demyelinating disease to naïve recipients, and induction of $PLP_{139-151}$-specific tolerance before infection prevented clinical disease (80). The authors suggest that both PLP139-BeAn and H147A PLP139-BeAn viruses induced PLP specific T cells, leading to early onset of demyelinating disease. No information is available about pathology and viral replication one week after PLP139-BeAn virus infection. It is also unknown whether this model is similar to TMEV infection or $PLP_{139-151}$-induced EAE clinically and histologically.

In this study, TMEV expressing an encephalitogenic PLP epitope as well as an APL of PLP could induce early-onset disease in the absence of a stimulus associated with CFA. This is in contrast to the infection of mice with a vaccinia virus construct expressing the entire coding region of PLP, which failed to induce CNS disease without a second challenge by CFA (81). Thus, TMEV might provide sufficient signals to induce autoreactive T cells in some circumstances. Importantly, the APL of PLP that is encoded in H147A PLP139-BeAn is not encephalitogenic even when administered with CFA in mice (82). This may mimic the situation of a recent clinical trial in MS, in which administration of an APL of MBP into MS patients resulted in induction of MBP-specific T cell proliferation and exacerbation of clinical signs (83,84).

5.2 Anti-neuroantigen antibodies as a therapeutic agent in TMEV infection

In contrast to the classical view of the anti-myelin immune responses playing a pathogenic role in CNS demyelinating disease, autoimmunity against myelin might play a beneficial role by promoting CNS regeneration: axonal regeneration and myelin regeneration (remyelination). In the EAE model, injection of a myelin component with IFA ameliorates clinical and pathological demyelinating disease. This therapeutic effect could be due to: 1) suppression of Th1 cell-mediated autoimmunity and 2) production of anti-myelin antibody that plays a direct role in remyelination. This latter role is in agreement with *in vitro* observations of antibody-mediated oligodendrocyte stimulation. Based on the initial observations by Traugott *et al* (85) of remyelination in EAE, Lang *et al* (86) conducted similar experiments with mice infected with the DA strain of TMEV. At three months p.i., mice

treated with subcutaneous injections of MBP and GC emulsified in IFA showed substantial CNS remyelination compared with control treated animals. In the following paper, however, they demonstrated that pretreatment of mice with SCH/IFA or MBP/IFA did not suppress clinical and histological disease in TMEV infection (65).

The discovery that certain autoantibodies can be beneficial in an animal model of CNS demyelination suggests that the presumed pathogenic role of antibodies in MS may need to be reevaluated. Using the TMEV model, Rodriguez and colleagues have shown a beneficial role of anti-neuroantigen antibodies due to their promotion of remyelination [reviewed in (87)]. Spontaneous remyelination is impaired in SJL/J mice infected with the DA strain of TMEV. Rodriguez and Lennon (88) observed that passive transfer of either antiserum or purified IgG from uninfected syngeneic animals immunized with SCH promoted remyelination by oligodendrocytes (CNS-type), but not by Schwann cells (PNS-type), in TMEV-infected mice. While astrocytes were common within areas of remyelination, inflammatory cells were less numerous in remyelinating areas than in demyelinating lesions. *In vivo* autoradiography with $[^3H]$ thymidine demonstrated that the majority of radiolabeled cells were MNCs, while remyelinated areas contained GC^--proliferating cells that might be immature oligodendrocytes, morphologically (89). However, subsequent experiments demonstrated that a similar extent of oligodendrocyte proliferation was also detected in mice treated with control sera, suggesting proliferation of oligodendrocytes is not sufficient for new myelin synthesis (90). Anti-SCH serum also stimulated proliferation of primary glial cell cultures *in vitro* (91). The effect of the treatment on anti-TMEV antibody production and virus persistence seemed to be inconclusive. A mild increase of anti-TMEV antibody titer was detected by an enzyme-linked immunosorbent assay (ELISA), but not by a plaque reduction assay; an increase of viral persistence was reported by immunohistochemistry against viral antigen, but not by virus plaque assays of CNS homogenates (92). Rodriguez *et al* (93) also demonstrated that treatment with antiserum or purified IgG directed against MBP promoted remyelination after TMEV infection without altering virus persistence or serum TMEV-specific antibody responses.

The Rodriguez group also generated a remyelination-promoting IgM mAb, SCH94.03, from the spleen cells of mice injected with SCH. SCH94.03 showed reactivity toward a red blood cell antigen, spectrin and several other protein antigens, astrocytes and oligodendrocytes, but not with MBP (94,95). SCH94.03 injection suppressed T cell infiltration and increased TMEV persistence in the CNS, while levels of TMEV-specific IgG were similar to controls (96). SCH94.03 neither reacted with any TMEV proteins as determined by Western blot, nor neutralized TMEV

in vitro (97). Treatment with SCH94.03 also reduced relapse rate, demyelination and meningitis in SJL/J mice with EAE induced by adoptive transfer of MBP_{91-103}-specific T cells (98). These results are consistent with the hypothesized immunomodulatory function of autoantibodies, although neither immune responses to MBP nor extent of remyelination was explored in this EAE model. Interestingly, however, SCH94.03 increased the rate of oligodendrocyte remyelination in a nonimmune, toxin-induced model of lysolecithin-induced demyelination (99).

Other IgM mAbs, SCH79.08, O1, O4, A2B5, and HNK-1, have also been shown to promote remyelination in TMEV models. SCH79.08 was established from mice immunized with SCH, reacts with MBP and shows intracellular, but not cell surface, staining of oligodendrocytes (100). O1, O4, A2B5, and HNK-1 antibodies recognize differentiation stage-specific surface antigens on oligodendrocytes. We do not know, however, whether these antibodies against oligodendrocyte precursors actually recognized the cells *in vivo*. Immunoperoxidase staining for markers expressed on presumed glial progenitor cells (O4, A2B5, and G_{D3}) was not successful in the adult mouse spinal cord in TMEV infection, even though the reagents worked in the neonatal rat optic nerve system *in vitro* (90).

Several antibodies join a list of immunoglobulins that enhance remyelination in the Theiler's virus model (101). The list includes pooled human intravenous IgG (IVIg), polyclonal human IgM, and two human IgM mAbs, sHIgM22 and sHIgM46, both of which were isolated from Waldenstrom's macroglobulinemia. Neither IVIg nor human IgM bound to human oligodendrocytes *in vitro*, while the two IgM mAbs bound to oligodendrocytes. Polyclonal human IgM and sHIgM22, but neither polyclonal IgG, anti-SCH IgG, nor IVIg, accelerated the rate of remyelination following lysolecithin-induced demyelination in SJL/J mice (99,102). Therefore, the authors suggested that IgG and IgM antibodies might function to enhance remyelination through different mechanisms.

The precise mechanisms of remyelination by the autoantibodies are unknown. It is unclear whether there is one single common mechanism which explains promotion of remyelination in all remyelination-promoting sera, IgG, and IgM antibodies. Because many of the remyelination-promoting antibodies bind to oligodendrocytes and/or myelin, a direct effect on the recognized cells has been hypothesized. However, since the remyelination-promoting autoantibodies have varying specificities, it is unlikely that each of the antibodies functions directly through a common antigen or receptor. The authors also suggested opsonization of myelin debris due to IgM antibody by phagocytes might enhance clearance of cellular debris from the damaged area, allowing the normal process of CNS repair to progress. Since Fc receptors on phagocytes do not generally bind

to the Fc portion of IgM, IgM likely interacts with C3b via its Cμ1 domain, thereby allowing antibody-antigen complexes containing IgM to indirectly mediate phagocytosis. Although by this mechanism, C3b, once fixed, can promote uptake via complement receptors on macrophages, the roles of complement and Fc receptor have not been tested in this model. Immunomodulation by autoantibody is also hypothesized. However, no data are available as to how autoantibody treatment might influence cellular immune responses to virus or myelin antigen.

Several other studies need to be performed to clarify the mechanism of remyelination, such as immunological and histological time course studies over a four-week antibody treatment period and *in vivo* trafficking of injected antibody. In addition, we do not know why autoantibodies stimulate CNS-type remyelination by oligodendrocytes, but not PNS-type remyelination by Schwann cells, despite the fact that the PNS also expresses antigens, including MBP, recognized by the autoantibodies (95). It should be noted that most remyelination-promoting studies used mice four to six months after TMEV infection, in contrast to the other TMEV research groups who use mice one to two months after TMEV infection. As discussed earlier, the mechanisms of demyelination might be different at these two time points.

Interestingly, among the autoantibodies, several (SCH94.03, SCH79.08, O1, O4, HNK-1), but not all (A2B5, sHIgM22), monoclonal antibodies have been shown to have characteristics of natural autoantibodies (100,101,103). Natural autoantibodies, usually IgMs whose physiological significance is unknown, are present in the serum of normal unimmunized animal, and represent a substantial fraction of the total Ig repertoire (104). Natural autoantibodies show polyreactivity toward multiple self and nonself antigens, and are typically encoded by unmutated germ line Ig genes (103). It has been shown that some viruses may act as polyclonal B cell activators, may release antigens not ordinarily recognized by the host immune system, or may augment the response to many antigens (105,106). Any of these mechanisms may explain the induction of autoantibodies or an increase of the levels of natural autoantibodies.

It is attractive to hypothesize that the presence or absence of remyelination-promoting antibody might alter the disease course in demyelinating diseases. Here, a lack of the autoantibodies would prevent remyelination in DA virus-induced progressive disease in SJL/J mice. It may be intriguing to test whether the autoantibody is involved in the pathogenesis of CD-1 mice infected with the WW strain of TMEV, who develop a relapsing remitting disease course, characterized by extensive PNS- and CNS-type remyelination (13).

Clinically, comparison of the levels of autoantibodies in patients with RR-MS versus PP- and SP-MS might be important. From a patient with MS,

a clone of a possible natural antibody was established (107). This oligodendrocyte–reactive IgM monoclonal antibody, DS1F8, is polyreactive and its antigen-binding domains are encoded by germ line genes. In addition, Matsiota *et al* (108) found that MS patients often had elevated CSF antibody levels against many autoantigens, but not against MBP, suggesting a local expansion of B cells producing natural autoantibodies. Whether these antibodies have any effect on demyelination is unknown.

6. CONCLUSION

In this chapter, we have reviewed the interactions of TMEV, myelin and anti-myelin immune responses. On virus entry, TMEV might use peripheral myelin protein P_0 as a virus receptor, and require myelin genes functionally or myelin itself structurally for virus persistence. In turn, the host down-regulates myelin gene expression and/or loses oligodendrocytes and myelin. While this leads to demyelination, it might also be beneficial to the host since it prevents virus spread in the CNS. Anti-TMEV humoral immune responses can help virus clearance, while some anti-viral antibodies might

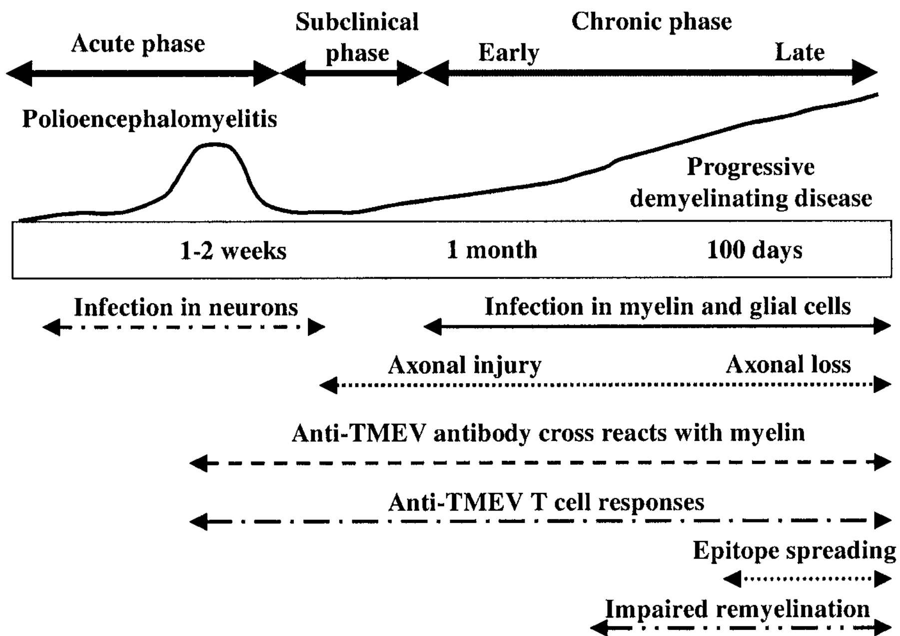

Figure 1. Myelin infection, anti-myelin responses, and other effector mechanisms during TMEV disease course.

cross-react with host myelin molecules, including GC, leading to exacerbation of demyelination. During the early chronic phase, cellular immune responses to TMEV, but not to myelin, were detected. However, epitope spreading seems to develop during the late chronic phase, and T cell responses to encephalitogenic epitopes of PLP, MBP and MOG, can be detected. Impaired remyelination could also contribute to disease progression. Here, the presence or absence of remyelination-promoting antibody might be important in disease remission. Of all the above interactions between virus, myelin, and autoimmune responses, no single mechanism may be solely responsible for demyelination. However, all of the interactions potentially contribute to progression of demyelinating disease in which a variety of different pathogenic mechanisms, such as oligodendrocyte infection and apoptosis, axonal injury and anti-TMEV immune responses, seem to act in parallel or sequence to cause myelin destruction (Figure 1).

ACKNOWLEDGEMENTS

The authors would like to thank Melina V. Jones, PhD, Jane E. Libbey, MS and Lisa K. Peterson, BS for many helpful discussions, and Nancy K. Burgess, BS, Isaac Z. M. Igenge and Kenneth B. Scott for their technical assistance. We are grateful to Ms. Kathleen Borick for preparation of the manuscript. This was supported by the NIH grant NS34497.

Chapter B3

THE ROLE OF ASTROCYTES, OLIGODENDROCYTES, MICROGLIA AND ENDOTHELIAL CELLS IN TMEV INFECTION

MC Dal Canto and CL VanderLugt
Department of Pathology, Northwestern University Medical School, Chicago, IL

Abstract: Chronic TMEV infection in susceptible strains leads to an inflammatory demyelinating disease modeling MS. TMEV antigen can be found abundantly in microglia and infiltrating macrophage, but viral growth is restricted in these cells. Viral persistence has been seen in astrocytes, microglia, and oligodendrocytes. However, infiltrating macrophage and, to some extent, resident microglia play an important role in antigen presentation, inflammation and epitope spreading.

Key words: Theiler's virus infection; demyelination; astrocytes; microglial cells; oligodendrocytes; viral persistence; epitope spreading

1. INTRODUCTION

1.1 TMEV infection

Theiler's murine encephalomyelitis virus (TMEV) is an enteric pathogen of mice belonging to the *Picornaviridae* family (1). Two groups of TMEVs include high neurovirulent strains such as GDVII and low neurovirulence TMEVs such as BeAn and DA. Intracerebral inoculation with GDVII results in a rapidly fatal encephalitis in which grey matter neurons are infected and lysed. In contrast, BeAn and DA strains experimentally injected into susceptible strains of mice result in an initial acute phase of grey matter involvement followed by a chronic phase of viral persistence, inflammation and demyelination in the white matter of the spinal cord (2), TMEV-induced demyelinating disease (TMEV-IDD).

The extent of acute phase grey matter involvement and the proposed mechanisms of the chronic phase demyelination depend largely on the strain of virus and the strain of mice infected. The initial acute grey matter

involvement following inoculation of the DA strain into SJL mice is characterized by microglial proliferation and neuronal necrosis. Surviving mice go on to develop TMEV-IDD. In contrast, intracerebral inoculation of BeAn into SJL mice results in a very limited and clinically silent early acute phase grey matter disease. Chronic demyelination in the BeAn/SJL model appears to be due to the Th1 inflammatory response rather than direct lysis of virally infected oligodendrocytes.

Histopathologically, TMEV-IDD resembles the human demyelinating disease multiple sclerosis (MS).

1.2 TMEV-IDD as a model of MS

There is evidence for a viral etiology (epidemiology) of multiple sclerosis (3, 4), making TMEV-IDD an important model of MS. Although no one virus has been shown to be consistently associated with MS, early infection may trigger events, through molecular mimicry (5) or epitope spreading (6), that eventually result in disease. Like TMEV-IDD, MS is an immune-mediated demyelinating disease characterized by perivascular CD4+ T cell and mononuclear cell infiltration, with subsequent primary demyelination of axonal tracts, leading to progressive paralysis (7). MS is generally considered to have an autoimmune component, however a direct cause-effect relationship between myelin reactivity and disease has not been established. Interestingly, although TMEV-IDD is due initially to a persistent CNS viral infection, autoimmune anti-myelin Th1 responses are seen during the chronic phase of disease.

Three interesting areas of investigation in TMEV-IDD include identification of the CNS cells harbouring the persistent infection, the antigen-presenting cells (CNS APCs) responsible for presenting viral antigen and inducing the Th1 inflammatory response leading to demyelination, and the CNS cells involved in epitope spreading, from viral epitopes to myelin targets, in this chronic inflammatory disease.

2. THE ROLE OF CNS GLIA IN TMEV-IDD

2.1 Persistent infection

Demyelination and the resulting clinical disease symptoms are not the consequence of viral lysis of oligodentrocytes, but are immune mediated, due to the inflammatory response in the CNS (8, 9). Viral persistence is however required for chronic disease, since mouse strains which clear the virus do not go on to chronic demyelination that characterizes TMEV-IDD. Therefore it is important to determine which cells harbor the persistent virus.

Initial observations using immuno-histochemistry demonstrated that viral antigens could be found in abundance in the spinal cord of TMEV infected

mice in macrophage/microglial cells and in astrocytes (10, 11). In contrast to the abundance of viral antigen, infections virus has been consistently shown to be low ($<10^4$ PFU). Viral persistence is routinely demonstrated by plaque assays of the spinal cord and brain tissue of infected mice. Historically, macrophage/microglia have been thought to be the major reservour of infectious virus. Macrophage depletion with mannosylated liposomes abrogated TMEV persistence (12). However, it had also been demonstrated that viral replication was blocked in these cells (11, 12).

Recently, Lipton et. al. analysed the copy number of TMEV genomes, plus- to minus-strand ratios, and full-length. Interestingly, large numbers of viral genomes were detected (13). To some extent, an abundance of viral antigen and viral genomes combined with very low amounts of infectious virus can be explained by neutralization of infectious virus via the immune response and its restricted growth in macrophages (13, 14), blocked after viral RNA replication.

Although macrophage/microglia have historically been thought to be the predominant cell type supporting TMEV replication, other cell types may be important for persistence. Both oligodendrocytes and astrocytes have been suggested to harbor TMEV *in vivo*. Oligodendrocytes isolated from infected SJL mice contained amounts of viral genome equal on a per cell basis to that of macrophages (13) and an oligodendrocyte line proved to be significantly more productive in terms of infectious virus (PFU) per cell than macrophages. However, most early immuno-histochemical studies showed little if any viral antigen in oligodendrocytes during TMEV-IDD.

Although astrocytes have been considered by some to be an unlikely source of viral persistence, early immunohistochemical studies demonstrated viral antigen in these cells during TMEV-IDD (10), and more recent work in our lab suggests rethinking this historic view (15). *De novo* viral protein synthesis was seen in astrocytes and, to a lesser extent, in oligodentrocytes and microglia, when these cells (obtained from neonatal mice) were infected *in vitro* in the presence of ^{35}S-methionine. Additionally, when a GFP-BeAn virus was used to infect microglia, oligodendrocytes and astrocytes *in vitro*, similar results were seen. *De novo* protein synthesis (GFP is translated as part of the viral leader) was clearly seen in astrocytes. Plaque assays and RNAse protection assays confirmed the findings that astrocytes from neonatal mice were productively infected *in vitro* to a greater extent than oligodendrocytes. Minimal cytopathic effects resulted from this infection. The most remarkable finding was that the ratio of viral replication in astrocytes versus microglial cells was 100 to 4 as quantitated by Image Quant analysis in a Phosphor Imager measuring negative RNA strand production in these cells. The production of negative strand RNA is the most sensitive method to measure true viral replication (Fig 1).

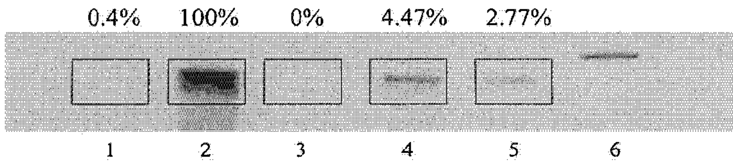

Fig 1. Rnase protection assay for the detection of TMEV replication. A positive RNA transcript, containing 208 specific TMEV nucleotides, was protected by the replicative, negative strand of TMEV in infected astrocytes and microglial cells. (1) Uninfected astrocytes, (2) infected astrocytes, (3) uninfected microglia, (4) infected microglia, (5) microglia infected in the presence of INF-gamma and (6) 258 base transcript probe. The amount of RNA protected was quan titated by Image Quant analysis in a Phosphor Imager. The values represent amount of the RNA protected in microglia as a percentage of the amount protected in astrocytes, which was assigned a value of 100. (Reproduced with permission from J Neuroimmunol 118:256-267, 2001)

While providing new data regarding the unexpected capacity of astrocytes to become infected by TMEV, these studies also confirm that viral transcription is restricted in microglia, as earlier studies had showed. Confocal microscopy of immuno-histochemical stains of the brain and spinal cord from mice with TMEV-IDD confirmed the *in vitro* results as staining with anti-TMEV antibody co-localized with GFAP staining. In fact, most astrocytes stained positive for viral antigen (Fig 2) (15).

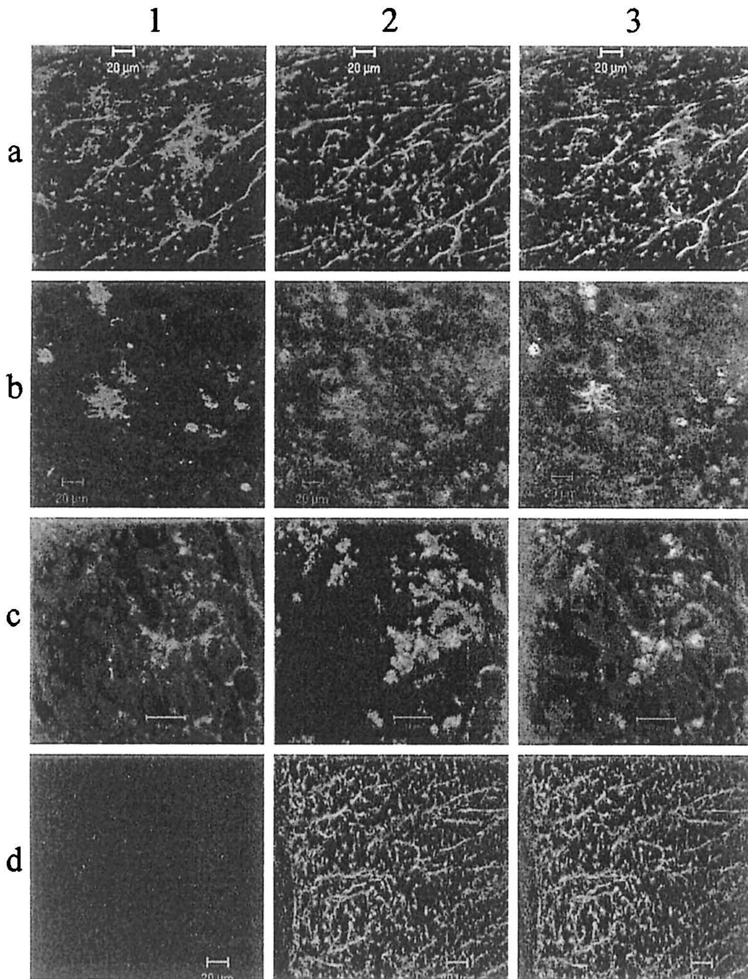

Fig 2. Immunohistologic analysis of spinal cord tissues from mice suffering from TMEV-induced demyelinating disease or EAE disease. Double immunostaining of frozen sections was done using both the BeAn antisera with a rhodamine conjugated secondary antibody (red) and different antibodies to cell specific markers with FITC-conjugated secondary antibodies (green). Column 1: viral antigen in (a) astrocytes, (b) microglia, (c) oligodendrocytes and (d) EAE. Column 2: (a and d) anti-GFAP for astrocytes, (b) MOMA-2 for macrophages, (c) anti-CNPase for oligodendrocytes. Column 3:colocalization of the two stains. Bar in row C measures 10 microns; all other bars measure 20 microns. (Reproduced with permission from J Neuroimmunol 118:256-267, 2001)

The relative resistance of oligodendrocytes to TMEV infection is of interest and supports earlier studies that showed different responses to infection by mature oligodendrocytes when compared with an immortalized, developmentally arrested oligodendroglial cell line (16). Those studies

demonstrated that infected mature oligodendrocytes, similarly to astrocytes, revealed very little, if any, cytopathic effect. In addition, when synthesis of mRNA for myelin proteins, such as MBP and MOG was investigated, no suppression could be demonstrated. This contrasted with the demonstration of both cytopathic effects and suppression of MBP and MOG mRNA synthesis in an immortalized line of oligodendrocytes which was arrested at an early developmental level. These studies suggest that adult, differentiated oligodendrocytes are quite resistant to TMEV cytopathic effects, both structurally and functionally, although a low level infection is permitted. On the other hand, developing oligodendrocytes are more susceptible to TMEV-induced injury, a conclusion that correlates with previous studies demonstrating direct oligodendroglial cytopathic effects in neonatal mice (17).

The importance of oligodendroglial resistance to TMEV infection is also underscored by the ability of oligodendrocytes to be stimulated into a remyelinating mode after demyelination produced by different strains of TMEV. Without stimulation, very little remyelination can be seen in SJL/J mice, in which demyelination is generally quite severe. In strains of mice in which the demyelinating process is more subdue, or when using certain TMEV strains, spontaneous remyelination can occur, however, most of the remyelinating activity is carried out by invading Schwann cells, and only a minority of the repair process is spontaneously carried out by oligodendrocytes (reviewed in 18). Recently, however, Rodriguez and his colleagues have demonstrated that oligodendroglial cells may be induced to produce abundant remyelination when appropriately stimulated.

Their initial studies utilized anti-spinal cord antiserum to stimulate remyelination in TMEV-infected mice (19). Later, IgM monoclonal antibodies were prepared, and these showed the same capability of enhancing oligodendroglia-mediated remyelination (20, 21). These studies suggested that binding of antibodies to the surface of oligodendrocytes initiated a series of events eventually leading to remyelination. Subsequently, these investigators demonstrated that an IgM antibody present in human serum was also capable to enhance remyelination in the CNS of demyelinated animals (22). These results were confirmed by using a recombinant human IgM antibody generated by DNA-mediated gene transfer (23). *In vitro* studies showed binding of this antibody to oligodendrocytes resulting in enhanced Ca entry into the cells. Studies *in vivo*, utilizing chronically TMEV-infected mice, clearly showed enhanced remyelination. These studies strongly suggest that IgM antibody binding to the oligodendroglial surface initiates a signaling cascade, that eventually results in enhanced remyelination. These studies open the possibility of using antibody therapy in MS patients to stimulate myelin repair.

Summary: During ongoing TMEV-IDD macrophage/microglia phagocytose viral particles but do not allow viral replication, blocked after transcription. Oligodendrocytes may be infected, but the bulk of active infectious virus replication is found in astrocytes. Oligodendrocytes, even after infection are

resistant to cytolysis and they may produce substantial remyelination when stimulated with antibody binding to their surface.

2.2 Antigen presentation and inflammation

Although viral persistence is necessary for disease, the immune response itself, not direct viral lysis, appears to cause the demyelination characteristic of TMEV-IDD. Therefore, another important area of investigation includes the identification of the cells in the CNS important in initiating and sustaining the immune response resulting in CNS inflammation and demyelination.

The brain has been considered an immune-privileged site due to the blood-brain-barrior (BBB). The BBB includes cerebrovascular endothelial cells (CVEs) and astrocytes. CVEs differ from endothelial cells in the capillaries of other organs by their continuous tight junctions and lack of transendothelial pathways. The foot processes from astrocyes cover almost the entire surface of the CVE basement membrane. Together these cells provide a continuous cellular barrier between the blood and the interstitial fluid limiting the entry of immune cells such as T lymphocytes and antibodies.

Activation of T cells requires two signals. The antigen-specific signal through the major histocompatibility complex (MHC) class II plus peptide and costimulatory signals, most notably through the B7 molecules on APCs. Efficient antigen presenting cells must take in antigen, process it into peptides which then are bound in the groove of the MHC class II molecule on its surface. Additionally, costimulatory molecules like CD40, B7-1 and B7-2 must be expressed in sufficient quantities for effective activation of CD4+ T cells. CNS cells express low to no levels of (MHC) class II, costimulatory and adhesion molecules and are therefore, under normal circumstances, not capable of activating T lymphocytes.

During an inflammatory immune response, however, the BBB is disrupted and activated T cells along with infiltrating peripheral monocytes/macrophage begin to traffic into the CNS. How this initiation of CNS inflammation occurs and which resident CNS cells serve as antigen presenting cells (APCs), for initiation and during ongoing inflammation, has been the subject of much investigation.

When treated *in vitro* with IFN-γ, SJL astrocytes (isolated from neonatal mice) upregulated adhesion molecules ICAM-1 and VCAM-1, in addition to MHC class II, invariant chain, H2-M, and costimulatory molecules CD40 and B7-1. These IFN-γ-treated astrocytes were capable of processing PLP139-151 peptide from intact proteolipid protein (PLP) and induced B7-1 dependent activation of Th1 lines and lymph node T cells (24). Soos *et al* also demonstrated that astrocyte clones are capable of processing and presenting protein antigen to activate T cells (25).

SJL astrocytes isolated from neonatal mice were compared with cloned SJL CVEs. *In vitro* studies demonstrated that although neither astrocytes nor CVEs constitutively express MHC class II, both cells up-regulated expression when incubated with IFN-γ alone. TNF-α inhibits IFN-γ-induced MHC class II up-regulation on CVEs, but not on astrocytes. Limited expression of costimulatory and adhesion molecules were found on CVEs as compared to astrocytes. B7-1, ICAM-1 and VCAM are found on astrocytes and upregulated by IFN-γ. CD40, another important costimulatory molecule, was expressed on neither CVEs or astrocytes. B7-1 and VCAM was very low on CVEs but VCAM was upregulated strongly by treatment with IFN-γ and TNF-α together. Not surprisingly, astrocytes, but not CVEs, elicit MHC class II-restricted T cell responses (26). These data suggest that astrocytes, in the inflammatory milieu of TMEV-IDD, can function as CNS APCs. CVEs, on the other hand, are less likely to participate. The question of whether CVEs could present antigen at the BBB to myelin-specific T cells remains unanswered.

Microglia are more efficient than astrocytes at processing and presenting antigen to T cells (27). Microglia are bone marrow-derived, macrophage-like cells of the CNS which migrate into CNS during development and are considered to be resident macrophage populations. Microglia are phagocytic and can process and present antigen, including the dominant myelin epitope in the SJL mouse, PLP139-151. When infected *in vitro* with TMEV, microglia upregulate MHC class II/I, cytokines including the "anti-viral" IFN-α/β, co-stimulatory molecules including B7-1/2 and CD40, and adhesion molecules like ICAM-1 to a similar extent as IFN-γ-treated microglia. Infected microglia can also process and present endogenous viral antigens to a virus specific T cell line (28). In MS, microglia were shown to phagocytoze myelin and express MHC class II plus costimulatory molecules (29).

Summary: Once CNS inflammation has been initiated, peripheral macrophage certainly play a major role in the inflammatory demyelination characteristic of MS and TMEV-IDD. Microglia, the resident macrophage cell of the CNS, are fully capable of participating in the demyelinating inflammation. They are likely infected, although abortively, and are able to process and present viral antigens to T cells. Astrocytes may also participate in this process since they are not only infected, but are also capable APCs when in an inflammatory environment. CVEs, however, are unlikely to take part in antigen processing and presentation during TMEV-IDD, although their proposed role in the initial migration of antigen-specific T cells across the BBB remains a possibility.

2.3 Epitope spreading

TMEV-IDD is initiated by virus infection and chronic disease progression requires viral persistence. In addition to infiltrating macrophage, CNS resident microglia and astrocytes are not only infected, but are also capable

of processing and presenting viral antigens to virus-specific T cells, thereby triggering CNS inflammation. Interestingly, although virus-specific T cell responses are detectable throughout TMEV-IDD, T cell responses against self myelin antigens arise at around day 50 post infection (6). This autoimmune component may have a role in the chronic nature of TMEV-IDD.

The mechanisms underlying the initiation and progression of MS are not well understood, however, like TMEV-IDD, viral infections may be important in induction while disease progression appears to be autoimmune. Several mechanisms in which virally induced disease may trigger autoimmunity have been hypothesized, including molecular mimicry, in which autoreactive T cells cross-reactive with a viral epitope are directly activated, non-specific T cell activation by a viral superantigen, and epitope spreading.

Epitope spreading is a process in which tissue debris (myelin in this case) is phagocytosed, processed and presented in an inflammatory environment. As a result of this presentation of self epitopes, self-reactive T cells are activated. Epitope spreading plays a major role in the progression of myelin destruction in the SJL mouse during relapsing experimental autoimmune encephalomyelitis (R-EAE), another MS model (30). For more information on epitope spreading in EAE see section A, chapter 23.

In TMEV-IDD, initiation of myelin damage is associated with the activation of mononuclear inflammatory cells by proinflammatory cytokines from TMEV-specific CD4+ T helper 1 (Th1) cells responding to viral epitopes presented by CNS resident APCs harbouring persistent virus. T cell proliferation to major encephalitogenic epitopes on PLP and myelin basic protein (MBP) (epitope spreading) can be detected by day 50 and delayed-type hypersensitivity (DTH) by day 90 PI, only after animals exhibit histological demyelination and clinical disease (31). The site of T cell activation during epitope spreading is not clear, however, CNS APCs may be important in this process.

In fact, endogenous presentation of viral and myelin epitopes by plastic-adherent CNS-resident mononuclear cells (CNS APCs) isolated from the spinal cords of mice with ongoing TMEV-IDD was clearly demonstrated at 90 days PI (32). In these assays, myelin-specific T cell lines were induced to proliferate by CNS APCs without the addition of antigen (endogenous presentation of antigen already present within and on the APCs). This antigen presentation was B7- dependent and MHC class II restricted. No endogenous presentation of viral epitopes was seen in APCs isolated from EAE (a non-viral model of MS) and no endogenous presentation of myelin epitopes could be detected using plastic-adherent CNS-resident mononuclear cells harvested from TMEV-IDD mice prior to onset of demyelination and clinical signs. These data suggest that immune mediated virally-induced inflammatory demyelination leads to presentation of myelin debris by CNS APCs. Autoreactive T cells are then activated and participate in the inflammatory response. For more information on autoreactive T cell activation in TMEV see section B, chapter 3 and 6.

The functional significance of epitope spreading was recently explored utilizing organotypic spinal cord explants from neonatal SJL/J mice. T cells were isolated from mice 50 days after TMEV infection, at the time when sensitization had been shown to be mainly limited to the major encephalitogenic PLP epitope. These cells, after stimulation with PLP, but not other myelin proteins were capable of demyelinating the myelinated cultures. These results strongly suggest that sensitization to myelin proteins in chronic TMEV infection is functionally significant (33).

Summary: Although viral infection of peripheral macrophages, CNS resident microglia, and astrocytes initiates the demyelination of TMEV-IDD, ongoing presentation of both viral and myelin antigen by these CNS APCs certainly perpetuates the inflammatory demyelination seen in this model of MS.

Chapter B4

IMMUNOGENETICS, RESISTANCE, AND SUSCEPTIBILITY TO THEILER'S VIRUS INFECTION

Roger W. Melvold and Stephen D. Miller
Department of Microbiology and Immunology, University of North Dakota School of Medicine and Health Sciences, Grand Forks, ND and Department of Microbiology-Immunology and the Interdepartmental Immunobiology Center, Northwestern University Medical School, Chicago, IL

Abstract: The genetic basis for differential susceptibility to Theiler's virus-induced demyelinating disease is complex and often confusing, similar to the situation seen in analyzing the genetic risk for human multiple sclerosis. Numerous genetic loci have been identified as influencing the likelihood of disease development, most prominently among them the class I *H2-D* locus which has the single most important effect of any of the loci studied thus far. Genetic analysis is complicated, however, by the fact that susceptibility to the disease is not inherited as a consistently dominant or recessive trait, and that the relevant loci can differ from one mouse strain to another. The system has proved amenable to the utilization of numerous transgenic and knock-out gene systems to analyze the disease process.

Key words: Theiler's murine encephalomyelitis virus (TMEV), demyelinating disease, multiple sclerosis, major histocompatibility complex (MHC), H2, H2-D, genetics

Multiple sclerosis (MS) has a suspected infectious etiology based on epidemiologic evidence that viral infections may play a role in initiation and/or exacerbation of the disease (1, 2), but also has a clear genetic basis (3-9). Similarly, there is clearly a genetic component to the risk of developing demyelinating disease in mice infected with Theiler's murine encephalomyelitis virus (TMEV) (10-18). TMEV is a single-stranded RNA virus belonging to the *Picornaviridae* family (19). TMEV-induced demyelinating disease (TMEV-IDD) is a natural chronic-progressive CNS demyelinating disease with similarities to primary-progressive MS (20, 21). CNS pathology in TMEV-IDD is initiated by viral capsid protein-specific $CD4^+$ T cells targeting virus persisting in CNS microglia, but autoreactive myelin-specific $CD4^+$ Th1 responses arise via epitope spreading and contribute to chronic pathology (22, 23). Myelin destruction is mediated largely by the production of the pro-inflammatory cytokines, IFN-γ and TNF-α (24). Both HLA and numerous non-HLA loci have been implicated in contributing to the risk of human MS, although in many cases the statistical associations are low as might be anticipated for a genetically complex disease in an outbred population (25, 26). Similarly, multiple genes are involved in determining whether the anti-viral immune responses in TMEV-infected mice will eventually lead to the destructive inflammatory responses associated with demyelination. In some cases, effects on human and murine demyelinating diseases have been attributed to homologous loci in the two species (27).

There are clear differences among various inbred strains of mice in susceptibility to the development of TMEV-IDD disease (Table 1), in terms of incidence, severity and time of onset. Some strains such as SJL/J, DBA/2J and SWR/J are highly susceptible and consistently develop severe demyelinating disease within a month of infection. Other strains such as C57BL/6 and C57BL/10 are highly resistant, with only an infrequent individuals developing disease after infection. Strains such as CBA and C3H (both $H2^k$) develop relatively mild forms of the disease. BALB/c mice ($H2^d$) can be either resistant or susceptible, depending upon the substrain (28, 29). However, even the susceptible BALB/c substrains tend to develop only moderately severe disease (2), and the severity of disease within some strains can also vary considerably (29). C57BR mice ($H2^k$) are generally considered resistant (30), but do begin to develop signs of disease after a lengthy interval, 100+ days, following infection (Miller, personal communication).

Table 1. Susceptible and Resistant Inbred and Congenic Mouse Strains

H2 type	Susceptible Strains	Resistant Strains
$H2^b$	129Sv	C57L, C57BL/6, C57BL/10
$H2^d$	BALB/c [1], DBA/2, NZW [2], B10.D2 [3]	BALB/c [1]
$H2^f$	B10.M [3]	
$H2^k$	AKR, C3H, CBA, B10.BR [3]	C57BR, B10.K [3]
$H2^q$	SWR, DBA/1, FVB	
$H2^s$	SJL	
$H2^r$	B10.RIII [3]	
$H2^u$	PL/J	
$H2^p$	P/J	
$H2^z$	NZB [2]	

1 BALB/cByJ and BALB/cCum substrains are resistant. BALB/cJ and BALB/cAnNCr substrains are susceptible (28).

2 Melvold (unpublished observations)

3 Reference 31

Resistance and susceptibility are not consistently dominant or recessive traits, but vary with the particular hybrid generated. Hybrids between different combinations of resistant and susceptible strains (Table 2) are sometimes susceptible, sometimes resistant, and sometimes intermediate. The outcome, therefore, is dependent upon the sum of the allelic interactions between the multiple loci that may vary between the susceptible and resistant parental strains. In comparisons among B10 congenics, where the non-*H2* genotypes are held constant, resistance is inherited as the dominant trait and susceptibility as the recessive trait (31). However, when both *H2* and non-*H2* genotypes are varied, this is not always true and the interactions between relevant loci may be complex. For example, hybrids between resistant C57BL/6 and susceptible DBA/2 mice are resistant, while those between resistant BALB/cByJ and susceptible DBA/2 mice are susceptible (32-34). Likewise, when susceptible SWR mice are crossed with either the resistant C57BL/6 or C57L strains (both carrying $H2\text{-}D^b$), the two types of resulting hybrid progeny have markedly different susceptibilities, despite the very close similarities of the two types of resistant parents (35). Comparable results have been found in EAE, another animal model for multiple sclerosis (36) where some crosses between resistant and susceptible strains produced resistant hybrid progeny, while other crosses produced susceptible progeny.

Human multiple sclerosis occurs more frequently in women than in men. In the TMEV model, differences in susceptibility between the two sexes have not been frequently noted, possibly because many studies employed

only one sex or the other. In some strain combinations, however, such differences have been reported. Among backcross and F2 progeny between the susceptible C57L and susceptible SJL strains, females were more frequently affected than males, by ratios ranging from 2:1 to 7:1. Similarly, among SWXL recombinant-inbred mice, generated between the susceptible SWR and resistant C57L strains, females were affected approximately 3 times as frequently as males (37).

Table 2. Hybrids Between Susceptible and Resistant Strains

Resistant Strain	Susceptible Strain	H2 genotype	Status	Reference
BALB/cByJ	SJL	$H2^b/H2^s$	Intermediate (60% affected)	38, 39
C57BL/6	SJL	$H2^b/H2^s$	Resistant (5-15% affected)	40
C57L	SJL	$H2^b/H2^s$	Susceptible (100% affected)	41
BALB/cByJ	DBA/2	$H2^d/H2^d$	Susceptible (85% affected)	34
C57BL/6	DBA/2	$H2^b/H2^d$	Resistant (0-10% affected)	32, 33
C57BL/10	DBA/2	$H2^b/H2^d$	Resistant	42
BALB/cByJ	BALB/cAnNCr	$H2^d/H2^d$	Resistant (30% affected)	28
BALB/cByJ	SWR	$H2^d/H2^q$	Susceptible (94% affected)	35
C57BL/6	SWR	$H2^b/H2^q$	Intermediate (44% affected)	35
C57L	SWR	$H2^b/H2^q$	Susceptible	35
BALB/cByJ	PL/J	$H2^d/H2^u$	Susceptible (78% affected)	Melvold (personal comm.)
C57BL/6	PL/J	$H2^b/H2^u$	Resistant (25% affected)	Melvold (personal comm.)

Immune response differences exist between strains in terms of immunodominant TMEV epitopes. For example, resistant C57BL/6 mice show stronger T proliferative responses to TMEV capsid proteins VP1 and VP3, while susceptible SJL mice proliferative more strongly to VP2 (43). In DTH assays, the two strains react equally to VP1 and VP3, but SJL shows a slightly stronger reactivity to VP2. No pattern of epitope specificity has been found, however, that is consistent across a variety of resistant and susceptible strains or H2 haplotypes.

Several specific loci have been shown to influence the development of demyelinating disease following TMEV infection. In addition, associations between disease and specific DNA polymorphisms have identified several chromosomal segments as containing loci influencing disease. The loci and chromosomal segments affecting TMEV persistence or actual susceptibility to TMEV-induced demyelination are enumerated in Table 3. Lipton and Melvold (40) initially identified the involvement of both *H2* and non-*H2*

genes. Numerous additional investigations (44-47) have demonstrated that major histocompatibility complex (MHC) genes are frequently of major effect in the differential susceptibility of inbred mouse strains to TMEV-IDD. Subsequent studies in several laboratories, utilizing different resistant-susceptible strain combinations, mapped the primary *H2* contribution to the class I *H2-D* locus (42, 48-50). β2-microglobulin deficient mice that are unable to express class I MHC molecules, and thus lack $CD8^+$ T cells, displayed an increased susceptibility (51-54). The importance of the MHC in the TMEV model is similar to human MS where statistical association of particular HLA genes with disease has been frequently reported (3, 7, 9, 25, 26).

Naturally existing polymorphisms at *H2-D* are usually important, with $H2\text{-}D^b$ usually associated with resistance, and $H2\text{-}D^{s,q,p,u,z}$ alleles associated with susceptibility. The $H2\text{-}D^d$ and $H2\text{-}D^k$ alleles are found in both susceptible and resistant strains, illustrating the joint effects of both *H2* and non-*H2* genomes. Utilization of strains carrying mutated or transgenic *H2-D* alleles confirmed the importance of this locus. Mutations of either the α1 or α2 domain of the $H2\text{-}D^d$ allele (49) or the $H2\text{-}D^b$ allele (42, 55) in resistant mice resulted in a change to the susceptible phenotype. Transgenic insertion of *H2-D* alleles associated with resistance into normally susceptible mice resulted in resistance (56-57). The importance of this *H2* class I locus suggests that H2-D restricted $CD8^+$ T cells have an important role in determining whether or not disease ensues after TMEV infection. $CD8^+$ cytotoxic T cells generated in TMEV-infected animals are directed preferentially against H2-D-restricted capsid proteins (58-61), although their precise role in pathogenesis or protection is yet unclear. At one week post-infection, the CNS of resistant mice contained TMEV-specific CTLs that were only H2-D restricted, although both H2-D and H2-K restricted TMEV-specific CTLs were present in the spleen (58). Susceptible strains had no TMEV-specific CTLs in the CNS during this same time period (58).

The importance of MHC genes in differential susceptibility to TMEV-induced demyelination (40, 42, 44-50), as well as their statistical association with the risk of multiple sclerosis in human populations (3-9) has led to experiments in which human HLA genes are inserted into mice to assess their effect on the development of demyelinating disease. This approach has led to insights in many disease models (62). Rodriguez and David (63) inserted the human HLA-B27 gene into susceptible B10.D2-$H2^{dm1}$ mice, and found that mice carrying the transgene exhibited less demyelination and lower expression of TMEV antigen than did non-transgenic controls. In

later experiments, mice lacking β2m and intrinsic class II gene expression were transfected with human DQ6 or DQ8 genes (64). While both types of transgenic mice exhibited similar levels of demyelination by 120 days post-infection, those with DQ8 developed demyelinated lesions more rapidly than did those with DQ6 (64).

Non-*H2* loci are also important in determining resistance or susceptibility (Table 3), as is readily apparent from comparing resistant BALB/cByJ and susceptible DBA/2J mice, both carrying $H2^d$. Utilizing various strain combinations, effects on susceptibility have been mapped to *Theiler's murine encephalomyelitis virus demyelination-1* (*Tmevd-1*) on chromosome 6 (38, 39, 47), *Tmevd-2* on chromosome 3 (65), *Tmevd-3* and *Tmevd-4* on chromosome 14 (66) and *Tmevd-5* on chromosome 11 (67). Several loci affecting TMEV persistence (e.g., *Tmevp-1*, *-2*, *-3* and *–pg1*) have also been identified (68-73), several of them on chromosome 10. Loci (*Tmevd-6*, *-7*, -*8*, *-9*) have recently been identified on chromosomes 1, 5 and 15 (74) that affect the severity of clinical signs. Differences between resistant B6 and susceptible SJL mice that affect the persistence of TMEV have been mapped to chromosomes 10 and 18, near the *Ifg* (*interferon-γ*) and *Mbp* (*myelin basic protein*) loci, (69, 70). A number of additional unnamed loci have been identified as well (see Table 3).

Rodriguez *et al* (75, 76) assessed the effects of deletions (50 - 70%) of T cell receptor Vβ genes, finding that intermediately susceptible B10.RIII mice (70% of Vβ genes deleted) had increased demyelination and viral loads. However, no other effects of deletion were found in normally resistant or susceptible animals. Bahk *et al* (77) found associations between susceptibility and particular VβCβ polymorphisms. The involvement of chromosomal regions near or including T cell receptor genes is paralleled in humans by observations that some Vα and Vβ alleles are not randomly represented in MS patients (78-81). Even such closely related strains as C57BL/6, C57BL/10 and C57L (all $H2^b$) have differences in non-*H2* genes affecting susceptibility evident in hybrid progeny produced by crossing these three strains with susceptible strains (35). For example, (D2 x B10.D2) F1 hybrids are more susceptible than (D2 x B6.C-H-2^d)F1 hybrids (Melvold, personal communication).

Table 3. Specific Loci/Chromosomal Segments Affecting Susceptibility

Locus	Chromosome	Effect	References
MHC			
H2 (entire complex)	17	Affects susceptibility	40, 42, 44-47
H2-D	17	Affects susceptibility	42, 44, 48-50
Non-MHC			
Tmevd-1	6 (near TCRβ)	Affects susceptibility	38
Tmevd-2	3 (near *Car-2*)	Affects susceptibility	65
Tmevd-3	14	Affects susceptibility	66
Tmevd-4	14	Affects susceptibility	66
Tmevd-5	11	Affects susceptibility	67
Tmevd-6	1	Affects severity of symptoms	74
Tmevd-7	5	Affects severity of symptoms	74
Tmevd-8	15	Affects severity of symptoms	74
Tmevd-9	1	Affects severity of symptoms	74
Tmevp-1	unknown	Affects TMEV persistence	68
Tmevp-2	10	Affects TMEV persistence	69-71
Tmevp-3	10	Affects TMEV persistence	71-73
Tmevpg1	10	Affects TMEV persistence	73
Tcrβ	6	Deletions/polymorphisms affect susceptibility	75-77
Eae3	3 (near *Tmevd-2*)	Affects susceptibility	34
shiverer	18	Affects susceptibility	82
Unnamed	18	Affects TMEV persistence	70
Unnamed	multiple loci	Expressed in non-hematopoietic tissues	72
Unnamed	??	Differs among SWR, C57BL/6 and C57 strains	35
UDP-galactose transporter	11	Required for entry of TMEV into mammalian cells	83

Comparisons between susceptible DBA/2J and resistant BALB/cByJ mice have implicated the same region of chromosome 3 as *Tmevd-2* and suggest the possibility that *Tmevd-2* may be identical (or very near) to *Eae3*,

a gene governing susceptibility to EAE (experimental autoimmune encephalomyelitis), an autoimmune model for MS (34). Interestingly, a region of human chromosome 5 that is homologous to the region of mouse chromosome 15 containing *Eae2* has been implicated in risk of MS (27).

Additional comparisons employing different combinations of susceptible and resistant strains indicate that the relevant differential loci vary from one combination to another. For example, the differences between susceptible DBA/2 and resistant C57BL/6 mice map to both the *H2-D* and *Tmevd-2* loci (65) while differences between resistant BALB/c and susceptible SJL mice are attributable jointly to *H2-D* and *Tmevd-1* (38, 39, 47). Interestingly, the *H2* complex is not always involved. Comparisons between resistant B6 and susceptible SWR mice indicate that susceptibility is due to a single non-*H2* locus other than *Tmevd-1* and *Tmevd-2*, while differences between C57L and SWR are strongly affected by *H2*, as well as non-*H2*, genes (35). Thus, the genetic basis for susceptibility or resistance to TMEV-IDD disease is a complex, multigenic one.

The genetically determined susceptible/resistant status of mice is not, however, immutable. Several resistant strains become susceptible if treated with various immunopotentiating agents prior to infection with TMEV. Normally resistant B6D2F1 hybrids become susceptible if treated with either low dose (2 - 20 mg/kg body weight) cyclophosphamide or low dose irradiation (50 - 300 rads) prior to infection (32, 33). C57BL10 and BALB/cByJ mice become susceptible if given low dose (200 - 300 rads) irradiation shortly prior to infection (28, 84-86). Thus exposure to such agents can reverse the intrinsic genetic "programming" of resistant animals, apparently by killing or inhibiting TMEV-specific $CD8^+$ and/or other regulatory T cells that can inhibit the inflammatory demyelination (85, 86). It should be noted that comparable treatments of normally susceptible animals do not have substantive effects on the severity of disease (28, 32, 33). However, Pullen *et al* (87) demonstrated that normally resistant C57BL/6 mice became susceptible if given LPS prior to infection, possibly due to alterations the innate immune response during infection. The difference between the *H2*-identical susceptible BALB/cAnNCr and resistant BALB/cByJ substrains is consistent with a single unmapped locus (28), and appears to be due to the lack of a $CD4^+$ T cell subset required for activation of $CD8^+$ T cells capable of preventing the development of inflammatory demyelination (88). These results are similar to those reported in EAE by Lando *et al* (36, 89). The differences between various immunopotentiating agents in their ability to convert specific resistant strains suggests that the genetic basis for resistance may differ among those

resistant strains. Thus the risk for an animal to develop demyelinating disease, whether induced by autoimmunity or by infection, involves at least three elements: (a) exposure to infection by TMEV, (b) genotype and (c) exposure to agents which can modulate the effects of genotype.

Utilization of mice bearing deleted or inactivated molecules suspected to be involved in the disease process has provided additional insight into the mechanisms regulating TMEV-IDD (Table 4). Deletions affecting expression of either MHC class I or class II molecules are associated with an increase in susceptibility. Loss of MHC expression in resistant animals , due to an absence of β2-microglobulin, inhibits $CD8^{+}$ T cell function and is associated with development of TMEV-induced demyelination (51-53). In strains that are already susceptible, this leads to exacerbation of clinical signs (54). Similarly, loss of MHC class II molecules leads to early phase neurological disease, although the pathogenesis may be different. The loss of class II molecules inhibits $CD4^{+}$ T cell function in generating both cellular and antibody responses and may eliminate much of the animal's ability to resist the infection altogether, leading to a viral encephalitis (90, 91). The loss of IFN-α and IFN-β receptors from normal resistant FVB mice led to a rapid infection and death due to loss of neural tissue after TMEV infection. Those who carried deletions of the IFN-γ receptor developed a late phase disease with demyelination (92).

Table 4. Loci Involved in Functions Pertinent to TMEV-IDD

Locus	Function	Reference
Beta-2-microglobulin	Loss results in non-expression of MHC I molecules	51-54
MHC class II	Deletion of MHC II genes is associated with susceptibility	90, 91
CD4	Loss leads to TMEV persistence and demyelination	93
Interferon-α, -β, -γ receptors	Deletion causes loss of cytokines associated with viral infection and inflammation	92
L-selectin	Reduced number of $CD8^{+}$ T cells in CNS	94
Perforin	Involved in killing of virally infected cells	95, 96

Normally resistant C57BL/6 mice bearing knock-out mutations of the L-selectin gene, involved in targeting of activated T cells to sites of infection, exhibited diminished CNS infiltration of $CD8^{+}$ T cells following TMEV

infection (94). This diminished infiltration, however, did not appear to inhibit CNS clearance of TMEV. Loss of the perforin gene, utilized by cytotoxic $CD8^+$ T cells to destroy TMEV-infected cells, led to increased viral load and demyelination in otherwise resistant animals (95, 96).

In summary, the genetic influence on the development of TMEV-induced demyelination is an exceedingly complex one similar to the genetic loci influencing susceptibility to MS. Not only are numerous loci, both MHC and non-MHC involved, but the precise combinations of such genes that are present in a particular animal have considerable influence on the outcome. A gene that may promote demyelination in one genetic setting, may promote resistance in another. A major role is clearly evident for loci of the *H2* complex, particularly the *H2-D* class I locus. However, the precise mechanisms by which these genes, and their products and the other genes with which they interact, ultimately produce the resistant or susceptible phenotypes still requires considerable investigation.

Chapter B5

THE ROLE OF T CELLS AND THE INNATE IMMUNE SYSTEM IN THE PATHOGENESIS OF THEILER'S VIRUS DEMYELIATING DISEASE

Julie K. Olson and Stephen D. Miller
Department of Microbiology and Immunology, Northwestern University Feinberg School of Medicine, Chicago, IL

Abstract: The immune response to TMEV involves activation of both the innate and adaptive immune responses. The innate immune response is the initial response by the host to a viral infection. The adaptive immune response follows the initial response and is mediated by $CD8^+$ and $CD4^+$ T cell and antibody responses specific to the viral antigens. CNS pathogenesis in TMEV-IDD is associated with long-term virus persistence in CNS-resident microglia and macrophages which leads to the activation of a virus-specific $CD4^+$ Th1 response. Myelin destruction is initiated by the bystander effector functions of CNS-resident mononuclear cells which are activated both directly by the innate immune response to persistent TMEV infection and indirectly by pro-inflammatory cytokines released by virus-specific Th1 cells. Initial myelin destruction leads to the release of myelin antigens and the subsequent activation of myelin epitope-specific autoreactive $CD4^+$ Th1 cells via epitope spreading which are largely responsible for chronic disease progression.

Key words: Theiler's murine encephalomyelitis virus (TMEV), demyelinating disease, multiple sclerosis, epitope spreading, molecular mimicry

1. Introduction

Theiler's murine encephalomyelitis virus (TMEV) infection triggers a two-step immune response directed towards the virus. The initial response is the innate immune response that occurs immediately following virus infection which is geared to control the early stages of virus replication. The second response is the adaptive or virus-specific immune response that arises with a few days and which is necessary to clear the virus infection from mouse strains which are resistant to induction of TMEV-induced demyelinating disease (TMEV-IDD). In susceptible mouse strains, however, virus is not cleared from the mouse resulting in a persistent infection of central nervous system (CNS) mononuclear cells including resident microglia and infiltrating peripheral macrophages. CNS viral persistence leads to a cascade of events in which pro-inflammatory cytokines released from virus-specific $CD4^+$ T cells cause initial macrophage-mediated myelin tissue damage, release of endogenous myelin antigens, and eventual activation of myelin epitope-specific autoreactive $CD4^+$ T cells via the process of *epitope spreading*. Thus, adaptive immune responses to both viral and self epitopes appear to be involved in the chronic-progressive pathogenesis of TMEV-IDD.

This chapter will begin with discussion of the distinct roles of TMEV-specific $CD4^+$ and $CD8^+$ T cell responses in both virus clearance and the initiation of CNS pathology. Secondly, the role of myelin-specific autoreactive $CD4^+$ T cells in chronic progressive disease will be discussed. Finally, the innate immune response to TMEV will be discussed in relation to the activation of persistently infected CNS mononuclear cells and their role as effector cells in axonal demyelination and as antigen presenting cells in CNS activation of both virus-specific and autoreactive T cells.

