89.1 INTRODUCTION

More than a decade ago, we wrote an update on the *Rhizobium*–legume symbiosis asking the question "what makes this symbiosis so special?" (Hirsch et al., 2001). Since that time, we have learned a great deal more about this important plant–microbe association. However, the story of symbiotic nitrogen fixation in legumes has become more complicated due to the discovery of several Betaproteobacteria, namely species of *Burkholderia* and *Cupriavidus*, which also establish nitrogen-fixing nodules on legumes. In this chapter, we expand our analysis of the *Rhizobium*–legume symbiosis to include the betarhizobia, specifically *Burkholderia*, and their relevance to this well-studied, beneficial interaction between bacterium and plant.

In particular, we examine the concept of host range, biogeography, as well as evolutionary history with respect to nodulation by *Burkholderia* and *Rhizobium* (see also Chapter 17). Phylogenetic analyses strongly indicate that both genera acquired the nodulation genes at approximately the same time as the legumes were evolving (Bontemps et al., 2010). We elaborate on this evolutionary theme as we delve into the even earlier history of these two nodulating and nitrogen-fixing bacterial families, with the goal of establishing an evolutionary description of this still incompletely understood symbiosis.

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

89.2 THE LEGUMES

The legumes (Fabaceae or Leguminosae) are the third largest family of flowering plants (>19,000 species); only Asteraceae and Orchidaceae are larger (Lewis et al., 2005). The family is monophyletic, but comprises three subfamilies (36 tribes), namely Caesalpinioideae, Mimosoideae, and Papillionoideae, which represent 22%, 10%, and 67%, respectively, of the family (Sprent, 2001). Of the three subfamilies, caesalpinioid legumes are less likely to be nodulated, but this is not because they evolved first (Sprent, 2007). Several caesalpinioid legumes considered to be "basal" are not found in the fossil flora in the early history of the family (Herendeen et al., 1992).

The structure of the flowers of the subfamily members differs significantly (Fig. 89.1), but legumes are incredibly diverse in many other features, including phytochemical profiles, nodulation status, and habitats. Legumes occupy deserts and grass-poor, succulent-rich, dry environments (S-biomes); tropical rain forests (R-biomes); grass-rich prairies and savannahs (G-biomes); temperate ecosystems (T-biomes); and agricultural systems derived from anthropogenic input. Numerous books and papers have described the biology, nodulation, and evolution of the legumes, so we describe only a few salient features in this chapter (Sprent, 2001; Doyle and Luckow, 2003; Lewis et al., 2005).

The legumes are believed to have evolved ca. 65–50 million years ago (Mya) in the late Cretaceous/early Tertiary after the K/T extinction (Lavin et al., 2005). This hypothesis is in part based on the discovery of legume fossils dating from the Paleocene (ca. 66–56 Mya; Herendeen et al., 1992) and also on molecular analysis developed from *matK* and *rbcL* phylogenies (Lavin et al., 2005). The evolutionary migration of legumes southward is postulated to have started north of the Tethys Sea, under warmer climate conditions, after the continents drifted apart (see Doyle and Luckow, 2003; Sprent, 2007). This boreotropical origin, deduced in part from the current habitats of legumes, is consistent with the migration of legumes from an S-biome to the R-, G-, and T-biomes (Lewis et al., 2005). Both molecular and fossil data suggest that legumes rapidly diversified into most of their major lineages within a relatively short period of time (ca. 55–50 Mya) (Herendeen et al., 1992; Doyle and Luckow, 2003; Lewis et al., 2005; Sprent, 2007, 2008). This is approximately the same time that the rest of the angiosperm families were evolving (Lewis et al., 2005). The boreotropical forest migration hypothesis has replaced the older Gondwanan theory in which legumes moved northward from their presumed sites of origin in Africa to South America and then, before the land masses drifted apart 165–145 Mya, to North America. Nonetheless, the boreotropical hypothesis leaves much unexplained, especially with regard to the evolution of legume nodulation (Sprent, 2008; see Chapter 3).

Although nodules have not been found in the fossil record, it is extremely likely that many of the legumes were already developing root nodules inhabited by nitrogen-fixing rhizobia by the time that the major lineages were established. The partnership between rhizobia and legumes is based on a pre-existing and ancient relationship, dating from the early Devonian (416–350 Mya) between arbuscular mycorrhizal fungi (AMF) and plants. The evolutionary origin of the genes important for root nodulation that was derived from the arbuscular-mycorrhizal (AM) symbiosis has been extensively studied and reviewed (Hirsch et al., 2001; Szczglowsky and Amyot, 2003; Streng et al., 2011; and others; see also Chapters 42, 54, 55, 108, 110).

89.3 THE RHIZOBIA

"Rhizobia" is the collective term given to bacteria capable of inducing the development of and then populating nitrogen-fixing nodules (Sprent, 2001). A long-standing debate exists over whether legumes and rhizobia coevolved or whether the plants selected for symbiotic bacteria, but the presence of horizontal gene transfer and the lack of parallel speciation between legumes and rhizobia might argue against a coevolutionary trajectory (Martínez-Romero, 2009; Young and Johnston, 1989).

Up to 2001, only the Alphaproteobacteria in the family Rhizobiaceae had been classified as rhizobia. These bacteria

Figure 89.1 Examples of flowers from the three legume subfamilies. (a) Caesalpinoideae: *Chamaecrista fasciculata* (N.A. Fujishige). (b) Mimosoideae: *Caliandra hematocephala* (A.M. Hirsch). (c) Papillionoideae: *Swainsona formosa* (W. Deng).

were first isolated from root nodules by Beijerinck (1890), and the name *Rhizobium* was suggested shortly afterwards by Frank (1889) (see additional references in Gyaneshwar et al., 2011; see Chapter 88). Until the 1980s, all the legume root-nodulating bacteria (RNB) were classified in the genus *Rhizobium*, which had been divided into fast and slow growers. After it became apparent that significantly greater differences than just growth rate existed, *Bradyrhizobium* (*Bradyrhizobiaceae*) was proposed by Jordan (1982) to encompass the slow-growing species whereas the name *Rhizobium* was retained for the fast growers. Using a molecular clock approach, the split between *Rhizobium* and *Bradyrhizobium* is estimated to have taken place 800–300 Mya depending on the gene analyzed (Turner and Young, 2000).

Rhizobium has also been subdivided into a number of distinct genera. Chen et al. (1988) isolated fast- and slow-growing rhizobia from nodules of soybean (*Glycine soja*) and from soil, and after analyzing cellular composition and by using methods such as DNA–DNA hybridization, serology, and phage typing, proposed a new genus, *Sinorhizobium*. Thus, the fast-growing isolate *Rhizobium fredii* was renamed *Sinorhizobium fredii*. In 2008, however, taxonomists questioned whether *Sinorhizobium* was distinct from the genus *Ensifer*, and the Judicial Commission of the International Committee on Systematics of Prokaryotes (2008) decided that it was not, and thus the name *Ensifer*, which had priority, was retained (see also Chapter 3). Later, other genera were described, including *Azorhizobium* (Dreyfus et al., 1988), which was placed in the family *Xanthobacteraceae*, and *Mesorhizobium* (Jarvis et al., 1997) in the *Phyllobacteriaceae*. The genus *Phyllobacterium* contains three rhizobial species that are closely related to *Mesorhizobium* (Valverde et al., 2005; Mantelin et al., 2006).

Concurrently, additional RNB from Rhizobiales were added to the list: *Devosia neptunia* (family *Hyphomicrobiaceae* (Rivas *et al.*, 2003)); *Ochrobactrum* (Trujillo et al., 2005; Zurdo-Piñeiro et al., 2007) (family *Brucellaceae*); *Microvirga* (Ardley et al., 2012; see Chapter 23); and *Methylobacterium* (family *Methylbacteriaceae*) (Jourand *et al.*, 2004). Each family that contains RNB also houses nonrhizobial species, some of which are pathogenic on animals or plants. For example, most of the *Xanthobacteraceae* are nonnodulating species and many *Brucellaceae* are human pathogens. As another example, *Bradyrhizobium* is closely related to the genus *Apifia*, which includes human pathogens (La Scola *et al.*, 2002).

Other novel species of rhizobia recently isolated include *Shinella kummerowiae* from the herbal legume *Kummerowia stipulacea* in China (Lin et al., 2008). This genus is closely related to *Rhizobium* and the bacteria are often found as nodule occupants and in soil samples, but had not been shown previously to induce nodules. The diversity of organisms that function as RNB is summarized in Figure 89.2.

89.4 THE BETARHIZOBIA

In 2001, two genera of the family *Burkholderiaceae*, *Burkholderia* and *Cupriavidus*, were reported to nodulate legumes, but at that time were not shown to induce effective, that is, nitrogen-fixing nodules on their hosts (Moulin et al., 2001; see Chapter 17). Much of the original work on the *Burkholderia* symbiotic species focused on *B. tuberum* and *B. phymatum*, but it was quickly shown that neither species re-infected the hosts from which they were originally isolated (*Aspalathus carnosa* and *Machaerium lunatum*, respectively). Later studies showed that both genera established nitrogen-fixing nodules with a number of legume hosts. The majority of *Burkholderia* species have been isolated from nodules of Mimosoideae, especially the genus *Mimosa*. *Mimosa* spp. are native to the Neotropics although a few endemics live in the Paleotropics, mainly in Madagascar, and also extend into southeast tropical Africa and India (Lewis et al., 2005; see Chapter 17).

Some *Burkholderia* species are free-living and function as soil-dwelling microbes in bioremediation or act as plant growth-promoting bacteria (PGPB) living as epiphytes on plants (de Bruijn, 2013). Still others appear to be endophytes based on their isolation from both legume and nonlegume hosts following surface sterilization of plant tissues (Compant et al., 2008). However, many of these species have not been rigorously confirmed as either endophytes or PGPB based on experimental studies, with the exception of *B. phytofirmans* (Sessitsch et al., 2005).

Yabuuchi et al. (1992) split *Burkholderia* from *Pseudomonas* homology group II and named the genus for W.H. Burkholder, who isolated the etiological agent of onion rot (Burkholder, 1942). *Burkholderia* species, other than the RNB (shown in Fig. 89.3), are ubiquitous in the environment and are found in soil, rhizosphere, clinical samples, plants, fungus, insects, and animals (Compant et al., 2008). *Burkholderia* species have long been associated with plant and animal pathogenesis, and all of the initial species moved from *Pseudomonas* to *Burkholderia* demonstrated virulence toward numerous plants and animals (Compant et al., 2008). However, efforts have been initiated to differentiate the symbiotic and environmental *Burkholderia* species from the opportunistic, mammalian, and plant pathogens, and have led to the proposal that the former be assigned to a new group/genus because it is phylogenetically distinct from the *Burkholderia* group (Angus et al., 2014, Estrada-de Los Santos et al., 2013, Suárez-Moreno et al., 2012; see also Chapter 17).

89.5 THE ROOT-NODULATING *Burkholderia* SPECIES

To study the evolution of symbiotic genes, Bontemps et al. (2010) prepared a phylogenetic analysis using partial

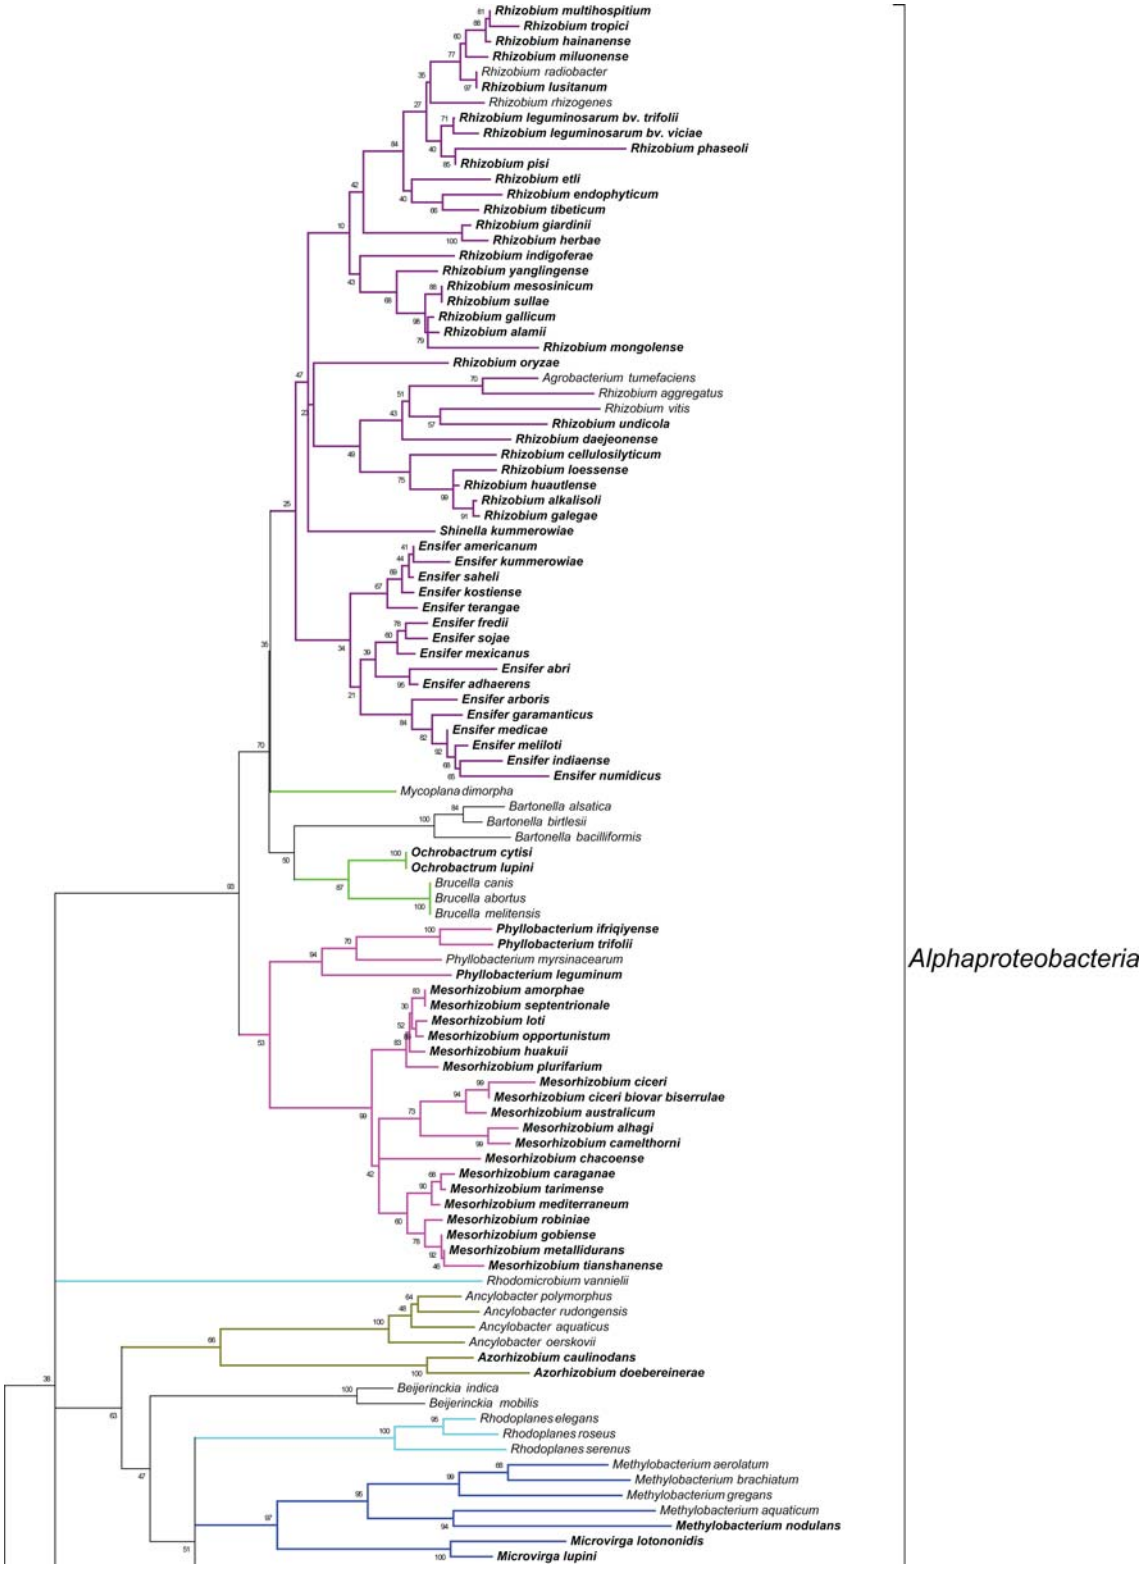

Figure 89.2 Unrooted phylogenetic reconstruction of 16S ribosomal RNA of rhizobial and related nonrhizobial species by Neighbor Joining. Bootstrap percentage after 1000 replications is shown on nodes. Scale bar represents the number of substitutions per site. Colored nodes represent each of the main families with genera containing rhizobia (in bold). Purple, *Rhizobiaceae*; green, *Brucellaceae*; pink, *Phyllobacteriaceae*; olive, *Xanthobacteraceae*; turquoise, *Hyphomicrobiaceae*; blue, *Methylobacteriaceae*; orange, *Bradyrhizobiaceae*; red, *Burkholderiaceae* (see also Chapter 17).

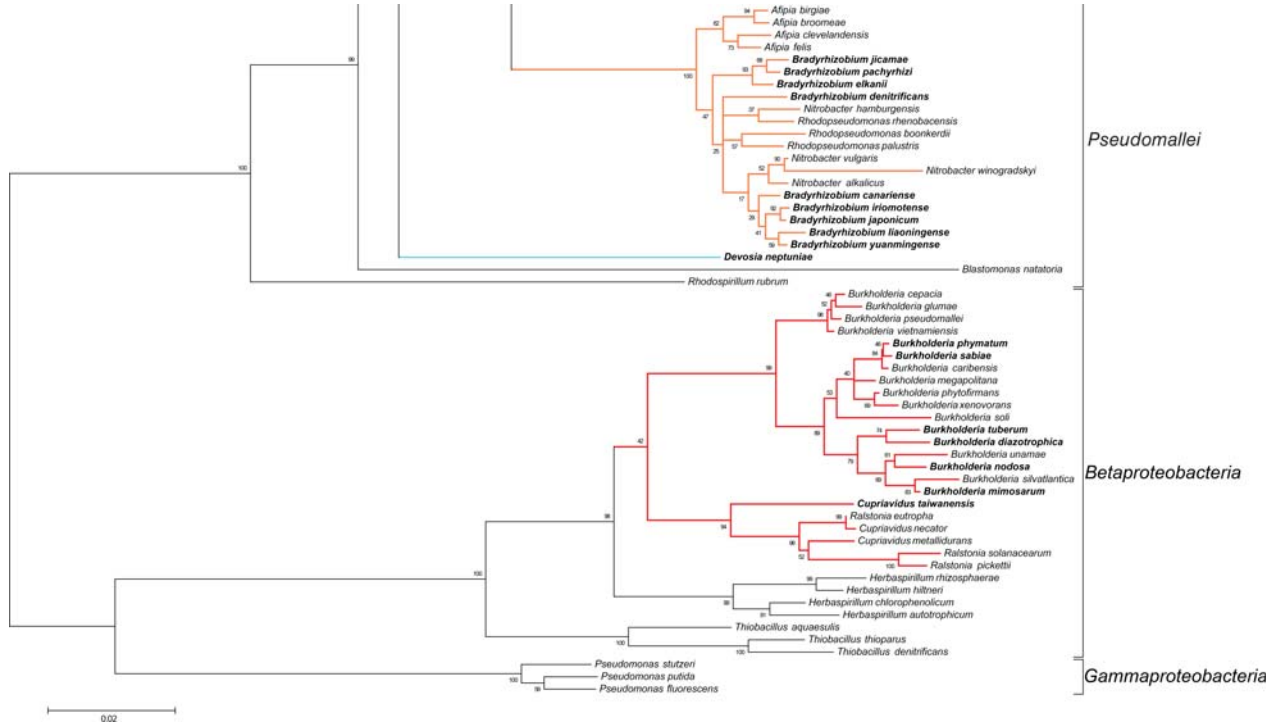

Figure 89.2 (*Continued*)

sequences of the 16S, *recA*, *nodC*, and *nifH* regions of isolates from nodules of 47 species of *Mimosa* spp. growing in various regions of Brazil. All sequences were highly homologous to *Burkholderia* species from seven distinct clusters (clades). Four of the seven clusters observed by Bontemps et al. (2010) contained named species of *Burkholderia* RNB (cluster 2, *B. phymatum*; cluster 4, *B. mimosarum*; cluster 5, *B. nodosa*; and cluster 6, *B. tuberum*). However, three clusters represented novel species (clusters 1, 3, and 7). Based on recent evidence, cluster 3 is closely related to the recently described *B. diazotrophica* (Sheu et al., 2013); one isolate within this cluster, *Burkholderia* sp. mpa3.10 shares over 99% 16S and *recA* sequence homology to *B. diazotrophica* (Walker & Watkin, *unpublished*). Isolates from cluster 7 may be related to the recently sequenced *B. phenoliruptrix* (de Oliveira et al., 2012), and are also closely related to *B. fungorum*. Cluster 1 may contain the recently described *B. symbiotica*, which is the first *Burkholderia* sp. RNB characterized that is not closely related to other Brazilian species (Sheu et al., 2012).

The study by Bontemps et al. (2010) gave us important insight into the evolution of nodulation in *Burkholderia* by showing that it had a long and stable genetic history (Angus and Hirsch, 2010), which is most likely as old as that of the nodulating Rhizobiales. Phylograms reconstructed from partial *nodC* sequences place South American *Burkholderia* symbiotic genes in a monophyletic group that is highly divergent from all other *nodC* sequences and further suggest that any *nod* gene transfer event that occurred must have taken place at least 50–60 Mya (Bontemps et al., 2010). This transfer of symbiotic genes coincides with the period when the legumes themselves were diversifying into their major lineages (Fig. 89.4).

The legume genus *Mimosa* is almost exclusively nodulated by species of *Burkholderia* (see also Chapter 17). *Mimosa* most likely followed a boreotropical migration from north to south and this theory is supported by fossil evidence in North America and Europe, but palynological data have also been collected in Africa (Herendeen et al., 1992). However, disjunct populations of *Mimosa* in South Eastern Africa, Madagascar, and India may have originated from long-distance oceanic dispersal (Simon et al., 2011). Some of these introduced populations might be coincident with the southern hemisphere locations of the isolated RNB *Burkholderia* species (Fig. 89.3).

In contrast to the South American *Burkholderia* species, the South African *B. tuberum* strains nodulate papillionoid legumes. This nodulation preference is correlated with nodulation (*nod*) and nitrogen-fixation genes (*nif*) gene sequence organization, which differ between the South

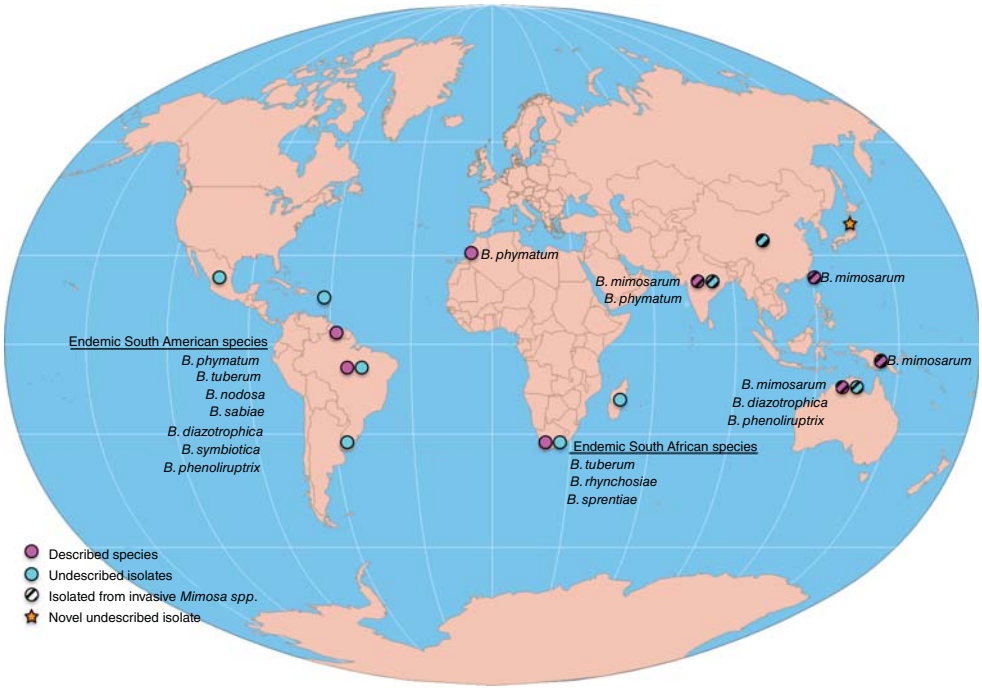

Figure 89.3 Distribution of characterized type strains and undescribed isolates of *Burkholderia*. Note the mostly southern hemisphere distribution of the strain isolations. Strain CCGE1002 (Mexico) is described as *B. tuberum* in Mishra et al., (2012).

African and South American RNB. One hypothesis posits that the establishment of *Mimosa* from long-distance oceanic dispersal may have led to the introduction of *B. tuberum* into South Africa, where it could have lost the ability to nodulate *Mimosa* in favor of the endemic Papillionoideae population following the lateral transfer of local *nod* genes (from alpha rhizobia?). *Mimosa* introduction has been observed in Australia with the accidental importation of South American *Burkholderia* species, including *B. diazotrophica* and *B. mimosarum* (Walker and Watkin, *unpublished*), on introduced *M. pigra* seeds (Parker et al., 2007).

The idea of introduced *Mimosa* species, however, does not adequately explain the distinct lineages of *Burkholderia* species found in South Africa that nodulate papillionoid legumes. The first lineage described is typified by the type strain *B. tuberum* STM678^T, originally isolated from *A. carnosa*, whereas a second lineage contains the recently described *B. rhynchosiae* (De Meyer et al., 2013a), which nodulates species of *Rhynchosia* (Garau et al., 2009). So far, no information is available about *nod* and *nif* gene organization in *B. rhynchosiae*, nor about how these symbiotic genes compare to those of *B. tuberum* STM678^T except for the fact that the *nodA* genes are 96% identical (Garau et al., 2009). Another lineage, *B. sprentiae*, is more closely related to *B. tuberum* STM678^T, but it nodulates *Lebeckia* spp. (De Meyer et al., 2013b). Numerous South African species have been recently isolated and many are in the process of being described (Beukes et al., 2013; De Meyer et al., 2014). Such studies will increase our understanding of this group of *Burkholderia* spp.

89.6 REGARDING THE EVOLUTION OF NODULATING *Burkholderiaceae* AND *Rhizobiaceae*

A limited fossil record exists for bacteria, except for cyanobacteria where fossils resembling these organisms have been reported from the Archean period of Earth history (Schopf, 2006; Javaux et al., 2010). Nonetheless, questions remain as to their actual identity and whether or not cyanobacterial photosynthesis evolved that early. In any case, most agree that marine bacteria probably evolved about 3.5 billion years ago (Gya). Undisputed microfossils from 1.2 Gya have been found (Horodyski and Knauth, 1994) (Fig. 89.4). Due to the debate about the exact nature of the fossils from 3.5 Gya, conclusions regarding bacterial evolution are based mainly on geochemical evidence, the detection of biomarkers, and isotope ratios (Fischer, 2008). The accumulation of such information has strongly suggested that bacteria achieved a terrestrial lifestyle (became terrabacteria) some 2.7–2.6 Gya (Watanabe et al., 2000) (Fig. 89.4). Moreover, it appears that many prokaryotic lineages were already evolved as early as 2.7–2.5 Gya, supporting the even older history for the earliest bacteria.

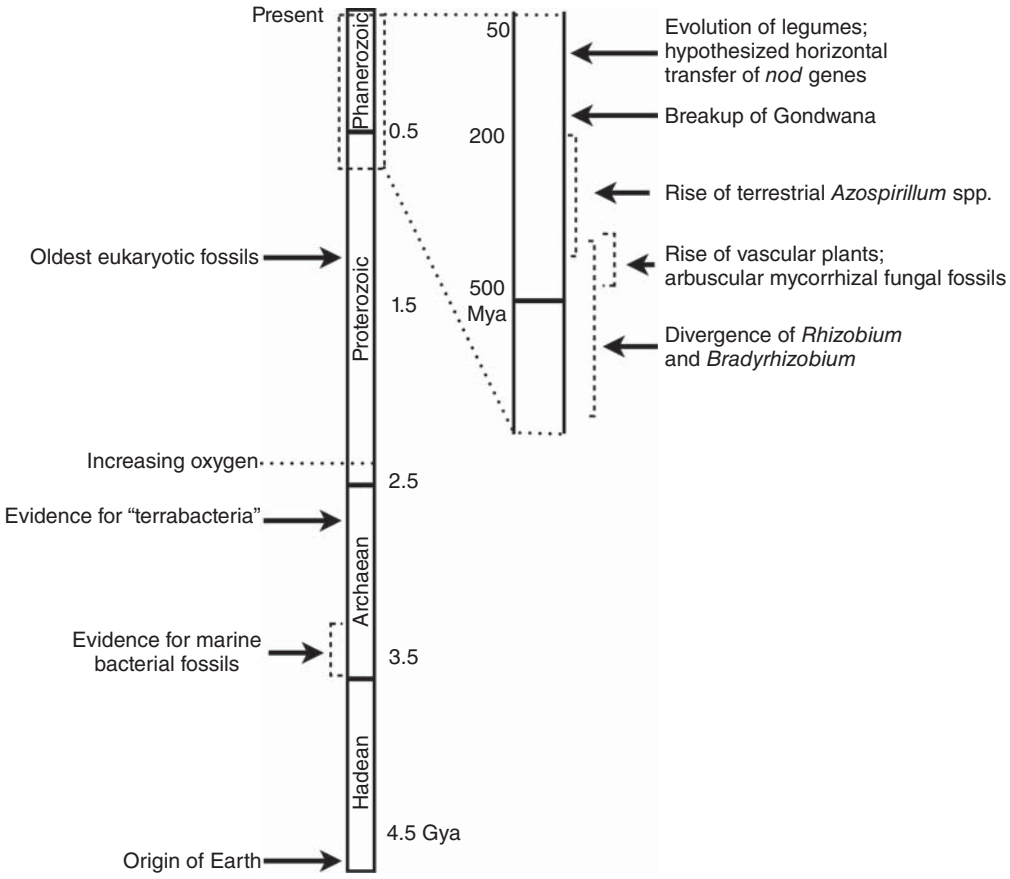

Figure 89.4 Timeline showing some key points in the evolution of the legumes and their associated nitrogen-fixing bacteria. (*Source:* Modified from Fischer (2008).)

More recently, genome analysis has been used to study bacterial evolution. Wisniewsky-Dyé et al. (2011) proposed the divergence of terrestrial azospirilla from their aquatic *Rhodosporillaceae* relatives had occurred ca. 200–400 Mya based on their distinct genomes. Almost half of the terrestrial azospirilla genomes appear to have been derived by horizontal gene transfer from Rhizobiales and other Alphaproteobacteria (greatest percentage) and also from Burkholderiales, suggesting that these groups evolved long before *Azospirillum* diverged. Therefore, Rhizobiales and Burkholderiales were likely to have been among the bacterial lineages that colonized the land prior to the evolution of the vascular plants, the vast majority of which established a symbiotic association with AMF (Fig. 89.4). Both fossil and molecular evidence date the AMF association with plants to have been present ca. 430–350 Mya in the early Devonian (Simon et al., 1993; Taylor et al., 1995). Because many of the plant genes involved in establishing the AM symbiosis and the nitrogen-fixing nodule are conserved and also because the initial microbial signal molecules are chemically related (see references in Hirsch and Fujishige, 2012; see Chapters 55, 110), the idea that nitrogen-fixing rhizobia coopted the ancient mycorrhizal signaling pathway to ensure root cell entry and subsequent nodulation for the proliferation and protection of the bacteria is well accepted.