2. Role of virus-specific T cell responses in disease resistance/ susceptibility

Susceptibility to TMEV-induced demyelinating disease has been associated with the $CD8^+$ T cell response by the finding that resistance/susceptibility is linked to the H2-D locus of MHC class I gene (1-4). A potent $CD8^+$ T cell response has been shown to mediate viral clearance in genetically resistant mice and a weak anti-TMEV CTL response and inability to clear the infection is associated with CNS viral persistence and subsequent demyelinating disease in susceptible mouse strains. Virus persistence in the CNS is associated with the later development of the

myelin-specific autoimmune responses leading to the chronic phase of disease in these mice. Mutations in the H-2D MHC class I locus of resistant mice leads to viral persistence and development of demyelinating lesions in these mice (5). CD8$^+$ T cell depletion in the resistant strains confers virus persistence and demyelination while CD8$^+$ T cell depletion in susceptible strains does not alter demyelination (6-9). TMEV infection of β2-microglobulin (β2M)-deficient mice, which lack expression of MHC class I expression and thus lack functional CD8$^+$ T cells, further demonstrates the critical role of CD8$^+$ T cells in disease resistance. Infection of β2M-deficient mice on the resistant C57BL/6 background resulted in the development of pathologic signs of demyelinating disease, while infection of β2M-deficient mice on the susceptible SJL background resulted in enhanced demyelination, earlier onset of disease and increased levels of persistence virus in the CNS (10,11). Further, adoptive transfer of CD8$^+$ T cells from TMEV-infected resistant mice into susceptible mice protected them from demyelinating disease following TMEV infection (12). Recent studies have identified the H-2D restricted epitopes from the TMEV capsid proteins that are recognized by CD8$^+$ T cells in TMEV infected resistant mice (13). Likewise, functional CD8$^+$ T cells specific for viral epitopes have been isolated from the CNS of infected susceptible SJL mice in which the epitopes are H-2K restricted (14). Therefore, the TMEV-specific CD8$^+$ T cells are activated following infection in both susceptible and resistant mice strains, however, the susceptible mice do not have the H-2D restricted response that has been linked to efficient viral clearance from the CNS.

In contrast to virus-specific CD8$^+$ T cell responses which are associated with disease resistance, susceptibility to TMEV-IDD is correlated with a strong CD4$^+$ T cell response to viral antigens. TMEV-IDD is a CD4$^+$ T cell dependent disease as demonstrated by numerous observations. Depletion of CD4$^+$ T cells in SJL/J mice infected with TMEV dramatically decreased disease incidence and delayed onset of demyelinating disease while a similar depletion of CD8$^+$ T cells did not lead to a decrease in demyelinating disease (6-8). The MHC class II-restricted CD4$^+$ T cell response can be recognized in infected mice by high level delayed type hypersensitivity (DTH) responses to viral antigens beginning at 7-10 days post-infection and continuing throughout the late chronic phase of disease (1,15). Mice resistant to TMEV-IDD develop a low level DTH response to viral antigens, but develop similar virus-specific T cell proliferative responses and serum antibody levels as susceptible mice (16). The immunodominant CD4$^+$ T cell determinant in the susceptible SJL/J mice has been mapped to the TMEV VP2 capsid protein, specifically VP2 70-86 (17). Systemic transfer of VP2

70-86 specific CD4+ Th1 cells into SJL/J mice infected with a suboptimal dose of TMEV increased the incidence and severity of demyelinating disease (6). Thus, VP2 74-86 specific CD4+ T cells have functional immunopathologic potential in virus infected mice. Minor CD4+ T cell epitopes have also been identified on other TMEV capsid proteins, VP1 (VP1 233-250) and VP3 (VP3 24-37) (18,19) and may also contribute to the immune-mediated demyelination.

TMEV-IDD is initiated by TMEV-specific CD4+ T cells which respond to persistent virus in the CNS (Figure 1). TMEV-specific CD4+ T cell

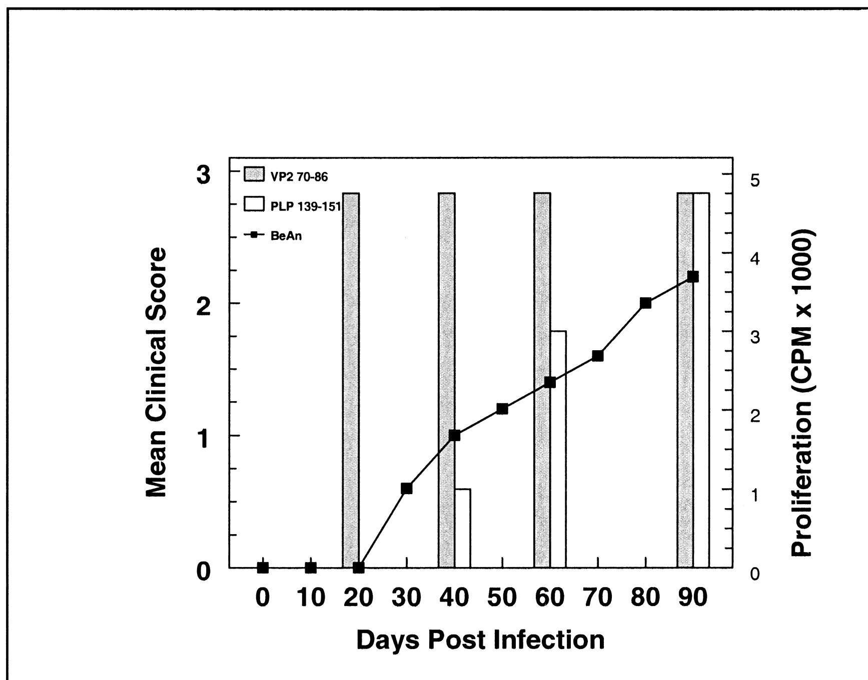

Figure 1. Temporal development of TMEV-IDD clinical disease and CD4+ T cell responses. SJL/J mice infected with BeAn strain of TMEV develop a chronic progressive demyelinating disease associated with clinical signs (line graph). CD4+ T cell responses to viral antigen (VP2 70-86) and myelin antigen (PLP139-151) were assayed from infected mice at various times following infection by splenic proliferation assays (bar graph).

responses are detected within 4-5 days following infection and persist for at least six months, while T cell responses to myelin basic protein (MBP) and proteolipid protein (PLP) are not detected until 50-60 days post infection which is after disease onset which typically occurs 30-40 days post-infection (20,21). Proof of the critical pathologic role for TMEV-specific CD4+ T

cells in *initiation* of demyelination is demonstrated by the observation that tolerance induced by intact TMEV virions coupled to syngeneic splenocytes prior to or shortly after virus infection, which specifically anergizes virus-specific Th1 responses (22,23), results in a dramatic reduction in the incidence and severity of demyelinating lesions and clinical disease in SJL/J mice subsequently infected with TMEV (24). Tolerance specifically reduced the virus-specific $CD4^+$ Th1 response in the mice and reduced the number of $CD4^+$ T cells infiltrating the CNS (24). Thus, the virus-specific $CD4^+$ T cells appear to play contrasting roles by contributing to virus clearance by serving as helper cells for virus-specific $CD8^+$ CTLs and B cells, but also by contributing to the initiation of demyelinating disease.

3. Role of myelin-specific T cell responses in TMEV-IDD

Neuroantigen-specific T cells do not play a significant role in disease initiation. As described previously, although responses to TMEV epitopes arise within 4-5 days post-infection, MBP and PLP responses are not detected prior to disease onset (30-40 days PI) (20,25) and induction of peripheral tolerance to mouse spinal cord homogenate (MSCH - a heterogeneous mixture of multiple neuroantigens) 7-14 days prior to TMEV infection fails to affect the initiation of TMEV-IDD and the accompanying virus-specific T cell and antibody responses (26). However, this tolerogenic regimen is extremely effective in preventing clinical and histologic signs of MSCH-induced relapsing EAE (R-EAE) and the accompanying neuroantigen-specific DTH responses (26,27). In addition, there appears to be no cross-reactivity between $CD4^+$ T cells specific for the immunodominant TMEV epitopes and myelin proteins indicating that the wildtype BeAn strain of TMEV contains no epitopes which *mimic* the immunodominant myelin epitopes in the SJL mouse (28).

Although myelin-specific responses appear to not be involved in disease initiation, they play an important role in the chronic stages of the disease process. Approximately 45-55 days post-infection (2-3 weeks after the onset of clinical disease), when myelin damage reaches a critical threshold, $CD4^+$ T cell responses to the immunodominant myelin PLP139-151 epitope appear (28), and as disease progresses T cell responses to multiple additional encephalitogenic myelin epitopes (*e.g.*, PLP56-70, MOG92-106, PLP178-191, and MBP84-104) arise in an ordered progression (21,28). Following i.c. infection with the wildtype BeAn strain of TMEV, anti-myelin epitope responses arise via epitope spreading as indicated by the late appearance of

anti-myelin T cells and lack of cross-reactivity between T cells specific for TMEV epitopes and myelin proteins and peptides and vice versa (28). Thus, epitope spreading appears to play a role in progression of TMEV-IDD similar to the roles we have described that intermolecular and intramolecular epitope spreading play in mediating relapses in two different models of myelin peptide-induced relapsing EAE (R-EAE) in the SJL mouse (29,30).

Relevant to the pathologic role of these autoreactive T cells, recent evidence has shown that PLP139-151-specific T cells can be found in the CNS of mice with chronic TMEV-IDD at 65 days post-infection(31) and that these autoreactive T cells can demyelinate *in vitro* organotypic CNS cultures (32). More importantly, we have reported that induction of peripheral tolerance to MP4 (a recombinant fusion protein comprising the 21.5 kD isoform of human MBP and a recombinant variant of human PLP) at 45 days post-infection attenuated disease progression and decreased demyelination and inflammatory cell infiltration in the CNS (31). In addition, antigen presenting cells isolated from the CNS of infected mice present myelin epitopes to myelin-specific $CD4^+$ T cells *in vitro* (33). Thus, autoreactive $CD4^+$ T cell responses to myelin epitopes develop only after clinical signs of demyelinating disease are evident, however these responses play a major pathologic role in mediating chronic progression of the disease (Figure 1). Collectively, these results are consistent with a model (Figure 2) wherein virus-specific $CD4^+$ Th1 cells responding to the persistent virus infection of CNS APCs secrete pro-inflammatory cytokines that recruit and activate mononuclear inflammatory cells that initiate myelin damage in the CNS (34). The damaged myelin is then processed and presented by CNS APCs and infiltrating macrophages to infiltrating autoreactive $CD4^+$ T cells which then secrete pro-inflammatory cytokines to perpetuate the chronic pathologic process. The epitope spreading hypothesis is also supported by observations that CNS APCs isolated from TMEV-infected mice 60-90 days post-infection endogenously present both virus and multiple myelin antigens to specific $CD4^+$ T cell lines, whereas CNS APCs isolated at 40 days post-infection endogenously present virus, but not myelin antigens (33). Thus, epitope spreading is the primary mechanism for initiation of the autoimmune response in TMEV-IDD (28).

4. TMEV-IDD Model of Molecular Mimicry

As described above, myelin-specific autoreactive $CD4^+$ T cell responses in TMEV-IDD are initiated by epitope spreading; however, autoimmune

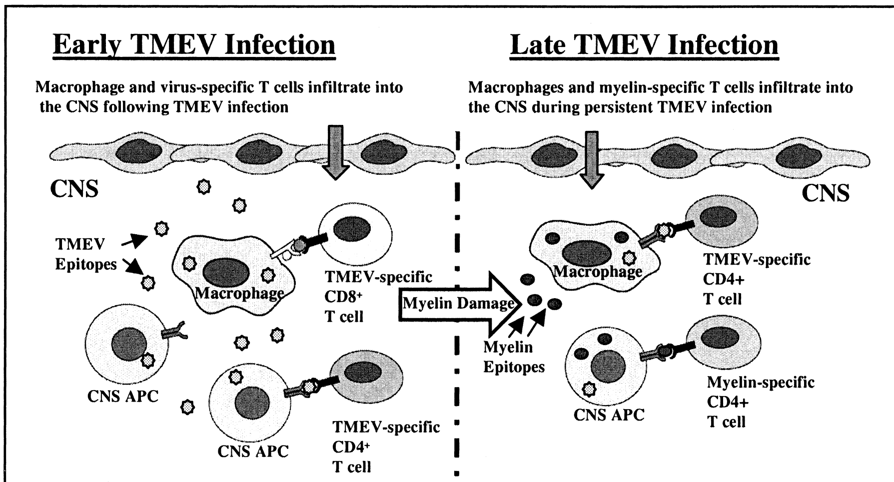

Figure 2. Model of Initiation and Progression of TMEV-Induced Demyelinating Disease. Infection of susceptible SJL/J mice leads to an inefficient $CD8^+$ CTL response resulting in virus persistence in the CNS. TMEV-specific $CD4^+$ T cells then infiltrate the CNS and release pro-inflammatory cytokines, promoting infiltration and activation of peripheral macrophages and CNS-resident APCs (microglia and astrocytes) which cause bystander myelin damage. Via the process of epitope spreading, myelin debris is then phagocytized and processed by microglia/macrophages and endogenous myelin epitopes are presented to myelin-specific autoreactive T cells which play the predominant role in chronic immunopathology..

responses can also be initiated by molecular mimicry during infection. Molecular mimicry is the activation of cross-reactive T cells during a virus infection which recognize both a viral epitope and a self epitope due to sequence homology. We have recently provided conclusive evidence that $CD4^+$ T cell-mediated molecular mimicry can be initiated following virus infection. A nonpathogenic mutant of TMEV was used to construct a model to test the ability of a virus to encode a self sequence and initiate autoimmunity by molecular mimicry (35). Infection of SJL/J mice with a recombinant TMEV containing the immunodominant PLP139-151 epitope resulted in a rapid-onset, severe demyelinating disease mediated specifically by PLP139-151 specific $CD4^+$ Th1 cells (35). The pathologic role of autoreactive T cells in mediating the early-onset demyelinating disease was demonstrated by the findings that tolerance induced with PLP139-151-coupled splenocytes prior to infection protected SJL mice from disease development and serial transfer of PLP139-151 specific $CD4^+$ T cells from infected mice to a naïve recipient resulted in induction of demyelinating disease (36). More relevant to proof of autoimmunity via molecular mimicry, infection of mice with recombinant TMEV containing a mimic PLP139-151 sequence derived from the protease IV gene of *Haemophilus*

influenzae resulted in an early onset demyelination concomitant with induction of $CD4^+$ T cell responses cross-reactive with PLP139-151 (35). Therefore, although infection with wildtype TMEV does not result in induction of autoimmunity via molecular mimicry, the virus provides the structure and specificity to facilitate study of a molecular mimicry model of virus-induced demyelinating disease.

5. Innate Immune Response Induced by TMEV Infection

The innate immune response occurs immediately following infection in response to pathogen-associated molecular patterns (PAMPs) integral to the pathogen, such as double-stranded RNA (dsRNA) derived from virus infection, lipopolysaccharide (LPS) from gram negative bacteria and peptidoglycan from gram positive bacteria. These molecular patterns are recognized by Toll like receptors (TLRs) which are a class of innate immune receptors identified in humans and mice. At least ten TLRs have been described in humans (37) and all require MyD88 in their signaling that leads to the activation of NF_kB resulting in expression of multiple innate immune cytokines, including type I interferons (IFN-α and IFN-β), IL-1, IL-12, TNF-α, *etc.* In virus infections, type I interferons are produced in response to dsRNA (38) which is commonly found in the replication cycles of multiple viruses, including TMEV, but which is not found in mammalian cells (39). The cellular response to dsRNA is dependent on the dsRNA-activated protein kinase R (PKR), a dormant enzyme directly activated by binding of dsRNA which leads, via the activation of NFκB, to the production of type I IFNs (40). In turn, type I IFN signaling takes place through an IFN receptor complex consisting of two alpha chains (type I IFN receptor) complexed with Jak1 and Tyk2. These kinases phosphorylate Stat1 and Stat2 respectively eventually leading to upregulation of MHC class I and II and many other downstream effects (41). A recent study has also reported that TLR3 binds dsRNA suggesting a TLR pathway for virus recognition by the innate immune response (42).

Relevant to the chronic-progressive pathogenesis of TMEV-IDD, we have shown that naïve microglia could be persistently infected with TMEV *in vitro* (43). Significantly, these infected microglia were activated to upregulate expression of cytokines involved in innate immunity (TNF-α, IL-6, IL-18 and, most importantly, type I interferons) along with upregulation of MHC class I and II, IL-12, various co-stimulatory molecules (B7-1, B7-2, CD40 and ICAM-1) and chemokines (MCP-1 and MIP-1α). Most significantly, TMEV-infected microglia were able to efficiently process and

present both endogenous virus epitopes and exogenous myelin epitopes to inflammatory $CD4^+$ Th1 cells whereas microglia exposed to UV-inactivated TMEV remained inefficient APCs. Thus, productive TMEV infection of microglia activates these cells to initiate an innate immune response which may lead to the activation of naïve and memory virus- and myelin-specific adaptive immune responses within the CNS and, in addition, causes them to elaborate pro-inflammatory molecules (e.g. iNOS and TNF-α) involved in myelin destruction. Collectively, these results suggest that astrocytes, activated microglia, and CNS-infiltrating macrophages (Figure 2), exposed to the pro-inflammatory cytokine environment encountered during immune-mediated TMEV demyelination and/or upon direct infection with TMEV have the potential of stimulating both activated (involved in initiation of disease) and naive (possibly involved in epitope spreading) virus/myelin-specific T cells which gain access to the CNS.

6. Conclusions

The immune response following TMEV infection of genetically susceptible mouse strains leading to chronic immune-mediated demyelination is a complex and multi-step process involving activation of innate immune signals within persistently infected CNS-resident APCs, $CD4^+$ and $CD8^+$ anti-viral T cells, and autoreactive myelin-specific $CD4^+$ T cells. Myelin destruction is initiated by virus-specific $CD4^+$ T cells responding to persistent virus infection resulting in the release of pro-inflammatory chemokines and cytokines which activate CNS-resident mononuclear to cause bystander myelin destruction. Subsequent release of myelin antigens into the inflammatory environment leads to epitope spreading and the activation of myelin-specific $CD4^+$ T cells that continue to perpetuate the chronic demyelinating process.

Abstract: Cytokines, chemokines and adhesion molecules play pivotal roles in the initiation and progression of TMEV-induced demyelinating disease. Furthermore, the same cytokines, chemokines and adhesion molecules are also important in induction of protective immune responses that are necessary to eliminate persistent viral infection. Thus, the type, level and timing of the initial responses of cytokines, chemokines and adhesion molecules upon viral infection, as well as consequent immune responses, will likely determine the pathogenic or protective outcome. The previous trials to intervene the development and progression of disease have been focused on the inflammatory Th1 responses. However, recent studies have indicated that these molecules induced directly by viral infection are important in clearing viral persistence and shaping adaptive immune responses. Therefore, investigations to block the initiation of the inflammatory responses, as the early events of cellular infiltration to CNS and cytokines/chemokines involved will be very valuable.

Key words: Chemokines, Cytokines, TMEV, Astrocyte, Microglia, Oligodendrocyte

Intracerebral infection of susceptible strains of mice with Theiler's murine encephalomyelitis virus (TMEV) leads to a chronic immune-mediated demyelinating disease of the central nervous system (CNS) that is very similar to human multiple sclerosis (MS). There are two subgroups of TMEV; the first group, which includes the GDVII and FA viruses, causes a rapid fatal encephalitis. The BeAn and DA viruses belong to the second subgroup, and cause a biphasic neurological disease in susceptible mice such as SJL/J (1). However, the clinical and histopathological symptoms of BeAn and DA differ in the acute phase of disease. Infection with the DA strain leads to an acute polioencephalitis in the gray matter causing flaccid limb

paralysis and neuron degeneration followed by chronic viral persistence in the white matter of the spinal cord leading to demyelination. The BeAn strain, on the other hand, is characterized by a clinically undetectable acute phase followed by a very similar chronic phase and demyelination in the white matter. Thus, the TMEV strain used in the experiments may affect the experimental outcome and consequent interpretations.

Demyelination in the white matter leading to clinical symptoms is associated primarily with cell-mediated immune responses, in particular inflammatory Th1 responses to both viral and autoantigens (2, 3). However, the role of cytotoxic T cells in pathogenesis of demyelination is not yet clear, although this cell population appears to be important for clearing viral persistence resulting in the protection from TMEV-induced demyelinating disease. The major $CD4^+$ and $CD8^+$ T cell epitopes of TMEV in resistant and susceptible mice have recently been determined; therefore studying the anti-viral immune response in the CNS is now feasible (2, 4, 5). Early studies with cytokines have mainly been focused on defining the Th types. Analysis of cytokines, chemokines and adhesion molecules involved in TMEV-induced demyelinating disease is quite complex since these molecules are produced by not only various activated immune cells but also many different CNS resident glial cells directly upon viral infection.

1. CYTOKINES

Due to the inflammatory nature of the immune response to TMEV, the cytokines produced by resident CNS cells and infiltrating immune cells are likely to play a key role in the pathogenesis of TMEV. TMEV-induced demyelinating disease (TMEV-IDD) appears to be mediated by $CD4^+$ T cells that gain access to the CNS after viral infection. The T cells that are found within demyelinating lesions of the CNS preferentially produce IFN-γ (5, 6), therefore the initial establishment of a T helper type 1 (Th1) response may be critical for the pathogenesis of TMEV. While the pathogenic role of $CD4^+$ T cells is well accepted, the role of $CD8^+$ T cells is controversial. However, it is conceivable that virus specific $CD8^+$ T cells are critical for viral clearance, as well as pathogenesis via IFN-γ production (5). A fine line of balance of various cytokines produced by glial cells, antigen presenting cells (APC), natural killer (NK) cells, as well as helper T cells and $CD8^+$ T cells, may contribute to protection or pathogenesis. Due to the inflammatory nature of immune responses in the CNS following infection with TMEV, the majority of the previous studies have focused on the cytokines associated with Th1 and/or Th2 responses.

1.1 Cytokines in the CNS following viral infection

Many studies have examined the production of various cytokines throughout the course of TMEV-IDD. Susceptible SJL/J mice demonstrate an early production of the inflammatory cytokines, Interferon (IFN)-γ, tumor necrosis factor (TNF)-α, and also the anti-inflammatory cytokines IL-10 and IL-4 within the CNS of infected mice during the preclinical phase of disease following viral infection, and these levels continue to rise into the chronic phase of disease (7, 8). Attempts have been made to determine the order of cytokine production in the CNS following viral infection and the results somewhat vary, i.e. Th1 associated cytokine production precedes Th2 associated cytokines in some studies (7, 9) and virtually the same time by others (8). Both resistant C57BL/6 and susceptible SJL/J mice show an early production of IFN-γ, IL-1, IL-6, IL-12 and TNF-α (10, 11). However, SJL/J mice show greater levels of these cytokines, particularly tumor growth factor (TGF)-β (11). It has been postulated that this increase in TGF-β may be responsible for the insufficient anti-viral immune response in SJL/J mice. Cytokine secretion during the acute phase is sustained during the chronic phase of disease in SJL/J mice. C57BL/6 mice, on the other hand, show very little cytokine secretion in the CNS at this late time point (10, 11). These studies indicate the importance of individual cytokines on the development and progression of disease. However, the cellular origin of the cytokines in these studies has not been elucidated and may reflect the level of many different inflammatory responses, in addition to the Th responses.

1.2 Cell types involved in cytokine production

The earlier studies have heavily emphasized on cytokine production by T cells. Due to the difficulties in isolating T cell population from the CNS, peripheral T cells specific for viral epitopes have frequently been analyzed. These early studies indicated that virus-specific T cells predominantly produce IFN-γ, a potent proinflammatory cytokine. Recent advancements in cytokine detection with small numbers of antigen-specific T cells utilizing ELISPOT and intracellular cytokine staining accompanied by flow cytometric analysis, have permitted to assess cytokine production by various infiltrating T cell populations. Again, the majority of virus-reactive T cells, including Th and CTL produce proinflammatory cytokines, like IFN-γ and TNF-α, although some subpopulations produce anti-inflammatory cytokines such as IL-4/IL-5 and/or IL-10 ((5, 6), Lyman and Kim, unpublished data).

Previous studies have indicated that the main reservoir of viral replication is microglia/macrophages in the CNS and depletion of macrophages protect mice from TMEV-IDD. Our initial studies indicate that the majority (>50%)

of microglias in the CNS of TMEV-infected SJL/J mice produce TNF-α, compared to a minor population (<5%) of macrophages (Mohindru and Kim, unpublished data). Infection of other glial cells (e.g. astrocytes, oligodendrocytes) within the CNS is also crucial for viral persistence. However, isolation and maintenance of these glial cells from infected adult mice are rather difficult.

Consequently, astrocytes, oligodendrocytes and microglia derived from neonatal mice have been utilized to investigate whether virus infection of these cell types directly induces the production of chemokines, cytokines and other surface and secreted molecules. Early studies using cultured murine astrocytes illustrated TNF-α production following TMEV infection (12). Recent studies with isolated glial cells, astrocytes in particular, indicate that the expression of various proinflammatory cytokine genes (e.g. IL-12, IL-6, TNFα, IL-1, IFNβ) is directly induced by TMEV infection via the NFκB pathway (Palma and Kim, unpublished). The cytokine induction in astrocyte cultures following TMEV infection has been further extended by using pathogenic and low-pathogenic viruses (13). This study shows that key proinflammatory cytokines, such as IL-12 and IL-1, are vigorously induced by the pathogenic virus, whereas much reduced levels by low-pathogenic virus. In addition, TMEV infection similarly induces the upregulation of several pro-inflammatory cytokines and molecules in isolated microglia cultures. Among these molecules are TNF-α, IL-6, IL-18, type I IFNs, and IL-12 (14).

In addition to the glial cells, it is possible that TMEV infection may also induce proinflammatory cytokines in professional antigen presenting cells, which critically affect the initial commitment of Th1/Th2 differentiation (13). Infection of isolated dendritic cells and macrophages with TMEV results in preferential upregulation of IL-12 production over IL-10, suggesting the importance of cytokines directly induced by TMEV infection in subsequent inflammatory immune responses.

1.3 Effects of manipulation of cytokine levels

In order to study the role of cytokines in the progression of demyelinating disease, the effects of these cytokines on the development of disease have been extensively investigated following the neutralization or overexpression of the key cytokines. Since TMEV-induced demyelinating disease is considered as an immune-mediated inflammatory disease, most of the early studies have focused on either inhibiting inflammatory cytokines or enhancing anti-inflammatory cytokine production (15).

IL-12 secreted by antigen presenting cells is critical in the Th1 commitment by naïve Th cells. By neutralizing IL-12 using a monoclonal

antibody (mAb), the immune response to TMEV and the disease progression have been studied in the absence of an effective Th1 response, which has been determined to be critical for the pathogenesis of TMEV-IDD. Two separate studies have yielded very different results. The first study showed that the elimination of IL-12 leads to suppression of disease, decrease IFN-γ and TNF-α production with a concomitant increase in the Th2 type cytokines IL-4 and IL-10 (16). The second report indicated that anti-IL-12 mAb treatment had no effect on TMEV-mediated pathology (17). The use of different strain of virus (BeAn and DA respectively), as well as the differences in the timing and dose of mAb treatments may have affected the experimental outcome.

IFN-γ is produced by many different cell types, including NK/NKT, Th as well as cytotoxic T cells and affects the immune system in many different ways. This cytokine is critically important for upregulation of proinflammatory cytokines and chemokines, activation of macrophages and NK cells, as well as molecules involved in cellular trafficking. The production of IFN-γ is drastically upregulated in the CNS following virus infection; therefore it is possible that the elimination of this cytokine may lead to protection from TMEV-IDD. Surprisingly, depletion of IFN-γ by the use of neutralizing mAbs or IFN-γ receptor-deficient mice, lead to an exacerbation of clinical symptoms rather than a protection from disease (18-20). However, intracerebral administration of recombinant IFN-γ also lead to exacerbation of disease (18). A likely explanation is that IFN-γ is necessary to activate microglias/macrophages, CTL and NK cells, that are critical for protective immunity. In the absence of IFN-γ, the initial anti-viral immune response may not be able to effectively clear virus from the CNS hence leading to enhanced disease. On the other hand, an excess amount of IFN-γ may lead to a highly inflammatory environment, which ultimately recruits and promotes more pathogenic Th1 cell responses in the CNS to inflict neurological damage.

TNF-α is another important pro-inflammatory cytokine produced in significant quantities early after viral infection by both lymphocytes and glial cells in the CNS. Both susceptible and resistant mice produce TNF-α, but susceptible mice produce higher levels during both the acute and chronic phases of disease (10, 11, 21). Administration of neutralizing anti-TNF-α mAb to susceptible mice at the time of disease onset suppresses the development of both clinical and histopathological signs of disease (21). In contrast, administration of anti-TNF-α prior to and during the course of infection does not suppress disease (22) and injection of recombinant TNF-α at those time points ameliorates disease. Thus, treatment regimens that differ in timing of administration appear to be critical for the outcome of the cytokine effects. Taken together, TNF-α may also have dual functions:

protective role in the initial stages of viral infection, perhaps by activating innate immunity and pathogenic effects after establishment of viral persistence by promoting inflammatory responses.

2. CHEMOKINES

Chemokines are low molecular weight chemotactic proteins that bind and signal through G protein coupled receptors. In many inflammatory diseases including MS, chemokines play an important role in mediating the infiltration of various inflammatory cells into sites of tissue damage. Much work has been done studying the role of chemokine/chemokine receptor expression in other animal models of MS including experimental autoimmune encephalomyelitis (EAE) and mouse hepatitis virus (MHV)-induced demyelinating disease. However, very little work determining the importance of these molecules in TMEV-IDD has been reported. Viral infection is known to induce various proinflammatory chemokines in many different cell types, which are detected in the inflammation sites induced by different infectious agents. In addition, activation of glial cells by certain chemokines or cytokines also results in further induction of the same or additional chemokines. Since the transmigration of inflammatory cells into the CNS is dependent on chemokines, these molecules are likely involved in the pathogenesis of TMEV-IDD.

Studies using the BeAn strain of TMEV showed early expression of monocyte chemoattractant protein (MCP)-1 (or CCL2), macrophage inflammatory protein (MIP)-1α (CCL3), IFN-γ inducible protein of 10 KDa (IP-10 or CXCL10), regulated on activation, normal T-cell expressed and secreted (RANTES, CCL5), and MIP-1β (CCL4) mRNAs in the CNS but not the periphery after infection with TMEV (23). As early as six days post infection with the DA strain of TMEV, mRNAs for IP-10, RANTES, and MCP-1 were detected in the brains of infected mice (24). There was a resurgence of the same chemokines during the chronic phase of disease and the chemokine gene expression appears to correspond well with viral persistence rather than the level of adaptive T cell responses (25). These chemokines are also found after infection with different TMEV strains, including GDVII and DA displaying different pathogenicity (26).

The above studies of chemokine gene expression *in vivo* strongly suggest the importance of these molecules for inflammatory responses in the CNS during TMEV infection. However, the cell types responsible for chemokine production as well as the sequence of the events are still elusive. Recently, the direct activation levels of chemokine gene expression after viral infection have been examined in various CNS cell cultures (27). Upon infection with

TMEV, the expression of RANTES, IP-10, MCP-1, MIP-1β, MIP-1α, and MIP-2 genes were upregulated in astrocytes, microglia, as well as oligodendrocytes, although the levels were somewhat different depending on the cell types. In whole brain cultures the pattern of chemokine expression is identical to that of astrocytes cultures (27), suggesting the importance of chemokine contribution by infected astrocytes in the CNS. Similar to viral infection, the proinflammatory cytokines, such as IFN-γ and TNF-α, were also able to upregulate the expression of chemokines by astrocytes. These results indicate that the identical chemokines are induced secondarily by stimulation with cytokines that are initially produced by virus-infected resident glial cells, infiltrating antigen producing cells, natural killer cells, as well as T cells in the CNS.

Studies assessing the role of chemokines in the pathogenesis of and/or protection from TMEV-IDD have not yet been reported. If the pathogenic mechanisms involved in TMEV-IDD are similar to the MHV-induced demyelinating disease (28, 29), inhibition of RANTES and/or IP-10 that are directly and primarily produced in astrocytes after TMEV infection (27), may decrease the pathogenesis of demyelinating disease. Such studies will provide important information regarding the role and mechanisms of various chemokines in the initiation and maintenance of inflammatory responses in the CNS leading to TMEV-induced chronic demyelinating disease. These studies will also present opportunity to compare to those involved in either autoimmune and/or other virally induced demyelinating disease models.

3. ADHESION MOLECULES

Adhesion molecules are important in the T cell-APC interaction, cellular trafficking, and transmigration of inflammatory cells into the CNS. While other adhesion molecules (e.g. VCAM-1) may be involved in the pathogenesis of TMEV-IDD, the role of intracellular adhesion molecule (ICAM)-1 (CD54) has been primarily studied. ICAM-1, expressed on APC is a member of the immuno-globulin superfamily and interacts with lymphocyte function associated antigen (LFA)-1 (or CD11a), expressed on T cells, granulocytes, monocytes and macrophages. Because the interaction between these molecules is critical for T cell activation as well as extravasation of lymphocytes into the CNS, attempts to inhibit this interaction were made by administrating neutralizing antibodies. Blocking the interaction leads to decreased incidence and severity of TMEV-IDD accompanied by decreased numbers of infiltrating $CD4^+$, $CD8^+$ and MHC class II^+ cells in the CNS resulting in inhibition of inflammatory demyelination. In addition, this treatment also decreased the levels of virus-specific DTH, T cell prolifer-

ation, and the production of IFN-γ and TNF-α with an increase in the production of IL-10 (30). In contrast, similar administration of neutralizing mAb against LFA-1 and/or ICAM-1 in another report showed no effect on the onset/severity or the extent of demyelination or inflammation (31). The first study administered the antibody prior to and during infection while the second study only began antibody treatment after virus infection during the acute phase of disease (7 d post-infection). ICAM-1 may be necessary for the migration of T cells through the CNS endothelium, therefore blocking ICAM-1 prior to infection may prevent this migration and hence the subsequent inflammation and demyelination. Thus, it is conceivable that all the necessary inflammatory T cell populations have already been infiltrated into the CNS at 7 days post-infection. Local amplification of T cells may occur in the CNS (32) and continuous cellular infiltration may not be necessary to sustain chronic inflammatory demyelinating disease in the presence of viral persistence. In addition, the ICAM-1/LFA-1 interaction functions as an important costimulatory signal for T cell activation and clonal expansion. Without this signal, T cell response to TMEV may be compromised or deviated to the non-pathogenic Th2 response.

The role of CD28/B7 (CD80/86) costimulatory molecules in the development of TMEV-IDD has also been investigated. Treatment with mAbs to B7-1 (CD80), but not B7-2 (CD86), resulted in significant inhibition of the Th1 response to viral epitopes and the consequent development of disease (33). However, blocking the costimulation at the time of TMEV infection enhances disease severity (34), suggesting that such a blockade may also inhibit the development of protective immune responses permitting unchecked viral replication. Thus, utilization of immuno-suppressive regimes may be difficult to balance between promoting the protective immune responses and inhibiting pathogenic inflammatory responses. The timing of the treatments appears to be critically important in determining the clinical outcome.

4. ROLE IN PATHOGENESIS OF DISEASE

The pathogenic mechanisms involved in virally induced demyelinating disease appear to be complex. Both the protection and pathogenesis are likely dependent on the levels of various chemokines, cytokines as well as adhesion molecules upregulated following viral infection. In general, the innate chemokine and cytokines responses induced upon viral infection are important in protecting the host by providing anti-viral functions. However, in the presence of viral persistence in susceptible mice, such innate responses may continuously stimulate pathogenic T cell responses leading to

CNS damage (2). For example, susceptible SJL/L mice are known to be deficient in NK/NKT cell compartment(s). Thus, the early viral clearance may be compromised and allow establishment of viral persistence in the CNS, despite the vigorous innate chemokine and cytokine responses after TMEV infection. Under the circumstances, chemokines and cytokines as well as adhesion molecules upregulated in various glial cells by viral infection will facilitate influx of various inflammatory cells, including virus-specific T cells (Figure 1). In addition, these chemokines and cytokines may also further stimulate adjacent glial cells to produce similar chemokines and cytokines, resulting in amplification of inflammatory responses in the CNS. Furthermore, these chemokines/cytokines as well as viral infections will further activate professional and non-professional antigen presenting cells (13, 35) and may reduce the threshold of T cell activation, leading to pathogenic Th1 cell responses specific for viral antigens as well as neuronal autoantigens (3). For example, proinflammatory cytokines such IFN-γ and TNF-α produced by activated Th1 cells stimulate astrocytes to enable effective presentation of viral epitopes to T cells for further T cell activation and expansion (36). Also, such cytokines further activate resident microglias and macrophages that are likely involved in tissue damage of CNS. In addition, certain cytokines such as TNF-α may also be directly cytotoxic to oligodendrocytes responsible for myelin production (37).

However, the same chemokines and cytokines as well as upregulated adhesion molecules may also be necessary to contain viral replication. For example, strong infiltrating Th1 as well as CTL responses that are effective for viral clearance in the CNS are necessary to be protective to TMEV-IDD. These virus-specific immune responses are also heavily dependent on the initial innate chemokine/cytokine responses. Therefore, investigations of these initial chemokine/cytokine responses in resistant and susceptible mice will be valuable in understanding the pathogenic/protective mechanisms involved in TMEV-IDD. The previous attempts to ameliorate this virally induced demyelinating disease by simply skewing against the Th1 response have met inconsistent outcomes. Often times, attempts to suppress inflammatory responses may have lead to viral expansion and persistence, resulting in exacerbation of chronic disease. On the other hand, this disease is immune-mediated and inflammatory immune responses need to be inhibited in order to prevent/treat the disease. Thus, fast and complete elimination of viral persistence before sustaining immune damage of the CNS tissues would be ideal for preventing virally induced immune-mediated diseases. Alternatively, selective upregulation of strong anti-viral immunity, while inhibiting inflammatory Th responses, may be essential for treating virally induced demyelinating diseases.

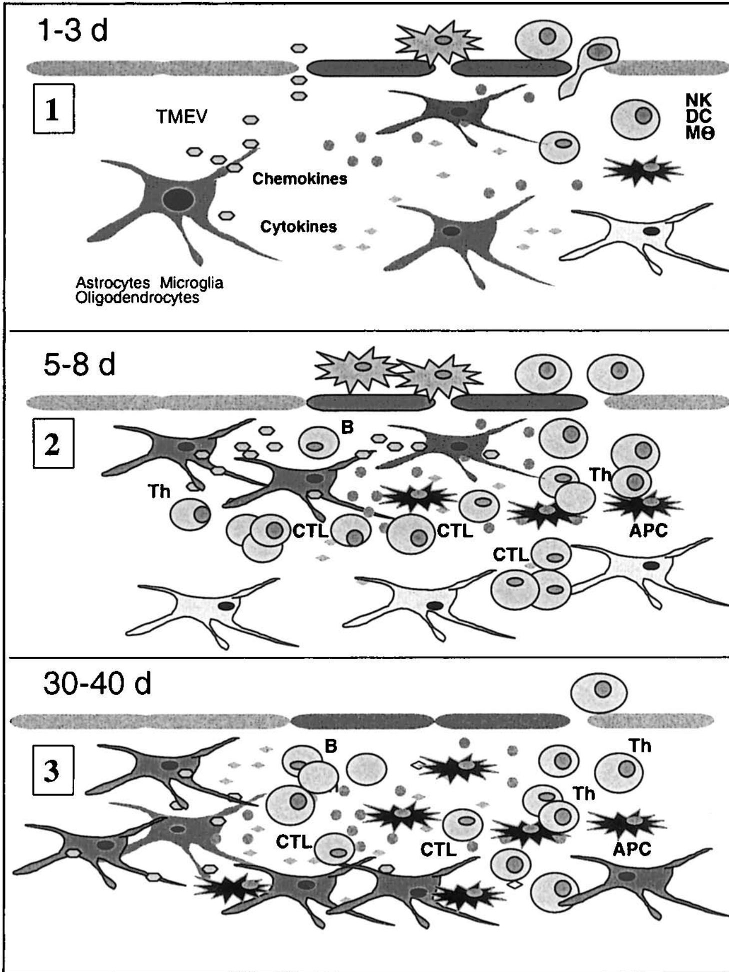

Figure 1: Schematic presentation of the steps involved in TMEV-induced demyelinating disease. (1) Early, (2) Acute and (3) Chronic responses in the CNS following viral infection. (1). At the Early stage, mainly chemokine, cytokine and adhesion molecule responses are directly induced in various glial cells upon viral infection. These molecules may further activate adjacent glial cells and facilitate cellular (NK, DC, macrophages, neutrophils) infiltration to the CNS. (2). At the Acute stage, various immune cells (B, Th and CTL) are infiltrated. These immune cells will be further stimulated/amplified by viral Ag-APCs (professional and non-professional). Virus will be neutralized and virus-infected cells will be eliminated by immune cells. (3). At the Chronic stage, viral persistence remains and continuous inflammatory responses are maintained in susceptible mice, whereas completely cleared viral persistence and the inflammatory response is resolved in resistant mice.

Chapter B7

MOLECULAR DETERMINANTS OF TMEV PATHOGENESIS

Stephen T. Guest and Raymond P. Roos
Department of Neurology, Committee on Virology, University of Chicago Medical Center.

Abstract: Strains of Theiler's murine encephalomyelitis virus (TMEV) can be divided into two subgroups based on their distinct biological activities. Members of the GDVII subgroup are highly neurovirulent and cause an acute, fatal encephalomyelitis. In contrast, members of the TO subgroup cause a mild encephalomyelitis early after infection followed by a late disease that is characterized by virus persistence, a low level of virus gene expression, and inflammatory demyelination.
Chimeric viruses constructed between members of the two subgroups have shown that the viral determinants for these distinct disease phenotypes are polygenic, and that interactions between different determinants on the viral genome are critical in determining disease phenotype. A point mutation in the internal ribosome entry site (IRES) of the 5'untranslated region of the GDVII subgroup strain can result in a virus with reduced neurovirulence that is able to persist. These results demonstrate that determinants for virus persistence are not unique to the TO subgroup strains, and identify the viral IRES as playing a critical role in determining TMEV pathogenesis. We have identified an 18kD protein known as L* that is present in TO subgroup strains but not GDVII subgroup stains, and appears to play a key role in virus persistence and demyelination. Disruption of L* expression results in a virus that grows well in cell culture but is unable to persist in the central nervous system or induce demyelination. Further investigations of TMEV-induced disease should provide insight into mechanisms that underlie virus persistence and virus-induced demyelination.

Key words: Theiler's murine encephalomyelitis virus, persistence, demyelination, L*, internal ribosome entry site

INTRODUCTION

Theiler's murine encephalomyelitis virus (TMEV) refers to a group of closely related viruses in the *Picornaviridae* family, genus *cardiovirus*. Strains of TMEV can be divided into two subgroups based on their distinct biological activities (Table 1). Members of the GDVII subgroup, which include GDVII and FA strains, are highly neurovirulent in weanling mice and display a large plaque phenotype when grown on cultured cells. Intracranial (IC) inoculation with as little as one plaque-forming unit (pfu) causes a severe, acute encephalomyelitis that is associated with a progressive flaccid paralysis of the hind limbs that leads to death within days to a couple weeks post-inoculation (PI). Members of the GDVII subgroup replicate in neurons and astrocytes of the gray matter in the central nervous system (CNS) and are not observed to induce demyelination. Members of the second TMEV subgroup, Theiler's original (TO) subgroup, include DA, BeAn, WW, Yale and TO strains. These strains, which display a small plaque phenotype when grown in cultured cells, fail to kill a weanling mouse despite IC inoculations of $>10^6$ pfu. During the first two weeks PI, TO subgroup strains replicate in neurons and astrocytes of the gray matter of the CNS, and induce a subclinical encephalomyelitis. By 3 weeks PI the encephalomyelitis resolves, at which time virus is primarily found in glia and microglial cells of the spinal cord white matter and is associated with foci of inflammatory demyelination. The white matter lesions peak at about 6 weeks, but continue throughout the life of the mouse. The inflammatory demyelination observed is similar to that seen in multiple sclerosis. Virus persists in the CNS with a restricted expression of viral genes, i.e., genome is present with relatively little viral protein or infectious virus production.

Table B7. Phenotypic Differences Between TMEV Subgroups

Phenotype	TO Subgroup Strains (DA, BeAn, TO, WW, Yale, etc.)	GDVII Subgroup Strains (GDVII, FA)
Neurovirulence (50% lethal dose)	- ($>10^6$ PFU)	++ (1 PFU)
Early Disease (Encephalomyelitis)	+	+
Late Disease (restricted virus expression, inflammation and white matter demyelination)	+	-

The complete genome of the GDVII strain as well as two TO subgroup strains, DA and BeAn, have been sequenced. Sequence analysis demonstrated 90% identity at the nt level and 95% identity at the amino acid (aa) level among the different strains of TMEV from the two subgroups [2, 3]. While this degree of similarity is relatively high, the differences that are present are located throughout the viral genome, suggesting that determinants for the very distinct disease phenotypes caused by the GDVII vs. TO subgroup strains are likely to be scattered over the TMEV genome.

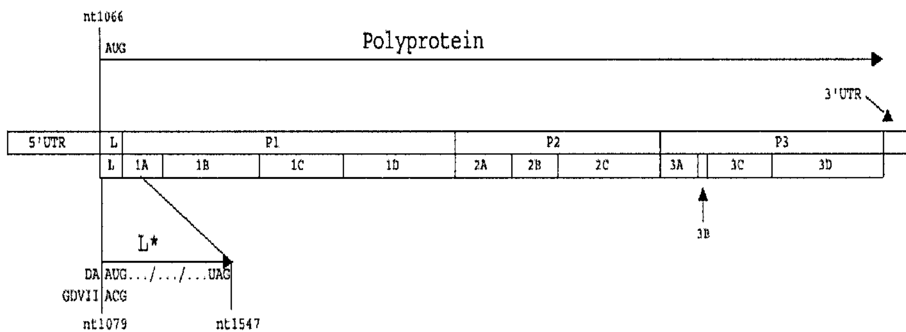

Figure B7. The TMEV genome of approximately 8,100 nucleotides. The polyprotein coding region is flanked upstream by a 5'UTR and downstream by a 3'UTR. The coding region for the polyprotein begins with the coding region for Leader (L) protein and is followed by genomic regions P1, P2 and P3. P1 is divided into 1A, 1B, 1C and 1D coding regions, which synthesize, respectively, the capsid proteins VP4, VP2, VP3 and VP1. P2 (which includes 2A, 2B and 2C) and P3 (which includes 3A, 3B, 3C and 3D) encode various nonstructural proteins. The initiating AUG codon for L* is located at nt 1079 for strain DA while the GDVII strain has an ACG in this position.

RECOMBINANT AND MUTANT VIRUS STUDIES

The generation of full-length cDNA clones derived from TO and GDVII subgroup strains of TMEV has made it possible to rapidly engineer chimeric cDNAs and recombinant viruses between the two subgroups. Studies utilizing these recombinant viruses have been aimed at determining the regions of the viral genome that are necessary for the subgroup-specific phenotypes, such as GDVII subgroup neurovirulence and TO subgroup persistence, demyelination, and restricted virus gene expression.

The recombinant virus studies have demonstrated that phenotypes such as virus neurovirulence, persistence and demyelinating activity are polygenic. Replacement of the capsid coding region of the TO subgroup strain DA with the capsid coding region from GDVII strain results in a recombinant virus that is almost as neurovirulent as wild type (wt) GDVII virus [4]; replacement of the 5' UTR along with the capsid coding region of DA with the corresponding regions of GDVII results in a virus with neurovirulence that is equal to that of the parental GDVII virus. This result demonstrates that the GDVII capsid coding region plays a key role in determining neurovirulence, and suggests that the DA capsid plays a role in virus persistence and demyelination (although later studies described below indicate that the latter suggestion needs to be modified). Surprisingly, replacement of DA regions coding for the carboxyl half of VP2, all of VP3, all of VP1, and the amino end of 2A with the corresponding regions of GDVII resulted in a virus (GD1B-2A/DA virus) that persisted and induced demyelination in mice, suggesting that a key determinant for the persistent, demyelinating phenotype may lie within the 5' half of DA VP2 [5] (but again, this suggestion was modified by later studies).

Another interpretation of the results from studies of GD1B-2A/DA virus is that GDVII strain does indeed contain determinants for persistence and demyelination, but that GDVII does not persist or demyelinate due to its extreme neurovirulence. In fact, investigations showed that virus persistence and demyelination can occur in a series of recombinant viruses in which different parts of the DA genome that span the length of the genome from the 5' terminus to the 3'UTR were replaced with the corresponding segments of the GDVII genome, suggesting that there is no single determinant for virus persistence and demyelination on the DA genome that cannot be substituted for by the corresponding region of the GDVII genome, i.e., GDVII contains determinants for virus persistence and demyelination [6].

The issue as to whether GDVII strain contains determinants for persistence and demyelination that are not apparent because of the virus' extreme neurovirulence was also examined by testing whether attenuation of a GDVII strain to a certain level will result in a virus that persists and demyelinates. It is clear that GDVII strain can be sufficiently attenuated so that it fails to efficiently grow in the CNS, and therefore will not persist or demyelinate; an example of one such virus is the leaderless GDVII virus, which is completely attenuated for growth in the CNS and therefore unable to persist [7]. We recently investigated this topic by examining GDVII strains with mutations in the IRES that alter the binding of the cellular factor polypyrimidine tract binding protein. These mutant viruses were attenuated, and at least one, GD91 [8], persisted in the CNS but failed to induce demyelination (Viktorova et al., manuscript in preparation). These results demonstrate that: TMEV persistence does not require the presence of the capsid of TO subgroup strains; attenuated GDVII strains (with one

nucleotide change, in the 5'UTR, compared to GDVII wt virus) are capable of persistence; persistence is not sufficient for demyelination. The lack of demyelinating activity by the attenuated GDVII virus may result from the absence of L* protein (see later) and/or the presence of GDVII rather than DA capsid proteins. Our studies demonstrate the importance of IRES-binding proteins in determining disease phenotype, a theme that recurs in discussions of the varying levels of L* vs. the polyprotein synthesis depending on different neural cell types.

Interactions between parts of the viral genome are not unexpectedly important in the virus' biological activities. Further studies with GD1B-2A/DA virus showed that introduction of a single, additional mutation in the DA backbone at aa residue 141 of VP2 from Lys to Asn (where Asn is the amino acid present in GDVII at this position, and corresponds to the position of Lys in DA), resulted in a virus (R5 virus) with increased neurovirulence that neither persisted nor induced demyelination [9]. These results demonstrated that interactions between parts of the genome can have dramatic effects on disease phenotype. In this case, interactions of a particular aa residue (141) in VP2 (that is normally present in GDVII) along with the capsid segment containing half of GDVII VP2, all of VP3 and all of VP1 presumably interfered with the activity of determinants for the persistent demyelinating phenotype of the TO subgroup strain.

The interactions between aa141 and the capsid can be better understood by taking advantage of the available three-dimensional crystal structure of TMEV [10, 11, 12]. In these structures, aa141 lies at the tip of the EF loop in the VP2 puff on the rim of the canyon region of the viral capsid coat. It is this canyon region that is thought to be the site of interactions between the virion and its still unknown cellular receptor(s). Therefore, it has been proposed that the importance of aa141 lies in its ability to alter interactions with cellular receptors present on specific cell types [13]. The presence of Asn in this position along with part of the GDVII capsid may prevent interactions of the virion with cellular receptors, specifically on cells in the white matter of the spinal cord. Support for this hypothesis has been provided by studies showing that R5 virus fails to spread from the gray matter to the white matter of the spinal cord of nude mice, whereas DA strain spreads efficiently [13]. The absence of a competent immune system in these mice indicates that the inability of this recombinant virus to spread is independent of the host immune response, providing further support that the Asn interferes with interactions between the virion and specific cellular receptors present on cells in the white matter of the spinal cord.

Although much has been learned from recombinant virus studies there are clear shortcomings to this approach. At times, the substitution of a genome segment of one strain into the genome of a strain from the other subgroup can disrupt key intratypic interactions important for disease

phenotype or even viability of the virus. For example, when two segments of the GDVII genome were substituted separately into the DA genome neither of the two resultant recombinant viruses displayed the phenotype of a recombinant virus which contained both of the GDVII genome segments [4]. In addition, some intertypic recombinant viruses have a defect in a critical function of the virus, such as assembly, leading to poor virus growth *in vitro*, and therefore preventing animal studies [14]. For these reasons, studies using recombinant viruses as a way of clarifying subgroup-specific disease phenotypes have been generally replaced by investigations involving site-specific mutation of particular nucleotides or aa residues.

THE ROLE OF L* IN TO SUBGROUP STRAIN DISEASE

L* in DA Strain-Infected Cells

We recently identified a coding region of TO subgroup strains that appears critical in virus persistence and demyelinating activity. This region codes for an 18 kD protein that we have called L*. L* was initially identified following *in vitro* translation of the DA RNA genome, but not of GDVII [15]. The L* protein is not an artifact of the *in vitro* translation system since L* is synthesized in DA, but not GDVII infected cells. L* synthesis starts at 4 hours PI, with an expression profile that closely mimics that of the viral polyprotein; the protein is stable throughout the course of the virus infection [16, 17].

L* is synthesized from an initiating AUG located 13nt downstream from the polyprotein's AUG of TO subgroup strains [18], out of frame with the polyprotein's reading frame [17]. Sequence analysis of different TMEV strains has shown that the initiating AUG for the L* reading frame is present in the RNA genome of all TO subgroup strains, while the genome of GDVII subgroup strains contains an ACG at this site in the genome; this result explains the apparent absence of L* synthesis following translation of GDVII RNA.

Comparison of the nucleotide sequence of the L* reading frame among different strains of the TO subgroup has shown that the predicted amino acid sequence of the L* reading frame is more highly conserved than the aa sequence of the overlapping polyprotein reading frame. This high degree of conservation of the L* reading frame suggests that L* has a function that is important for the virus. Additionally, the presence of an L* AUG in TO, but not GDVII, subgroup strains suggests that it plays a role in a TO subgroup-specific phenotype, such as persistence, demyelination, and

restricted virus gene expression. These suggestions were found to be valid, as described below.

L* and TO Subgroup Strain Persistence and Demyelination

L* has been shown to play a critical role in determining virus persistence and the demyelinating phenotype of TO subgroup strains. Work from our laboratory has shown that viruses containing mutations that prevent L* protein expression, whether by mutating the L* initiating AUG to ACG (DAL*-1 virus) or by creating stop codons in the L* reading frame (DAL*stop virus), grow at wt levels in cultured cells but are unable to persist and induce demyelination in the CNS [17, 19, Viktorova et al. unpublished]. DAL*-1 virus induces an acute encephalomyelitis similar to that produced by wt virus and grows to a similar titer at 1 week PI; however, at 45 days PI, there is no evidence of the DAL*-1 viral genome and scant evidence of inflammation or demyelination in the CNS. Both DAL*-1 and DAL*stop viruses are cleared following infection, with little evidence of demyelination, indicating that the actual L* coding region rather than the additional translational start site is key to the mutant phenotype.

The importance of L* in TO subgroup persistence and demyelination was initially called into question by Michiels and colleagues [20]. These investigators were working with a *different* full-length clone of DA, pTMDA, than the one used by our group. Surprisingly, Michiels and colleagues found that substitution of an ACG mutation for the L* initiating AUG in pTMDA resulted in a virus (which we will call TMDAL*-1 virus) that persisted and demyelinated almost as well as the wt TMDA virus. However, a more recent study from this group found that: TMDAL*-1 virus does in fact produce small amounts of the L* protein, presumably through initiation at the ACG; the small amount of L* produced by TMDAL*-1 virus is presumably able to facilitate virus persistence and demyelination, however, mutations which introduce a stop codon in the L* reading frame of pTMDA (and produce *no* L*) result in viruses that fail to persist and demyelinate [21]. Together, these studies support our thesis that L* plays a key role in determining TO subgroup persistence and demyelination.

Although L* is important for TO subgroup persistence and demyelination, the recombinant virus studies at first glance suggest that L* may not be essential for these activities. For example, some GDVII/DA recombinant viruses that replace the DA L* AUG with the GDVII ACG are able to persist and demyelinate. However, Michiels and colleagues demonstrated that a small amount of L* is synthesized from the ACG of wt GDVII, suggesting that L* may be synthesized in these recombinant viruses and that L* may indeed be essential for virus persistence and demyelination.

The precise mechanism(s) by which L* allows TO subgroup strains to persist and induce demyelination is unclear. There is evidence that L* perturbs the immune response, and therefore may play a role in allowing the virus to escape clearance by the host's immune system [22]. DA wt virus infection of certain mouse strains (e.g., C57Bl/6 mice) that are resistant to the persistent, demyelinating infection induced by TO subgroup strains generate an anti-virus cytolytic T-lymphocyte (CTL) response 7 DPI (and this response clears the virus), while mouse strains (e.g., SJL mice) susceptible to TO-induced disease do not generate a virus-specific CTL (and the absence of this response fosters virus persistence) [23, 24]. In contrast to this latter situation, inoculation of SJL mice with DAL*-1 virus results in a virus-specific CTL response, virus clearance and an absence of the demyelinating disease [22]. Our recent data involving wt and DAL*-1 virus infections of CD4-/- and CD8-/- mice as well as adoptive transfer studies suggest that L* inhibits a CD4+ T cell –dependent activity that is capable of clearing DA virus from susceptible mice [Lin, X, Ma, X, Rodriguez, M, and Roos, R.P., submitted]

The Role of L* in Microglial Infection

L* may play a role in TMEV infection of microglia, a key CNS cell in which the virus persists. *In vitro* experiments have shown that members of the GDVII subgroup are growth restricted in cultured macrophage cell lines, whereas the DA strain grows to high titer in these cells [25]. Additional studies showed that a recombinant GDVII-type virus engineered to contain the L* coding region from the DA strain gained the ability to productively infect cultured macrophages. In an analogous way, a DA strain that lacks L*, as is the case with DAL*-1 virus, lost the ability to productively infect cultured macrophages [26]. These results suggest that the L* protein is necessary for efficient infection of macrophages by TMEV. In addition, work from our laboratory has shown that the GDVII strain and DAL*-1 virus are significantly more efficient at inducing apoptosis of cultured macrophages than DA, suggesting that the L* protein has an antiapoptotic effect in macrophages [19]. In summary, L* allows the virus to efficiently replicate in macrophage cells, a major site for virus persistence, and the virus persistence in this cell type is enhanced by inhibition of virus-induced apoptotic cell death.