Thus, this brings up the question as to whether ancestral Rhizobiales and/or Burkholderiales could have been coparticipants in the origin of both plant–mycorrhizal associations and nitrogen-fixing symbioses. For the Betaproteobacteria, the answer is probably yes based on *Burkholderia* symbionts being present within AMF hyphae. *Candidatus Glomeribacteria gigasporarum* (CGG) is an obligate endobacterium that lives surrounded by a membrane within the cytoplasm of AMF cells, which themselves are obligate biotrophs and dependent on their plant hosts (Jargeat et al., 2004). However, no evidence for *nif* genes was uncovered (Jargeat et al., 2004), suggesting that the CGG ancestor was unlikely to be a diazotroph although it is sister to free-living *Burkholderia* species that fix nitrogen as well as to *B. rhizoxinica* HKI 0454^T (Ghignone et al., 2004), an endophyte of the phytopathogenic fungus *Rhizopus*, the causal agent of rice-seedling blight (Partida-Martinez et al., 2007). In spite of its small genomes and lack of *nif* genes, some 250,000 CGG cells are estimated to live within one

fungal cell (Bianciotto et al., 1996) and at least 20,000 per spore (Lumini et al., 2007), strongly suggesting that these microbes provide benefits to their host. Indeed, the bacteria were found to improve the fitness of Gigasporaceae by promoting presymbiotic hyphal expansion and branching (Lumini et al., 2007).

Based on studies of various betaproteobacterial genomes, the difference in mutation accumulation in CGG differs from free-living *Burkholderia* species and from the *Burkholderia* endosymbionts of *Rhizopus*, strongly suggesting an ancient interaction with the fungus (Castillo and Pawlowska, 2010). Similar to insect symbionts, CGG and *B. rhizoxinic*a have reduced genomes, but the fungal pathogen has a large number of genes associated with virulence (Lackner et al., 2011). Moreover, *B. rhizoxincia* can be grown in culture and re-infect its fungal host (Moebius et al., 2014). In contrast, CGG is unable to synthesize several essential amino acids and vitamins, and is totally dependent on its host for carbon, nitrogen, and phosphorous (Ghignone et al., 2012). The complex network seen in this tripartite symbiosis strongly suggests a different pattern of molecular evolution than that observed in the free-living *Burkholderia* species or *B. rhizoxincia* (Castillo and Pawlowska, 2010). Whether or not an ancient *Burkholderia*–AMF–plant symbiosis is the ancestor of the nodulation pathway (see Chapters 51, 59, 110) may be difficult to prove, but it is not clear whether any better candidate presents itself. To our knowledge, the evidence for a Rhizobiales endosymbiont living in association with AMF cells has not been reported.

89.7 FINAL COMMENTS AND PERSPECTIVES

Strong evidence for distinct *Burkholderia* populations in South America and Southern Africa exists, but so far not much is known about the Indian *Burkholderia* populations (Fig. 89.3). The Indian *Burkholderia* RNB may be closely related to RNB isolated from *Dalbergia* legume nodules in Madagascar although this strain was identified at the time as *B. cepacia* and lacks *nod* genes (Rasolomampianina et al., 2005). Although *Burkholderia* strains have been isolated from nodules of legumes growing in Australia, so far no *nod* genes have been detected in these (R. Walker, *unpublished*). For China and Europe, no reports of *Burkholderia* RNB from **endemic** legumes have been described. Clearly more isolations need to be made. Thus, it appears that Southern Africa and South America are the major centers for *Burkholderia* evolution (see also Chapter 17).

To explain these apparently disparate centers of origin of the RNB *Burkholderiacae*, it is important to remember that ca. 200 Mya, South America, Africa, India, and Australia were all part of the single continent Gondwana. If *Burkholdericeae* and *Rhizobiaceae* date from this time, and based on timing of the divergence of *Bradyrhizobium* and *Rhizobium* and the presence of *Burkholderia* in AMF (Fig. 89.4), it is a formal possibility that the two families were members of the Gondwanan microflora. Thus, it can be deduced that certain *Burkholderia* species such as *B. tuberum* originated when South Africa and South America were still connected, which might explain the disparate localization of *B. tuberum* with the mimosoid (South American) and papillionoid (South African) legumes after the continents split. The example of a South American *B. tuberum* is the strain *Burkholderia* CCGE1002, which was isolated from nodules of *Mimosa occidentalis* growing in Mexico and has characteristics typifying both the South African and South American strains (Mishra et al., 2012; Ormeño-Orrillo et al., 2012). Strain CCGE1002 is *B. tuberum* based on a concatenated sequence of 16S RNA and four housekeeping genes (Agapakis et al., *unpublished*), but not if based on *nodA* or *nifH* (Mishra et al., 2012), However, in contrast to South African *B. tuberum* STM678^T and *B. tuberum* related strains such as *B. rhynchosiae*, *B. dilworthii*, and *B. sprentiae* (De Meyer et al., 2013a,b, 2014), CCGE1002 has a *nod-nif* gene arrangement upon a symbiotic plasmid that is similar to that of other *Mimosa*-nodulating *Burkholderia* strains except it has an integrase gene terminating the operon (Agapakis et al., *unpublished*). In addition, the *nod* and *nif* genes of the Mimosoideae-nodulating *Burkholderia* strains are not closely related to those of the Papillionoideae-nodulating South African *B. tuberum* strains (Mishra et al., 2012). Bontemps et al. (2010) placed the acquisition of the symbiotic genes by RNB at about the same time as when the legumes were diversifying. We propose that the presence of different legume subfamilies, Mimosoid versus Papillionoid, as well as the influence of different biogeographies on the two once connected continents facilitated the divergence of *Burkholderia* RNB into separate lineages, accounting for the *Mimosa*-nodulating strain CCGE1002 versus the Papillionoideae-nodulating *B. tuberum* STM678^T and related species (see also Chapter 19).

Finally, which of the RNB evolved first, the alpharhizobia or betarhizobia? If *Burkholderia* species inhabited fungal cells at the time of the emergence of the vascular plants, this strongly suggests their ancient origin. The timeline implies that *Burkholderia* may have associated with plants some 500 Mya via the AM symbiosis, and in the process, recruited the capacity for an intimate interaction with the plant from AMF via an unknown mechanism. This hypothesis suggests that *Burkholderia* could have been the source of the nodulation genes via lateral transfer of genes if a nonreduced genome ancestor associated with the fungi. However, an alternative hypothesis, as previously mentioned (Hirsch et al., 2001), is that the original source of these genes was outside either *Burkholderiaceae* or *Rhizobiaceae* because of their lower G + C content compared to the rest of the genome. For both groups of RNB, the genome G + C

content is higher overall than that of the nodulation genes. Potential recruitment of *nodB* and *nodC* from other bacteria or fungi is a distinct possibility, but more elusive is the source of the gene-encoding NodA, the protein responsible for adding a fatty acyl chain onto the resulting free amino group of the nascent Nod factor.

Based on the isolations of *Burkholderia* RNB so far (Fig. 89.3), it appears that the RNB group is confined to the southern hemisphere except for CCGE1002, which was isolated from nodules in Mexico, as well as some undescribed isolates from China. However, based on fossil data, the distribution of many legume genera is very different from what it was predicted to be 65 Mya. The greatest diversity at the generic level then and now is in tropical America and Africa/Madagascar (Herendeen et al., 1992). Coincidentally, this distribution overlaps with that of the *Burkholderia* RNB. Of the North American fossil flora, many extant relatives are now restricted to South America possibly as a result of climatic constraints (Herendeen et al., 1992). A more extensive focus on *Burkholderia* RNB and their hosts is needed to obtain a more complete knowledge of legume and symbiont biogeography.

Exploring the origins of nodulation provides insight into the evolution and diversity of symbiosis more broadly. Interactions between plants and microbes have an ancient and important history. The role of the *Burkholderia* RNBs in that history, especially in the southern hemisphere, demonstrates the potential value of these strains in future agricultural applications as well as in our broad understanding of ecological and evolutionary relationships (see also Chapter 17).

90.1 INTRODUCTION AND DISCUSSION

90.1.1 Plant Growth Promoting Rhizobacteria (PGPR)

The rhizosphere is the area of soil influenced by plant roots. It is composed of microbial populations that are somehow different than the rest of the soil populations, generally denominated as the "rhizosphere effect" (de Bruijn, 2013).

Among the microorganisms inhabiting the rhizosphere it is possible to isolate a wide variety of viruses, bacteria, protozoa, and fungi. Some microbial species are capable of promoting root and plant growth (de Bruijn, 2013). Other species are neutral and some are deleterious to plant growth (Helman et al., 2011). In this chapter, we deal with some well-characterized bacteria that are known to promote root and plant growth directly and have good potential to be commercially applied for increasing the yields of agricultural crops; they are generally denominated as PGPR (Plant Growth Promoting Rhizobacteria; de Bruijn, 2013). PGPR with potential to directly promote crop yield include species from the *Azospirillum, Herbaspirillum, Gluconacetobacter, Burkholderia, Pseudomonas,* and *Paenibacillus* genera, among others. The genus *Azospirillum* is the most widely commercially used in agriculture, especially in South America, and will be reviewed in more detail. We are not including in this chapter indirect biological control for plant growth promotion (see de Bruijn, 2013).

The genus *Herbaspirillum* (beta proteobacteria) comprises several diazotrophic species (see Chapter 93). Some colonize root surfaces but are also capable of endophytic and systemic colonization of several plant species (Reis et al., 2007). An additional nitrogen-fixing endophyte PGPR, which is capable of colonizing sugarcane and other plants, is *Gluconacetobacter diazotrophicus* (alpha proteobacteria) (Reis et al., 2007). Nitrogen-fixing, plant-associated *Burkholderia* (beta proteobacteria) represent great potential for agrobiotechnological applications (Caballero-Mellado et al., 2007; see Chapters 17 and 89). The bacterial genus *Pseudomonas* (gamma proteobacteria) also comprises many bacterial species with agricultural importance. Some such as *P. syingae* are plant pathogenic bacteria of important crops and have been extensively studied. Other *Pseudomonas* species are involved in disease suppression and/or direct plant growth promotion (Glick et al., 2007; de Bruijn, 2013). The genus *Paenibacillus* comprises over 30 species of facultative anaerobes and endospore-forming, periflagellated, heterotrophic,

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

low G + C gram-positive bacilli (see Chapter 92). *Paenibacillus polymyxa* is of biotechnological potential, mostly due to its biological control properties (Lal and Tabacchioni, 2009). The *Azospirillum* genus (Baldani et al., 2005) belongs to the alpha proteobacteria and comprises free-living, nitrogen-fixing, vibrio- or spirillum-shaped rods that exert beneficial effects on plant growth and the yield of many agronomically important crops. Azospirilla are able to fix nitrogen in association with plants but most inoculation experiments and systems evaluated so far indicate that nitrogen fixation does not play a major role in plant growth promotion (Helman et al., 2011).

The PGPR species mentioned above have been subjected to extensive studies to elucidate their colonization capabilities of surfaces and of interior of plants, and their physiological and molecular mechanisms involved in promoting plant growth (see de Bruijn, 2013). Genomes of several species are now available and the extensive knowledge acquired will possibly enable a more comprehensible biotechnological use of the bacteria as commercial products in the near future.

The main issues that have been investigated on mechanisms of direct plant growth promotion and are commonly reviewed in the literature remain to some extent controversial and there are only few clear demonstrations of their involvement, especially under more natural field conditions (Helman et al., 2011, Cassán and García de Salamone, 2008a). In this chapter, the PGPR effect will be evaluated with emphasis on the applied aspects of the *Azospirillum*–plant interactions.

One of the most pronounced effects of inoculation with azospirilla and other diazotrophic PGPRs on root morphology is the proliferation of root hairs as observed in several grasses, cereals, and legumes. However, morphologically, the proliferation and morphology of root hairs is not similar when comparing inoculation with different PGPR species (Dobbelaere and Okon, 2007). Inoculation can also promote the elongation of primary roots and increase the number and length of lateral roots. Again, when observed in detail, the morphological effects differ with the different PGPR inoculum. The most clear and distinct effects on root morphology have been observed after inoculation with Azospirillum species and strains (Dobbelaere and Okon, 2007).

The morphological effects on roots are generally dependent on the inoculum concentration and are consistent with the exogenous indole-acetic acid (IAA) levels secreted by *Azospirillum,* indicating that they are mainly due to the production and secretion of IAA by the bacterium (see also Chapter 91). There is evidence that secretion of cytokinins and gibberellins by the bacteria is also involved, but most important could be the IAA/cytokinin ratio (Spaepen et al., 2009). Another diffusible molecule involved, as in the case of *A. Brasilense,* is nitric oxide (NO), a key signaling molecule involved in a wide range of functions in plants (Molina-Favero et al., 2008; see also Chapter 64).

The described effects on root growth and activity mainly in the case of *Azospirillum* result in enhanced mineral and water uptake from the soil by the inoculated roots. This has been repeatedly demonstrated under greenhouse and field conditions in various important crops such as maize and wheat (Dobbelaere and Okon, 2007).

Biological nitrogen fixation (BNF) in diazotrophic PGPR inoculated plants (maize, wheat and other grasses) as well as in sugarcane has been investigated in detail by various techniques including the acetylene reduction assay (ARA), the ^{15}N dilution technique, $^{15}N_2$ fixation, ^{15}N natural abundance, and Kjeldhal N-content measurements (Dobbelaere and Okon, 2007). In most grain and forage crops the contribution of nitrogen fixation by *Azospirillum* has been estimated to be no more than 10 kg N/ha/year. The quantities of fixed nitrogen supplied to some cultivars of sugarcane and rice by *G. diazotrophicus* and other PGPR have been estimated to be as high as 50% of the required plant nitrogen (Reis et al., 2007). Since there are many other diazotrophs colonizing the surface and internal tissues of sugarcane roots and rice, it has been difficult to assess the specific contribution of diazotrophic bacteria in the inoculum (Fibach-Paldi et al., 2012).

Some of the unresolved questions for agronomic interactions of PGPR and plants deal with PGPR colonization dynamics, whether PGPR are continuously colonizing and promoting growth of developing roots or alternatively, the major effects are at early stages of root development. Comparable questions are whether nitrogen fixation by the association is continuously taking place or especially at certain stages of plant growth such as inflorescence and grain filling.

Under field conditions, the success of inoculation depends on achieving a high number of bacteria on the root surface and/or the root tissue. There is a need for bacterial colonization in relatively high numbers (10^6–10^7 per g or cm of plant tissue) in order to obtain a significant impact on plant growth promotion derived from BNF, phosphorous solubilization, or disease control (Helman et al., 2011; Spaepen et al., 2009). P-solubilization and BNF are clearly observed and measured in pure cultures when there are $\sim 10^{10}$ cfu/ml; very seldom, high numbers (above 10^4–10^5 cfu) have been counted in plant tissues in the field.

The relevance of PGPR endophytic colonization and its possible advantages in comparison to colonization in the rhizosphere remain to be convincingly demonstrated mainly under field conditions. So far, researchers consider it somehow more logical that endophytic colonization would be more efficient for plant growth, but this needs more investigations (see de Bruijn, 2013). Recent detailed studies support the observations that dual inoculation of *Azospirillum* and some PGPR in legumes (alfalfa, beans, vetch, soybeans and chick peas among others) results in increased production of plant flavonoids and enhanced capacity to induce *Rhizobium nod*-genes expression

(Dardanelli et al., 2008; see Chapter 50). The presence of *Azospirillum* in the legume rhizosphere activates the hydrolysis of conjugated phytohormones and flavonoids in the legume root tissue, thus leading to release of compounds in their more active forms. Results from co-inoculation experiments suggest that IAA and NO produced by *A. brasilense* are key components of enhancement of secretion of *nod*-gene inducing flavonoids in the roots (Dardanelli et al., 2008; Star et al., 2012; Cassán et al., 2009; Hungria et al., 2013).

90.1.2 Field Experiments

Extensive field inoculation experiments with *A. brasilense* carried out in Israel in the 1980s (Okon et al., 1988) clearly show an average significant increase in crop yield of maize, wheat, sorghum, and other forage grasses. In these cases, the seeds were inoculated with freshly prepared peat inoculants (Okon and Labandera-González, 1994; Helman et al., 2011; Cassán and García de Salamone, 2008a).

In earlier field experimentation, when the plant growing properties of *Azospirillum* were considered as derived from BNF and the number of bacteria in the inoculant was not carefully monitored, the commercial exploitation of *Azospirillum* was limited. At this stage, inoculation responses were considered as inconsistent. Further developments emphasize the importance of research and development for improved formulations, the existence of a regulatory frame guaranteeing inoculant quality, and also the need for a network of communication and diffusion systems, with a unique message for the farmers, in order to achieve good field results.

More recently (1998–2013), there have been hundreds of reports of field inoculation experiments utilizing mainly *A. brasilense* liquid or peat-based commercial inoculants, under varied climatic and soil conditions, mainly in Argentina, Uruguay, Brazil, and Mexico (Fuentes-Ramirez and Caballero-Mellado, 2005; Cassán and García de Salamone, 2008b), and also in other parts of the world (Okon and Labandera-González, 1994; Helman et al., 2011).

Statistically significant increases in crop yield have been obtained with intermediate and adequate levels of N, P, K, microelements and water, with high bacterial concentrations (10^9 cfu per g or ml) and inoculants of good physiological status (Spaepen et al., 2009). These inoculant products have been increasingly approved and registered by government agencies, inoculant companies, associations, and official agricultural research institutions (Helman et al., 2011; see also Chapter 101). Thus, based on extensive field experimentation with proper agronomic design and accurate statistical evaluation of crop yield parameters, it is well accepted that the inoculation practice has the potential to promote crop yield in fields. Following the reported success of the PGPR inoculants, there has been an extension of research and inoculant quality controls for these microorganisms and at the same time different companies initiated development and commercialization of products. Commercial inoculants have been regularly applied in recent years; there has been a surge in the inoculation practice with *Azospirillum*, with estimations of about 2–2.5 million doses used in 2012 in Brazil, mainly in maize (Hungria et al., 2010, 2013). The MERCOSUR region was especially receptive to these developments.

90.1.3 Field Experimentation in Uruguay: A Test Case for Development of PGPR Inoculants

In 1990, the Department of Soil Microbiology of Uruguay MGAP, [Department of Soil Microbiology, General Direction of Natural Renewable Resources, Ministry of Livestock, Agriculture and Fisheries (Departamento de Microbiología de Suelos – Dirección General de Recursos Naturales Renovables, Ministerio de Ganadería Agricultura y Pesca, Montevideo, Uruguay – DMS-DGRNR MGAP in the Spanish acronyms)] started a new research line on PGPR emphasizing on *Azospirillum* under controlled and field conditions in legumes and gramineous plants. Preliminary results proved to be very erratic, and because of this MGAP decided to invite Dr. Yaacov Okon in 1992–1993 to analyze available data on PGPR and develop suitable techniques for *Azospirillum* inoculant formulation and quality control. During the consultancy, the first regional workshop on *Azospirillum* took place in August 1993 (Okon and Labandera-González, 1994). The aim of the emerging PGPR project was to enlarge the use of inoculants to other crops following the success of using rhizobial inoculants for legumes.

In 2004, a technical cooperation agreement was signed between the MGAP and Lage & Cia for the validation of a liquid formulation based on *Azospirillum* (Graminosoil brand). One of the relevant aspects in the working procedure was the methodology employed in the trials, where in addition to evaluating crop response to inoculation (dry matter production and grain yield), rhizospheric and endophyte *Azospirillum* determinations were always performed, comparing non-inoculated controls with inoculated treatments, to determine the plant–bacteria relationship and to have better elements for the interpretation of the results.

It is important to note that initial research work on *Azospirillum* in Uruguay focused on studying the bacteria's plant growth promoting and stimulant effects mainly under low levels of nitrogen fertilization. Nevertheless, mainly in the last decade, grain crop production systems in Uruguay were using relatively high levels of chemical fertilizers, with better adjustment to crop requirements. Consequently, it was understood that *Azospirillum* inoculants should aim to increase crop yields rather than intending a substantial decrease in the doses of chemical fertilizers. For this reason, recent field trials were conducted following actual

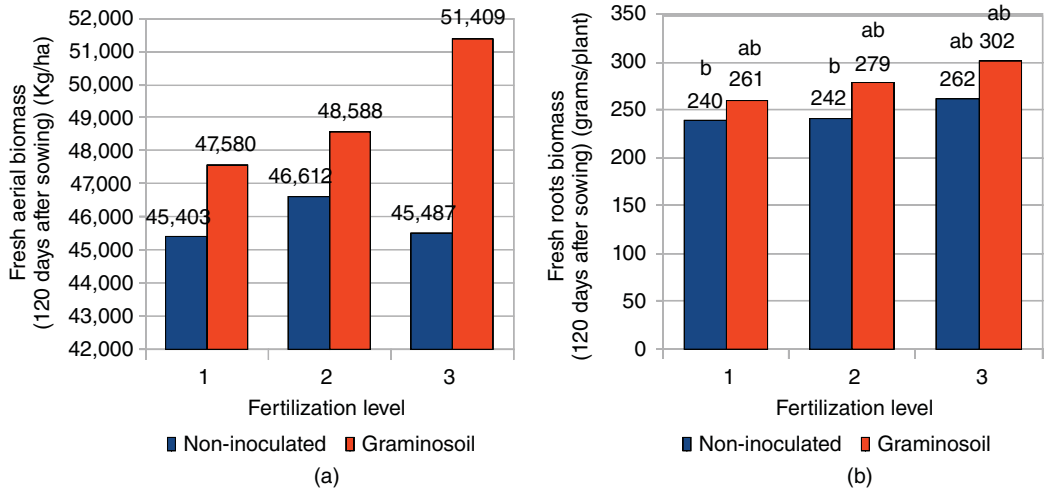

Figure 90.1 Fresh above-ground maize biomass (a) and fresh root according (b) to seed treatment and level of fertilization. Fertilization levels: 1 – no fertilization (neither at planting nor 60 days after), 2 – 0-21/23-0 130 kg/ha at planting; no fertilization 60 days after planting, 3 – 0-21/23-0 130 kg/ha at planting; urea 120 kg/ha 60 days after planting (Casaretto and Labandera, 2008).

fertilization recommendations in terms of doses and ways of application. One of the main production factors that influence yield expression in dry crops in Uruguay is the water regime, since it varies extensively within and between seasons. For this reason, it is often difficult to optimize yield, since although there is a good adjustment of management factors (genetics, length of fallow, planting date, sowing technology and fertilization), rainfall ends up being crucial, either by lack or excess of rain at key moments. Knowing the mechanisms of action of *Azospirillum* and its ability to stimulate root growth, it was considered that *Azospirillum* inoculation could contribute to increase, but most importantly, stabilize yields.

Evaluations of Graminosoil application in maize and sorghum were performed in greenhouse and commercial fields during four consecutive seasons (2003/2004, 2004/2005, 2005/2006 and 2006/2007) (Figs. 90.1–90.4). The evaluated parameters were *Azospirillum* concentration in the inoculant and inoculated seed, *Azospirillum* concentrations in the rhizosphere and inside the root (endophytes), crop establishment, aerial and root dry matter at different physiological stages, and grain yield. Considering the expected responses, these determinations were performed frequently during the crop cycle.

In all experiments the liquid inoculant used had a high azospirilla concentration (10^9 cfu/ml), recovering 10^4 cfu/maize seed, both in non-treated seeds and those treated with chemical fungicides (Carbendazim 250 g/l + Thiram 250 g/l).

Five maize greenhouse trials were conducted, obtaining increases of 30–40% in root biomass and 14–27% in above ground biomass due to inoculation. Similar responses were also obtained in sorghum (C. Labandera, unpublished).

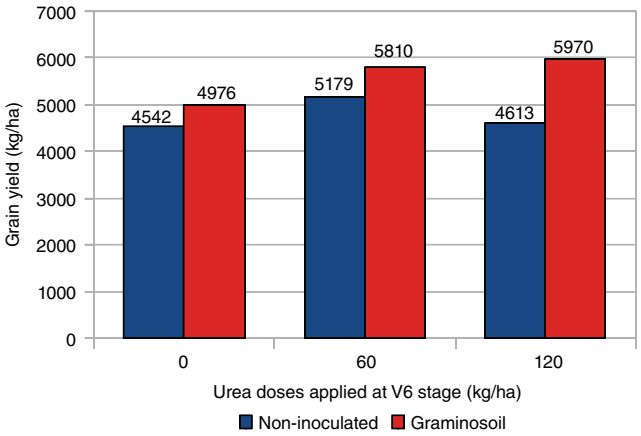

Figure 90.2 Production of maize grain yield in response to inoculation and urea doses at V6. Fertilization at planting: Urea 60 kg/ha + 18-46-0 60 kg/ha. Urea at V6 stage: 1 - none, 2 - 60 kg/ha urea. 3 - 120 kg/ha urea (Hoffman et al., 2008).

In maize field trials there was an increase in the number of bacteria due to inoculation, both in the rhizosphere and inside the roots, of about 2–5 times with respect to the uninoculated control. Following inoculation of maize roots and the aerial part, biomass was significantly increased at different growth stages. Increased production of roots has a direct effect on water and nutrient uptake in inoculated crops. Furthermore, there is an additional value of increased root and stubble input to the system, allowing higher organic matter levels and improving the physical conditions of the productive soil layers, especially in no-tillage systems (C. Labandera, unpublished; Helman et al., 2011).

Figure 90.1a and b shows the results obtained in the field trial performed in 2004/2005 season. In this trial, the greatest differences in aerial biomass production were obtained in

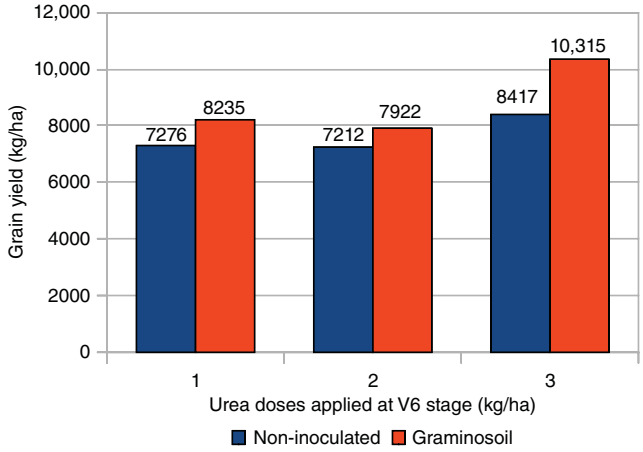

Figure 90.3 Production of maize grain yield in response to inoculation and urea doses at V6. Fertilization at planting: 0-21/23-0 200 kg/ha + 18-46-0 150 kg/ha + Kcl 80 kg/ha. Urea at V6 stage: 1 - none, 2 - 60 kg/ha, 3 - 120 kg/ha (Hoffman et al., 2008).

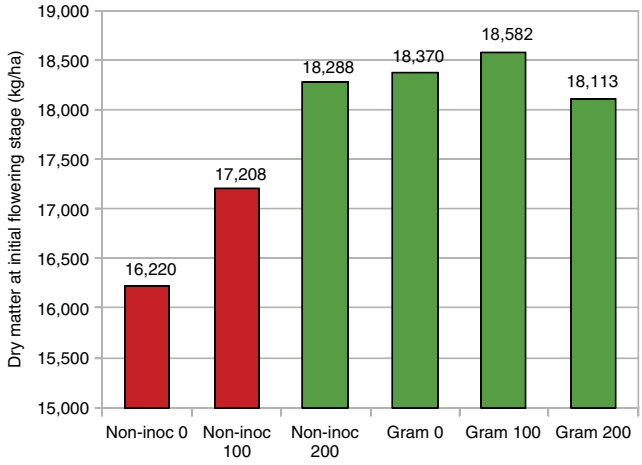

Figure 90.4 Aerial dry matter production of maize at the beginning flowering. Fertilization at planting: urea 50 kg/ha. Urea at V6 stage: 1 - none, 2 - 100 kg/ha, 3 - 200 kg/ha. gram-Inoculated with GRAMINOSOIL, Martino, M. personal communication 2008.

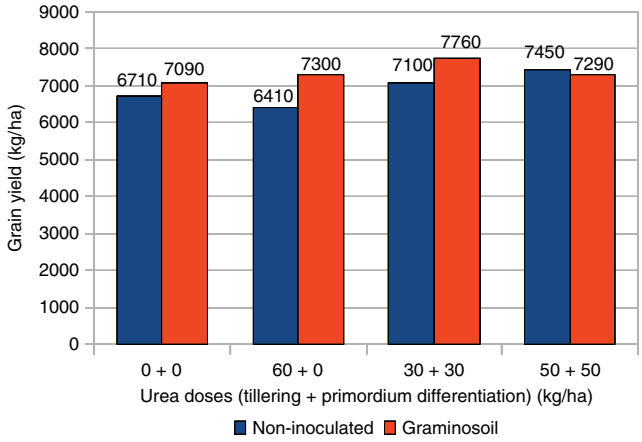

Figure 90.5 Rice yield response to inoculation and doses of urea. Fertilization at planting: 18-46-0 150 kg/ha. Urea at tillering and initial reproductive stage: 1 - none, 2 - 60 kg/ha at tillering, 3 - 30 kg/ha at tillering and 30 kg/ha at initial reproductive stage, 4 - 50 kg/ha at tillering and 50 kg/ha at initial reproductive stage. Chebataroff, N et al personal communication 2007.

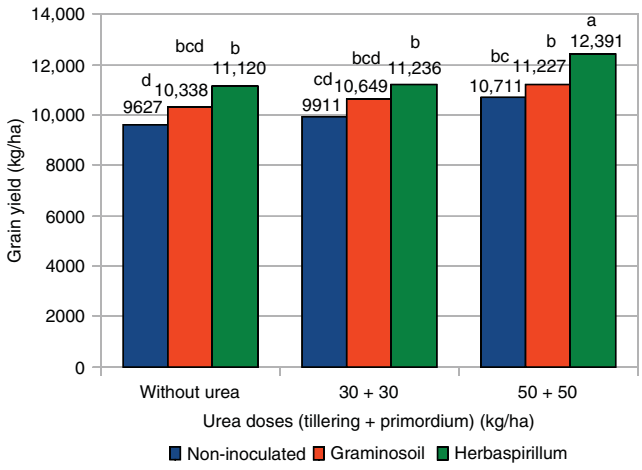

Figure 90.6 Rice yield response to inoculation and doses of urea. Fertilization at planting: 18-46-0 130 kg/ha. Urea at tillering and initial reproductive stage: 1 – none, 2 - 30 kg/ha at tillering and 30 kg/ha at initial reproductive stage, 3 - 50 kg/ha at tillering and 50 kg/ha at initial reproductive stage. Chebataroff, N et al., personal communication, 2009.

the inoculated treatments with higher doses of fertilizer; this would indicate a more efficient use. Moreover, inoculated plants without fertilization reached yields similar to those of the uninoculated control, with higher levels of fertilizer.

Other field trials to evaluate Graminosoil were conducted by private consulting firms in different crops (Figs. 90.2–90.6).

Although interaction in dry matter production and grain yield was not significant, inoculation with *Azospirillum* always maintained higher levels of biomass and grain yield, particularly with high doses of nitrogen (Fig. 90.2).