Cell-Type Specific Regulation of L* Synthesis

The critical role of the L* protein in the TO subgroup strain-induced persistent CNS infection and demyelinating disease highlights the importance of regulating translation of L* in addition to the polyprotein. We have hypothesized that the presence of cell-specific IRES-binding proteins regulate whether ribosomes initiate translation at the L* rather than the polyprotein start site, leading to different ratios of L* to polyprotein synthesis in different cell types. Neural cells in which ribosomes preferentially synthesize L* over the polyprotein (with an associated decrease in synthesis of the polyprotein) might have the following important properties key to TO subgroup strain disease: translation from the L* reading frame may lead to a restricted expression of the viral polyprotein; a combination of increased L* production and decreased polyprotein production may help the virus avoid recognition and clearance by the immune system; increased L* production may prevent virus-induced apoptosis in cells that support virus persistence. Our studies found that the ratio of L* synthesis to VP2 synthesis varied in rabbit reticulocyte lysates in comparison to BHK-21 cells, and also in different tissue culture cell types [27]. In addition, recent investigations have shown that the presence of different IRES-binding proteins in different cell types regulates the efficiency of translation of the viral polyprotein of TMEV and has a profound effect on disease phenotype [8].

CONCLUSION

TMEV infection provides an excellent model system for the study of virus persistence and virus-induced demyelinating disease. The identification of the critical role of the L* protein, capsid proteins, and the viral 5'UTR in determining the demyelinating disease caused by the TO subgroup strains represent important steps towards a full understanding of TMEV-induced disease. Continued investigations of the L* protein and its function should provide additional insight into the mechanism by which TO subgroup strains of TMEV persist and induce demyelination in the host. Identification of factors involved in regulating translation of the L* reading frame in various cell types *in vivo* will also enhance our understanding of TMEV-induced disease. Lastly, identification of the host cell receptor(s) and an understanding of the interaction of receptor with the virus capsid proteins will further answer questions about virus tropism and spread in the host CNS.

Chapter B8

NITRIC OXIDE IN TMEV

Emilia L. Oleszak[1], Jacek Kuzmak[1], Arun Varadhachary[2] and Christos D. Katsetos[3]

Abstract: We and others have previously investigated the role of inducible nitric oxide synthase (iNOS) on early acute and late chronic demyelinating disease induced by Theiler's Murine Encephalomyelitis Virus (TMEV). Infection of susceptible SJL mice with this virus serves as an excellent model of virus-induced demyelinating disease, such as multiple sclerosis (MS). iNOS transcripts and protein were detected in brains and spinal cords of TMEV-infected SJL mice during early acute disease, which resembles polioencephalomyelitis. Similar level of expression of iNOS has been found in resistant B6 mice, which develop only early acute disease. Weak iNOS staining was detected in reactive astrocytes and in leptomeningeal infiltrates in TMEV-infected SJL mice at 42 days post infection (p.i.), corresponding to early phase of chronic demyelinating disease, but not at 66 and 180 days p.i. corresponding to advanced and terminal stages of the disease, respectively. Results from other laboratories demonstrated that, blocking of NO by treatment of TMEV-infected SJL mice with amino guanidine (AG), a specific inhibitor of NO resulted in delay of late chronic demyelinating disease. However this protective effect of NO inhibitor depended on the temporal phase of the disease, type of cells expressing iNOS and the time of administration of AG. The results from our laboratory suggests that NO expressed during early acute disease is beneficial to the host through induction of apoptosis of infiltrating T cells and resolution of encephalitis, but its role in myelin/oligodendrocytes damage during late chronic demyelinating disease is not clear and it may depend on availability of superoxide and formation of peroxynitrite.

Key words: nitric oxide, TMEV, multiple sclerosis

1. INTRODUCTION

Theiler's virus (TMEV) induces a biphasic disease in susceptible strains of mice (such as SJL). Early acute disease (polioencephalomyelitis) is characterized by replication of the virus in gray matter(1-4). This phase of disease is associated with neuronophagia and inflammatory infiltrates in the cerebral gray matter and anterior horn cells of spinal cord(4, 5). Within two to three weeks the virus is partially cleared and approximately 35 days p.i. susceptible mice develop late chronic demyelinating disease. The virus persists at very low level in microglia/macrophages, astrocytes and oligodendrocytes(1, 5-9). Heavy inflammatory infiltrates comprised of $CD4^+$ and $CD8^+$ T cells, macrophages, and few B cells are present, exclusively in the spinal cord(7, 9, 10). Demyelinating lesions are associated with perivascular and parenchymal inflammatory infiltrates. TMEV-induced late chronic demyelinating disease is an excellent animal model for human MS(1, 2, 7, 9, 11). Resistant strains of mice (such as C57BL/6) develop only early acute disease, clear the virus completely and do not develop demyelinating disease. MS is the most common inflammatory demyelinating disease in humans. It has been suggested that T cells specific for a myelin component such as MBP (Myelin Basic protein, PLP (proteolipid) and/or MOG (myelin oligodendrocytes protein), and activated microglia/macrophages participate in myelin damage(12-15). Epidemiological evidence suggests that MS could be triggered by virus (es) acquired before puberty.

The mechanism(s) of the pathogenesis of inflammatory demyelinating diseases is not well understood. Although oligodendrocytes/myelin may be damaged by a direct attack of cytotoxic T cells, other cells, including $CD4^+$ T cells, activated macrophages, and microglia may contribute to myelin destruction by the production of cytokines, such as IL-1, IFN-γ, and TNF-α,.and reactive oxygen and reactive nitrogen species(14, 16). Nitric Oxide (NO) is a short lived, highly reactive molecule with free radical properties. It is synthesized by nitric oxide synthase (NOS) by converting of L-arginine to L-citrulline, reviewed in(17, 18). There are three isoforms of NOS; NOS-type I and NOS-type III are calcium dependent and are constitutively expressed. This results in the production of physiological levels of NO which acts as second messenger in the NO signaling pathway in the neuronal and cardiovascular system. The NOS-type II (iNOS, inducible NOS) is calcium independent and is produced in large amounts during innate and adaptive immune responses(19-24). NO produced during an innate immune response clearly contributes to the killing of intracellular microorganisms and parasites(25-27). Less is known about a role of NO in the generation and regulation of an adaptive immune response, including inflammation.

It has been suggested that NO may exhibit cytotoxic, regulatory, and immunosuppressive properties, including induction of apoptosis and autoimmune disease, reviewed in (28-30). Such a wide array of biological actions of NO suggests that iNOS may have different functions in different cells. The immunoregulatory action of NO is likely mediated through its effect on cytokines and other inflammatory molecules by regulation of the transcription factor, NF-activating protein-1 (AP-1) by targeting the Th1/Th2 balance(29, 31-33). On the other hand, NO produced by microglia/macrophages could be a potent neurotoxin and mediates TNF-α neurotoxicity toward oligodendrocytes(16, 34-36). The toxic effect of NO is likely attributed to the nitrosylation of target iron-sulfur proteins, including enzymes involved in DNA replication and repair and in blocking mitochondrial respiration(37, 38). The uncoupling of the electron transfer chain in mitochondria will result in production of oxygen free radicals. Reaction of NO with a superoxide will lead to formation of extremely toxic peroxynitrite ($ONOO^-$)(39-41). Peroxidations of membranes and swollen oligodendrocyte cell bodies have been described in the CNS of patients with MS(42). Nitrosylation of tyrosine in proteins has been demonstrated in a number of neurodegenerative and inflammatory conditions of the CNS(43-45).

In the inflammatory conditions of CNS, such as viral encephalitis and EAE (experimental allergic encephalomyelitis), iNOS is expressed in macrophages, microglia and/or astrocytes, and possibly neurons but not oligodendrocytes(41, 43, 45-51). The role of iNOS has been examined in a number of encephalitis's induced by viruses, such as corona, flavi, rhabdo, Borna, rabies, herpes, Japanese encephalitis, Venezuelan encephalitis and several others, revealing that NO may contribute to the pathogenesis of the disease(52-60). Alternatively, NO may have a protective role in a viral infection.

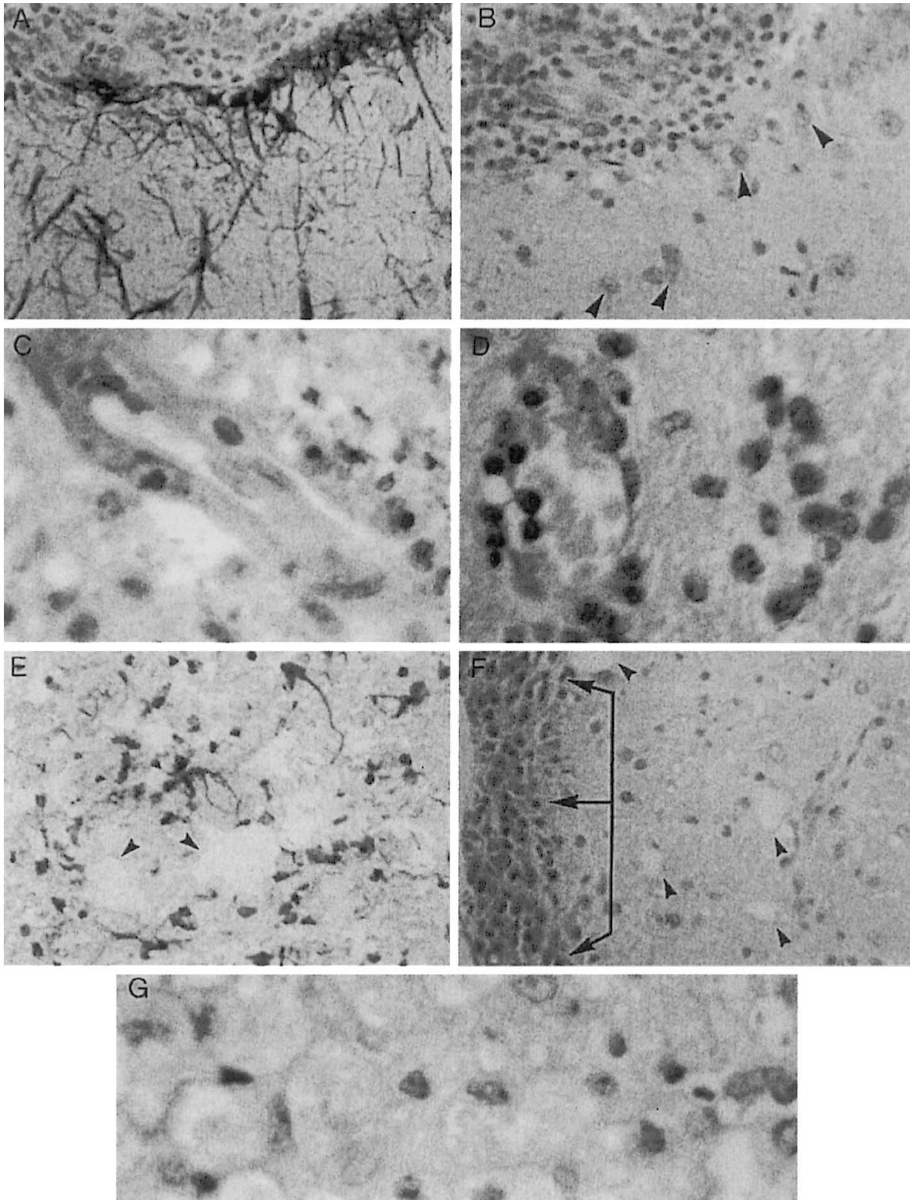

Figure B8-1.

IHC localizations of GFAP (A) and iNOS protein in the CNS of SJL mice at 10 (A-C), 6 (D), 42 (E and F), and 66 (G) days p.i. (A) Encephalitis and poliomyelitis phase: an area of intense leptomeningeal inflammation accompanied by reactive astrogliosis in the subjacent brain parenchyma, which is highlighted by GFAP staining. (B) Same field from an immediately adjacent section exhibiting iNOS-like staining in reactive subpial astrocytes (arrowheads) as well as in scattered monocytes/macrophages in the overlying leptomeningeal infiltrate (top

portion of photomicrograph). (C) Encephalitis and poliomyelitis phase: iNOS-like localization in hypertrophic endothelial cells of a blood vessel amidst an area of necrotizing encephalitis. (D) Encephalitis and poliomyelitis phase. iNOS-like staining in cells of the monocyte/macrophage lineage and in vascular endothelial cells from an area of spinal grey matter inflammation. (E) Early stage of spinal cord demyelination exhibiting a number of scattered iNOS-positive astrocytes in a background of incipient vacuolar changes (arrowheads) suggestive of early demyelination involving the lateral column. (F) Spinal cord demyelination phase: Focal, weak, and ill-defined iNOS-like immunoreactivity is detected among leptomeningeal infiltrates (the three arrows) which are encroaching upon the lateral funiculus of the spinal cord. Note vacuolar change in the lateral column (arrowheads). (G) Spinal cord demyelination phase: Lack of iNOS-like staining in large foamy (myelin-laden) macrophages in full-blown demyelinating lesions in the posterior columns of the thoracic cord. (Original magnifications: A, B, E, F x400; C, D. G x1000)

1.1 iNOS in TMEV infection.

We have examined the expression of iNOS transcripts and protein in the CNS of TMEV-infected mice during early acute and late chronic demyelinating disease(61). Both susceptible (SJL) and resistant (B6) strain of mice were infected i.c. with the DA strain of TMEV and infected mice were sacrificed at 0, 3, 6, 10 days p.i. (SJL and B6), corresponding to early acute disease and at 39, 42, 66–67 and 180 days p.i. corresponding to late chronic demyelinating disease (SJL only). Mock-infected mice were injected i.c. with medium alone and they were sacrificed at 6 and 39 days p.i. iNOS transcripts were determined by RT-PCR, followed by Southern blotting, as described(61); the presence of iNOS protein was determined by immunohistochemical staining using affinity-purified polyclonal rabbit anti-iNOS antibody (61). These antibodies are iNOS specific and do not react with NOS type I and NOS type II.

Although both strains of TMEV-infected mice develop polioencephalomyelitis (gray matter inflammatory disease), confirmed by histological analysis (Fig.1), none of the animals showed overt neurological signs. We did not detected any transcripts for iNOS in brain and spinal cord of mock-infected animals examined at day 6 and 39 p.i. and very little iNOS transcripts were present at day 3 p.i. In contrast, high levels of expression of iNOS transcripts were detected in the CNS of TMEV-infected SJL and B6 mice at 6 and 10 days p.i. In general, higher levels of iNOS expression were detected in brains of SJL and B6 mice than in the spinal cords. Immunohistochemical staining of CNS tissue enabled the identification of cells which expressed iNOS during early acute disease. At 6 and 10 days p.i. iNOS was expressed in strains of TMEV-infected mice in areas of intense inflammation in reactive astrocytes (Figs. 1A & B), monocytes/macrophages and hypertrophic endothelial cells (Figs. 1C, 1D). Few perivascular

monocytes-like cells in leptomeninges were also iNOS positive, while lymphocytes were negative(61). Normal endothelial cells and smooth muscles cells were consistently negative for iNOS. To confirm that reactive astrocytes were the major cell type expressing iNOS, we stained adjacent sections with antibodies to GFAP (glial fibrillary acidic protein) or with antibodies to iNOS. Cells which were positive for iNOS were also positive for GFAP. The profile of iNOS staining in the spinal cord was similar to that described for encephalitis. We have not detected any iNOS-like immunoreactivity in normal interfascicular fibrous astrocytes, protoplasmic astrocytes, Bergmann's glia or oligodendrocytes. Rod-shaped microglia-like cells were also consistently negative. iNOS protein was essentially undetectable in the brain and spinal cord of naive mice.

We have examined expression of iNOS in late chronic demyelinating disease(61). iNOS transcripts were detected in spinal cords of TMEV-infected SJL mice at 39 days p.i., which corresponds to the beginning of inflammatory demyelinating disease (61). Less iNOS transcripts were detected in brains of these mice. Immunohistochemical staining confirmed expression of iNOS protein in fibrillary astrocytes in areas of inflammation (Fig.1E) and in leptomeningeal infiltrate (albeit weak) at 42 days p.i. (Fig.1F). iNOS protein was not detected in the CNS of TMEV-infected B6 mice at 42 and 67 days p.i. and, as expected, there were no overt pathological changes in the brains and spinal cords of these mice. In contrast, extensive inflammatory disease, demyelination and gliosis were demonstrated in TMEV-infected SJL mice at day 39, 67 and 180 p.i. However, we did not detect any iNOS transcripts nor iNOS protein at day 67 p.i. (advanced phase of demyelinating disease) or at 180 days p.i. (terminal phase of disease) associated with hind leg paralysis and incontinence). Foamy-myelin-laden macrophages were always negative (Fig.1G).

1.1.1 DISCUSSION

We have demonstrated that during early acute disease induced in TMEV-infected SJL and B6 mice iNOS is expressed in the brain and spinal cord of infected animals, predominantly in hypertrophic astrocytes, monocytes/macrophages and endothelial cells in the area of inflammation (61). During late chronic demyelinating disease, iNOS has been detected in fibrous astrocytes and meningeal infiltrates of spinal cord but only during the early stages (39 days p.i.) of late chronic demyelinating disease (SJL mice) and not at 66days p.i. or at 180 days p.i. (terminal stage of the disease). We have also demonstrated that during early acute disease there is high level of apoptosis of T cells undergoing activation induced cell death, while there is paucity of apoptosis of T cells infiltrating the CNS of TMEV-infected SJL

mice during late chronic demyelinating disease (unpublished observations). We suggest that NO produced by reactive astrocytes and macrophages/microglia during early acute disease triggers apoptosis of infiltrating T cells. Conversely, lack of expression of iNOS in the CNS during late chronic demyelinating disease (days 66 and 180 p.i.) may relate to the very low level of apoptosis of these T cells. Induction of apoptosis of MBP-specific T cells by NO producing astrocytes (functioning as antigen presenting cells) has been described(62). Molina-Holgado(63) recently reported that in brain astrocytes infected in vitro with TMEV there is high expression of iNOS and that IL-4 and IL-10 down regulate expression of iNOS by modulation of NF-κB activity. We have demonstrated high level of expression of proinflammatory cytokines in the CNS of TMEV-infected mice during early acute and late chronic demyelinating disease (64). However, IL-4 transcripts have been detected primarily during late chronic demyelinating disease. It is therefore possible to suggest that IL-4 down regulates expression of NO in astrocytes in SJL mice during late chronic demyelinating disease, which may result in inhibition of apoptosis. According to this postulate, expression of iNOS during early acute disease would be beneficial to the host, because NO could be responsible for eliminating infiltrating T cells through down regulation of Bcl-2 and induction of AICD, leading to restoration of homeostasis in the CNS. Thus, NO may function as an anti-inflammatory or immunosuppressive molecule during early acute disease. Immunosuppressive effect of macrophage-derived NO on T cells has also been reported (25, 28, 29). However, lack of iNOS expression (down regulated perhaps by IL-4/NF-κB) during late chronic demyelinating disease in TMEV-infected mice may be detrimental to the host by blocking apoptosis of infiltrating T cells. On the other hand, down regulation of NO production in the CNS of TMEV-infected mice may represent an effort of the host to curb formation of peroxinitrite, an extremely toxic molecule, which may lead to peroxidation of membranes and formation of nitrotyrosine. Whether nitrotyrosine is present in the CNS of TMEV-infected mice is not known. NO is a weak oxidant and acts rather like an antioxidant and only in reaction with superoxide it forms peroxynitrite, very toxic molecule. We and others demonstrated the expression of iNOS and nitrotyrosine in reactive astrocytes and monocytes/macrophages in Multiple Sclerosis lesions(43, 45). In general the expression of iNOS and nitrotyrosine seems to depend on the extent of lesion activity (acute vs. chronic).

The unexpected protective or destructive role of NO in induction and progression of EAE is also well known, reviewed in(65).

The effect of specific iNOS inhibitor, amino guanidine (AG) on mice infected with DA strain of TMEV has been examined(66). Treatment of

TMEV-infected mice starting at day 28 p.i. till day 49 p.i. significantly decreased inflammation, demyelination and axonal necrosis. This treatment was associated with decreased apoptosis of CNS infiltrating cells, presumably monocytes or lymphocytes. Early treatment (starting at day 7 p.i.) was not effective(66). When TMEV-infected mice were treated starting at day 14 p.i., only demyelination and axonal necrosis were decreased while the level of inflammation was not changed(66). These results suggest that inflammation and demyelination and axonal damage may be differentially down regulated by treatment of TMEV-infected mice with NO inhibitors at different times of infection. The outcome of treatment may depend on the level of activation of macrophages/microglia and astrocytes, which produce NO but also on availability of superoxide. The role of iNOS in TMEV induced demyelinating disease has also been examined using BeAn strain of the virus (instead of DA strain routinely employed in our laboratory). The BeAn strain of TMEV replicates with different kinetics in the CNS of SJL mice(67). For example, mice infected with BeAn show clinical signs of disease such as extensor spasm and hind leg of paralysis at 50 days p.i., whereas, mice infected with DA strain of TMEV do not show these signs earlier than 180 days p.i. Treatment of SJL mice infected with BeAn strain of TMEV with AG during the effector phase of the disease (initiating treatment at 15 days p.i.) resulted in significant delay of inflammatory demyelinating disease (67). Interestingly, iNOS was detected at low levels in monocytes/macrophages (MOMA-positive) in leptomeninges and perivascular spaces, but not in astrocytes, in TMEV infected mice between 0 and 15 days p.i.(67). The maximum expression of iNOS was observed at day 60 p.i. In contrast, iNOS expression was high in the CNS of SJL mice infected with DA strain of TMEV between 6 and 10 days p.i., but was not detectable at 66 and 180 days p.i. Treatment of TMEV (BeAn)-infected mice with AG in the induction phase (starting at day 1 p.i.) did not alter the course of the disease(67). The authors suggested that protective effect of AG on inflammatory demyelinating disease observed in BeAn infected mice when treatment had begun 15 days p.i. was associated with suppression of activation and proliferation of inflammatory macrophages and lymphocytes(67). The results of these experiments suggest that the effect of NO on inflammatory demyelinating disease induced by these two strains of TMEV may depend on the kinetics of disease, time of appearance of inflammatory infiltrates, type of cells which express iNOS and time of administration of the inhibitor.

THEILER'S MURINE ENCEPHALOMYELITIS VIRUS (TMEV)-INDUCED DEMYELINATION

Apoptosis in TMEV infection

[1]Mary Lou Jelachich, and [2]Howard L. Lipton

Abstract: Apoptosis, one aspect of programmed cell death, is initiated by cell death receptor-ligand interactions and in response to cellular stress. Environmental stressors, such as increased temperature, and intracellular stressors, such as viral infection, result in the activation of caspase cascades leading to cell death. Intracerebral inoculation of susceptible mouse strains with the picronavirus TMEV results in the chronic infection of the central nervous system white matter and concomitant demyelination. This review examines the evidence for TMEV-induced apoptosis in vitro and in vivo.

Keywords: TMEV, apoptosis, demyelination, picornavirus

DEFINITION OF APOPTOSIS

Apoptosis is defined as the initiation of a cascade of cellular processes leading to cell death. Hallmarks of apoptosis include membrane inversion and exposure of phosphatidylserine residues, blebbing, fragmentation of the nucleus, chromatin condensation, and DNA degradation. These features distinguish apoptosis from necrosis, which results from injury and is characterized by cell swelling, no nuclear condensation, and cell rupture (1-3). There are two other recently described phenomena of programmed cell death (PCD): apoptosis-like PCD, which presents some features of apoptosis but lacks densely packed chromatin; and necrosis-like PCD, which is

typified by the absence of chromatin condensation but utilizes a signaling pathway (4).

Cellular degradation occurs through a cascade of cysteine proteases that cleave at aspartic acid residues in the P1 position (caspases) and target a restricted set of proteins necessary for the cell's integrity (2). Caspases have been classified as "initiator" or "apical" (caspases 2, 8, 9, 10, 11), which begin the apoptotic cascade (5-8) and "effector" or "executioner"caspases (caspase 3, 6, 7), which cleave vital cellular proteins (9).

Pathways to Cell Death

There are two well-recognized pathways of apoptosis induction (10, 11), an intrinsic pathway that depends on the cell's ability to recognize cytoplasmic and/or nuclear damage, and an extrinsic pathway that relies on signaling through death receptors expressed on the cell surface (Figure 1).

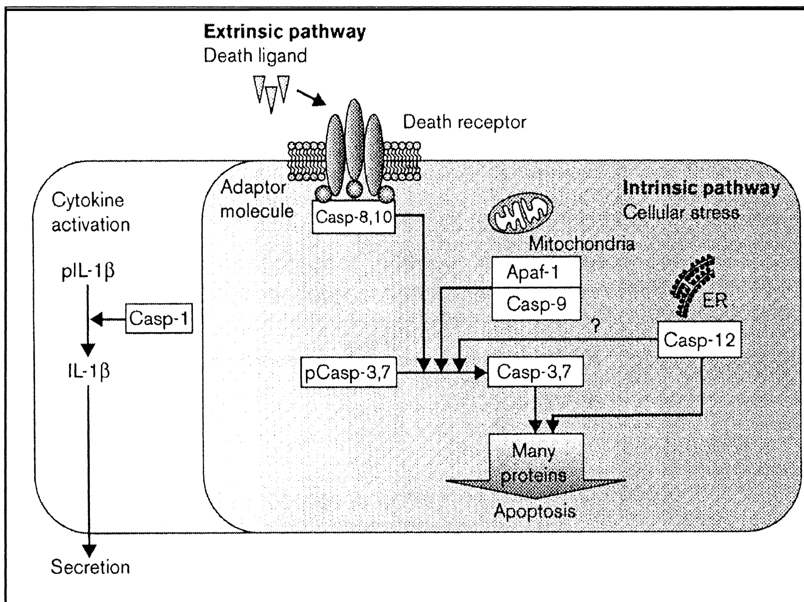

Figure 1. Schematic representation of the caspase pathways. The extrinsic pathway, which is initiated by trimerization of death receptors by their ligands, leads to activation of initiator caspases 8 and 10, and results in the cleavage of the executioner caspases 3 and 7. The intrinsic pathway, which is activated by cellular stress, leads to mitochondrial membrane permeability, cytochrome c release, the formation of an Apaf-1-caspase 9 complex with subsequent cleavage of caspase 9 and activation of the executioner caspases. "Reprinted from Current Opinion in Structural Biology, 10, Marcus G. Grutter, Caspases: key players in programmed cell death, 649-655. Copyright (2000), with permission from Elsevier".

Intrinsic Pathway

The intrinsic apoptosis pathway is activated when the cell detects intracellular metabolic disturbances and forms a complex called the apoptosome, which consists of cytochrome c, Apaf-1 (apoptosis-activating factor-1), and caspase 9. Such alterations can be induced chemically by compounds that affect DNA integrity (topoisomerase, staurosporine), or oxidative stress (12-15) or environmentally by heat, radiation, nutrient deprivation (16) or virus infection (4, 17). In any case, it appears that mitochondrial permeability and subsequent release of cytochrome c are essential for the formation of the apoptosome, activation of caspase 9 and ensuing cell death through caspase 3 activation (18). Recent evidence by Lassus et al. (8) using adenoviral oncogene E1A-transformed human fibroblasts and several cancer cell lines suggest that caspase 2 may be responsible for mitochondrial membrane permeability that initiates the formation of the apoptosome. However, O'Reilly et al. (19) have reported that caspase 2 is not required for thymocyte or neuronal apoptosis. Whether caspase 2 is an early integral component of the intrinsic apoptotic pathway or a cell specific component in the apoptotic process remains to be determined.

The basic debate in this field concerns the role of mitochondria in apoptosis, i.e. do mitochondria and bcl-2 proteins control apoptosis by activating the caspases or do caspases trigger apoptosis which results in mitochondrial rupture and amplification of the caspase cascade (20).

Extrinsic Pathway

The extrinsic pathway is dependent on signaling through the cell surface death receptors by their ligands, tumor necrosis factor (TNF)-α/TNF-receptor, Fas/FasL, and TRAIL/ TRAIL-receptors (2, 9). TNF-α and Fas have been studied extensively, while characterization of the more recently defined TRAIL and its receptors lag behind. Ligand binding and receptor oligomerization leads to the formation of the death-inducing signal complex (DISC) and recruitment of the Fas-adapter protein, FADD, through death domains (DDs). FADD, in turn, recruits caspase 8 and 10 through death effector domains (DEDs) located at the other end of the molecule from DDs. Activation of caspase 8 by binding to the DISC promotes cleavage of downstream caspases 3, 6, 7 (9). These smaller effector/executioner caspases degrade various cellular components, leading to the cell's demise.

Truncation of the Bcl-2 interacting protein, Bid, by caspase 8 leads to Bcl-2 inhibition, mitochondrial permeability, and amplification through apoptosome formation (9).

TMEV-INDUCED APOPTOSIS

Cytopathic Effect vs. Apoptosis

While the relationship between virus-induced cytopathic effect (CPE) and virus-induced apoptosis is unclear, the effect of many virus infections on cells is now described as apoptotic. Both DNA and RNA viruses have devised strategies to inhibit or curtail apoptosis, some viruses have both anti- and pro-apoptotic strategies, and still others depend on apoptosis for their dissemination (for reviews see (4, 21)). Apoptotic response to infection by the picornaviruses TMEV and poliovirus (small RNA viruses) appears to depend on the cell's permissiveness for virus infection, i.e., cells that restrict virus replication undergo apoptosis, while CPE predominates in permissive cells (22-24). Agol et al. (24) have described a switch from a pro-apoptotic program early in poliovirus replication in HeLa cells to CPE during the later stages of a productive virus infection. When poliovirus replication is restricted, the switch to CPE does not occur. In TMEV, morphologic changes and DNA laddering indicative of apoptosis could only be discerned in cells that restricted virus replication (22, 23)

TMEV-Induced Apoptosis in Cultured Cells

The activation/differentiation state of the macrophage determines whether this cell is susceptible to TMEV infection. While precursor macrophage cell lines do not support virus replication, the differentiated cells become infected and undergo apoptosis (Figure 2) (25, 26). Because macrophages appear to bear the largest virus-antigen burden *in vivo* (27)

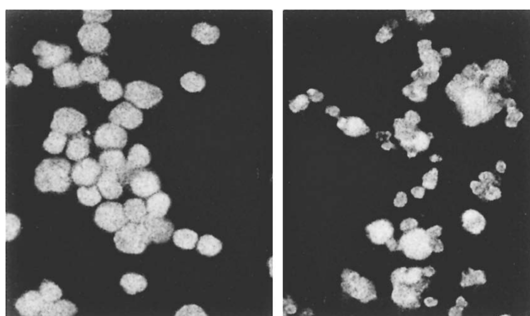

Figure 2. Apoptosis and TMEV antigen expression in undifferentiated (left) or differentiated (right) M1 cells. Cells were infected with TMEV-BeAn virus (MOI = 10) and examined 20 h later for virus antigen (green) by staining with polyclonal rabbit anti-TMEV followed by a FITC-labeled secondary antibody; nuclei (pink) were visualized by DAPI and PI staining.

and are necessary for persistence (28), macrophage cell lines are the best-studied restrictive cells. Analyses of several macrophage cell lines for their ability to support TMEV replication (22, 26, 29) revealed ~100-fold lower virus replication and titers than in permissive BHK-21 cells, but abundant virus antigen and extensive apoptosis.

In a recent analysis of TMEV replication in bone-marrow-derived macrophages from SJL/J and interferon-α/β (IFN-α/β) receptor-negative mice (30), maximal numbers (30-50%) of TMEV-positive cells were detected 27-54 h after infection, but after 13 days in culture, viable cells showed no evidence of virus antigen. At the low MOI used in these cultures, the TMEV-infected cells produced sufficient IFN-α/β to protect the remaining uninfected cells from virus infection and apoptosis. We recently found that mouse peritoneal macrophages undergo apoptosis as a result of TMEV infection at a high MOI (20-50), although about 50% the TUNEL+ cells did not contain virus antigen (manuscript in preparation). The fact that only one-half of the cells in both bone marrow derived- and peritoneal macrophage cultures are infected suggests that in these cultures cells may be at different stages of macrophage differentiation/activation. However, macrophage subsets have not been identified with available markers, and the effect of cell cycle on susceptibility to TMEV infection has not been explored in primary cells. Alternatively, the amount of IFN-α/β in cultures may selectively protect some cell subsets.

TMEV infection has been studied in microglia, the resident central nervous system (CNS) macrophages (29, 31) (32). In one study (31), the TMEV-infected microglial cell line Ra2 showed no evidence of apoptosis as assessed by DNA degradation and TUNEL, whereas both were evident in the macrophage cell line P388D1. In both cell lines, virus titers were very low. Although virus-induced apoptosis or virus replication was not directly measured in another study of primary microglia, TMEV-infected cells showed up-regulated expression of surface markers and cytokines associated with antigen presentation and activation, and were persistently infected for 1-2 weeks as determined by flow cytometric detection of virus antigen (32). The data suggest that microglia are persistently infected without evidence of cell death and may be the reservoir for continual virus infection and concurrent inflammation.

A study by Zheng et al. (33) of primary CNS cultures for TMEV infection of glial cells and apoptosis indicated that both astrocytes and oligodendrocytes supported virus replication (titers $8x10^7$ and $1x10^7$ pfu/ml, respectively), whereas microglia showed much lower titers ($3x10^4$ pfu/ml). Oligodendrocytes exhibited incomplete CPE and microglia showed DNA laddering indicative of apoptosis. Since astrocytes supported virus

replication without evidence of apoptosis, the authors suggested that astrocytes may be the primary cell type responsible for TMEV persistence in the CNS of susceptible mice. By contrast, Olson et al. (32) reported that TMEV antigen persisted in microglia for 2 weeks without evidence of CPE or apoptosis. Thus, there is still controversy about the primary cell type infected and undergoing apoptosis, possibly due to differences in isolation procedures from neonatal brains or virus concentrations and strains used for infection.

Anderson and colleagues (34) have recently characterized TMEV-infected neonatal cerebellar explant cultures, which produced virus within 24 h after infection and maintained a constant yield of ~10^4 pfu/culture for 72 h. Lactic dehydrogenase release at 48 h but not at 72 h indicated initial necrosis and recovery, respectively, whereas apoptosis increased steadily until 72 h after infection. Microscopic examination of infected cultures at 72 h revealed apoptotic nuclei and condensed axons separated from the surrounding myelin, but no myelin destruction. The investigators concluded that TMEV can directly induce apoptosis in CNS-derived neuronal granule cells without contribution of an anti-viral immune response. Since oligodendrocytes could not be identified in the explants, infection and apoptosis of cells that actually produce the myelin sheath could not be determined. Moreover, this type of study addresses only the acute phase of TMEV infection, not virus persistence and apoptosis in the chronic phase of disease.

TMEV-Induced Apoptosis in Animals

Intracerebral inoculation of TMEV in susceptible SJL mice results in a biphasic CNS disease, an initial polio-like disease primarily affecting neurons, and a chronic phase in which the virus persists in glial cells not neurons and leads to an inflammatory, demyelinating pathology.

TUNEL analysis of TMEV-infected spinal cord sections revealed numerous apoptotic cells in acute disease (1-2 weeks) in mice infected with DA virus (35-37) and in the chronic disease (> 30 days) in mice infected with BeAn or DA virus (36, 38, 39). Although Tsunoda et al. (37) reported the frequency of apoptotic cells as "seldom" in the DA-induced chronic disease (>30 days after infection),

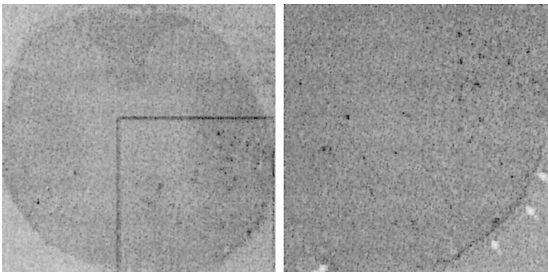

Figure 3. ***TMEV BeAn-infected SJL/J mouse spinal cord 69 days after infection. Apoptotic cells are labeled by TUNEL staining (50X) (left). The boxed area is in the left panel is shown at higher magnification on the right (200X). TUNEL-positive cells are prominent in areas of demyelination.***

some apoptotic cells could be identified as oligodendrocytes and macrophages, but not astrocytes. In contrast, Palma et al. (35) identified mainly astrocytes as TUNEL-positive 120 days after BeAn infection of SJL mice. Very few CD4+ cells were apoptotic, and other apoptotic cells were not identified. At this late stage of infection, the number of hypertrophic fibrillary astrocytes was increased indicating an active astrogliosis. In other studies of spinal cord segments examined at earlier times after infection, TUNEL-positive cells were readily observed, although the cell phenotypes were not defined (36, 39). Examination of apoptosis during the course of chronic TMEV-induced demyelinating disease revealed an increase in mean number of apoptotic cells as the disease progressed (Figure 3) (38). Approximately 75% of the apoptotic cells were identified as T cells, 10% as macrophages, and 1% or less as astrocytes; about 14% of TUNEL-positive cells were left unidentified, but were postulated to be B cells and/or oligodendrocytes. These data differ from those of Palma et al. (35), who identified apoptotic astrocytes and not T cells, but agree with Zheng et al. (33), who reported apoptosis in microglia and not astrocytes. In summary, studies of TMEV-induced apoptosis show that either few or many cells undergo apoptosis in vivo, the majority of apoptotic cells are either astrocytes or T cells, after infection microglia either die by apoptosis or survive, and, apoptosis either does or does not play a role in pathogenesis. Clearly, more definitive studies are required to determine the role of apoptosis in TMEV-induced pathogenesis.

PICORNAVIRUS ANTI-APOPTOTIC MECHANISMS

Infection of susceptible mice with the low-neurovirulence TMEV strains DA and BeAn results in a persistent virus infection and chronic demyelinating disease, while high-neurovirulence strain GDVII infection is fatal in 7-10 days with as little as 1 pfu. The DA and BeAn strains translate an 18 kb protein, L* from an alternative reading frame in the leader sequence that is not present in the high-neurovirulence strains (40). Ghadge et al. (41) reported that GDVII virus infection induced apoptosis much more efficiently than DA in a macrophage cell line, P388D1, and that DA virus with a mutation to eliminate L* translation resembled GDVII in its ability to quickly shut-off host protein synthesis and induce apoptosis. Thus, L*'s function was thought to be anti-apoptotic. However, the virus yield was unchanged in that study; if L* acts to delay the onset of apoptosis, virus replication should proceed for longer periods and virus titers should increase,

whereas in the absence of L*, apoptosis should be faster and virus titers lower.

In studies of several other investigators using a different macrophage cell line (J774-1), recombinant DA viruses translating L* replicated in cells, whereas DA virus constructed to express the GDVII leader or mutated DA L* sequences did not (42, 43). Those authors suggested that L* is required for virus growth in macrophages, but apoptosis kinetics were not assessed with these recombinant viruses. The definitive role of L* in apoptosis induction awaits further clarification.

An interesting viral anti-apoptotic mechanism is the reduction of tumor necrosis factor (TNF)-α receptor by poliovirus non-structural proteins (44). In that study retroviral vectors with non-capsid genes were analyzed for their ability to inhibit induction of apoptosis by TNF-α and Fas. Interestingly, while protein 2A, which turns off host protein synthesis, sensitized cells to TNF-α-induced apoptosis, proteins 2B and 3A, with unclear functions, suppressed it. Analysis of the mechanism by which protein 3A suppresses apoptosis revealed that brefeldin A, like poliovirus 3A, reduced the level of TNF-α receptor (44). Those experiments implicate Golgi transport inhibition as the mechanism of TNF-α removal from the cell surface. Whether TMEV proteins have a similar function remains to be determined.

ROLE OF APOPTOSIS IN TMEV-INDUCED DEMYELINATING DISEASE

That apoptotic cells exist in the spinal cord of mice with TMEV-induced demyelinating disease (TMEV-IDD) has been well-documented, although no consensus exists about the apoptotic cell phenotype. It is also known that perforin-deficient mice are unable to clear the virus and die within 2 weeks (45), indicating that the cytolytic machinery of the CD8+ T cells is required for control of the initial virus infection. Finally, virus antigen is known to persist for the lifetime of the infected animal. What is not clear is how apoptosis might contribute to the pathogenesis of the disease. One hypothesis is that macrophage phagocytosis of infected, apoptotic cells account for the continuing presence of virus antigen in macrophages in the spinal cord, so that apoptosis might play only a passive role in the persistence. Apoptosis of infected macrophages/microglia might also serve to restrict virus infection by suppressing virus production keeping virus titers low and allowing protection of the surrounding cellular environment by IFN-α/β. Apoptotic macrophages/microglia might also release IL-1, an inflammatory cytokine, which may propagate an inflammatory response (see Figure 1).

The presence of apoptotic T cells in TMEV-IDD suggests that activation-induced cell death (AICD) is taking place, since there is no evidence that T cells become infected with TMEV. AICD in TMEV-susceptible mouse strains has not been examined. If AICD is defective, it is possible that activated T cells remain in the spinal cord too long, resulting in an overabundance of cytokines and maintenance of an inflammatory response. Alternatively, if AICD occurs too quickly, the stimulating antigen may not be efficiently eliminated.

Induction of AICD in T cells involves Fas/FasL and TRAIL/TRAIL-R interactions (46), molecules that are increased in MS patients (47). Recently, the anti-apoptotic protein Bcl-X_L was found to be up-regulated in multiple sclerosis patients (48), raising the possibility of a dysregulated balance between pro- and anti-apoptotic proteins in this disease and suggesting a promising area of research.

While oligodendrocyte- and astrocytes-induced apoptosis by direct BeAn virus infection in vivo remains controversial, virus infection of derived cell lines in vitro does result in apoptosis. Besides the elimination the myelin-producing oligodendrocytes, phagocytosis of these cells and myelin debris by macrophages might result in efficient antigen presentation of myelin peptides capable of stimulating antigen-specific T cells and propagating an additional inflammatory response. This expansion would result in further CNS damage and exacerbation of the clinical symptoms in the mice.

Further studies of TMEV-IDD are needed to address the role of L* in persistence and pathogenesis, the contribution of apoptotic astrocytes, macrophages and oligodendrocytes to pathogenesis, and the role of apoptotic dysregulation in the disease process. Understanding the mechanism of apoptosis control in this model system would offer insights and direction for MS research.

CORONA VIRUS-INDUCED DEMYELINATION

Chapter C1

HISTOPATHOLOGY IN CORONAVIRUS-INDUCED DEMYELINATION

Ehud Lavi
Division of Neuropathology, Department of Pathology & Laborator Medicine., University oj Pennsylvania, School of Medicine, Philadelphia, PA 19104

Abstract: The experimental model system of coronavirus mouse hepatitis virus (MHV) induced demyelination in 4-6 week old C57Bl/6 or Balb/c mice exhibits a biphasic disease and two distinct forms of virus-induced demyelination. During the acute phase of the disease MHV infection causes acute encephalitis, and some strains of virus cause also hepatitis. Infection with the JHM strain of MHV causes severe panencephalitis, whereas MHV-A59 causes mild to moderate encephalitis involving specific limbic and limbic related areas of the brain and brain stem. The target cells are neurons and glia including oligodendrocytes. Demyelination during the acute stage is due to cytolytic infection of oligodendrocytes. After two weeks, the disease process enters a chronic stage of immune-mediated demyelination, in the presence of high levels of anti-viral antibodies and persistent low levels viral RNA in glial cells, without detectable levels of infectious virus or viral antigens.

Key words: Demyelination, mouse hepatitis virus (MHV), coronaviruses, nidoviruses, histopathology, pathology, pathogenesis, autoimmunity.

INTRODUCTION

The mechanism of demyelination in the model system of MHV-induced demyelination has been the subject of intense controversy. In the early years following its original description, the MHV model has been considered a perfect example of virus-induced demyelination due to direct cytolytic effect on oligodendrocytes, as opposed to EAE and the Theiler's virus induced encephalomyelitis model, which were considered the prototypes of autoimmune demyelination. In recent years, evidence was presented in favor of an immune-mediated mechanism in MHV-induced demyelination. However, examining the strong evidence that supports each mechanism it

appears that the only explanation for to this discrepancy is that the two mechanisms co-exist in the same model. While the early descriptions referred to the cytolytic mechanism of acute infection, the later evidence described the mechanism that dominates the chronic disease. In the following chapter the histopathological features of MHV disease of the brain will be described for the two stages of the disease.

MHV INDUCD ACUTE ENCEPHALITIS

Some strains of MHV are purely hepatotropic (e.g. MHV-2) (Hirano et al. 1981), some are primarily neurotropic (e.g. JHM) (Robb et al. 1979), while others (MHV-A59, MHV-S and MHV-3) are both hepatotropic and neurotropic (Virelizier et al. 1975; Barthold and Smith 1983; Lavi et al. 1986). MHV infection has been extensively used as a model system for viral persistence and for acute and chronic neurologic diseases (Weiner 1973; Knobler et al. 1981; Stohlman and Weiner 1981; Sorensen et al. 1982; Wege et al. 1982; Barthold and Smith 1983; Buchmeier et al. 1984; Lavi et al. 1984; Perlman et al. 1990). The experimental models of neurotropic MHVs exhibit a bi-phasic disease. Acute meningoencephalitis (with or without hepatitis) is the major pathologic process in the first two weeks following inoculation. Subsequently, subacute and chronic diseases develop, which can be either an inflammatory demyelinating disease (in JHM and A59) or vasculitis (in MHV-3).

MHV enters and spreads into the brain primarily by hematogenous spread. This conclusion is based on the fact that injection of virus into one hemisphere produces a simultaneous appearance of viral antigen in both hemispheres at the same time. When the route of infection is by intracerebral injection virus quickly enters the blood circulation and re-enters the brain, and other target organs such as liver, by hematogenous spread. However, following intranasal inoculation of mice, virus can be traced propagating from the olfactory system into limbic system structures and their connections in the brain stem. Thus interneuronal transport has been suggested as an additional mode of spread within neuronal cells during acute encephalitis (Barthold 1988; Lavi et al. 1988; Barnett et al. 1993). In addition, the fact that the virus travels from cerebral hemispheres to brainstem and then to spinal cord (Perlman et al. 1990) suggests an interneuronal transport.

During the acute phase of the disease the JHM strain of MHV causes severe panencephalitis, involving the telencephalon, diencephalon, brain stem, cerebellum and spinal cord. In contrast to the pantropic property of wt JHM, MHV-A59 and certain mutants of JHM produce a limited CNS disease restricted to specific locations of predilection. These include the olfactory

and limbic systems, and certain basal nuclei, which are physiologically connected with the limbic system.

Acute MHV encephalitis cuases a lytic infection of cells including neurons, astrocytes and oligodendrocytes (Lampert et al. 1973). This finding raised the speculation that demyelination is caused only by direct cytolytic effect of the virus on oligodendrocytes.

THE MHV DEMYELINATING DISEASE

The first description of the ability of MHV to cause demyelination was in 1949. Cheever and co-workers isolated JHM, a strain of MHV, from the brains of mice with hind leg paralysis (Cheever et al. 1949). A detailed histological analysis by Bailey et al revealed disseminated encephalomyelitis and areas of demyelination with sparing of axons in the brain and spinal cord (Bailey et al. 1949). Twenty-four years later, Leslie Weiner studied in more details the pathogenesis of demyelination induced by JHM (Weiner 1973). He found that the development of demyelination was a function of the age of mice, the dose of virus and the route of inoculation. The study was focused on demyelination during the 7-15 days post infection. There was evidence of viral antigen but no evidence of immunopathology. Immunosuppressive treatment did not abolish demyelination and taking all this information together the study concluded that JHM-induced demyelination was due to a cytopathic effect of the virus on oligodendrocytes. In the same year Lampert and co-workers came to the same conclusion. They studied by electronmicroscopy the ultrastructural pathology of JHM-induced acute demyelination, 3-6 days after infection. They found acute encephalomyelitis with patchy demyelination in the brainstem and spinal cord. They also found viral particles consistent with the appearance of coronaviruses in the cytoplasm of oligodendrocytes. The obvious conclusion from that study was that JHM replicated in oligodendrocytes and killed some of them causing demyelination.

Both JHM and A59 then cause subacute and chronic inflammatory demyelination in the brain, but mainly in the spinal cord (Stohlman and Weiner 1981; Lavi et al. 1984). Propagation of virus from the initial site of infection in the brain to the spinal cord occurs by transport of the virus in neurons and astrocytes (Sun and Perlman 1995). Astrocytes in particular may play an important role in this process by secreting cytokines and producing iNOS (Sun et al. 1995). Perivascular mononuclear (lymphocytic/macrophage) inflammatory infiltration of meninges and Virchow-Robin spaces is seen adjacent to areas of destruction of myelin, denuded, but otherwise intact axons, and macrophages containing myelin debris are seen in various areas of white matter, especially in the spinal

cords of infected animals (Lampert et al. 1973; Weiner 1973; Fleury et al. 1980; Lavi et al. 1984). Recurrent demyelination, remyelination, regeneration of oligodendrocytes and increased myelin basic protein gene expression have been demonstrated in various MHV model systems (Herndon et al. 1975; Herndon et al. 1977; Kristensson et al. 1986). These features parallel many of the pathologic findings seen in multiple sclerosis in contrast to the monophasic viral or post viral human demyelinating diseases such as acute disseminated encephalomyelitis (ADEM), and progressive multifocal leukoencephalopathy (PML).

Several laboratories including our own showed evidence of persistent coronavirus infection in both glial cell cultures and in animals. Persistent virions were demonstrated in chronic infection with ts mutant of JHM (Knobler et al. 1982), and persistence of viral genome was found following infection with MHV-A59 (Lavi et al. 1984). Persistent infection of glial cultures with MHV-A59 was used to demonstrate induction of MHC class I expression on astrocytes and oligodendrocytes, mediated by a soluble factor (Suzumura et al. 1986; Suzumura et al. 1988; Lavi et al. 1989). MHC class II induction mediated by viral particles has been demonstrated in glial cell infection with JHM (Massa et al. 1986). In the last decade the role of an immune mediated pathogenesis as the major mechanism of chronic MHV-induced demyelinating disease has been suggested based on indirect evidence. Adoptive transfer of demyelination with T cells from JHM-infected rats and in-vitro sensitivity to myelin basic protein suggested the possibility that MHV induced demyelination can be at least in part an immune-mediated, EAE-like disease (Watanabe et al. 1984). Immunosuppression of mice infected with JHM decreased the incidence of demyelination suggesting that the chronic demyelinating disease is immune-mediated (Wang et al. 1990).

ACKNOLEDGEMENTS

This work was supported in part by grants from the NIH and the National Multiple Sclerosis Society. The intellectual and technical contributions of Li Fu, Yun Li, Jayasri Das Sarma, Talya Schwartz, Donna M. Gonzales and Elsa Aglow are greatly appreciated.

Chapter C2

THE ROLE OF ASTROCYTES, MICROGLIA, AND ENDOTHELIAL CELLS IN CORONAVIRUS-INDUCED DEMYELINATION:

Induction of cytokines and other signaling mechanisms

Yun Li and Ehud Lavi*
*Division of neuropathology, Department of Pathology and Laboratory Medicine, University of Pennsylvania, School of Medicine, Philadelphia, PA 19104. *Present address: Department of Pathology and Laboratory Medicine, Weill Medical College of Cornell University, New York, NY 10021*

Abstract: Infection of neurotropic strains of coronaviruses in susceptible animals results in acute encephalomyelitis followed by a chronic demyelinating disease, similar to multiple sclerosis (MS). Although the mechanism of chronic coronavirus-induced demyelination is not entirely clear, studies show that it is mostly immune-mediated. Astrocytes, microglia and endothelial cells play an important role in normal functions as well as in immunologic and pathologic processes in the central nervous system (CNS). The interaction between coronaviruses and these cells induces various inflammatory mediators including cytokines, chemokines, MHC and NO, which acting in concert are involved in the pathogenesis of demyelination.

Key words: astrocytes, microglia, endothelial cells, coronavirus, demyelination

1. INTRODUCTION

Astrocytes, microglia and endothelial cells play an important role in the pathogenesis of coronavirus, mouse hepatitis virus (MHV)-induced disease in mice in several ways. All three cell-types are targets to various degrees of MHV infection during acute and chronic disease. Secondly, astrocytes and microglia are also targets of apoptotic cell death, presumably as a direct consequence of infection. In addition, astrocytes and microglia serve as reactive proliferating cells, as normally seen in viral encephalitis and other types of CNS injury. Finally all three cell-types are considered part of the CNS innate immune system, and as such are responsible for pro-

inflammatory immune reactions. These reactions involve secretory functions of a variety of pro-inflammatory molecules including cytokines, chemokines, upregulation of major histocompatibility complex (MHC) and NO molecules and a variety of downstream signal transduction and related molecules. CNS disease, especially demyelination could be a result of a combination of viral cytopathic effect on cells and the secondary pathologic effect of toxic inflammatory mediators, thus fulfilling the concept of autoimmunity. Indirect proof for this concept comes from studies in which immuno-suppression ameliorated chronic MHV-induced demyelination. In the following paragraphs we will briefly review the normal functions of astrocytes, microglia and endothelial cells and evaluate how these functions are affected in relationship to the pathogenesis of virus-induced CNS disease.

1.1. Astrocytes

Historically two groups of glial cells were identified in the CNS: the macroglia, including astrocytes, oligodendrocytes, and ependymal cells, and microglia. More recently microglial cells have been identified as bone marrow derived and not of neuroectodermal origin, and therefore cannot be considered as true glial cells.

Astrocytes, the main CNS glial cells have a number of important physiological properties related to CNS homeostasis. Astrocytes have a dynamic role in regulating neuronal function (Sofroniew et al. 1999; Haydon 2000) by the release of neurotrophic factors, guidance of neuronal development, contributing to the metabolism of neurotransmitters, and regulating extracellular pH and K^+ levels. Astrocytes influence the formation and maintenance of the blood-brain barrier (BBB), a structure that serves to limit entry of blood-borne elements into the CNS. Astrocytic foot processes are in close apposition to the abluminal surface of the microvascular endothelium of the BBB, and soluble factors secreted by astrocytes appear to be involved in the maintenance of the BBB. Thus, astrocytes contribute to both the structural and functional integrity of the BBB (Wolburg-H 1995).

Astrocytes also serve as one of the immune effecter cells in the CNS. Astrocytes play a significant role during infectious and autoimmune diseases of the CNS. As part of the BBB, astrocytes are in close proximity to endothelial cells and secrete cytokines, chemokines and adhesion molecules (Lee et al. 2000). Cultured astrocytes express a wide range of molecules with neurotropic properties such as nervous growth factor (NGF), glial-derived growth factor (GDGF), and ciliary neurotropic factor (CNTF). In response to activation by interferons astrocytes express class I and class II MHC antigens. The expression of the costimulatory molecules B7 and

CD40 in astrocytes is controversial (Aloisi et al. 1998; Soos et al. 1999; Nguyen and Benveniste 2000).

The ability of astrocytes to function as bona fide antigen presenting cells (APCs) is also controversial. Early studies documented the ability of class II MHC-positive astrocytes to function as APCs in vitro (Fierz et al. 1985; Fontana et al. 1986; Takiguchi and Frelinger 1986). These studies clearly indicate that astrocytes exposed to IFN-γ have the capacity to express molecules such as class II MHC, invariant chain, H2-M, B7-1, and B7-2, enabling them to efficiently process and present self antigens and activate both naive and memory T cells. However, there is also a large body of evidence indicating that astrocytes function as nonprofessional APCs by promoting mainly Th2 responses and/or apoptosis of T cells, which may be important for recovery from Th1-mediated CNS inflammation (Meinl et al. 1994; Weber et al. 1994).

1.2. Microglia

Microglia constitutes 12% of the cells in the CNS, which are the principal immune cells in the CNS and play a significant role in the host defense against invading microorganisms. The CNS endogenous microglia share many properties with macrophages, having developed from a common precursor cells (Nelson et al. 2002). Features common to microglia and systemic macrophages include the expression of innate immune receptors and the ability to phagocytose pathogens, cells or cellular debris (Ling and Wong 1993; Williams et al. 1994).

The functions of microglia in the CNS include phagocytosis, antigen presentation, production and release of cytokines, eicosanoids, complement components, and excitatory amino acids such as glutamate, oxidative radicals, and nitric oxide (Gehrmann et al. 1995). Three states of microglia have been identified based on developmental and pathophysiologic studies: (1) the resting, ramified microglia present in normal CNS; (2) the activated non-phagocytic microglia found in areas involved in CNS inflammation (3) the reactive, phagocytic microglia observed in areas of trauma and infection. Microglia can express class I and II MHC antigens, Fc receptors (I-III), complement receptors (CR1, CR2, CR4), β2-integrins, intercellular adhesion molecule-1 (ICAM-1), and costimulatory molecules B7-1 and B7-2 (Minagar et al. 2002). Numerous studies have confirmed the role of microglia as important APCs within the CNS (Aloisi et al. 2000; Becher et al. 2000), while the role of astrocytes remains controversial.

1.3. Endothelial cells

Traditionally, the CNS has been regarded as an immunologically privileged site. The CNS lacks lymphatic vessels and is sealed by the BBB.

The cellular basis for the BBB is at the levels of both the CNS microvascular endothelial cells and the choroid plexus epithelial cells. The BBB is an important mechanism for protecting the brain from fluctuations in plasma composition and from circulating agents such as neurotransmitters and xenobiotics capable of disturbing neural function (Abbott and Romero 1996). The barrier also plays an important role in the homeostatic regulation of the brain microenvironment necessary for the stable and coordinated activity of neurons (Abbott 2002). The brain endothelium has lower levels of endocytosis/transcytosis than peripheral capillaries, but has a number of specific transport and enzyme systems, which regulate molecular traffic across the endothelial cells. The brain endothelium also contains specific enzymatic systems such as monoamine oxidase that support the protective and detoxifying roles of the BBB. Cerebral microvascular endothelial cells are also considered as potential APCs because of their large cumulative surface and their unique anatomical location between circulating T cells and the extra-vascular sites of antigen exposure. Thus BBB covers a number of static and dynamic properties that enable the endothelium to protect and regulate the brain microenvironment (Abbott and Romero 1996).

The BBB phenotype develops under the influence of associated brain cells, especially astrocytes. *In vitro* cell culture models have provided a great deal of information about the key role of astrocytes in the induction of the BBB phenotype in brain endothelium (Bauer and Bauer 2000). The chemical nature of the glial-produced inductive signal(s) is currently unclear. TGF-β (Tran et al. 1999), GDNF (Utsumi et al. 2000), bFGF (Sobue et al. 1999), IL-6 and hydrocortisone (Hoheisel et al. 1998) have been shown to modulate endothelial differentiation and induction. In addition to a role in barrier induction and maintenance, astrocytes may play active roles in modulating BBB permeability by the release of several humoral agents including glutamate, aspartate, taurine, ATP, ET-1, NO, TNFα, MIP2 and IL-1β, although the regulation of this release is not well understood (Abbott 2002). Interestingly, it has recently been shown that endothelial cells induce the differentiation of astrocyte precursor cells into astrocytes in vitro, which is mediated by endothelial cell production of leukemia inhibitory factor (LIF) (Mi et al. 2001). Thus endothelium and astrocytes are involved in two-way induction. It is clear that endothelial cells are involved in both long- and short-term chemical communication with neighboring cells, with astrocytes being of particular importance.