Increases in maize grain yield at higher levels of N fertilization (Fig. 90.3) and shoot dry matter yield (Fig. 90.4) were obtained in two more field experiments.

Yield increases in rice plots were obtained when seeds were inoculated with Graminosoil and showed to be important in productive and economic terms. Actually, this line of work includes agronomic evaluations of ENDO-RICE inoculant, formulated with a native strain of *Herbaspirillum* (Punschke, and Mayans, 2011).

In conclusion, there has been for several years a clear consistent plant growth promotion and yield increases of important crops in Uruguay, following inoculation with commercial formulations of PGPRs.

90.1.4 Inoculant Production

Following the extensive basic and applied research on PGPR, inoculants for more than 30 years (Helman et al., 2011) commercial inoculant products, field experimentation and international quality control procedures have been established (see also Chapter 101).

The inoculant production process starts with the scaling up of recommended strain(s) for the target crop, according to the institution of reference in each country, when required. The pure cultures are normally maintained at −80 °C, delivered in agar slant tube cultures growing on the appropriate medium. Scaling up is carried out in a sterile liquid medium culture in an agitator and with controlled temperature for the appropriate period of time. When the growth period is completed, the purity of the culture is confirmed in agar plates by microscopic observation and Gram test; DNA fingerprinting procedures may also be performed (see de Bruijn, 2013). When that liquid culture is determined suitably, it is used to inoculate an industrial fermenter (Fig. 90.7).

Sampling of industrial fermenters is done daily and not only at the end of fermentation. In addition to the already mentioned controls, an estimation of microbial growth is carried out by spectrophotometry. For peat-based inoculants, the peat has to be previously neutralized, ground to 200 mesh, raked in polyethylene bags, and sterilized by Gamma radiation. Impregnation is made aseptically, puncturing the bag with a needle and then sealing the hole. For liquid inoculants, the broth is packaged aseptically (Fig. 90.8). The final inoculant product is subjected to quality control. However, it is highly recommended to have an additional quality control performed by the reference institution (RI).

90.1.5 MERCOSUR: Regulatory Framework and Quality Control

The achievements of the use of PGPR inoculants, mainly following field experimentation in the world has been summarized (Okon and Labandera-González, 1994; Helman et al., 2011).

PGPR research and inoculant development in MERCOSUR was initiated during the workshop on *Azospirillum* held at MGAP, Montevideo, August 1993. Its conclusions were published (Okon and Labandera-González, 1994). In 1998, all MERCOSUR countries signed "Recommendation 9/97, SGT 8 Agriculture, MERCOSUR/GMC/RES 28/98," which includes the obligation to register inoculants and to establish a "RI" for each country, as well as defining its responsibilities. Actually, each country has adapted its own regulations according to it (see Chapter 101).

Argentina has IMYZA INTA Castelar as its RI and the Secretary of Agriculture SENASA is in charge of registering inoculants. Az39 is the recommended *Azospirillum* strain to inoculate maize and wheat. In 2005, the network "Red de Control de Calidad de Inoculantes (REDCAI) (Inoculants

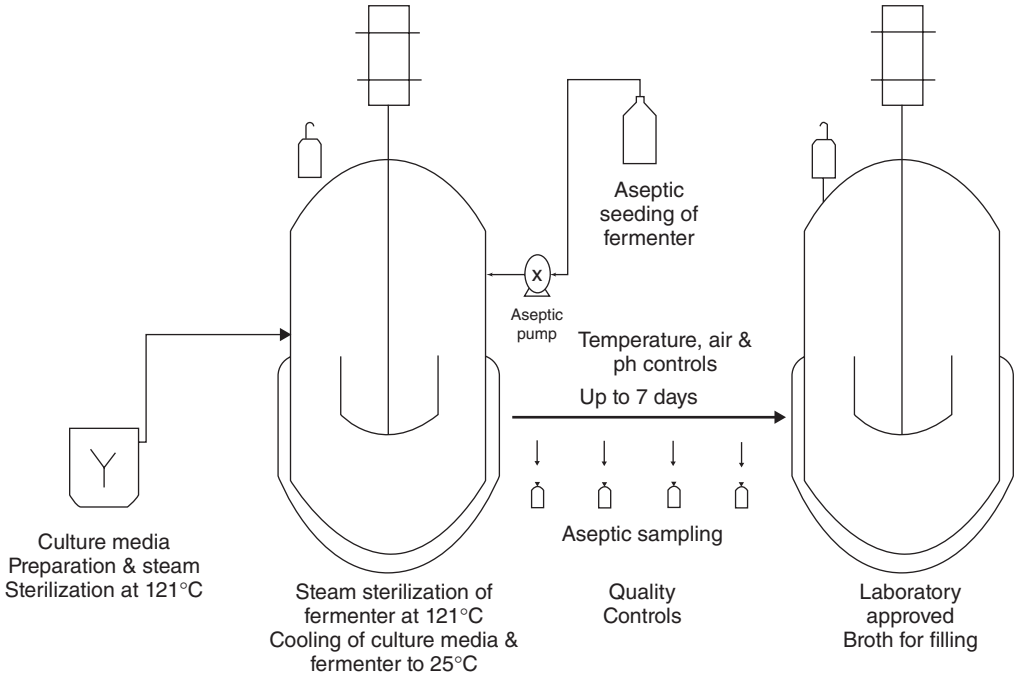

Figure 90.7 Industrial inoculant fermentation process.

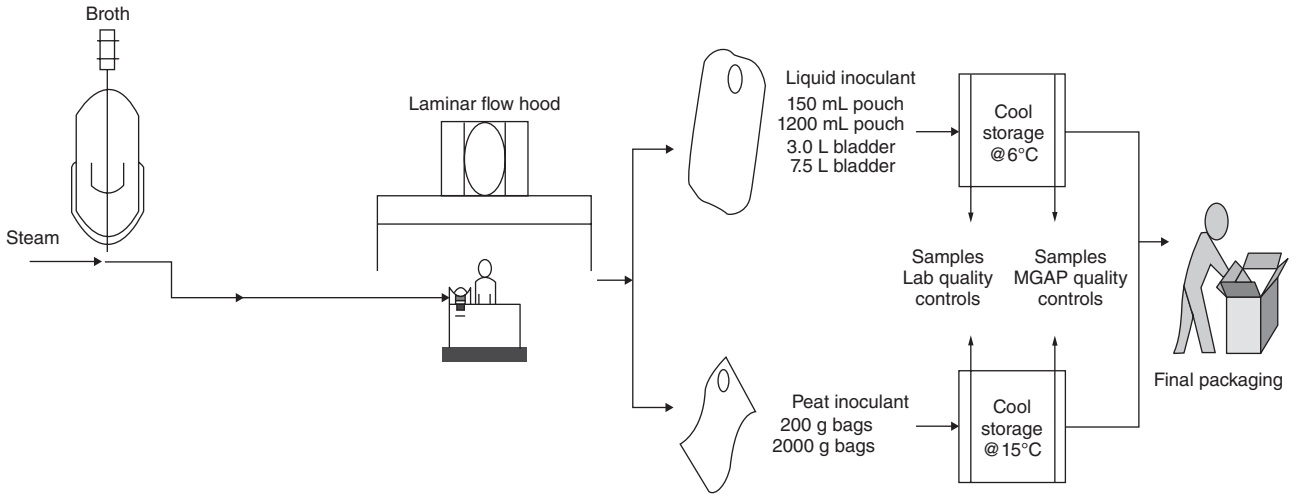

Figure 90.8 Inoculant aseptic filling and packing.

Quality Control Network)" was established as a member of the Division for Agricultural and Environmental Microbiology of the Argentinian Association of Microbiology, with the aim of creating and validating a set of methodological tools for the evaluation of inoculants (I Taller Iberoamericano REDCAI – RED BIOFAG, Asociación Argentina de Microbiología, Programa Iberoamericano de Ciencia y Tecnología para el Desarrollo, October 2010) (I Ibero-American Workshop REDCAI-REDBIOFAG, Argentinean Association of Microbiology, Ibero-American Science and TECHNOLOGY Program for Development). Procedure document 2 of REDCAI (Cassán et al., 2010) established the protocol for the quality control of *Azospirillum* inoculants.

Argentina is a pioneer in the development of PGPR inoculants and their field application. In the early 1980s, Silder Barrios and Enrique Rodríguez Cáceres began their work in obtaining several isolations of *Azospirillum* from diverse areas of their country. They formulated peat-charcoal based inoculants, which reached 84 days of shelf life in concentrations higher than 1×10^8 cfu/g (Puente et al., 2008). These researchers followed the guidelines of J. Döbereiner and Y. Okon to obtain several strains (Rodriguez Cáceres et al., 2008). The solid culture media "RC" was developed for isolation and identification of *Azospirillum* (Rodríguez Cáceres, 1982). Those strains were the initial material of the collection of the current Institute of Agricultural Microbiology and Zoology, IMYZA INTA Castelar. At the urging of Edgardo Muñoz Ratto, SENASA was the first institution of MERCOSUR to open registration for *Azospirillum*-based inoculants.

Proyecto Inocular emerged at the beginning of the last decade, led by Alejandro Perticari in a partnership between INTA and 25 inoculant companies, with the aim of promoting the technology of soybean inoculation, later extending it to other PGPRs, with more emphasis on *Azospirillum*. The local companies were the ones that started to develop *Azospirillum* inoculants (Table 90.1), with some of them that formulate mixtures of *Azospirillum* and other PGPR (Table 90.1). Laboratorios Alquimia was the first to launch a commercial product, Graminante. Its carrier is a wettable powder consisting of calcium carbonate and magnesium carbonate, registered as 20259 for maize and 20260 for wheat in 1992.

A few years later, work began simultaneously in Uruguay and Argentina with Graminosoil, a sterile peat-based inoculant, reaching high initial concentrations of *Azospirillum* per gram but with rapid death of the bacteria; authorization for open sale in Uruguay was obtained in 1992; and the registration number was 20284 for maize and 20285 for wheat in Argentina in 1994. Owing to difficulties in the use of peat-based inoculants in both countries, it was decided to change the carrier of Graminosoil to an aqueous media with at least 1×10^8 cfu/ml with 6 months shelf life.

Brazil has FEPAGRO as it RI. Strains Ab-V4, Ab-V5, Ab-V6, and Ab-V7 are recommended to inoculate maize and Ab-V1, Ab-V5, Ab-V6, and Ab-V8 for wheat (Hungria, 2011). The current recommendation for *Azospirillum* strains arises in part from the work carried out by Fabio Pedrosa at the Molecular Biochemistry and Biology Department of the Federal University of Paraná (Araujo, Solón, personal communication, March 2013). *Azospirillum*-based inoculants need to be registered at the Ministry of Agriculture, Livestock, and Food Supply (MAPA, in its Portuguese acronym) before being sold on the market and they must contain at least one of the recommended strains for each crop. Normative Instruction 30 sets the official methods for inoculant analysis. The Network of Laboratories for Recommendation, Standardization, and Dissemination of Microbial Inoculants of Agricultural Interest (Red de Laboratorios para Recomendación, Padronización y Difusión de Tecnología de Inoculantes Microbianos de Interés Agrícola - RELARE)

meets on a biannual basis, bringing together people from MAPA, EMBRAPA, Universities, ANPII (the inoculants chamber), and representatives from companies that are not associated to ANPII. Each RELARE may suggest that MAPA incorporate or discharge strains from FEPAGRO's recommendations. Table 90.1 summarizes the strains actually used by Brazilian companies.

Paraguay is a country that has received a large number of Argentinian and Brazilian farmers, who brought along with them their agricultural practices, among them, grain inoculation, and have created demand for the products they used in their own countries. NUTRICHEM, of CHEMTEC Company, is the first co-inoculant produced in Paraguay that contains *Azospirillum* and *Pseudomonas* (Table 90.1). Resolution 564 and its Annex regulate the registration of inoculants with Servicio Nacional de Calidad y Sanidad Vegetal y de Semillas (SENAVE; National Service for Plant and Seed Quality and Health) (Galeano Samaniego, M and Marecos, C, personal communication, 2013).

Uruguay appointed MGAP as its reference institution. More than 95% farmers inoculate their legume seeds. Adoption of this practice comes from a successful strategic country plan that started in the early 1950s, developed by MGAP with the objective to increase animal productivity through the

improvement of natural pastures by the use of phosphorous fertilizers and inoculated legumes focusing in the diffusion of the technology to reach farmers. *Rhizobium* legume inoculant production and its use are regulated in the country by Decrees MGAP 546/81 and MGAP 7/99 while other PGPR inoculants are by Resolution MGAP 03/2013. There are three *Azospirillum* inoculants on the market (Table 90.1) and one product, ENDO RICE, that contains a strain of *Herbaspirillum* isolated from local flood irrigated rice systems (Punschke and Mayans, 2011).

MERCOSUR may allow registration of an inoculant with strains that are not recommended, but the registrant company shall submit reports of efficacy under laboratory and greenhouse conditions, together with data from at least 3 years of field trials in three different agro-ecological zones.

90.1.6 Summary and Concluding Remarks

The experience achieved with *Rhizobium* inoculants in relation to storage, use, and management of inoculants and treated seeds (see also Chapter 97) has been transferred to PGPR products. Good inoculation procedures are important to achieve uniform distribution and high average load of bacteria on every seed. It is imperative for the efficiency of the process to use specifically designed inoculation machinery for each kind of seed. It is always recommended to follow the guidelines stated on the label. Every inoculant company should have information about compatibility of their product with chemical treatments used on the seeds, such as fungicides, insecticides, and bird repellents, as they may affect viability of bacteria on inoculated seeds. The timing between inoculant applications and sowing, as well as crop management (previous crop, type of sowing, seed density, fertilization, and irrigation) need to be planned for an optimal inoculant response.

It is important to point out that the degree of adoption and relative agronomic success of the use of PGPR inoculant technologies will depend on the quality of the products and their characteristics (powdered, peat based or liquid) and the way of application. Therefore, in order to ensure permanent adoption of the technology, it is necessary to

- have a coordinated multidisciplinary research institution to provide technical bases for inoculant formulation and application, such as carriers, strains, concentration, transportation and storage conditions, shelf period, recommendations, and precautions for use;
- have a regulatory framework setting high standards to assure inoculant quality in the market;
- develop a unique communication program to be transferred to agricultural engineers, extension agents, and farmers, based on local agronomic expected responses.

Auxin Signaling in *Azospirillum brasilense*: A Proteome Analysis

Stijn Spaepen and Jos Vanderleyden
Department of Microbial and Molecular Systems, Centre of Microbial and Plant Genetics, KU Leuven, Heverlee, Belgium

91.1 INTRODUCTION

The auxin family is by far the best studied family of plant hormones. Still, major breakthroughs have been reported recently concerning the molecular mechanisms of auxin signaling, with the isolation of receptor, transport, and signal transduction proteins (Santner and Estelle, 2009; Zhao, 2010). Auxin synthesis is not restricted to plants. Diverse bacterial and fungal species are known to produce auxin, with indole-3-acetic acid (IAA) as the best documented auxin molecule (Spaepen et al., 2007). In the plant-growth promoting rhizobacterium (PGPR) *Azospirillum brasilense*, IAA production has been extensively studied and multiple biosynthesis pathways have been shown, with the pathway via indole-3-pyruvate (Trp → indole-3-pyruvate → indole-3-acetaldehyde → IAA), the most abundant one in the presence of the precursor tryptophan (Prinsen et al., 1993). In addition, more recent is the discovery of IAA as a signaling molecule in some bacteria and lower eukaryotes such as *Escherichia coli* (Bianco et al., 2006), *Agrobacterium tumefaciens* (Liu and Nester, 2006), and *Saccharomyces cerevisiae* (Prusty et al., 2004). Also in *A. brasilense*, IAA can influence gene expression. The key gene in IAA production (encoding an indole-3-pyruvate decarboxylase – *ipdC*) is upregulated by the end-product IAA (positive feedback regulation) (Vande Broek et al., 1999). Recently, we analyzed the transcriptional changes caused by auxin (exogenously added or endogenously altered by inactivation of the *ipdC* gene) for *A. brasilense* demonstrating that IAA is an important trigger for *A. brasilense* to enter into an interaction with plants (Van Puyvelde et al., 2011). To further investigate the signaling role of IAA in *A. brasilense*, a comparative proteome analysis of the wild-type strain and an auxin-impaired mutant (inactivation of *ipdC* gene) was conducted to identify differentially expressed proteins. Identification of these proteins can further unravel the complex role of IAA in the physiology of *Azospirillum*.

91.2 METHODS

The wild-type strains *A. brasilense* Sp245 (Baldani et al., 1986) and auxin-impaired mutant FAJ0009 (Costacurta et al., 1994) were grown in Luria–Bertani medium (per liter: 10 g tryptone, 10 g NaCl, 5 g yeast extract) supplemented with 2.5 mM $CaCl_2$ and 2.5 mM $MgSO_4$ (L* medium). Samples for protein extraction were taken at early-exponential growth phase (OD_{595} 0.3–0.35). Protein purification, sample preparation, protein separation, and protein identification were carried out as described by De Mot and Vanderleyden (1989) and De Mot et al. (2007). In short, proteins were isolated by the phenol procedure and after precipitation solubilized in lysis buffer (7 M urea, 2 M thiourea, 4% CHAPS, 2% DTT, 2% IPG buffer pH 4–7 – GE Healthcare). Protein concentrations were determined using the PlusOne 2D Quant Kit (GE Healthcare). Separation of the isolated proteins was performed by isoelectric focusing using nonlinear Immobiline DryStrips (24 cm, pH 3–7; GE Healthcare). After rehydration of the strips, proteins (50–100 µg) were applied by cup loading. After focusing, the reduced strips were mounted on SDS-PAGE gels

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

(12.5% polyacrylamide; $20 \times 24\,cm^2$), and the proteins were separated according to their molecular weight using an EttanDalt Six electrophoresis system (GE Healthcare). After separation and protein fixation, gels were stained overnight using Sypro Ruby (Invitrogen). After rinsing, gels were scanned with a Typhoon 9400 imager (GE Healthcare). The scanned gel images were analyzed using the ImageMaster 2D Platinum software (GE Healthcare). After normalization of the spot intensities, the ratio (threshold value of 1.3) between corresponding spots in the two conditions (wild-type versus mutant – three biological repeats per strain) was determined. These spots were cut from gels using an Ettan Spotpicker (GE Healthcare). For protein identification, the proteins were tryptic digested in-gel, and the eluted peptides were analyzed by quadrupole–time-of-flight (Q-TOF). Mass fingerprints were submitted to MASCOT database for identification using the genome sequence of *A. brasilense* Sp245 (Wisniewski-Dyé et al., 2011; see Chapter 25) as search database.

91.3 RESULTS AND DISCUSSION

The role of auxin biosynthesis in *A. brasilense* was further examined using a comparative proteome analysis. Therefore, the proteome map of cells harvested in the exponential phase of both the wild-type and auxin-impaired mutant was generated (see Fig. 91.1).

Comparative analysis of the spot intensities of the two proteome maps revealed about 15 proteins that could be identified to be differentially expressed in FAJ0009 compared to the expression level in *A. brasilense* Sp245. As FAJ0009 is a knock-out mutant in the key gene of IAA production, *ipdC*, and produces only 10% IAA of the wild-type level, we can speculate that these proteins are regulated directly or indirectly by IAA. Eight of these differentially expressed proteins could be confidently identified by Q-TOF analysis.

Two proteins were upregulated in FAJ0009 (see Table 91.1). The upregulation of the heat-shock protein DnaK is somehow surprising compared to the observations in IAA-treated *E. coli* cells: nontreated *E. coli* cells have a lower DnaK level than IAA-treated cells. It was suggested that IAA improves *E. coli*'s defense response against adverse conditions (Bianco et al., 2006). In *A. brasilense*, we observed the opposite effect since the DnaK level is higher in the low IAA background (i.e., in FAJ0009). The second identified protein, inosine-5′-monophosphate dehydrogenase GuaB, catalyzes the first step in the guanosine biosynthesis converting inosine-5'-monophosphate into xanthosine-5′-monophosphate. This protein has also been shown to be involved into stress resistance in the symbiotic bacterium *Rhizobium tropici* CIAT899. A *R. tropici guaB* mutant was unable to grow under elevated temperatures and was defective in symbiosis with common bean (Riccillo et al., 2000).

Six proteins were found to be downregulated in the mutant strain FAJ0009 (see Table 91.2). The indole-3-acetic acid biosynthesis controlling (IaaC) protein, identified as a repressor for IAA production (Vande Broek et al., 2005), is slightly downregulated, indicating that the mutant recues its auxin production by lowering the level of the IaaC protein.

A remarkable observation is the strong downregulation of the sugar-binding periplasmic protein SbpA. This protein was previously identified being upregulated (at both transcript and protein levels) by root exudates (Van Bastelaere et al., 1993, 1999). The protein is involved in the uptake of galactose and possibly functions in the chemotaxis of *A. brasilense* to the plant root (Van Bastelaere et al., 1999). The downregulation of SbpA in the mutant strain FAJ0009 indicates that auxin production is needed to have

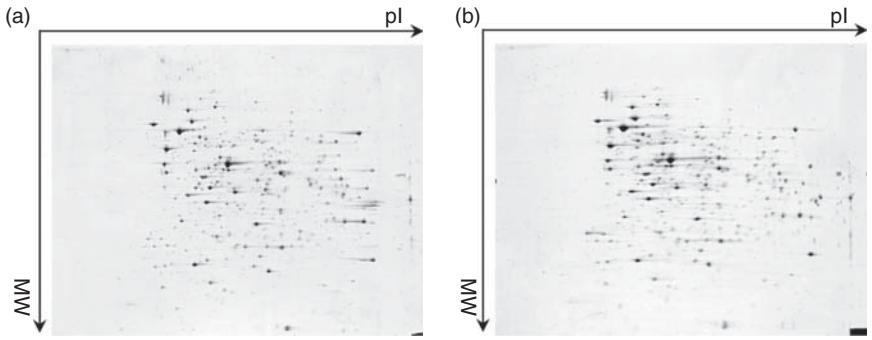

Figure 91.1 Two-dimensional PAGE analysis of proteins of *A. brasilense* and auxin-impaired mutant FAJ0009. Profile of proteins extracted from early-exponential phase (a) wild-type and (b) FAJ0009 cells. Proteins were separated according to pI (horizontally) and molecular weight (vertically) as described in the text.

Table 91.1 Proteins That are Upregulated in FAJ0009

Gene ID	Protein Name	Fold Induction
AZOBR_10493	Chaperone protein DnaK	1.38
AZOBR_p130122	Inosine-5′-monophosphate dehydrogenase	1.69

Table 91.2 Proteins that are downregulated in FAJ0009

Gene ID	Protein Name	Fold Repression
AZOBR_10236	Cysteine synthase	1.30
AZOBR_40353	Indole-3-acetic acid biosynthesis controlling protein	1.54
AZOBR_p280093	Extracellular solute-binding protein	1.55
AZOBR_40113	Cobaltochelatase small subunit	1.55
AZOBR_140167	Succinic semialdehyde dehydrogenase	2.14
AZOBR_p440163	Sugar-binding periplasmic protein SbpA	5.76

expression of certain parts of the chemotaxis system of *A. brasilense*. The *sbpA* gene was also identified to be upregulated by *N*-acyl-homoserine lactone (AHL)-dependent quorum-sensing in a proteome analysis of rice-associated *Azospirillum lipoferum* B518 (Boyer et al., 2008). However, it is difficult to link these results to our data, since AHLs are not synthesized by *A. brasilense* species (Vial et al., 2006).

Other downregulated proteins in FAJ0009 are cysteine synthase (or *O*-acetylserine(thiol)-lyase – CysK), involved in cysteine biosynthesis and tellurite resistance in *A. brasilense* Sp7 (Ramirez et al., 2006), an extracellular solute-binding protein, which is the periplasmic substrate-binding component of a putative ATP-binding cassette (ABC) transporter, and the small subunit CobS of cobaltochetalase, involved in the incorporation of the cobalt ion in the prosthetic tetrapyrrole group via the aerobic pathway for the synthesis of cobalamin or vitamin B_{12} (Holliday et al., 2007). As for GuaB, cobalamin biosynthesis is essential for symbiosis as demonstrated using cobalamin biosynthesis mutants for the *Sinorhizobium meliloti–Medicago sativa* and *Sinorhizobium fredii–Vigna radiata* symbiosis (Campbell et al., 2006; Medina et al., 2009).

The last identified downregulated protein in FAJ0009 is the succinic semialdehyde dehydrogenase GabD, catalyzing the conversion of succinate semialdehyde into succinate (which can enter the tricarboxylic acid cycle (TCA) cycle). It is involved in the metabolism of amino acids such as glutamate and tyrosine, but a role in bacteria–plant interactions has not yet been described.

The same conditions used in this proteome analysis (comparing wild-type and *ipdC* mutant cells from early-exponential phase) were already applied in a transcriptome analysis (Van Puyvelde et al., 2011). Therefore, we compared the differential expression data between the transcript and protein levels. However, for most differentially expressed proteins, no significant differential expression at the transcript level was observed. The only exception is the *iaaC* gene: a lower expression to the same extent as at the protein level was observed in the microarray analysis (1.50-fold repression in FAJ0009 – P value <0.001). Interestingly to note is the strong induction of the extracellular solute-binding protein AZOBR_p280093 at the transcript level, but this is only observed by the addition of external IAA.

In general, no major overlaps between expression at the transcript and protein level could be observed. This is not specific for this study: integration of "omics" studies is still challenging and not always straightforward (Kint et al., 2010).

91.4 CONCLUSION

Two-dimensional gel electrophoresis is a powerful high-throughput technique to analyze differentially expressed proteins. This technique was applied on *A. brasilense* to identify the role of IAA biosynthesis in the bacterial physiology. Proteome analysis of cells grown till early-exponential growth phase indicates that major differences can be observed at the level of protein expression between wild-type strain and the *ipdC* knock-out mutant FAJ0009. Nevertheless, it is difficult to pinpoint-specific processes associated with these changes: as for the changes at the transcriptional level, the identification of some differential proteins points toward a role in bacterial adaptation to stress and the plant environment.

Further experiments are planned to unravel differentially expressed proteins at other stages in the growth phase to further investigate the role of IAA in the bacterial physiology.

ACKNOWLEDGMENTS

We thank Els Mercier for the experimental work, Geert Schoofs for advice on 2D-PAGE analysis and PROMETA (KU Leuven) for Q-TOF analysis of protein identification. We acknowledge financial support from Research Foundation-Flanders (FWO-Vlaanderen – grant G.0632.08). S.S. is a recipient of a postdoctoral fellowship grant from FWO-Vlaanderen.

92.1 INTRODUCTION

Ash et al. (1993) first described the genus *Paenibacillus* based on an analysis of the 16S rRNA gene sequence to accommodate the former "group 3" of the genus *Bacillus*. The name "paene" in Latin means almost, and therefore, the *Paenibacillus* is almost a *Bacillus*. The comparative 16S rRNA sequence analysis revealed that rRNA "group 3" bacilli represent a phylogenetically distinct group, exhibiting high intragroup sequence relatedness, and this species is only remotely related to *B. subtilis*, the canonical *Bacillus* species (Govindasamy et al., 2011).

Members of the genus *Paenibacillus* are facultative anaerobic organisms with G + C contents ranging from 45 to 54 mol% (Shida et al., 1997). Phenotypically, the species of this group react weakly to Gram's stain, and even young cultures appear gram-negative. This genus is composed of endospore-forming bacteria that differentiate into ellipsoidal spores, which distinctly swell the mother cell (Govindasamy et al., 2011).

Endospore-forming bacteria are essentially ubiquitous in agricultural systems. Common physiological traits important to their survival include the production of multilayered cell wall structures, the formation of stress-resistant endospores, and the secretion of peptide antibiotics, peptide signal molecules, and extracellular enzymes. However, significant variation exists in other key traits, including nutrient utilization, motility, and physicochemical growth optima (Gardener, 2004). Native populations of *Bacillus* and *Paenibacillus* occur abundantly in most rhizosphere soils and plant tissues and are differently colonized by distinct subpopulations (Mahaffee and Kloepper, 1997; Seldin et al., 1998).

Members of the *Paenibacillus* genus are widely distributed in nature and have diverse physiological characteristics. At present, there are 141 *Paenibacillus* species

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

[http://www.bacterio.cict.fr/p/paenibacillus.html], including 21 species having nitrogen-fixing ability: *P. polymyxa* (Grau and Wilson, 1962), *P. macerans*, *P. durus*, and *P. peoriae* (Montefusco et al., 1993), *P. borealis* (Elo et al., 2001), *P. graminis* and *P. odorifer* (Berge et al., 2002), *P. brasilensis* (von der Weid et al., 2002), *P. massiliensis* (Roux and Raoult, 2004), *P. wynnii* (Rodríguez-Dias et al., 2005), *P. sabinae* (Ma et al., 2007a), *P. zanthoxyli* (Ma et al., 2007b), *P. donghaensis* (Choi et al., 2008), *P. forsythiae* (Ma and Chen, 2008), *P. sonchi* (Hong et al., 2009), *P. riograndensis* (Beneduzi et al., 2010), *P. sophorae* (Jin et al., 2011a), *P. jilunlii* (Jin et al., 2011b), *P. beijingensis* (Gao et al., 2012), *P. brassicae* (Gao et al., 1993), and *P. taohuashanense* (Xie et al., 2012). This genus harbors strains of industrial and agricultural importance. Some of these organisms excrete diverse assortments of extracellular polysaccharide enzymes to hydrolyze complex carbohydrates (Shida et al., 1997), such as glucanotransferase, chitinase, amylase, cellobiohydrolase, agarase, cellulose, and proteases (Aguilera et al., 2001; Sakiyama et al., 2001; Alvarez et al., 2006; Aktuganov et al., 2008; Moon et al., 2011). A number of *Paenibacillus* species also produce polysaccharides (Yoon et al., 2002) and antifungal and antimicrobial agents (Chung et al., 2000; Rosado and Seldin, 1993; Mavingui and Heulin, 1994; Walker et al., 1998; Sakiyama et al., 2001; Tupinambá et al., 2008).

The niche specificity and important ecological activities in *Paenibacillus* species span phylogenetic boundaries. Most species survive as saprophytes in soils, which are the primary reservoirs of these bacteria together with strains belonging to the *Bacillus* genus, and most viable cells exist as inactive spores at any given time (Nicholson, 2002). Furthermore, multiple species can be recovered as epiphytes and endophytes of plants and animals, and foodstuffs and composts are derived from these structures (Stahly et al., 1992; Slepecky and Hemphill, 1992). The rich variety of organic substrates and microniches present in these environments supports a complex milieu of microbial species; therefore, it is not surprising that multiple species of bacilli inhabit these niches (Gardener, 2004).

Numerous *Paenibacillus* species might contribute to the health status of plants in a variety of ways. A considerable number of isolates belonging to this genus have been used as agents of biological control against phytopathogens (Jung et al., 2003; von der Weid et al., 2005; Li et al., 2010; Tu et al., 2013). Yet, the successful application of these agents requires comprehensive knowledge of their ecology. In addition, the safety and efficacy of inoculants are largely determined by the ecological success of strains in the environments in which they are introduced. Better knowledge of the diversity, distribution, and action of bacilli is extremely important for the identification of new strains, the formulation of inoculants, and the determination of the types of plantation these bacteria might be associated with (Gardener, 2004).

Species of the *Paenibacillus* genus are typically beneficial free-living soil bacteria (Garbeva et al., 2003; Lee et al., 2007; Beneduzi et al., 2008a, 2008b) that influence plant growth and health, conferring one or more growth-promoting characteristics as plant growth-promoting rhizobacteria (PGPR) (Kloepper et al., 1989).