Maintenance of the adult BBB appears to depend on continuing exchange of inductive signals between glia and endothelium, and disturbance of this induction may be instrumental in several neuropathologies involving BBB dysfunction, such as tumors and MS.

2. Animal models of coronavirus induced demyelination

Coronaviruses constitute a large group of positive-stranded RNA viruses that are associated with a wide variety of respiratory, gastrointestinal, and neurological diseases in animals and humans. However there is no conclusive evidence that any human neurological diseases, such as MS, may occur as a result of human coronavirus infection.

MS is an inflammatory demyelinating disease of the CNS that is characterized by mononuclear cell infiltration into the CNS, myelin degradation and oligodendrocyte loss. It is the most common neurological disease affecting young adults (Ewing and Bernard 1998). The etiology and pathogenesis of MS have yet to be elucidated but are probably multifactorial, involving both genetic and environmental factors (Ewing and Bernard 1998). Several viruses have been associated with demyelinating processes including human coronaviruses (HCoV) and murine coronavirus (MHV). Intracerebral infection of susceptible mice with neuroadapted strains of mouse hepatitis virus (MHV) results in an acute encephalomyelitis followed by a chronic demyelinating disease similar to the pathology of the human MS (Lavi et al. 1984; Lavi et al. 1986; Houtman and Fleming 1996; Lane and Buchmeier 1997), serving as models for this diseases. The two strains of MHV that have been used in the majority of studies of MHV infection in the CNS are MHV-A59 and JHM (MHV-4).

The mechanism of MHV induced demyelination is still not well understood. Although it was initially believed to result from direct viral lysis of oligodendrocytes, chronic demyelination was demonstrated to be largely immune mediated in more recent reports. The immune response to MHV infection is critical in host defense as well as the development of demyelination (Houtman and Fleming 1996; Wu et al. 2000). However, the precise role of individual components of the immune system in this process is not known and need intense investigation.

3. The role of astrocytes, microglia, and endothelial cells in MHV-induced CNS demyelination

The fact that the nude mice were unable to clear virus and still develop demyelination suggests that conventionally educated T cells are not an essential component for demyelination. That means that either the $\gamma\delta$ subset of T cells, natural killer cells, or microglia, astrocytes, or even endothelial cells, may participate and/or be responsible for the demyelinating process.

3.1 The innate immune system of the CNS

To protect the host from the invasion of foreign organisms and pathogenic insults, the immune system has evolved into two parts: one is

responsible for immediate, relatively generic, action against external agents, known as the "the innate immune system". The other component of the immune system responds specifically to an external threat and requires plasticity and memory, which is called the "adaptive or acquired immune system". These two systems are not separate, but are functionally intertwined and the actions of one have a profound effect on the other (Medzhitov and Janeway 1997).

B and T lymphocytes are the cellular members of the adaptive immune system. These cells are generated in primary lymphoid tissues (bone marrow, thymus) and re-circulated in secondary lymphoid structures (lymphnode, spleen). The innate immune system on the other hand uses mainly phagocytic cells (including monocytes/macrophages, and polymorphonuclear phagocytes) as a first line of defense against foreign structures. Astrocytes and microglia are the principal innate immune cells in the CNS concomitant with inflammatory brain disease and play a significant role in the host defense against invading microorganisms.

3.2 The immune response within the CNS upon viral infection

Although the CNS has been characterized as an immune privileged site, it is also the site of blood-borne inflammation, either in response to exogenous antigens (infection) or as a result of disrupted peripheral tolerance to self antigens (autoimmnunity). The microenvironment of the CNS, shaped by its structural and cellular components, participates in the physiological immune process that occurs within the CNS and is at least in part responsible for the extent of immune response within the CNS upon viral infections. Glial and microglial cells play a pivotal role in both acute and chronic phases of coronavirus infection, which could lead to the production of a variety of inflammatory molecules in glial cells including cytokines, chemokines, MHC and nitric oxide (NO) that have been associated with the pathogenesis of demyelination.

3.4. MHC class I and II expression

The MHC class I and II antigens play an important role in demyelination following infection by MHV of resident cells of the CNS. Infection of the CNS with MHV-A59, a neurotropic murine coronavirus, induces class I MHC antigen expression on oligodendrocytes and astrocytes (Suzumura et al. 1986; Suzumura et al. 1988; Lavi et al. 1989), cells that do not normally express detectable MHC surface antigens. The role of MHC class I in demyelination remains complex because of reports indicating that demyelination can occur in MHV-infected mice that lack either stable

expression of the MHC class I molecule or functional CD8+ T cells (Gombold et al. 1995). Because MHC class I antigens play a key role in interaction between cytotoxic T cells and target cells, the induction of MHC class I antigens could potentially allow glial cells to interact with or become a target for immunocytes.

The MHC class II molecules play a critical role in induction of immune responses through presentation of processed antigens to $CD4^+$ T-helper cells. Although class II MHC molecules are essential for lymphocyte development, antigen presentation, and T-cell activation, inappropriate class II expression has been implicated in several autoimmune diseases, including rheumatoid arthritis, inflammatory bowel disease, and MS (Grusby and Glimcher 1995). Class II MHC molecules are normally expressed on professional APCs, such as B cells, macrophages, dendritic cells, and thymic epithelium, expression on other cell types, including astrocytes, can be induced and/or regulated by cytokines, neurotransmitters, and neuropeptides. Astrocytes were the first CNS cell type shown to express class II MHC molecules upon IFN-γ stimulation in vitro (Wong et al. 1984). The cytokine TNF-α, while having no influence alone on class II MHC expression, enhances IFN-γ-induced class II MHC expression on astrocytes (Panek et al. 1994). Infection of astrocyte cultures derived from MHV-susceptible Lewis rats with MHV-JHM resulted in induction of MHC class II, whereas no such induction was observed in astrocytes from disease-resistant Brown Norway rats (Massa et al. 1986; Massa et al. 1986). A number of soluble mediators have been shown to inhibit class II MHC expression in astrocytes, which include TGF-β, IL-1β, IFN-β, IL-4, glutamate, vasoactive intestinal peptide, norepinephrine, and nitric oxide (Rohn et al. 1996). The expression of MHC II on phagocytic microglia implies the capacity of microglia as APCs. Phagocytic microglia is often regarded as potentially cytotoxic in both acute and chronic CNS disorders. MHC class II expression by phagocytic microglia also corresponds to the elevated expression of potentially cytotoxic substances in the CNS, among which nitric oxide and TNF-α are notably involved in the death of oligodendrocytes and demyelination (Benveniste 1997; Eugster et al. 1999). A study on the demyelinating *twitcher* mouse has shown that the number of reactive microglia and the concomitant demyelination is significantly reduced when the *twitcher* mouse carries an MHC II null background (Matsushima et al. 1994). Therefore, MHC II expression by activated microglia in chronic neurodegenerative disorders may indicate that the activated microglia become cytotoxic (Zhang et al. 2001).

Expression of MHC class II has been shown to be important in demyelinating disease in some animal models, such as TMEV and EAE (Borrow and Nash 1992). However, mice deficient in MHC class II

expression are capable of having demyelination following infection with MHV-JHM (Houtman and Fleming 1996). Therefore, the expression of MHC class I or II may play some role in the MHV-induced demyelination, but neither one is absolutely necessary for this process.

3.5. Cytokines and chemokines production

Astrocytes and microglia produce a variety of cytokines and chemokines upon stimulation with a variety of factors including viral infection. Although expression of cytokines and chemokines is controlled and balanced in the normal, healthy, CNS, aberrant expression occurs in CNS diseases such as AD, MS, HAD, Parkinson's disease, and in brain injury/trauma. In many of these diseases, astrocytes and microglia are responsible for some of the production of cytokines and chemokines, whereas blood-borne inflammatory cells are responsible for the rest. Both *in vitro* and *in vivo* studies have documented the ability of astrocytes to produce interleukin-1, -6, and -10 (IL-1, -6, and -10); interferon (IFN)-α, and -β; colony-stimulating factors GM-CSF, M-CSF, and G-CSF; TNF-α; TGF-β; and chemokines including RANTES, IL-8, monocyte chemoattractant protein-1 (MCP-1), and IFN-γ-inducible protein-10 (IP-10) (Dong and Benveniste 2001). Cytokines that have been demonstrated to be produced by microglia are IL-1, 2, 3, 4, 6, 8, 10, IFN-γ, TNF-α, TGF-β, and CSF. Cytokine/chemokine communications between microglia and astrocytes are involved in the balance of protective and destructive actions by these cells. Both cell types may play a dual role, amplifying the effects of inflammation and mediating cellular damage as well as protecting the CNS. Thus, interactions between T lymphocytes, microglia, and astrocytes play a major role in the pathogenesis of nerological diseases such as MS.

Chemokines are small chemotactic cytokines that modulate leukocyte recruitment and activation during inflammation. Chemokines have been implicated in a variety of normal CNS functions (i.e., neuronal progenitor migration, axon guidance and adhesion, oligodendrocyte proliferation, and intercellular communication) although more and more evidence supports their role in CNS disease and injury such as Alzheimer's disease and HAD. In particular, chemokines are induced in the demyelinating disease MS, and numerous animal models for demyelination including experimental autoimmune encephalomyelitis (EAE), Theiler's and MHV-induced demyelinating disease, experimental autoimmune neuritis, and twitcher, a murine model of globoid cell leukodystrophy (Glabinski and Ransohoff 1999; Hoffman et al. 1999; Kieseier et al. 2000).

Many cells in the body can secrete chemokines, including astrocytes and microglia. MHV infection of the CNS results in an orchestrated expression of chemokine genes including IFN inducible protein of 10 kDa/ CXCL10,

monokine induced by IFN-γ/CXCL9, CCL2, CRG-2, MCP-1, MCP-3, RANTES, Mig, macrophage inflammatory protein-1β/CCL4, CCL5, and CCL7 (Lane et al. 1998). Neutralization of IP-10 or Mig at the time of infection with MHV results in increased mortality, higher viral loads and markedly decreased T cell infiltration into the CNS (Liu et al. 2000; Liu et al. 2001). In contrast, mice treated with RANTES antiserum have delayed viral clearance, decreased T cell infiltration, and significantly less demyelination than do untreated mice, but show no change in mortality (Lane et al. 2000). Also certain chemokine receptors including CCR1, CCR2 and CCR5, have been shown to regulate the gateway for inflammatory cell entry into the CNS. CCR1-deficient mice have reduced CNS inflammatory responses in the MOG-induced EAE model (Rottman et al. 2000), and CCR5-deficient mice have negligible inflammation after disseminated *C. neoformans* infection of the CNS (Huffnagle et al. 1999). Therefore, chemokines have an important role in host defense as well as demyelination induced by viral infection by attracting T lymphocytes and macrophages into the CNS.

Cytokines are a large and diverse group of polypeptides ranging in size from 8 to 26 kDa, which major function is activation of the immune system and inflammatory responses. In most acute encephalitis cytokines such as IL-1, TNF-α, IL-6 and IFN-γ are detected in the CNS of infected mice. Depletion of IFN-γ leads to decreased virus clearance and greater mortality. However, neutralization of TNF-α did not appear to affect either T cell recruitment or virus clearance. Except for astrocytes and microglia, edothelial cells are another possible cellular source of cytokine including IL-1, IL-6 and TNF-α, as well as some cytokines receptors IL-1R1 and IL-1R2 .

In our laboratory we analyzed the ability of MHVs with different neurotropic phenotypes to modulate the expression of cytokines in astrocytes and microglia in primary cultures from newborn C57BL/6 mice. The results show that infections of cultures with neurotropic viruses MHV-A59 and JHM up-regulate IL-1β, IL-6, IL-12p40, IL-15 and TNF-α mRNA in both astrocytes and microglia, significantly more than infection with the non-neurotropic virus MHV-2. Similar up-regulation was observed in mouse brains during acute encephalitis and in mouse spinal cords during the chronic inflammatory demyelinating disease but a different profile was seen in the liver during acute hepatitis. There are close interactions between the five upregulated cytokines. Studies of MHV-A59 infections in cultures derived from cytokine knockout mice indicate that IL-12 and TNF-α are the upstream molecules that cause the subsequent up-regulation of the other three cytokines. Furthermore we found that infection with neurotropic MHVs induce up-regulation of a set of chemokines in astrocytes and microglia, including MIP-1, MIP-3, MCP-2, MCP-5, MIG. This pattern of

cytokine/chemokine response in astrocytes and microglia is similar to the Th1 response of lymphocytes and appears to be associated with the neurotropic properties of the virus strain. These studies allow us to study the unique contribution of CNS local immune cells to the process of MHV disease and thus provide new insights into the pathogenesis of MHV-induced neurological diseases as well as the general role of brain immune cells and cytokines in the process of immune-mediated diseases of the CNS (Li et al. 2004).

Several reports studied the role of cytokines in the chronic demyelinating process. The cytokines IL-1β, TNF-α, IL-6 are expressed by astrocytes which are located near the sites of demyelination in chronically infected spinal cords (Perlman 1998). A wide range of cytokines have been detected in MS lesions, and IL-1α and β, IL-6, TNF-α, and IFN-γ may participate in the CNS demyelination process (Benveniste 1998). Cytokines such as IFN-γ, TGF-β, IL-1, IL-4, and IL-10 may regulate class II MHC expression (Han et al. 1999; O'Keefe et al. 1999). Cytokines induce increased expression of chemokines, stimulate adhesion molecules on endothelial cells, and allow leukocyte entry into the CNS. Thus cytokines are involved in the initial phase as well as the development stages of demyelination.

Studies using knockout mice have shown that neither perforin, Fas-FasL, TNF-α, IL-10 or IFN-γ are required for demyelination (Haring and Perlman 2001). Our own studies in knockout mice indicate that deficiency of IL-6 and IL-12p40 does not decrease the level of demyelination induced by MHV-A59 infection compared to wide type C57BL/6 mice. Thus, none of the single cytokines plays a crucial role in demyelination, however, we still did not rule out that a combination of cytokines may be required for demyelination. Chemokines may play a role in demyelination. RANTES is a proinflammatory chemokine that act as a chemoattractant for a variety of lymphocytic and myeloid cell types including monocytes and granulocytes (Lane et al. 2000). Inhibition of RANTES has been shown to reduce MHV induced demyelination (Lane et al. 1999). An alternative hypothesis is that MHV could potentially damage oligodendrocytes by disrupting the function of astrocytes, which in turn affect oligodendrocytes (Sun and Perlman 1995).

3.6. Regulation of Th1/Th2 development

Activation of $CD4^+$ T-helper (Th) cells within the CNS plays an important role in regulating immune responses, inflammation and ultimately repair, during a variety of CNS diseases. The types of Th cells are distinguished by the profiles of cytokines that they produce. Th1 cells produce the cytokines IL-2, IL-12, IFN-γ, LT-α, and tumor necrosis factor (TNF), leading to macrophage activation, inflammation, and tissue damage (Rengarajan et al. 2000). Th1 cells have been implicated in the pathogenesis

of CNS autoimmune diseases such as MS and EAE (Owens et al. 2001). In contrast, Th2 cells produce the cytokines IL-3, IL-4, IL-5, IL-6, IL-7, IL-10, IL-11, and IL-13, that mediate humoral immune responses and inhibit macrophage functions (Rengarajan et al. 2000). Within the CNS, Th2 type cytokines play a role in down-regulating Th1 responses and macrophage activation. The presence of IL-12 and IFN-γ facilitates Th1 development; while IL-4 promotes Th2 differentiation.

Cytokines are the most prominent factors determining the development and polarization of Th cells. However these cytokines are not produced by T cells but by APCs such as DCs, B lymphocytes and macrophages. Astrocytes and microglia are also the source of cytokines within the CNS that can influences Th1 versus Th2 responses (Aloisi et al. 1997; Stalder et al. 1997). According to our own studies IL-12, the crucial cytokine facilitating Th1 development, can be produced by astrocytes/microglia upon MHV infection in vitro. Regulation of class II MHC, B7, and CD40 expression are also involved in the T cells polarization.

3.7. NOS activation and NO production

Nitric oxide (NO) is a pleiotropic molecule with important functions in vascular regulation, neuronal function, and immunological processes. Of the three isoforms of nitric oxide synthase (NOS), NOS2 is recognized as an important inflammatory mediator, with both protective and immunopathological capabilities (Nathan and Xie 1994). Macrophage production of NO by NOS2 is part of the effector phase of the immune response to numerous pathogens, including viruses (MacMicking et al. 1997; Reiss and Komatsu 1998). NOS2-generated NO may contribute to the pathology of demyelination by exerting cytotoxic effects on oligodendrocytes (Merrill et al. 1993) and by regulating proinflammatory factors such as cytokine and chemokine secretion (Remick and Villarete 1996; Brenner et al. 1997; Merrill and Murphy 1997).

Both astrocytes and microglia express NOS-2 and release NO upon virus stimulation in vitro. Moreover, these cells are the likely source of NOS-2 expression during CNS inflammation *in vivo* (Mitrovic et al. 1996). During the acute phase of MHV infection of mice, expression of NOS2 by macrophages is up-regulated, whereas NOS2 synthesis is confined to astrocytes during the chronic demyelinating disease (Sun et al. 1995; Grzybicki et al. 1997).

The role of NO and NOS2 in MHV-induced demyelination is still controversial. Inducible NOS2 transiently contributes to MHV-induced demyelination. Inhibition of NOS2/NO by aminoguanidine (AG), a selective inhibitor of NOS2 activity, slows the progression of MHV-induced demyelination by controlling inflammation and modulating chemokine

expression in the CNS (Lane et al. 1999). More recent studies show that NOS2 function is not required for demyelination in mice infected with MHV-JHM (Wu et al. 2000). Although NO may have a transient role in the early steps of demyelination, it is not necessary for disease to develop. Infection of NOS2 knockout (-/-) and NOS2(+/+) mice with MHV resulted in similar kinetics of viral clearance from the brain and comparable levels of demyelination. MHV-infected NOS2(-/-) mice displayed a marked decrease in mortality as compared to infected NOS2(+/+) mice, which correlated with a significant decrease in the number of apoptotic cells present in the brain. These studies indicate that NOS2-generated NO contributes to apoptosis of neurons but not demyelination following MHV infection (Chen and Lane 2002).

Of note, MHV-induced demyelination differs from that observed in other model systems since inhibition of NO production by AG ameliorates demyelination in rodents with adoptive EAE and mice infected with Theiler's murine encephalomyelitis virus (Cross et al. 1994; Rose et al. 1998).

3.8. The disruption of the BBB

The BBB has been assumed to be an effective barrier for blood cells. However, during viral infections or autoimmune diseases of the CNS, T lymphocytes are activated and migrate into the CNS and initiate the cellular events leading to inflammation and demyelination within the CNS white matter. The endothelial BBB has been considered the obvious place of entry of circulating lymphocytes into the CNS. The vascular endothelium is the first element that leukocytes encounter. Immune-specific interactions between lymphocytes and cerebral endothelium have been excluded as an initial mechanism. Adhesion interaction between T cells and endothelia must precede transmigration (Hart and Fabry 1995). Certain adhesion molecules seem to be critically involved in this process for example intercellular adhesion molecule 1(ICAM-1) and vascular cell adhesion molecule 1(VCAM-1) are up-regulated on the endothelial cells. Dissociated cultures of cerebral endothelial cells prepared from surgical resections of adult CNS tissue express an array of adhesion molecules whose expression is modulated by encounter with T cells or the cytokines they produce (Calabresi et al. 1997). Chemical mediators, particularly chemokines, regulate the synthesis, surface expression, and avidity of adhesion molecules. The most important adhesion molecule pairs are the selectins (E, L and P), the immunoglobulins ICAM-1 and VCAM-1, and the beta 2 and beta 1 integrins (e.g., LFA-1 and VLA-4), which play a role in a number of pathological processes (Cotran and Mayadas-Norton 1998). Various inflammatory mediators, primarily pro-inflammatory cytokines including

TNF-α and IL-1β, activate endothelial cells. Endothelial cells can also be induced to express MHC class II and B7 in vitro (Prat et al. 2000). Furthermore, they inhibit antigen presentation by other APC in co-cultures. The basis for this inhibition is still unknown.

The BBB may have a protective role against spreading of MHV-A59 into the CNS, by specific restriction of viral entry into endothelial cells of cerebral origin (Godfraind et al. 1997).

4. CONCLUSIONS

The effector mechanisms of coronavirus-induced demyelination are complex and largely redundant. The brain resident cells respond to infection by coronavirus by producing various inflammatory mediators including cytokines, chemokines, MHC and NO, which could act in concert to orchestrate an inflammatory pathology in the CNS. This argues for an indirect immunologic mechanism by which coronavirus infection could be implicated in a pathogenesis of the CNS diseases. However, one can conclude from all these data that no single molecule is absolutely required for coronavirus-induced demyelination, neither cytokines, MHC class I or II, nor NOS2. Furthermore, no specific immune cell population is essential for coronavirus-induced demyelination, neither CD4 T cells, CD8 T cells, nor hematogenous macrophages (Gombold et al. 1995; Sutherland et al. 1997). Therefore, coronavirus-induced demyelination may be a result of multiple mechanisms, which still need further investigation.

Chapter C3

AXONS AND NEURONS IN CORONAVIRUS-INDUCED DEMYELINATION

Ajai A. Dandekar and Stanley Perlman
Departments of Pediatrics and Microbiology and Interdisciplinary Program in Immunology, Univerisity of Iowa, Iowa City, Iowa, USA

Abstract: Infection of mice with the coronavirus mouse hepatitis virus induces primary demyelination in susceptible strains of rodents. Although demyelination is the primary pathological process detected in the central nervous system of infected mice, axonal dysfunction and damage also occur concomitantly with demyelination. This process is T cell mediated, with either CD4 or CD8 T cells sufficient for MHV-induced axonal damage. A striking feature is that axonal damage occurs early in the disease process, at nearly the same time as demyelination is first observed. Axonal damage in MHV-infected mice has many similarities with the parallel process in humans with multiple sclerosis.

Key words: Coronavirus, demyelination, axonal damage, T cells

1. INTRODUCTION

The human disease multiple sclerosis (MS) is characterized by focal demyelinating lesions throughout the white matter of the CNS (1, 2). In multiple sclerosis, immune-mediated damage to oligodendrocytes and/or the myelin sheaths accounts for this pathology. The process of demyelination results in electrical conduction deficits and other alterations in axonal physiology, and previously had been assumed to account for the clinical signs and symptoms of MS.

As described elsewhere in this volume, several older studies identified axonal damage as part of the disease process in MS (3). A series of recent reports confirmed that permanent damage to neurons and their axons also occurs within these demyelinating lesions (4-6). In one study (7), N-acetyl

aspartate, a neurotransmitter, was diminished throughout the CNS in patients with progressive MS, while those patients with relapsing-remitting MS exhibited reduced levels of N-acetyl aspartate only in areas of demyelination. This reduction in N-acetyl aspartate correlated with axonal loss detected by either magnetic resonance imaging or electron microscopy of involved tissue.

Other studies of patients with MS have examined the characteristics of axonal damage, using immunohistochemistry with antibodies to nonphosphoneurofilament H or amyloid precursor protein to visualize damaged axons (5, 6). The preponderance of axonal damage occurred in demyelinating lesions, with the remainder of damage found adjacent to these lesions.

Axonal damage in MS may account for a significant amount of the clinical signs and symptoms seen in the progressive phase of disease. Progressive MS is poorly correlated with the size or number of demyelinating lesion seen by MRI, suggesting that axonal pathology, not demyelination, may be the primary cause of the irreversible deficits that are observed (8). One interpretation is that demyelination and remyelination may explain the relapsing-remitting phase, while progressive disease results from irreversible axonal pathology (9).

Axonal damage has been reported in several animal models of MS, including in rodents with experimental autoimmune encephalomyelitis (EAE) and in mice with demyelination induced by Theiler's encephalomyelitis virus or mouse hepatitis virus, strain JHM (MHV) (10-13). Although it had long been believed that MHV-associated demyelination occurs primarily as a result of virus-induced destruction of oligodendrocytes, accumulating data from multiple studies indicate that CD4 and CD8 T cells are essential in the pathological process (14, 15) (see also chapter C4 of this volume). In this review, we summarize data showing that this T cell-mediated demyelination occurs concomitantly with axonal damage in MHV-infected mice.

2. TEMPOROSPATIAL PROFILE OF AXONAL DAMAGE IN MHV INFECTION

As described elsewhere in this volume, several models of MHV-induced demyelination are studied in different laboratories. In one model, splenocytes are transferred from MHV immune mice to syngeneic immunodeficient mice [mice with severe combined immunodeficiency or with genetic disruption of recombination activation gene 1 ($RAG1^{-/-}$)] infected with the neuroattenuated variant of MHV, 2.2-V-1 (16). Both SCID

and RAG1$^{-/-}$ mice lack B and T lymphocytes (17) and as such are unable to mount an adaptive immune response to MHV. While immunocompetent C57Bl/6 (B6) mice develop demyelination ten to twelve days after intracranial inoculation with MHV, their RAG1$^{-/-}$ or SCID counterparts develop, instead, a fatal acute encephalitis at 14-18 days post infection (p.i.). Clinical and histological evidence of demyelination, with accompanying macrophage/microglia infiltration, can be detected within seven to ten days of transfer.

Most recent work has been performed using MHV-infected RAG1$^{-/-}$ mice as recipients. In this adoptive transfer model, either CD4 or CD8 T cells can mediate demyelination and disease. T cells are necessary for the demyelinating process since transfer of splenocytes depleted of CD4 and CD8 T cells results in no demyelination. RAG1$^{-/-}$ recipients of CD4 T cell-enriched splenocytes (CD8 T cell-depleted) or CD8 T cell-enriched splenocytes (CD4 T cell-depleted) also develop demyelination, although with different kinetics than recipients of undepleted splenocytes. CD4 T cell enrichment results in a rapid course of disease, with mortality by day 7 p.i., while CD8 T cell enrichment results in a protracted course of disease (as compared to wild type), with mortality at day 14-16 p.i. or later. Strikingly, up to 50% demyelination is observed in recipients of CD8 T cell-enriched populations by 15 days p.i. This model system was used to determine the kinetics of axonal damage and relationship to demyelination in MHV-infected mice.

2.1 The relationship between demyelination and axonal damage in MHV-induced disease

Spinal cords were harvested from MHV-infected RAG1-/- mice at 7 days after adoptive transfer (10 days p.i.) of MHV immune splenocytes. We examined zinc formalin-fixed, paraffin-embedded sections for demyelination and axonal damage. Areas of myelin damage were determined using the chemical stain luxol fast blue (LFB) with quantification as previously described (18). We further assessed the distribution of macrophages/microglia using mAb to the macrophage-specific protein F4/80 (Serotec, Oxford, England) and viral antigen (using the MHV nucleocapsid-specific mAb 5B11.2, provided by Dr. M. Buchmeier, The Scripps Research Institute, La Jolla, CA) by immunohistochemistry. Additionally we stained for axonal damage using an antibody specific for nonphosphoneurofilament H (mAb SMI-32 (Sternberger Monoclonals, Lutherville, MD). This protein is largely found in damaged axons, but is also expressed in the cell body and proximal processes of a fraction of unaffected neurons.

In areas of demyelination, there was abundant staining with SMI-32, indicating axonal damage. Examination of the staining pattern revealed continuous axonal staining, suggestive of intact, demyelinated axons, discontinuous staining patterns consistent with Wallerian degeneration of the axon, and terminal ovoids indicative of axonal transection (Figure C3-1). We detected a large infiltrate of macrophages/microglia in areas of demyelination, consistent with a role for these cells as the terminal effectors of MHV-induced demyelination. It seems likely that these cells also partly mediate axonal damage. These areas of demyelination had relatively little viral antigen staining, suggesting that myelin and axonal damage occurred during the process of viral clearance by infiltrating lymphocytes and macrophages/microglia.

Next we analyzed areas of white matter adjacent to demyelinating lesions. These periplaque regions exhibited abundant staining for virus antigen, with a modest infiltration of macrophages as compared to areas of demyelination. This most likely represents an early infiltrate of macrophages into virus-infected white matter. This infiltration of macrophages was accompanied by roughly half the level of staining for nonphosphoneurofilament H as detected in areas of frank demyelination.

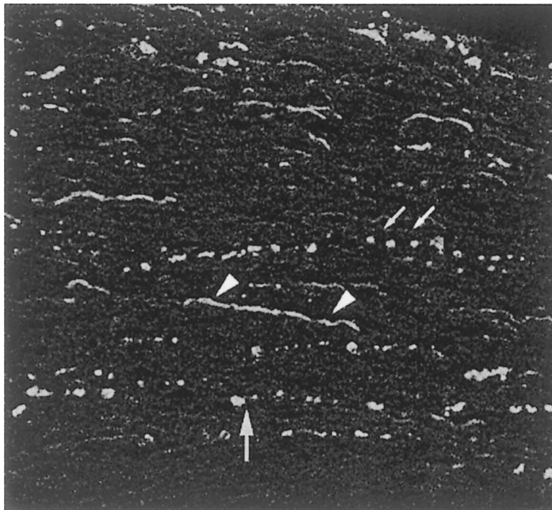

Figure C3-1. MHV-induced axonal damage. Midsagittal spinal cord sections from MHV-infected mice were stained with mAb SMI-32. An area of demyelination within the white matter is shown. Three different types of axonal pathology are indicated. Arrowheads: a demyelinated axon. Small arrows: a degenerating axon. Large arrow: a terminal ovoid, consistent with axonal transection.

Areas of normal appearing white matter distant from demyelinating lesions, as assessed by staining with LFB, were generally devoid of macrophages and viral antigen, although scattered virus-infected cells were occasionally detected in these regions of the spinal cord. These areas had only limited staining with mAb SMI-32. This staining may have resulted from direct viral damage to the axon, since viral antigen has been detected throughout axons (19). Alternatively, and we believe more likely, axonal damage was occurring distal to a demyelinating lesion.

Two methods were used to quantify the amount of axonal damage in the spinal cords of MHV-infected mice. In one method, midsagittal sections of whole spinal cords were stained with mAb SMI-32, analyzed by confocal microscopy, photographed and digitalized. The numbers of pixels fluorescing above background were counted (Figure C3-2A). This method quantifies total damage throughout the spinal cord, but because the majority of the spinal cord does not exhibit demyelination, tended to blunt differences between samples. To address this issue, the number of SMI-32 positive blebs in areas of demyelination, areas adjacent to demyelination, or normal appearing white matter was counted in a blinded fashion (Figure C3-2B). Quantification of the amount of axonal damage (Figure C3-2B) revealed that there were roughly twice as many SMI-32 positive axons in areas of demyelination, on average, than in adjacent areas, while there was minimal damage in distant normal-appearing areas of white matter.

Finally, we investigated the kinetics of axonal damage in relationship to the appearance of demyelination. Spinal cords of mice at 4.5 days p.i. were

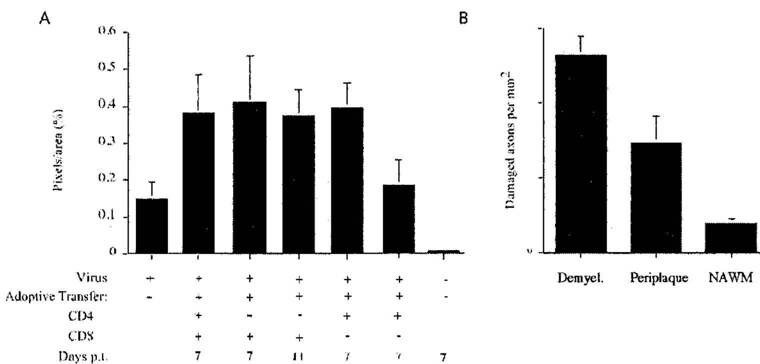

Figure C3-2. Quantification of axonal damage in MHV-infected mice. A, Whole spinal cords (midsagittal sections) were stained with SMI-32, photographed and digitalized, and the number of positive pixels was counted and expressed as a percentage of total spinal cord area.

B, the number of terminal ovoids in areas of demyelination, areas adjacent to demyelination ("periplaque" areas) or areas of normal appearing white matter (NAWM) were counted.

analyzed using the stains described above. This is the first time point at which demyelination is detectable. Surprisingly, axonal damage, as measured by SMI-32 positivity, was found in these mice. This occurred only in areas of early macrophage infiltration and viral antigen, suggesting that demyelination and axonal damage occur concomitantly, and are mediated at least in part by the same effector agents.

2.2 Contribution of CD4 and CD8 cells to axonal damage

As previously published (16), there are substantial differences in clinical disease and in demyelination between recipients of CD4 T cell- and CD8 T cell-enriched splenic populations. We reasoned that these differences in phenotype could be related to differences in the amount of axonal damage mediated by these two cell types. Therefore, the adoptive transfer system was used to elucidate the contribution of CD4 and CD8 T cells to the pathogenesis of axonal damage. MHV-infected $RAG1^{-/-}$ mice received splenocytes enriched for either CD4 or CD8 T cells three days p.i. We quantified the amount of axonal damage by measuring the number of pixels above background in spinal cords stained with mAb SMI-32 and analyzed by confocal microscopy.

Mice receiving splenocytes depleted of both CD4 and CD8 T cells did not develop demyelination and also did not develop axonal damage (Figure C3-2A). Mice that received splenocytes treated with complement only exhibited 0.4% of mAb SMI-32 immunoreactivity across the spinal cord. Surprisingly, no difference in total mAb SMI-32 immunoreactivity could be detected between the spinal cords of recipients of CD4 T cell- or CD8 T cell-enriched splenocytes. The amount of axonal damage was not different statistically from that observed in recipients of undepleted populations of cells. In addition, the amount of axonal damage was not well correlated with the extent of demyelination. These results show that axonal damage did not explain the differences in clinical disease observed between the recipients of undepleted and T cell subset-enriched splenocytes.

3. FUTURE DIRECTIONS

Axonal damage appears to be important in the pathological process in all demyelinating diseases, including MS, EAE, and viral models of

demyelination, including MHV-infected mice (5, 10-13). In the model of MHV-induced demyelination described herein, clinical disease and demyelination occur rapidly and reproducibly after adoptive transfer of immune T cells, making it ideal for the dissection of the processes leading to axonal damage in demyelinating disease.

Although CD4 and CD8 T cells both contribute to demyelination and axonal damage, the mechanisms by which these processes are mediated remains to be determined. CD8 T cell-mediated demyelination is interferon-γ mediated, whereas CD4 T cell-mediated demyelination is increased in the absence of this cytokine (20, 21). Demyelination itself is associated with changes in the cytoskeletal structure of the associated axon (22). In mice with genetic disruption of the proteolipid protein gene, axonal dysfunction is observed in the presence of normally compacted myelin (23, 24). In some models, demyelinated axons appear to be able to compensate for the loss of myelin by upregulating ion channels necessary to maintain conduction (25, 26). Other demyelinated axons fail to do so, leading to severe conduction defects and axonal dysfunction. It is likely that T cells and macrophages/microglia, by creating a pro-inflammatory milieu, contribute to the pathogenesis of axonal injury.

Important issues to be resolved include identifying the effector molecules and cells that cause axonal damage and determining if axonal injury is a necessary consequence of demyelination. Once the mechanisms of axonal dysfunction and damage are better understood, it may be possible to design therapy to minimize axonal disease in MHV-infected mice, and ultimately, in humans with MS.

Chapter C4

THE ROLE OF T CELLS IN CORONA-VIRUS-INDUCED DEMYELINATION

Cornelia C Bergmann[1], Stephen A Stohlman[1], and Stanley Perlman[2]

Keck School of Medicine University of Southern California, Los Angeles, CA 90033[1] and University of Iowa, Iowa City, Iowa 52242[2]

Abstract: Mice infected with neurotropic strains of coronavirus develop acute encephalomyelitis and eliminate infectious virus. However, control of acute infection is incomplete resulting in persistence of viral RNA in the central nervous system (CNS) associated with ongoing primary demyelination. A high prevalence of virus specific CD8 and CD4 T cells within the CNS correlates with *ex vivo* cytolytic activity and IFN-γ secretion, which are both required for virus reduction during the acute infection. Although most infected cell types are susceptible to perforin mediated clearance, IFN-γ is required for controlling infection of oligodendrocytes. Furthermore, by enhancing class I expression and inducing class II expression within resident CNS cells IFN-γ optimizes T cell receptor dependent functions. In addition to its direct anti viral activity, these multifactorial effects make IFN-γ more essential than perforin for viral control. CD4 T cells enhance CD8 T cell expansion, survival and effectiveness. Although both CD8 and CD4 T cells are retained within the CNS during persistence, they cannot control viral recrudescence in the absence of humoral immunity. Demyelination can be mediated by either CD8 or CD4 T cells; however, although a variety of effector molecules have been excluded, a dominant common denominator remains elusive. Thus concerted efforts to control infection coincide with a variety of potential mechanisms causing chronic demyelinating disease.

Key words: CNS, demyelination, IFN-γ, perforin, T cells, mouse hepatitis virus

INTRODUCTION

Neurotropic strains of mouse hepatitis virus (MHV) produce an acute demyelinating encephalomyelitis in rodents (reviewed in 1-3).

Following infection with the JHM strain of MHV (JHMV) survivors have no detectable infectious virus by 2 weeks p.i., but viral antigen (Ag) and RNA persist within the CNS, predominantly in spinal cords up to 2 years p.i. Although persistently infected mice exhibit few clinical abnormalities, histological examination shows ongoing primary CNS demyelination consistent with the pathological changes characterizing the human demyelinating disease multiple sclerosis. Experimental CNS infection by MHV thus provides an excellent model to study the role of inflammatory cells during ongoing demyelination associated with persisting virus.

The majority of research focusing on the role of T cells in MHV pathogenesis has used the JHMV 2.2v-1 monoclonal antibody (Ab) neutralization escape mutant (1-3). This variant has several advantages in studying virus-induced demyelination when compared to parental JHMV and other variants: i) Most mice survive the infection, with demyelination observed in all survivors. ii) The cellular tropism of most JHMV strains for microglia, astrocytes and oligodendroglia is retained; neurons are only rarely infected. iii) Hepatitis, which is transient following infection with the MHV-A59 strain and may confound analysis of CNS specific immune responses, is rare following i.c. infection. Much of the data discussed within this chapter pertain to this variant.

Several independent studies demonstrate that both CD4 T cells and CD8 T cells are required to control acute virus replication within the CNS, thereby protecting from an otherwise lethal infection (1-3). However, T cell-mediated protection against JHMV is generally provided at the cost of immune-mediated demyelination (1-7). Demyelination also occurs in mice with T cell deficiencies following infection with either JHMV (5) or MHV-A59 (8). Nevertheless, mice defective in B cells or anti-virus antibody secretion all develop severe demyelination (9,10), negating a prominent role of humoral immune responses. Irrespective of the controversies regarding mediators and perpetuators of demyelination, the final effector cells are believed to be activated macrophages/microglia (1,2,6,11). This chapter focuses on mechanisms of viral clearance and how activated T cells may contribute to immune pathology in JHMV-infected mice with an emphasis on the complexity of interactions involved.

CONCERTED ANTI-VIRAL EFFORTS OF T CELLS

Although neutrophils, macrophages, NK cells and B cells constitute early infiltrates, T cells, most prominently the CD8 subset, provide the most

critical anti-viral functions (3). A protective role for T cells in acute JHMV pathogenesis was demonstrated by the failure of both SCID and nude mice, genetically deficient in T cells, to clear JHMV resulting in lethality within 12-16 days (5,6). Selective depletion of either CD4 or CD8 T cells both diminished viral clearance, implicating a contribution of both T cell subsets (1-3). In addition, adoptive transfer of either virus specific CD8 T cells or CD4 T cells protected mice from acute encephalomyelitis (1-3). However, whereas CD8 T cells afforded protection by clearing infectious virus, distinct CD4 T cell donor populations varied in their ability to mediate direct anti viral function (1). The precise role that T cells have in viral clearance and MHV-induced demyelination is an area of active investigation, as discussed below.

T Cell Priming, CNS Recruitment, and Effector Function

Mapping of T cell epitopes has greatly facilitated phenotypic and functional analysis of both CD8 and CD4 T cell expansion and recruitment into the CNS (3; see Chapter C6). Virus specific CD8 T cells are detectable in the CNS by day 6 p.i. and accumulate to high frequencies within the CNS by day 8 p.i. as demonstrated using MHC class I/peptide tetramers, intracellular IFN-γ staining, as well as ELISPOT technology (3,12-16). During acute infection, up to 40% of CD8 T cells in the CNS respond to a single immunodominant epitope in both BALB/c and C57BL/6 mice (3,12-16). By contrast, the frequency of virus specific CD8 T cells in the periphery is ~10-20 fold lower (3,12,13). Detection of virus specific CD8 T cells in cervical lymph nodes (CLN) and spleen 2 days prior to the CNS supports priming, expansion, and differentiation in the periphery, rather than the CNS (17). The high prevalence of virus specific T cells in the CNS correlates with virus specific *ex vivo* cytolysis by CNS derived cells, a property not detected in unfractionated spleen or CLN cells (3). Although these observations suggested acquisition of effector function within the CNS, virus specific cytolytic effectors can be demonstrated following CD8 T cell enrichment from splenocytes at day 7 p.i. (17). The rapid accumulation of armed effector CTL results in a potent regional response which efficiently reduces viral titers, but does not prevent persistence. Furthermore, despite protection and

enhanced viral clearance achieved by transfer of JHMV specific CD8 T cells, virus could still be detected in oligodendrocytes (18), a major target of replication for the JHMV 2.2v-1 variant (1-3,18-20).

Distinct Anti-Viral Functions of IFN-γ and Perforin

The suggestion that oligodendrocytes are more resistant to CD8 T cell mediated anti-viral function compared to other glial cell types prompted investigation of T cell effector functions utilized for protection. Anti-microbial T cell mediators include perforin, granzymes, and Fas-FasL, as well as soluble agents such as IFN-γ, TNF and selected chemokines (21;22). A unique aspect of JHMV pathogenesis is that the immunological mechanisms clearing infectious virus are cell type specific (19,20). Studies in genetically deficient mice revealed that replication in astrocytes and microglia is controlled via perforin mediated cytolysis, but not Fas/FasL interactions (19,23). Furthermore, abrogation of TNF-α by mAb treatment did not affect viral clearance (24). By contrast, IFN-γ controls replication in oligodendrocytes (20). Both cytolytic and IFN-γ effector mechanisms peak between days 8-10 p.i., coincident with maximal T cell infiltration (13,14,25). The inability to achieve sterile immunity, despite concerted action of these anti-viral mediators, suggested downregulatory mechanisms or viral evasion from T cell function. Although CTL escape variants play a prominent role in disease progression of weanling mice protected by neutralizing Ab, they appear to play no role in immune competent adult mice (3; see Chapter C6). However, the number of CNS T cells gradually decrease after day 10 p.i., despite the continued presence of Ag positive cells and viral RNA (13-15). Furthermore, Ag specific cytolytic activity at a single cell level rapidly declines by day 14 p.i. and remains absent thereafter (13). Loss of cytolytic activity is independent of either demyelination (14) or viral recrudescence in Ab deficient mice (9,12). The apparent inability to enhance T cell recruitment/function even during virus recrudescence (9,12) suggests restricted access or Ag driven apoptosis; however, there is no evidence to support increased apoptosis by high Ag levels *in vivo* (26). Whether CD8 T cells are downregulated by release of inhibitory factors within the local CNS environment or by the presence of suppressor cells is unknown.

Contrasting the loss of cytolysis, mRNA and ELISPOT analysis suggests that IFN-γ secretion in the CNS appears to continue after clearance of infectious virus (13,25). Furthermore, unlike the permanent loss of perforin mediated cytolysis, IFN-γ mRNA levels increase during JHMV reactivation in the CNS of B cell deficient μMT mice (26). The contradictory finding of reduced numbers of IFN-γ secreting cells in μMT

mice (12) may reside in potential apoptosis of μMT derived CD8 T cells upon *in vitro* stimulation, as apoptosis is not increased *in vivo* (26). Irrespective of the extent of IFN-γ secretion, the balance between loss of cytolytic activity but continued cytokine secretion appears to reflect an attempt to control infection while reducing CNS immunopathology.

Overall the results suggest that IFN-γ is more vital than perforin in the hierarchy of immune effectors controlling JHMV infection and mortality. The nonredundant roles for both IFN-γ and perforin are more clearly evident by pathogenesis studies in mice deficient for both perforin and IFN-γ (27). These mice exhibit ongoing viral replication in all glial cell types coincident with a high mortality rate by day 14 p.i. Adoptive transfers demonstrate that wt memory CD8 T cells were most efficient in reducing virus, while perforin deficient T cells were slightly less efficient. IFN-γ deficient T cells had no affect on reducing viral titers. The inefficiency of IFN-γ deficient donor CD8 T cells to provide protection coincided with diminished class I upregulation and an absence of class II expression on resident microglia. IFN-γ mediated upregulation of class I Ag processing expression (28) is especially crucial within the CNS due to the paucity of MHC expression in the healthy, quiescent CNS (29,30). As both IFN-γ and TNF-α release as well as perforin mediated killing are strictly dependent on MHC–TCR contact (31), CD8 T cells initially recruited by chemokines (32) are likely to be less effective in exerting effector function *in vivo* in an IFN-γ deficient environment. In addition to its direct anti-viral role, IFN-γ thus enhances both CD8 and CD4 T cell function by upregulating MHC class I and class II presentation. The correlation between Ag recognition and elicitation of effector function has clear consequences for the efficiency of distinct effector functions *in vivo*. Whereas release of IFN-γ can be triggered by a subset of antigen presenting cells and act on a distal, non MHC expressing cell types, perforin mediated cytolysis can only be exerted on cells presenting viral Ag. The multifactorial effects of IFN-γ within the CNS thus shed light on the higher efficacy of IFN-γ compared to perforin in anti JHMV effector mechanisms.

Auxilliary and Direct Anti-Viral Functions of CD4 T Cells

The precise role of CD4 T cells as direct anti-viral mediators are less well understood, especially their contribution to anti-viral IFN-γ secretion. The majority of CD4 T cells accumulating within the CNS are virus specific (33), similar to CD8 T cells. Depletion of CD4 T cells prevents JHMV clearance from the CNS (1-3). Although transferred JHMV specific CD4 T

cells protect from acute disease, the mechanisms of protection may be unrelated to IFN-γ mediated control (1). CD4 T cells also provide crucial accessory function by enhancing expansion of virus specific CD8 T cells and maintaining CD8 T cell viability within the infected CNS (12,34). Although depletion of CD4 T cells does not prevent CD8 T cells from entering the CNS parenchyma, it compromises their viability, as indicated by increased apoptosis (34); the mechanisms involved remain obscure. Predominant localization of CD4 T cells in the perivascular and subarachnoid spaces during JHMV infection is consistent with recent data demonstrating that Fas/FasL interactions, a mechanism of CD4 T cell mediated cytolysis, does not contribute to JHMV clearance, encephalomyelitis or demyelination (23,34).

T CELL FUNCTION DURING PERSISTENCE

A hallmark of JHMV persistence and ongoing demyelination is significant CNS retention of virus specific CD8 and CD4 T cells (12-16). Persisting T cells appear tightly linked to persisting virus as a source for chronic activation, as shown by the disappearance of T cells from the CNS of mice infected with a JHMV variant that does not persist (15). However, the percentages of virus specific cells within the CD8 T cell compartment remain remarkably similar throughout infection, negating selective enrichment or loss of cells with virus specificity (13-16). Despite an apparently dormant T cell state, several observations support an active turnover process: i) Persisting CD8 T cells exhibit restricted fine-specificity (35); ii) A reversed pattern of immunodominance emerges comparing acute and persistently infected CB6F1 (H-2^{dxb}) mice (13); and iii) CD69 expression is sustained during persistence, indicative of chronic CD8 T cell activation (13). Sustained CD69 expression has been observed on persisting, yet activated CD8 T cells in the CNS, lung and liver, following other viral infections (36-38).

Despite an apparent role for continued Ag presentation in T cell survival within the CNS, there is also evidence to support the contrary. CD8 T cells are readily maintained in the CNS following challenge of influenza virus immune mice with a heterologous neurotropic influenza virus (36). Unlike the JHMV model, there was no evidence for persistent infection and these cells retain *ex vivo* cytolytic capacity. The phenotype of these cells is reminiscent of peripheral memory CD8 T cells found in nonlymphoid organs (39), suggesting that T cell retention within the CNS may in part reflect

peripheral memory T cells. However, in the JHMV model ultimate disappearance of all T cells in the absence of JHMV RNA in both brains and spinal cords suggests persisting RNA supports active T cell maintenance by ongoing chemokine release and/or continued Ag presentation. The source and renewal of such persisting T cells is under investigation.

The sufficiency of T cells for protection during MHV persistence has been challenged by the discovery of viral recrudescence in mice deficient in Ab (8,9,26). The necessity of Ab in controlling persistent infection is supported by the accumulation of virus specific Ab secreting cells within the CNS of wt mice (40). T cells may nevertheless contribute to control during the chronic phase, perhaps by secreting IFN-γ and supporting B cell differentiation and/or survival.

T CELLS AS CORRELATES OF DEMYELINATION

T cells control viral replication in several models of viral CNS infection, but are also key mediators of the pathological changes associated with encephalitis and/or demyelination (1-7,41,42). During JHMV infection both CD4 or CD8 T cells alone are capable of inducing demyelination (7). Unlike TMEV induced demyelination, there is little evidence for involvement of an autoimmune CD4 T cell component or epitope spreading. A prominent role for CD4 T cells is however indicated by clinical improvement as well as remyelination of JHMV infected mice treated with anti-IP-10 Ab (32). IP-10 treatment specifically reduced CD4, not CD8 T cells within the CNS, suggesting CD4 T cell dependent pathology in persistently infected mice. Secretion of RANTES leading to increased macrophage recruitment may be one mechanism (32). Mice deficient in perforin, IFN-γ, TNF-α, NOS2 and IL-10 all develop demyelination similar to that in wt mice (19,20,24,43,44), suggesting none of these effector molecules alone dominate the demyelinating process. Recent findings demonstrating that CD4 and CD8 T cells contribute to demyelination via different mechanisms (45,46) further complicate understanding the network of effector molecules involved. Infection of mice deficient in recombination activation gene 1 activity ($RAG^{-/-}$) or SCID mice results in no demyelination. However, adoptive transfer of splenocytes from mice immunized with JHMV resulted in demyelination within 7 days post transfer (5-7). Splenocytes enriched for either CD4 or CD8 T cells mediated demyelination, although no demyelination was observed if both subsets were deleted. Further, reconstitution of infected $RAG^{-/-}$ mice using T cell subsets selectively deficient in T cell effector functions indicate that IFN-γ, but not perforin or TNF-α is crucial for CD8 T cell mediated demyelination (45).

By contrast, the absence of IFN-γ severely enhances demyelination mediated by CD4 T cells (46). Surprisingly, increased demyelination was not necessarily correlated with the amount of activated macrophages/microglia within the white matter. Furthermore, although virus replication was diminished to some extent after adoptive transfer of CD4 or CD8 T cells from wt or immunodeficient donors, only transfer of populations from immunocompetent B6 mice effected virus clearance (7). Contrasting a detrimental role of IFN-γ in demyelination by T cell transfers into infected H-2^b $RAG^{-/-}$ mice, adoptive transfers of memory CD8 T cells into H-2^d SCID mice suggest that both IFN-γ and perforin together propagate the demyelination process, but that CD8 T cell IFN-γ secretion alone does not increase pathology (Parra & Stohlman, unpublished). Finally, demyelination following JHMV infection can also be caused by non virus-specific bystander CD8 T cells, albeit only following activation by cognate Ag (47). Bystander CD4 T cells do not cause demyelination (Haring & Perlman, unpublished). In a recent study demyelination was shown to be γδ T cell-mediated in nude mice (48).

The complex linkages between IFN-γ, MHC class I and II expression, and chemokines have made it extremely challenging to delineate distinct pathways leading to demyelination. For example, impaired MHC and costimulatory molecule expression on resident CNS cells in the absence of IFN-γ are likely to ameliorate perforin and TNF mediated cell damage, but at the cost of increased virus load. Furthermore, macrophages/glia activation may be reduced, in turn affecting chemokine secretion (32). Together the current evidence suggests that JHMV induced demyelination is influenced by the balance between virus replication predominantly in oligodendroglia, distinct immune effector functions mediated by both CD4 and CD8 T cells and their effects on glia/macrophage activation.

CONCLUSIONS

T cell mediated immune responses within the CNS can be both beneficial by clearing infectious agents, and detrimental by destroying tissue, triggering autoimmunity, and activating resident cells. The CNS responds rapidly to coronavirus infection by chemokine mediated recruitment of specific as well as bystander T cells. Recognition of cognate Ag presented by MHC is crucial in triggering Ag-specific T cell function both during virus

and auto-Ag induced inflammation. However, prolonged T cell stimulation by foreign as well as self Ag promotes immune pathology, such as demyelination. The ubiquitous upregulation of class I during inflammation allows both IFN-γ and perforin mediated anti-viral functions. Whereas perforin secretion is directed, only affecting cytolysis of Ag presenting cells, IFN-γ can act on neighboring and distal cells not expressing MHC. Soluble mediators, i.e. IFN-γ and RANTES, may have detrimental effects by perpetuating chemokine secretion by astrocytes and recruiting activated macrophages. Efforts to link sustained immune activation to ongoing chemokine secretion and Ag recognition during viral persistence will provide clues for candidate factors promoting macrophage/microglia dependent demyelination and CNS pathogenesis.

Abstract: Pathogenesis induced by mouse hepatitis virus (MHV) infection of rodents is characterized by acute viral encephalomyelitis and demyelination which progresses to a persistent CNS infection associated with ongoing myelin loss, pathologically similar to multiple sclerosis (MS). Although humoral immunity appears redundant for the control of acute virus replication, it is vital in maintaining virus at levels detectable only by RNA analysis. T cell mediated control of acute infection cannot be sustained in antibody (Ab) deficient mice, resulting in virus reactivation. The protective role of Ab during persistence is strongly supported by detection of Ab in the cerebrospinal fluid of MHV infected rodents and maintenance of virus specific Ab secreting cells (ASC) in the CNS long after virus clearance. Ab mediated neutralization constitutes the major mechanism of protection, although fusion inhibition also plays a minor role. Delayed accumulation of ASC, concomitant with a decline in T cell function, assures control of residual virus while minimizing T cell mediated pathology. Although there is little evidence for a detrimental role of Ab in demyelination, an association between Ab mediated protection and remyelination is unclear.

Key words: CNS, demyelination, mouse hepatitis virus, B cells, Antibody.

HUMORAL IMMUNITY AND MULTIPLE SCLEROSIS

MS is a chronic demyelinating disease of the CNS characterized by inflammation and white matter destruction, but of unknown etiology (1). The chief pathological features are focal areas of myelin loss associated with an

inflammatory response consisting of B cells, T cells and macrophages (2). The relative contribution of each of these individual immune components remains poorly understood. A variety of cellular and humoral abnormalities have been observed in MS patients (2). The seminal findings of elevated Ig in CSF (3) as well as humoral involvement in demyelination during experimental allergic encephalomyelitis (EAE) (4) were the first hints implicating humoral components in the demyelinating disease. Increased B cell abundance as well as detection of myelin specific Ab in acute lesions with active ongoing demyelination compared to older, inactive lesions have supported their possible involvement in the disease pathogenesis (5,6). Although T cell studies have predominated this field of research based on the detection of activated T cells in MS plaques and involvement of T cells in EAE, current research in both MS and MOG protein induced EAE has re-ignited interest in the potential role of humoral immunity in the pathogenesis of demyelinating disease (2,7).

One hallmark of MS is that cerebral spinal fluid (CSF) in ~90% of patients is characterized by the presence of oligoclonal immunoglobulin (Ig) bands which exhibit restricted isoelectric focusing points (3,7). The CSF Ig response is sustained by resident B cells not represented in peripheral compartments (8). The IgG sequences feature extensive somatic mutations suggesting active antigen (Ag) driven B cell selection and clonal expansion (8). Oligoclonal bands are also encountered routinely following CNS infections with measles virus, Herpes simplex virus-1 and mumps virus; however, the majority of the Ig are specific for the causal agent (9). Moreover, detailed studies into the clonality of B cells in both CSF and MS plaques has revealed no single dominant Ag target. These Ab express varied Ag specificities from myelin components, oligodendrocyte protein, viruses, cell nuclei, endothelial cells, fatty acids, gangliosides, and axolemma (7,10). Auto Ab could potentially contribute to demyelination by various mechanisms including Ab dependent cell mediated cytotoxicity (ADCC), stimulation of Fc receptors expressed on NK cells or macrophages/microglia resulting in release of inflammatory molecules, opsonization of myelin resulting in phagocytosis by macrophages, or complement activation. Direct evidence of Ab mediated mechanisms in MS lesions was revealed with the detection of IgG deposition on the borders of the actively demyelinating plaques along with the presence of activated complement fragments and complexes (11). Ab eluted from MS plaques preferentially bind to CNS self Ag (7), although this reactivity to a variety of CNS Ag could also be due to liberation of Ag as a consequence of inflammatory tissue destruction. It thus appears that a concerted action of humoral and cellular factors could participate in the induction and/or maintenance of an inflammatory response specific for CNS Ag.

MHV PATHOGENESIS

Infection of the CNS with MHV produces an acute encephalomyelitis associated with a focal loss of myelin. Virus replicates in various CNS cell types including astrocytes, oligodendroglia and microglia / macrophages. Distinct mechanisms of CD8 T cell mediated control are required to clear virus from the CNS as described elsewhere in this book (12,13). As virus replication is controlled, focal myelin loss however, is increased, suggesting a temporal lag between the maximal number of virus infected cells and the loss of myelin. The inability of cell mediated immunity to completely eliminate virus results in a non-productive persistent infection confined to the CNS, predominantly in spinal cord oligodendroglia. Persistent infection is associated with ongoing myelin loss and repair. These traits make MHV infection of the CNS along with Theiler's murine encephalitis virus infection and EAE the three primary murine models to study mechanisms underlying both encephalomyelitis and demyelination (12,13).

HUMORAL IMMUNITY AND ACUTE INFECTION

Analysis of viral pathogenesis in mice depleted of T cell subsets, distinct T cell functions or humoral components demonstrated that acute infection by MHV-JHM strain (JHMV) is controlled by cellular immune responses (12,13). Humoral responses are redundant during acute infection as shown by initial virus clearance in the CNS of B cell deficient mice with similar kinetics to wt mice (14,15). Unlike the almost complete clearance of JHMV which expresses the immunodominant spike protein derived S510 epitope, infection with the MHV-A59 strain, which lacks this CTL epitope revealed minimal clearance in the B cell deficient mice, thus emphasizing the dominant role of cellular immunity (16). Similarly, mice deficient in T cells were unable to clear virus (12,13). Consistent with a redundant early role of humoral immunity, examination of serum anti-viral Ab titers showed that IgM and IgG are detectable only after the majority of the infectious virus has already been cleared from the CNS (12,17). Moreover, examination of the two biological activities of the Ab response directed at the spike protein, i.e., neutralization and fusion inhibition (17), determined that while neutralizing Ab was initially detectable by day 10 p.i., when most of infectious virus had

already been cleared from the CNS, fusion inhibiting Ab was not detected until much later (day 21 p.i.). Thus the delayed appearance of serum Ab relative to virus clearance further supported a minor, if any role of Ab early in the adaptive host response to acute infection.