PGPRs indirectly or directly affect plant growth. The direct promotion of plant growth through PGPRs typically involves facilitating resource acquisition or modulating plant hormone levels (Glick, 2012). PGPRs can fix atmospheric nitrogen and supply it to plants, and some *Paenibacillus* species consistently show a great capacity to fix atmospheric nitrogen *in vitro* (Elo et al., 2001; Berge et al., 2002; Jin et al., 2011a). These species synthesize siderophores that solubilize and sequester iron from the soil and provide it to plant cells (Beneduzi et al., 2008a,b; Wen et al., 2011). Many strains synthesize several different phytohormones that stimulate various stages of plant growth (Çakmakçi et al., 2007; da Mota et al., 2008; Beneduzi et al., 2008a, 2008b; Lal and Tabacchioni, 2009) and might possess mechanisms for the solubilization of minerals, such as phosphorus (Hayat et al., 2010; Vazquez et al., 2000), that subsequently become more readily available for plant growth. A particular PGPR might affect plant growth and development through one or more of these mechanisms. The indirect promotion of plant growth occurs when PGPRs, acting as biocontrol bacteria, reduce the inhibitory effects of various pathogenic agents on plant growth and development (Glick, 2012). The direct antagonism of plant pathogens by *Paenibacillus* spp. has been well reported, and several strains can be used as biocontrol agents (von der Weid et al., 2005; Ryu et al., 2006; Senthilkumar et al., 2007; Zhou et al., 2008; and many others).

In recent years, *Paenibacillus* and *Bacillus* spp. have attracted considerable attention due to their advantages over other PGPR strains in inoculant formulations, stable maintenance in rhizospheric soil, and increased potential in sustainable agriculture (Govindasamy et al., 2011).

92.1.1 *Paenibacillus riograndensis*

Beneduzi et al. (2008b) investigated 311 strains of bacilli (primarily species of the genera *Bacillus* and *Paenibacillus*), displaying the important plant growth-promoting characteristics of isolates from seven distinct wheat production zones of the Rio Grande do Sul State, south Brazil. Of those isolates, SBR5, CSR16, SVPR30, and EsR7 were identified by the 16S rRNA gene sequences as strains of *Paenibacillus* sp. and selected for use in additional *in vivo* experiments in a greenhouse. The results showed that these species efficiently promoted a significant increase in the shoot and dry matter of wheat [*Triticum aestivum*] plants (Fig. 92.1).

The diazotrophic strain SBR5 was selected as a morphological, phylogenetic, and physiologically novel PGPR

Figure 92.1 The effect of inoculation of native PGPR isolates on wheat growth promotion, 30 days after sprouting. Plants were inoculated with CSR16 (1), SBR5 (2), SVPR30 (3), and EsR7 (4) strains; (5) plant was inoculated with *Paenibacillus polymyxa* ATCC 10343 strain; (6) positive control (plant was irrigated with mineral fertilizer solution); (7) negative control (plant was irrigated with distilled water).

bacterium, referred to as *Paenibacillus riograndensis* (ri.o.gran.den.sis. N. L. masc. adj. *riograndensis* referring to Rio Grande do Sul, the State located in southern Brazil, where the strain was isolated; Beneduzi et al., 2010).

The bacteria of strain SBR5^T are gram-variable, rod-shaped, sporulating and motile. The isolate produces ellipsoidal spores with a typical striped pattern. On GB medium, the colonies are circular, convex, white, and translucent and typically grow 1–2 mm in diameter within 24 h at 28 °C. The optimal growth temperature is 28 °C, and the optimal growth pH is 7. Strain SBR5^T displays PGPR characteristics, as it is able to fix nitrogen and to produce siderophores and indole-3-acetic acid (Beneduzi et al., 2010).

SBR5^T is phylogenetically related to members of the genus *Paenibacillus*, and the closest related species include *P. graminis* RSA19^T [98.1% similarity], *P. odorifer* TOD45^T [95.8%], and *P. borealis* KK19^T [96.3%]. The phylogenetic analysis based on *nifH* sequences revealed that the SBR5^T strain also clustered together with species of the genus *Paenibacillus* and showed high levels of *nifH* gene sequence similarity with *P. graminis* [78%], *P. wynnii* [79%], *P. odorifer* [77%], and *P. borealis* (74%] (Beneduzi et al., 2010).

Among the 814 genome sequences of Firmicutes listed in the Microbial Genomes of the National Center for Biotechnology Information, Paenibacillaceae comprise 51 genome projects, and the sequencing of the genome of the plant growth-promoting strain *Paenibacillus riograndensis* SBR5^T is now complete (Beneduzi et al., 2011). These data have been deposited in GenBank under the accession number DB SUB001272.

92.2 GENETIC AND FUNCTIONAL CHARACTERIZATION OF *Paenibacillus riograndensis*

92.2.1 Nitrogen-Fixing Genes

The great versatility of the secondary metabolism of many gram-positive bacteria makes these organisms suitable as biocontrol organisms against many different threats. From gram-positive bacteria, much is already known about human and animal pathogens. However, few studies have focused on beneficial plant-microbe interactions and plant growth-promoting gram-positive bacteria. For instance, the well-studied biological nitrogen fixation (BNF) has not yet been fully understood in gram-positive bacteria. The structural components for BNF have been identified and are primarily the same as those described in gram-negative bacteria, but the regulation of this process, which is crucial for enzyme functioning, has not been characterized for most of the gram-positive gene clusters. BNF is extremely costly, with respect to the energetic of this process, as 16 ATP molecules are used for each N_2 converted to ammonium, suggesting that tight regulation must occur (Dixon and Kahn, 2004).

Plant-associated gram-positive bacteria exist in two phyla: the Firmicutes and the Actinobacteria. *Frankia* spp. (Actinobacteria) are able to fix nitrogen in the free-living state and symbiotically with the non-legumes of a taxonomically diverse group of Angiosperms (Gtari et al., 2012; see Chapters 24, 35, 42, 43, 55, 75).

The typical regulation of nitrogen fixation for gram-positive bacteria is somehow different from that of gram-negative bacteria, potentially reflecting the lack of transcriptional control through the usual NifLA system present in gram-negative bacteria (see Chapters 9, 10, 11). However, in a recent study of *P. durus*, the authors showed that the presence of ammonium, even at high concentrations, did not inhibit the expression of *nifH* and *anfH*. For this bacterium, there are at least three copies of the *anfH* gene, although one of the copies is not transcribed (non-functional gene) (Teixeira et al., 2008). These authors suggest that, in the case of *P. durus,* regulation might occur at the post-translational level (see Chapter 13). Three copies of the *nifH* gene were also identified in *P. sabinae*, using RT-PCR (reverse transcription polymerase chain reaction) (Hong et al., 2012), and the expression of all copies was detected under

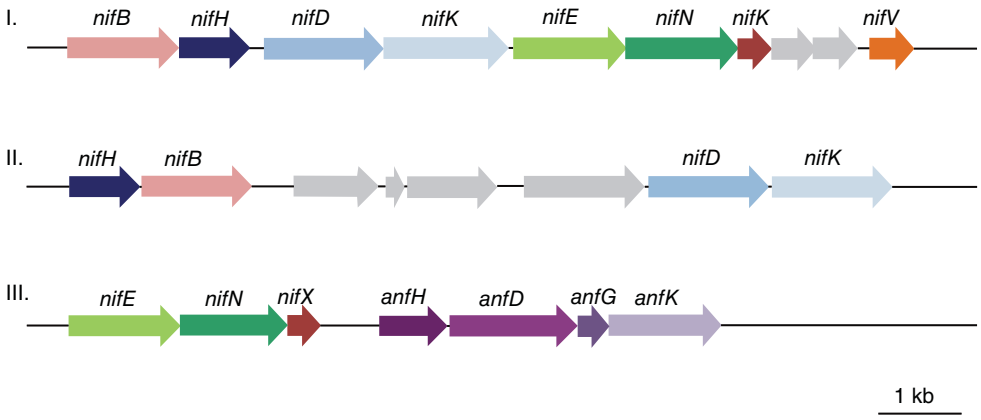

Figure 92.2 The genetic organization of the three clusters containing nitrogen fixation-related genes found in the *Paenibacillus riograndensis* genome.

nitrogen-fixation conditions. In the same study, the promoter regions of all *nifH* copies were tested in a heterologous system [*Escherichia coli* JM109], and the results indicated the activation of the promoters without the NifA activator, which is typically required for the activation of nitrogen fixation genes in gram-negative bacteria. A much different organization is identified in *Clostridium* diazotrophic species, such as *C. pasteurianum* (Kassap and Chen, 2005). In this bacterium, six copies of the *nifH* gene exist. Although the functionality of these copies has not been demonstrated, the transcription of the different copies can be detected using RT-PCR (Kassap and Chen, 2005).

In the plant growth-promoting bacterium *P. riograndensis, nif* operons have been described (Fig. 92.2): one complete operon containing *nifBHDKENXorf1orf2nifV* genes, located in a cluster; and an incomplete operon, with *nifHBorf1orf2orf3orf4DK* genes, and two copies of the *nifU* gene elsewhere in the genome. An *anf* operon was also identified in this genome, with *nifENXanfHDGK* genes.

The presence of an alternative nitrogenase gene cluster was also described for *P. azotofixans* (Rosado et al., 1998) and *C. pasteurianum* (Wang et al., 1988).

Preliminary studies for promoter characterization of the putative operons from nitrogen fixation genes in *P. riograndensis* have confirmed the lack of activation in the incomplete operon; however, activity of the *nif* and the *anf* operons has been reported. Using conventional nitrogen-limiting media, the bacterium makes use of the complete *nif* operon, activating Mo–Fe nitrogenase (G. Fernandes, personal communication). Similar to *P. durus* (Teixeira et al., 2008), the *anfH* gene and the entire promoter are also used in nitrogen fixation, as shown in the promoter tests with *P. riograndensis* (Fig. 92.3). Based on these results, experiments using culture media without the addition of molybdenum should demonstrate the increased promoter activity of the *anf* and *nif* operons.

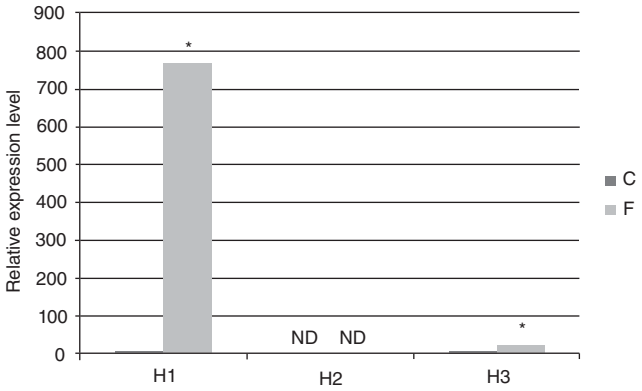

Figure 92.3 *Paenibacillus riograndensis* expression profile under nitrogen fixation conditions. The relative expression levels of the *P. riograndensis nifH1* (H1), *nifH2* (H2), and *anfH* (H3) genes (normalized to 16S rRNA expression) under standard nitrogen fixation conditions (F, cultivated on TBNR [N-free] medium) and control non-fixing conditions (C, cultivated on KB [N-rich] medium). ND: non-determined. * indicates statistically significant differences ($P < 0.05$, Student's T test) in comparison to control conditions.

92.2.2 Plant Growth-Promoting Characteristics

P. riograndensis was first isolated from wheat cultivated in the fields in south Brazil, in a study where bacteria were selected according to their ability to promote plant growth (Beneduzi et al., 2008b). The characteristics tested included nitrogen fixation, indolic compound and siderophore production, and phosphate solubilization, which showed a positive phenotype for this isolate (Beneduzi et al., 2008b). In the molecular studies of this bacterium, the *nifH* gene was amplified, and a phylogeny was reconstructed based on that sequence (see Chapters 3, 8, 20, 77). The phylogeny resulting from the NifH amino acid sequence was comparable to that of the 16S rDNA gene (Beneduzi et al., 2008b, 2010).

The phenotypical analysis and inoculation tests, using wheat as the host plant, confirmed the beneficial aspects of this bacterium toward the growth of this plant (see Fig. 92.1).

The isolate that generated the new species was able to produce a great amount of indolic compounds *in vitro* after 144 h of incubation (Beneduzi et al., 2008b). This important feature represents the direct effect of a PGPR to increase plant root growth and, in turn, to enhance plant nutrition. Other *Paenibacillus* species also show enhanced indolic compound production, such as *P. polymyxa* (Lebuhn et al., 1997; Quyet-Tien et al., 2008). The production of IAA (indolic-acetic-acid) from the tryptophan pathway (Quyet-Tien et al., 2008) has been previously demonstrated in *P. polymyxa*. In *P. riograndensis,* however, no genes with products involved in the tryptophan pathway were identified (Beneduzi et al., 2011). The exact mechanism used by this bacterium for the production of the plant hormone remains elusive.

Another important characteristic of a PGPR is the synthesis of siderophores, which chelate iron from soil and internalize the complex siderophore-Fe, providing iron in the soluble form for plants. The ability to grow in media when iron is unavailable was previously demonstrated in *P. riograndensis* (Beneduzi et al., 2008b). The type of siderophore produced or how it is transported in the bacterial cell is still not fully understood. However, copies of the genes *fhuCDB*, coding for siderophore recognition and uptake, were identified in the genome of *P. riograndensis*. There are four operons encoding these genes in this bacterial genome and two copies of the transcriptional regulator *fur*, which is the regulator of global iron metabolism (Beneduzi et al., 2011). Siderophore production has also been demonstrated in other species of the *Paenibacillus* genus. In the *P. elgii* strain, a gene cluster encoding the siderophore paenibactin was recently identified (Wen et al., 2011). *P. polymyxa* has previously demonstrated siderophore production, secreting small quantities of hydroxamate-type siderophores (Raza and Shen, 2010). These authors suggest that there might be a different mechanism for iron acquisition in this bacterium.

There is little information concerning the genetic process of phosphate solubilization in bacteria, although this phenotype is of great importance for a PGPR. Because many *Bacillus* species have demonstrated phosphate solubilization *in vitro* (Rodriguez et al., 2006), *Paenibacillus* species also present this feature. *P. riograndensis* was able to grow in media containing the insoluble form of phosphate complexed with calcium, suggesting that this bacterium possesses the ability to use mineral phosphate associated with hydrated oxides. The roots of plants associated with the bacterium can easily make use of the converted phosphate. A recent publication describes the solubilization of phosphates from the bacterium *P. polymyxa* under different phosphate sources (Wang et al., 2012).

Another important feature of PGPR is the production of antibiotic antagonistic substances. In the genome of *P. riograndensis,* genes with products related to antibiotic synthesis or transport were identified. Three different ORFs for the biosynthesis of monooxygenase antibiotic were annotated, and several genes with products related to the antibiotic tetracycline, such as efflux pumps, and membrane and resistance proteins, have been identified. Several other ORFs presenting products that function as resistance proteins for other antibiotics were also annotated. In other *Paenibacillus* species, the production of and resistance to antibiotics are also common. The recent release of a draft genome from *P. elgii* showed multiple sets of genes related to antibiotic biosynthetic pathways (Ding et al., 2011). Similarly, the existence of resistance genes has been described for several different strains of *P. polymyxa* (Jeong et al., 2011; Ma et al., 2011; Kim et al., 2010).

92.3 OTHER FEATURES OF *P. riograndensis* SPECIES

As with many bacillus, *P. riograndensis* has the capacity for sporulation (Beneduzi et al., 2010). Gram-positive bacteria use this feature as a survival strategy, according to the environment in which they are present. As soil bacteria, sporulation might confer an advantage when facing hostile conditions. Many genes related to this feature were identified in the *P. riograndensis* genome. Genes with functions related to germination, maturation, and spore structure have been identified in the *P. riograndensis* genome (Table 92.1). This feature was also investigated in *P. polymyxa* strains (Huo et al., 2010, 2012). In addition, the pathogenic species *P. larvae* presents remarkable endospore formation and has been the focus of recent research endeavors (Lindstrom et al., 2008; Alvarado et al., 2013).

Other interesting features for soil bacteria include chemotaxis and flagella formation. The genome of *P. riograndensis* presents a great number of ORFs related to these characteristics. Motility-related genes might provide an advantage to the bacterium in the soil, providing a mechanism to search for better conditions when the environment is not favorable. Another species of this genus that also displays chemotaxis-related motility is *P. vortex*. Many chemotaxis-related genes have been identified in the genome of this bacterium (Sirota-Madi et al., 2010). In *P. riograndensis*, the chemotaxis genes are located in the same cluster as the flagella formation genes.

The *P. riograndensis* bacterium possesses the important characteristics of a PGPR, and this potential was previously demonstrated *in vitro* through inoculation tests. In the future, this bacterium might be used in the formulation of an inoculant for wheat (*Triticum aestivum*), which is the natural host plant of this bacterium, and perhaps other grasses as well.

Table 92.1 Sporulation related ORFs identified in the *P. riograndensis* genome

ORF	Clusters of Orthologous Groups (COG) Classification	Product
0004.0005	D-Cell cycle control, cell division, chromosome partitioning	Spore cortex biosynthesis protein YabQ
0115.0001	R-General function prediction only	Spore maturation protein
0115.0002	R-General function prediction only	Spore maturation protein
0118.0005	R-General function prediction only	Lipoprotein LpqB, GerMN domain protein spore germination protein M
0207.0012	M-Cell wall/membrane/ envelope biogenesis	Spore coat-associated protein, camelysin
0212.0011	R-General function prediction only	GerA spore germination protein
0231.0035	R-General function prediction only	Spore germination protein
0231.0036	R-General function prediction only	GerA spore germination protein
0417.0018	M-Cell wall/membrane/ envelope biogenesis	Putative spore coat protein F
0417.0021	M-Cell wall/membrane/ envelope biogenesis	Putative spore coat protein F
0420.0009	M-Cell wall/membrane/ envelope biogenesis	Small acid-soluble spore protein alpha/beta type
0440.0004	M-Cell wall/membrane/ envelope biogenesis	Spore coat-associated protein JA
0579.0057	R-General function prediction only	GerA spore germination protein
0579.0060	R-General function prediction only	Spore germination protein

The full understanding of the microorganism is essential for the use of this bacterium in association with plants. The first step toward this goal was achieved after the sequencing of the genome of this bacterium, and based on the information obtained other gram-positive bacteria might also be used as PGPRs.

ACKNOWLEDGMENTS

This work was financed through a grant and fellowships from the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq/Brazil), Fundação de Amparo à Pesquisa do Estado do Rio Grande do Sul (FAPERGS, Brazil), and the Instituto Nacional de Ciência e Tecnologia (INCT) da Fixação Biológica do Nitrogênio.

93.1 LPS BIOSYNTHESIS MECHANISM IN *H. seropedicae*

Lipopolysaccharides (LPS) are outer membrane components of the gram-negative bacteria composed of three biosynthetically distinct structures: lipid A, core oligosaccharide, and O-antigen (Goldman and Hunt, 1990).

In most bacteria, the LPS biosynthesis genes are clustered with monosaccharide biosynthesis and modification genes, glycosyltransferases, sugar ABC-type transport systems, O-antigen ligase, polymerase, and other related genes (Reeves and Wang, 2006). The analysis of the *H. seropedicae* genome sequence (NC_014323) revealed the presence of several genes coding for proteins probably involved in LPS biosynthesis. These genes are dispersed in the genome, constituting small operons, a feature similar to that observed in *Gluconacetobacter diazotrophicus* (Bertalan et al., 2009).

Sequence analyses and the chemical structures elucidated by Serrato et al. (2012) helped suggest the biosynthetic pathway of the lipid-A portion of *H. seropedicae* LPS (Fig. 93.1). *H. seropedicae* LPS has five different fatty acids as constituents: 3OH-$C_{12:0}$ (54.6 mol% of LPS fatty acids), $C_{16:0}$ (29.4 mol%), 3OH-$C_{10:0}$ (11.0 mol%), $C_{12:0}$ (2.9 mol%), and $C_{14:0}$ (2.0 mol%) (Serrato et al., 2012). However, only the position of two N-substituted 3OH-$C_{12:0}$ in both β(1–6)-linked GlcN has been determined.

The O-antigen biosynthesis occurs through the transfer of UDP-sugars by glucosyltransferases to an acyl carrier undecaprenyl-PP to form the polymeric unit. *H. seropedicae* has 23 glucosyltransferase genes that could be responsible for those transfers. LPS saccharide constituents analysis showed five different monosaccharides: rhamnose (35.9 mol%), N-acetyl glucosamine (28.2 mol%), glucose (27.5 mol%), 3-deoxy-mano-oct-2-ulopiranosonic acid (6.2 mol%), and 4-N-arabinose (2.1 mol%) (Balsanelli et al., 2010). There are four described systems responsible for the O-antigen polymeric unit export and final assembly: Wzy/Wzx-, Wzm/Wzt-, synthase-, and Wzk-dependent systems (reviewed by Cuthbertson et al., 2010; Valvano, 2011). *H. seropedicae* gene content suggests that this bacterium uses an ATP-based transporter, the Wzm/Wzt-dependent system. In these systems, the polymeric O-antigen is formed on the cytoplasmic side of the plasma membrane prior to its export through an ABC-type transporter (Raetz and Whitfield, 2002; Valvano, 2003). After transport to the outer face of the plasma membrane, a specific glycosyltranferase called WaaL catalyzes a saccharyl transfer reaction from undecaprenyl-PP-O antigen to the lipid-A-core, forming the

LpxA (*Hsero_2190*) is a UDP-N-acetylglucosamine O-acyltransferase, LpxC (*Hsero_0343*) lipid-A-disaccharide synthase, LpxD (*Hsero_2188, 4206*) UDP-3-O-(3-hydroxymyristoyl) glucosamine N-acyltransferase, LpxH (*Hsero_1865*) UDP-2,3-diacylglucosamine hydrolase, LpxB (*Hsero_2191*) lipid-A-disaccharide synthase, WaaA (*Hsero_0475*) Kdo transferase, ArnA (*Hsero_2086*) UDP-glucuronic acid decarboxylase/UDP-4-amino-4-deoxy-L-arabinose formyltransferase, ArnB (*Hsero_2088*) UDP-4-amino-4-deoxy-L-arabinose--oxoglutarate aminotransferase, ArnC (*Hsero_3963*) undecaprenyl-phosphate 4-deoxy-4-formamido-L-arabinose transferase, ArnD (*Hsero_4680*) 4-deoxy-4-formamido-L-arabinose-phosphoundecaprenol deformylase, ArnE (*Hsero_2089*) and ArnF (*Hsero_2091*) 4-amino-4-deoxy-L-arabinose-phosphoundecaprenol flippase subunit, and ArnT (*Hsero_0857, 2090*) 4-amino-4-deoxy-L-arabinose transferase.

complete LPS molecule. The LPS is then exposed to the outer membrane by a polysaccharide export protein (Wza) by a mechanism still to be known (Valvano, 2003, 2011).

93.2 LPS BIOSYNTHESIS REGULATION IN *H. seropedicae*

The expression of *H. seropedicae* LPS metabolism genes was tested using three *lacZ* fusions with genes involved in different levels of the biosynthesis. The first fusion evaluated the regulation of monosaccharide biosynthesis through analysis of the expression of the operon *rfbGgalErfbBC*, part of the rhamnose biosynthesis pathway, the major monosaccharide component of *H. seropedicae* LPS (Balsanelli et al., 2010). The second fusion evaluated the regulation of transport and assembly of lipid A-core portion through the analysis of expression of the operon *rfaLmsbAHsero3567rfaJJ2* (data not shown). The third fusion evaluated the regulation of assembly of the complete LPS molecule through the analysis of expression of the *waaL* (codes for O-antigen ligase) promoter (Balsanelli et al., 2013). The expression of the fusions was tested in the presence of maize plants, plant-derived compounds, antibiotics, and calcium ions.

Surprisingly, in the case of all the tested fusions calcium ions increased the expression of LPS metabolism genes. Addition of Ca^{+2} to *H. seropedicae* cultures led to a shift of polymerization level of O-antigen portion of the LPS, causing an increase in high molecular weight molecules (Balsanelli et al., 2010). Calcium is involved in several bacterial cellular processes, such as cell cycle and division, pathogenesis, motility, and chemotaxis (Michiels et al., 2002; Dominguez, 2004). Changes in intracellular Ca^{2+} concentration also alter the stability and activity of several enzymes, indicating that Ca^{2+} can act as a metabolic regulator (Rampersaud et al., 1991; Holland et al., 1999; Michiels et al., 2002; Dominguez, 2004). Indeed, Ca^{2+} plays an important role as a factor of host recognition and specificity in many bacteria (Economou et al., 1990; Ehrhardt et al., 1996; Gehring et al., 1997; Felle et al., 1998; Broughton et al., 2006). Under natural conditions, *H. seropedicae* could access calcium ions from the plant apoplast, where their concentration varies from 1 to 10 mM (Bush, 1995; Lecourieux et al., 2006), suggesting that transcription of LPS genes is upregulated in the bacterium when it enters living plant tissues. The mechanism of Ca^{2+}-dependent transcription regulation in *H. seropedicae* needs further investigation.

Polymyxin B sulfate and salicylic acid (SA) also alter the expression of the *rfb* operon, suggesting that the biosynthesis of LPS may be triggered by chemically aggressive compounds. The response of bacteria to SA through differential gene expression may be important to guarantee their survival upon entering the plant. For example, SA was shown to downregulate fitness and virulence factor production in *Pseudomonas aeruginosa* PA14 (Prithiviraj et al., 2005). In *Agrobacterium tumefaciens,* SA inhibited the induction of virulence genes (Yuan et al., 2006).

Some plant signals, such as flavonoids (see Chapter 50), might signal to the bacteria the presence of the plant host and induce expression of genes necessary for colonization, including the LPS genes. The plant flavonoid naringenin increased the expression of the *rfb* operon and *waaL*. Tadra-Sfeir et al. (2011) showed that *H. seropedicae* responds to naringenin by modifying the cell wall through altered expression of genes involved in outer membrane, cell wall, and peptidoglycan metabolism. Changes in the cell surface are documented in other bacteria that interact with plants, and probably such changes play a role in the interaction between the endophyte *H. seropedicae* and its host plants (Broughton et al., 2006; Quéré et al., 2006; Staehelin et al., 2006).

The expression of the three fusions was evaluated during the early interaction with maize. In addition to the fact that the presence of the plant increased LPS genes expression of surrounding free-living bacteria, a remarkable induction was observed in the cells attached to the maize root surface. Such induction suggests a role for the LPS as an anchoring molecule to the host.

In summary, *H. seropedicae* LPS synthesis is induced during interaction with maize by plant signals, indicating the importance of this molecule during host colonization.

93.3 LPS AS A BACTERIAL PROTECTION BARRIER

The bacterial surface makes the first contact with host cells and the host chemical defenses. Among several surface polysaccharides, the LPS of gram-negative bacteria is thought to be a protective wall, rendering bacteria resistant to a variety of plant defense molecules (Nikaido, 1994; Erbs and Newman, 2003). This protection barrier function is stressed by the fact that LPS allows the traverse of hydrophobic molecules at about 1–2% of the rates observed with typical phospholipid bilayers (Plesiat and Nikaido, 1992; Allende and McIntosh, 2003). Indeed, LPS has two potential ways to act as barrier: the packed saccharide portion of the molecule that forms a hydrophilic wall (Snyder et al., 1999), and the fatty acid portion of the lipid-A that constitutes a hydrophobic wall (Brandenburg et al., 1997; Andra et al., 2004). Several transcriptome analyses showed that the expression of cell envelope biosynthesis genes is modified during interaction with the host (D'Haeze and Holsters, 2004), indicating changes in the capsule structure. Such modifications can allow the bacteria to mimic the host immune system and suppress or evade immune reactions, to counteract the plant defense and proceed with the establishment of the interaction (Lerouge and Vanderleyden, 2002).

Changes in LPS structure often result in increased sensitivity to antimicrobial peptides, detergents, and other chemical stresses (Campbell et al., 2002; Lerouge and Vanderleyden, 2002; Jofré et al., 2004), such as sodium dodecyl sulfate (SDS), polymyxin B, and plant-derived flavonoids and SA. SA, a plant phenolic secondary metabolite, is a key regulator of plant defenses in response to a wide variety of pathogens (Martinez-Abarca et al., 1998; Prithiviraj et al., 2005; Stacey et al., 2006). During infection, SA, apart from acting as a bactericidal agent, triggers plant long-lived resistance to pathogens by either a localized or a systemic acquired response (Durrant and Dong, 2004; Prithiviraj et al., 2005). *H. seropedicae* is resistant to low concentrations of SA (up to 25 μg/ml) (Balsanelli et al., 2010), similar to the concentrations accumulated in bacterial infection sites of plants (16–23 μg/ml) (Huang et al., 2006). Alterations in LPS structure decreased this resistance, suggesting that the *H. seropedicae* LPS acted as a barrier to SA, preventing it from entering into the bacteria. This resistance to SA may be important to guarantee bacterial survival upon entering the plant, ensuring endophytic colonization. In fact, *H. seropedicae* mutants that display LPS alterations showed decreased endophytic colonization compared to the wild type (Balsanelli et al., 2010; 2013).

93.4 LPS AS AN ANCHORING SITE FOR BINDING ROOT LECTINS

Apart from the general function of protection barrier displayed by LPS molecules, a much more specific role for these molecules was described during attachment of *H. seropedicae* to the maize root surface.

Maize inoculation assays showed that efficient attachment of *H. seropedicae* requires the O-antigen of LPS, since the number of wild-type bacteria attached to maize root surfaces was approximately 100-fold higher than that of the mutant strains lacking the O-antigen. The possible role of bacterial outer membrane proteins in the attachment step was discarded because proteinase-K-treated bacteria attached normally on the roots. Also, the SDS-PAGE profile of outer membrane protein extract from LPS mutants was not different from that of the wild type, indicating the involvement of LPS O-antigen in attachment. On the other hand, when the roots were treated with proteinase-K, wild type attachment decreased to similar levels of the LPS mutants, suggesting that maize root proteins could act as receptors for bacterial attachment. The attachment capacity of the wild type strain was also reduced to a level equivalent to that of the LPS mutants when the assay was performed in the presence of isolated wild type LPS, glucosamine, or N-acetyl glucosamine, suggesting that these compounds blocked bacterial attachment sites. These data suggest that *H. seropedicae* LPS O-antigen participates in the attachment step of colonization by anchoring the bacterium to plant lectins through its N-acetyl glucosamine residues. Wheat germ agglutinin (WGA), a lectin with high affinity toward N-acetyl glucosamine, is present on surfaces of wheat seedlings and on root tips of adult wheat plants (Mishkind et al., 1983), and may therefore be a site for specific attachment of rhizobacteria contributing to bacterial adhesion to the root surface (Del Gallo et al., 1989). The WGA lectin was able to agglutinate *H. seropedicae* wild type cells, but not the *waaL* mutant (lacks the LPS O-antigen), in a concentration-dependent manner, indicating that the lectin is capable of binding to the *H. seropedicae* cell surface. WGA also inhibited attachment of wild type *H. seropedicae* to maize and wheat plants, but not that of LPS mutant, further supporting the LPS–lectin binding model for attachment.

Three lectin-like proteins from maize roots (MRLs - *M*aize *R*oot *L*ectins) were purified by affinity chromatography on an N-acetyl glucosamine-agarose column, since this monosaccharide inhibits *H. seropedicae* attachment to maize roots. Mass spectrometry analysis showed that proteins MRL-1 and MRL-2 are similar to uncharacterized jasmonate-induced maize proteins. Both proteins have a jacalin-like domain with six sugar binding sites, which may bind mono- or oligosaccharides with high specificity (Raval et al., 2004). MRL-3 contains a B chain domain, a two-domain lectin with aromatic residues that can interact with the nonpolar face of saccharides and polar residues for hydrogen bond formation to the sugar hydroxyl groups (Boraston et al., 2004). These proteins showed agglutination activity against wild type *H. seropedicae*, but failed to agglutinate the *waaL* mutant strain. The agglutination reaction was severely diminished in the presence of N-acetyl glucosamine. Moreover, addition of the MRL proteins as competitors in *H. seropedicae* attachment assays decreased the adhesion of the wild type to maize roots 80-fold. The results suggest that N-acetyl glucosamine residues of the LPS O-antigen bind to the MRLs, an essential step for efficient bacterial attachment and colonization.