Transfer of monoclonal Ab specific for different virus structural proteins including spike, nucleocapsid and matrix proteins prior to or concomitant with JHMV infection nevertheless resulted in protection from virus induced mortality, but was not always associated with reductions in virus replication (12,18-20). The mechanisms of protection by pre-established Ab may merely reside in neutralization of the bolus of infectious virus prior to establishing CNS infection. Alternatively, Ab may modify tropism by prevention of infection of critical cells specifically neurons, thereby increasing survival rates (18,19). In other models, suckling mice weaned on immunized dams or transgenic mice which express neutralizing IgA in the milk are protected from acute JHMV induced encephalomyelitis; however, the role of Ab in these models is unclear (21,22). A variable percentage of protected weanling mice exhibit a delayed onset of acute encephalitis associated with demyelination. However, delayed onset with progressive disease is associated with CTL escape variants rather than Ab escape mutants or the loss of Ab mediated protective mechanisms (21).

Irrespective of the apparent redundancy of Ab in controlling acute infection, flow cytometric analysis of CNS inflammatory cells from infected wt mice revealed that mature B cells ($CD19^+/sIg^+$) are rapidly recruited into the CNS along with T cells (12,17). Furthermore, following the peak of virus replication, a low but constant percentage of B cells (5-7%) is retained in the CNS during viral persistence (12,17). A potential Ab independent, innate anti-viral effector function of B cells *in vivo* was initially suggested by the observation that B cells from naïve mice exhibit the ability to lyse virus infected target cells *in vitro*. Lysis is mediated through an interaction between viral receptor expressed at high levels on B cells and the viral spike protein expressed on the surface of infected cells (23). This unique cytolysis is inhibited by Ab specific for the viral spike protein, which *in vivo* is detected only after CNS virus replication has been initially controlled. Hence the absence of Ab early during infection could allow B cells to interact with virus infected cells *in vivo*, thereby contributing to viral control. However, convincing evidence for this mechanism was negated by studies in transgenic mice containing B cells unable to secrete anti-viral Ab (15). These mice cleared virus with similar kinetics as B cell deficient mice, excluding an effect of innate B cell function *in vivo*.

B cells are recruited to and activated in secondary lymphoid organs following infection (24,25). It has been shown that Ag within the CNS drains to cervical lymph nodes (CLN), which are the major sites of B cell

activation following intrathecal administration of Ag (25). However, virus specific Ab secreting cells (ASC) appear in the spleen prior to detection in the CLN (17). While there was no major increase in virus specific IgM ASC, the frequencies of IgG ASC increases almost four fold in the CLN compared to spleen suggesting that the majority of initial activation occurs in the spleen, followed by transient CLN accumulation. No virus specific ASC were observed in blood, consistent with previous data suggesting that ASC do not migrate by this route (25). It is assumed that activated B cells/plasmablasts traffic to the target organ containing Ag where they differentiate to plasma cells and secrete Ab (25). Recruitment kinetics of anti-viral ASC into the CNS revealed that low frequencies detected prior to maximal viral replication increased only slightly as virus replication was controlled (17). Thus, based on: 1) the inability of B cells to express detectable anti-viral activity, 2) the paucity of plasma cells in the peripheral lymphoid compartments at any time post infection and 3) the appearance of serum Ab and virus specific ASC within the CNS following viral clearance, humoral immunity appears to have play a redundant role during acute MHV infection of the CNS.

HUMORAL IMMUNITY AND VIRAL PERSISTENCE

Humoral immunity protects the CNS from infection by prevention of virus dissemination from peripheral sites. However, if CNS infection is already well established prior to induction of Ab responses, Ab can help further reduce infectious virus (26) or maintain viral persistence at non-detrimental levels (17). The beneficial effect of an early Ab response was demonstrated in the rat model of JHMV infection. Resistant Norway rats exhibit a more rapid and robust neutralizing Ab response, determined by detection of serum and CSF Ab and ASC compared to susceptible Lewis rats (27). Incomplete virus clearance in B cell deficient mice at days 12-14 p.i. support that neutralizing Ab, which first appears by day 10 p.i., indeed may act in concert with T cells during the later stages of acute infection to completely eradicate infectious virus from CNS, particularly as resident CD8 T cells lose their CTL activity (15,28). This prompted detailed analysis of the emergence of ASC relative to the decline in T cell activity within the CNS. Virus specific ASC were barely detectable in the peripheral compartments following virus clearance in mice (17). Furthermore, despite early recruitment of ASC into the CNS, only a minority was virus specific (17). However, the limited recruitment of virus specific ASC into the CNS

towards the end of the acute phase, at days 10-12 p.i., was followed by a dramatic increase, which continued up to day 21 p.i. While there was a slight decrease in virus specific IgM ASC, frequencies of IgG ASC in the CNS remained constant. The majority of the ASC at this time point were of the IgG2b isotype indicating massive expansion of this subtype specific Ab, with fewer numbers of IgG2a and IgG1 ASC. Preferential expansion of ASC during this period of infection, concomitant with down regulation of CTL activity and inflammation, implies a major role for ASC in CNS during both the terminal phase of acute infection and during chronic infection.

Virus specific ASC are retained in the CNS, although there is a decline following the peak of expansion. The relatively long-term presence of ASC accompanied by the decline of other inflammatory cells, including T cells and macrophages, in addition to reactivation of virus in B cell deficient mice enforce the role of Ab in controlling viral persistence in the CNS. Following virus clearance from the CNS in wt mice, viral Ag can be detected beyond day 35 p.i. and viral RNA for up to a year (13). Virus specific ASC were found at higher frequencies in the CNS compared to bone marrow or any other peripheral compartment even at 90 days p.i. (Tschen & Stohlman, unpublished). This is in contrast to detection of plasma cells predominantly in the bone marrow following resolution of peripheral infections (24). The persistence of plasma cells within the CNS appears to be a common trait of many viral CNS infections (26,29). While the majority of Ag is cleared from the brain during persistence, viral Ag and RNA are detectable for longer periods of time in the spinal cord (13). Spinal cords also exhibited increased ASC by histology compared to brain, thereby signifying a causal relationship between prolonged retention of ASC and viral Ag / RNA (16). A variety of cellular and soluble factors could also contribute to the survival of these cells in the CNS: cytokines including TNF-α, interleukins 1, 2, 4, 6 and 10, nerve growth factor, or stimulation with CD40L on T cells and Fc receptors on microglia / macrophages. The possible presence of chemokines such as SDF-α, MIP-3β or BLC could also contribute towards long-term retention of plasma cells in the brain. Although trapping of B cells cannot be excluded, these data suggest that the CNS provides a nourishing microenvironment that facilitates retention and maintenance of ASC.

Neutralizing Ab is maintained at relatively high levels in the serum beyond 90 days p.i. (Tschen, unpublished). Given the short half life of Ab, maintenance of Ab secretion may be attributed to one or a combination of factors: (i) re-exposure to Ag due to persistent low grade chronic viral infection; (ii) structural homologies of viral and CNS Ag generating cross reactive responses; (iii) persistent Ag presentation by dendritic cells; (iv) presence of long lived plasma cells in either bone marrow or the CNS. Work

is ongoing to find a causal relationship between long-lived plasma cells and possible sustaining factors, viral control, and demyelination.

Virus recrudescence in the CNS of Ab deficient mice strongly implies a more crucial protective function of persisting ASC versus T cells during chronic infection (14-17). Virus reactivation is accompanied by sustained clinical disease and high mortality rates in contrast to recovery of wt mice that had cleared infectious virus (14-16). A similar picture was observed in transgenic mice, which contained B cells that could not secrete anti-viral Ab (15,16). Following initial virus clearance, virus reactivated in the CNS of the transgenic mice by day 14 p.i. albeit at a slower, but statistically insignificant rate compared to B cell deficient mice, thus ruling out a prominent role of innate B cell effector function (15,16). In addition to multiple Ag positive cells compared to wt mice, histological examination suggested differential Ag tropism in the transgenic mice containing B cells as compared to B cell deficient mice during reactivation (15). While Ag was detected in all CNS cell types in B cell deficient mice, similar to acute infection, the transgenic mice containing B cells harbored Ag predominantly in oligodendrocytes. Preferential elimination of virus from astrocytes and microglia, suggests either B cell lytic activity during persistence or increased class II mediated stimulation of virus specific CD4 T cells. Irrespective of potential B cell mediated lysis in transgenic mice, this mechanism is irrelevant in wt mice, which have neutralizing Ab in the CNS at this time (15). Oligodendroglial tropism in these mice is reminiscent of the resistance of these cells to perforin-mediated cytolysis (30). However, it appears that following initial virus clearance, the CNS environment preempts further T cell mediated antiviral effects. There is no evidence for either increased CD8 T cell recruitment or re-expression of CTL activity in response to reactivation in Ab deficient mice (15,28). Such an altered CNS environment, likely resulting from T cell mediated or virus induced pathology, emphasizes the necessity for alternative, less destructive modes of protection during recovery, such as provided by Ab.

These observations are reinforced by protection of B cell deficient mice treated with polyclonal neutralizing Ab at time points simulating the appearance of serum neutralizing Ab in wt mice following i.c. inoculation (14-16). Ab transfer reduced virus to almost undetectable levels in recrudescing recipients at 21 days p.i., compared to high titers in the CNS of control mice. These results in B cell deficient mice, in conjunction with the burst of virus specific ASC in wt mice between days 12 and 21 p.i., clearly suggested that control of viral persistence in glial cells is solely dependent on anti-viral Ab. Further investigation of the mechanisms involved in Ab mediated protection revealed that only neutralizing Ab and to a limited

extent, fusion inhibiting Ab could reduce virus reactivation (31). Monoclonal Ab specific for matrix, nucleocapsid protein or even spike protein with no neutralizing activities were unable to suppress virus reactivation (31). Suppression of virus reactivation appears to require the constant presence of Ab, as virus reemerged following discontinuation of Ab administration resulting in increased mortality rates. The transient nature of virus control is comparable to other infectious models wherein immunocompromised mice required continuous infusion of Ab to control virus replication (26,32).

Other humoral components do not appear to play a major role in virus clearance. Analysis of MHV infection in mice devoid of complement (C3) revealed no role for complement in virus clearance (16,18). Furthermore, complete clearance of virus in FcR deficient mice (16) and the ability of neutralizing F(ab)2 fragments to afford protection (33) indicate a minor role for ADCC mechanisms in virus clearance, although each mechanism may suffice to make individual contributions.

ANTIBODY AND DEMYELINATION

Despite the presence of oligoclonal Ig bands in CSF of MS patients, there is little evidence for the involvement of Ab responses during most experimental virus induced demyelinating diseases. Robust demyelination is induced by both JHMV and MHV-A59 strains in B cell deficient mice as well as transgenic mice containing B cells, but deficient in virus specific Ab (14-16). These data support multiple studies implicating T cells and macrophages/microglia as the prominent players in the initiation of demyelination during MHV infection (12,13). However demyelination in Ab deficient mice does not exclude other humoral mechanisms, including complement and FcR, as contributors to the demyelinating process. Furthermore, infection of nude mice demonstrated the presence of demyelinating plaques albeit to a lesser degree than wt mice, supporting a role for humoral immune responses in the demyelinating process (34). Infected SCID and RAG-/- mice, deficient in both B and T cells, by contrast, do not develop demyelination. Adoptive transfer of splenocytes from immunized nude mice into infected SCID mice however failed to induce demyelination (34), leaving a pathogenic role for B cells controversial. Nevertheless, a pathogenic role for humoral immunity was also suggested by the detection of IgG, complement (C9) deposits and plasma cells in areas of actively demyelinating plaques in Lewis rats (35). While an Ab-dependent role in initiation of demyelination is not established, the presence of ASC with viral as well as yet unidentified specificities in the CNS does not exclude a possible involvement in the demyelinating process. Following Ag

clearance in wt mice, demyelination is reduced compared to increasing levels of demyelination in B cell deficient mice (14,15). Whether this is due to higher viral load or absence of B cells or Ab is unclear. Although the effect of Ab on remyelination has not been studied in this model, Ab mediated control of viral recrudescence and thereby prevention of further virus induced cell death, results in less severe demyelination in wt mice as compared to infected B cell deficient mice. Furthermore, preliminary analysis of B cell deficient mice protected by the transfer of Ab, suggests an ameliorating, rather than detrimental effect on demyelination, similar to the TMEV model (31,36). These results support an overall beneficial role of Ab in MHV induced CNS pathogenesis, predominantly by enhancing elimination of infectious virus and controlling viral persistence. Further studies are required to assess potential effects of Ab and other components of humoral immunity on the dynamic processes of myelin loss and repair.

CONCLUSIONS

In summary, despite unequivocal evidence that acute CNS infection is controlled by T cells with minimal B cell involvement, B cells and Ab regulates viral persistence. Virus reactivation in the CNS in mice devoid of antiviral Ab results in increased demyelination. A protective role of B cells is supported by accumulation of virus specific ASC following T cell mediated clearance. The prominent mechanism of Ab mediated protection appears to reside in its neutralizing activity. Furthermore, humoral immune mediated control does not appear to initiate or enhance the severity of demyelination. Thus, an evolving model of biphasic immune control of viral infection of the CNS has developed with acute clearance and initiation of demyelination being controlled by T cells while viral persistence and possibly repair is regulated by humoral immunity.

Chapter C6

THE ROLE OF T CELL EPITOPES IN CORONAVIRUS INFECTION

Taeg S. Kim* and Stanley Perlman*,(
*Affiliation: *Interdisciplinary Program in Immunology, (Departments of Microbiology and Pediatrics, University of Iowa, Iowa City, IA .*

Abstract: Multiple MHV-specific CD4 and CD8 T cell epitopes have been identified in C57Bl/6 and BALB/c mice. In particular, at least two CD8 T cell epitopes are recognized in C57Bl/6 mice. In one model of MHV persistence, mutations are detected in the immunodominant CD8 T cell epitope recognized in this strain. These mutations contribute to virus persistence and to the development of more severe clinical disease.

Key words: Coronavirus, CTL escape, demyelination

1. INTRODUCTION

In most viral infections, host defense mechanisms are efficient and result in rapid clearance of the virus. Stable memory populations of T and B cells develop and protect the host from subsequent infections with the same agent. Viruses, in turn, have evolved mechanisms to evade the host immune response and are able to establish long-term persistent infections. Much has been learned over the past several about the strategies that viruses use to evade the immune response [reviewed in (1)]. This review will be focused on one strategy used by viruses to persist, i.e., the selection of cytotoxic CD8 T cell (CTL) escape variants. The first part of this article will discuss aspects of the T cell immune response to MHV, with a focus on CD4 and CD8 T cell epitopes recognized in rodents. Second, CTL escape in the context of mice infected with the neurotropic JHM strain of mouse hepatitis virus (MHV) will be described in detail.

2. CELL-MEDIATED IMMUNITY DURING MHV INFECTION OF RODENTS

The importance of CD4 and CD8 T cells in virus clearance in rodents infected with MHV is well documented, as described elsewhere in this volume (Chapter C4). In several studies, the CD8 and CD4 T cell epitopes recognized by MHV-specific lymphocytes have been identified. C57Bl/6 (B6) and BALB/c mice are used in most studies of MHV-induced pathogenesis and, as a consequence, most of the epitopes are H-2^b- or H-2^d-restricted. A summary of the epitopes identified thus far is shown in Table 1. These epitopes were identified using either splenocytes after *in vitro* stimulation or, alternatively, lymphocytes harvested from the CNS of infected mice. In the latter case, cells were analyzed in direct *ex vivo* cytotoxicity assays. In BALB/c mice, a CD8 T cell epitope encompassing residues 318-326 of the nucleocapsid (N) protein (epitope N318), was immunodominant (2) whereas, in B6 mice, two CD8 T cell epitopes encompassing residues 510-518 and 598-605 of the surface (S) protein (epitopes S510 and S598) were recognized (3, 4). Both are located within a hypervariable region of the protein that can tolerate deletion or mutation without loss of viability (5). CD4 T cell epitopes have also been identified in both strains of mice. In BALB/c mice, CD4 T cell epitopes were identified within the N protein whereas in C57BL/6 mice such epotopes were located within the S and transmembrane (M) proteins (6-8). These CD4 T cell epitopes are present outside the hypervariable region of the S protein.

Table 1. Summary of epitopes recognized by CD4 and CD8 T cells in MHV-infected rodents

Cell type	Host	Protein	Residues
CD8 T cell[2]	BALB/c mice	N	318-326
CD8 T cell[3,4]	B6 mice	S	510-518
CD8 T cell[4]	B6 mice	S	598-605
CD4 T cell[9]	Lewis rat	N	361-458
CD4 T cell[7]	B6 mice	M	128-147
CD4 T cell[8,10]	B6 mice	S	329-343
CD4 T cell[10]	BALB/c mice	S	329-343
CD4 T cell[6]	BALB/c mice	N	266-279
CD4 T cell[8]	B6 mice	S	358-372
		S	408-422

3. CTL ESCAPE IN MHV-INFECTED MICE

3.1 Overview of selection of CTL escape variants in viral encephalomyelitis

Infection with virulent variants of the JHM strain of MHV cause an acute fatal encephalitis in all susceptible rodents. Disease is largely confined to the central nervous system, with variable, albeit minor, infection of the liver. A persistent infection was noted in several studies when either mice were infected with attenuated strains of virus or when infection with virulent virus was modified by treatment with anti-viral antibodies or T cells (11). In one model, clinical disease manifested by hindlimb paralysis and histological evidence of demyelination developed several weeks after virus inoculation (12). In this model, suckling B6 mice (10 to 14 days old) were inoculated intranasally with a virulent variant of MHV. If nursed by naïve dams, they uniformly developed an acute encephalitis. However, when nursed by dams previously immunized

Table 2. Summary of mutations in epitope S510 identified in B6 mice with hindlimb paralysis.

Position	1	2	3	4	5	6	7	8	9
Contact		*M	M	T	M	T	M/T		M
WT epitope	**C**	**S**	**L**	**W**	**N**	**G**	**P**	**H**	**L**
Variant epitopes		F(2)$^{\Delta}$	R(2)	R(7)	H(1)	V(2)	H(2)		
		Y(1)	F(3)	G(1)	D(2)	R(1)	L(6)		
		P(2)	P(2)	C(1)	S(12)	E(1)			
					T(1)				
(untested)					K(1)			R(1)	F(1)

The immunogenicity of the mutated epitopes was tested in cytotoxicity assays. The amino acid changes listed above resulted in a greater than 20 –fold decrement in ability to sensitize cells for CTL lysis , except for the L to P change noted at position 2 (4 fold decrement) (15). Some mutations were not analyzed in these assays *(untested)*. *MHC (M) or TCR (T) contact residues based on published data (16). $^{\Delta}$ Numbers in parenthesis represent the number of animals from which the indicated mutations were detected.

to MHV, they were protected from the acute encephalitis. A variable fraction (40-90%) developed clinical disease and a demyelinating encephalomyelitis 3-8 weeks after inoculation. Infectious virus could be isolated from all mice with clinical disease but not from those that remained asymptomatic. Subsequent analysis of viral RNA harvested from the infected CNS revealed the presence of mutations in the immunodominant CD8 T cell epitope (epitope S510) in all samples of RNA and viruses isolated from symptomatic mice (Table 2) (13). These mutations abrogated recognition by epitope S510-specific CD8 T cells in direct *in vivo* cytotoxicity assays using CNS-derived cells. These mutations were detected at early times and mutations were not detected in epitope S598 or in the regions flanking the epitopes (14). Mutations in epitope S510 were not detected in most mice that remained asymptomatic or in persistently infected mice with severe combined immunodeficiency (SCID) (14). These results suggest that CTL escape variants were selected by immune pressure and consequently contributed to the establishment of virus persistence and to the development of a demyelinating encephalomyelitis.

3.2 Requirements for selection of CTL escape variants in the CNS

1. Immunodominance. It is conceivable that a CTL response directed against a single immunodominant epitope favored the emergence of virus mutants abrogating CTL recognition. In B6 mice infected with MHV, epitope S510 was immunodominant, with up to 50% of the CD8 T cell response in the CNS directed at this epitope, as determined by either direct *ex vivo* intracellular interferon-γ assays or by staining with MHC class I/peptide tetramers (17, 18). The CD8 T cells were fully activated as measured by cytokine secretion, cytotoxic function and expression of activation markers, at least during the acute infection. This strong immune response to the immunodominant epitope is likely to be a major factor facilitating the selection of CTL escape variants. In support of this, mutations in the subdominant CD8 T cell epitope (epitope S598), an epitope with substantially less functional avidity have never been detected. This was true even when suckling mice were infected with virus mutated in epitope S510 so that epitope S598 became the dominant target for the CD8 T cell response (19). In other viral infections, epitopes with strong functional avidity were preferentially mutated at early times after inoculation (20). One apparent exception to this observation is that mutations were never identified in the immunodominant CD4 T cell epitope recognized in B6 mice (epitope

M133-147, Table 1), but mutations were detected in a subdominant CD4 T cell epitope (epitope S328-347, Table 1). However, the biological significance of this mutation is not known since CD4 T cell recognition to the mutated epitope was not affected by this mutation (8).

2. Hypervariable region. It is imperative that the CTL epitope mutations do not inactivate the virus. The two CTL epitopes (epitopes S510 and S598) recognized in B6 mice are located within a region of the protein that is highly permissive to both deletions and amino acid changes without the loss of infectivity (5). Presence of epitopes within this hypervariable region may provide an optimal genetic background for CTL escape, while keeping virus viable. Epitope S598 is also located in this hypervariable region, but mutations in this epitope were not detected. At present, it is not known whether the lack of mutations in epitope S598 reflect an effect on virus viability. It is now possible to address this issue, using recently described methods of reverse genetics (21). Alternatively, there may be insufficient immune pressure to select CTL escape mutations because the epitope has a low functional avidity (4) or because it is expressed relatively poorly on the cell surface. Mutations in epitopes with high functional avidity were detected at early times during the course of other persistent viral infections whereas mutations in epitopes with low functional avidity were not detected until disease had progressed (20, 22, 23).

3. Infection of suckling B6 mice. CTL escape variants were selected only in B6 mice (H-2^b background) inoculated at the suckling stage (10-14 days old) with virulent MHV-JHM and protected from acute encephalitis by nursing with dams previously immunized to MHV. In other models of MHV persistence, immunocompetent adult mice were inoculated with attenuated strains of MHV (11). Virus was cleared under these conditions, but viral RNA and ongoing demyelination were readily detected. CTL escape mutants were never detected in these mice. The host strain is also important in the selection of CTL escape mutants. Suckling BALB/c mice never develop a late onset demyelinating encephalomyelitis. The immunodominant CD8 T cell epitope recognized in BALB/c mice is located in a protein (nucleocapsid [N] protein) that is highly conserved among coronaviruses (2, 24). Consistent with the lack of clinical disease, mutations are never detected in this epitope (N318-326).

One explanation for the observation that CTL escape only occurred in suckling B6 mice relates to the role of anti-MHV antibody in pathogenesis. Vertical transmission of maternal neutralizing antibody plays a crucial role not only in providing protection from acute encephalitis but also for establishing a milieu for selection of CTL escape variants. Levels of neutralizing antibodies need to be sufficient to control the acute infection but

insufficient to achieve sterile immunity. Our recent data showed that, as maternal antibody waned, production of anti-MHV antibody by infected suckling B6 mice was substantially lower than by suckling BALB/c mice. Most striking was the lack of anti-MHV antibody producing cells in the CNS of B6 mice infected at the suckling stage (A. Dandekar and SP, unpublished data). Since anti-MHV antibodies provide a crucial role in preventing recrudescence of infectious virus in infected mice (25), lack of locally produced antibody may allow virus to continue to replicate and therefore predispose to the selection of CTL escape mutants. Interestingly, suckling BALB/c mice, which never show evidence of CTL escape, mount a robust humoral immune response in the CNS. Of note, Brown Norway, but not Lewis rats, mount a strong anti-MHV antibody response in the CNS. MHV causes a clinically silent demyelinating encephalomyelitis in Brown Norway rats, whereas Lewis rats develop symptomatic clinical disease, with elevated levels of infectious virus present. These results also suggest an important role for CNS-derived anti-MHV antibody in controlling the infection (26).

4. Monospecific polyclonal epitope S510-specific CTL response. As discussed above, CTL immune pressure focused on an immunodominant CTL epitope may favor selection of CTL escape variants by virtue of the significant loss of immune recognition when the epitope is mutated. However, this phenomenon may be less likely if CD8 T cells specific to the epitope are polyclonal (27). To determine the diversity of the epitope S510-specific T cell response, TCR Vβ element usage and the complexity of the complementary determining region 3 (CDR3) were determined. Epitope S510-specific CD8 T cells were obtained from the CNS of acutely and chronically infected mice by staining with peptide S510-loaded MHC class I tetramers and FACS analysis. A large number of different Vβ elements were detected within the epitope S510-specific population. Furthermore, analysis of CDR3 regions from this population revealed the presence of 400-600 different clonotypes per infected mouse, with many sequences common in all animals (17). This polyclonal response was not protective against the CTL escape, however, since it was functionally monospecific, with a strong focus on the center of the MHC class I/peptide complex (15).

5. Anatomical location of persistent virus. Since the CNS is a site of immune privilege, CTL escape mutants, once selected, may be able to replicate more efficiently in an environment with a less than optimal anti-MHV immune response. This may contribute to high level virus persistence, and eventually, to the development of clinical disease.

4. BIOLOGICAL SIGNIFICANCE OF CTL ESCAPE VARIANTS IN MHV-INFECTED MICE

Accumulating data suggest that evasion of the immune response by selection of CTL escape mutants occurs in several persistent infections, including humans infected with HIV, hepatitis B virus or hepatitis C virus and primates infected with SIV or hepatitis C virus (20, 28-30). A causal relationship between the presence of CTL escape variants and clinical outcomes is difficult to establish in infected humans or primates. Thus, the maternal antibody protection model described above is useful for determining the role of these variants in virus pathogenesis.

Pewe et al. (19) showed that escape from the CTL response was a major factor in disease progression in MHV-infected mice. Infection of suckling mice with CTL escape mutant virus resulted in higher mortality and morbidity than observed in mice infected with wild type virus. Furthermore, sequencing of infectious virus isolated from chronically infected mice revealed a lack of heterogeneity among isolates from a single animal. These data indicated that viral variants were selected during early infection and, once selected, they were fixed permanently, possibly due to continuous positive selection by CTL, ultimately leading to clinical disease.

5. CONCLUDING REMARKS

CTL escape has been demonstrated in several persistent infections. MHV-infected mice provide an excellent model for determining the role of these phenomena in viral pathogenesis. The results thus far show that CTL escape variants have a selective advantage and enhance clinical disease and demyelination. Although a specific virus has not been identified as an etiological agent in patients with MS, the development of CTL escape mutants provides a plausible mechanism for how a persistent, virus infection controlled by the immune system could progress to cause more significant disease. Further efforts will be directed at determining the mechanism of CTL escape and to determine why CTL escape has been identified in only a fraction of persistent viral infections.

CORONAVIRUSES AND NEUROANTIGENS:

myelin proteins, myelin genes

Pierre J. Talbot, Annie Boucher, Pierre Duquette [1], and Edith Gruslin

INRS-Institut Armand-Frappier, Institut national de la recherche scientifique, Université du Québec, Laval, Québec, Canada H7V 1B, and [1] Pavillon Notre-Dame, Centre hospitalier de l'Université de Montréal, Université de Montréal, Montréal, Québec, Canada H2L 4K8

Abstract: Multiple sclerosis (MS) is an autoimmune disease in which autoreactive T cells specific to central nervous system (CNS) myelin antigens are activated. Although disease etiology remains unknown, coronaviruses are suspected to be involved in MS pathology. Molecular mimicry, the recognition of two antigens by a single immune cell, could be the mechanism explaining the link between a viral infection and MS through activation of myelin-reactive T cells by a virus infection in a genetically predisposed individual. Evidence supporting this hypothesis in humans has been accumulated in our laboratory. Human coronavirus (HCoV) – myelin cross-reactive T-cell lines (TCL) were predominantly found in MS patients compared to patients with other neurological or inflammatory diseases, or healthy controls. Moreover, virus-myelin T cell cross-reactivity was confirmed at the clonal level. Molecular mimicry between infectious pathogens such as the ubiquitous human respiratory coronaviruses could, in genetically susceptible individuals, play a role leading to the development of MS. Together with other possible mechanisms such as bystander effects, epitope spreading or even superantigenic activities, this pathogen-associated immune induction could play a role in maintaining and broadening the autoimmune response associated with MS pathology.

Key words: autoimmunity, T cells, central nervous system, virus, molecular mimicry

1. INTRODUCTION

Multiple sclerosis (MS) is an autoimmune disease of the central nervous system (CNS) characterized by inflammation and myelin destruction. Even

though MS was described more than 130 years ago, its exact etiology remains unknown. A genetic predisposition is suggested and HLA genes are suspected to be involved (1, 2). Environmental factors are also associated with the triggering of this pathology. Indeed, epidemiological studies with identical twins demonstrate a low MS concordance between siblings and specific patterns of worldwide disease distribution point out the role for environmental factors, such as microbial agents (3, 4).

Amongst environmental factors potentially related to MS is a long list of more than 20 viruses. These viruses have been associated with MS by different experimental approaches: isolation of virus particles from tissues of MS patients (5), antibodies specific to virus found in central nervous system (CNS) of MS patients (6, 7) or demonstration of virus gene expression in the CNS of MS patients (8-14).

2. NEUROANTIGENS

Tolerance is described as a mechanism established to create and maintain a state of non-response to autoantigens. In the CNS, some proteins were found to activate the immune system: myelin basic protein (MBP), proteolipid protein (PLP), myelin associated glycoprotein (MAG), myelin oligodendrocyte glycoprotein (MOG), myelin oligodendrocyte basic protein (MOBP), CNPase (2',3'- cyclic nucleotidyl 3'-phosphodiesterase), transaldolase, S100β and α-B-crystallin (15, 16). All of these proteins were found at one time or another to activate autoreactive T lymphocytes in MS patients and therefore are suspected in maintaining or amplifying autoimmune reactions observed in the disease (17-20). Those neuroantigens, previously cryptic, might have been liberated in the CNS milieu following damages to the myelin sheath, and made available for antigen presentation.

How tolerance is broken in MS is still not understood. The suggested potential mechanisms are related to the initiation or propagation of the autoimmunity observed in MS. Superantigens could lead to a potent non-specific activation of a given T-cell receptor (TCR) Vβ family. Non-specific bystander effects of inflammation could also hold a key role. Moreover, determinant (epitope) spreading would broaden the immune response towards the recognition of new autoantigens. Finally, molecular mimicry between self-proteins and microbes represents another possible mechanism that could be involved in breaking tolerance and could explain the association of several infectious pathogens with MS etiology and exacerbations.

3. MS AND CORONAVIRUSES

Coronaviruses are enveloped virus with a diameter of approximately 120 nm and that exhibit characteristic crown-shaped projections on their surface (21). Their genome consists of a very long positive-stranded RNA. Coronaviruses are responsible for 10 to 35% of common cold in humans (22) and were associated with more serious diseases such as respiratory distress in newborns (23), severe acute respiratory syndrome (SARS), and severe diarrhea (24).

The association between coronavirus and MS is strengthened by observations in mice. Indeed, murine coronavirus infection of susceptible mice leads to an inflammatory demyelination. This virus-induced demyelination is similar to MS in several aspects, providing a widely studied model for this neurological autoimmune disease (23, 24).

In humans, it was demonstrated using different experimental approaches that coronaviruses are neuroinvasive, i.e. that they can reach the CNS. First, virus was isolated from the brains of MS patients (27). Second, titers of antibodies specific to human coronaviruses were described to be higher in cerebrospinal fluids of MS patients than controls (28). Third, coronavirus RNA was detected in the brain of MS patients by RT-PCR and by *in situ* hybridization (11, 12, 14).

Furthermore, coronavirus neurotropism, the capacity to infect CNS cells, has also been demonstrated in humans. An acute infection by human coronaviruses was demonstrated in primary cultures of human microglia and astrocytes (29) as well as oligodendrocytes (Talbot *et al.*, unpublished data). In addition, a persistent infection by coronavirus was demonstrated in cell lines from nervous system (30, 31).

These observations demonstrated that coronavirus could reach the CNS and infect neural cells. Although it cannot be concluded from these observations that coronaviruses do cause MS, it suggests an association between CNS viral infection and this neurologic disease. In addition, epidemiological studies have shown that MS relapses were often preceded with respiratory tract infections (30). Interestingly, coronavirus reinfections are in fact possible (22).

4. T CELL CROSS-REACTIVITY TO CORONAVIRUS AND MYELIN PROTEINS

Several mechanisms have been proposed to explain how a viral infection could lead to an autoimmune disease. Amongst these mechanisms is molecular mimicry. According to this model, a non-self agent first activates

an immune cell. Then, the cell recognizes a self-element that shares antigenic conformation with the pathogen and directs a response towards it. Individuals who are genetically predisposed to respond to this antigenic determinant of a pathogen having a similar conformation to a determinant on a self-antigen could develop an autoimmune response following infection. Shared sequences or similar determinant conformations between coronavirus and myelin proteins such as myelin basic protein (MBP) and proteolipid protein (PLP) have been identified (33-35). Molecular mimicry provides a unifying mechanism that could explain both the genetic and environmental aspects in the triggering of MS.

The molecular mimicry hypothesis would indeed explain observation of T cell lines (TCL) cross-reactive to both myelin antigen (Ag) and human coronavirus (HCoV) we have reported in MS patients (36). In this study, peripheral blood lymphocytes from MS patients and healthy controls were used to select long-term MBP- and HCoV-reactive T cell lines. A summary of these results is shown in Table 1. MBP T-cell lines were found as frequently in MS patients than in healthy controls. All the participants tested seropositive for coronavirus, as expected (22). Interestingly, TCL from ten of sixteen MS patients and two of fourteen control subjects showed cross-reactivity between myelin and viral antigens, for a proportion of such lines of 29% in MS patients and only 1.3% in healthy donors. Such cross-reactivity is thus highly significantly observed in MS patients. Therefore, in genetically predisposed individuals, T cells could be primed and activated following a systemic infection; the activated lymphocyte would enter the CNS and could establish a response towards myelin antigens. Myelin-reactive T lymphocytes could also have a role in broadening the immune response and increasing tissue damage. Coronavirus-myelin cross-reactive lymphocytes could thus initiate, maintain and/or amplify autoimmunity.

Table 1. Overall number of coronavirus-myelin cross-reactive TCL produced from MS patients and healthy donors. Cross-reactive TCL are obtained in a highly significant proportion ($p<0.0001$) in MS patients versus controls, with 29% out of TCL generated from the peripheral blood compared to only 1.3% (Talbot, 1996).

Donors	n	Lines	Cross-reactive T-cell lines		
		(CD4+)	Lines	n	%
MS	16	134	39	10	29
Healthy Controls	14	155	2	2	1.3

Although these findings regarding T-cell cross-reactivity between human coronavirus and myelin antigen are consistent with the molecular mimicry hypothesis, experiments at the clonal level were needed to prove that a single T cell was indeed activated by both viral and myelin antigens.

5. CLONAL T-CELL CROSS-REACTIVITY

Studies conducted at the molecular level reinforce and confirm the molecular mimicry hypothesis in MS (37). It was essential to examine coronavirus-myelin cross-reactivities at the T cell clonal level since TCL are made of a heterogeneous cell population: more than one TCR could have been involved in the measured cross-reactive response. Similar to the previous study involving TCL, long-term primary T cell clones (TCC) were also derived from the peripheral blood of MS patients. Selecting antigens used in this study were both known human coronavirus serotypes (229E and OC43) as well as two CNS proteins, MBP and PLP. Briefly, TCL were first selected with either one of the selecting antigen and positive cells were then cloned by limiting dilution; tritiated thymidine incorporation assays determined antigenic-specitifities (38). Table 2 shows that a total of 145 monospecific TCC were obtained from twenty-two patients, out of thirty-two patients studied. Many TCC were positive to coronavirus antigens, with about 80% of the TCC cultures selected with either HCoV-229E or HCoV-OC43.

Interestingly, ten cross-reactive long-term primary TCC were also cultured from six out of thirty-two MS patients (Table 2). While some patients led to very poor TCC production, other patients could lead to more then one cross-reactive TCC. These TCC were selected with myelin antigens (PLP and MBP, both encephalitogenic in genetically predisposed rodents) and HCoV. Half of these patients were HLA-DRB1*1501, a genetic susceptibility associated with MS (1). TCC produced were CD4+. HLA-typing and antigenic specificities of all ten cross-reactive TCC are described in Table 3. The selecting antigen is identified for each clone. Interestingly, two TCC selected with viral antigens recognized both myelin antigens. The TCR Vβ chains were also identified for six of those TCC and hypervariable regions were also determined through sequencing analysis (37).

Even if the method used to obtain the TCC is reliable, clonality was double-checked by diversity PCR. TCR were sequenced and only one TCR β chain was identified by PCR on several bacterial colonies issued from the same transformation. Assuming that the TCC obtained bear only one TCR, this study shows that a single TCR can recognize two different antigens, one from a human coronavirus, and the other from a myelin antigen that is targeted by T lymphocytes in MS. Such a cross-reactive phenomenon could be an elegant framework to explain the origin of an autoimmune disease as MS.

Thus, the T cell cross-reactivity between HCoV and myelin proteins in MS patients was confirmed at the single cell level. Combined with our previous results of highly significant coronavirus-myelin T-cell cross-

reactivities in MS patients compared to healthy controls (36), it appears that molecular mimicry could represent a signicant pathogenic mechanism associated with MS pathogenesis.

Table 2. Overall number of both monospecific and coronavirus-myelin cross-reactive TCC produced from the peripheral blood of thirty-two MS patients. Selecting antigens used for that experiment were both known serotypes of human coronavirus, HCoV-229E and HCoV-OC43, as well as two CNS proteins, MBP and PLP. Long-term primary human TCC were generated by limiting dilution of antigen-specific TCL. (37, 38)

TCC	Donors (n)	Number of TTC Produced with Viral Antigens		Number of TCC Produced with Myelin Antigens		Total
		HCoV-229E	HCoV-OC43	MBP	PLP	
Monospecific	22/32	80	34	19	12	145
Cross-reactive	6/32	4	2	2	2	10

Table 3. Antigenic specificity patterns of ten coronavirus-myelin cross-reactive TCC obtained from six MS patients. The HLA-typing for each patient from which those TCC were produced is shown. The selecting antigen is identified in bold.

TCC	HLA-DR	Antigenic Specificity	
P7-a	11,17	**HCoV-OC43**	MBP
P8-a	15,17	**HCoV-229E**	MBP
P12-a	13	**PLP**	HCoV-229E
P12-b	13	**PLP**	HCoV-229E
P12-c	13	**MBP**	HCoV-229E
P13-a	15	**MBP**	HCoV-229E
P13-b	15	**HCoV-OC43**	MBP and PLP
P22-a	13,15	**HCoV-229E**	MBP
P22-b	13,15	**HCoV-229E**	MBP and PLP
P24-a	7,17	**HCoV-229E**	MBP

6. MS SPECIFICITY OF T-CELL CROSS-REACTIVITY

In order to verify whether coronavirus-myelin T-cell cross-reactivity is more significantly associated with MS, TCL were established from the peripheral blood of patients having neurological or inflammatory disease and from healthy controls (Talbot *et al.*, unpublished data). In this study, TCL

cross-reactive for both myelin (MBP, PLP) and human coronavirus antigens were found in four out of eleven MS patients, in a proportion of 3.4% of all TCL derived from the peripheral blood. Only one out of ten patients having neurological or inflammatory disease showed such cross-reactive TCL, for a proportion of 0.5% of the overall TCL produced from the peripheral blood. The latter proportion (0.5%) of cross-reactive TCL was obtained from healthy donors, where a cross-reactive TCL toward myelin and coronaviral Ag was found in only one out of twelve donors. These results are shown in Table 4. Cross-reactive TCL were found more often in MS patients. It is too early to say that such antigenic pattern is clearly related to MS, however, it remains of great interest to explore those antigens regarding molecular mimicry and neurodegeneresence.

Thus, cross-reactive TCL for myelin proteins and HCoV seem to be more abundant in the peripheral blood MS patients than in healthy patients. Moreover, the cross-reactivity observed appears to be found in MS, an autoimmune neurological disease, but not in other inflammatory or neurological diseases.

7. CONCLUSIONS

The etiology of MS, an autoimmune neurologic disease, is unknown. Coronaviruses are suspected to be involved in MS pathology. Molecular mimicry, the recognition of two antigens by one single immune cell, could be the mechanism explaining the link between a viral infection and MS. Evidence of molecular mimicry between coronavirus and myelin antigens have been described in humans by our laboratory. Cross-reactive TCL were found predominantly in MS patients compared to patients with other neurological or inflammatory diseases, or healthy controls. Moreover, the T cell cross-reactivity was confirmed at the clonal level. However, it is important to keep in mind that the role of molecular mimicry does not exclude the participation of other immune mechanisms such as bystander effects, determinant spreading or even superantigens in the triggering or development of this autoimmune disease. All those mechanisms could play a role in maintaining or broadening the autoimmune response. The association of infection by a ubiquitous virus such as the human coronavirus with the development of multiple sclerosis in genetically susceptible individuals most likely represents the result of an aberrant induction of immune responses towards myelin proteins, possibly coupled to a persistent virus infection of the central nervous system that may activate glial cells (39), induce neuronal loss (40) and be associated with local immunopathology (41).

Table 4. To assess whether coronavirus-myelin cross-reactive TCL were only found in MS or could also be detected in other diseases, 13 MS patients, 10 patients suffering either of a neurological or an inflammatory disease, as well as 12 healthy controls were studied in comparison. For each group, TCL were produced and selected with MBP, HCoV-229E or HCoV-OC43, then were tested with a proliferation assay against both CNS proteins and both human coronavirus serotypes. The coronavirus-myelin cross-reactive TCL are shown in bold; those are also compared to the overall monospecific TCL number produced during the experiment to determine the percentage of cross-reactive TCL generated per studied group of donors. N.D. indicates that the test was not performed and results are not determined (selecting antigen indicated at the top of each column and antigen used for proliferation assay indicated on the left).

Abstract: MHV-A59 coronavirus infection produces a transient episode of demyelination that is followed by spontaneous remyelination. This paradigm provides a complex lesion environment to examine cellular and molecular mechanisms involved in successful CNS remyelination. Our work in this model has focused on the roles of platelet-derived growth factor and fibroblast growth factor 2 in regulating oligodendrocyte progenitor responses required for remyelination.

Key words: platelet-derived growth factor, fibroblast growth factor, estrous cycle, gender, demyelinating disease, remyelination, coronavirus, cuprizone

1. INTRODUCTION

Insufficient remyelination results in prolonged neurological impairment in demyelinating disease states, such as multiple sclerosis. A critical determinant of remyelination is regulation of oligodendrocyte lineage responses. Surviving and/or newly generated oligodendrocyte lineage cells must be recruited to appropriate sites within demyelinated tissues and induced to differentiate and form myelin. Each of these oligodendrocyte lineage cell responses appears to be regulated by signals within the lesion environment, such as growth factors, cytokines, and cell-cell interactions.

The pathology of multiple sclerosis (MS) lesions is heterogeneous between patients, with at least four fundamentally different patterns of

demyelination (12). Therefore, analysis of experimental models of demyelination with distinct mechanisms of pathogenesis is warranted. In addition, different experimental models have advantages for examining specific aspects within the course of demyelinating diseases. The mouse model of murine hepatitis strain A59 (MHV-A59) coronavirus infection serves as a relevant model for analyzing the cellular and molecular components involved in spontaneous remyelination. The complexity of MHV-A59 lesions includes infiltration of CD8+ and CD4+ T cells, B lymphocytes producing immunoglobulins, macrophages, and reactive glial cells (15,21). These lesion components are variably exhibited among categories of MS lesions.

The potential function of molecules that can promote remyelination in MS lesions, such as growth factors, is ideally analyzed in the context of a complex lesion environment due to contributing effects of cytokines, chemokines, infiltrating lymphocytes, and reactive cells. However, this complex lesion milieu can also make it difficult to delineate effects that are specific to the remyelination process. For this purpose, analysis of oligodendrocyte lineage responses is facilitated by comparison with a simpler lesion model, such as ingestion of cuprizone (14). Growth factor effects common to experimental lesions of diverse pathogenesis, such as MHV-A59 and cuprizone models, are most likely to be applicable more generally to demyelinating diseases.

This chapter will review recent findings of the expression and function of specific growth factors in MHV-A59 and cuprizone models of spontaneous remyelination. In addition, the complexity of the MHV-A59 model will be exemplified by discussion of the modulation of the disease course in correlation with gender and estrous cycle status. This modulation of the MHV-A59 disease course is also relevant to modulation of MS disease activity.

2. DISEASE SEVERITY IN THE MHV-A59 MODEL

Intracranial infection of female C57Bl/6 mice at 28 days of age with 1000 plaque forming units (PFU) of MHV-A59 virus produces a characteristic progression of demyelinating disease. Demyelination begins within the first week post-injection (wpi), with more extensive areas of myelin degeneration by 2 wpi (1,9). During this progression of demyelination, mice exhibit loss of motor function, and virus is present in cells of the white matter (9). In subsequent weeks, clearance of virus and myelin debris occurs, remyelination is initiated, and recovery of motor function proceeds (9,21). However, among mice similarly infected with MHV-A59, there is variability in the proportion of mice that exhibit distinct results from asymptomatic,

mild paresis, severe paralysis, to mortality. Early studies reported mortality rates that ranged from 11% (1) to 70% (11).

To take advantage of knockout mice for the analysis of growth factors and cellular components involved in spontaneous remyelination in this model, we needed to optimize the reproducibility of the MHV-A59 infection outcome. This objective led us to explore more quantitative methods to monitor disease progression and identify determinants of variation in disease severity, including mortality.

Intracranial MHV-A59 injection of 1000 PFU at 28 days of age has been used to maximize demyelination and minimize mortality compared to infection of younger mice (1,2,21). However, in addition to an age factor, a correlation was also observed between weight and mortality. Female 28-day old mice that eventually died during the acute infection weighed 12 ± 0.34 g (mean ± s.e.; n = 25) while survivors weighed 13.5 g ± 0.22 (mean ± s.e.; n = 51) ($p < 0.0005$, unpaired t-test). Accordingly, subsequent experiments used only mice weighing 13-15 g at 28 days of age.

Variability of infection outcome still occurred among female mice within these weight and age restrictions. Measures were already in place to minimize experimental variability from animal husbandry and experimental treatment. Additional tests were conducted to quantify the neurological effects of MHV-A59 lesions and determine whether the infection outcomes were clearly different, which would suggest an additional factor contributing to infection outcome. A "hang time" test of limb motor function and grasping was chosen to assess the result of MHV-A59 infection because the lesion predilection sites include the spinal cord white matter adjacent to the ventral root exit zones throughout all spinal cord levels (8,10,21).

To perform the hang time test, mice were placed onto a wire cage top, and once the mice had gripped the bars the top was turned upside-down and held horizontally above a table (similar to ref. 23). The length of time that each mouse held onto the bars was recorded, up to a maximum of 60 seconds. Control mice easily grasped the cage top bars with paws, often curled tails around the bars, and moved around to explore while upside-down (Figure 1A). In contrast, mice with impaired limb motor function could not grasp cage top bars with paws, rarely curled tails around bars, and dropped off prior to the 60 seconds maximum time limit (Figure 1B). Inability to hold on was associated with demyelination, as evident in previous reports of the histopathology of MHV-A59 infected mice (1,21).

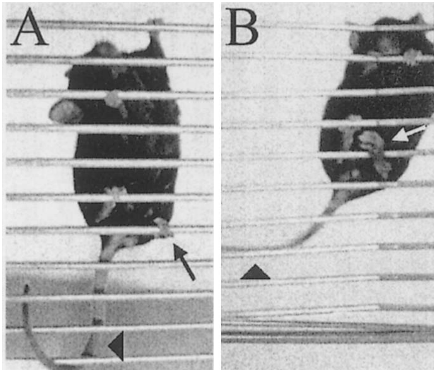

Figure 1. **Control (A) and MHV-A59 infected (B) mice shown hanging from a cage top during hang time tests.** The control mouse can easily grasp the bars with paws (black arrow) and tail (black arrowhead). The MHV-A59 infected mouse has hind limb and tail impairment so that the paws cannot normally grasp the bars (white arrow) and the tail is limp (black arrowhead).

The time course of individual mouse hang time performance over 4 wpi showed that some mice had only mild motor dysfunction while others had severe motor dysfunction (Figure 2). Operational definitions for mild and severe groups can be made several ways. One method is to sum hang times over the disease course, through 4 wpi when many mice have fully recovered. Clustering of subgroups of mice is evident as either a low summed hang time (severe motor dysfunction) or a high summed hang time (mild motor dysfunction). However, to allow mice to be used prior to the recovery phase, a practical set of criteria was needed by 2 wpi. After testing the hang time of mice at 7, 10, and 14 days post-infection (dpi), a mouse that had 2 or 3 hang time values of > 30 seconds <u>or</u> recovered to a 60 second hang time by 14 dpi was categorized as only mildly affected. A mouse that had 2 or 3 hang times ≤ 30 seconds <u>and</u> did not recover to 60 seconds by 14 dpi was categorized as severely affected.

In many models of experimental demyelination involving the spinal cord, disease severity is commonly quantified by a clinical scoring system. An adapted clinical rating has been applied in the MHV-A59 model (21). The clinical score scale is a measure of impairment based upon observed paresis or paralysis of limbs, so that 0 = no observable paresis/paralysis, 1-5 = paresis/paralysis in 1-5 limbs, respectively (such as limp tail, abnormal limb contracture or extension, dragging of limb, abnormal lateral movement of limb), and 6 = morbidity. The clinical scores of mildly affected mice over time are significantly less than the clinical scores of severely affected mice (Figure 2). However, the limited unit range of the clinical score scale does not detect individual variation as well as the hang time test in the MHV-A59 model.

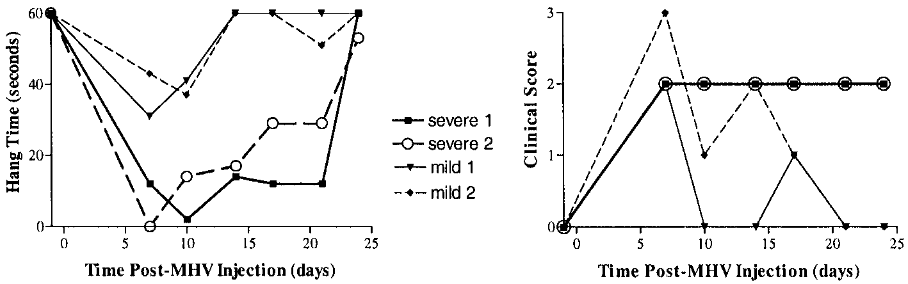

Figure 2. **Examples of hang time and clinical score results.** Individual records are shown for 2 mildly affected mice and 2 severely affected mice as representative examples of the variability in disease severity. The same mice are shown in both graphs. The hang times shown on each day are the averages of 3 trials.

3. MHV-A59 DISEASE SEVERITY RELATIVE TO GENDER AND ESTROUS CYCLE

Sex hormones have a role in disease susceptibility and severity in MS, which has been replicated in experimental autoimmune encephalomyelitis (EAE) in SJL mice (25). While females are more susceptible to MS than males (26), a worse survival curve is associated with male gender in primary progressive MS (6). In females with relapsing-remitting MS, worsening disease activity has been reported to vary with estrous cycle stage, but results attempting to correlate further to hormone levels have produced conflicting results (4,19,24,29).

To identify an underlying factor in the variability of disease severity in our MHV-A59 model, estrous cycle stage was monitored using vaginal smears (7)(Figure 3). Severely affected female mice were more likely to be in diestrus or metestrus during the early effector stage of the pro-inflammatory response (4 dpi). Estradiol and progesterone are relatively low at these stages of the estrous cycle. Female mice in proestrus or estrus (at 4 dpi), when estradiol and progesterone levels are elevated, more frequently experienced a milder outcome after MHV-A59 infection. Interestingly, EAE was ameliorated in SJL mice treated with estradiol at a sustained high dose, regardless of the dose of progesterone used in combination (25). However, the dose of estradiol needed to significantly decrease EAE severity was above levels that occur naturally during the estrous cycle (25). Thus, the MHV-A59 pathogenesis may be very sensitive to variation of hormone levels during the estrous cycle.

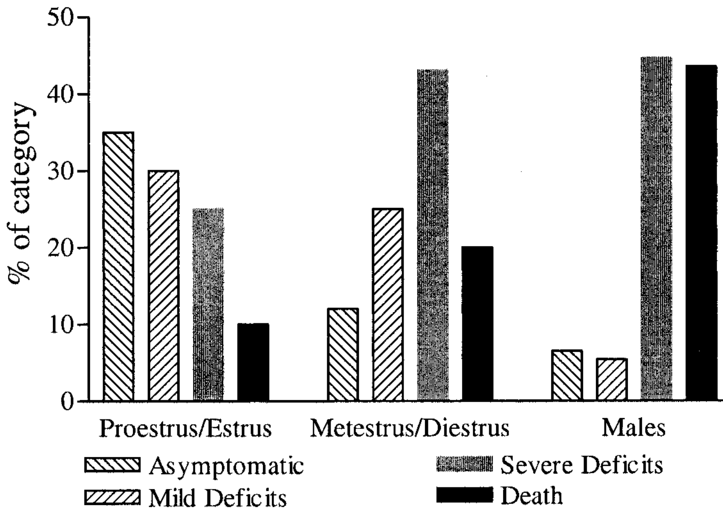

Figure 3. **Outcome of MHV-A59 infection in female mice, at different stages of the estrous cycle, and male mice**. The outcome of infection in each mouse was based upon hang time score using the classification described in the text. Each value represents mice combined from at least 3 separate infection experiments. Female mice, Proestrus/Estrus $n = 20$, Metestrus/Diestrus, $n = 129$; combined from 6 separate sets of infections; sampling difference reflects the proportional difference in the duration of the stages within the 4 day mouse menstrual cycle. Male mice, $n = 92$; combined from 3 separate sets of infections.

Male mice in this MHV-A59 model clearly had a more severe disease course and higher rate of mortality than female mice. A Th1 cytokine response, specifically interferon gamma, is required for clearing of the MHV-A59 virus from oligodendrocytes and resolution of the disease as a model of transient demyelination (18). Male hormonal conditions favor a bias towards Th2 cytokine production rather than a Th1 response (28), which may correlate with a lack of interferon gamma production in lesions of males and explain the increased rates of mortality compared to females.

4. GROWTH FACTOR EXPRESSION FOLLOWING DEMYELINATION

Discussion of growth factor pathways in MHV-A59 lesions will focus on oligodendrocyte lineage responses during remyelination. Given the variability of MHV-A59 disease severity noted above, studies of growth factors in this model utilize only the mice that are classified as "severe" to provide a reproducible status. Also, when possible, findings in the MHV-A59 model will be compared with the cuprizone model to establish common mechanisms.

Experimental models with different pathogenesis indicate that, when remyelination occurs, oligodendroglial repopulation of demyelinated lesions may result from a common mechanism: local proliferation and recruitment of oligodendrocyte progenitor cells. *In vitro* studies predict that specific growth factors regulate the oligodendrocyte progenitor responses needed for myelination during development and for remyelination (*i.e.* proliferation, migration, differentiation, and survival). Among the growth factors known to regulate the oligodendrocyte lineage, platelet-derived growth factor (AA homodimer, PDGF) and fibroblast growth factor 2 (FGF2) warrant high priority for analysis.

In vitro studies have documented the ability of PDGF and FGF2 to regulate responses of oligodendrocyte lineage cells isolated from normal neonatal and adult CNS. During development, neonatal oligodendrocyte progenitors proliferate in response to PDGF or FGF2, and grow as a self-renewing cell line in the combination of PDGF and FGF2 (5,16,22). PDGF and FGF2 can also enhance the proliferation of oligodendrocyte progenitor cells isolated from normal adult rodent CNS (13,27). FGF2 treatment of more mature stages of the oligodendrocyte lineage inhibits terminal differentiation (3).

In vivo studies have supported the hypothesis that growth factors may regulate oligodendrocyte progenitor responses involved in myelin repair. At the onset of remyelination (4 wpi) in spinal cords of MHV-A59 lesioned mice, increased expression of PDGF-A and FGF2 ligands, as well as the corresponding receptors, indicated the potential for each to act upon oligodendrocyte lineage cells involved in remyelination. Immunostaining for PDGF-A ligand demonstrated increased expression in reactive astrocytes in remyelinating lesions (21). *In situ* hybridization to detect PDGF-A mRNA revealed a 2.9 fold increase in the number of labeled cells in sections from MHV-A59 infected mice vs. PBS-injected control mice (21). Similar *in situ* hybridization of FGF2 demonstrated markedly increased signal in reactive astrocytes and microglia localized within and near white matter lesions (17). Over the course of MHV-A59 disease progression, FGF2 mRNA transcript abundance peaked at 4 wpi as greater than 5-fold over non-lesioned levels (17). At a corresponding stage in cuprizone demyelination, a similar increase was observed for FGF2 (2) and PDGF-A mRNA (unpublished observation). Interestingly, in both models the increased signal for FGF2 is clearly localized to the lesion while the increase in cells with detectable PDGF-A is much more widely distributed in the tissue. These distributions may indicate differences in the influence of these growth factors on the oligodendrocyte lineage cell response.

In addition to demonstrating the increased expression of PDGF-A and FGF2 mRNA, expression of corresponding receptors on oligodendrocyte lineage cells has been examined *in vivo*. In lesioned white matter undergoing remyelination after MHV-A59 infection, the number of cells expressing FGF receptors increased as much as 5-fold (17). Oligodendrocyte progenitors expressed receptors for both FGF2 and PDGF (specifically PDGFαR, the alpha form of PDGF receptor) (7,20,21). Oligodendrocytes also expressed FGF receptors (19,20).

In both the MHV-A59 model and the cuprizone model, the oligodendrocyte progenitor proliferative response corresponds with expression of PDGFαR (2,21). During early remyelination, there is a dramatic increase in the number of cells that are expressing PDGFαR mRNA transcripts and have incorporated bromodeoxyuridine (BrdU; indicative of DNA synthesis) during a 4-hour terminal *in vivo* pulse. In contrast, mature oligodendrocytes did not exhibit substantial proliferation. Taken together, these studies support the prediction that PDGF and FGF2 may play a role in the successful generation of oligodendrocyte lineage cells and subsequent remyelination observed in this mouse model; the ligands and receptors are expressed at an appropriate stage of the disease process and with the appropriate cellular localization, and association with a proliferation indicator.

A specific role of PDGF and FGF2 in regulating proliferation during remyelination has been demonstrated by culturing oligodendrocyte lineage cells from spinal cords of MHV-A59 infected mice. Approximately 20% of the white matter is demyelinated throughout the rostrocaudal levels of the spinal cord as a result of MHV-A59 infection (8). This extent of tissue involvement is sufficient for isolation of a population of oligodendrocyte progenitor cells that is significantly more proliferative than the population derived from normal adult mouse spinal cord (1). PDGF and FGF2, produced by reactive astrocytes and microglia within the cultures, are significant mitogens regulating this proliferative response (8). Interestingly, in cultures derived from different time points after MHV-A59 infection, the oligodendrocyte progenitor response varies with the disease stage; proliferation is more robust during the demyelination phase while differentiation is more extensive during remyelination (8).

Knockout and transgenic mice can test the function of growth factors throughout the progression of demyelination and remyelination, as has been done for FGF2 knockout mice (2). In both MHV-A59 and cuprizone models, oligodendroglial repopulation of lesions was enhanced in the absence of FGF2. During early remyelination, oligodendrocyte lineage cell proliferation and survival were not altered by the FGF2 genotype – possibly because other growth factors sufficiently supported these lineage responses (see ref. 2).

Thus, during remyelination, absence of FGF2 may promote oligodendroglial regeneration by enhancing oligodendrocyte progenitor maturation. This *in vivo* distinction among potential roles of FGF2 in differentiation versus proliferation demonstrates that transgenic and knockout mouse models are important for testing growth factor roles in the context of the lesion environment throughout the disease progression. The expression and activity of growth factors, and other regulatory molecules, change throughout the disease course. In addition, the oligodendrocyte lineage population changes with progressive stages of the disease course. Therefore, the effect of a given growth factor on the oligodendrocyte lineage population may vary *in vivo* during the disease course.

5. CONCLUSION

Future therapeutic developments may make it possible to intervene to promote remyelination for MS patients in which the disease progression can be arrested. Effective treatments to promote repair of demyelinated lesions will need to be tailored to the specific pathology of the patient and adapted for the disease stage. Animal models are clearly an important component for identifying and testing the potential roles of growth factors as candidate interventions to promote remyelination.

Chapter C9

CHEMOKINES IN CORONAVIRUS-INDUCED DEMYELINATION

Matthew J. Trifilo[*], Michael T. Liu, William G. Glass, and Thomas E. Lane[*1]

[*]*Department of Molecular Biology and Biochemistry, University of California, Irvine, CA 92697-3900*

Abstract: Inflammation within the central nervous system (CNS) is critical in the development of the neuropathology associated with the human demyelinating disease multiple sclerosis (MS). Recent studies have identified a family of soluble proinflammatory molecules called chemokines that are able to direct leukocyte infiltration into the CNS in response to infection or injury. Identification of chemokines within and around demyelinating lesions in MS patients indicate a potential role for these molecules in contributing to the pathogenesis of MS. To address this issue, we have used mouse hepatitis virus (MHV) infection of the CNS to understand the dynamic interaction of chemokine expression as it relates to inflammation and neuropathology. Our results indicate that chemokine expression within the CNS results in persistent recruitment of both T lymphocytes and macrophages and results in subsequent myelin destruction. Herein, we demonstrate the complexity of the chemokine response to MHV infection of the CNS and the delicate balance that exists between host defense and development of disease.

Key words: Chemokines, T lymphocytes, Macrophages, Demyelination

1. INTRODUCTION

Mouse hepatitis virus (MHV) is a single strand, positive sense RNA virus that is a member of the Coronaviradae family. As with many viruses, the disease induced by MHV infection depends upon a variety of different factors such as host and viral genetics as well as the dose and route of

inoculation. For example, intracranial (i.c.) infection of susceptible strains of mice such as C57BL/6 (H-2^b background) with the neuroattenuated variant MHV strain J2.2v-1 results in infection of glial cells and oligodendrocytes resulting in an acute encephalomyelitis accompanied by white matter destruction. Type I interferons are expressed early following infection and this correlates with recruitment of neutrophils and natural killer (NK) cells into the CNS. Although not completely understood, it is thought that these components of the innate immune response control viral spread prior to the entry of virus-specific T cells as well as participate in amplifying chemokine expression within the CNS that results in the induction of the adaptive immune response. $CD8^+$ T cells are the primary effector component of the adaptive immune response and are able to eliminate infectious virus from the host through secretion of IFN-γ (oligodendrocytes) and perforin-mediated cytolysis (astrocytes and microglia) (1,2). $CD4^+$ T cells can also directly participate in reducing viral burden presumably through the release of antiviral cytokines such as IFN-γ. However, $CD4^+$ T cells also play an essential role in host defense by providing support for $CD8^+$ T cells (3,4). Although both $CD4^+$ and $CD8^+$ T cells are potent anti-viral effector cells within the CNS, sterile immunity is not achieved and viral RNA and protein persist primarily within white matter tracts in which astrocytes and oligodendrocytes are the predominant cellular reservoirs for virus.

Viral persistence in white matter tracts results in a chronic demyelinating disease in which foci of demyelination are associated with areas of viral RNA/antigen. Clinically, mice develop loss of tail tone and a partial to complete hind-limb paralysis. Recent reports have indicated that MHV-induced demyelination is complex and involves immunopathologic responses against viral antigens expressed in infected tissues. MHV infection of immunosuppressed or immunodeficient mice results in high titers of virus within the CNS and increased mortality but no detectable demyelination (5). Further, adoptive transfer of MHV-immune splenocytes restores demyelination to the infected recipients suggesting a role for immune cells in driving demyelination (5). We have recently demonstrated that $CD4^{-/-}$ mice displayed a significant reduction in the severity of demyelination as compared to $CD8^{-/-}$ and immunocompetent wildtype mice suggesting an important role for $CD4^+$ T cells in amplifying the severity of white matter destruction (6). Additional support for T cells in contributing to demyelination comes from a recent report by Wu *et al.* (3) that demonstrated that both $CD4^+$ and $CD8^+$ T cells are important in mediating myelin destruction following adoptive transfer into MHV-infected $RAG1^{-/-}$ mice. Although B cells and/or antibodies have been shown to play an important role in controlling the recrudescence of virus during the chronic stage of disease, they are not important in MHV-induced demyelination (7). We and

others have found that macrophages/microglia are also important in contributing to demyelination (3,6,8). Current evidence suggests that demyelination in MHV-infected mice is not the result of epitope spreading and induction of an immune response against neuroantigens as has recently been reported to occur during Theiler's virus-induced demyelination (9). It is likely that T cells present within the CNS of MHV-infected mice are specific for viral antigens and these cells drive demyelination by producing and/or influencing the production of cytokines/chemokines that amplify and support inflammation. Therefore, collective evidence points to a role for inflammatory T cells in contributing to macrophage/microglia infiltration and activation that results in myelin destruction. Collectively, these studies illustrate the complexity of the MHV system as it relates to the immune response and demyelination.

Given the importance of both T cells and macrophages in amplifying the severity of myelin destruction in persistently infected mice, it is clear that maintenance of a chronic inflammatory response is important with regards to the neuropathology of this model system. Numerous cytokines including TNF-α, IL-1β, and IL-6 are produced by activated astrocytes within the CNS of persistently infected mice (10). Working in concert or individually, these molecules may contribute to disease and myelin destruction by attracting T cells and macrophages into the CNS. However, the soluble signals that regulate CNS invasion by inflammatory cells likely consist of additional factors. With this in mind, studies from our laboratory have focused on chemokines (*chemo*tactic cyto*kines*) and the role these molecules have in MHV-induced demyelination. This chapter will focus on recent studies evaluating the functional significance of chemokine expression as it relates to disease development following MHV infection of the CNS.

1.1 Chemokines and Chemokine Receptors

Chemokines are a family of small molecular weight, secreted proteins that have been shown to target the migration of specific populations of leukocytes (Reviewed in 11). The chemokines are currently divided into four subfamilies based upon the arrangement of conserved cysteine residues in the amino-terminus of the protein (structural criteria) and what leukocytes are targeted, e.g. monocytes, macrophages, granulocytes, neutrophils, and T lymphocytes (functional criteria)(11-13). A variety of lymphoid and nonlymphoid tissues can produce chemokines, often in connection with the initiation or progression of inflammation (11). However, recent evidence also identifies a role for chemokines in the regulation of normal leukocyte migration into, out of, and within lymphoid tissues and organs (14,15).

Much attention has focused on two distinctive groups of chemokines, the CXC and CC chemokines, because of their appearance in numerous disease models, including MS (11,16,17). The CXC family can be further subdivided into two groups based upon the presence of a glutamic acid-leucine-arginine (ELR) motif on the amino terminus. The appearance of the ELR motif encodes for chemotaxis of neutrophils, whereas its absence dictates the recruitment of lymphocytes and monocytes (11,13,18,19). In general, the CC chemokines share chemoattractant properties with non-ELR CXC chemokines, attracting monocytes, T lymphocytes, basophils, and eosinophils and have little or no effect on neutrophils (11,13).

As mentioned above, chemokines can be produced in the presence or absence of inflammation. However, much attention has focused on the beneficial and detrimental role of chemokines in leukocyte recruitment in response to infection (11,13, 20-28). A wide variety of cell types can produce chemokines in response to pathogen, including monocytes, macrophages, lymphocytes, neutrophils, endothelial cells, fibroblasts, and astrocytes. Although many of these cells can produce a diverse array of chemokines, specific chemokine production appears to be linked to the type and strength of the stimuli present. Chemokines are able to induce leukocyte migration into tissue by promoting the adherence and extravasation of leukocytes across the vascular endothelium. Once inside the inflamed tissue, leukocytes are able to migrate across chemokine gradients towards the highest localized concentration. These gradients are established through the binding of the highly basic chemokines to the acidic extracellular matrix on the luminal side of the endothelium. This interaction may also allow for reduced chemokine diffusion and help establish a fixed gradient towards the site of infection (29).

Although in vitro studies have shown extensive redundancy in the chemotactic properties of chemokines, in vivo studies utilizing knockout mice and neutralizing-antibodies have suggested that in response to viral infection of the CNS, chemokines are able to selectively attract distinct leukocyte populations (20-24). Importantly, accumulating evidence indicates that this non-redundant recruitment may influence a variety of CNS diseases by initiating events culminating in neuroinflammation (20,30,31). In addition to their prominent role in inflammation, chemokines may also directly contribute to disease progression by exerting a cytotoxic effect upon host tissue (32). Furthermore, there is increasing evidence that chemokines are able to influence the activation and differentiation (Th1 vs. Th2) of T cells (22,33).

Chemokines act through binding specific receptors present on the surface of numerous cell types. The majority of chemokine receptors belong to the seven-transmembrane G protein-coupled receptor superfamily. Unlike the

specificity observed between most ligand receptor pairs, chemokines exhibit a high level of promiscuity, capable of productively binding to multiple chemokine receptors and chemokine receptors can functionally bind multiple chemokines (34-37). Following chemokine binding to its cognate receptor, signaling events are initiated that result in various cellular processes including increases in intracellular calcium, production of cytokines and chemokines, adhesion to the endothelial matrix, and chemotaxis (38). Interestingly, numerous CXC and CC chemokines can also bind to a receptor identical to the Duffy blood group antigen that is present on the surface of erythrocytes (39-41). Binding of chemokines to these receptors does not result in intracellular signaling events, instead it appears to reduce the level of circulating chemokines that may decrease unwanted interactions between chemokines and leukocytes within the blood, maximizing the ability of circulating leukocytes to migrate to highly concentrated chemokine levels at the site of infection (40,42,43).

Leukocytes can limit chemokine signaling by effectively down-regulating chemokine receptor expression or by uncoupling the downstream signaling events from the chemokine receptor, allowing for immediate control of chemokine signaling. Additionally, leukocytes exposed to high concentrations of an individual chemokine can become desensitized via phosphorylation of chemokine receptors limiting leukocyte movement at the site of infection (34,44).

Chemokine receptors can be identified on nearly all lymphocyte populations. However, the expression pattern of certain receptors appears to correlate with the activation state of the cell. For this reason, specific chemokine receptors have been utilized to determine the activation state of specific sub-populations of T lymphocytes. For example, expression of the chemokine receptor CCR7, which is necessary for migration into secondary lymphoid tissues, has been localized to the surface of naïve T cells and a subpopulation of memory cells (45). In contrast, T cells expressing the chemokine receptors CXCR3, CCR1 and/or CCR5 selectively migrate into inflamed tertiary tissues, indicating an important role for these chemokine receptors and their respective ligands in promoting an inflammatory response (20,24,45-47).

1.2 Chemokines and Multiple Sclerosis

Expression of chemokines has been associated with demyelinating plaque lesions present in MS patients (48,49). Hvas and colleagues (48) demonstrated expression of the CC chemokine CCL5 by infiltrating T-lymphocytes surrounding MS plaque lesions. Elevated levels of the non-

ELR CXC chemokines CXCL10, CXCL9 as well as CCL5 were found in the CSF of MS patients during periods of clinical attack (49). In addition, astrocyte expression of CXCL10 has been reported in plaque lesions present in MS patients (49). Recent work has demonstrated a direct correlation between clinical progression in the severity of MS with leukocyte infiltration into the CNS suggesting that production of CXCL10, CXCL9, and CCL5 may contribute to the pathogenesis of MS by recruiting T cells and macrophages into the CNS (49). Further, MS patients display increased expression of CXCR3 and CCR5, the cellular receptors for CXCL10, CXCL9, and CCL5, respectively, within the CNS as compared to control patients (49). T cells expressed both CXCR3 and CCR5 whereas macrophages/microglia were found to express CCR5 (49). Further support for chemokines and chemokine receptors in contributing to recruitment of activated leukocytes comes from a recent study by Baranzini et al. (50) that demonstrated increased expression of CCR1 (signaling receptor for CCL5 and CCL3) and CCR5 within the brains of MS patients. Collectively, these data emphasize the need for a better understanding the functional significance of chemokine and chemokine receptor expression as it relates to demyelination in MS patients.

1.3 MHV Infection and Chemokine Gene Expression

MHV infection of the CNS results in a well-orchestrated expression of chemokine genes which appears to be dictated, in part, by viral burden (51, Table I). CXCL10 mRNA transcripts are detected within 1 day following infection and co-localize with areas of MHV replication. At this time, the cellular source of CXCL10 transcripts are primarily ependymal cells lining the lateral ventricle (51). By day 6 p.i., virus has spread throughout the brain parenchyma and a robust inflammatory response, characterized primarily by $CD4^+$ and $CD8^+$ T cells and macrophages, is established within the brain. Chemokines expressed at this time include CXCL9, CXCL10, CCL2, CCL3, CCL5 and CCL7 (51). *In situ* double-labeling revealed that astrocytes are the predominant cellular source of mRNA transcripts for CXCL9 and CXCL10 during the acute stage of disease (21,51). In addition, MHV-infection of mouse cultured astrocytes results in the rapid induction of numerous chemokine genes including CXCL1, CXCL10, CCL2, CCL4, and

Table I. Summary of chemokine expression with clinical and pathological features following MHV infection of the CNS

[d]Demyelination was determined by Luxol fast blue staining of paraffin-embeded brain and spinal cord sections.

CCL7 (6). UV-inactivated MHV was sufficient to trigger low level chemokine gene expression indicating that viral replication is not necessary to induce expression of these genes (51). *In vivo* analysis of the chemokine receptor mRNA profile indicates increased expression of CCR1, CCR5, and CXCR3 during the acute stage of disease (20,24). Confocal microscopy revealed that macrophages (determined by F4/80 antigen expression) express CCR5 (24). In addition, studies have shown that both $CD4^+$ and $CD8^+$ T cells infiltrating into the brain express CXCR3 (20).

1.4 Functional Significance of Chemokine Expression during MHV-Induced Demyelination

CXCL10 and CCL5 are the predominant chemokines expressed in the CNS of persistently infected mice undergoing demyelination (51) (Table I). Moreover, CXCR3 and CCR5 expression (receptors for CXCL10 and CCL5, respectively) is also detected at this time (20,24). These findings have

parallels in human neurodegenerative diseases. Glial cell expression of CCL5 and CXCL10 as well as CXCR3-and CCR5-positive mononuclear cells have been reported within demyelinating lesions present in patients with MS (49,52). Moreover, increased levels of CXCL9, CXCL10 and CCL5 are present within the cerebral spinal fluid of MS patients during periods of clinical attack and their presence correlates with increased numbers of inflammatory cells (49). Therefore, the overlap in chemokine and chemokine receptor expression profiles within the demyelinating CNS of MHV-infected mice and MS patients provides an opportunity to assess the functional significance of these molecules as it relates to demyelination in the MHV model system.

1.5 CCL5 and Disease

Intracranial infection of $CD4^{-/-}$ and $CD8^{-/-}$ mice with MHV resulted in increased mortality and delayed clearance of virus from the CNS demonstrating an important role for T lymphocytes in host defense against MHV-induced CNS disease (6). Interestingly, infected $CD4^{-/-}$ mice displayed significantly less severe inflammation and demyelination as compared to $CD8^{-/-}$ and wildtype C57BL/6 mice. FACS analysis of the cellular infiltrate present within the CNS of infected mice revealed that $CD4^{-/-}$ mice contain fewer activated macrophages and significantly lower levels of CCL5 mRNA transcripts and protein when compared to $CD8^{-/-}$ and C57BL/6 mice. These data suggested that $CD4^{+}$ T cells are the predominant source of CCL5 following MHV infection of the CNS, although it is also possible that $CD4^{+}$ T cells influence expression of CCL5 by other cell populations through the release of cytokines and/or chemokines. Additional cellular sources such as $CD8^{+}$ T cells, macrophage and glial cells must be considered due to the fact that CCL5 mRNA transcripts and protein are detected, albeit at lower levels, within the CNS of $CD4^{-/-}$ mice. In light of the fact that CCL5 exerts a potent chemotactic effect on both T cells and macrophages, these data suggest that the reduction in macrophage infiltration and the severity of demyelination into the CNS of $CD4^{-/-}$ mice is causally related to the reduced CCL5 levels observed.

To provide a direct test of CCL5 importance in contributing to MHV-induced CNS inflammation and demyelination, MHV-infected C57BL/6 mice were treated with anti-CCL5 antisera immediately following MHV infection and the severity of disease evaluated. Treatment lead to a disease in C57BL/6 mice similar to the phenotype observed in $CD4^{-/-}$ mice with mice displaying a significant reduction in the severity of demyelination. Decreased macrophage infiltration in anti-CCL5 treated mice correlated with the reduced severity of demyelination supporting the observations with

MHV-infected $CD4^{-/-}$ mice (6). These observations reinforce the functional significance of CCL5 expression during virus-induced CNS disease indicating that this chemokine has an important role in the recruitment of macrophages into the CNS following MHV infection. Moreover, administration of neutralizing anti-CCL5 antibodies to MHV-infected mice in which disease e.g. demyelination and paralysis is already established resulted in a marked improvement in neurologic disease that correlated with reduced T cell infiltration and a reduction in the severity of myelin destruction (Glass and Lane, unpublished observations). Collectively, these data highlight the important role of CCL5 signaling in both host defense and disease pathogenesis by regulating leukocyte accumulation within the CNS of MHV-infected mice.

Having established that CCL5, a major signaling ligand of CCR5, is important in contributing to demyelination in MHV-infected mice by attracting macrophages into the CNS, studies were performed to further characterize the contributions of CCR5 to neuroinflammation and demyelination in MHV-infected mice. Analysis of CCR5 expression within the CNS of MHV-infected mice revealed that the majority of cells expressing this receptor were macrophage/microglia (24). MHV infection of $CCR5^{-/-}$ mice did not result in an increase in either morbidity or mortality as compared to infected $CCR5^{+/+}$ mice. In addition, clearance of virus from the CNS of infected $CCR5^{-/-}$ mice was not impaired and this correlated with equivalent levels of infiltrating T cells into the CNS when compared to MHV-infected $CCR5^{+/+}$ mice. These data indicate that the expression of this receptor does not contribute to host defense. However, demyelination was reduced in MHV-infected $CCR5^{-/-}$ mice and this correlated with reduced levels of infiltrating macrophages as compared to $CCR5^{+/+}$ mice. These data suggest that CCL5 signaling through CCR5 is an important mechanism whereby macrophages are able to enter the CNS and contribute to demyelination. Additional support for the importance of CCR5 signaling in leukocyte migration comes from recent studies from our laboratory examining the outcome of MHV infection of CCL3 knock-out mice. In addition to CCL5, CCL3 is able to bind and signal through CCR5 and trigger T cell and macrophage activation and trafficking. Intracranial infection of $CCL3^{-/-}$ mice resulted in diminished T cell and macrophage accumulation within the CNS that correlated with a significant reduction in demyelination as compared to MHV-infected wild-type mice (22). Therefore, these data demonstrate that CCR5 signaling by either CCL3 or CCL5 enhances both T cell and macrophage trafficking and accumulation within the CNS of MHV-infected mice and this correlates with the severity of myelin destruction.

Signaling through CCR5 appears to selectively regulate the trafficking of subsets of T cells into the CNS of MHV-infected mice. Adoptive transfer of

virus-specific $CD4^+$ T cells derived from MHV-immunized $CCR5^{+/+}$ mice and expanded to the immunodominant epitope present in the matrix protein spanning residues 133-147 into MHV-infected $RAG1^{-/-}$ mice resulted in T cell accumulation within the CNS and increased CCL5 expression that correlated with macrophage infiltration and demyelination (53). In contrast, adoptive transfer of virus-specific $CD4^+$ T cells obtained from immunized $CCR5^{-/-}$ mice resulted in only limited numbers of T cells present within the CNS and diminished CCL5 expression that correlated with a reduction in macrophage infiltration and demyelination. Examination of chemokine receptor expression on virus-specific $CD4^+$ T cells derived from $CCR5^{+/+}$ and $CCR5^{-/-}$ mice indicated a marked decrease in mRNA transcripts for several receptors. Notably, CXCR3, which is the signaling receptor for CXCL10, was significantly reduced. These data imply that CCR5 signaling may regulate expression of additional chemokine receptors which enhance T cell trafficking into target tissues. In contrast, CCR5 signaling is not required for trafficking of virus-specific $CD8^+$ T cells into the CNS (Glass and Lane, unpublished observations). However, CCR5 does appear to contribute to effector functions of $CD8^+$ T cells as $CD8^+$ T cells lacking CCR5 exhibit increased production of IFN-γ and increased cytolytic activity as compared to wildtype mice. These data highlight the importance of chemokines and chemokine receptors with regards to the trafficking and activation of specific subsets of T cells as it relates to host defense and disease progression in the MHV model system.

1.6 CXCL10 and Disease

As mentioned above, the pattern of chemokine expression as well as the appearance of the respective chemokine receptors on the surface of activated T cells suggested that these molecules may control the migration of lymphocytes following viral infection of the CNS. Although many chemokines are expressed at specific times during the course of MHV infection, one of the most prominent chemokines expressed is CXCL10 (51). Analysis of the functional contributions of CXCL10 during the acute stage of disease indicated a direct role in activated $CD4^+$ and $CD8^+$ T cell chemotaxis into the CNS. The correlation between T cell infiltration and demyelination following MHV infection as well as the appearance of CXCL10 during the chronic stage of MHV disease suggested that this chemokine may also contribute to T cell mediated myelin destruction. To address the functional contributions of CXCL10 to MHV induced demyelination, mice were treated with anti-CXCL10 neutralizing antibodies 12 days following i.c. infection. Strikingly, anti-CXCL10 treatment not only stopped further progression of myelin destruction, but decreased the severity

of clinical symptoms as compared to mice treated with control antibody (31). Histological analysis revealed that reduced clinical symptoms correlated with a dramatic reduction in the level of demyelination within anti-CXCL10-treated mice. Furthermore, this decrease in behavioral deficits correlated with the presence of increased levels of remyelination within the CNS as assessed by electron microscopy. Analysis of T cell infiltration following anti-CXCL10 treatment indicated a dramatic reduction in $CD4^+$ T cells while $CD8^+$ T cell levels remained similar to control. The preferential effect on $CD4^+$ T cells was in contrast to effects observed following anti-CXCL10 treatment during the acute stage of disease, where both $CD4^+$ and $CD8^+$ T cell migration was compromised (20). However, analysis of CXCR3 expression on infiltrating lymphocytes during both the acute and chronic stage of MHV infection indicated that while both $CD4^+$ and $CD8^+$ T cells express abundant CXCR3 expression during the acute disease, $CD4^+$ T cells preferentially express increased levels of the CXCL10 receptor during chronic disease, suggesting that receptor expression is responsible for selective $CD4^+$ T cell migration (31). Regardless, these results indicate that $CD4^+$ T cell infiltration can contribute not only to myelin destruction, but also inhibit remyelination following MHV infection. These results indicate that one mechanism by which CXCL10 can contribute to demyelination is by recruiting activated $CD4^+$ T cells into the CNS that can participate in disease pathogenesis.

1.7 Conclusion

MHV infection of the CNS provides a consistent, reliable model in which to study not only host response to viral infection but also to determine the contributions of chemokines to neuroinflammation and demyelination. Although the studies mentioned above indicate a complex web of chemokines and chemokine receptor expression, analysis of individual chemokines utilizing knockout mice and neutralizing antibodies has indicated specific and selective roles for these molecules within the CNS. As depicted in Figure 1, chemokines are expressed within the CNS throughout MHV infection, and have now been shown to participate in the recruitment and/or activation of cells based on their temporal expression. Indeed, early expression of CXCL10 contributes to the development of the innate response that can both control viral replication and further amplify chemokine production aiding in the establishment of the adaptive immune response (Trifilo and Lane, unpublished observations) (Figure 1, **1**). By day 7 p.i., robust expression of numerous CXC and CC chemokines (see Table I) are detected within the CNS. Highlighted is CXCL10 and CCL5 expression that are critical for the infiltration of T cells ($CD4^+$ and $CD8^+$) and activated

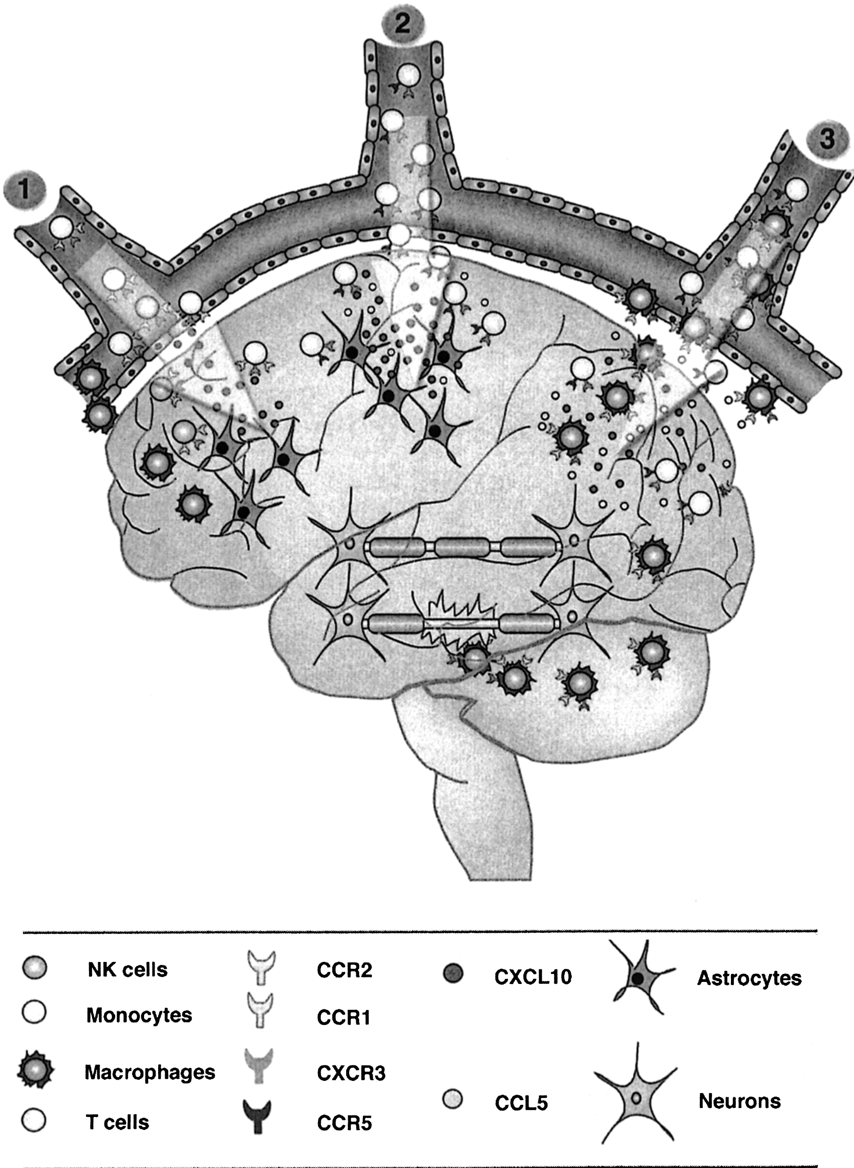

Figure C9-1. MHV infection of the CNS

macrophages (20,24) (Figure 1, **2**). T cell infiltration mediates clearance of replicating virus from the CNS by 12 days p.i. through the release of cytokines (ie. IFN-γ) and cell mediated cytolysis (CTL). Although

replicating virus can no longer be detected, viral protein and RNA persist after 12 days p.i., resulting in chronic expression of both CXCL10 and CCL5 (Figure 1, **3**). These chemokines induce the chronic recruitment of activated T cells and macrophages that subsequently participate in demyelination. This model reveals the protective and destructive properties chemokines posses based on both the level and time of expression.

Collectively, our data indicate that chemokines can play specific and selective roles in T lymphocyte and macrophage recruitment within the CNS (CXCL10 and CCL5) as well as contribute to the activation of virus-specific T cells (CCL3). More importantly, although numerous chemokines are detected within the CNS following MHV infection, it is clear that these molecules function in a nonredundant manner, thus meriting further studies on chemokines with regards to the role of these molecules in viral-induced CNS disease. Finally, the data clearly demonstrate that chemokines and their receptors may represent viable targets in modulating the severity of human nueroinflammatory diseases including MS.

Chapter C10

CORONAVIRUS RECEPTORS

Fumihiro Taguchi
National Institute of Neuroscience, NCNP, 4-1-1 Ogawahigashi, Kodaira, Tokyo 187-8502, Japan

Abstract: The major receptor for murine coronavirus, mouse hepatitis virus (MHV), is identified as a protein, cell-adhesion molecule 1 in the carcinoembryonic antigen family (CEACAM1), which is classified in the immunoglobulin superfamily. There are four CEACAM1 isoforms, with either four or two ectodomains, resulting from an alternative splicing mechanism. CEACAM1 is expressed on the epithelium and in endothelial cells of a variety of tissues and hemopoietic cells, and functions as a homophilic and heterophilic adhesion molecule. It is used as a receptor for some bacteria as well. The N terminal domain participates in mediating homophilic adhesion. This domain is also responsible for binding to the MHV spike (S) protein; the CC' face protruding in this domain interacts with an N terminal region of the S protein composed of 330 amino acids (called S1N330). The binding of CEACAM1 with MHV S protein induces S protein conformational changes and converts fusion-negative S protein to a fusion-positive form. The allelic forms of CEACAM1 found among mouse strains are thought to be an important determinant for mouse susceptibility to MHV.

Key words: CEACAM1, cell adhesion molecule, carcinoembryonic antigen, mouse hepatitis virus

1. INTRODUCTION

The Coronavirus family includes a number of different viruses that infect a variety of animal species, causing numerous diseases, mainly in organs of the enteric, respiratory and central nervous systems. They are

classified into three distinct groups in terms of serological cross-reactivity and sequence homology. Group 1 consists of porcine transmissible gastroenteritis virus, human coronavirus (HCoV) 229E, feline infectious peritonitis virus and so on. Group II includes mouse hepatitis virus (MHV), HCoV-OC43, bovine coronavirus and some others. Group III is comprised of avian coronaviruses; infectious bronchitis virus and turkey coronavirus. All of these viruses infect animals in a highly species-specific fashion, although some of them can experimentally infect animals different from their natural hosts. The receptor protein for group I viruses has been revealed to be an aminopeptidase N, while the receptor for MHV in group II is a protein classified in the immunoglobulin (Ig) superfamily. The receptors for other viruses in group II, as well as for viruses in group III, have not yet been identified. In this chapter, I describe the receptor for MHV as well as the interaction of MHV receptor and the virus spike (S) protein. The receptors of other coronaviruses can be found in a review article (1).

2. RECEPTORS FOR MHV

2.1 Discovery of MHV receptor proteins

MHV infects mice, but few other species. The major target organs are the liver, intestine and central nervous system. This host-species specificity or organ tropism of MHV has been thought to be determined mainly by the cellular receptor for MHV. A series of studies carried out by Kay Holmes and her colleagues, which began with analysis of differential susceptibility to MHV infection among mouse strains, has led to the finding of a major MHV receptor molecule. Boyle et al. found that the plasma membranes isolated from MHV-susceptible BALB/c mouse hepatocytes or enterocytes contained a 110 to 120-kDa protein that binds to MHV particles, but those derived from MHV-resistant SJL mice lacked such a protein (2). This finding suggested that the difference in MHV susceptibility among mouse strains is determined by this protein, presumably the MHV receptor. By using monoclonal antibody (MAb) CC-1 specific to 110-120 kDa protein from BALB/c, they purified a protein of ca. 110 kDa and determined the amino acid sequence in its N terminal region, from which the 110-kDa protein was postulated to be a glycoprotein classified in the carcinoembryonic antigen (CEA) family (3, 4). Finally, they isolated a gene encoding this protein, which was revealed to be cell adhesion molecule 1 in the CEA family of the Ig superfamily [formerly called biliary glycoprotein1 (Bgp1) and currently termed CEACAM1] (5). MHV non-permissive BHK cells transfected with this gene were converted to MHV-susceptible cells, indicating that this

molecule is the receptor for MHV. It was also found that MHV-resistant SJL mice express a homologous protein (6, 7).

Two other species of glycoprotein, Bgp2 (8) and pregnancy-specific glycoprotein (9), both of which belong to CEA family members, were thereafter found to serve as the MHV receptor in mouse species. However, none of these are as highly efficient as CEACAM1 in terms of receptor functionality or receptor utility by MHV strains. Human CEA glycoprotein works as an MHV receptor as well (10).

2.2. Structure and functional regions of major MHV receptor proteins

CEACAM1 is a member of the Ig superfamily and its prototypical 120-kDa glycoprotein consists of four ectodomains (in the order of N, A1, B and A2 from the N terminus), a transmembrane region (TM) and a cytoplasmic tail (Cy) (Fig. 1, 11). The N domain is similar to an Ig-variable domain, and the three other domains resemble a C2 Ig-constant domain. Four different isoforms of CEACAM1 are known to exist, and have been produced by alternative splicing (Fig. 1). Two of the isoforms have 4 ectodomains and the other two have 2 domains, consisting of an N terminal and A2 domains, one of which has either a short or long Cy. The two-domain protein is 48 to 58 kDa in size. CEACAM1 has two allelic forms, CEACAM1^a and CEACAM1^b (Fig. 1). The former is expressed in most laboratory mouse strains, while the latter, insofar as is currently known, is expressed only in MHV-resistant SJL mice (12). In wild mice, however, both of those forms are widely distributed (13). The major structural differences between CEACAM1^a and CEACAM1^b lie in the N domain, which differs in 29 of its 108 amino acids (6, 7). CEACAM1^a is 10- to 100-fold higher than CEACAM1^b in terms of receptor function (14, 15). There is no apparent difference in virus-binding activity as examined by a neutralization test between the 4-ectodomain isoform and the 2-domain CEACAM1^a (16). However, mice deleting the 4-domain CEACAM1^a and expressing the 2-domain isoform alone are more resistant to MHV than those expressing both of the 4- and 2-domain isoforms (17). Thus, there could be a difference between them in terms of MHV receptor function in mice. On the contrary, CEACAM1^b isoform containing 4 domains neutralizes MHV-A59 strain more efficiently than does the isoform containing 2 domains (N and A2 domains), while both of these isoforms showed similar neutralization activity to MHV-JHM strain (16), suggesting a virus-strain specificity in the interaction with CEACAM1.

The N domain is responsible for receptor function (18). Since the CEACAM1 splice variant deleting the A1 and B domains is functional, then it is evident that these domains are not necessary for receptor function. The CEACAM1 isoform containing the N and second A1 domains is also

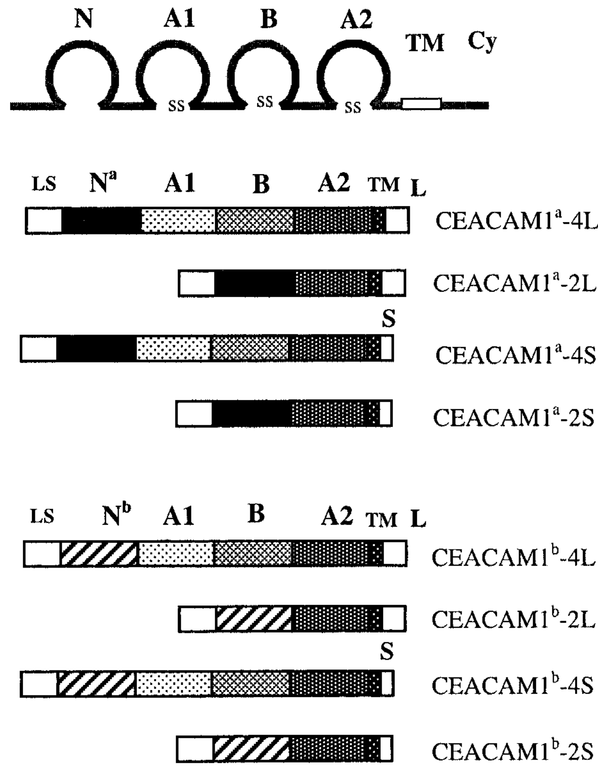

Fig. 1. Schematic structure of a major MHV receptor CECACM1: Four distinct isoforms of CECAM1exist in each CEACAM1[a] and CECAM1[b] allelic forms. There are four or two ectodomains resembling Ig-V or -C domain. Also, long (L) or short (S) cytoplasmic tail (Cy) is known. LS; leader sequence, TM; transmembrane domain.

functional, indicating that the fourth A2 domain is not absolutely critical. Although CEACAM1 consisting of N domain alone bound MHV, it did not work as a functional receptor when expressed on CEACAM1-negative cells (18). However, the chimeric CEACAM1 having the N domain linked to the mouse poliovirus receptor homolog deleting N domain that has a binding specificity to poliovirus served as a functional receptor for MHV (19). As a result of these reports, it is believed that the N domain alone is sufficient for receptor function; however, when expressed on the cell surface, CEACAM1 containing the N domain alone was buried among the various molecules expressed on the cell surface because of its shortness and hence it failed to bind to viruses (19). By using a soluble form of

CEACAM1, we have recently found that CEACAM1 with N domain alone converted MHV S protein from a fusion-negative to fusion-positive form (20). Collectively, the N domain is sufficient for the MHV receptor function. Detailed analysis using N domain deletion mutants of CEACAM1 showed that a stretch composed of 19 amino acids (aa34 to 52) in the N domain is particularly important for receptor function (21). The stretch is located in the CC' loop in the N domain composed by β-strands and is supposed to protrude from the N domain (22, 23). The difference in receptor function observed between $CEACAM1^a$ and $CEACAM1^b$ results from a 6-amino-acid difference in the above-described 19 amino acids in the N domain (14).

2.3. Distribution and biological function of CEACAM1

CEACAM1 is reported to be distributed in various cells in different organs, not only in the target organs of MHV, but also in those in which MHV infection has not been detected. A high level of CEACAM1 expression is reported on epithelium and endothelial cells of a variety of tissues, and in hemopoietic cells, such as monocytes, macrophages, granulocytes and their precursors, the B cells, activated T cells and thymic stromal cells (11, 24). It is also demonstrated on both apical membranes of epithelial cells as well as on sites of cell-cell contact (e.g., between hepatocytes, stratified epithelia, junctional epithelium that forms a transition zone between gingival epithelium and teeth, and between pericytes and endothelial cells of blood vessel walls). Furthermore, during early mouse embryonic development, CEACAM1 is abundantly expressed in endodermal and mesenchymal derivatives (25), but is not detected by immune histochemistry in any type of cells in the brain (26). However, MHV infection in the brain was blocked by anti-CEACAM1 MAb CC-1 (27). Also, a CEACAM1 isoform with 2 domains was detected by RT-PCR in the brain (28). These findings suggest that the CEACAM1 molecule is expressed, albeit in very small amounts, in some cell populations of the brain.

The major biological function of CEACAM1 is cell adhesion. It serves as both a homophilic and heterophilic adhesion molecule (11). Homophilic adhesion, confirmed by in vitro studies of rodent and human CEACAM1, is thought to be important in the embryonic organization of the intestinal epithelium and liver hepatocytes , in placental trophoblasts, during muscle and tooth development and vascularization of the central nervous system (24). CEACAM1 also plays an important role in neutrophil activation and adhesion during inflammatory responses (29), lymphoregulation and immunosurveillance (30), angiogenesis (31), and the negative regulation of cell proliferation (11, 24). Heterophilic adhesion of CEACAM1 to other

CEACAM family members has been shown (32). Also, heterophilic adhesion to *Opa* proteins of *Neisseria gonorrhoeae*, *Neisseria meningitis* and *Haemophilus influenzae* mediates their infections (33, 34), indicating that CEACAM1 is a receptor for those bacteria. This also facilitates bacterial colonization of the gut and bacterial phagocytosis by neutrophils and is involved in the initial tethering of granulocytes to E-selectin on the endothelium prior to their transendothelial migration during inflammatory responses. It was recently shown that homophilic adhesion of CEACAM1 involves N-terminal domain interactions. The GFCC'C" face of the N domain, which includes the MHV binding site CC' region, is responsible for homophilic interaction (22).

3. INTERACTION OF CEACAM1 AND MHV S PROTEIN

The MHV S protein comprising a petal-like projection on virion surface is the ligand for the CEACAM1 molecule. The projection is composed of two or three molecules of the S1-S2 heterodimer derived from S protein. S protein is a type I glycoprotein. It is synthesized and co-translationally glycosylated as a 150-kDa, protein, becomes as 180-200 kDa protein after modification of glycans and cleaved by a host-derived proteinase into two subunits, N terminal S1 and C terminal S2 (35). S1 comprises an outer knob-like structure of the spike, and S2 consists of the stem-like part beneath the knob (36). S1 and S2 units are associated by non-covalent linkage, and they can be easily dissociated from each other by denaturing reagents or even during a purification process. Alpha-helices constructed by the heptad repeats in the S2 play an important role for oligomerization of S1-S2 heterodimers, though there is another determinant in the S1 for oligomerization (37). Following its synthesis, the S protein is incorporated into the envelope of viral particles after interaction with viral integral membrane protein in the internal compartments from endoplasmic reticulum to the Golgi apparatus. The S protein is also transported to the plasma membrane.

The N terminal region in the S1 composed of 330 amino acids (S1N330) is responsible for binding to CEACAM1 (38). Among S proteins of a variety of MHV strains, there are three conserved regions in S1N330 (S1N330-1, -II and -III) composed of 10 or more identical amino-acid stretches (39). Site-directed mutagenesis analysis suggested that two of these regions, S1N330-1 and –II, located far from one another, are involved in receptor binding (39). Studies using MHV variants containing mutations in S1N330-I confirmed the significance of this region in receptor binding (40). S1N330-III was recently suggested to be responsible for

virus entry into the cell in combination with a region in the S2 (41). Denaturing of S1N330 abolished the receptor-binding activity, indicating that the tertiary structure composed of different regions in the S1N330 or/and the dimerization of S1 which takes place within S1N330 (37) is important.

The interaction of MHV S protein and CEACAM1 leads to the S protein functional conversion from a fusion-negative to a fusion-positive form (42). Recently, it was also shown that this functional activation is accompanied with conformational changes in the S protein; receptor-bound S protein has a fraction resistant to proteinase digestion, while receptor-unbound S protein is susceptible (43). These functional and structural changes of the S protein greatly resemble those of the envelope protein of retroviruses that take place after they bind to their receptors (44, 45), suggesting that MHV enters cells in a fashion similar to that of retroviruses.

4. MHV RECEPTOR AND ITS IMPLICATIONS FOR MOUSE SUSCEPTIBILITY TO MHV

A number of investigators have reported that BALB/c, C57BL and most other mouse strains, later revealed to have a *Ceacam1*^{a} *(1*^{a}*)* gene, are susceptible, while SJL mice with a *Ceacam1*^{b} *(1*^{b}*)* gene are resistant (46, 47). Genetic analyses indicated that a single dominant gene located on chromosome 7 is responsible for susceptibility to MHV (47). The *Ceacam1* could be a gene determining susceptibility, since 1) the 1^{a} makes mice susceptible and 2) *Ceacam1* is also mapped on chromosome 7 (48). The expression of either 1^{a} or 1^{b} in CEACAM1-negative cells converted them to MHV susceptible, suggesting that allelic differences in receptor proteins were not sufficient to explain the differences in mouse susceptibility to MHV (6, 7). In detailed studies, however, cells transiently expressing 1^{a} were 10 to 100 times more sensitive to MHV than were cells expressing 1^{b} (14, 15), indicating a small, but significant difference between 1^{a} and 1^{b}. This also suggested that the MHV receptor expressed in SJL is still functional. If the receptor allele controls MHV susceptibility, then SJL should be relatively, but not completely, resistant to MHV. SJL mice are, in fact, resistant to MHV when challenged with a low dose of virus, but susceptible when inoculated with a high dose of virus (49, 50). These observations suggest that *Ceacam1* is a gene controlling MHV susceptibility. Of 120 mice of (BALB/c x SJL) F2 and backcrossed mice to SJL, all mice with *1*^{a}*/1*^{a} and *1*^{a}*/1*^{b} genotypes were susceptible, while all mice with *1*^{b}*/1*^{b} genotype were resistant after infection with a low dose of virus (12). This implies the MHV receptor gene and MHV-susceptibility

gene are identical, and if not, they are located within 0.86 cM on chromosome 7. To finally examine whether the receptor gene is identical to the gene that controls MHV susceptibility, gene replacement is a useful strategy. The MHV susceptibility of BALB/c mice in which $1^a/1^a$ is replaced by $1^b/1^b$ and SJL mice in which $1^b/1^b$ is replaced with $1^a/1^a$ will conclusively establish whether the MHV receptor gene is the gene which controls the MHV susceptibility of mice.

Chapter C11

APOPTOSIS IN MHV-INDUCED DEMYELINATION

Talya Schwartz[§] and Ehud Lavi*

*Department of Pathology and Laboratory Medicine, University of Pennsylvania, School of Medicine, Philadelphia, PA.. Present address: [§]National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda MD 20892, *Department of Pathology and Laboratory Medicine, Weill Medical College of Cornell University, New York, NY 10021*

Abstract: Mouse hepatitis virus (MHV) induced encephalitis, hepatitis and chronic demyelinating disease involves inflammatory and parenchymal cell death. TUNEL assays and electron microscopy reveal that brain parenchymal cells such as neurons, astrocytes, microglia/macrophages and oligodendrocytes are undergoing apoptosis during acute and chronic infection with a neurotropic strain MHV-A59. Although apoptosis is a normal phenomenon in helping the turnover of inflammatory cells, apoptosis of brain parenchymal cells may have significant implications for the pathogenesis of viral-induced demyelination.

Key words: apoptosis, astrocytes, microglia, macrophages, coronavirus, demyelination

INTRODUCTION

Coronavirus mouse hepatitis virus (MHV) strain A59 causes severe acute hepatitis, focal meningoencephalitis, and chronic demyelinating disease. It serves as an experimental model for multiple sclerosis (MS). A closely related strain (MHV-2) causes acute hepatitis and meningitis without encephalitis or demyelination. The pathogenesis of MHV-induced demyelination in mice is not completely understood and a potential mechanism of apoptosis was suggested. Previous studies showed apoptotic T cells, astrocytes, and oligodendrocytes in demyelinating areas following infection with JHM, another neurotropic-demyelinating strain of MHV (Barac-Latas *et al* 1997).

However, the distribution of demyelination has been suggested to correlate better with macrophage infiltration than with the apoptotic cells (Wu and Perlman 1999). In the chronic demyelinating disease induced by Theiler's virus, apoptotic astrocytes were found in demyelinating lesions (Palma *et al* 1999). In experimental allergic encephalitis (EAE), the disease was much milder in mice lacking Fas-Fas ligand molecules, suggesting that apoptosis plays a role in the disease (Waldner *et al* 1997).

APOPTOSIS IN MHV-INDUCED DISEASE

To study apoptosis in MHV-A59 disease we used the experimental model system of MHV-A59 and MHV-2 infection in 4-week-old male C57BL/6 and B6MRL-Fas-lpr (lpr) mice (Schwartz, Fu et al. 2001; Schwartz, Fu et al. 2002). Mice were injected intracerebrally (I.C.) with $2.5x10^3$, 25 and 5 PFU of MHV-A59, 25 and 5 PFU of MHV-2. B6MRL-Fas-lpr mice were injected I.C. with 25 and 5 PFU of MHV-A59. Mock-infected mice were injected I.C. with L2 cell lysate. Mice were sacrificed on days 1,3,5,7,9,11,and 30 (2-3 mice per time point per virus, during the acute stage and 52 mice on day 30). Brain, spinal cord and liver were removed and placed in 10% normal buffered formalin and embedded in paraffin. Five µm thick sections were stained with LFB and H&E. Detection of in situ DNA fragmentation was done with fluorescein *in situ* cell death detection kit (Boehringer Mannheim, Indianapolis, Indiana) as specified by the manufacturer. Double labeling for TUNEL with viral antigen, and TUNEL with specific markers for astrocytes, oligodendrocytes, and macrophages was performed by immunohistochemistry. The analysis was performed by the avidin-biotin-phosphatase based technique (Biomeda, Foster City, CA) using fast-red or vector blue (Vector laboratories, Burlingame, CA) as a staining substrate and a 1:200 dilution of rabbit anti-MHV-A59 polyclonal antibody, 1:100 dilution of monoclonal glial fibrillary acidic protein (Lee *et al.* 1984), 1:500 carbonic anhydrase II (Cammer *et al* 1985) or 1:50 rat anti mouse F4/80 antigen (Serotec Inc., Raleigh, NC), respectively.

TUNEL staining was detected in the brains and livers of mice infected with MHV-A59 and MHV-2. Extensive liver apoptosis was observed in both MHV-2 and MHV-A59 infections. Co-localization of A59 viral antigen and TUNEL staining was detected in hepatocytes. Apoptosis was found in the brain parenchyma of MHV-A59 infected mice and meningial apoptosis was found in both infections. The kinetics, intensity and pattern of apoptosis correlated with the inflammatory events. Mock-infected mice

were apoptosis-negative in all tissues. No apoptosis was identified in the spinal cord during the acute stage.

TUNEL staining was observed exclusively in the spinal cords with demyelinating lesions of 15 mice infected with MHV-A59. No apoptosis was detected in the spinal cords of 3 MHV-A59 infected mice without demyelination, 28 MHV-2 infected mice and 10 control mice. TUNEL staining was negative in the brains and the livers of all infected mice.

To assess the role of the apoptotic cascade in the demyelination process, lpr mice were infected with MHV-A59 virus. Two of 5 mice in both groups developed demyelination, however the extent of demyelination in the spinal cord was significantly less in the lpr mice compared to wt mice (10% and 34% demyelinating quadrants respectively).

Recently mice were infected with MHV-A59 and simultaneously implanted with subcutaneous ALZET osmotic pumps that were filled with a pan-caspase inhibitor Z-Val-Ala-D1-Asp-fluromethylketone (Z-VAD-fmk). This treatment has been previously shown to be effective in the treatment of apoptosis in EAE and also reduce the amount of demyelination. The treatment was given continuously at a dose of 1 mg per day, at a delivery rate of 1microliter per hour, for 30 days, beginning 1 day prior to the infection with the virus. While encephalitis was not different between the treated and untreated mice, demyelination was significantly reduced in the treated mice. In 4 mice receiving A59 and anti-pan-caspase treatment demyelination was found in only 3/76 spinal cord quadrants (3.94%), whereas 6 untreated A59-infected mice in the same experiment had 18/120 demyelinating quadrants of spinal cord (15%), and mice receiving only treatment without infection had no demyelination. Although these studies are preliminary due to small number of animals, they may support an important role for apoptosis in autoimmune demyelination as in EAE and Theiler's virus induced demyelination.

Double labeling for TUNEL-positive nuclei and specific markers for astrocytes, oligodendrocytes and macrophages was observed. Quantification studies demonstrated 3-5% oligodendrocytes, 1-2% astrocytes and 70% macrophages, double stained.

DISCUSSION

Apoptosis was observed in mice following infection with MHV-A59 and MHV-2. The kinetics, intensity and pattern of the apoptotic staining correlated well with the distribution of inflammation. However, apoptosis was found in both inflammatory cells (macrophages and possibly lymphocytes), and parenchymal cells such as hepatocytes, oligodendrocytes,

neurons and astrocytes. The involvement of parenchymal cells in CNS apoptosis and the location and temporal relationship between apoptosis and pathology (either encephalitis or demyelination), may indicate that apoptosis is indeed a significant factor in the pathogenesis of the disease and not a merely epiphenomenon. This conclusion is also supported by the reduced demyelination in animals lacking the Fas-lpr pro-apoptotic molecule and mice receiving prolonged pan-caspase inhibitor treatment. Since these treatments affect both inflammatory cells and parenchymal cells the result may be the balance between two opposing trends. A recent report documented the ability of oligodendeocytes to undergo apoptosis in culture upon infection with MHV-A59 (Liu, Cai et al. 2003). This in vitro model greatly supports the hypothesis that death of oligodendrocytes and demyelination due to MHV are caused at least in part by apoptosis. A previous study did not find any difference in the extent of demyelination between wt and lpr mice 13 days following JHM infection (Parra *et al* 2000). However, the different results may be due to the differences in strains of the virus or time points examined.

In conclusion, apoptosis may play an important role in both acute and chronic MHV disease. The relationship between apoptosis, inflammation and tissue damage is yet to be defined, but can possibly be defined through further dissection of the apoptotic cascade.

Chapter C12

THE ROLE OF METALLOPROTEINASES IN CORONA VIRUS INFECTION

Norman W. Marten and Jiehao Zhou
Keck School of Medicine, University of Southern California, Los Angeles, CA 90033

Abstract: Infection with neurotropic strains of mouse hepatitis virus (MHV) results in rapid leukocyte infiltration into the central nervous system (CNS). The inflammatory response controls virus replication but fails to mediate sterile clearance. The persistence of viral RNA and inflammatory cells within the CNS is associated with the development of ongoing demyelination. Matrix metalloproteinases (MMPs) are a family of proteases involved in degradation of the extracellular matrix (ECM). During inflammatory responses MMPs are thought to play a significant role in breaking down the basement membrane surrounding blood vessels as well as parenchymal ECM thereby facilitating leukocyte infiltration. MMPs have also been associated with activation of chemokines and perhaps more significantly the degradation of myelin proteins and generation of autoantigens. Recent examination of MMP expression during MHV infection suggests that MMP-3, -9 and -12 are involved in the inflammatory response. The proinflammatory effects of these MMPs are likely tempered by induction of tissue inhibiter of metalloproteinase-1 expression.

Key words: Central nervous system (CNS), demyelination, matrix metalloproteinase (MMP), mouse hepatitis virus, tissue inhibiter of matrix metalloproteinase (TIMP).

INTRODUCTION

Mouse hepatitis virus (MHV) can cause respiratory, enteric, hepatic or neurologic infections depending on the viral strain, age of the host and route of infection (33). MHV infection of the central nervous system (CNS) as a model of demyelinating disease has been studied extensively using strains

derived from either the neurotropic JHM strain (MHV-JHM; MHV-4 serotype) or the MHV-A59 strain, which is both hepatotropic and neurotropic (33,43). As described by others, and ourselves acute MHV infection of the CNS induces a potent inflammatory response involving neutrophils, macrophages, NK, B and T cells (33,43,52). In order to reach the site of infection, however, these cells must overcome physical barriers represented by the blood brain barrier as well as the dense extracellular matrix (ECM) of the CNS parenchyma. The ability of leukocytes to extravasate from blood vessels and cross the parenchymal tissues is presumably dependent on the activity of extracellular proteases. One family of proteases, which are often associated with inflammatory responses are the matrix metalloproteinases (MMPs). The descriptions of MMP regulation and function during normal physiological as well as pathological conditions have been described in numerous publications (32,23,41), thus only a brief summary is provided herein.

BACKGROUND

MMPs comprise a large group of endoproteinases that, in conjunction with other proteases, mediate degradation during remodeling of the extracellular matrix (ECM). Twenty four different MMPs have been identified and classified as collagenases, gelatinases, stromelysins, matrilysin and membrane type MMPs (MT-MMPs) based on their substrate specificities and protein domain structures (24,34). These proteases are produced by a wide range of cell types, including endothelial, inflammatory and stromal cells (18,23,32). Regulation of MMP activity has been classically defined as occurring at three distinct levels. Primary regulation of MMP activity occurs at the transcriptional level (5,12,22,30,40). MMP gene expression can be induced by a wide range of signals including acute phase cytokines such as IL-1α and -β, IL-6 and TNF-α, and chemokines such as MCP-1, MIP1β, and RANTES (6,12,22). A second level of regulation for MMP activity is post-translational, as MMPs require proteolytic cleavage of their proenzyme form to become activated (4,34). Following translation, most proMMPs are released into the extracellular space. By contrast, a subgroup of membrane associated MMPs, the MT-MMPs, may play a role in the processing of secreted proMMPs to their active form (20). The final level of control for MMP activity resides in their regulation by a small group of specific inhibitors, the tissue inhibitors of metalloproteinases (TIMPs) (7). TIMPs function primarily as specific inhibiters, binding to MMPs in a 1:1 stoicheometry. Interestingly, there is

evidence that TIMPs may also act as chaperone proteins during the processing of MMPs from proenzyme to active form, suggesting that they can promote as well as inhibit MMP enzymatic activity, at least for MMP-2 (42,44).