The maize GlcNAc-binding lectins have homologs in other grasses such as wheat, rice, and sorghum, plants that are highly colonized by *H. seropedicae*. Indeed, lectins of several cereals, such as wheat, rye, barley, and rice, are related and can be inhibited by GlcNAc and its oligomers (Stinissen et al., 1985), suggesting that *H. seropedicae* may attach onto root surface in a similar manner in those hosts.

Azospirillum brasilense also interacts with WGA, although it is not clear which outer membrane polysaccharide is involved with this binding (Konnova et al., 1994). Co-inoculation of *H. seropedicae* and *A. brasilense* on maize plantlets showed that different bacterial species containing N-acetyl glucosamine in their outer layer may compete to colonize maize roots (and probably other grasses), and that the structure of such polysaccharides may contribute in determining the specificity of plant–bacteria interactions.

During competition, attachment of both species is reduced when compared to separated inoculation, probably due to sharing a conserved mechanism to bind to GlcNAc-lectins. The question of how exactly such plant proteins promote the binding of rhizobacteria on the root remains unsolved. Some lectins present membrane domains (including MRL-3) that could anchor them on the plant cell membrane, and consequently anchor the bacteria. However, several lectins seem to be secreted in the rhizosphere, agglutinating bacteria in the root mucilage or trapping them in the plant cell wall.

In summary, *H. seropedicae* uses the LPS as anchoring molecules that bind to root NAcGlc-lectins, enhancing the efficiency of bacterial attachment that confers a competitive advantage in the rhizosphere.

93.5 CONCLUSION

The LPS biosynthesis mechanism in *H. seropedicae* is highly conserved among gram-negative bacteria, despite the fact that the genes are dispersed in the genome. The regulation of expression of those genes in *H. seropedicae* seems to be unique, being dependent on plant signals and calcium levels, indicating the important role of LPS in the interaction with the host. The interaction between LPS O-antigen and the MRLs is a key step for the establishment of the bacteria onto the root, enhancing *H. seropedicae* attachment and conferring a competitive advantage during colonization of root surfaces. Such advantage may indicate a preferential access to the inner tissues. During colonization of these inner tissues, a complete LPS molecule appears to be necessary for resistance to plant basal defenses.

Associative bacteria such as *H. seropedicae* display molecular factors that facilitate the adhesion and colonization of plant surfaces and then the invasion of inner tissues. The expression of these molecular factors, including LPS, appears to be under the control of signals sent by the plant. This complex molecular communication between *Herbaspirillum* and plant hosts ensures an efficient association, which results in the promotion of plant growth and increased productivity. Interestingly, the already described molecular mechanisms used by *H. seropedicae* to interact with hosts share similarity to that described for some pathogenic bacteria, which may allow the bacteria to efficiently colonize diverse crops. LPS is a foremost and important factor of *H. seropedicae* for plant colonization, but other factors present in its genome are also required for the interaction. Future work, especially by using omics approaches such as the transcriptomic profile of the bacteria during attachment to maize roots, will identify new molecular players of this interaction and allow improving the model for the establishment of *H. seropedicae*–poacea association.

94.1 INTRODUCTION

The development and extension of biological based economy, the so-called "sustainable bioeconomy," is a major focus of scientific research and technological development in many countries, including Germany and Brazil. The German government recently launched a 6 billion Euro developmental program to develop a biological based economy. In Brazil, an important focus on development and support is on bioenergy crops such as sugarcane, which have ideal climatic conditions for high biomass development with high sugar content. The global goal for energy crops is to

*These authors contributed equally.

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

reduce the dependence on fossil energy sources – which are limited, which increase the price, and which, most importantly, cause major climatic problems for Planet Earth. The challenge is to grow energy crops, such as sugarcane, with the lowest inputs of fossil energy that is required to drive the industrial Haber–Bosch process of reducing atmospheric dinitrogen to ammonia, the basis for plant nitrogen fertilizer. In Brazil in particular, sugarcane plays a fundamental role in the production of bioethanol, which is used as a substitute for fossil fuels in combustion engines. In 2010, almost 10 million ha of sugarcane was planted in Brazil (IBGE, 2010) and approximately half of the cane juice has been fermented to produce alcohol as a biofuel. In contrast to many other energy crop systems, the overall energy balance in Brazilian sugarcane/bioethanol production is clearly positive (Boddey et al., 2008). For most other bioenergy processes, the overall energy balance is around one or even below. Since the energy to be spent for the synthesis of industrial nitrogen fertilizer is a major input, the reduction of fertilizer application would make the energy production even more attractive and efficient in terms of global climate change impact.

The biological nitrogen fixation (BNF) potential of sugarcane with its associated bacteria had come into focus already some decades ago (Döbereiner, 1961; Ruschel et al., 1975). Using ^{15}N-isotope enrichment tracing and natural abundance techniques, it was demonstrated that some sugarcane cultivars could derive up to 70% of plant nitrogen from BNF (Lima et al., 1987; Urquiaga et al., 1992; Boddey et al., 2001; see Chapter 108). A major breakthrough in the characterization of the diazotrophic bacteria, especially in plant associations, was the use of nitrogen-free semisolid media, such as NfB, JNfB, or LGI (Döbereiner, 1995), to efficiently enrich microaerobic nitrogen-fixing bacteria. This resulted in the characterization of many new diazotrophic species, such as *Gluconacetobacter diazotrophicus*, *Herbaspirillum seropedicae*, *Burkholderia tropica*, *Azospirillum amazonense,* and others (Cavalcante and Döbereiner, 1988; Reis et al., 2004; Perin et al., 2006; Baldani and Baldani, 2005; see Chapter 88). However, it could not yet be determined which of these bacteria contributed to the plant nitrogen fixation. It became clear that a diversity of diazotrophic bacteria are distributed in the whole plant, colonizing roots, stem, and leaves endophytically (James et al., 1994). Inoculation experiments with single or mixtures of diazotrophic bacteria were performed, which finally led to the development of the five-strain inoculum introduced by Embrapa Agrobiologia, Seropédica (Oliveira et al., 2003; Oliveira et al., 2006; Oliveira et al., 2009). These inoculations are presently being performed at different places in Brazil. Significant plant growth promotion effects have been found in production-scale field trials, but the level of BNF could not be increased significantly (Schultz et al., 2012). It also became apparent that the diversity of diazotrophic bacterial community of sugarcane plants is quite variable in different regions and cultivars (Asis et al., 2000; Asis et al., 2002; Magnani et al., 2010; Beneduzi et al., 2013; Suman et al., 2001). While a diversity of *Gluconacetobacter diazotrophicus* was found in many studies on different continents using LGI-semisolid media as an enrichment approach, in some other trials it was almost completely missing. In general, within the bacterial diversity retrieved from sugarcane by regular cultivation techniques without enrichment for diazotrophs, the diazotroph community was only found as a minor fraction (Magnani et al., 2010).

An alternative to the cultivation approach is the application of cultivation-independent molecular approaches, using 16S rDNA and *nifH*- or *nifD*-DNA probes, (see Chapters 3, 8, 20, 77) which have the advantage of covering also organisms that are slow growing or generally difficult to grow in pure culture. Several other plants have been investigated in detail with this approach, such as potato, maize, or rice (Roesch et al., 2006; Sessitsch et al., 2002, 2012), which has led to new insights in the diversity of diazotrophs in these systems and the overall bacterial community. Concerning sugarcane, Ando et al. (2005) retrieved for the first time *nifH*-sequences from sugarcane. More recently, Thaweenut et al. (2011), Burbano et al. (2011), and Fischer et al. (2012) studied *nifH*-transcripts in different sugarcane cultivars under different growth conditions. They found, besides *nifH*-sequences of other diazotrophs, also *nif*-transcripts of *Bradyrhizobium* and *Rhizobium* spp. In this chapter, the characterization of the diversity of active bacteria (16S cDNA) and active diazotrophs (*nifH* cDNA) in the sugarcane cultivar RB867515 is described, and the cultivation of *Bradyrhizbium* spp. from this plant using the legume trap plant *Vigna unguiculate* (cowpea) and direct cultivation on plates is presented.

94.2 MATERIALS AND METHODS

94.2.1 Greenhouse and Field Experiments

Greenhouse and field experiments were conducted at the Embrapa Agrobiologia CNPAB institute and experimental field station (22°45′S, 43°40′W and 26 m above sea level) in Seropédica, Rio de Janeiro, Brazil. The soil (Itaguai series) is classified as a Planosol (FAO) or Typic Fragiaquult (USDA, Soil Taxonomy). The soil characteristics in the 0–20 cm layer were pH (in H_2O) 5.4, 1.1 $cmol_c$ Ca^{2+}/dm^3; 0.2 $cmol_c$ Mg^{2+}/dm^3; 0.1 $cmol_c$ AL^{3+}/dm^3; 26.1 mg P/dm^3; 27.0 mg K/dm^3; 0.48% organic carbon, 0.83% organic matter, and 0.043% N. In the greenhouse experiment the cultivar RB867515 was tested in a Sand-Teosint Mix with six plants per pot; after 4 weeks the plants were harvested.

In the field experiments, the plants (cultivar RB867515) were grown for 2 years; the sugarcane plants were analyzed in late summer (March) of the first and second year. While there was no N-fertilization in the greenhouse experiment, there were plots in the field experiments that received urea (120 kg/ha). When the sugarcane plants were inoculated with the five-strain Embrapa-inoculum, the plots received no N-fertilization; more details are presented in Fischer et al. (2012).

94.2.2 DNA/RNA Extraction and PCR Approaches Characterizing the Bacterial Diversity *in planta*

RNA and DNA extractions of plant material were performed using the phenol–chloroform extraction method combined with the column-based AllPrep DNA/RNA Mini Kit (Qiagen, Germany) to purify and isolate RNA and DNA from 400 mg plant material as described by Toewe et al. (2011). Contaminating DNA in the RNA extractions was detected using a 16S rRNA coding gene targeted PCR (polymerase chain reaction) using the primers 341F and 907R (Muyzer et al., 1996). Contaminating DNA was removed using RQ1 RNA-free DNase (Promega, USA). An important step in this reverse transcription polymerase chain reaction (RT-PCR) protocol was that the cDNA was synthesized with the Omniscript RT Kit (Qiagen, Germany) using random primers (Promega, USA) to achieve a mostly unbiased reverse transcription. All PCR reactions were performed using the TopTaq Kit (Qiagen, Germany) in a PEQStar 96 Universal thermocycler (Peqlab, Germany). 16S rRNA cDNA was amplified using the primers 341F and 907R (length about 550 bp) (Muyzer et al., 1996). The annealing temperature for the PCR reaction was 56.5 °C and had 30 cycles. *nifH* mRNA was amplified using nested PCR with the primers PolF and PolR for the initial amplification (Poly et al., 2001) and *nifH*For and *nifH*Rev (length about 314–317 bp) for the second amplification step as described in Roesch et al. (2006). In the second PCR, the annealing temperature was 55 °C, and 33 cycles were used. Amplicons were verified using agarose gel electrophoresis. Genomic DNA from pure cultures of *Herbaspirillum seropedicae* HCC103, *H. rubrisubalbicans* HRC54, *Azospirillum amazonense* CBAmC, *Burkholderia tropica* Ppe8, and *Gluconacetobacter diazotrophicus* PAL5 (diazotrophs in the inoculation mix) was used as positive *nifH*-amplification controls using this nested PCR approach.

Amplicons of the 16S- and *nifH*-cDNA were purified using NucleoSpin® Extract II Kit (Macherey-Nagel, Germany) and cloned using Topo TA Cloning® Kit (Invitrogen, USA) according to the manufacturer′s instructions. Sequencing was performed using BigDye® Terminator (BDT) v3.1 Sequencing Kit (Invitrogen, USA) on an ABI 3730 sequencer (Applied Biosystems, Germany). See details of sequence analysis in Fischer et al. (2012). Evolutionary relationships in the phylogenetic tree were conducted using ARB software (Ludwig et al., 2004) with a neighbor-joining algorithm (Saitou and Nei, 1987).

94.2.3 Preparations for the Isolation of Endophytic Bacteria from Sugarcane

Unlignified white shoot roots from 5-month-old sugarcane plants (cv. RB867515) growing at the Embrapa Agrobiologia experimental field station were collected in June 2012. The roots were thoroughly washed with tap water and surface-disinfected by sequential immersion in 70% ethanol for 30 s, and in undiluted commercial bleach (2.5% hypochlorite) under gentle agitation for 8 min. Then the roots were washed six times with sterile water and the disinfection procedure was evaluated by plating 100 µl of the last washing water on plates containing yeast mannitol agar (YMA) (Vincent, 1970). In addition, the disinfected roots were placed on YMA plates for 10 s before continuing the isolation procedure. These plates were incubated for at least 10 days to permit bacterial growth.

The disinfected roots (1.8 g) were macerated in a sterile mortar and suspended in 17 ml saline solution (NaCl 0.85%). Seeds of *V. unguiculata* (cowpea) were surface-disinfected by immersion in ethanol (70%) and then in undiluted commercial bleach for 5 min. After washing six times with sterile water, the seeds were germinated on water agar (0.8%) for 3 days at 28 °C in the dark.

94.2.4 Isolation of Rhizobia from Sugarcane Tissues Using In Vitro Grown *V. unguiculata* Plants

*S*urface-disinfected *V. unguiculata* seedlings were transferred to 150 ml tubes with slopes of agarized Norris solution and 15 tubes were inoculated with 1 ml of sugarcane root suspension each. Negative controls (three plants) received 1 ml sterile saline solution and positive controls were inoculated with 1 ml of a suspension of strain BR3299 ($OD_{600} = 0.1$) (Radl et al., 2014). The plants were grown in a growth chamber at 25 °C with 12 h photoperiod under artificial light. Sterile water was added when necessary. Thirty days after inoculation, the occurrence of nodulation was evaluated. Nodules were collected and superficially disinfected by immersion in ethanol (70%) for 2 min, followed by treatment with undiluted commercial bleach for 3 min. After washing six times with sterile water, nodules were crushed on YMA plates, which were incubated at 28 °C for 7 days. Purity of bacterial isolates was checked by repeated streaking on fresh plates. Trap-plant isolates received names based on the number of the trap plant they were isolated

from, followed by a sequential number, as follows: P (# *V. unguiculata* plant - # isolate). Representative isolates were individually inoculated on *V. unguiculata* plants to check the nodulation capability, using the same methodology.

94.2.5 Isolation of Rhizobia from Sugarcane Tissues by Direct Plate Cultivation

Aliquots of 100 µl of 10^{-1} and 10^{-2}-fold diluted root extracts were dispersed on plates with modified YMA, containing as the carbon source mannitol (1 g/l) or a combination of the *Bradyrhizobium* spp. preferential carbon sources arabinose (0.5 g/l) and sodium gluconate (0.5 g/l) (Tong and Sadowsky, 1994). Incubation was performed at 28 °C for up to 21 days and slow-growing isolates were selected. Isolates were named as M or AG (mannitol or arabinose/sodium gluconate, respectively) followed by sequential numbers.

94.2.6 Genotypic Grouping of the Isolates by ERIC-PCR

ERIC-PCR was carried out with cell suspensions of the isolates under study as template in 20 µl volumes containing GoTaq® DNA Polymerase (Promega) and primers ERIC 1 (5′ATGTAAGCTCCTGGGGATTCAC 3′) and ERIC 2 (5′AAGTAAGTGACTGGGGTGAGCG 3′), basically as described previously (Woods et al., 1993). After PCR cycling, aliquots of 10 µl were loaded on 2% agarose TAE gels and electrophoresed for 4 h at 80 V. The molecular weight marker 1 kb plus ladder (Invitrogen) was used as reference. To determine genetic relatedness of isolates, a dendrogram was constructed based on the gel images that were analyzed using BioNumerics software version 6.6 (Applied Maths, Belgium), as described by Rademaker et al. (2000) with the DICE index, by the unweighted pair-group method of arithmetic averages (UPGMA). Optimization and tolerance levels were adjusted to 1.75.

94.2.7 PCR, Sequencing of 16S rRNA and *nifH* Genes, and Phylogenetic Analysis

PCR reactions were conducted using cell suspensions in sterile ultrapure water as template with GoTaq® DNA Polymerase (Promega, USA). 16S rRNA genes were amplified using the primers 27F and 1492R (Lane, 1991). The *nifH* gene was amplified with primers nifHF and nifHI (Laguerre et al., 2001). Reactions of isolates that did not produce amplicons using primers nifHF and nifHR were submitted to PCR with primers PolF and PolR (Poly et al., 2001). The PCR products were partially sequenced using primer 1492R for 16S rRNA and primer nifHI for the *nifH* gene using an ABI 3730xl DNA analyzer (Applied Biosystems, Germany). The 16S rRNA sequences (accession numbers KF113075-KF113106) and the *nifH* sequences (accession numbers KF113052-KF113074) have been deposited in the NCBI GenBank.

All sequences were submitted to blast analyses (Altschul et al., 1997), and for phylogenetic analyses, the sequences from reference strains and sequences obtained in the present study were aligned and analyzed using the ARB software (Ludwig et al., 2004).

94.2.8 Acetylene Reduction Assay (ARA)

For ARA, JMV medium (Reis et al., 2004) with some modifications was used, containing (in g/l) 5.0 mannitol, 0.6 K_2HPO_4, 1.8 KH_2PO_4, 0.2 $MgSO_4$, 0.1 NaCl, 0.02 $CaCl_2 \cdot 2H_2O$, 0.002 $Na_2MoO_4 \cdot 2H_2O$, 0.00235 $MnSO_4 \cdot H_2O$, 0.0028 H_3BO_3, 0.00008 $CuSO_4 \cdot 5H_2O$, 0.00024 $ZnSO_4 \cdot 7H_2O$, 0.0001 Biotin, 0.0002 pyridoxol-HCl, 0.0656 Fe-EDTA, 1.6 agar, pH 6.5. Three dosages of nitrogen source were tested: 0, 0.04, and 0.4 g/l yeast extract. Serum vials (20 ml) were filled with 10 ml semisolid media, inoculated with 20 µl cell suspensions in sterile water and closed with cotton plugs. After 5 days incubation at 30 °C, vials were sealed with rubber stoppers and 10% of the air space was replaced with acetylene gas. After 3 h incubation at 30 °C, 0.5 ml aliquots of the gas phase were analyzed by gas chromatography with flame ionization, using Perkin Elmer F11 equipment with a 50 cm Poropak N column at 70 °C. Nitrogenase activity was determined, after comparison to a standard curve, as the quantity (nmol) of ethylene produced per vial during the 3 h incubation period.

94.3 RESULTS

94.3.1 Cultivation-Independent Assessment of Diazotrophs in Sugarcane Cultivar RB867515

The characterization of the bacterial community colonizing sugarcane roots and leaf sheaths was first investigated using general primers for 16S rRNA-gene to obtain an overview about the entire communities in the greenhouse experiment. Four weeks after inoculation of the sugarcane plants (cultivar RB867515) with the 5-strain inoculum of Embrapa Agrobiologia, RNA was extracted from roots and leaf sheaths. The composition of bacteria in the samples is presented in Figure 94.1.

The predominance of alpha-proteobacteria is up to 70% especially in the inoculated roots, followed by beta- and delta-proteobacteria. Among the alpha-proteobacteria, sequences of *Acetobacteriaceae*, *Rhodospirillaceae,* and *Bradyrhizobiaceae* were identified. In the leaf sheaths also

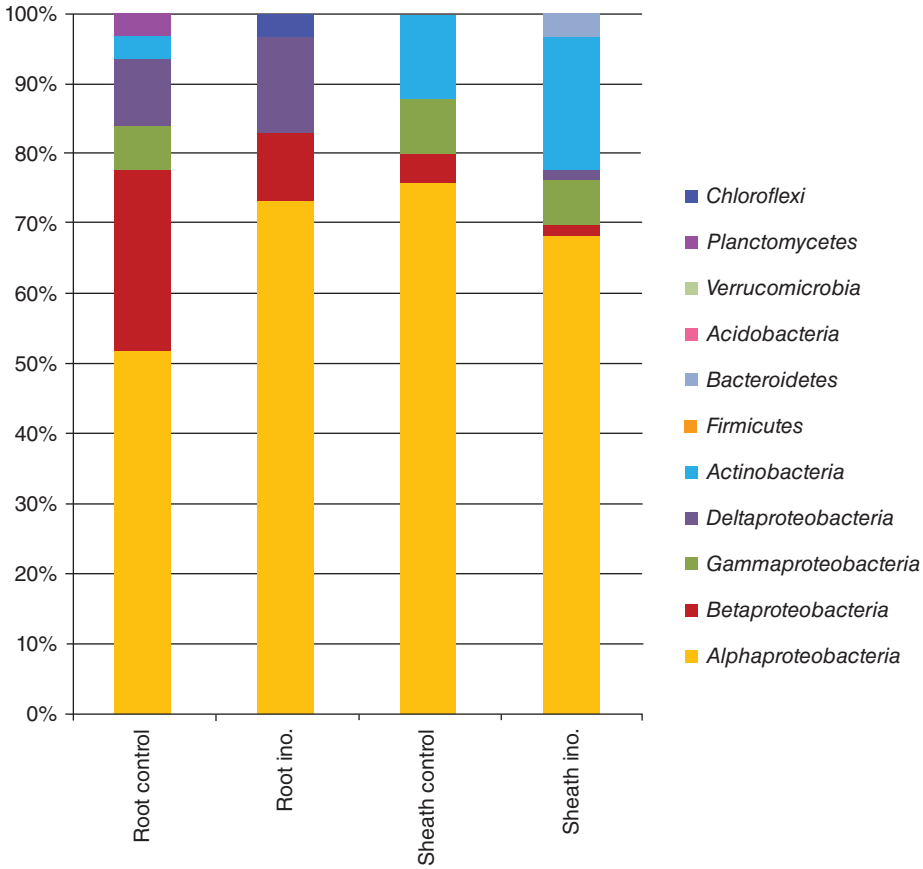

Figure 94.1 Bacterial composition (based on 16S rRNA cDNA) in root and leaf sheath samples after 4 weeks under greenhouse conditions.

alpha-proteobacteria dominated; after inoculation with the bacterial mixture, *Herbaspirillum* sp. *Gluconacetobacter* and *Bradyrhizobium* were found. Thus, there were indications that the inoculum may have been established, but obviously there were other bacteria, such as bradyrhizobia, regularly present, which may have come from the plant material.

In the field experiment (Fig. 94.2) performed at the field station of Embrapa-Agrobiologia in Seropédica, the effect of N-fertilization and inoculation with the 5-strain bacterial mix was investigated (Fig. 94.3).

At the harvest in March 2008, the difference between 16S rRNA DNA, representing the bacterial community, and cDNA, representing the active bacterial community, is only visible in some subpopulations. Within the alpha-proteobacteria, no sequences could be found that were related to *Gluconacetobacter diazotrophicus* or *Azospirllum amazonense*, which were part of the inoculum. Also, neither *Herbaspirillum seropedica* nor *Burkholderia tropica*-related 16S rRNA DNA-sequences could be identified, while other *Burkholderia*-, *Herbaspirillum*- and *Ralstonia*-related sequences were found (data not shown). Apparently, the strains from the inoculum were not part of the dominating community at the time of sampling (March, late summer).

Figure 94.2 Field trial at Embrapa Agrobiologia, Seropedica, 2008.

However, there were a number of clone sequences identified related to *Bradyrhizobium* spp. (Fig. 94.4) and other Rhizobiales (not shown).

16S cDNA and the *nifH*-transcripts in sugarcane roots and leaf sheaths of the same fields were investigated in March 2009. Reinoculation with the 5-strain inoculum was performed after the first cut in 2008. A high diversity of 16S cDNA and *nifH*-transcripts could

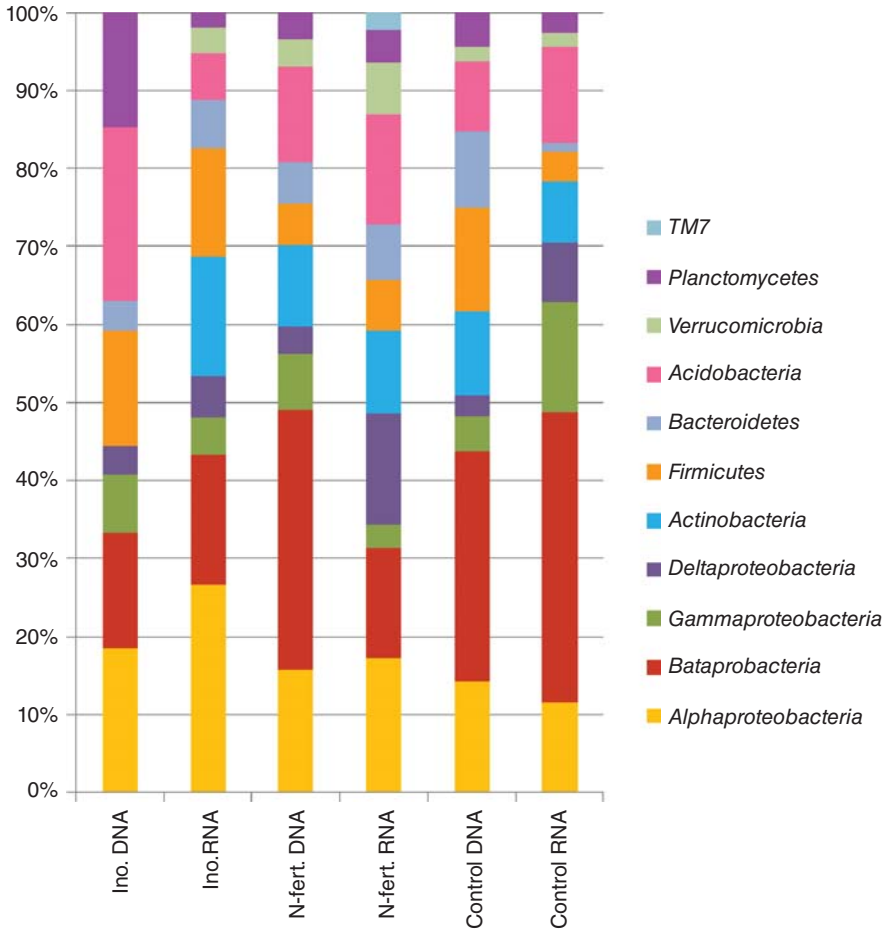

Figure 94.3 Bacterial composition (16S rRNA sequence diversity from RNA and DNA) from root samples of the field trial 2008.

be retrieved from these sugarcane plants (Fischer et al., 2012). *Gluconacetobacter diazotrophicus nifH*-cDNA, as well as 16S cDNA-sequences identical to the inoculated strain were found in ample amount in leaf sheaths of inoculated sugarcane plants (Fischer et al., 2012). However, 16S cDNA and *nifH*-cDNA of the other inoculant strains could not be found. A detailed sequence analysis of the *nifH*-sequences of each of the inoculation strain revealed that *Azospirillum amazonense* CBAmC as well as *A. amazonense* DSM2787 harbor a *Bradyrhizobium*-like *nifH*-sequence. However, this sequence could also not be found within the *nifH* cDNA-sequences retrieved from the sugarcane plants. However, 16S cDNA- and *nifH* cDNA sequences of a new type of bacterial species within the *Ideonella–Azohydromonas–Herbasprillum* cluster was found very frequently mostly in leaf sheaths (not shown). Besides other not yet cultured bacteria from the *Burkholderiaceae*, many 16S cDNA and *nifH* cDNA-sequences from *Bradyrhizobium* were found in roots (Fig. 94.5). *Rhizobium* spp. sequences were retrieved mostly from leaf sheaths (Fischer et al., 2012).

94.3.2 Isolation and Characterization of *Bradyrhizobium* sp. from Sugarcane Cultivar RB867515 by Direct Plate Cultivation and by Using *V. unguiculata* Trap Plants

On the basis of the results obtained with culture-independent approaches, we conducted experiments aiming to isolate bacteria from the genus *Bradyrhizobium* from sugarcane tissues, by inoculating extracts of surface-disinfected sugarcane roots directly on plates or on *V. unguiculata* (cowpea) trap plants. After the disinfection procedure of sugarcane roots, no bacteria grew when water of the final washing step was spread on YMA plates or when disinfected and washed root fragments were placed on YMA plates. This suggested that the procedure was effective in removing the root surface-associated microbial community.

Thirty days after individually inoculating 15 *in vitro* grown *V. unguiculata* plants with 1 ml of the extract obtained by macerating the disinfected roots, 13 of these plants presented nodules from which bacteria could be isolated.

Figure 94.4 Phylogenetic tree (neigbor-joining) of 16S rRNA gene of *Bradyrhizobium* spp. Sequences were obtained from the field trial 2008 (purple), from plate isolation approach (green), and trap plant approach (blue).

Three un-inoculated control plants did not present nodules, whereas the positive control nodulated abundantly. From the nodules formed on the 13 plants inoculated with sugarcane root extract, a total of 112 bacterial isolates was obtained (Rouws et al., 2014). These isolates received names as follows: P followed by [number of *V. unguiculata* plant]-[isolate number]. The large majority (109 isolates) grew slowly and alkalinized the culture medium, characteristics typical of the genus *Bradyrhizobium* (Kuykendall, 2005). Three isolates (P5-2, P5-21 and P5-25) were fast-growing and showed a neutral/acidic reaction on YMA. These data indicated that *V. unguiculata* nodule-inducing bacteria occur as endophytes in roots of sugarcane cv. RB 867515.

ERIC-PCR fingerprinting was applied to identify genotypic redundancy among the 112 isolates. When all isolates/strains were grouped with a low level of correlation (28% similarity) this analysis revealed 28 distinct ERIC profiles. Some identical fingerprint profiles were shared by up to 36 isolates, showing that some genotypes were redundant in the collection. Isolates sharing identical ERIC-PCR profiles were obtained from nodules of the same plant, but also from nodules of independent *V. unguiculata* plants inoculated with the same aliquot of sugarcane root extract. Some ERIC-PCR profiles (13) represented fewer isolates and several profiles represented unique isolates in the collection. The relative abundance of certain ERIC-PCR profiles may reflect the abundance of the respective bacterial genotype in the sugarcane roots, differences in colonization efficiency of the *V. unguiculata* trap plants by different bacterial genotypes, or differences in bacterial growth rate.

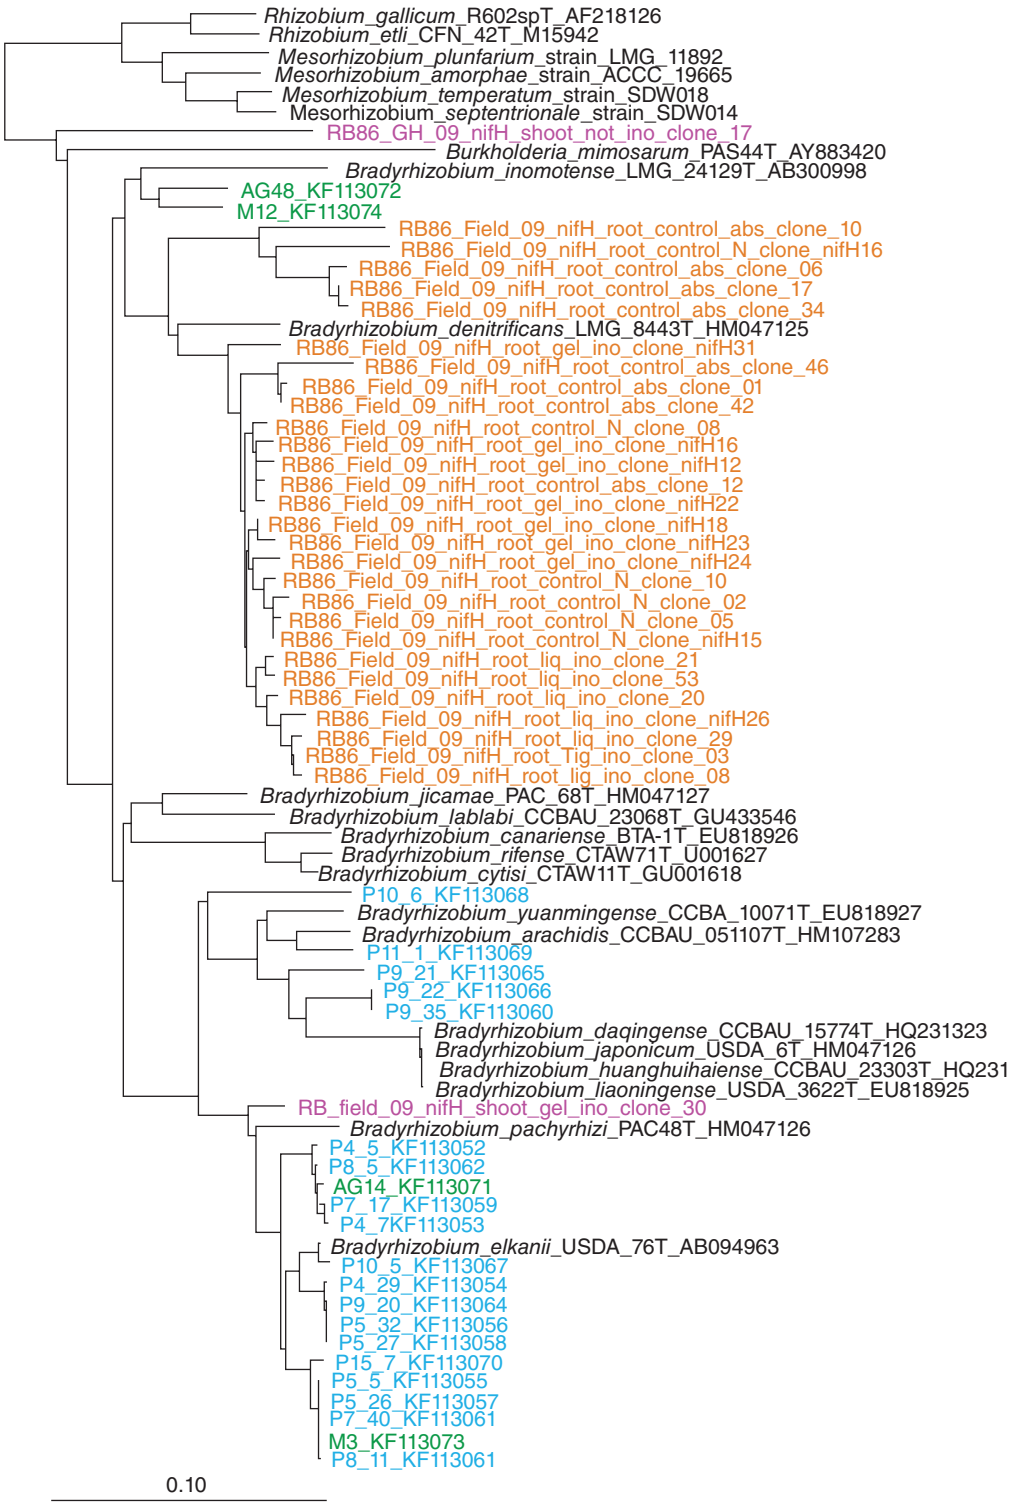

Figure 94.5 Phylogenetic tree (neigbor-joining) of *nifH* of *Bradyrhizobium* spp. Sequences were obtained from the greenhouse trial 2009 (pink), from the field trial 2009 (orange, see Fischer et al. (2012)), from plate isolation approach (green), and trap plant approach (blue).

Based on the ERIC-PCR profiles, 23 representative isolates were selected for more detailed analyses.

In addition to these trap plant isolates, the direct plate cultivation strategy permitted the selection of eight slow-growing and one fast-growing *nifH*-containing isolates (determined by PCR analysis). Sequence analyses of the 16S rRNA gene of these 32 isolates confirmed that 28 belong to the genus *Bradyrhizobium*, 1 isolate (AG46) was most closely related to the genus *Methylobacterium*, 1 isolate to the genus *Herbaspirillum* (AG47), and the 2 fast-growing isolates (M30 and P5-2) grouped together with species from the genus *Rhizobium* (Fig. 94.4).

When individually inoculated on *in vitro* grown *V. unguiculata* plants, all but one (the fast-growing isolate P5-2) trap plant isolates were able to nodulate. However, among the direct plate isolates only M3 and AG14 were able to induce nodules, whereas the other *Bradyrhizobium* spp. isolates (M12, M21, AG41 and AG48) were not. This observation demonstrated that the culture strategy had a significant influence on the isolation of specific groups of bacteria. It also showed that sugarcane plants harbor besides nodulating *Bradyrhizobium* spp. also Bradyrhzobia that are unable to nodulate a promiscuous legume such as *V. unguiculata*.

For 21 of these selected isolates, the partial *nifH* gene was sequenced and the sequences were aligned with *nifH* genes from reference strains and with the *nifH* cDNA sequences described in the present study (Fig. 94.5). These analyses showed that de *nifH* gene of most isolates, including the nodule-inducing direct plate isolates M3 and AG14, clustered together in a branch with the *B. elkanii* strain USDA 76^T. It was interesting to note that the *nifH* gene of the other two *Bradyrhizobium* spp. direct plate isolates M12 and AG48 were quite dissimilar from this cluster and were more similar to some *nifH* cDNAs obtained in this study. This emphasized that the culture strategy may greatly influence the diversity of bacteria recovered from an environmental sample.

Twelve representative isolates were tested for *in vitro* nitrogenase activity by ARA. The majority (M3, AG14, P5-2, P8-11, P10-5, P11-1 and P15-7) did not present any detectable activity (data not shown). However, four isolates presented significant nitrogenase activity in a semisolid medium containing 0.4 g/l yeast extract, as determined by the quantity of ethylene produced: M12 (7 nmol), AG48 (51.7 nmol), P9-20 (17.7 nmol), and P9-21 (3.5 nmol). Therefore, some sugarcane endophytic *Bradyrhizobium* spp. could fix nitrogen without being associated to a nodule environment, a prerequisite for sugarcane-associated BNF.

94.4 DISCUSSION

The important contribution of microbes to overall plant performance was revived in recent years when the term "plant microbiome" became popular (Turner et al., 2013). Metagenomic approaches enabled the analysis of plant associated microbes, including the endophytic microbial community, with high throughput genome sequencing approaches.

In energy crops, the awareness of the importance of bacterial impacts on plant nutrition and health goes back much longer. Fostered by the successful discoveries by the group of Johanna Doebereiner of several new diazotrophic bacterial genera and species several decades ago, energy plants such as sugarcane were also investigated in detail (Döbereiner, 1961; Döbereiner, 1995; see Chapter 88). In *Pennisetum purpureum,* another promising energy plant for the tropics, thorough estimates of ^{15}N natural abundance measurements demonstrated similar high rates of BNF in some cultivars as was found in sugarcane (Urquiaga et al., 2012; Morais et al., 2012). Using cultivation-based approaches, a diversity of diazotrophic bacteria were found in several cultivars of field-grown *Pennisetum* (Videira et al., 2012). Based on enrichment and isolation studies on nitrogen-free semisolid media – such as NfB, JNfB, LGI – *Enterobacter cloacae* and other *Enterobacter* spp. were isolated, which were shown to harbor *nifH*-genes. Besides *Gluconacetobacter diazotrophicus*, diazotrophic *G. sacchari* were also characterized for the first time, which apparently had acquired their *nifH*-genes from *Enterobacter* spp. colonizing *P. purpureum.* When the diversity of diazotrophs was studied with a cultivation-independent approach by cloning the 16S rDNA and *nifH*-gene from roots and stems of *P. purpureum*, a much higher diversity of diazotrophic community, became apparent (Videira et al., 2013). After the experience with sugarcane and the demonstration of a considerable occurrence of *Bradyrhizobium* and *Rhizobium* sequences, it was not a surprise to find *nifH*-transcripts from these bacterial genera also in *Pennisetum* cultivars (Videira et al., 2013). Therefore, similar research efforts should also be brought forward in *Pennisetum* to isolate *Bradyrhizobium* spp. using the legume trap plant approach and other more direct plate isolation techniques, as were applied in sugarcane (Rouws et al., 2014). It is quite obvious that the successful approach of enrichment and isolation of diazotrophic bacteria using nitrogen-free semisolid media leads to the isolation of only a subfraction of the whole community of diazotrophic bacteria from non-leguminous plants.

The occurrence of *Rhizobium* and *Bradyrhizobium* sp. in non-leguminous plants had attracted already quite intense attention, especially in cropping systems, where a monocot crop (such as rice or wheat) and legumes (clover or soybean) are used in alternation for hundreds of years, such as in the Nile valley and delta in Egypt (Yanni et al., 2001; see Chapter 111). A diversity of *Rhizobium leguminosarum*

bv.trifolii isolates could be obtained from rice roots, which colonize rice plants endophytically and exert a plant-growth promoting effect. *Rhizobium leguminosarum* was also shown to colonize roots of wheat and other non-leguminous plants (Schloter et al., 1997). While stimulation of growth of rice by selected *R. leguminosarum* bv. trifolii strains could be demonstrated repeatedly (Yanni et al., 2001; see Chapter 111), evidence for *in planta* nitrogen fixation could not be found. Photosynthetic bradyrhizobia have also been isolated from the African wild rice *Oryza breviculata* (Chaintreuil et al., 2000). A recent study reported on the isolation of an endophytic *Bradyrhizobium* sp. isolate (strain AT1) from sweet potato and ARA analyses and ^{15}N-isotope dilution studies suggested that this strain might increase plant growth through BNF (Terakado-Tonooka et al., 2013).

As demonstrated in our study, a high diversity of *Bradyrhizobium* and *Rhizobium* bacteria was found active as nitrogen-fixing bacteria in sugarcane, because a large number of transcripts of the *nifH*- and also 16S rRNA genes were found in roots and stems of field grown sugarcane variety RB867515. This constitutes evidence for an important role of these bacteria under natural conditions. Therefore, attempts are now under way to inoculate axenically grown sugarcane plantlets with the *Bradyrhizobium* spp. isolates originating from the same sugarcane cultivar and to demonstrate not only efficient endophytic colonization but also *in situ* active nitrogen fixation. Detailed laboratory studies of these bacteria may find specific adaptations to the metabolic scenario of sugarcane to finally establish an efficiently nitrogen-fixing symbiotic system. A final proof of *in planta* nitrogen fixation would be to demonstrate fixation of $^{15}N_2$-gas by sugarcane plants inoculated with *Bradyrhizobium* spp. isolates originating from sugarcane.

ACKNOWLEDGMENTS

This contribution is written in memory of Dr. Johanna Döbereiner, who pioneered research on diazotrophic bacteria and nitrogen fixation in energy crops already several decades ago. Financial support has been from CNPq (Instituto Nacional de Ciência e Tecnologia FBN and projeto universal process 477231/2012-8), Faperj (process E-12/111.398/2012), and the Deutsche Forschungsgemeinschaft (Grant Ha 1708/9). Additional support from the Helmholtz Zentrum München and Embrapa is greatly acknowledged.

Chapter 95

How Fertilization Affects the Selection of Plant Growth Promoting Rhizobacteria by Host Plants

Pedro B. da Costa and Luciane M. P. Passaglia

Departamento de Genética, Instituto de Biociências, Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil

95.1 INTRODUCTION

Currently, 40% of the world's population is fed by the increased crop productivity that results from the use of fertilizers (UNEP, 2007). However, fertilizer production is dependent on limited fossil fuels, the use of which is harmful to vital natural resources. This dependence creates a completely unsustainable situation that will prevent humanity from maintaining its current food production system: it is estimated that food production worldwide will either change or collapse within a few years. Obviously, this issue requires the attention of the scientific community.

Fertilizers supply plants with important nutrients, allowing growth and productivity that is much greater than those obtained with unfertilized plants. Chemical fertilizers were first used in the mid-nineteenth century in Europe, when low levels of phosphates in the soil endangered continuous food production in industrialized countries (Dawson and Hilton, 2011; Neset and Cordell, 2011). Traditional organic fertilization did not recycle enough phosphate to replace what was removed during increasingly large harvests in lands that had been cultivated for centuries. The discovery of rock phosphate as an amendment to crops in 1840 allowed the continuity of the agricultural system, avoiding a food production crisis for 1.5 billion humans on earth (Dawson and Hilton, 2011). However, by the start of the twentieth century, the lack of biologically available nitrogen for crops presented a new challenge for scientists and farmers. The Haber–Bosch process, developed in 1909, enabled ammonia to be synthesized from atmospheric nitrogen and to be used in crop production (as well as in explosives and ammunition production, as World War I was about to occur). In subsequent years, man-made reactive nitrogen greatly increased food production, and the inventors of the ammonia synthesis process received two Nobel prizes, one in 1918 and another in 1931. After the food shortages caused by World War II, there was intense investment in crop production policies, especially in enhancing plant responsiveness to fertilizers, greatly increasing the productivity and profitability of farming systems (Dawson and Hilton, 2011). This new technological package (heavily dependent on fertilizers, pesticides, herbicides, and fertilizer-responsive high-yield plant varieties) was adopted by several developing countries, giving rise to the Green Revolution (Evenson and Gollin, 2003). These developments greatly improved food security and prevented starvation of millions of people, but they have come with a steep cost to nature (see Chapters 5, 109).

The excessive use of pesticides has damaged many ecosystems and caused health problems for human workers, and the high-yield varieties of rice, wheat, corn, and soybeans developed in Europe and the United States have resulted in decreased use of native varieties and crops. Furthermore, local farming has become overshadowed by industrialized farming. Agriculture has grown completely dependent on the use of chemical NPK fertilizers to ensure food production at the required levels. However, the

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

production of fertilizers is dependent on non-renewable resources. Despite manifold improvements, the Haber–Bosch process still used today consumes natural gas to break down the strong triple bond of atmospheric dinitrogen and to supply free H to form two molecules of NH_3 out of N_2 and CH_4, consuming about 1.1% of the entire world's energy production (Dawson and Hilton, 2011; FAO, 2011). There is no other feasible source of reactive nitrogen at an industrial scale: it cannot be harvested, extracted, or mined. Its only source is chemical synthesis, and the only economically viable fuel for its production is natural gas. Reactive nitrogen can also be produced through water hydrolysis, but such an approach is not yet cost-effective.

Nevertheless, nitrogen is not the only finite source that humanity utilizes to produce food: the reserves of rock phosphate, the main source of P for fertilizers, are also limited and non-renewable. The largest reserves of rock phosphate are found in only five countries, and 77–85% of the phosphate supply is found only in Morocco (which holds a significant part of this reserve in a conflict zone). Approximately 90% of all phosphate mined on earth is used for fertilizer production, but only approximately 20% of the phosphate removed from the reserves ever reaches the consumers' tables, illustrating the remarkable inefficiency of the entire production process. The peak of rock phosphate production might be reached as soon as 2033 – from this point on, prices should increase while supply decreases (Dawson and Hilton, 2011).

Potassium is the least troublesome of the NPK nutrients. It is also mined from underground, but salty lakes (Römheld and Kirkby, 2010) or even ocean waters could be used as a secondary and renewable source of potassium because it is found at naturally high concentrations in salty bodies of water (400 mg/l of K against 0.06 mg/l of P) (Dawson and Hilton, 2011). Additionally, high concentrations of potassium in soils and water are not harmful to human health nor do they threaten wildlife (Ramasamy et al., 2005); in addition, they usually do not create detectable environmental damage.

Fertilizers applied to crops can also run off because significant portions of the introduced nutrients are not taken up by crops and escape to the environment, causing damage. Depending on the soil characteristics, 0.4–90% of the applied fertilizers might not be taken up by crops, with losses of 50% being very common (Adesemoye and Kloepper, 2009; Simpson et al., 2011). This means that millions of tons of expensively processed nutrients are washed away by rain or volatized to the atmosphere, causing nutrient imbalances around the world. Biologically active nitrogen and phosphate can reach water bodies, creating disturbances in nutrient cycling and availability and causing eutrophication in rivers, lakes, and coastal waters. An excess of P causes algal blooms of cyanobacteria (which are often toxic) because P is the major nutrient that limits their development. In P-rich conditions, a few cyanobacteria outcompete other phytoplankton species and drastically change the biological component of water bodies. Eutrophication has a negative impact on public health, the economy, and the environment, including water hypoxia (consumption of dissolved oxygen by bacterial decomposition, which leads to fish death by suffocation), changes in trophic webs, biodiversity loss, blocking of sunlight from the water column, toxic algae blooms, changes in water quality for human consumption, and other such effects (Carpenter et al., 1998; Lau and Lane, 2002). Many coastal waters are in severe danger, as this type of damage is difficult to control because it is non-punctual (unlike sewer water from cities, which has a punctual geographical origin) and is difficult to counter because it affects entire environments.

While P causes severe damage to water bodies, reactive nitrogen can be volatized to the atmosphere by microbial nitrification and denitrification, causing damage on a global scale. These volatized gases (especially N_2O) might return to the soil in regions far away from farming centers, creating nutrient unbalances, altered growth rates, and biodiversity changes (UNEP, 2007). Approximately 75% of all anthropically generated N_2O comes from agriculture. N_2O is a very dangerous greenhouse gas because it is very stable (it survives in the atmosphere for approx. 100 years) and very potent (1 g of N_2O has the global warming potential of 300 g of CO_2) (UNEP, 2007). Another problem that agriculture faces is the reduction in farming lands, meaning there is the need for even greater productivity. The world's best areas for high crop productivity due to good soil conditions were historically adjacent to cities, but such farms are quickly being replaced by urban expansion. Even if the best agricultural practices are used on the most fertile lands, the financial gain from farming cannot compete with the financial gain from turning these lands into high-profile residential areas (Singh et al., 2011).

The production and release of artificially produced reactive nitrogen compared to the amount of nitrogen fixed naturally by diazotrophs gives us a picture of the scale of the problems generated by these processes. The continual increase in the use of fertilizers worldwide has resulted in a release of reactive nitrogen that is now equal to the amount of naturally fixed nitrogen worldwide, seriously threatening the natural cycling of this nutrient. Approximately 100 million tons of both man-made and natural reactive nitrogen are produced every year, effectively doubling the amount of nitrogen available to the biosphere. This is one of the most disrupted natural cycles man has interfered with, and this disruption will seriously compromise precious water resources sooner rather than later if left unchecked (FAO, 2011; UNEP, 2007).

Thus, humanity faces a truly unsustainable situation: it is completely dependent on an environmentally dangerous (with respect to both use and production), limited natural resource, the supply of which is expected to decline sharply in less than 50 years. This situation cannot continue for an indefinite time. Thankfully, there are many alternatives to

this traditional system, including improved techniques and materials for fertilizer use and production. One very promising technology is the utilization of plant growth-promoting rhizobacteria (PGPR), which can easily reduce up to 50% of the use of fertilizers on a crop without any loss in productivity (Baldani et al., 1986; Alves et al., 2003; Hayat et al., 2010; Good and Beatty, 2011; Miransari, 2011; see Chapters 88, 90, 92).

95.2 THE EFFECT OF FERTILIZERS ON THE USE OF PGPR

95.2.1 Fertilizers Reduce Nitrogen Fixation by PGPR

The use of fertilizers influences the relationship between PGPR and their host plants. Nitrogen fixation by diazotrophs may be reduced or even halted by the use of nitrogen fertilizers in soils because the presence of reactive nitrogen in the soil acts as a repressor for the nitrogen fixation mechanism. Because the whole cascade is energetically expensive for the bacteria, they will not activate their nitrogen fixation mechanism if it is much easier to simply take the reactive nitrogen from the soil. It has been widely reported that nitrogen fertilization reduces the number and activity of root nodules in legumes and affects the diversity of *nifH* genes in microbial populations (Kolb and Martin, 1988; Muthukumarasamy et al., 2007; Prakamhang et al., 2009). This issue has already been extensively discussed and is not the focus of this review.

95.2.2 Fertilizers Interfere with Plant Selection of PGPR with Respect to Two Traits Simultaneously: Phosphate Solubilization and Auxin Production

Previous work from our group (Costa et al., 2012) demonstrated an interesting correlation between phosphate solubilization and the indolic compound production abilities of bacteria isolated from different NPK fertilization conditions. Root-associated diazotrophs isolated from rice plants under unfertilized conditions have shown higher phosphate solubilization activity and lower indolic compound production, while root-associated bacteria isolated from rice plants under light fertilization conditions (50% fertilizer dose) have shown higher indolic compound production and lower phosphate solubilization activity. In addition, the indolic compound production of rhizospheric bacteria isolated from rice plants grown under unfertilized conditions was higher than the indolic compound production displayed by root-associated bacteria, and the phosphate solubilization ability was higher in rhizospheric bacteria isolated from rice plants under light fertilization conditions compared to the root-associated bacteria. Plants were effectively hosting bacteria based on their plant growth-promoting traits (PGP) characteristics: nutrient solubilization over hormone production in poor nutrient conditions and hormone production over nutrient solubilization in moderate nutrient conditions. Rhizospheric and root-associated bacterial populations isolated from full nutrient conditions (100% fertilizer dose) were very similar with respect to their phosphate solubilization activities and indolic compound production, suggesting that at such fertilization levels, these two PGP traits were not important factors for plant-driven bacterial selection. We also found an inverse correlation between these two PGP traits: good phosphate solubilizers were not good indolic compound producers, and good indolic compound producers were not good phosphate solubilizers. Still, the isolates could present an intermediary phenotype or poor expression of both PGP traits. There appears to be no naturally occurring good phosphate solubilizers that are also good indolic compound producers. These findings have a series of implications.

First, plants select bacteria according to their specific PGP traits in response to the specific nutrient availability. It is not of benefit to the plant to host better hormone producers (found in the rhizosphere) in a situation where nutrients are more limiting. Once nutrients were more readily available, the plant left the best phosphate solubilizers in the rhizosphere and kept the best hormone producers inside the tissues. This result could mean that nutrient solubilizers are better PGPR in nutrient-poor conditions and that hormone producers are better PGPR in nutrient-moderate conditions. When we tested some selected strains in a field experiment, the good phosphate solubilizers (originally isolated from unfertilized conditions) could only enhance plant growth under unfertilized conditions, while the good growth hormone producers (originally isolated from light fertilization conditions) only improved plant growth under light fertilization conditions (Costa et al., 2012). Under heavy fertilization conditions, these two PGP traits were not driving factors for plant growth. It is interesting to note that the isolates promoted growth only in the environments they were isolated from and that PGPR prospection usually takes bacteria from conventional crop fields (under 100% fertilizer) and tests them for optimal use at the 50% fertilizer level. These findings help us to better select PGPR candidates according to the target field conditions as well as help us to direct the PGPR bioprospection according to the PGP trait of interest.

Results similar to those described above have already been reported. Poonguzhali et al. (2006) studied the effects of organic and chemical fertilization on rhizospheric and endophytic isolates of Chinese cabbage. While the focus of their work was on the principal component analysis (PCA) grouping of taxonomic and substrate utilization characteristics of

the microbiota, a factorial analysis considering the interaction effect between the niche and the fertilization condition was missing. Using the data available from this paper, we performed a two-way ANOVA analysis of the indolic acetic acid (IAA) production ability of the isolates in relation to niche and fertilization interaction effects. There was a significant interaction between these factors ($p = 0.04$), indicating that the IAA production ability was higher for the endophytic isolates than for the rhizospheric isolates when they were subjected to chemically fertilized conditions, but in the unfertilized condition, the rhizospheric isolates were the best indolic compound producers. Dias et al. (2008) also studied the IAA production and phosphate solubilization abilities of endophytic bacteria isolated from strawberry plants. He reported that the best indolic compound producers were not the best phosphate solubilizers. These studies agreed with our proposed model for IAA production. It has already been reported that the application of phosphate fertilizer at many different levels may increase the general bacterial biomass, including phosphate solubilizers (Hu et al., 2009; Chu et al., 2007; Gu et al., 2009). In addition, phosphate fertilization may reduce the phosphate solubilization activity and potential of the microorganisms (Hu et al., 2009) because they no longer need to expend so much energy to solubilize a more readily available resource.

95.2.3 Effects of Fertilization on Siderophore Production

Although the effects of different nitrogen fertilizers on rhizosphere pH is well documented (Kurek and Jaroszuk-Ściseł, 2003), there is little published work regarding the effects of fertilization on siderophore production, even if pH affects iron bioavailability directly. A previous work (Costa et al., 2012) showed that rhizospheric bacteria isolated from heavy fertilization conditions presented higher siderophore solubilization indexes (a ratio of halo and colony size on a plate trial) than endophytic bacteria isolated from the same condition, while both rhizospheric and endophytic bacteria isolated from light fertilization and unfertilized conditions presented similar siderophore solubilization indices. Another report showed that there were no differences in siderophore production due to the addition of straw or manure to crop soil when compared to an untreated control (Rodgers-Gray and Shaw, 2001). A previous work also suggested that there was a slight correlation between siderophore production and phosphate solubilization (Costa et al., 2012) that needed further confirmation. Perhaps the increase in siderophore production due to fertilization is linked to the higher bacterial biomass and diversity caused by the use of fertilizers, as siderophore production is related to bacterial competition and exclusion due to iron nutrition limitation (Weyens et al., 2010).

95.2.4 Fertilizers Reduce the Activity of ACC-Deaminase by Bacterial Isolates

Some bacteria may produce the enzyme 1-aminocylopropane-1-carboxylate (ACC)-deaminase, which hydrolyzes ACC to α-ketobutyrate and ammonia. ACC is the immediate precursor of ethylene, an important plant hormone that regulates growth according to its concentration and the plant's physiological condition (Arshad and Frankenberger, 2002). Because high levels of ethylene are expected to inhibit root development, bacteria that prevent its synthesis by hydrolyzing the immediate precursor ACC might help plant root development and growth, as has been shown in several studies (Long et al., 2008; Babalola, 2010; Miransari, 2011; see Chapter 71). Because ethylene production is sensitive to the nutrient status around the roots (Abeles et al., 1992) and increases under nutrient-deficient stress conditions (Glick et al., 1998; Jalili et al., 2009), one might expect that its production relates closely to fertilizer application, ultimately leading to shifts in the rhizobacteria community structure or function.

There is evidence suggesting that the use of fertilizers reduces the effectiveness of ACC-deaminase activity. Shaharoona et al. (2006) tested three strains belonging to the *Pseudomonas* genus that were selectively isolated from the maize rhizosphere for ACC production in field assays under different fertilization conditions. All treatments received P and K at 100 and 50 kg/ha, respectively, but N was added at 175 kg/ha only for some treatments. While two strains were able to induce plant growth even in the presence of the N fertilizer, their effectiveness was greater in the absence of the N fertilizer compared to the control. Furthermore, the third isolate tested promoted plant growth only in the absence of the N fertilizer. In their subsequent work (Shaharoona et al., 2008), two isolates of *Pseudomonas fluorescens* that presented ACC-deaminase activity were tested in greenhouse and field trials. In greenhouse trials, both isolates were able to increase plant root weight and biomass in the presence of 0, 25, 50, 75, and 100% NPK fertilizer of 120-100-60 kg/ha, respectively, but the efficiency of the inoculation clearly decreased with increasing fertilizer levels. This pattern was repeated in the field trials, as several yield measurements were improved by both isolates under different fertilization conditions, but their growth efficiency compared to the non-inoculated control was greater under lower fertilization conditions. There were significant negative correlations between the inoculation efficiency and the increasing fertilizer application for various yield parameters in both greenhouse and field trials. In Zabihi et al. (2010), four *Pseudomonas* strains presenting ACC-deaminase activity were tested on wheat plants in greenhouse and field trials under different P fertilization conditions of 0, 25, and 50 kg/ha. While the 25 kg/ha dose of P fertilizer generally

presented the best productivity with respect to yield, in some cases, the highest PGPR activity was achieved at zero P fertilization and with decreasing efficiency as the fertilization levels increased.

These reports suggest that ACC-deaminase becomes less important as the plant liberates less ethylene in response to stressful nutritional conditions. In fully fertilized conditions, less ethylene is produced, and ACC-deaminase no longer functions to elongate root length. This PGP trait activity ceases to be a very important trait of the rhizosphere community under such conditions. It is tempting to speculate that the number, activity, and niche occupation of ACC-deaminasing bacteria under different fertilization conditions might change.

95.2.5 Effects of Fertilization on Bacterial Motility

There is no information about the effects of fertilizer on bacterial motility, even though motility and bacterial dispersion are important factors for successful root colonization (Babalola, 2010; Turnbull et al., 2001b; Kristin and Miranda, 2013). Bacterial mobility is also related to nutrient availability, as nutrient limitation increases motility, and high nutrient concentrations reduce swimming speed and the selective advantages for higher motility (Mitchell and Kogure, 2006; Matz and Jürgens, 2003). A study by Turnbull et al. (2001a) showed that mobile *Pseudomonas* strains attached to roots more successfully than non-mobile strains in low-nutrient media, while high-nutrient media reduced general attachment by mobile and non-mobile strains to an equal extent. Thus, less mobile bacteria could survive in crop soils due to fertilization-induced increased nutrient availability, which ultimately might hinder plant–bacteria interactions. The exact impact of this possible interaction should be looked into, as nutrient excesses might generate "lazy" bacteria that are less suitable for use as PGPR.

95.2.6 Effects of Fertilization on Antagonism

Antagonism effects vary greatly because each single plant–antagonist–pathogen relationship is different. Several biotic and abiotic characteristics that influence rhizosphere composition might affect antagonistic relationships as well. For example, organic agriculture and the use of organic composts contribute to the improvement of soil quality, increase microbial richness and evenness, promote a decrease in pathogenic damage, and prevent diseases in the soil (Chaparro et al., 2012; Wu et al., 2008; Bulluck et al., 2002). However, the type of chemical or organic fertilizer as well as the type of compost used might greatly influence the effectiveness of antagonism (Kurek and Jaroszuk-Ściseł, 2003; Wu et al., 2008; Hoitink and Fahy, 1986). The enhancement of antagonism is more likely to occur with the use of organic fertilizers than chemical fertilizers, but this enhancement is still subject to many potentially disruptive biotic and abiotic factors.

95.2.7 Fertilizers Affect the Bulk Soil, Rhizospheric, and Endophytic Bacterial Populations in Different Ways

It has been established that plants select certain types of bacteria to execute specific functions (Hartmann et al., 2008). One can see this by looking at shifts in the associated microbiome following environmental changes or comparing the bacteria found in the different niches of the rhizobiome: endophytic and rhizoplane bacteria, rhizospheric bacteria, and bulk soil bacteria. These groups of bacteria represent different communities that are subjected to different selective pressures and challenges. As the physical distance from the roots increases, the total bacterial population decreases in number but increases in diversity. Bulk soil works as a "storage area" of very different bacteria, and a subset of the diversity found in bulk soil will be selected by plants to join the rhizosphere, creating the "biased rhizosphere." In the same manner, endophytic bacteria are a subset of the more diverse rhizospheric bacteria. Plants are expected to greatly control which bacteria will be found in which niche (Hartmann et al., 2008).