MMPs and their inhibitors are involved in remodeling of the ECM during normal physiological conditions. However they have also been associated with diverse pathological processes from rheumatoid arthritis to tumor invasion and metastasis (16,25). A number of MMPs and TIMPs have also been associated with the CNS inflammatory/demyelinating disease multiple sclerosis (MS) in humans (2,32) as well as its rodent model experimental autoimmune encephalitis (EAE) (10,38). In the case of MS, these include MMP-1, -2, -3 -7 and -9 and TIMP-1 (2,11,32). These MMPs and TIMPs have been detected by immunohistochemistry in both inflammatory infiltrates and activated glia within acute MS lesions as well as perivascular infiltrates. Following EAE induction in mice, MMP-3, -9, -12 and -14 as well as TIMP-1 gene expression were induced within the CNS (38). MMP-1 and -10 were also induced although to a lesser degree than the aforementioned genes (38). The induction of MMP-7 mRNA expression was not detected but the presence of MMP-7 protein has also been reported during EAE in rats (10). The consistent association of MMP and TIMP expression with inflammatory demyelinating disease suggests that MMPs play either a direct or indirect role in promoting CNS pathology (2,27,32). However, as discussed below, identifying specific MMPs and their exact role in promoting inflammatory/demyelinating has proven to be difficult.

MMP AND TIMP EXPRESSION DURING CORONAVIRUS INFECTION

In vitro infection of human astrocytic and microglial cell lines with human coronavirus induced up-regulation of MMP-2 and -9 protein suggesting that virus infection can up-regulate MMP expression within the CNS (15). The mechanism by which MMPs were up-regulated by infection where not known, however, virus infection of the glial cell lines induced expression of IL-6, TNF-α and MCP-1, which are all inducers of MMP expression (15). Transfer of non-infectious supernatants from infected cultures to uninfected cells was sufficient to induce expression of MMP-2 and -9. MMP expression, including MMP-2 and -9, is also elevated in naïve transgenic mice, which express IL-6 and TNF-α within the CNS (38). These observations suggest that viral infections induce expression of chemokines/cytokines, which in turn induce MMP expression in neighboring cells (15,38).

Recent examination of MMP gene expression within the brains of mice infected with lethal and attenuated MHV-JHM variants showed that MMP-3 and -12 mRNA were rapidly up regulated during acute infections (51, 53). By contrast, infection did not alter transcription of the genes encoding MMP-2, -9, -11 or -14, which were constitutively expressed in the CNS of naïve BALB/c mice (51). These data are summarized in Table 1. Kinetic analysis of MMP expression indicated that MMP-3 and MMP-12 expression peaked by 6 days post infection (p.i.) in accord with viral load, however, expression was significantly higher in lethally infected mice (51,52). Comparisons of MMP/TIMP expression in infected irradiated and control mice revealed relatively little loss in MMP or TIMP expression in immunosuppressed mice (51). These results indicated that CNS resident cells were responsible for the majority of MMP-3, and -12 gene expression detected within the brain and that this gene induction was relatively independent of the presence of inflammatory cell infiltration. Expression of MMPs constitutively expressed in naïve mice (MMP-2, -9, -11, -14) were unaffected by immunosuppression.

Table 1: MMP and TIMP expression within the CNS during MHV infection[a].

Virus induced expression	Constituative expression	Not Detected
MMP-3	MMP-2	MMP-1
MMP-9[b]	MMP-11	MMP-7
MMP-12	MMP-14	
TIMP-1	TIMP-2	
	TIMP-3	

[a] RNA was prepared from brains of MHV-JHM infected mice. Relative gene expression was determined by RNase protection assay.
[b] Analysis of MMP-9 expression by RNase protection assay did not reveal an increase in MMP-9 expression in RNA prepared from total brain. However, analysis of MMP expression from $CD45^{hi}$ inflammatory cells isolated from the CNS indicated that MMP-9 expression was increased during MHV infection.

Four TIMPs have been characterized and all are capable of inhibiting a range of MMPs (7,23). Basal expression of TIMP-1 is low but readily induced in response to a multitude of inflammatory signals (5,7). By comparison, TIMP-2, -3 and -4 are expressed constitutively and alterations in their expression are less frequently associated with inflammatory responses (26,31,38). Examination of naïve and MHV-JHM infected brains revealed that TIMP-2 and -3 were unaffected by the infection (51) (Table 1). By contrast, MHV infection induced rapid expression of TIMP-1 (51) (Table 1). TIMP-1 expression peaked by 6 p.i. in conjunction with MMP-3 and -12 expression (51,52). TIMP-1 expression was higher in lethally infected mice compared to sublethally infected mice suggesting that expression is dependent on viral load and/or virulence. TIMP-1 expression has been reported to be associated with both tissue resident cells as well as most

inflammatory cells (7). Expression levels of TIMP-1 were higher in irradiated, immuncompromised mice compared to control animals, indicating that most TIMP-1 is produced by CNS resident cells (51).

Analysis of whole brain samples for MMP RNA and protein failed to detect induction of MMP-9 expression during MHV infection (51), which was in sharp contrast to its prominence in MS. However, subsequent analysis of individual cell populations sorted from infected brains indicated that MMP-9 gene expression is up regulated several fold among infiltrating inflammatory cells (Zhou, unpublished data) (Table 1). Similarly, a strong induction in TIMP-1 expression within the inflammatory cell populations (Zhou, unpublished data) suggests that T cells are, at least in part, a source of both MMP-9 and TIMP-1 as both of these genes are co-expressed by T cells (35). Furthermore, analysis of cell extracts prepared from infiltrating cells revealed that MHV infection also induced a sharp rise in the level of intracellular MMP-9 protein (51, 53). The increase in intracellular MMP-9 protein was attributed to the presence of polymorphonuclear cell infiltrates in response to infection (51, 53). Neutrophil synthesis of MMP-9 differs from other cell types in two key ways. First, in contrast to mononuclear cells, which release MMP-9 directly into the extracellular space, neutrophils store MMP-9 proenzyme in granules for release during degranulation (35), therefore permitting neutrophils to rapidly release large quantities of MMP-9 in the absence of *de novo* synthesis. Second, expression of MMP-9 in neutrophils is not linked to co-expression of TIMP-1 as is the case for T cells (35). Thus, MMP-9 from neutrophils is regulated at the level of degranulation as opposed to gene transcription and co-expression of TIMPs. These data suggest MMP-9 is likely released from both mononuclear and polymorphonuclear infiltrates during JHMV infection. Thus, with the exception that MMP-7 was not detected during MHV infection (51), the overall expression patterns for both MMPs (-3, -9 and -12) and TIMP-1 during MHV infection, EAE and MS are extremely similar.

ROLE OF MMPS IN DEMYELINATION

Linkage between MMP/TIMP expression during demyelinating disease has been well chronicled (32,38,51). By contrast, determining a definitive role for MMPs during demyelinating disease has proven to be far more elusive. During inflammatory processes within the CNS, MMPs most likely play two key roles: 1) Breaking down the basal lamina surrounding the blood brain barrier, thereby allowing inflammatory cells to enter the CNS (35) ; and 2) breaking down connective tissues linking tightly packed CNS resident cells, thereby allowing inflammatory cells to migrate along chemokine gradients towards the sites of infection/injury (18,50). Other key

mechanisms in the genesis of inflammatory demyelination have been associated with MMPs. These include activation of cytokines and chemokines, such as the conversion of TNF-α from pro to active form (8) and increasing the potency of the chemokine IL-8 (48). Furthermore, activated MMP-3 can convert pro-MMP-9 into it active form (13). Thus MMP-3 produced by CNS resident cells may be involved in activating pro-MMP-9 synthesized by inflammatory cells. Activation of these proinflammatory proteins by MMPs increases the potential for immune mediated damage to the CNS.

A number of MMPs including -3, -9, and -12, which are common to many demyelinating diseases, are capable of breaking down proteins of the myelin sheath (8,9,39). The consequences of this are two fold. First, induction of an inflammatory response to a foreign antigen within the CNS may non-specifically initiate destruction of the myelin sheath through the release of MMPs. Second, generation of potential autoreactive self-antigens by MMP mediated breakdown of myelin proteins may initiate specific responses against oligodendroglia resulting in additional demyelination (36,39).

Of the MMPs associated with MHV infection of the CNS, MMP-9 and its specific inhibitor, TIMP-1, are of particular interest for several reasons. MMP-9 and TIMP-1 are produced by both activated inflammatory as well as CNS resident cells (19,35,47). MMP-9 is specific for type IV collagens, which make up the basement membrane surrounding the blood brain barrier (49). This suggests that MMP-9 contributes to the ability of activated inflammatory cells to cross this barrier. Support for the role of MMP-9 in T cell trafficking comes from MS patients undergoing IFN-β treatment, one of the few therapeutics shown to have a positive effect. Although no single conclusive mechanism for the anti-inflammatory activity of IFN-β has been demonstrated, MMP-9 gene expression is down regulated by IFN-β (30,45,46). Conversely, TIMP-1, which inhibits MMP-9, is up regulated by IFN-β (37). This suggests that one of the mechanisms by which IFN-β works is through inhibition of MMP-9 mediated inflammatory cell trafficking. These data are supported by treatment of EAE mice with MMP inhibitors, which have generally prevented disease induction or reduced clinical symptoms when treatment was initiated after active disease was apparent (17,21,28).

CONCLUSIONS

MMP and TIMP expression are closely associated with the human demyelinating disease MS as well as experimental animal models of

demyelinating disease. MMP expression within the CNS is most likely up regulated by the presence of inflammatory cytokines. However, as stated previously, confirmation of a specific role for MMPs in the inflammatory process is lacking. The use of knockout mice to determine the role of specific MMPs in inflammatory responses have generated mixed results, particularly in regard to blood brain barrier breakdown and inflammatory cell infiltration across endothelial cell barriers (1,3,14,29). This may in part be explained by the large number of MMPs with overlapping specificities as well as the presence of other proteases. Thus, although MMP expression is clearly associated with inflammatory responses during demyelinating disease, the role of individual MMPs as active participants or simply as markers remains to be determined.

Chapter C13

MOLECULAR DETERMINANTS OF CORONAVIRUS MHV- INDUCED DEMYELINATION

Li Fu and Ehud Lavi*
*Division of Neuropathology, Department of Pathology & Laboratory Medicine, University of Pennsylvania school of medicine. Philadelphia, PA 19104-6100. *Present address: Department of Pathology and Laboratory Medicine, Weill Medical College of Cornell University, New York, NY 10021*

Abstract: Mouse hepatitis virus (MHV) is a member of the coronavirus family of the *nidovirales* order. MHV is an enveloped virus with single-stranded, positive genomic RNA of about 31kb. Infection of susceptible strains of mice with the MHV-JHM and A59 strains results in acute encephalomyelitis and chronic demyelinating disease with features similar to the human demyelination disease multiple sclerosis (MS). Because the mechanism of demyelination in MS is not completely understood, various experimental models, including MHV infection in mice, have been used to study the pathogenesis of inflammatory autoimmune demyelination. The spike (S) glycoprotein of MHV has been implicated as the most critical genomic determinant of MHV pathogenesis and demyelination. However, other genes and proteins are likely to contribute to MHV pathogenesis as well.

Key words: Mouse hepatitis virus (MHV), Coronaviruses, Nidoviruses, Molecular determinants, Demyelination, Multiple Sclerosis (MS).

THE MHV GENOME

The MHV genome is approximately 31 kb of single-stranded RNA of positive polarity. The genomic organization consists of 7 functional genes, 5 of which encode structural proteins (Fig 1). Genes 2b, 3, 5b, 6 and 7 encode the structural proteins hemagglutinin-esterase (HE) in some strains of MHV, spike (S), membrane (M), envelope (E) and nucleocapsid (N) [1]. The remaining genes encode non-structural proteins. The nucleotide sequences have been determined for 3 strains of MHV: A59, JHM and MHV-2. The

structural protein genes are clustered at the 3′ of the genome, whereas the 5′ third of the genome consists of a single gene encoding a large polyprotein comprising of viral polymerase, proteases and associated nonstructural proteins. The nucleotide sequence at the 5′ end contains a 65 to 85 nucleotide-long leader RNA, followed by 200 to 500 non-translated nucleotides. The first 60% of the length of the genome, roughly 20 Kb from the 5′ end, consists of two overlapping open reading frames, ORF 1a and 1b, that encode the viral RNA- dependent RNA polymerase, proteases and helicase. At the overlapping region between ORF 1a and 1b there is a 7-nucleotide slippery sequence and a pseudoknot structure, essential for ribosomal frame shifting. Several of the non-structural proteins are not essential for viral replication *in vitro* but may play a role in viral pathogenesis. An important aspect of MHV biology is the high frequency of RNA-RNA recombination between different, but closely related MHVs, when mixed in the same culture. RNA recombination is likely an important mechanism of viral evolution and may contribute to viral pathogenesis.

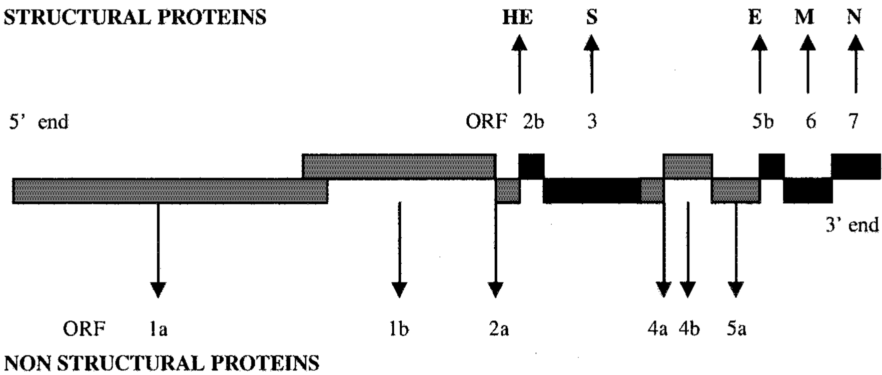

Figure 1 . Schematic diagram of the MHV genomic organization.

STRUCTURAL-FUNCTIONAL RELATIONSHIP OF MHV

The virions of MHV contain a nucleocapsid protein (N), which binds to the viral RNA to form a helically symmetric nucleocapsid. Surrounding the nucleocapsid is a membrane envelope, which contains 3 or 4 major glycoproteins: the spike (S), the membrane (M), the small envelope protein (E), and in some strains such as MHV-JHM, the hemagglutinin-esterase protein (HE) [1-4].

Upon infection of susceptible cells the MHV genomic RNA serves as a template for the negative strand RNA synthesis, which, in turn, is used for the synthesis of genomic and subgenomic mRNAs [2]. Each mRNA has a leader RNA of about 70 nucleotides at the 5' end [3]. The exchange of leader RNA is a common phenomenon during coronavirus replication and mRNA 1 can be synthesized during MHV infection with or without a 9-nucleotide sequence (UUUAUAAAC) located immediately downstream of the leader RNA of the 5' terminus of MHV [4]. Studies of naturally occurring and artificially constructed defective interfering (DI) RNAs have shown that both 5'- and 3'-terminal portions of the MHV genome are required for making the DIs functional [5, 6]. More specifically, the 5' cis-acting elements essential for MHV-JHM and A59 DI RNA replication have been mapped to 5' 474 nucleotides of which at least 446 nucleotides are required [6]. At the 3' end of the MHV genome 417 to 463 nucleotides is the minimal number of nucleotides required for replication [5]. Using interspecies-targeted RNA recombination, MHV-JHM gene 4 was genetically inactivated. Interestingly, the virus lacking gene 4 replicated in tissue culture cells with similar kinetics as the wild type virus. Thus ORF 4 is not essential for viral growth in tissue culture or in the CNS of the infected host [7]. Likewise, the deletion of the 2a/HE gene cluster did not affect viral growth in vitro; deletion of the 4/5a gene cluster merely decreased viral replication rate by 10 fold [8].

The function of the M protein has been recognized as the predominant constituent of virion architecture. However, the function of HE protein has yet to be established other than the hemagglutinating and acetyl-esterase activities [9]. The HE protein forms disulfide-linked homodimers and strains of viruses that express this protein show a second, shorter fringe of peplomers on their virions. The small envelope protein E, has been shown to be translated both in vivo and in vitro. The E and M proteins are both necessary and sufficient for the formation and extracellular release of particles appearing structurally identical to MHV virions, thus suggesting that the E and M proteins are important for virion assembly [10, 11].

The N protein of MHV is a 50-60 kDa phosphoproteins with overall high basic amino acid content and 3 structural domains [12]. The functions of the N protein involve interactions between N and viral RNAs [13, 14]. The internal gene I, a large open reading frame embedded entirely within the 5' half of N gene, has been proved not essential for the replication of MHV either in tissue culture or in its natural host [15]. The middle domain of N is responsible for RNA binding. N binds certain regions of coronavirus RNA more efficiently than nonviral RNA and the binding specificity for encapsidation and packaging in the context of virus-infected cells may be

influenced by interactions with the membrane protein (M) or possibly other viral proteins [16].

THE SPIKE GLYCOPROTEIN (S)

Forming the spikes on the virion surface, the spike protein (S) of coronavirus MHV has a variety of important biological activities. The S protein is a transmembrane glycoprotein of about 180 kDa with 4139 nucleotides in length, encoding two posttranslational subunits: S1, predicted to form the globular head, and S2, predicted to form the stalk of the glycoprotein. The MHV S protein plays a critical role in viral pathogenesis, including functions in both viral entry and spread within the host [17, 18]. The S1 portion may independently bind to cellular receptors and the S2 portion is responsible for fusion of viral and cellular membranes [19]. The S protein is also the target for both humoral and cellular immune responses [20-22]. The S protein contains determinants of neurovirulence and demyelination [23-26].

Studies to determine molecular determinates of MHV pathogenesis have been limited by the large size of the MHV genome. For many years the size of the MHV genome presented an obstacle for the construction of a full-length cDNA clone, which would be amenable for genetic manipulations. The construction of a plasmid vector, pMH54, containing the entire 3' of the MHV-A59 genome downstream from the hemagglutinin esterase gene and two marker restriction sites *avrII* and *sbfI,* marked a new stage in pathogenesis studies. The availability of this construct allowed the introduction of different S genes into the background of MHV-A59 and the introduction of site directed mutatation into S or other genes [27, 28]. Using targeted RNA recombination between the trandfected and manipulated pMH54 plasmid and an infectious virus, various properties of the S protein were studied in the past few years.

Replacing the S gene of MHV-A59 with the S gene of the highly neurovirulent MHV-4, increased the virulence of the new recombinant virus substantially [23, 29] Alterations in both S1 and S2 resulted in reduced viral replication in the brain, associated with decrease in neurovirulence [25]. Mutations and deletions in the hypervariable region (HVR) suggested that the HVR was important for neurovirulence [25, 30-32]. In addition, the H716D amino acid substitution correlated with a delayed fusion phenotype, but without loss of hepatotropism [33, 34]. Q159L amino acid substitution affected hepatotropism and demyelination [35, 36] and L1114R (within the S2 region) has been speculated to play a role in the conformation of spike and in the dynamic interaction between S1 and S2 [37, 38]. The S gene was also found to contain determinants of hepatotropism [39].

Infection of MHV-A59 in 4-week-old C57BL/6 mice produces a biphasic disease with acute hepatitis and meningoencephalitis followed by chronic CNS demyelination [40-42]. Thus infection of mice with MHV-A59 has been used as an animal model for the human demyelinating disease multiple sclerosis (MS) [43-46]. MHV-2, previously recognized as mainly hepatotropic virus with only weakly neurotropic properties [47-50], was shown to produce severe hepatitis and meningitis, without encephalitis and demyelination [26, 51]. The weak neurotropic properties of MHV-2 made this strain ideal for a comparative study with the closely related, neurotropic, demyelinating strain MHV-A59 [52]. We first sequenced the entire genome of MHV-2 and compared it with that of MHV-A59 [52]. We then studied the role of the S gene in demyelination by replacing the S gene of MHV-A59 with that of MHV-2, using targeted RNA recombination. The new recombinant viruses (Penn98-1, 2) were more virulent than A59, but unable to induce demyelination in C57BL/6 mice [26]. Thus we hypothesized that demyelination determinants map to the S gene of MHV-A59.

To further explore which specific regions of the S gene are directly responsible for the demyelinating phenotype, we studied a set of random recombinant viruses (ML-7, ML-8, ML-10, and ML-11) that were produced by co-infection of cultures with MHV-2 and LA-7, a ts mutant of MHV-A59 [53]. All of these recombinant viruses were unable to induce demyelination *in vivo. In vitro* study ascertained that this group of recombinant viruses was able to replicate to the same titers as their parental viruses in L2 cells tissue cultures. Morphologically, the viruses ML-7, ML-8 and ML-10 produced large plaques and syncytia (similar to MHV-A59), whereas ML-11 produced small plaques as MHV-2. Sequencing of the S genes of ML-7, ML-8 and ML-10 revealed that they contained three common mutations, I375M, L652I, and T1087N [54]. The I375M mutation is located downstream from the receptor-binding site, the L652I mutation is located in the Hypervariable (HVR) region of the S gene and the T1087N mutation is located between the two-heptad repeat regions. Since these viruses were derived from a recombination between LA-7 and MHV-2, we also sequenced the S gene of LA-7 and we confirmed that the S gene of LA-7 contained the exact same three mutations implicating LA-7 as the source of these mutations. In addition, the sequence results of the S gene of ML-11 confirmed that the S gene of ML-11 was identical and was derived from to the S gene of MHV-2 [51].

We then investigated the role of the three amino acid substitutions in MHV-A59-induced demyelination. We first produced viruses with all 3 amino acid substitutions by targeted recombination. The virulence of Penn2K-1 and 2 was dramatically reduced (LD50>50,000pfu) although Penn2K-1 and 2 exhibit similar kinetics of replication as their parental virus

MHV-A59 in L2 cell cultures. Pathogenesis studies of Penn2K-1 and 2 showed only mild encephalitis and hepatitis when high doses were used for infection (50,000pfu I.C). No demyelination was found with any dose of virus used for infection. Thus we hypothesized that one of the 3 amino acid substitutions or a combination of two or three of these mutations marked genomic determinants of CNS demyelination.

Using site directed mutagenesis and targeted recombination; we then made a series of recombinant viruses containing each one of the 3 points mutation and each of the combined 2 point mutations. In vitro studies showed that all of these recombinant viruses exhibited similar kinetics of replication in L2 cell culture. The virulence of all of these recombinant viruses was reduced compared to wtR-A59. The recombinant viruses with the T1087N mutation (Penn99-1 and 2) were the most virulent (LD50=20,000pfu) among these recombinant viruses. The virulence of all other recombinant viruses, including the I375M point mutation (Penn01-1 and 2), the L652I point mutation (Penn01-3 and 4) and I375M-L652I two point mutation (Penn2K3 and 4), I375M, and T1087N two point mutation (Penn01-5 and 6), L652I, and T1087N two point mutation (Penn01-7 and 8), were all significantly attenuated (LD50>50,000pfu). The reduced virulence correlated well with the reduced in severity of hepatitis and encephalitis. Interestingly, demyelination was not influenced by the reduction of virulence because most of the recombinant viruses with one or two combined amino acid mutations were significantly less virulent but demyelination-positive. It further confirmed that the induction of demyelination is a separate pathologic property that does not depend on the intensity of prior encephalitis or hepatitis during the acute phase [26]. Penn2K-3 and 4, the combination of mutations in S1 (I375-M, L652I) did not produce demyelination in C57BL/6 mice even when mice were infected with the highest dose (50,000pfu, I.C.). We then searched for additional mutations around amino acid 375 and eventually found that N345S was a single point mutation that abolished demyelination (Fu et al, manuscript in preparation). Thus we identified a region in the S1 gene downstream from the receptor-binding domain that controls demyelination.

SUMMARY.

The S gene controls a variety of biologic functions many of them are important for pathogenesis. Our laboratory identified a region around amino acid 345 of the S gene, outside and downstream from the receptor-binding domain that appears to control demyelination. Further studies are underway to define the functions of this region in virus-host interactions. Crystallization studies will determine whether the three

dimensional folding of this S1 region of the molecule may enable a spatial interaction between this site and the other two mutation sites which may affect viral host interaction and subsequently pathogenesis. More detailed mutagenesis, coupled with functional studies such as studies of receptor binding, S1-S2 separation, and fusion properties, will also be helpful in elucidating the mechanism of MHV neuropathogenesis.

DEMYELINATION INDUCED BY OTHER VIRUSES

Chapter D1

SEMLIKI FOREST VIRUS INDUCED DEMYELINATION

John K. Fazakerley
Centre for Infectious Diseases, College of Medicine and Veterinary Medicine, University of Edinburgh, Summerhall, Edinburgh, EH9 1QH, UK.

Abstract: SFV infection of the laboratory mouse provides an excellent model to study age-related virus virulence, virus neuroinvasion and the pathogenesis of acute encephalitis and demyelination. The A7(74) strain is avirulent in weaned mice. Following intraperitoneal infection this virus is neuroinvasive and crosses the blood-brain barrier to establish focal infections in neurons and oligodendrocytes. Virus replication is for the most part restricted and non-destructive in these cells and in the absence of immune responses virus persists. In immunocompetent animals focal lesions of inflammatory demyelination develop throughout the CNS including the olfactory nerves. $CD8^+$ T-lymphocytes are required for the generation of these lesions. Animals have abnormal visual evoked responses and may develop limb paralysis.

Key words: Semliki Forest virus, demyelination.

1. VIRUS STRAINS

SFV is an alphavirus of the *Togaviridae*. Naturally the virus is found in Africa where it has been shown to infect horses and man. The virus is spread by mosquitoes. In man infection results in a mild febrile illness (Mathiot et al, 1990). SFV has been studied for many years in the laboratory mouse as an experimental model system to understand viral and immunological events in viral encephalitis and virus induced CNS demyelination (Atkins et al, 1985; Fazakerley and Buchmeier, 1993; Fazakerley et al, 1997; Fazakerley and Walker 2003). The virus is relatively simple, it has an approximately 12 kb genome of single-stranded positive

sense RNA. This has been cloned (Garoff et al, 1980; Takkinen et al, 1986) and as with many positive stranded RNA viruses, studies of site directed mutants are proving to be a powerful approach to mapping areas of the genome responsible for individual phenotypic characteristics (Glasgow et al, 1994; Santagati et al, 1995; Santagati et al, 1998). The genome has a replicase gene which undergoes sequential post-translational processing to produce a complex of four polypeptides (nsP1-4) which mediate RNA replication. The viral structural proteins (the capsid C, and 3 glycoproteins, E1, E2 and E3) are encoded within a separate transcriptional unit controlled by a subgenomic promoter. A major determinant of virulence resides in the nsP3 protein, a component of the viral replicase (Tuittila et al, 2000). There are a number of strains of the virus derived from independent isolates by passage through mice or cell culture. The most commonly studied strains are L10, prototype and A7 and A7(74) which are respectively, virulent and avirulent in adult mice. As with all virus infections the route of inoculation, the dose of virus, the age of the mice and the genetics of both virus and host affect the outcome of infection. All SFV strains are virulent in neonatal and suckling mice by all routes of inoculation. A number of viruses generated by mutagenesis have also been studied, from the point of view of demyelinating disease, the most notable of these is M9 (Barrett et al, 1980).

2. AGE-RELATED VIRULENCE AND RESTRICTED REPLICATION

In neonatal mice all strains of this virus spread rapidly around the brain and infection is rapidly fatal. As the mice age some strains are less able to spread in the CNS and there is a sharp age-related virulence (Fleming, 1977; Oliver et al, 1997; Oliver and Fazakerley, 1998). In the mature CNS the A7(74) strain has a restricted replication and remains confined to perivascular foci (Pathak and Webb, 1978; Fazakerley et al, 1993; Oliver et al, 1997). This age-related virulence is not a function of the maturity of specific immune responses as this strain of the virus remains confined to small, predominantly perivascular foci in athymic *nu/nu* mice or mice with severe combined immunodeficiency (Fazakerley et al, 1993; Fazakerley and Webb, 1987b; Amor et al, 1996). Interestingly, widespread CNS infection can be established in adult mice by treatment with gold compounds prior to infection. It is unclear how this works but gold in common with other heavy metals is thought to have an affect on neuronal differentiation (Scallan and Fazakerley, 1999). Events in age-related virulence are well described with intranasal infection. Following intranasal infection SFV can track along the olfactory nerve to enter the CNS in the olfactory bulb (Kaluza et al, 1987;

Oliver and Fazakerley, 1998). For the A7(74) strain of SFV, spread of infection along olfactory and other CNS pathways is dependant upon neuronal maturity (Oliver et al, 1997; Oliver and Fazakerley, 1998). The virus can only replicate efficiently in immature developing neurons. Following intranasal infection, in the immature brain of weanling mice virus can be observed to sequentially infect the olfactory nerve layer, periglomerular cells, mitral cells and granule cells of the olfactory bulb and then to exit into secondary olfactory areas such as the olfactory tubercle and the anterior olfactory nucleus (Oliver and Fazakerley, 1998). In the immature brain this wave of infection is followed by a wave of apoptotic cell death (Allsopp and Fazakerley, 2000; Fazakerley and Allsopp, 2001). Interestingly and in complete contrast, infection of mature neurons appears to be non-destructive and can be persistent (Fazakerley and Webb, 1987b; Amor et al, 1996; Donnelly et al, 1997). This phenomenon of restricted virus replication in mature CNS cells may be highly relevant to demyelinating disease. It is also observed with measles virus in subacute sclerosing panencephalitis and in animal models (Schneider-Schaulies et al, 1995). The inability of viruses to replicate fully or efficiently in mature CNS cells coupled with a relative resistance of these highly specialized and irreplaceable cells to initiate programmed cell death upon infection may be crucial in establishing CNS infection (Allsopp and Fazakerley, 2000; Fazakerley 2001). This may only be eliminated by immune mediated destruction and consequent demyelination (Fazakerley and Walker, 2003).

3. ENTRY INTO AND SPREAD WITHIN THE BRAIN

SFV has the advantage of being neuroinvasive as well as neurotropic, allowing study of virus entry into the CNS and the functioning of the blood-brain barrier. In weaned (> 3 weeks of age) mice following intraperitoneal (ip) inoculation, SFV replicates in muscles including skeletal, smooth and cardiac muscle (Pusztai et al, 1971; Amor et al, 1996). A high titer plasma viraemia is detectable by 24 hours. This usually falls after 48 hours and virus is generally undetectable in the blood by 4 days (Pusztai et al, 1971; Fazakerley et al, 1993). All strains which have been studied (L10, A7, A7(74)) are neuroinvasive. Original electronmicroscopic studies of infected mouse brains did not observe virus replication in cerebral vascular endothelial cells and the authors suggested virus was transported without replicating in them (Pathak and Webb, 1974). However, an in vitro study in immature mouse endothelial cells showed good virus replication (Dropulic and Masters, 1989). Virus replication was also subsequently observed in

suckling mouse primary cerebral vascular endothelial cell cultures (Soilu-Hanninen et al., 1994). In the same study, viral RNA and proteins were detected in brain endothelial cells by in situ hybridization and immunostaining between days 1 and 7 post-infection with the highest frequency of positive cells on days 3 and 4. Other in situ hybridization and immunostaining studies have not reported positive cerebral vascular endothelial cells (Fazakerley et al, 1993; Gates et al, 1984; Balluz et al, 1993).

Once across this barrier the virus infects adjacent cells resulting in striking perivascular foci of infection (Fazakerley et al, 1993). It is likely that other strains also enter the CNS predominantly by this route. Infection of the brain via the olfactory nerves can also occur (Kaluza et al, 1987; Oliver and Fazakerley, 1998). Whether this is of relevance following ip infection is not clear. All strains of the virus appear to infect both neurons and oligodendrocytes but not astrocytes and only rarely meningeal, ependymal or choroid plexus cells (Balluz et al, 1993; Pathak and Webb, 1983).

In weaned mice, SFV infection of the CNS occurs by 24h. Thereafter titers rise, rapidly with the virulent strains (eg L10) until death at 3 or 4 days, or more slowly with the avirulent strains (eg A7(74)) to reach a peak around 3 days after which titers begin to fall (Pusztai et al, 1971; Fazakerley et al, 1993). Avirulent A7(74) virus cannot be detected in the brain by plaque assay after day 8, by the more sensitive $ICLD_{50}$ after day 11 and by in situ hybridization after day 14 (Jagelman et al, 1978; Suckling et al, 1978; Fazakerley et al, 1993). RT-PCR studies following M9 infection indicate that viral RNA can be detected in the brain for even longer periods, >90 days (Donnelly et al, 1997). Following A7(74) infection antibody producing plasma cells in the brain and intrathecal anti-viral antibody are detectable for months suggesting persistence of viral antigen (Parsons and Webb, 1984; Parsons and Webb, 1989). In the absence of specific immune responses the A7(74) virus can persist in CNS cells, apparently without damage and essentially for the life of the mouse (Fazakerley et al, 1983; Amor et al, 1996).

4. BLOOD-BRAIN BARRIER CHANGES

With avirulent strains, early infection of the adult CNS detectable by 24 h is followed a few days later by a biphasic mononuclear cell pleocytosis (Parsons and Webb, 1982b). Measurement of albumin and IgG in the cerebrospinal fluid demonstrates a disturbance of the blood-brain barrier between days 4 and 10 (Parsons and Webb, 1982a; SoiluHanninen et al,

1994). Disruption of the blood-brain barrier at day 5 has also been observed by the detection of fibrinogen in the brain parenchyma adjacent to cerebral blood vessels (SoiluHanninen et al, 1994). The cause of the blood brain barrier disruption is unclear; it could be a direct viral effect, for example destruction of endothelial cells as is observed in culture (SoiluHanninen et al, 1994), a direct result of the passage of inflammatory cells across the barrier or it could be mediated by cytokines, for example interferon-gamma. The leaky barrier does corresponds to the time of increasing inflammatory cell infiltration and reduction of brain virus titers. Pleocytosis is apparent from 4 days and subsides by 9 days but cell counts in the cerebrospinal fluid do not return to normal for weeks and immunoglobulins are synthesized locally by invading B-lymphocytes (Parsons and Webb, 1984; Parsons and Webb, 1989).

5. ANTIBODY RESPONSES

SFV A7(74) infection of BALB/c mice results in a rapid and neutralizing serum IgM antibody response followed rapidly by an IgG2a response and a much slower IgG1 response (Fazakerley et al, 1993). SCID mice which have no serum anti-viral antibodies have both a persistent viraemia and a persistent CNS infection (Amor et al, 1996), whereas *nu/nu* mice control the viraemia as seen in immunocompetent mice but *nu/nu* mice have a persistent CNS infection. The *nu/nu* mice produce serum anti-viral IgM but not IgG (Suckling et al, 1982) suggesting that this may be controlling the viraemia but unable to eliminate the CNS infection. That this is the case is confirmed by resolution of persistent viraemia but not CNS infection by transfer of day 7 *nu/nu* mouse serum to infected SCID mice (Amor et al, 1996). In contrast, transfer of high titer IgG sera from immunocompetent BALB/c mice to SCID mice eliminates both the viraemia and CNS virus, at least that detectable by infectivity assay (Amor et al, 1996). Whether this is complete eradication of all viral sequences is not clear since it has not been checked by techniques such as RT-PCR. Antibodies are highly effective in protecting mice from challenge with a lethal dose of SFV. A number of B-cell epitopes have been mapped on the viral glycoproteins (Boere et al, 1984; Snijders et al, 1991) and even a single monoclonal antibody directed to the E2 envelope glycoprotein has been shown to protect mice against a virulent infection (Boere et al, 1983). Combinations of linear B-cell epitopes and B and T cell epitopes have been tested as potential vaccine candidates (Snijders et al, 1991; Snijders et al, 1992a).

6. INFLAMMATORY RESPONSES

Mice infected with SFV have good delayed-type hypersensitivity responses to the virus (Kraaijeveld et al, 1979) and T-cell epitopes for some haplotypes have been mapped (Snijders et al, 1991; Snijders et al, 1992b; Snijders et al, 1992a). Expression of cellular adhesion molecules on cerebral vascular endothelial and infiltrating mononuclear cells, cytokine expression and the phenotype of infiltrating mononuclear cells during SFV A7(74) infection have been studied in two systems BALB/c and Biozzi ABH mice (SoiluHanninen et al, 1994; SoiluHanninen et al, 1997; Morris et al, 1997; Parsons and Webb, 1989; Smith et al., 2000). It is possible that these two mouse strains differ in the kinetics of events but the following presents a synthesis. By immunostaining, interleukin (IL) –1α and 1β, IL-10, and TGF-β are detectable at 3 days; GMCSF, IL-2 and TNFα at 7 days and IFN-γ and IL-6 at 10 days. Increased expression of ICAM-I on cerebral vascular endothelial cells and adjacent cells occurs from day 3, with a peak somewhere between days 5 and 10. Expression of VCAM-I is maximal around 7 to 10 days and is limited to the blood vessels. Major histocompatibility type-I and –II expression are detectable on endothelial and other blood vessel associated cells by 7 days. Immunostaining studies indicate that $CD8^+$ cells, LFA-1^+ cells, Mac-1^+ cells and VLA-4^+ cells are all first observed in the infected brain at 3 days and that $CD8^+$ cells dominate the early phase of infection while $CD4^+$ T-lymphocytes are detectable from 7 days to at least 35 days. Numbers of $B220^+$ B-lymphocytes increase dramatically from 7 days to a peak at 21 days. The parenchymal MHC-I^+ cells form a network surrounding the foci of infection in which the level of MHC-I staining decreases with distance from the infected cells. MHC-II^+ cells, probably pericytes can be observed adjacent to blood vessels in areas of infection and MHC-II^+ astrocytes and microglial cells are present in the areas of infection and inflammation (Morris et al, 1997).

7. NEUROPATHOLOGY

Semliki Forest virus (SFV) infection of adult mice results in a demyelinating meningoencephalomyelitis. An intense inflammatory response characterized by perivascular cuffing with invading cells spreading into the parenchyma is apparent histologically from 3 days (Parsons and Webb, 1982b). Areas of inflammatory infiltrates correspond to the areas of infection (Subak-Sharpe et al, 1993; Morris et al, 1997). Perivascular cuffs are a prominent feature of the neuropathology and are maximal between 7 and 10 days. Demyelination is first apparent by luxol fast blue staining of

paraffin sections around 14 days post-infection but small focal lesions are apparent by electron microscopy at 10 days (Suckling et al, 1978; Kelly et al, 1982). In the optic nerve there are lesions of demyelination and changes in visually evoked responses and axonal transport (Tremain and Ikeda, 1983). These are features which also occur in MS. Adoptive transfer studies in SCID and *nu/nu* mice and studies in mice immunosuppressed with total body irradiation, cyclophosphamide, cyclosporin or cycloleucine all demonstrate that T-cell responses are pathogenic and are required to generate the lesions of demyelination (Fazakerley et al, 1983; Fazakerley and Webb, 1987c; Fazakerley and Webb, 1987b; Fazakerley and Webb, 1987a; Amor and Webb, 1987; Amor et al, 1996). Treatment of infected mice with anti-VLA-4 antibodies dramatically reduces CNS cellular infiltrates and demyelination (Smith et al, 2000). Depletion of $CD8^+$ cells with a monoclonal antibody greatly reduces demyelination whereas depletion of $CD4^+$ cells reduces the extent of the inflammation but not that of demyelination (Subak-Sharpe et al, 1993). Given the requirement for $CD8^+$ cells and that the virus infects oligodendrocytes, the most likely mechanism of demyelination would seem to be $CD8^+$ T-cell destruction of virally infected oligodendrocytes, though this remains to be proven following for example, adoptive transfer of SFV-specific cytotoxic T-cell clones or lines into *nu/nu* or SCID mice. Mice infected with SFV A7(74) generate CNS antigen specific autoantibodies, are more sensitive to the induction of experimental allergic encephalomyelitis and have T-cells which cross react between viral and CNS epitopes (Amor and Webb, 1988); Mokhtarian and Swoveland, 1987; Mokhtarian et al, 1996). At present the role of autoimmune responses in the generation, exacerbation or perpetuation of SFV A7(74) induced demyelinating lesions remains unclear.

ACKNOWLEDGEMENTS

I am grateful to the UK Multiple Sclerosis Society which has over many years supported the study of Semliki Forest virus induced demyelinating disease.

Chapter D2

THE PATHOGENESIS OF CANINE DISTEMPER VIRUS INDUCED DEMYELINATION

A biphasic process

Wolfgang Baumgärtner[1] and Susanne Alldinger[2]
[1]Institut für Pathologie der Tierärztlichen Hochschule Hannover, Germany, [2]Institut für Veterinär-Pathologie der Justus-Liebig-Universität Giessen, Germany

Abstract: Canine distemper is induced by canine distemper virus (CDV), a morbillivirus of the Paramyxoviridae family closely related to measles virus. CDV infection frequently results in the affection of the central nervous system (CNS). Besides a polioencephalitis, distemper leukoencephalitis (DL) is the main sequela of CDV CNS infection. Demyelination in DL appears to be a biphasic process. Initiation of demyelination is ascribed to a direct action of the virus as there is a prominent intralesional expression of viral proteins and mRNA. Early lesions are accompanied by the presence of few CD8+ lymphocytes and single CD4+ cells and an up-regulation of the major histocompatibility complex class II (MHCII). In this phase, tumour necrosis factor-α (TNF-α), CD44, a hyaluronate receptor, and matrix-metalloproteinases (MMPs) as well as their inhibitors (TIMPs) are up-regulated. Plaque progression seems to be an immunopathological process. The strong reduction or absence of viral protein and mRNA expression is associated with a vigorous immune response. CD8+ lymphocytes dominate within the lesions while CD4+ lymphocytes and B cells are mainly found perivascularly. Simultaneously, there is a strong up-regulation of MHCII and the pro-inflammatory cytokines interleukin (IL) -6, IL-8, IL-12, and TNF-α. The pro-inflammatory cytokines Il-1ß, IL-2, and interferon-γ are lacking. The anti-inflammatory cytokines IL-10 and transforming growth factor-ß are not influenced by the CDV infection. CD44 , TIMPs and single MMPs are strongly diminished.

Summarized, in CDV induced demyelinating leukoencephalitis, plaque genesis is a biphasic process with various factors associated with lesion initiation or progression. Understanding the mechanisms of demyelination in these two phases might allow insights into the pathogenesis of demyelinating diseases of man.

1. INTRODUCTION

1.1 Canine distemper virus

Canine distemper (CD) was decribed for the first time in Europe in 1761 (Mitscherlich, 1938) and the virus etiology was confirmed by Carré in 1905 (Fankhauser, 1982). The natural host spectrum of CDV comprises all families of the order Carnivora (Deem et al., 2000). In humans, the participation of CDV in the pathogenesis of Paget's disease of bone (Gordon et al., 1991, Mee et al., 1998, Mee et al., 1999, Helfrich et al., 2000, Ooi et al., 2000) and multiple sclerosis (MS; Cook et al., 1978 and 1987, Vollmer and Waxman, 1991, Hodge and Wolfso, 1997, Hernan et al., 2001) has been speculated but lacks final verification.
Canine distemper virus belongs to the genus morbillivirus of the Paramyxoviridae family and is closely related to measles virus (Pringle, 1999). CDV is an enveloped negative stranded virus (Kingsbury, 1990). It contains 6 structural proteins, the nucleocapsid (NP), phospho (P), and the large (L) protein (core proteins) and the membrane (M), hemagglutinin (H), and fusion (F) protein (surface proteins; Hall, 1980, Örvell, 1980, Diallo, 1990). The NP proteins catalyze transcription and replication in the host cell (Kingsbury, 1990). The M protein is involved in virus maturation as it connects the surface glycoproteins with the nucleocapsid (Kingsbury, 1990). The F protein manages the fusion of the virus with the host cell or the infected cell to the neighbour cell (Diallo, 1990). The H protein mediates the attachment of the virus to the host cell by neuraminic acid binding receptors (Hall et al., 1980; Kingsbury, 1990) and determines viral tropism and cytopathogenicity (von Messling et al., 2001). The function of the non-structural proteins V and C is not clear. Recently, another non-structural protein has been detected that seems to allow virus replication in different species (Wang et al., 1998). CD9, a tetraspan transmembrane protein is associated with CDV induced cell-cell fusion but not virus-cell fusion (Schmid et al., 2000). Signalling lymphocyte activation molecules (SLAMs; CD150) act as cellular receptors for CDV and other morbilliviruses (Tatsuo et al., 2001, Tatsuo and Yanagi, 2002). There is only one serotype but there are several cocirculating genotypes of the virus (Haas et al., 1997). CDV strains display different properties. Some strains are associated with polioencephalitis (Snyder Hill) while others induce demyelinating leukoencephalitis (R252, A75-17; Summers and Appel, 1994).

1.2 Forms of canine distemper encephalitis

Canine distemper encephalitis can be classified in different subtypes according to morphological changes and brain areas affected. The type of neuropathological changes depend on the virus strain, age and immune status of the affected animal (Krakowka and Koestner, 1976, Summers et al., 1984a, Pearce-Kelling et al., 1990, Raw et al., 1992). **Polioencephalitis** is a rare manifestation of CDV infection and is predominantly observed in the cortex and the nuclei of the brain stem, neurons and protoplasmic astrocytes being the mainly affected cell populations (Baumgärtner et al., 1999). Distemper polioencephalitis includes the subgroups "old dog encephalitis" (Lincoln et al., 1973, Imagawa et al., 1980), inclusion body encephalitis (Nesseler et al., 1997, and 1999), and post-vaccinal encephalitis (Hartley, 1974, Bestetti et al., 1978).

In contrast, distemper **leukoencephalitis** (DL) is a common finding and has been known for a long time. "Swelling of myelinated nerve fibres" was described by Cerletti in his work "about various forms of encephalitis and myelitis in dogs with canine distemper" as early as 1912. Scherer (1944), a German neuropathologist was among the first to compare DL white matter lesions to acute multiple sclerosis and he is the one who gave the impulse to use canine distemper as a model to study the pathogenesis of human demyelinating diseases (Koestner, 1975, DalCanto and Rabinowitz, 1982). Lesions in DL are mainly found in the cerebellum and less frequently in the cerebral white matter and the spinal cord (Baumgärtner et al., 1999). Demyelination is consistently observed in fibre tracts in close proximity to the ventricles like the rostral medullary velum, cerebellar peduncles, and optic tracts (Summers and Appel, 1994). Studies tracking the route of CDV invasion and the mode of distribution of the virus in the brain showed ependymal infection and spread of the virus to the subependymal white matter indicating CNS infection along the cerebrospinal fluid (CSF) pathways (Vandevelde et al., 1985a). This finding matches the observation of Higgins et al. (1982a) who found a productive infection of the choroid plexus of the fourth ventricle and ependymal cells. In addition, hematogenous spread of CDV in the CNS is mediated by the association of the virus with lymphocytes (Rochborn, 1958, Summers et al., 1979) and plasma (Krakowka et al., 1989) or via infection of endothelial cells and subsequent spread to pericytes and astrocytic processes (Axtehelm, Baumgärtner, 1989). DL lesions are categorized in acute, subacute non-inflammatory, subacute inflammatory, chronic, and sclerotic (Krakowka et al., 1985, Alldinger et al., 1993, Gaedke et al., 1999). Acute lesions are characterized by focal vacuolation and mild astro- and microgliosis.

Subacute non-inflammatory plaques display primary demyelination, astrogliosis with formation of gemistocytes and multinucleated giant cells, and microgliosis occasionally accompanied by malacia and scavenging gitter cells. Axonal injury is expressed by spheroid formation. Subacute inflammatory and chronic lesions are infiltrated by mononuclear inflammatory cells accumulated in the parenchyma orin the perivascular space. In sclerotic plaques demyelinated areas are replaced by astrocytic scar tissue (Baumgärtner et al., 1989, Alldinger et al., 1993, Wünschmann et al., 1999, Gaedke et al., 1999).

Plaque genesis was intensely studied in naturally and experimentally CDV infected dogs (McCullough et al., 1974a and c, Raine, 1976, Summers et al., 1979, Higgins et al., 1982b, Summers and Appel, 1987). In experimentally infected dogs, primary changes such as vacuolation and spongious disaggregation of the subependymal and subpial white matter are light microscopically observed 24 days post infection (d.p.i.). The vacuols grow in number and size to form a demyelinated plaque. Transmission electron microscopically the vacuolations turn out to be an edema of the myelin sheath (Summers et al., 1987). According to Wisniewski et al. (1972) and Higgins et al. (1982a) the separation starts at the intraperiod line. The edema of the myelin sheath compresses axons and spheroids are formed. This change is named complex necrosis by Higgins et al. (1982b). The plaque periphery constitutes a growth zone, where myelin edema can be observed (Summers et al., 1987). Loss of compact myelin starts 27 d.p.i. in experimentally infected dogs. Astrocytes separate intact myelin segmentally from the axon (Higgins et al., 1982b). Summers, (1987) however, observed, that loss of compact myelin begins by spiral wrapping of cytoplasmic processes of macrophages followed by concentric stripping of myelin lamellae away from the axon. Myelin fragments are found as extracellular myelin droplets (Summers et al., 1987) or in the cytoplasm of macrophages/microglia (Wisniewski et al., 1972, Raine, 1976, Summers et al., 1987), astrocytes (Raine, 1976, Summers et al., 1987) or in single oligodendrocytes (Summers et al., 1987). Remyelination is feature of older demyelinating lesions in the presence of intact axons (Wisniewski et al., 1972), McCullough et al., 1974b, Higgins et al., 1982b, Summers et al., 1987).

2. DEMYELINATING DISTEMPER ENCEPHALITIS

2.1 Cell tropism

The pathogenesis of CDV induced demyelination is still largely unknown. In experimental studies, CDV appears in the CNS 9 d.p.i. (Appel, 1969) and is found in astrocytes, neurons, microglia, ependymal cells, leptomeningeal cells, and choroid plexus epithelial cells (Appel, 1969, Vandevelde, 1980, Alldinger et al., 1993a; Wünschmann et al., 1999). Infection of **oligodendrocytes** has been the focus of numerous studies in the last years with contradictory results. Using light and transmission electron microscopy, a direct oligodendrocyte was observed by several investigators (McCullough et al. 1974b, Raine 1976, Blakemore et al. 1989). However, other studies did not detect oligodendrocyte infections in vivo (Vandevelde et al., 1983) and several in vitro investigations did not succeed in confirming an oligodendrocyte infection in primary brain cell cultures infected with different CDV strains (Zurbriggen and Vandevelde, 1983, Vandevelde et al., 1985b, Zurbriggen et al., 1986, 1987a and b). Employing molecular techniques, the question on the role of oligodendrocytes in CDV infection was resumed. Zurbriggen et al. (1993) demonstrated a restricted infection of oligodendrocytes. Furthermore, Graber et al. (1995) and Zurbriggen et al. (1998) found a down-regulation of the expression of a variety of oligodendroglial genes after restricted CDV infection. The same group investigated the participation of apoptosis or necrosis in cell death induced by CDV in vivo and in vitro and found, that neither of them played a significant role (Schobesberger et al., 1999). Recently, it has been shown, that oligodendrocytes are present in chronic lesions, and thus demyelination precedes oligodendrocyte loss in CDV induced encephalitis (Schobesberger et al., 2002).

Astrocytes are the main cell population infected by CDV. In non-inflammatory lesions in the cerebellar white matter of dogs with acute distemper, doublelabelling techniques unveiled, that 64% of astrocytes within a lesion were infected and this cell population provides 95% of all infected cells (Mutinelli et al., 1988). Infected astrocytes form gemistocytes, syncytia (Summers and Appel, 1985) and have a glassy cytoplasm (Vandevelde et al., 1983). They lose their cell processes and glial fibrillary acidic protein (GFAP) positive fibrils are newly arranged being concentrated around the nucleus (Zurbriggen et al., 1986). Among other CNS cell populations astrocytes display cytoplasmic and intranuclear inclusion bodies. The paradoxical intranuclear accumulation of the NP protein of an RNA virus seems to be a sign of cellular stress (Oglesbee and Krakowka, 1993).

2.2 Viral persistence

In spite of a strong virus-specific intrathecal immune response, early lesions without overt inflammation can be observed in the vicinity of chronic lesions with prominent invasion of inflammatory cells (Alldinger et al., 1993). Clearence of viral antigen is associated with the presence of inflammation and intrathecal virusspecific antibodies. However, these chronic lesions, devoid of viral antigen coexist with acute plaques containing a high viral load (Bollo et al., 1986). A detailed immunohistological investigation upon the distribution of CDV proteins and their epitopes in different lesion types showed, that in acute and subacute lesions without inflammation, expression of the M, H, and F proteins is only slightly diminished compared to the core proteins. However, plaques with severe inflammation are either devoid of viral antigen or exhibit NP- and P-specific immunoreactivity restricted to the periphery with simultaneous reduction or loss of surface proteins. The intracellular distribution of the proteins varies. Exclusively the NP and P proteins are found in the cell nucleus and the cell processes in addition to the cytoplasm (Alldinger et al.,1993). It can be assumed, that the nucleocapsid itself is infectious as shown for measles virus (Rozenblatt et al., 1979). The presence of the core proteins in cell processes is suspicious of a possible spread of the virus along this pathway in order to escape immune surveillance (Alldinger et al., 1993) as has been shown in cell culture studies (Zurbriggen et al., 1995J Virol). The hypothesis of the intralesional persistence of viral mRNA in the absence of proteins was disproved by molecular studies (Müller et al., 1995, Gaedke et al., 1999). In the grey matter, however, more CDV RNA than protein is found suggestive of impaired translation of CDV and a possible mode of viral persistence (Müller et al. 1995). Studies on distemper inclusion body polioencephalitis support the hypothesis of restricted grey matter infection as a mechanism of viral persistence (Nesseler et al., 1999). According to in vitro investigations, persistence of CDV in the brain appears to be due to non-cytolytic selective spread of the virus with very limited budding (Vandevelde and Zurbriggen, 1995; Zurbriggen et al., 1995). An analysis of the nucleotide- and deduced amino-acid sequences of the NP and M genes yielded results supporting the notion, that the NP and the M gene harbour determinants of viral persistence (Stettler et al., 1997).

2.3 Immunopathology

CDV-associated immunosuppression (Krakowka et al., 1975a) is an important manifestation of canine distemper. It is caused by the lytic effect of the virus on lymphocytes and macrophages during the caute phase of the disease and can be found months after viral clearence (Krakowka et al., 1975a and 1980). The recovery of the lymphatic tissue, coincides with the invasion of the CNS by inflammatory cells. Immunophenotyping of the cellular immune response in DL revealed, that only few inflammatory cells are found in acute and subacute non-inflammatory lesions. In this phase, CD8+ cells dominate and might be involved in viral clearence or contribute as antibody-independent cytotoxic T cells to early lesion development (Wünschmann et al., 1999). This hypothesis is supported by the finding, that occurrence of T cells in early demyelinating lesions correlates with sites of viral replication and coincides with the demonstration of an early immune response against the nucleocapsid protein of CDV. T cell migration to the CNS is suspected to be triggered by activated microglia secreting chemokines. Hence, a marked IL-8 activity is present in the CSF of dogs with acute lesions. Resting T cells of the early stages of the disease might facilitate the later development of the intrathecal immune response and associated immunopathological complications (Tipold et al., 1999). Subacute inflammatory and chronic lesions are massively infiltrated by inflammatory cells. CD8+ cells may function as cytotoxic effectors. CD4+ cells are suspected of initiating a delayed-type hypersensitivity reaction in these older lesions (Wünschmann et al., 1999). Immunpathological mechanisms involved in CD plaque pathogenesis are emphasized by up-regulation of the major histocompatibility complex class II (MHCII) in DL brains. Following CDV infection, there is a mild up-regulation of this molecule in acute increasing to severe in chronic lesions. MHCII is present on microglia, endothelial, meningeal, choroid plexus epithelial, ependymal, and intravascular cells. Virtually all cells forming perivascular infiltrates are MHCII-positive. Although MHCII is up-regulated throughout the white matter an accentuated expression is found in CDV-antigen positive acute and subacute plaques. In chronic plaques MHCII expression is especially prominent in areas with reduced or absent viral antigen expression indicating that non-viral antigens may play an important role as triggering molecules in the chronic phase of demyelination (Alldinger et al., 1996).

The term "bystander demyelination" was used to describe the myelin damaging effect of proteolytic enzymes released by stimulated macrophages (Cammer et al. 1978) to explain myelin destruction in the absence of obvious oligodendrocyte infection. Other macrophage mediators, including reactive

oxygen species (ROS), seemed to be involved in DL demyelination (Bürge et al., 1989; Griot et al., 1989a and b and 1990).

The humoral immune response, i.e. the intracerebral presence of B cells and their importance for intrathecal antibody production during chronic demyelinating distemper leukoencephalomyelitis is well documented (Vandevelde et al., 1982, 1986, Alldinger et al., 1996). B cells especially producing immunoglobulins of the IgG subtype are found, at variance within chronic lesions and in perivascular infiltrates (Vandevelde et al., 1982, Alldinger et al., 1996). Besides a prominent CDV-specific humoral immune response in serum and cerebrospinal fluid (Vandevelde et al., 1982, 1986, Rima et al., 1991) anti-myelin specific antibodies are found (Krakowka et al., 1973, Vandevelde et al., 1986). Consequently, a mechanism of demyelination based on complement-dependent antibody mediated humoral cytotoxicity is discussed (Vandevelde et al., 1982). However, the pathological significance of anti-myelin antibodies remained doubtful as high titres of these antibodies are also detected in dogs with resolving lesions (Vandevelde et al., 1986). Furthermore, antibody-dependent T-cell mediated cytotoxicity was suspected as many intralesional and perivascular cells are T lymphocytes and there is a simultaneous occurrence of perivascular B and CD4+ cells (Vandevelde et al., 1982, Alldinger et al., 1996, Wünschmann et al., 1999). The simultaneous decline of intrathecal antibody production and clinical improvement were suggestive of a deleterious role of the humoral immune response (Vandevelde et al., 1982). Cell to cell communication and interaction between immune cells and resident or activated brain cells were investigated by studying cytokine expressions in DL. Accordingly, demyelination is frequently associated with interleukin (IL)-1, -12, tumour necrosis factor (TNF) and transforming growth factor (TGF) mRNA expression in the blood of dogs with natural CD. IL-6 transcripts are only found in animals with early CNS lesions. Simultaneous occurrence of pro- and anti-inflammatory cytokines in whole blood preparation from most of the dogs with CD, favored the hypothesis of a complex most likely disease stage dependent orchestrated cytokine expression (Gröne et al., 1998). In the CSF of dogs naturally infected with CDV, TNF and IL-6, associated with disease exacerbation and IL-10 and TGF, indicative of remission, are often observed simultaneously and can not be assigned to specific disease stage. IL-10 remains the most frequently detected cytokine indicating that the stage of inactivity prevails (Frisk et al., 1999). An immunohistochemical in situ study revealed, that IL-1 is expressed to varying degrees in all types of lesions and is most often present in CD3 (T lymphocytes) and BS-I (microglia/brain macrophages) positive cells in early plaques and in cells comprising perivascular cuffs found in chronic lesions. IL-6 expression is present in all lesions and follows a similar distribution pattern as IL-1. IL-12

is observed only in individual perivascular cells. TNF-α is mainly associated with astrocytes and might be involved in the pathogenesis of early demyelination in DL (Gröne et al., 2000). According to an in situ semi-quantitative RT-PCR study, there is a prominent up-regulation of the pro-inflammatory cytokines IL-6, IL-8, IL-12, and TNF-α in early distemper CNS lesions. Other pro-inflammatory cytokines such as IL-1, IL-2, and interferon (IFN)-γ are not detected. Conversely, IL-10 and TGF-ß, though detectable in most distemper cases, experienced no significant up-regulation following CDV infection and lesion development. The lack of increased expression of anti-inflammatory cytokines might represent an early derailment of the immune response in demyelinating distemper leukoencephalitis (Markus et al., 2002).

2.4 Extracellular matrix

In view of the importance of astrocytes as major source of extracellular matrix (ECM) proteins (Montgomery, 1994) and their significance for maintaining structure and relationships in the brain, the consequences of a CDV infection of this cell population seemed to be an important question to be addressed. Asher et al. (1991) demonstrated, that a hyaluronate-based ECM must exist in the canine CNS as glial hyaluronate binding protein (GHAP) is demonstrated immunoelectron microscopically in the space between myelin sheaths and astrocytic processes. The importance of the ECM is stressed by the observation, that In acute and subacute demyelinating encephalitis, a plaque-associated CD44-up-regulation is found that parallels astrocyte activation. CD44 plays a dual role for the progression of the demyelination process. Ligation of this receptor might induce chemokines and cytokines and hence initiate and perpetuate the inflammatory process. In chronic lesions, CD44 expression declines together with the number of GFAP-positive astrocytes. In addition, in this plaque type, CD44 is expressed on the cell membrane of perivascular mononuclear cells, possibly marking memory cells (Alldinger et al., 2000). Matrix-metalloproteinases (MMPs) , zinc dependent enzymes, that cleave molecules of the extracellular matrix and their inhibitors (TIMPs) are most prominently up-regulated in acute and subacute non-inflammatory lesions and are expressed mostly by astrocytes and microglia. In this phase, they might contribute to lesion initiation. In older lesions, MMP and TIMP expressions decline apart from MMP-11, -12, and –13 favoring the hypothesis of the

TIMP-MMP imbalance as the motor for lesion progression (Miao et al., 2002).

3. CONCLUSIONS

Demyelinating distemper leukoencephalitis represents a biphasic disease. Lesion initiation is most likely directly virus-induced and is supported by the actions of CD8+ cells, inflammatory cytokines including TNF-α as well as specific MMPs. The second or immunopathological phase of demyelination is associated with a massive infiltration of inflammatory cells, antigen presentation, a preponderance of pro-inflammatory cytokines and a TIMP-MMP imbalance in the absence of virus. Obviously, CDV does not lead to myelin destruction on a direct pathway, but interferes with sensitive control mechanisms between brain cells, immune cells myelin, and the extracellular matrix.

ACKNOWLEDGEMENTS

The authors' projects were supported by grants of the Deutsche Forschungsgemeinschaft and the Hertie-Stiftung.
The authors want to thank Annette Artelt for skilful technical assistence and Ute Zeller for photographic support.

INDEX

A

Accessory molecules, 118–119
N-Acetylaspartate, 136–138
Active transfer
  in EAE induction, 17, 18*f*
  vs. adoptive in EAE induction, 15–16
Addressins, in EAE, 160–161, 165–167
Adhesion molecules, in EAE, 160–172
  addressins in, 165–167
  CD44 in, 171
  cytokine regulation of, 172
  E-selectin in, 165
  integrins in, 167–169
  L-selection in, 162–163
  laminins in, 170–171
  leukosialin (CD43) in, 169–170
  MECA-325 in, 171–172
  non-adhesion functions of, 167
  P-selectin in, 163–165
  PECAM-1 in, 169
  selectins and addressins in, 160–162, 161*f*
Adhesion molecules, in TMEV, 665–666
Adjuvants, in EAE, 75–81. *See also under* Experimental allergic encephalopathy (EAE)
Adoptive transfer, in EAE, 6
  of T cells, 20, 21*f*
  vs. active transfer, 15–16
Agrin, 422–423
Alpha lipoic acid, 403
Altered peptide ligands, 206–207
  in EAE, 462–463
Alum, 79–80
Amyloid precursor protein, 140
Anaphylatoxin receptors, 251
  in brain, 252–253
Androgens, 554
Antibodies, in EAE, 271–273
Antigen presentation, microglia/macrophages and, 116–119
Antigen-specific strategies, for EAE, 456–463. *See also under* Immunomodulation, of EAE
Antineuroantigen antibodies, in TMEV, 605–609
Apoptosis, definition of, 697–700, 698*f*
Apoptosis, in coronavirus-induced demyelination, 831–834
  discussion for, 833–834
  introduction to, 831–832
  MHV on, 832–833
Apoptotic cell death, in EAE, 508–518
  conclusions for, 517–518
  definiton and detection of, 509–510
  immunotherapy for, 516–517
  introduction to, 508–509
  mechanisms of, 512–514
  phagocytosis in, 514–515, 515*f*
  T cell and CNS inflammation in, 510–512, 511*f*
Astrocytes
  in autoimmune disease, 87–98
    conclusions for, 98
    costimulation role of, 94–95
    inflammatory mediators expression of, 96–97
    introduction to, 87–89
    in MHC class II antigen presentation, 89–93, 90*f*–92*f*
  in canine distemper demyelination, 872
  microanatomy of, 28
Astrocytes, in coronavirus-induced demyelination, 717–729
  animal models for, 721
  introduction to, 717–720
  mouse hepatitis virus and, 721–729
    BBB disruption in, 728–729
    chemokine production in, 724–726
    class I and II antigen expression in, 722–724
    conclusions for, 728–729
    cytokine production in, 724–726
    innate immune system in, 721–722
    NO production in, 727–728
    Th1/Th2 regulation in, 726–727
Astrocytes, in TMEV
  antigen presentation in, 623–624
  epitope spreading in, 624–626
  inflammation in, 623–624
  introduction to, 617–618

persistent infection in, 618–623, 620*f*, 621*f*
Atorvastatin, on Th1, 292
Atrophy, in multiple sclerosis, 137
Autoantibodies, in TMEV, 605–609
Autoimmune disease model
EAE as, 30–31
in EAE costimulation, 473–477, 474*f*
Autoimmunity, from B-cells, 273
Axonal injury
in coronavirus-induced demyelination, 736–742
in TMEV, 584–588, 585*f*, 587*f*
Axonal loss
in multiple sclerosis, 135–140
atrophy in, 137
clinical disability from, 139
demyelinated lesions in, 136–137
history of, 135–136
normal appearing white matter in, 137–138
pathological detection methods for, 139–140
Axonal loss, in EAE, 141–146
abnormality timing in, 142–143
agents associated with, 144–145
cytotoxic cells in, 143–144
disability correlation with, 145
immune modulation and, 146
interventions for, 145–146
models for, 141–142
molecular changes in, 143
primate model in, 570, 571*f*
selectivity of, 142
vs. dysfunction, 141

B

B cells and antibodies, in EAE, 155
antibody production in, 272–273
autoimmunity and, 273
CD4+ T cells and, 272
cytokines and, 273
cytotoxicity and, 276
demyelination pathogenesis and, 273–276
introduction to, 271–272
oponization in, 276
as regulatory cells, 217–218
B7-1, 474–477, 474*f*
in epitope spreading, 501
in TMEV antigen presentation, 623–624
B7-2, 474–477, 474*f*
Basement membrane, in BBB, 437–439, 437*f*, 438*f*
Blood-brain barrier (BBB)
in coronavirus-induced demyelination, 728–729
Semliki Forest virus on, 861–862
Blood-brain barrier (BBB), in EAE, 417–441
breakdown of, 157
encephalitogenic T cell recruitment across, 433–439
antigen presentation in, 433–434
basement membrane in, 437–439, 437*f*, 438*f*
blood-cerebrospinal fluid barrier in, 440
endothelium traffic signals in, 434–437
endothelial PECAM-1 in, 431–432
introduction to, 417–418
leakiness of, 428–430, 429*f*
leakiness of, inflammatory mediators in, 432–433
outlook for, 440–441
P-selectin on, 164–165
physiological aspects of, 418–428
development in, 419–423, 422*f*
differentiation in, 419–423, 422*f*
history in, 418, 419*f*
maintenance in, 419–423, 422*f*
tight junctions in, 425–428, 426*f*, 428
in vitro models in, 423–425, 424*f*
Brain, atrophy of, 137
Bystander activation, 529–531
in canine distemper virus demyelination, 874–875

C

N-Cadherin, 421
Calcitrol, 532–533
Calcium-activated neutral proteinase, 407–409
Calpain, 407–408
Canine distemper demyelination, 868–877
encephalitis from, 872–877
cell tropism in, 872
conclusions for, 877
extracellular matrix in, 876–877
immunopathology of, 874–876
viral persistence in, 873
forms of, 870–871
introduction to, 869
Cannabinoids, 146
Captopril, on IL-1 production, 292
Caspases, 698, 698*f*
in EAE, 408
CCL5, 810–812

CD-28, 475–477
 in costimulation requirements, 481
CD-40, 118–119
CD4 cells, in coronavirus-induced demyelination, 750–751
CD4+ T cells
 B-cells on, 272
 in coronavirus-induced demyelination, 741
 in EAE, 204–205
 in TMEV resistance, 647–649, 648*f*
  molecular mimicry in, 650–652
  myelin-specific cells in, 649–650, 651*f*
CD28, in MS, 479–480, 479*f*
CD44, 171
CEACAM1, and MHV interaction, 824–825
Cell tropism, 872
Cellular autoimmune response, in TMEV, 601–604
Central nervous system (CNS)
 apoptotic cell death in, 510–512, 511*f*
 demyelination in EAE, 29–30, 34–35, 34*f*, 35*t*
 endothelial cells of, 156–160
  cellular transmigration of, 158–159, 158*f*
  general properties of, 156–157
  inflammatory mediator expression of, 159–160
 inflammation in, 510–512, 511*f*
 inflammation in, EAE and, 29, 33–34, 33*f*, 34*t*
 leukocyte recruitment in, 156–157
 microanatomy of, in EAE, 27–28
 microglia and macrophages in, 112–114
Ceramide galactosyltransferase (CGT), 51
Cerebrospinal fluid, and BBB, 440
Chemokine system, in EAE, 365–375
 antichemokine treatment strategy for, 370–372
 CNS endothelial cell expression of, 159
 conclusion for, 375
 expression of, 368–369
 genetically modified animals and, 370–372
 IFN-γ on, 325
 introduction to, 365–366
 receptors of, 366–368, 367*t*, 369–370
 in T cell recruitment across BBB, 436
Chemokines, in coronavirus-induced demyelination, 724–726, 803–815
 CCL5 and, 810–812
 chemokine receptors in, 805–807
 conclusions for, 814*f*, 813815
 CXCL10 and, 812–813
 introduction to, 803–805
 MHV infection on, 808–810, 809*t*
 multiple sclerosis and, 807–808
Chemokines, in TMEV, 664–665
CIITA expression, 90–93
Ciliary neurotrophic factor, 144–145
 in EAE, 348–349
CNPase, 60
Common marmoset. *See* Primates, EAE in
Complement system, in EAE, 247–263
 anaphylatoxin receptor upregulation in, 256
 brain inflammation and, 252–253
 components of, 247–251
  anaphylatoxin receptors as, 251
  innate immune response as, 248, 249*f*
  lytic terminal complex as, 250, 250*f*
  MAC sublytic effects as, 251
  phagocytosis as, 249–250
 demyelination and, 256–262
  activation of, 256–257
  axonal damage in, 259, 259*f*, 261*f*
  MAC in, 257–259, 258*f*
  MAC in, sublytic assembled, 261–262
  neuroprotection mechanisms in, 260
  therapeutic implications of, 262–263
 disease amelioration and, 253–254, 254*f*
 lesions and, 254–255, 255*f*
Complete Freund's adjuvant, on EAE, 76–77
Coronavirus-induced demyelination, 697–852
 apoptosis in, 831–834
  discussion for, 833–834
  introduction to, 831–832
  MHV on, 832–833
 astrocytes in, 717–729 (*See also* Astrocytes, in coronavirus-induced demyelination)
 axons and neurons in, 736–742
  axonal damage and demyelination relationship in, 737–741, 739*f*, 740*f*
  CD4 and CD8 cells in, 741
  future directions for, 741–742
  introduction to, 736–737
 chemokines in, 803–815 (*See also* Chemokines, in coronavirus-induced demyelination)
 cornavirus receptors in, 819–826
  CEACAM1 and MHV interaction on, 824–825
  introduction to, 819–820

MHV receptors and, 820–824
MHV receptors and susceptibility in, 825–826
endothelial cells in, 717–729 (*See also* Endothelial cells, in coronavirus-induced demyelination)
histopathology of, 711–714
humoral immunity in, 758–766
acute infection and, 760–762
antibodies and, 765–766
conclusions for, 766
MHV pathogenesis and, 760
multiple sclerosis and, 758–759
viral persistence and, 762–765
metalloproteinases in, 836–842
background of, 837–838
conclusions for, 841–842
introduction to, 836–837
MMP and TIMP expression in, 838–840, 839*t*
MMPS demyelination role in, 840–841
microglia in, 717–729 (*See also* Microglia, in coronavirus-induced demyelination)
molecular determinants in, 846–852
MHV genome and, 846–847, 847*f*
MHV structural-functional relationship in, 847–849
spike glycoprotein S in, 849–851
summary for, 851–852
neuroantigens in, 779–786
conclusions for, 785–786, 786*t*
introduction to, 779–780
multiple sclerosis and, 781
T cell clonal cross-reactitvity to, 783–784, 784*t*
T cell cross-reactitvity to, 781–782, 782*t*
T cell cross-reactitvity to, MS and, 784–785
tolerance and, 780
spontaneous remeylination in, 719–799
conclusions for, 799
disease severity in, 792–795, 794*f*, 795*f*
disease severity in, sex hormones on, 795–796, 796*f*
growth factor expression on, 796–799
introduction to, 791–792
T cell epitopes in, 770–776
cell-mediated immunity in, 771, 771*t*
conclusion for, 776
CTL escape in, 772–775, 772*t*
CTL escape in, significance of, 776
introduction to, 770
T cells in, 746–754
anti-viral efforts of, 747–748
CD4 cells and, 750–751
CNS recruitment and, 748
conclusions for, 753–754
as demyelination correlates, 752–753
function during persistence of, 751–752
IFN-γ and, 749–750
introduction to, 746–747
perforin and, 749–750
priming and effector function of, 748
Costimulation, in EAE, 472–484
antigen determinate spreading in, 478
in antigen presentation, 118–119
astrocytes as, 94–95
CD28 requirements for, MS in, 479–480, 479*f*
conclusions for, 484
costimulation requirements in, 481
intravenous tolerance dependence in, 481–482
introduction to, 473
multiple sclerosis (MS) and, 473
multiple sclerosis relevance to, 478
as organ-specific autoimmunity model, 473–477, 474*f*
pathways regulating, 483
peripheral tolerance in, 482
requirements of, 481
T cells in, naive *vs.* memory, 477–478
CTLA-4, 474–477, 474*f*
in costimulation tolerance, 482
Cucurmin, 292
Cuprizone, 537–538
CXCL10, 812–813
Cytokines, in TMEV, 660–664
Cytokines, in EAE, 285–301
on adhesion molecule expression, 172
anti-inflammatory, 296–299
IL-4 as, 296–297
IL-5 as, 297
IL-10 as, 297–298
IL-10 family as, 298
IL-13 as, 298
IL-25 as, 299
TGF-β as, 299
B-cells on, 273, 275–276
in BBB leakiness, 432–433
cellular sources of, 285–286, 286*t*–287*t*
CNS endothelial cell expression of, 157, 159
IFN-β on, 329–330

paradoxical effects of, 300–301
proinflammatory, 289–296
IL-1 as, 289
IL-2 as, 289–290
IL-3 as, 290
IL-6 as, 290
IL-7 as, 290–291
IL-9 as, 291
IL-12 as, 291–293, 294*f*
IL-17 as, 293
IL-18 as, 293
IL-23 as, 293–294, 294*f*
IL-27 as, 295
osteopontin as, 296
TNF as, 295–296
receptors for, 288
T cell subsets in, 288–289
T lymphocytes on, 208–211

D

Demyelinated lesions, in MS, 136–137
Demyelination
canine distemper in, 868–877 (*See also* Canine distemper demyelination)
coronavirus-induced, 697–852 (*See also* Coronavirus-induced demyelination)
Semliki Forest virus (SFV) in, 858–864 (*See also* Semliki Forest virus (SFV))
Demyelination, in EAE, 29–30, 34–35, 34*f*, 35*t*
complement system and, 256–262
macrophage activity in, 122–123
microglia activity in, 114, 122–123
proteases and peptidases in, 393–410 (*See also* Proteases and peptidases, in EAE)
Demyelination, in TMEV
apoptosis and, 697–705
inflammatory response and, 579–583, 581*f*
Diet, in EAE, 536–537
DM20, 52–57, 54*t*, 56*f*

E

Encephalitogen
identification of, 5–6
T cell properties in, 19*t*
Encephalomyelitis, experimental allergic, 3–572. *See also* Experimental allergic encephalomyelitis (EAE)
Endothelial cells, in coronavirus-induced demyelination, 717–729
animal models for, 721
introduction to, 717–720
mouse hepatitis virus and, 721–729
BBB disruption in, 728–729
chemokine production in, 724–726
class I and II antigen expression in, 722–724
conclusions for, 728–729
cytokine production in, 724–726
innate immune system in, 721–722
NO production in, 727–728
Th1/Th2 regulation in, 726–727
Endothelial cells, in TMEV
antigen presentation in, 623–624
epitope spreading in, 624–626
inflammation in, 623–624
introduction to, 617–618
persistent infection in, 618–623, 620*f*, 621*f*
Endothelial PECAM-1, 431–432
Environmental influences, in EAE, 524–540
conclusions for, 540
diet as, 536–537
hyperbaric oxygen as, 539–540
infectious agents as, 525–531, 525*t*
bystander activation in, 529–531
molecular mimicry in, 528–529
superantigen activation in, 526–527
introduction to, 524–525
solar radiation as, 531–535
ultraviolet light in, 532–533
visible light in, 533–535
stress as, 535–536
temperature as, 538–539
toxins as, 537–538
trauma as, 531
Epitope spreading, in TMEV, 601–604
Epitope spreading, in EAE, 478, 492–502
disease induction and, 493
disease progression and, 499–500
intermolecular, 494–495
intramolecular, 494
introduction to, 492–493
mouse models for, 493–494
peptide-specific tolerance in, 500
spreading cascade in, 495–498, 497*f*
therapeutic strategies for, 500–502
TMEV in, 498–499
Estrogens, 554–556
Ethidium bromide, 538
Experimental allergic encephalomyelitis (EAE), 3–572
adhesion molecules in, 160–172 (*See also* Adhesion molecules, in EAE)

adjuvants in, 75–81
complete Freund's adjuvant as, 76–77
introduction to, 75–76
other adjuvants as, 79–80
pertussis as, 77–78
protective effects of, 78–79
apoptotic cell death in, 508–518 (*See also* Apoptotic cell death, in EAE)
astrocytes in, 87–98
conclusions for, 98
costimulation role of, 94–95
inflammatory mediators expression of, 96–97
introduction to, 87–89
in MHC class II antigen presentation, 89–93, 90*f*–92*f*
axonal loss in, 141–146 (*See also* Axonal loss, in EAE)
B cells and antibodies in, 271–276 (*See also* B cells and antibodies, in EAE)
blood-brain barrier in, 417–441 (*See also* Blood-brain barrier (BBB), in EAE)
chemokine system in, 365–375 (*See also* Chemokine system, in EAE)
clinical signs and disease course in, 7*f*, 8, 8*t*
T cells in, 207–208
CNS endothelial cells in, 156–160
cellular transmigration of, 158–159, 158*f*
general properties of, 156–157
inflammatory mediator expression of, 159–160
complement system in, 247–263 (*See also* Complement system, in EAE)
costimulation in, 472–484 (*See also* Costimulation, in EAE)
cytokines in, 208–211, 285–301 (*See also* Cytokines, in EAE)
environmental influences in, 524–540 (*See also* Environmental influences, in EAE)
epitope spreading in, 492–502 (*See also* Epitope spreading, in EAE)
free radicals in, 381–390 (*See also* Free radicals, in EAE)
genetics of, 183–193
genome scans for, 187–188
multiple sclerosis in, 183–185
myelin and major histocompatibility complex (MHC) in, 185–187, 186*t*
non-MHC autosomal susceptibility loci in, 188–193
growth factors in, 345–354 (*See also* Growth factors, in EAE)
histopathology of, 27–42
as autoimmune disease model, 30–31
CNS demyelination in, 29–30, 34–35, 34*f*, 35*t*
CNS inflammation in, 29, 33–34, 33*f*, 34*t*
CNS microanatomy in, 27–28
in Lewis rat, 39–41, 40*t*
in mice, C57B1/6, 36–38, 37*f*, 38*f*
in mice, NOD, 38–39
in mice, SJL/J, 35–36, 36*t*
as multiple sclerosis model, 31–32
in rhesus monkeys and marmosets, 41–42
history of, 4–7
adoptive or passive EAE in, 6
early studies in, 4–5
encephalitogen identification in, 5–6
relapsing EAE in, 6
transgenic models in, 7
hormone and gender on, 548–558 (*See also* Hormone and gender, in EAE)
immunomodulation of, 452–463 (*See also* Immunomodulation, of EAE)
induction of, 13–23
active transfer in, 17, 18*f*
active *vs.* adoptive transfer in, 15–16
adoptive T cell transfer in, 20, 21*f*
antigenic preparations in, 16–17
autoreactive T cell line isolation in, 18–19, 19*t*
clinical manifestation in, 21–22, 21*f*
disease evaluation in, 21–22, 21*f*
introduction to, 13–15
lymph node harvest in, 18
lymphocyte proliferation assays in, 19–20
summary for, 22–23
inflammatory cell migration in, 154–155, 156*f*
interferons in, 315–332 (*See also* Interferons, in EAE)
introduction to, 3
microglia and macrophages in, 111–123 (*See also* Microglia and macrophages, in EAE)
neuroantigens in, 47–64
conclusions for, 64
introduction to, 47–48
myelin biochemistry in, 49–64 (*See also* Myelin, biochemistry of)

myelin cell biology in, 48
pathogenesis of
epitope spreading in, 499–500
IFN-γ on, 317–319
in primates, 562–572 (*See also* Primates, EAE in)
proteases and peptidases in, 393–410 (*See also* Proteases and peptidases, in EAE)
T cell migration in, 154–155, 156*f*
T lymphocytes in, 203–228 (*See also* T lymphocytes)
Extracellular matrix, in canine distemper demyelination, 876–877

F
Fibroblast growth factor, in EAE, 352
Free radicals, in EAE, 381–390
chemistry in, 383–384, 383*f*
conclusions for, 389
introduction to, 381
nitric oxide effects in, 388–389
nitric oxide generation in, 382–383
nitric oxide multiple roles in, 389
peroxynitrite *vs.* nitric oxide in, 386–387
reactive nitrogen species in, 385–386
reactive nitrogen species molecular targets in, 384–385
Freund's adjuvant, on EAE, 76–77

G
Gangliosides, 50
Gender, in EAE, 552–556. *See also* Hormone and gender, in EAE
Genetics, of EAE, 183–193. *See also under* Experimental allergic encephalomyelitis (EAE)
Glial cells, microanatomy of, 28
Glial growth factor, in EAE, 349
Glucocorticoids, in EAE, 549–552
Glutamate, 144
Glycerophospholipids, 50
Growth factors, in coronavirus-induced demyelination, 796–799
Growth factors, in EAE, 345–354
ciliary neurotrophic factor in, 348–349
conclusions for, 354
fibroblast growth factor in, 352
glial growth factor in, 349
insulin-like growth factor-1 in, 349–352
introduction to, 345–346
neurotrophins in, 346–348
T cell encephalitogenic neuroprotection in, 352–353
Growth hormone-releasing hormone, 558
Guillian-Barre syndrome, 528–529
Gut mucosal immune system, 457–458

H
Histopathology
of experimental allergic encephalomyelitis (EAE), 27–42 (*See also under* Experimental allergic encephalomyelitis (EAE))
of TMEV demyelination, 579–588
axonal injury in, 584–588, 585*f*, 587*f*
inflammatory demyelination in, 579–583, 581*f*
introduction to, 579
Hormone and gender, in EAE, 548–558
conclusions for, 558
gender differences in, 552–556
effector phase and, 554
encephalitogenic T cells in, 553–554
sex hormones and, 554–556
susceptibility and severity in, 552
glucocorticoids in, 549–552
mechanism of action for, 551
neonatal therapy with, 552
restraint stress and, 550–551
severity modulation by, 549–550
withdrawal of, 551
introduction to, 548–549
other hormones in, 557–558
pregnancy in, 556–557
Humoral autoimmune response, to neuroantigens, in TMEV, 598–600
antimyelin antibodies in, 598–599
molecular mimicry in, 600, 600*t*
Hyperbaric oxygen, for EAE, 539–540

I
ICAM-1, 167–168
ICOS, 483
IFN-γ, in coronavirus-induced demyelination, 749–750
Immunogenetics, in TMEV, 629–638
DNA polymorphisms in, 632–637, 635*t*
incidence and severity in, 630–632, 632*t*
introduction to, 630
mechanisms regulating, 637–638, 637*t*
Immunomodulation, of EAE, 452–463

antigen-specific strategies for, 456–463
altered peptide ligands in, 462–463
gut mucosal immune system in, 457–458
intravenous tolerance in, 461–462
mucosal immunization and tolerization in, 458–459
mucosal immunotherapy in, 460–461
mucosal tolerance in, 456–457
nasal tolerance in, 461
oral tolerance in, 457
oral tolerance in, pathway deletion and, 459–460
introduction to, 452–463
non-specific strategies for, 454–456
Th1 *vs.* Th2 in, 452–453, 456, 459–460, 462
Immunopotentiation, 75
Immunotherapy, for EAE, 516–517
Incomplete Freund's adjuvant, on EAE, 76–77
Infectious agents, in EAE, 525–531, 525*t*
molecular mimicry in, 528–531
superantigen activation in, 526–527
Inflammation
astrocyte role in, 96–97
in BBB leakiness, 432–433
chemokines in, 120–121
from cytokines, in EAE (*See* Cytokines, in EAE)
cytokines in, 119–120, 285–301
in EAE, 29, 33–34, 33*f*, 34*t*
free radicals and, 381–389 (*See also* Free radicals, in EAE)
IFN-β on, 328–329
reactive oxygen species in, 121–122
T cell migration in, 154–155, 156*f*
in TMEV demyelination, 580–583, 581*f*
Innate immune response, in TMEV, 652–653
Insulin-like growth factor-1, in EAE, 349–352
Integrins, in EAE, 167–169
Interferon beta
on adhesion molecule expression, 172
in immunomodulatory therapy, 517
Interferons, in EAE, 315–332
IFN-α and IFN-b as, 326–330
mechanisms of, 327–330
in vivo evidence for, 326–327
IFN-γ as, 317–325
mechanisms of, 322–325
pathogenesis and, 317–319
production of, 320–321
in vivo evidence for, 321–322
IFN-τ as, 330–332
introduction to, 315–317
Interleukins, in EAE inflammation
IL-1, 289
IL-2, 289–290
IL-3, 290
IL-4, 296–297
IL-5, 297
IL-6, 290
on SAG, 527
IL-7, 290–291

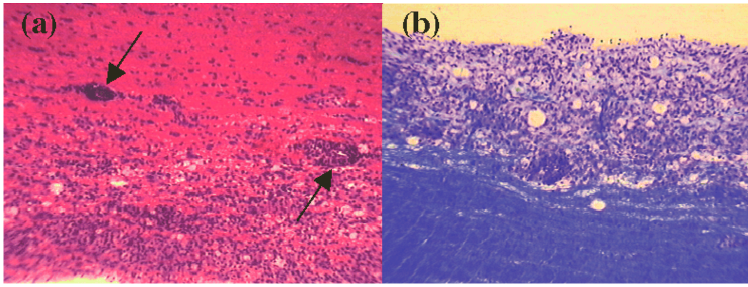

Figure 3-1: Serial longitudinal sections of spinal cord from a C57Bl/6 mouse with MOG induced EAE. (a) In the haematoxylin-eosin-stained section there is an intense mononuclear inflammatory infiltration of the peripheral white matter, with two perivascular cuffs at the margin of the affected area (arrows). (b) In the Luxol fast blue stained section the extent of the demyelination of this area of peripheral spinal cord white matter can be seen relative to the normally myelinated deeper tissue.

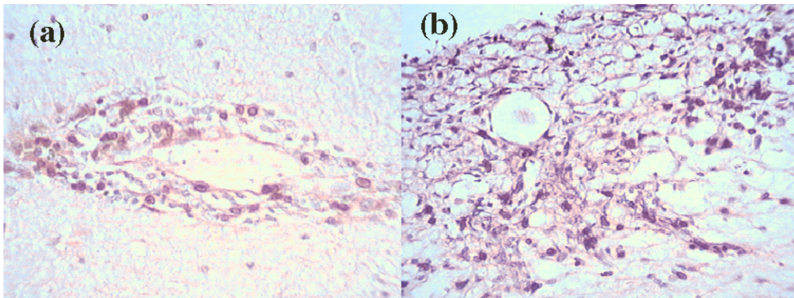

Figure 3-2: Immunohistochemical labelling of sections of spinal cord from a C57Bl/6 mouse with MOG induced EAE. These are formalin fixed, paraffin wax-embedded tissues that have been labelled for expression of CD3 using a cross-reactive polyclonal rabbit anti-human CD3 antiserum in an avidin-biotin immunohistochemical technique. (a) Shows T lymphocytes within a perivascular cuff in affected spinal cord white matter. (b) Shows an area of peripheral spinal cord white matter demyelination, throughout which are scattered individual T lymphocytes.

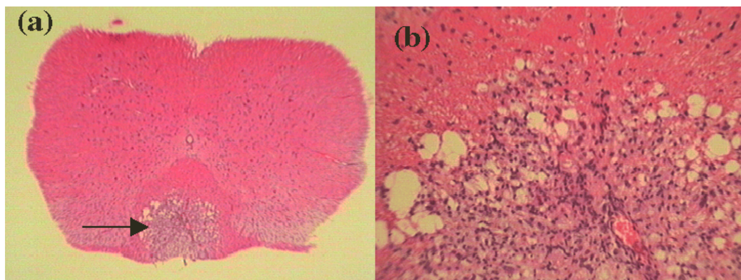

Figure 3-3: Sections of spinal cord from a C57Bl/6 mouse with MOG induced EAE-stained by haematoxylin-eosin. (a) There is an intense inflammatory and demyelinating lesion within the ventral white matter of the cord (arrowed). (b) Higher power view of the margin of this lesion with unaffected white matter, shows extensive macrophage-dominated inflammation.

Chapter A3

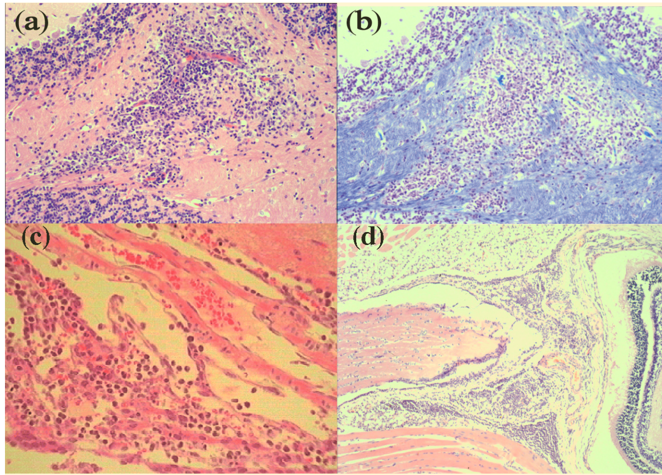

Figure 3-4: Tissues from C57Bl/6 mice with MOG induced EAE stained by haematoxylin and eosin (a, c and d) and Luxol fast blue (b). (a) High power view of cerebellar white matter showing a prominent area of perivascular cuffing with mononuclear inflammatory cells, with extension of the lesion into the parenchyma. (b) This serial section shows that demyelination is restricted to the area occupied by the inflammatory infiltrate, with uninflamed parenchyma showing normal staining reaction. (c) Section through the meninges, showing a mixed inflammatory infiltration throughout the meningeal layers. (d) Section through the retina, optic disc and optic nerve. There is an intense inflammatory infiltration surrounding the optic nerve (perineuritis). This comprises chiefly neutrophils and there are scattered neutrophils within the optic nerve tissue.

Chapter A4

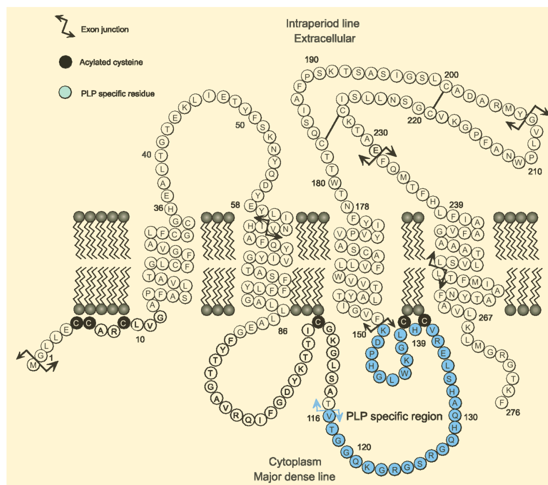

Figure 2: Proteolipid protein 1 structure. PLP1 is predicted to have four transmembrane domains, and both the amino and carboxy-termini in the cytoplamic compartment. A 35-amino acid long domain shaded in blue represents the PLP1-specific region of the protein. Cysteine residues that are predicted to be acylated are shaded in black.

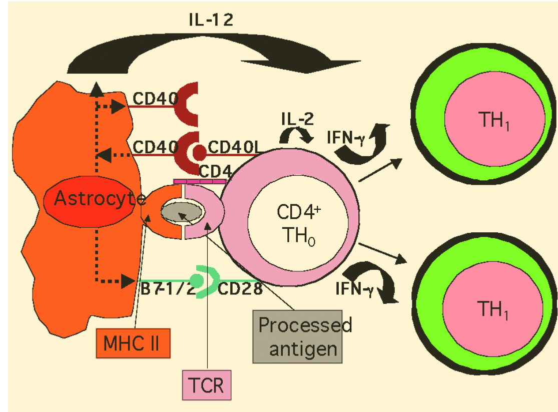

Figure 1: In order for antigen (Ag) presentation in the context of major histocompatibility complex (MHC) class II to occur, some absolute requirements have to be met. An MHC class II heterodimer on the cell surface of an antigen presenting cell (APC) contain and antigen binding groove, which can load a linear peptides that are typically 13-20 amino acids in length. A T cell can bind to Ag within the MHC class II binding groove with its T cell receptor. Only T cells that express the accessory surface molecule CD4 are capable of recognizing and binding linear peptide antigen (Ag) in the context of the MHC class II. Ag-activated T cells express CD40 ligand (CD40L), which engages to the costimulatory molecule CD40 on the cell surface of APC. Cross linking of CD40 and CD40L enhances expression of other costimulatory molecules on APC's, namely B7-1 (CD80), and B7-2 (CD86). Furthermore, engagement of CD40 leads to secretion of the cytokine IL-12, which induces the differentiation of naïve Th0 cells to effector CD4+ Th1 cells. These Th1 cells secrete increased amounts of proinflammatory cytokines like interferon (IFN)-g and IL-2. INF- g is required for induction of class II MHC molecules on nonprofessional antigen presenting cells (APC), including astrocytes. Some studies suggest that IFN-g also causes astrocytes to upregulate expression of B7 (B7-1 and B7-2) molecules, which are required for CD28 T cell costimulation. Thus, in cell-mediated immunity, cross-activation occurs between APC and T cell.

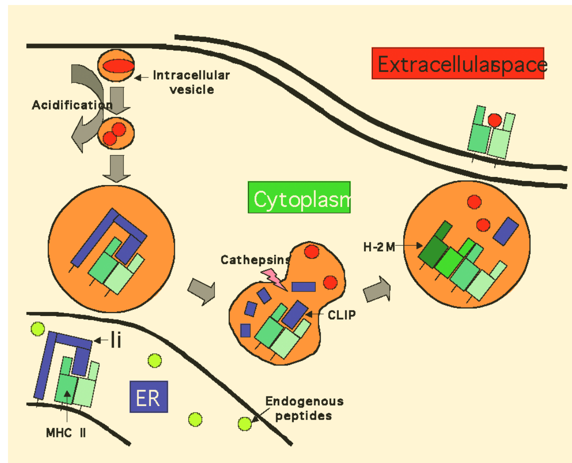

Figure 2: The endocytic compartment. Exogenous protein antigen (Ag) is taken up into an antigen presenting cell (APC) by endocytosis and broken down into peptide through acidification and proteolysis. The major histocompatibility complex (MHC) class II heterodimer is assembled in the endoplasmatic reticulum (ER) and then stabilized by the invariant chain (Ii). Within the ER, the Ii initially is a trimer that can bind three MHC class two heterodimers (not shown). The Ii blocks the MHC class II Ag binding groove, in order to prevent endogenous peptides in the ER from binding. Subsequently, the Ii targets the delivery of MHC class II dimers to the endosomal compartment, where it modulates proteolytic enzymes. Cathepsins are a group of cystein and aspartyl proteases that play a key role in the endosomal degradation of Ag and Ii. The last component of the Ii that remains bound to the MHC class II binding groove is named CLIP. The MHC class II like molecule (H-2M) catalyzes the release of CLIP and low stability peptides from the MHC class II Ag binding groove, and stabilizes empty MHC class II until high affinity peptide can be loaded. H-2M cannot bind Ag itself, and it is not expressed on the cell surface. Peptide loaded into the MHC class II binding groove can now be transported to the cell surface and presented to CD4+ T cells.

Chapter A6

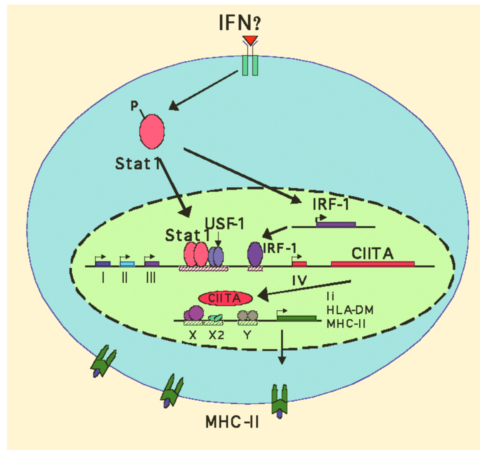

Figure 3: The major histocompatibility complex (MHC) class II transactivator (CIITA), a transcriptional co-activator, is the key molecule that directs interferon-gamma (IFNg)-inducible MHC class II expression in nonprofessional antigen presenting cells (APC) and constitutive MHC class II expression in professional APC. CIITA expression is controlled at the level of transcription by differential activation of multiple nonhomologous promoters. CIITA promoter, pIV, which contains a GAS site, E-box, and IRF element, directs IFNg-inducible CIITA expression in non-professional APC. It has been demonstrated that statins decrease IFNg inducible MHC class II surface expression through inhibition of CIITA pIV.

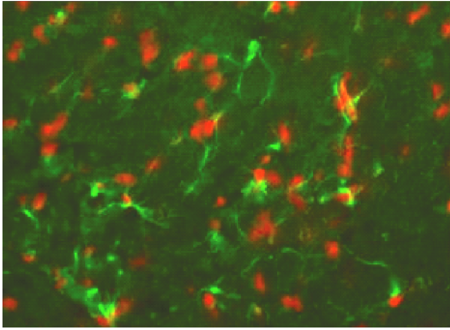
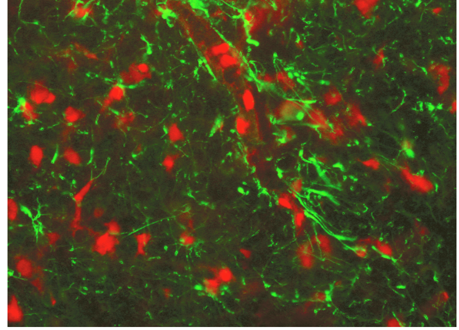
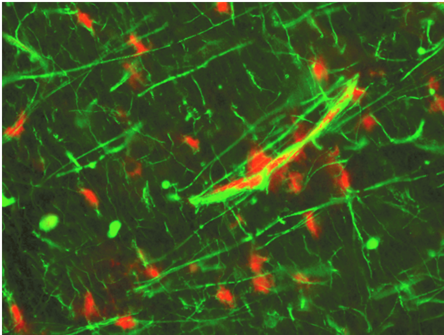
Figure 1 (continued)



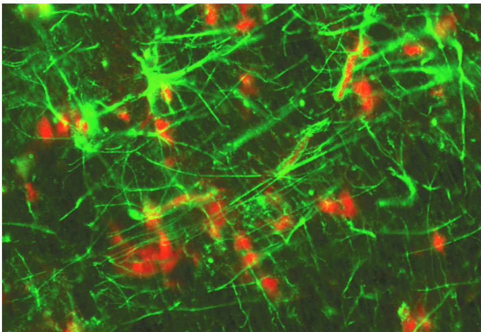
ADAM 17 expression in normal control rat brain parenchyma



ADAM 17 (TACE) expression by perivascular astrocyctes in spinal cord of EAE rats



ADAM 17 expression by endothelial cells and astrocytes within spinal cord of EAE rats.



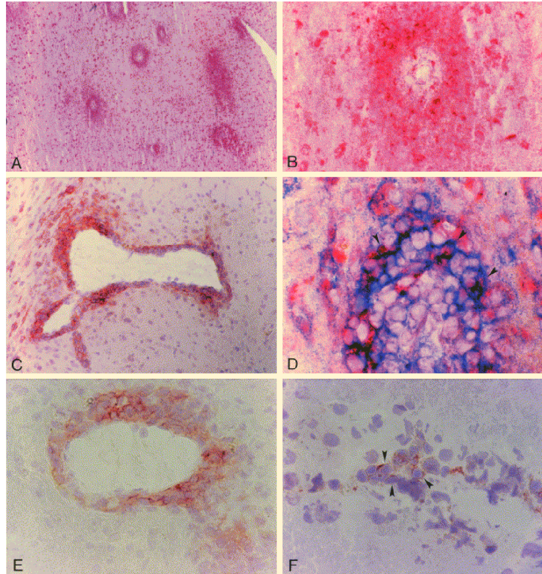


Figure 2: Expression of accessory molecules and cytokines in marmoset EAE brain. (a) Acid phosphatase (red) expressed by infiltrating macrophages and activated microglia (magnification = x40); (b) Detail of (a), showing extensive perivascular infiltration by macrophages (red)(x200); (c) CD40 (red) expressed on infiltrating mononuclear cells (x100); (d) Doublestaining showing macrophages with cytoplasmic acid phosphatase activity (red) and membrane CD40 expression (blue). Arrowheads indicate examples of macrophages expressing CD40 (x650); (e) CD40L (red) expressed on perivascular mononuclear cells (x200); (f) Scattered CD40L-expressing cells (red) within an infiltrate (x325). Figure reproduced with permission, from ref 17.

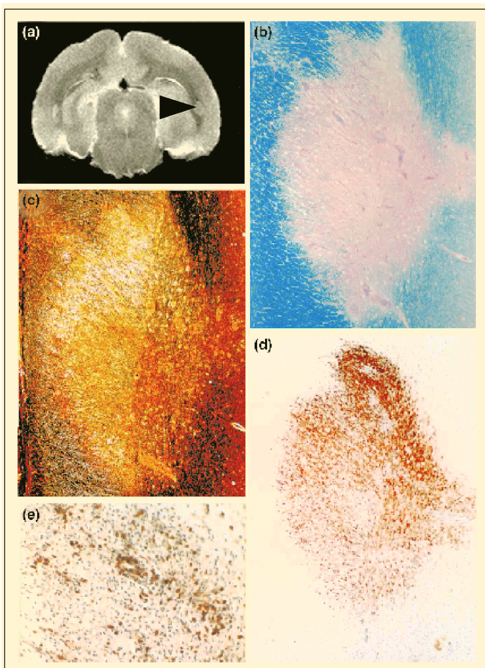

Figure 4: Histopathology of a magnetic resonance imaging (MRI)-detectable lesion in common marmosets. (a) coronal slice of a T2-weighted MRI recorded post mortem shows at least three MRI-detectable lesions (magnification = x2.5). The lesion indicated with the arrowhead was processed for histology. (b) Klüver-Barrera staining visualises myelin in blue, showing strong demyelination (x99). Within the same lesion axonal conservation was confirmed by Bielschowsky silver impregnation (x 99). The presence of numerous 27E10-positive macrophages (orange) (d) and CD3+ T-cells (brown) (e) classifies the lesion as late-active (x246). Figure reproduced with permission, from ref 14.

Chapter B3

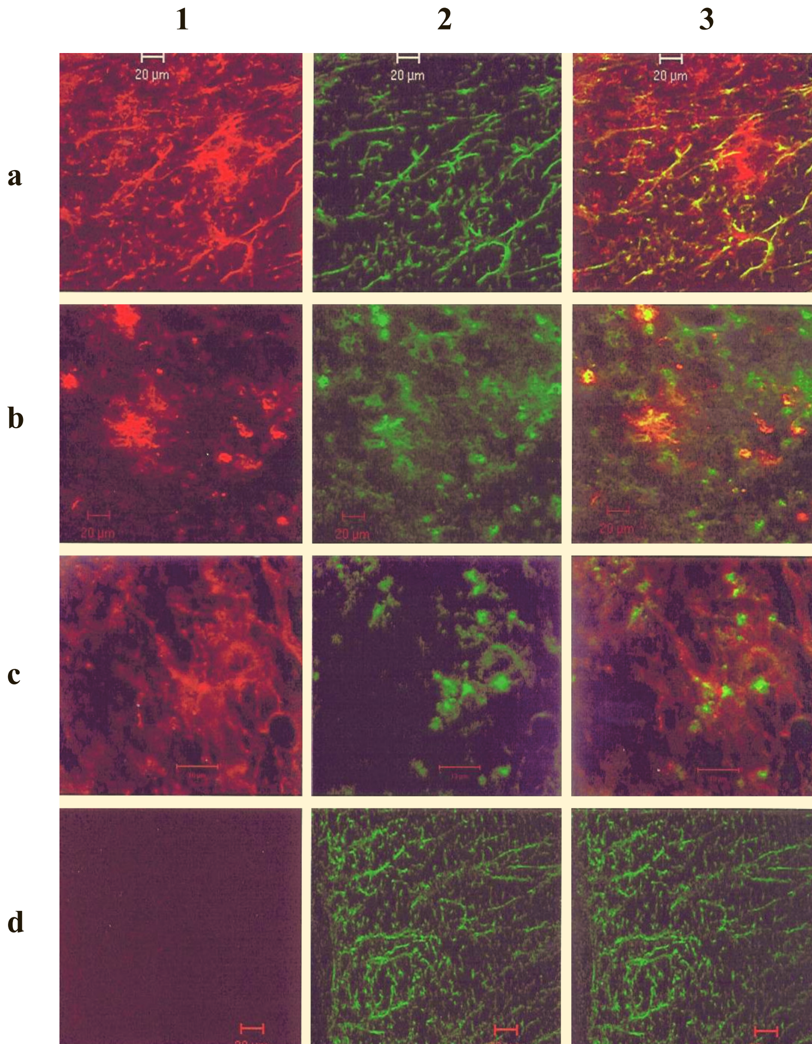

Figure 2: Immunohistologic analysis of spinal cord tissues from mice suffering from TMEV-induced demyelinating disease or EAE disease. Double immunostaining of frozen sections was done using both the BeAn antisera with a rhodamine conjugated secondary antibody (red) and different antibodies to cell specific markers with FITC-conjugated secondary antibodies (green). Column 1: viral antigen in (a) astrocytes, (b) microglia, (c) oligodendrocytes and (d) EAE. Column 2: (a and d) anti-GFAP for astrocytes, (b) MOMA-2 for macrophages, (c) anti-CNPase for oligodendrocytes. Column 3:colocalization of the two stains. Bar in row C measures 10 microns; all other bars measure 20 microns. (Reproduced with permission from J Neuroimmunol 118:256-267, 2001)

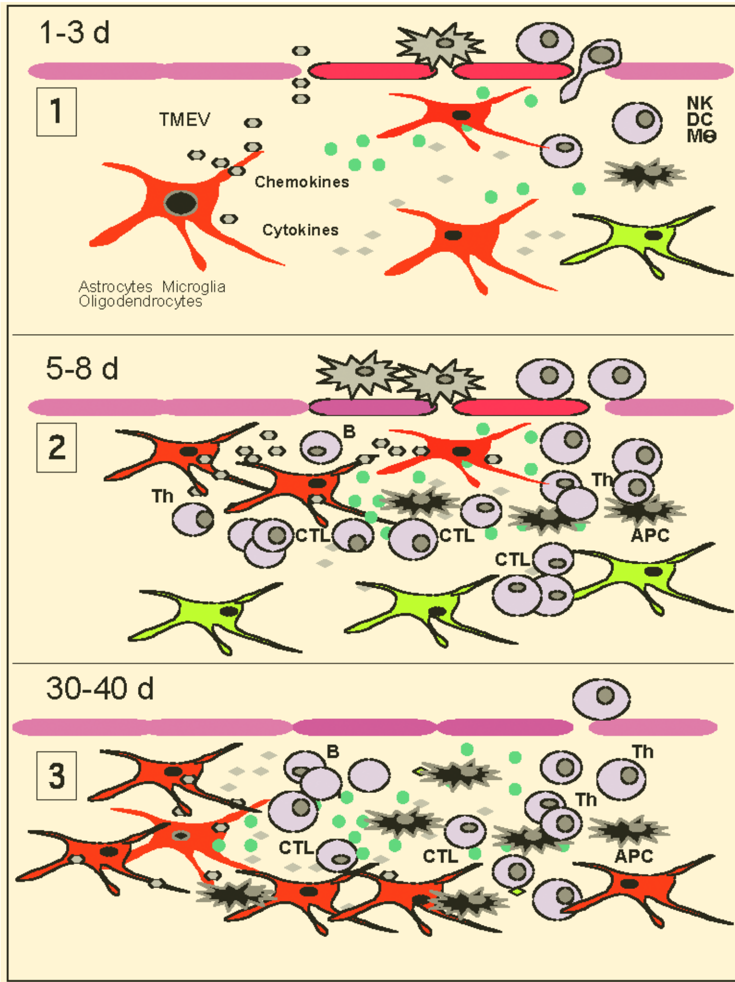

Figure 1: Schematic presentation of the steps involved in TMEV-induced demyelinating disease. (1) Early, (2) Acute and (3) Chronic responses in the CNS following viral infection. (1). At the Early stage, mainly chemokine, cytokine and adhesion molecule responses are directly induced in various glial cells upon viral infection. These molecules may further activate adjacent glial cells and facilitate cellular (NK, DC, macrophages, neutrophils) infiltration to the CNS. (2). At the Acute stage, various immune cells (B, Th and CTL) are infiltrated. These immune cells will be further stimulated/amplified by viral Ag-APCs (professional and non-professional). Virus will be neutralized and virus-infected cells will be eliminated by immune cells. (3). At the Chronic stage, viral persistence remains and continuous inflammatory responses are maintained in susceptible mice, whereas completely cleared viral persistence and the inflammatory response is resolved in resistant mice.

Chapter B8

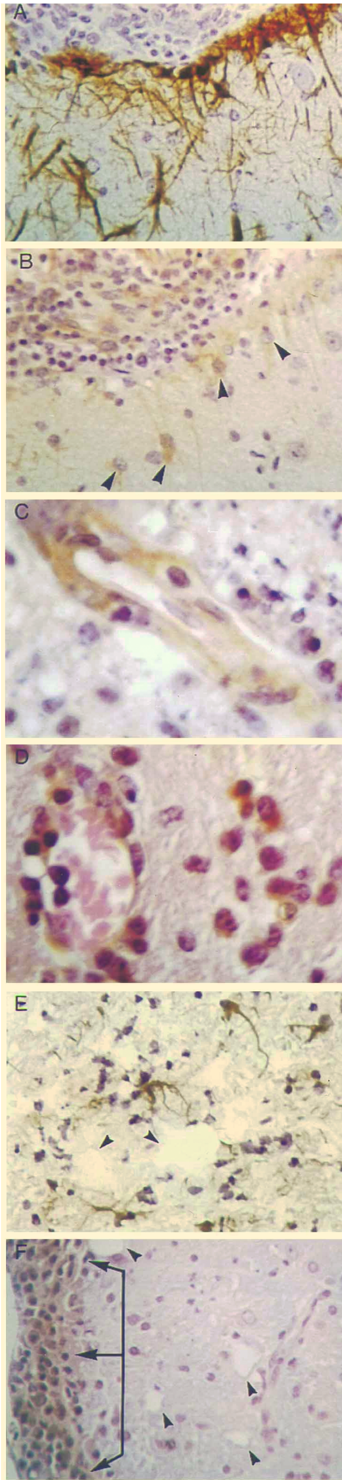

Figure B8-1: IHC localizations of GFAP (A) and iNOS protein in the CNS of SJL mice at 10 (A-C), 6 (D), 42 (E and F), and 66 (G) days p.i. (A) Encephalitis and poliomyelitis phase: an area of intense leptomeningeal inflammation accompanied by reactive astrogliosis in the subjacent brain parenchyma, which is highlighted by GFAP staining. (B) Same field from an immediately adjacent section exhibiting iNOS-like staining in reactive subpial astrocytes (arrowheads) as well as in scattered monocytes/macrophages in the overlying leptomeningeal infiltrate (top portion of photomicrograph). (C) Encephalitis and poliomyelitis phase: iNOS-like localization in hypertrophic endothelial cells of a blood vessel amidst an area of necrotizing encephalitis. (D) Encephalitis and poliomyelitis phase. iNOS-like staining in cells of the monocyte/macrophage lineage and in vascular endothelial cells from an area of spinal grey matter inflammation. (E) Early stage of spinal cord demyelination exhibiting a number of scattered iNOS-positive astrocytes in a background of incipient vacuolar changes (arrowheads) suggestive of early demyelination involving the lateral column. (F) Spinal cord demyelination phase: Focal, weak, and ill-defined iNOS-like immunoreactivity is detected among leptomeningeal infiltrates (the three arrows) which are encroaching upon the lateral funiculus of the spinal cord. Note vacuolar change in the lateral column (arrowheads). (G) Spinal cord demyelination phase: Lack of iNOS-like staining in large foamy (myelin-laden) macrophages in full-blown demyelinating lesions in the posterior columns of the thoracic cord. (Original magnifications: A, B, E, F x400; C, D. G x1000)

Chapter C9

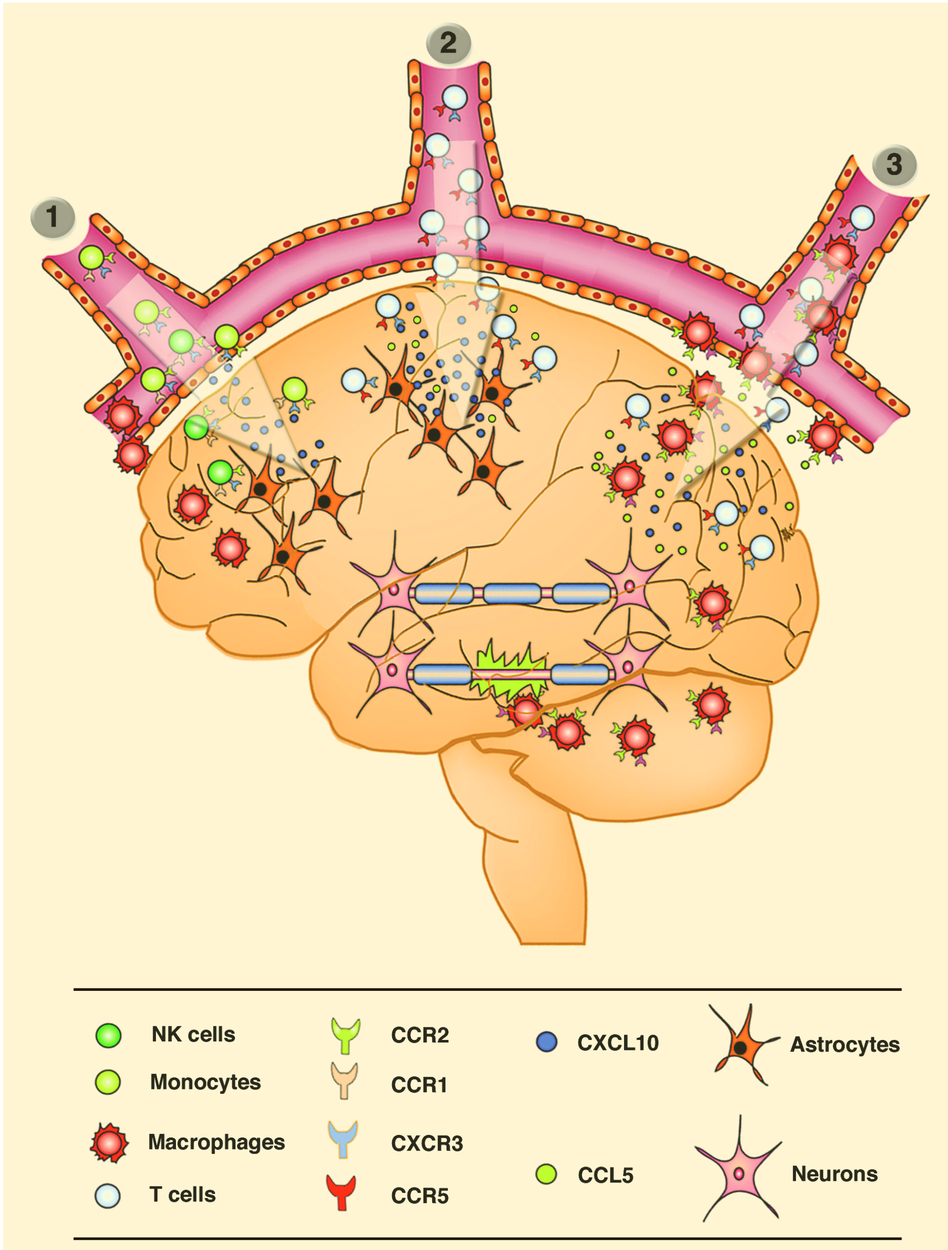

Figure C9: MHV infection of the CNS