There are many reports that show differences between the taxa or function of endophytic and rhizospheric bacteria. Seghers et al. (2004) used a denaturing gradient gel electrophoresis (DGGE) approach with maize samples to show that type I methanotrophs were present in both endophytic and rhizospheric communities, while type II methanotrophs were present only in the rhizospheric community. In addition, the methanotroph diversity was higher after organic fertilization compared to chemical fertilization. Wang et al. (2009) detected significant differences between root-associated and rhizopheric ammonia-oxidant bacteria from rice under different N fertilization conditions. Most of the root-associated and rhizospheric samples clustered differently in a PCA when Terminal-restriction fragment length polymorphism (T-RFLP) patterns were compared. These authors observed a trend wherein the relative abundance of *Nitrosomonas* increased relative to *Nitrosospira* with the increase of N fertilization right after the application of fertilizers. Pariona-Llanos et al. (2010) showed that organic fertilization resulted in greater endophytic bacterial numbers than chemical or no-fertilization conditions in sugarcane. Two enzymes related to active penetration of plant cells were also screened, and it was found that pectinase activity was more present after chemical fertilization, while endoglucanase activity was more present after organic fertilization. Unfertilized conditions had lower occurrence of both traits.

Ferrara et al. (2011) studied endophytic and rhizospheric enterobacteria of the *Enterobacter* and *Klebsiella* genera isolated from sugarcane in commercial fields and compared some PGP traits. They found that amino acid release was greater in endophytic isolates while antagonism and nitrogen fixation were greater in rhizospheric isolates, but IAA production was similar in both niches. Many PGP traits can be differentially selected by plants under different conditions; thus, there are no "typical" endophytic or rhizospheric bacteria (besides the symbiotic legume-rhizobium), but instead, plants select bacteria according to their current needs.

95.3 CONCLUSIONS

As we can see, fertilization works differently on PGPR from different niches and on several different traits of the community. Community genera composition, bacterial concentration, enzyme production, antagonism, nitrogen fixation, nutrient solubilization, and genetic and functional diversity of rhizospheric and endophytic bacteria were all affected differently by fertilization. Fertilization affects many important PGP traits, community structure, and the efficiency of PGPR inoculation. Simple experiments with double-cross comparisons of endophytic and rhizospheric communities of fertilized and unfertilized conditions may still reveal many of the preferred PGP traits of the plants. The discovery of the selected attributes may greatly increase inoculation efficiency because researchers might be able to inoculate crops with the "more favored" PGPR under field conditions.

Endophytic and rhizospheric bacteria under fertilized and unfertilized conditions can be statistically compared in many ways. For continuous PGP traits, a two-way factorial ANOVA with a simple main effect analysis as a post-hoc test can reveal interesting interaction effects. However, one must not forget to confirm the homogeneity of variances before testing: IAA production levels frequently violate this assumption and should be treated with a non-parametric Kruskal–Wallis test followed by Dunn's post hoc test. Discrete traits can be easily compared with the chi-square statistic, with multiple layers and residue analysis used to single out the conditions and traits that occur outside expected values. Finally, plot multivariate statistics such as CatPCA (Categorical Principal Component Analysis) and MCA (Multiple Correspondence Analysis) can greatly facilitate simultaneous visualization of the multiple correlations between PGP traits, bacterial taxa, and environmental conditions, as long as numeric, ordinal, nominal, and supplementary variables are treated as such. For more information on multivariate statistics for microbial ecology, see Ramette (2007).

Many research institutes worldwide have standing long-term trials involving different fertilization conditions at experimental stations, which are perfect for identifying these interactions and which greatly facilitate studies that take this type of statistical approach. A single practiced microbiologist who knows what comparisons must be made can isolate, screen, and analyze the PGP traits of hundreds of isolates in just 6 months, which also facilitates the studies that take this type of approach. Given the relative ease and plentitude of opportunities to run this comparison, the intense biological interaction of PGPR with fertilizers, and the importance of this issue with respect to resource conservation and economic sustainability, additional research on this topic that takes this approach is greatly encouraged.

96.1 INTRODUCTION AND DISCUSSION

According to Verón et al. (2006), 40% of the world's surface is threatened by desertification-related problems, and consequently the degradation of soil quality due to drought and salinity. Drought and salinity are considered the most important abiotic stresses in many areas in the world, and it is estimated that 1 billion people worldwide populate these lands. Of particular importance to the agricultural industry is the impact of these harsh environmental conditions on the soil-borne endogenous group of proteobacteria, the rhizobia (Zahran, 1999; Fierer et al., 2003; Griffiths et al., 2003; Dardanelli et al., 2012).

The *Rhizobiaceae* is a bacterial family of enormous agricultural importance due to their ability to fix atmospheric nitrogen in an intimate relationship with plants in root or stem nodules enhancing growth under nitrogen-limiting conditions. This relationship is negatively impacted by drought-related stresses (Jones et al., 2007; Zahran, 1999). In addition, these bacteria can also improve drought tolerance of agricultural crops (Grover et al., 2011; Zahran, 2010; Dodd and Pérez-Alfocea, 2012; Bianco and Defez, 2009). To make optimal use of the process of nitrogen fixation, seed inoculation companies apply *Rhizobium* strains to the seed surface that are selected for their ability to efficiently colonize the rhizosphere and fix nitrogen. Unfortunately, many inoculants remain unreliable because of the inability of bacterial cells to persist under adverse conditions, negatively affecting colony-forming units (CFU) of added rhizobia (Kosanke et al., 1992; Deaker et al., 2005; Catroux et al., 2001; Smith, 1992; Bullard et al., 2004; Herridge, 2007; see Chapter 97). Furthermore, Ilyas and Bano (2012) provided a nine-point list of characteristics that plant growth-promoting rhizobacteria (PGPR) should have for successful dry-base formulation development. This list includes desiccation resistance.

The ability of selected strains to survive desiccation depends on many factors, for example, the drying method used, such as forced-drying using vacuum versus air-drying, the media used, the speed and severity of drying, the extent and speed of rehydration, the growth phase, the drying temperature, the availability of solutes, and the carrier material (Vriezen et al., 2006; 2007). In addition, intragenic

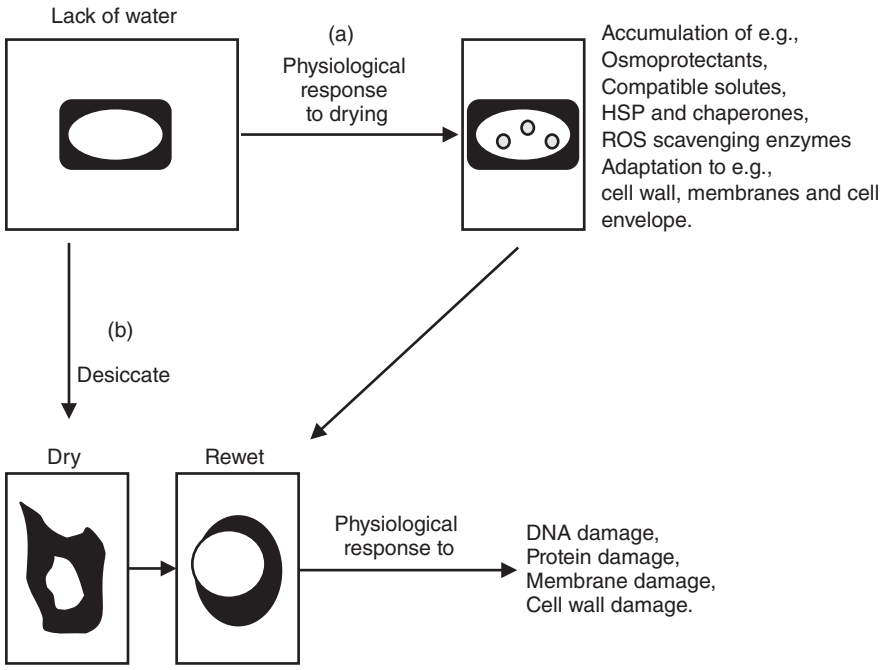

Figure 96.1 Model representing two hypothetical pathways for responses of rhizobia to desiccation stress and desiccation-induced damages. The "preceding-storage induction" pathway (a) implies a response to water, osmotic, or salt stress, and the "post-storage induction" pathway (b) implies a response to the desiccation-induced damages upon rewetting. Reprinted with permission from Vriezen et al. (2007).

differences to cope with desiccation stress affect survival. For example, slow growers tend to be more desiccation resistant than fast growers (Zahran, 2001). These data suggest that no single trait affects the ability of rhizobia to survive desiccation but that several mechanisms are likely responsible (Vriezen et al., 2006; 2007; 2013).

In a review by Vriezen et al. (2007), the authors provided a hypothetical model for the response of rhizobia to desiccation (Fig. 96.1). The model includes two not mutually exclusive physiological responses. Upon drying, rhizobia sense the consequences of drying, which may be the lowering of water activity (A_w), accumulation of solutes, and concentration of enzymes. Thus far it remains unclear as to how desiccation is sensed and resistance is mediated (Vriezen, 2005; Vriezen et al., 2007; Hirsch, 2010; see Chapters 39, 40). The response likely includes the accumulation of osmoprotectants and compatible solutes known to increase desiccation survival. For example, trehalose increases the ability to survive desiccation (McIntyre et al., 2007). In addition, heat shock protein (HSP) and chaperones and reactive oxygen species (ROS) scavenging enzymes accumulate (Feng et al., 2002; Cytryn et al., 2007). In contrast, when cells are desiccated, cells are not active; thus, damage accumulates due to the inability to repair them. Consequently, upon rewetting and regaining of metabolism cells get the opportunity to repair damage accumulated during storage or that acutely appears upon rewetting. These damages include damage to DNA, and damage to membranes and the cell wall (Humann et al., 2009; Potts, 1994; Leslie et al., 1995; Vriezen et al., 2012; Salema et al., 1982; Bushby and Marshall, 1977b; see Chapter 39).

Although improvement of long-term survival and seed inocula storage time has been the focus of desiccation research, relatively little work has focused primarily on the bacterial cell. Most, if not all, research only used culturability as a measure to estimate survival consequently marginalizing often the vast majority of cells not forming colonies. However, what is the fate of the cells not forming colonies? Recently, Vriezen et al. (2012) described the appearance of viable but not-culturable (VBNC) *Sinorhizobium meliloti* cells upon desiccation and resuscitation. Because a major target for desiccation stress is the cell membranes, they hypothesized that cells, which lost the ability to form colonies, have compromised cell membranes (Potts, 1994; Leslie et al., 1995). Thus, it was expected that all cells not forming colonies were membrane compromised. To test this, Vriezen et al. (2012) applied the live/dead stain to cells after desiccation. This stain uses two dyes, syto-9 and propidium iodide, which differ in their ability to cross the cytoplasmic membrane. Syto-9 can always cross the membrane and stains all cells green. However, propidium iodide can only cross the membrane when the permeability is increased and stains the cell red. These red cells are dead. When this stain was used on rhizobial cells prior to and after drying, unexpected results were obtained. The data presented in Figure 96.2 shows that two staining methods (crystal violet and live/dead) yielded the same results prior to drying, after 3 days at 100% RH and after 3 days at 22% RH. The increase in countable cells at 100% RH conforms to what one expects since an increase in colony-forming units was observed over 3 days at 100% RH in previous studies (Vriezen et al., 2006). However, a change in the

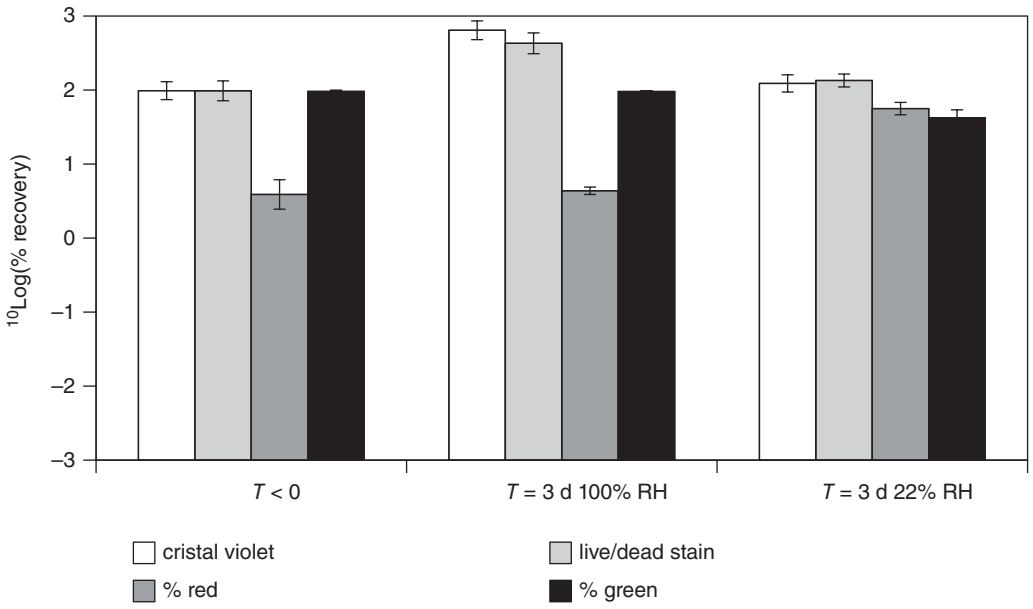

Figure 96.2 Survival and recovery of *S. meliloti* cells after drying and rewetting. Quantitative recovery of cells (direct count) after 3 days of storage under 100% or 22% RH on nitrocellulose filters (white bar = cristal violet, light grey bar = Live/dead, dark grey bar = red%, black bar = green%). All error bars represent the SEM. Reprinted with permission from Vriezen et al. (2012).

fraction of red (dead) and green (living cells) was observed. Prior to drying, the red fraction of cells was very low ($4.4 \pm 0.5\%$) and increased substantially during desiccation to $56.9 \pm 10.6\%$. During this process, culturability decreased to 3.1%. If it is assumed that the colony-forming cells are a fraction of the viable cells, we can only conclude that many cells are alive but are not able to form colonies and are in a VBNC state. This VBNC state exists in many microorganisms, including rhizobia (Manahan and Steck, 1997; Alexander et al., 1999; Basaglia et al., 2007; Räsänen et al., 2001; Vriezen et al., 2012; Catroux et al., 2001). The induction of this physiological state by desiccation is a novel and very relevant observation since only cells able to form colonies can infect plants, as reported for strain *S. meliloti* 41 (Basaglia et al., 2007). The term VBNC applies directly to the observations presented in Figure 96.2: Cells of *Sinorhizobium meliloti* 1021, which were rehydrated after desiccation, can be divided into three different fractions of cells after desiccation, the membrane-compromised (MC), the viable but not culturable (VBNC), and the culturable cells (colony-forming units, or CFU) and correspond to fraction III, II and I in Vriezen et al. (2012) respectively.

96.2 THE MEMBRANE-COMPROMISED (MC) FRACTION

96.2.1 Fraction III

That cell membranes are a target for desiccation is not novel; however, the extent to which desiccation compromises membranes in *Sinorhizobium meliloti* 1021 is unexpected. In the aforementioned study, $56.9 \pm 10.6\%$ of cells stain red and have lost membrane integrity, indicating that of the very substantial number of cells not forming colonies ($100 - 3.1\% = 96.9\%$), 59% have nonfunctional membranes. Thus, the loss of membrane integrity is the main cause of death for *Sinorhizobium meliloti* 1021. Vriezen et al. (2012) hypothesized that this desiccation-induced loss of membrane integrity can be explained by changes in phase transition of phospholipid membranes due to the removal of water affecting the phospholipid head spacing and due to rehydration and the consequent breakage of the cell wall. Furthermore, lipid peroxidation and Fe^{3+}-catalyzed oxidation also lead to the loss of structure of the membranes when cells are not able to repair damages (Deaker et al., 2004; Potts, 1994). Under normal wetted conditions, membranes are in the liquid crystalline phase (Fig. 96.3a). Upon the extraction of water phase transition occurs leading to the gel-phase of the membrane. Upon rewetting, phase transition occurs again, leading to leakage of cell constituents from the cell and to the loss of membrane integrity and cell death.

Phase transition can be followed using Fourier Transformation Infra-Red (FTIR, Leslie et al., 1995) spectroscopy in which the vibration frequency of the phospholipid head groups is measured (Fig. 96.3b). Upon decreasing temperatures, this frequency decreases, indicating membrane transition. The temperature at which this transition occurs is the midpoint temperature. Interestingly, if ambient temperature is higher than the membrane midpoint temperature, no phase transition occurs upon drying and rewetting, reducing cell death. However, when drying takes place at an ambient

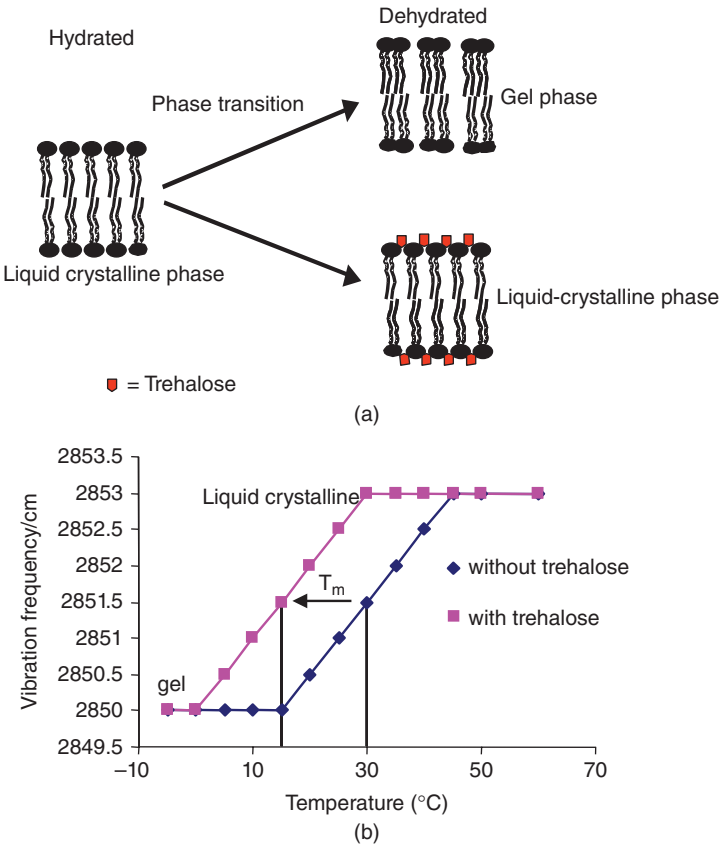

Figure 96.3 Membrane properties: (a) Phase transition from liquid crystalline to gel phase and prevention by trehalose (amended from Welsh, 2000). (b) Vibration frequencies of the phosphate head groups and the effect of trehalose on the midpoint temperature (Tm) (amended from Leslie et al., 1995).

temperature below the midpoint temperature, cell death due to membrane transition is increased. A consequence of a change in membrane midpoint temperature can be seen in the change in vibration frequency (Fig. 96.3b). When the midpoint temperature is lowered one expects the temperature at which phase transition occurs to be lower, resulting in a wider window of ambient temperatures higher than the midpoint temperature, increasing survival. Survival data indicates that this is what happens after desiccation of *Sinorhizobium meliloti* 1021. An increase in viability was observed with increasing temperature with a maximum at 37 °C, indicating that this process may underlie the phenomenon (Vriezen et al., 2006).

The structural adaptations to membrane phospholipids that affect fluidity and midpoint temperature are the following: nonreducing sugars such as trehalose stabilize the phospholipid head spacing of the membranes, leading to a decrease in the membrane midpoint temperature and increased survival even at lower ambient temperatures (Fig. 96.3a and b). In addition, longer fatty acids decrease fluidity leading to an increase in the midpoint temperature. Furthermore, an increase in *cis*-bonding, and thus an increase in unsaturation, leads to increased fluidity, and a lower midpoint temperature (Leslie et al., 1995). Therefore, a decrease in the unsaturated/saturated (u/s) ratio of membrane phospholipids leads to a lower fluidity and a higher midpoint temperature. Boumahdi et al. (1999) studied survival after desiccation of *S. meliloti*, *B. japonicum*, and *B. elkanii* in relation to the growth-phase and the fatty acid u/s ratio. Even though differences in u/s were found depending on the growth phase, these differences did not correlate with the ability to survive desiccation at many RHs (3–83.5% RH) except under the following conditions: In *B. elkanii*, an increase in saturation leads to a decrease in desiccation survival at 67.8% RH at 30 °C, and in *B. japonicum*, the same was seen at 3% and 22%RH. While the expected correlations were seen in bradyrhizobia under certain conditions, this was not seen in *S. meliloti* RCR2011. In another publication by Boumahdi et al. (2001), growth at decreased water activities (A_w) affected the u/s ratio in *S. meliloti* 2011, *B. elkanii*, and *B. japonicum*. This effect was strongest in *B. elkanii*. Surprisingly though, with decreasing A_w a decrease in u/s ratio was found, counter-intuitive to what one would expect in order to survive water stress with the membrane as major target. Why these correlations were not observed across the range of A_w's, RHs, strains, and growth phases tested is unclear. However, it indicates that other mechanisms underlie these phenomena.

In addition to the responses described above, hypothetically, an increase in the concentration of hopanoids

should increase fluidity and lower the midpoint temperature. Hopanoids are the prokaryotic equivalent of cholesterol in eukaryotes (Kannenberg and Poralla, 1999; Kannenberg et al., 1995). Their function remains unknown; however, their presence in membranes leads to reduced permeability and increased order of membranes above the midpoint temperature at which molecular disorder threatens membrane stability. These aliphatic compounds have also been identified in *Rhizobium* but to our knowledge have not yet been studied in relation to desiccation survival.

96.3 THE VIABLE BUT NONCULTURABLE (VBNC) FRACTION

96.3.1 Fraction II

The second most important fraction in a culture of cells after desiccation is formed by the VBNC cells. Many environmental factors have been identified inducing a VBNC state in bacteria, such as temperature stress, osmotic upshift, and oxygen stress, tap water and the VBNC inducing component copper in *A. tumefaciens* and *R. leguminosarum* (Oliver, 2005; Räsänen et al., 2001; Manahan and Steck, 1997; Alexander et al., 1999). Moreover, desiccation can induce a VBNC state in *E. cloacae* and *S. meliloti* (Pederson and Jacobsen, 1993; Vriezen et al., 2012). This VBNC fraction can be divided into two subfractions, those cells for which VBNC is reversible and can be resuscitated (temporarily nonculturable), and those for which VBNC is a permanent state (permanently nonculturable) (Maraha, 2007). In a paper by Hammes et al. (2011), the authors named these two fractions "potentially reversible, starved or injured" and "irreversible, or dying/dead". The demarcation of these two fractions is a hard to assess amount of DNA and protein damage. It remains unclear as to which level of damage leads to death or the inability to resuscitate.

Several researchers have attempted to understand the conditions modulating the culturability of bacteria. Barry et al. (1956) noted that autoclaving media leads to an increase in H_2O_2, decreasing CFUs. The addition of sodium pyruvate and catalase to the medium can increase resuscitation in many organisms (Mizunoe et al. 1999; Imazaki and Nakaho, 2009). However, this approach proved unsuccessful in *S. meliloti* 1021 and 41 (Basaglia et al., 2007; Vriezen et al., 2012). It appears that all desiccation- and O_2 limitation-induced VBNC cells are in a permanent state of nonculturability under the conditions tested (Basaglia et al., 2007; Toffanin et al., 2000). In contrast, a very slow supply of oxygen could resuscitate some cells (Basaglia et al., 2007). These results indicate that resuscitation from the VBNC state differs between *E. coli* and *Rhizobium*, even though O_2 damage may occur in both cases.

One explanation for the occurrence of desiccation-induced rhizobial VBNC cells is that these cells are without a functional template for the replication of DNA but have intact membranes. DNA is a major target of desiccation in microorganisms inducing double strand breaks in *E. coli* and *D. radiodurans* (Asada et al., 1979; Mattimore and Battista, 1996). In support of this hypothesis are the observations by Humann et al. (2009), who isolated a desiccation sensitive *Sinorhizobium* mutant with a Tn*5* insertion in its *uvr*C locus, which is involved in DNA repair (see Chapter 39). Therefore, the inability to repair desiccation-induced DNA damage leads to a decrease in CFUs and likely to an increase in VBNC cells in rhizobia.

To identify additional physiological responses potentially involved in the VBNC state of rhizobia, we consulted three studies addressing the physiological responses of the VBNC state in *Pseudomonas* and *E. coli*, both proteobacteria. The proteins identified in these three studies are summarized in Table 96.1 (Maraha, 2007; Asakura et al., 2008; Muela et al., 2008). Several loci, OmpW, HisJ, and ProX, were found in both proteobacteria in more than one study. Surprisingly, OmpW, found to be strongly expressed in VBNC cells in several microorganisms and studies, could not be identified in *S. meliloti*. Actually, only HisJ has significant identity in *S. meliloti* 1021 (>95% of the query sequence, and >30% identity). Using the same criteria, five more loci were identified and are DdpA, TpiA, LeuD, OppA, and EF-TU, which, together with HisJ are the first set of *S. meliloti* candidate loci affecting the VBNC state. Interestingly, neither the loci identified by Humann et al. (2009) nor those involved in trehalose metabolism (Reina-Bueno et al., 2012; McIntyre et al., 2007; Flechard et al., 2010) or those responsive upon desiccation (Cytryn et al., 2007) were identified (see Chapter 39), indicating that DdpA, TpiA, LeuD, HisJ, OppA, and EF-TU represent a novel set of candidate loci for the rhizobial VBNC state.

How do these observations relate to rhizobia? Identification of the proteins mentioned above indicates that damage to amino acid metabolism and protein synthesis may result in permanent VBNC cells in *Rhizobium*. For example, Asakura et al. (2008) showed that HisJ, LeuD, and OppA were increased in an oxidative- and osmo-tolerant *E. coli* strain, while TpiA was decreased compared to an oxidative- and osmo sensitive *E. coli* strain after passing through the GI track. This would indicate that strains not sensitive to oxygenic stress, and thus "VBNC resistant," have increased expression of HisJ, LeuD, and OppA. In Muela et al. (2008), EF-TU (TufA, involved in recruiting charged tRNA to the a-site on the rhibosome) was found expressed in the VBNC state in phosphate-buffered saline (PBS). According to Barcina and Arana (2009), and conforms the findings by Kong et al. (2004) in *Vibrio vulnificus* and Asakura et al. (2008) in *E. coli*. Hydrogen peroxide-sensitive *Vibrio* cells, having lost catalase activity, are entering the VBNC state and have increased OmpW and TufA levels.

**NI = Not identified.

The hypothesis stated above is further supported by the identification of *rel*A mutants with a desiccation-sensitive phenotype by Humann et al., (2009; see Chapter 39). RelA (stringent response) is stimulated by aminotriazole (AT), a histidine analog inducing histidine starvation (Wells and Long, 2002; Krol and Becker, 2011). Histidine starvation induces *rel*A and therefore the stringent response. HisJ mutants potentially induce histidine starvation. These findings support the hypothesis that desiccation induced VBNC cells are affected in amino acid metabolism and translation. A substantial part of the permanently nonculturable rhizobial cells after desiccation may thus be irreversible VBNC, or dying/dead due to substantial amounts of DNA and protein damage.

96.4 THE CULTURABLE FRACTION (CFU)

96.4.1 Fraction I

The CFU fraction is the smallest of the three recognized fractions of rewetted *Sinorhizobium meliloti* 1021 after desiccation. This fraction is so small (3.1%, Vriezen et al., 2012) that it falls within the error of measurement of the MC fraction (±10.6%). Thus, even a doubling in the fraction of culturable cells would not be reflected in a significant change in dead and living cells. It is the culturable fraction that counts in formulations of rhizobia since nongrowing but living cells do not contribute to nodule formation (Basaglia et al., 2007). Therefore, understanding the conditions and cellular responses that increase this fraction remains of crucial importance. Even though no data exist on how osmotic stress and temperature affect the appearance of VBNC and MC fractions, more is known about these conditions in relation to desiccation survival.

96.4.2 Effect of Osmotic and Salt Stress

In a review by Vriezen et al. (2007), the authors hypothesized about the effect of NaCl stress on the ability of *S. meliloti* to survive desiccation. Exposure to NaCl during drying increases the ability to survive desiccation even considering that salt stresses, osmotic stresses, and desiccation stress are very different in essence. Osmotic stress is the abundance of solutes, salt stresses, and of (non) toxic ionic compounds, while desiccation stress results from the lack of water. The reason for the hypothesis is the available data indicating an overlap in response between the stresses reviewed by Vriezen et al. (2007). The conclusions were that (i) chloride stress induces a response in combination with nutrients from the media that lead to an increase in survival, (ii) the response is strain specific and (iii) the increase in CFU during NaCl-mediated desiccation is physiological in origin. Even though the response of *S. meliloti* to NaCl does increase CFU after desiccation, it only excludes some aforementioned stresses from inducing these physiological responses. However, in their review Vriezen et al. (2007) argued that screening for loci responsive to NaCl stress would select loci potentially involved in survival during desiccation. In support of this are the findings by Streeter (2003) that NaCl increases intracellular trehalose content in *Bradyrhizobium japonicum*, and the finding by Humann et al. (2009), who showed that a *rpo*E2 mutant was sensitive to desiccation (see Chapter 30). RpoE2 is a response regulator for envelope stress. The hypothesis is further supported with the identification of the *S. meliloti* 1021 mutant with a Tn*5lux*AB transcriptional fusion inserted in a NaCl-inducible putative open reading frame (ORF, *ngg*) sensitive to survival during desiccation (Vriezen et al., 2005 and Vriezen et al., 2013). Ngg is responsive to NaCl stress and also affects the ability of *S. meliloti* 1021 to survive desiccation.

Which NaCl-mediated responses affect survival during desiccation? We address four potential responses. Firstly, although certain compatible solutes and osmoprotectants accumulate during NaCl and osmotic stress and have a positive effect on the survival during desiccation of *Rhizobium*, others have not. For example, the recently identified NaCl-induced loci *asnO* and *ngg* involved in the production of the dipeptide NAGGN show differential responses to desiccation (Vriezen et al., 2005; Vriezen et al., 2013; Sagot et al., 2010). A Tn*5lux*AB insertion in locus *asn*O does not lead to a decrease in survival during desiccation, while an insertion in locus *ngg* does. This indicates that NAGGN accumulation as a response to NaCl stress does not affect the ability to survive desiccation since both loci are involved in the synthesis of NAGGN. In contrast, compatible solutes such as sucrose and trehalose are known to affect survival by their stabilizing abilities of the cell membrane. Trehalose accumulates in osmo-stressed rhizobia and provides protection against desiccation by maintaining membrane integrity during drying and rewetting (see Chapter 97). Its presence may explain the increase in desiccation survival during the stationary phase and when rhizobial cells are exposed to NaCl (Welsh and Herbert, 1999; Breedveld et al., 1990; 1993; Streeter, 2003; Leslie et al., 1995; Potts, 1994; Reina-Bueno et al., 2012; McIntyre et al., 2007; Flechard et al., 2010). Gouffi et al. (1998; 1999; 2000) found that trehalose and sucrose are synthesized *de novo* during exponential growth. Uptake mechanisms in rhizobia were also described; an *agl* operon for trehalose/maltose and sucrose uptake (*smb03060-03065*) was identified by Willis and Walker (1999), and Jensen et al. (2002) identified an alternative trehalose/maltose/sucrose operon (*thu*, *smb20324-20330*). Domìnguez-Ferreras et al. (2006) showed that the *thu* operon is upregulated during an osmotic

upshift and the importance of the osmotic stress-responsive loci *ots*A and *tre*S in trehalose accumulation. McIntyre et al. (2007) showed that *ots*A provides resistance to desiccation. Interestingly, trehalose synthesis genes (*ots*AB and *tre*S) are increasingly expressed during drying of *Bradyrhizobium japonicum* (Cytryn et al., 2007) and Sugawara et al. (2010) shows that *tre*S and *tre*Y mutants of this organism have lower survival rates after desiccation.

Wei et al. (2004) and Miller-Williams et al. (2006) also identified *Sinorhizobium* mutants unable to grow at increased NaCl concentrations. The mutations causing these phenotypes were traced to genes involved in the central metabolism, such as elongation factors, chaperones, and cell division proteins. Moreover, expression of genes for DNA ligases was higher as was the expression of a putative DNA polymerase, an invertase and a ribonuclease. These observations are most interesting considering VBNC cells may not be able to resume growth after exposure to desiccation conditions due to extensive DNA damage. Whether these responses affect desiccation resistance or the appearance of desiccation-induced VBNC cells in *Rhizobium* remains to be seen.

Polysaccharides are of interest with respect to desiccation since adaptations of the polysaccharide composition have been observed for *S. meliloti* undergoing osmotic stress and are known to affect survival during dry conditions (Breedveld et al., 1990; Lloret et al., 1998; Chenu, 1993). Vanderlinde et al. (2011) identified a *R. leguminosarum* Tn*5* mutant in which exopolysaccharide (EPS; see Chapter 36) production positively correlates with desiccation resistance. The open reading frame mutated is *RL2975*; however, a similar ORF does not exist in *S. meliloti*. The mutant was not sensitive to hyperosmotic stress, or to detergents, suggesting that the outer membrane was not affected. However, it is naïve to consider polysaccharides a panacea to all desiccation-related issues. Vriezen et al. (2007) evaluated many reasons why this is not the case and gave examples of studies resulting in contradictory observations. For example, a decrease in survival of colony-forming rhizobia was observed upon the addition of polysaccharides when dried at a RH > 3%, but an increase in survival at 3% relative humidity (Mary et al., 1986). Polysaccharide-producing variants of *Rizobium trifolii* in sandy soil and under fast drying conditions showed no consistent improvement in survival (Bushby and Marshall, 1977a). Osa-Afiana and Alexander (1982) showed that, when dried slowly in Collamer silt loam, the production of EPS decreases survival during desiccation of *Bradyrhizobium japonicum* strains, even though polysaccharides did increase survival of *R. trifolii* 412 in a Lima silt loam (Pena-Cabriales and Alexander, 1979). The reason for these apparent contradictions is likely due to the complexity of- and ambient conditions during desiccation. A polysaccharide may provide protection under one condition while is detrimental under other conditions. The mechanisms by which polysaccharides provide protection are not clear and specific properties of polysaccharides have different effects on a microorganism's ability to survive desiccation. Four of these properties are (i) buffering against changes in water content, (ii) exclusion of toxic compounds, such as Cl^- and O_2, (iii) the final water content of polysaccharides under ambient conditions, and (iv) the effect of hysteresis in the water retention isoterms of polysaccharides (Potts, 1994; Rinaudo, 2004; Chenu, 1993).

Existing data on the environmental conditions affecting polysaccharide production show that an increase in osmotic pressure results in enhanced production of high molecular weight (HMW) succinoglycan over low molecular weight (LMW) succinoglycan (Breedveld et al., 1990) and that the expression of genes involved in EPSI production are upregulated during salt stress (Rüberg et al., 2003, Jofré and Becker, 2009; see Chapter 36). These observations suggest that in *S. meliloti* NaCl-dependent EPS production leads to the production of HMW succinoglycan, resulting in an increase in CFUs after desiccation. In addition, structural changes under the influence of osmotic and salt stress have also been reported for lipopolysaccharides (LPS) (Bhattacharya and Das, 2003; Lloret et al., 1995). Interestingly, Lloret et al. (1995) found a different LPS content in EFB1 cells grown on different salts, while polyethylene glycol (PEG) 200, which causes only osmotic stress, does not induce such a change. These differential responses may correlate with the differences in survival during desiccation when exposed to several different salts and argue for a potential role of LPS in survival during desiccation (Vriezen et al., 2006). Indeed, Vanderlinde et al. (2010; 2011) and Vanderlinde and Yost (2012) showed that a mutation in the *fab*F1 and *fab*F2 gene in *R. leguminosarum* involved in LPS formation increased sensitivity to desiccation and osmotic stress. Thus, structurally intact LPS are important in protecting *R. leguminosarum* cells against desiccation.

Vriezen et al. (2007) hypothesized that enzymes involved in the production of HMW succinoglycan would positively affect CFUs. For example, mutations in *S. meliloti* ExoP (Smb21506) was found to block polymerization of EPS1, and ExoQ (Smb20944) is required for the production of HMW succinoglycan (González et al., 1998; Jofré and Becker, 2009). In support of this theoretical consideration was the ~5-fold induction of *exo*P in desiccated *Bradyrhizobium japonicum* (Cytryn et al., 2007). Interestingly, in *S. meliloti* depolymerization of HMW leads to the production of LMW succinoglycan, which is ExoK (Smb20955) and ExsH (Smb20932) mediated (York and Walker, 1998). However, Cytryn et al. (2007) did not find these genes in their induction studies.

Lastly, Cytryn et al. (2007) found an upregulation of glycogen synthase (*glg*A) during desiccation. Glycogen may assist in restoring cell volume after osmotic shock (Han et al.,

2005). The *glgA2*, *glgB2*, and *glgX* genes involved in glycogen metabolism (*smb20704, smb21447, smb21446* respectively) are higher expressed during exposure to osmotic stress and may have a role in desiccation survival.

96.4.3 The Impact of Temperature

Theoretically, temperature is involved in survival during desiccation through the phase change of membranes during drying and rewetting leading to the loss of membrane integrity (Leslie et al., 1995). The logical consequences of this process would be that an increase in drying temperature prevents membrane transition. Vriezen et al. (2006) and the authors of this chapter (Fig. 96.4) found a positive correlation between survival and temperature with an optimum at 37 °C. This indicates a potential physiological response to temperature affecting survival after desiccation.

Vriezen et al. (2007) reviewed the conditions in soil and seed inocula and concluded they do not support the *in vitro* observations, because many different researchers obtained contradictory results. They concluded that at least one additional factor must exist applying an unknown, yet overruling stress to dry cells. For example, (i) dry seed inocula have a water activity of 0.45–0.6, and thus still contain a relatively high amount of water (Smith, 1992; Deaker et al., 2004; see Chapter 97). (ii) Isolated rhizobia show large differences in their ability to respond and adapt to life at high temperature which is not necessarily linked to their ability to survive desiccation (Trotman and Weaver, 1995). Therefore, heat-tolerant strains may not have an increased ability to survive desiccation, unless temperature, rather than drought, is the superimposed stress. However, the identification of a *Azorhizobium sesbania* Tn*5* mutant sensitive to drought and temperature reveals a genetic basis for this response in some strains (Rehman and Nautiyal, 2002). In addition, Reina-Bueno et al. (2012) identified an *ots*A mutant of *R. etli* that was affected by drying, but also lost the response to temperature.

The molecular responses to stress in rhizobia were recently reviewed by Alexandre and Oliveira (2012) and include heat-inducible small heat shock proteins (HSP) (Ono et al. 2001; Münchbach et al., 1999), the heat shock proteins DnaKJ, GroESL, and GroEL (Minder et al. 1997; Rodrigues et al. 2006; Rodrìguez-Quiñones et al., 2005; Fischer et al., 1993; see also Chapter 40), transcriptional regulation by RpoH (Narberhaus et al., 2006; Ono et al., 2001), and EPS and LPS (Nandal et al., 2005). Potential sensing mechanisms involve *cis*-acting ROSE elements or RNA thermometers (Waldminghaus et al., 2005; Narberhaus et al. 2006; Nocker et al. 2001), and thermo-induced changes in DNA structure and nucleoid-associated proteins (Shapiro and Cowen, 2012; Steinmann and Dersch, 2013). However, no papers were found on rhizobial thermosensing by responding to changes in cell membranes.

Several of the aforementioned mechanisms may affect survival of rhizobia after desiccation (Cytryn et al., 2007). These authors showed an increase in expression of *gro*ESL-related chaperones, indicating a potential involvement of these genes in survival during desiccation in *Bradyrhizobium japonicum.* It is likely that similar mechanisms exist in *Sinorhizobium meliloti*. Furthermore, Domìnguez-Ferreras et al. (2006) identified several loci responsive to an increase in osmotic and salinity stress also associated with the temperature response. Most interestingly, RpoE2 (Smc01506), affecting survival during desiccation, also controls 44 genes involved in the heat-shock response (Humann et al., 2009; Sauviac et al., 2007; see Chapters 39, 40). Therefore, RpoE2 may regulate the part of the osmotic and temperature response also affecting its ability to survive and grow after desiccation.

96.4.4 NaCl and Temperature: An Interconnected Response to Desiccation?

Intellectually it makes sense that microorganisms respond to an increase of solutes or to temperature in order to respond to desiccation. However, how likely is it to have a molecular junction of a NaCl-inducible gene that, when knocked out, leads to temperature-dependent desiccation sensitivity? In addition to some NaCl-induced loci described earlier, locus *smb01590*, found by Vriezen et al. (2013), also affects survival during desiccation (Fig. 96.4). Interestingly, the ability of the mutant carrying a Tn*5lux*AB insertion in ORF *smc01590* (Sce-1) to survive desiccation is better, albeit not significant ($P = 0.22$), than that of the reference strain at 4 °C. While survival of the reference strain increases with increasing temperature, survival of Sce-1 decreases with increasing temperature, leading to a much better survival of the reference strain at 37 °C. There are at least two different not mutually exclusive explanations for the observation. Firstly, this observation suggests the involvement of the membrane in this process, since the reference strain does respond exactly as explained above: If ambient temperature is higher than the membrane midpoint temperature, no phase transition occurs, reducing cell death and increasing culturability. When drying takes place at an ambient temperature below the midpoint temperature, cell death due to membrane transition is increased.

In mutant Sce-1, it appears that the inability to correctly adjust the membrane midpoint temperature at increased temperature leads to the opposite effect. At 4 °C, cell death in the reference strain and the mutant strain is comparable. At 4 °C, both strains experience an ambient temperature lower than the membrane midpoint temperature, leading to similar survival rates. However, at increased temperatures, the reference strain experiences an ambient temperature comparable or higher than the midpoint temperature, which increases

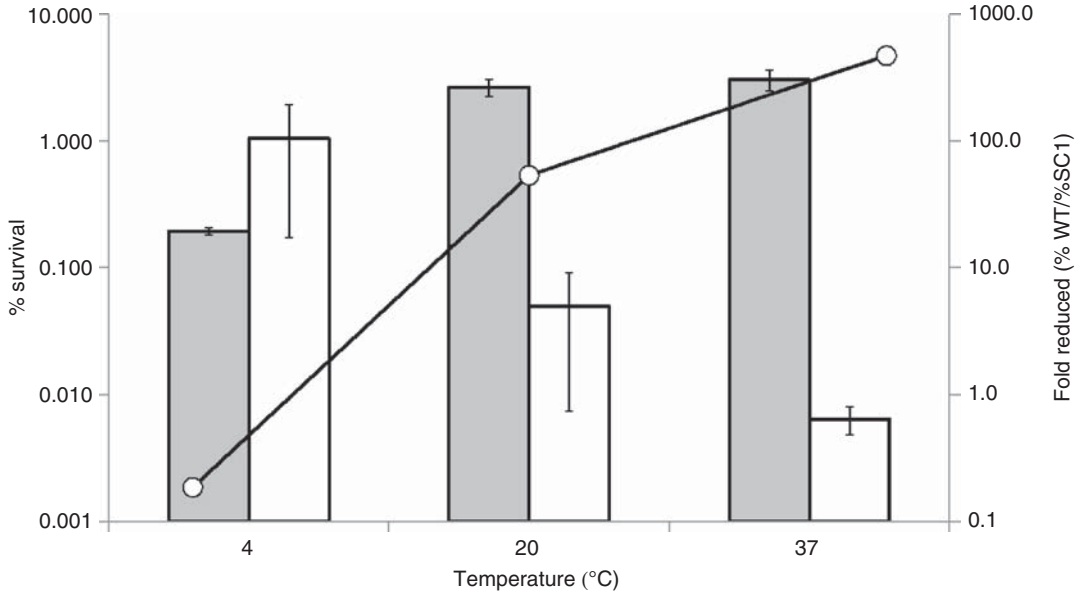

Figure 96.4 Survival after desiccation of *S. meliloti* 1021 (WT, grey bar) and the *smc01590*::Tn*5lux*AB mutant (Sce-1, white bar) and the fold difference in survival of Sce-1 relative to WT (open circle) at 4, 20 and 37 °C.

survival. Owing to the inability to lower the midpoint temperature, the Sce-1 mutant still experiences an ambient temperature lower than the midpoint temperature, leading to a reduced survival compared to the reference strain.

Alternatively, a defect in the temperature response in strain Sce-1 potentially leads to reduced survival rate with increasing temperature. The lack of production of heat shock proteins and chaperones may explain this phenomenon. The postulated nonexclusivity of the two hypothetical explanations allows that one of the responses to NaCl is the decrease in the midpoint temperature.

Interestingly, prodomain analysis of the aminoacid sequence indicates that Smc01590 encodes a 210AA peptide with a leader peptide targeting the cytoplasmic membrane. Smc01590 also contains an SH2/SH3 domain. SH3 domains are called molecular velcro (Morton and Campbell, 1994) due to their ability to form strong bonds with other proteins by targeting proline-rich areas, which are also found in the sequence. Its location and these domain/motif interactions suggest that Smc01590 can form membrane-located proteinaceous structures stabilizing the membrane. Prodomain also predicts several cytoplasmic kinase sites, which are commonly involved in signal transduction directly or indirectly involved in sensing- and maintaining membrane stability. Thus, it appears that Smc01590 is potentially a sensor in a signal transduction pathway, in which changes in membrane fluidity due to temperature and osmotic pressure lead to the expression of downstream loci involved in the lowering of the membrane midpoint temperature. This protein and its locus appear not under RpoE2 control, and may be part of a novel signaling network.

Chapter 97

Making the Most of High Quality Legume Inoculants

Rosalind Deaker

97.1 INTRODUCTION

In Australia and many other countries around the world, legume inoculants are subject to quality control. The regulatory systems applied vary between countries (Herridge et al., 2002; Bullard et al., 2005). In Canada, Uruguay, and France, quality control is covered by legislation, in the United States it is self-regulated, and in Australia, New Zealand, and South Africa participation is voluntary (see also Chapters 90, 101).

High quality legume inoculants are essential for optimum nodulation and nitrogen fixation by the applied rhizobia but do not guarantee efficacy. Inoculant efficacy is dependent on the rhizobial strain, inoculum potential, survival of rhizobia during delivery to crops, distribution in soil, rhizosphere competency, competition with resident soil rhizobia, and tolerance to unfavorable soil conditions and agrichemicals (Brockwell et al., 1980; Herridge et al., 2002; Deaker et al., 2004; Howieson and Ballard, 2004; Denton et al., 2013).

Adoption of inoculation is dependent on the same conditions that apply to other technologies. Some of the conditions for adoption of technology listed by Guerin and Guerin (1994) include complexity, integration into farming practices, and observable outcomes. The decision to inoculate and the choice of inoculant formulation are largely dependent on convenience and ease of use. Farmers often determine the need to inoculate based on crop history, soil conditions, and inoculation success (Herridge et al., 2002; Denton et al., 2013).

Inoculants are available as either solid or liquid formulations. These different products provide flexibility in application and can be distributed to crops either via the seed or directly to the soil. In Australia, peat-based inoculants are most commonly used.

Granular, freeze-dried, and liquid inoculants are also available but less widely adopted. Peat inoculants are applied in most cases to seed; however, this can be a laborious and difficult task and the market for commercially inoculated or preinoculated seed has grown considerably in the last decade.

In this review, we discuss the quality of Australian legume inoculants and their potential efficacy in relation to both established standards and application techniques (see also Chapter 101). In particular, limitations to efficacy of legume inoculants are highlighted and opportunities for future research are identified.

97.2 WHAT IS INOCULANT QUALITY?

Legume inoculant quality can be defined by a combination of several factors. Factors contributing to peat inoculant quality were described by Roughley and Pulsford (1982) and form

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

Table 97.1 Current numerical standards for australian legume inoculants

Product	Count		Expiry (months from date of testing)
	Fresh	Expiry	
Peat (cfu/g)	$\geq 1 \times 10^9$	$\geq 1 \times 10^8$	12–18
Liquid (cfu/mL)	$\geq 5 \times 10^9$	$\geq 1 \times 10^9$	6
Granules (MPN/g)	$\geq 1 \times 10^7$	$\geq 1 \times 10^6$	6
Freeze dried (cfu/vial)	$\geq 1 \times 10^{12}$	$\geq 5 \times 10^{11}$	6

Numerical standards for CB376 for *Lotononis bainesii* are 2×10^8 cfu/g moist peat (2×10^7 cfu/g at expiry). Contaminants in peat, liquid, and freeze-dried products should be absent at 10^{-6} dilution when counted according to ALIRU protocols. Colonies are reacted against appropriate antisera to test for strain trueness and RAPD PCR profiles are randomly checked. Moisture potential of five packets of peat must not be lower than $-\log_{10}$ 4.8 Pa. Batches may be re-submitted within 4 weeks of expiry and expiry extended for a further 6 months if criteria are met. Standard for liquids are based on 3 l bottle used to treat 1 tonne seed. Standard for freeze-dried based on vial is used to treat 1 tonne seed. (Information on standards from Gemell, Hartley and Hartley, 2007)

the basis for quality control tests carried out in Australia by the Australian Inoculant Research Group (AIRG, formerly ALIRU, AIRCS and U-DALS). They include the following:

1. The number of rhizobia per gram of peat carrier
2. Effectiveness of rhizobial strains with intended hosts
3. Moisture content*
4. Freedom from contamination*.

* Important to determine confidence in shelf life.

In addition to these, Lupwayi et al. (2000) lists formulation that is effective and easy to apply, adequate packaging, and clear labeling with instructions for application as important determinants of quality. However, emphasis is given to numerical standards in most quality control systems.

97.3 DEVELOPMENT OF LEGUME INOCULANT STANDARDS

Inoculant standards are set on the basis of the number of viable rhizobia applied to seed. For practical purposes the number is often expressed as the number of rhizobia per gram of inoculant product and therefore application rate must be considered when standards are calculated. The standard for moist peat cultures, of 10^9 cfu/g, was calculated based on a retail standard of 10^8 cfu/g with a multiplication factor of 10, which reflected an average death rate reported by R. Date and R. Roughley in their Masters of Science Theses [R. Roughley, pers comm.]. The retail standard was calculated as the number of rhizobia per gram of peat required that would result in the minimum standard of 300 rhizobia per seed when applied at the manufacturer's recommended rate (Roughley, 1964; Date, 1970).

Ultimately, it is the agronomic performance and number of rhizobia per hectare that is important. However, efficacy is not the same at all sites because of the great diversity of environmental, biotic, and edaphic conditions and although universal standards are applied to inoculants they are agronomically unrealistic. Without adequate practical means of determining the microbiological requirements at each site, standards are based largely on the maximum possible inoculum potential for each formulation.

In the *Rhizobium* Newsletter (1964), Roughley suggested an increase in inoculant standards from 100 rhizobia per seed to 300 rhizobia per seed. Soon after, the minimum standard was increased to 1000 per seed. These changes occurred as a result of improved manufacturing technology. Roughley and Pulsford (1982) commented that research to improve inoculant quality tended to slow when standards could be reached easily and for that reason standards should be under constant review.

Quality standards for inoculant products are usually established to represent a compromise between theoretical and practical possibilities. The current standards for legume inoculants in Australia are listed in Table 97.1 (see also Chapter 101).

97.4 QUALITY AND SHELF LIFE OF AUSTRALIAN LEGUME INOCULANTS

Roughley and Pulsford (1982) stated that the shelf lives of inoculants should be calculated from data collected at the point of sale as temperature during storage and handling may vary widely. Shelf life is dependent on a number of factors including packaging, carrier material, strain, and storage conditions during distribution (Thompson, 1991; Hartley et al., 2005). Most inoculants should be stored at cool temperatures, preferably with refrigeration; however, some strains are better suited to storage at higher temperatures (e.g., 26 °C for some tropical bradyrhizobia).

Table 97.2 Summary of point-of-sale peat inoculant data collected by ALIRU from 2004–2008 (see also Chapter 101)

Species	Total no. packets	Age not known	No. of packets failed			Proportion contaminated (%)	Proportion low count (%)
			Contaminated	Low count + contaminated	Low count		
Annual medic	29	5	4	—	—	13.8	0
Chickpea	64	28	8	1	—	14.1	1.6
Cowpea	66	2	12	3	—	22.7	4.5
Faba bean	86	9	15	1	3	18.6	4.7
Lucerne	134	15	19	—	—	14.2	0
Lupin	137	45	30	6	3	26.3	6.6
Field pea	128	35	12	2	—	10.9	1.6
Pigeon pea	71	—	7	—	7	9.8	9.9
Sub. clover	109	13	14	—	6	12.8	5.5
White clover	49	7	3	2	8	10.2	20.4

97.5 QUALITY OF PEAT INOCULANTS

Australian legume inoculants were collected from retail outlets between 2004 and 2008 and quality was determined as part of an ongoing survey by AIRG (then ALIRU). A summary of the data from peat inoculants is presented in Table 97.2 including the total number of inoculants tested, the number of inoculants for which age was not known, and the number of inoculants that failed due to substandard rhizobial numbers; inoculants that were contaminated with high numbers of non-rhizobial organisms and those that had both substandard counts and contamination.

Contamination in retail samples occurred consistently across inoculant groups and the percentage of contaminated batches ranged between 9.8 and 26.3% (see also Chapter 101). This indicates either that contaminants are systematically introduced during injection or more likely that gamma irradiation is unable to completely eradicate contaminant organisms. A much smaller percentage of inoculants failed because of low numbers. No lucerne or annual medic inoculants and only 1.6% of chickpea and pea/field pea inoculants failed due to low numbers. Five percent of faba bean, cowpea, and subterranean clover inoculants fell below the numerical standards. By far, the highest failure rate was with white clover at 20.4%.

Data from retail surveys were compared with data from the same peat batches submitted to ALIRU at the point of manufacture in Figure 97.1. The data are presented as box plots to illustrate data distribution.

Comparison of the median, range, and distribution of rhizobial numbers at the point-of-sale (retail) batches of peat inoculants and counts from the corresponding batches at the point of manufacture (fresh) indicate a degree of disparity between the two survey points, which varies with strain. Numbers of rhizobia in inoculants for chickpea and lucerne were the most stable with the least disparity between measured parameters. The data for fresh and retail batches had a comparable distribution and only a small drop in numbers. The greatest disparity between survey data was observed with inoculants containing *Rhizobium* spp. (faba bean, pea, and clovers), indicating relative instability of this genus in peat stored in the retail environment. Rhizobial numbers in inoculants containing *Sinorhizobium* and *Bradyrhizobium* were more stable. However, retail data for lupin inoculant indicated high variability of bradyrhizobial numbers.

The reason for disparity between fresh and retail batches is most probably related to variable storage conditions. Survival of rhizobia in peat is high when peat is stored continuously at 4 °C, indicating the potential for long shelf lives (Herridge et al., 2014). However, these results suggest that this is not the case when peat inoculants are distributed. Roughley et al. (1995) found that strains of *Rhizobium* spp. were more sensitive to temperatures between 30 and 40 °C than *Bradyrhizobium* spp. and *Sinorhizobium* spp. strains that were affected at 40 °C. Fluctuations in temperature between 40 and 25 °C resulted in a general decline in numbers over time and survival was dependent on the amount of time stored at each temperature. Peat inoculants in this survey were collected from various conditions including from cool warehouses and sheds, at ambient temperatures in retail shops some of which were air conditioned, refrigerators, and cool rooms. Clearly, the provision of ideal storage temperatures during distribution is a major constraint to assurance of peat inoculant quality and shelf life.

Several inoculants obtained on retail surveys were beyond expiry (see also Chapter 101). However, even when data from inoculants outside the expiry date were removed from analysis, some of the faba bean and clover inoculants still had numbers below the minimum standard. In the case of white clover inoculants, more than 25% [9] of samples were below the minimum standard within the 12-month shelf life. Fewer subterranean clover (1) and faba bean (3) inoculants were below $\log_{10}$ 8.0 inside their shelf lives. There were more samples with low counts when data from

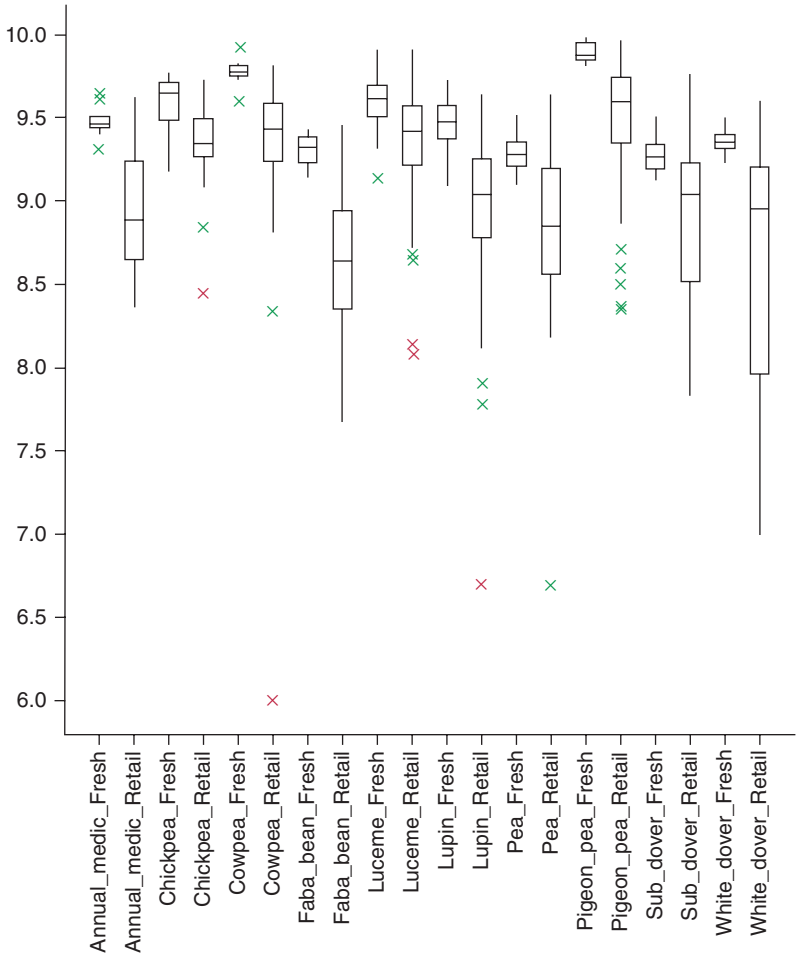

Figure 97.1 Box plot of $\log_{10}$ transformed number of rhizobia per gram of peat inoculant counted at the point of sale (Retail) and the number at the point of manufacture (Fresh) corresponding to the same batch with data outside expiry removed.

inoculants beyond expiry were included, reinforcing the importance of expiry dates for inoculants.

Variability in numbers during storage of legume inoculants is species/strain dependent rather than resulting from variable production practices. It is evident that the relative decline in numbers coupled with inherent strain variability in tolerance to fluctuations in storage conditions should be considered when determining confidence in shelf life of inoculants.

97.6 QUALITY OF GRANULAR AND FREEZE-DRIED INOCULANTS

The current minimum standard for granular inoculants is 6.0 $\log_{10}$ cfu/g at expiry. Point-of-sale data indicated that inoculants prepared from granulated peat had high numbers with a mean of 7.3 $\log_{10}$ cfu/g, a minimum of 6.0 $\log_{10}$ cfu/g, and a maximum of 8.8 $\log_{10}$ cfu/g. The numbers in drier, clay-based granules were generally lower, with a few reaching the minimum standard. The conditions in commercially available granular formulations are considerably different from those in moist peat. Generally, as granular carriers are not pre-sterilized, high numbers of rhizobia obtainable in moist peat culture are difficult to achieve and rhizobial quality of granular inoculants is variable as a result. The change in quality between manufacture and point of sale was not determined for granules as granular inoculants are not submitted to AIRG at the point of manufacture and expiry dates are not always displayed on labels (see also Chapter 101).

One of the major advantages of freeze-dried and liquid inoculant formulations is the reduced risk of contamination. Freeze-dried products have the additional advantage that long-term survival is usually good whereas liquids tend to have a shorter shelf life. Australian freeze-dried inoculant products maintained good survival of rhizobia during storage up to 648 days [1.8 years] for faba bean, 446 days (1.2 years) for lupin, and 557 days (1.5 years) for chickpea with little indication that the numbers were declining. This suggests that extension of shelf life could be possible for freeze-dried inoculants. While there was some variability in rhizobial numbers, the effect of variation in storage conditions in retail outlets was less evident for freeze-dried inoculants than for peat inoculants (data not shown). As variation was consistent from production through storage it

is probable that the main source of variation occurs during production.

97.6.1 Variable Shelf Life

For quality reasons, AIRG distributes authenticated "mother cultures" for each legume species to industry every year. Thus, for most legume species, the shelf life of their respective inoculant is given 12 months (one season). However, the shelf life of peat inoculants for lupin and chickpea (Hartley et al., 2005), faba bean/lentil and field pea (Gemell, Hartley and Hartley, 2003, 2004) was extended from 12 months to 18 months after consideration of several factors including survival of rhizobia within the inoculant over time; survival on seed, and field performance. Extension of shelf life beyond the current growing season has financial benefits for industry as near end-of-season inoculants are still of high quality at the start of the following season. Freight costs are significantly reduced when inoculants can be stored for 18 months. However, there are several reports in the literature of changes to rhizobial cell morphology and physiology during storage in peat (Dart et al., 1969; Feng et al., 2002; Casteriano et al., 2013) and liquid (Maurice et al., 2001), which may have implications for effective nodulation. As agronomic performance is the ultimate test of rhizobial efficacy, it is suggested that any consideration of extended shelf life of inoculants should be supported by the appropriate field data.

97.7 CONTAMINATION IN LEGUME INOCULANTS

Roughley and Vincent (1967), published a manuscript that resulted in widespread improvements to the quality of legume inoculants. The source of peat, moisture content, pH, and choice of neutralization agent and drying temperature were important factors. They also concluded that the high numbers of rhizobia were best supported in peat that had been previously sterilized, preferably by gamma irradiation. In all studied cases, gamma-sterilized peat sustained the highest numbers of rhizobia over time.

Boonkerd (1991) presented data for rhizobial numbers in both sterilized and unsterilized peat in Thailand, which was stored at different temperatures. He found that there was an interaction between sterility, storage temperature, and survival and that this varied between strains. Numbers of both peanut and cowpea rhizobia were predominantly affected by peat sterility whereas storage temperature had a greater effect on soybean rhizobia with better survival at 10 °C regardless of sterility. Generally, inoculants in Thailand prepared using sterile peat are assigned a longer shelf life and lower application rate because of higher numbers.

In the quality control laboratory at AIRG, growth of rhizobia on yeast–mannitol agar is often observed to be inhibited by the presence of contaminants. Inhibition of growth of *Rhizobium leguminosarum* bv. *trifolii* by *Pseudomonas aeruginosa* has also been reported by Olsen et al. (1994b). It is clear from these results that many of the contaminants found in peat produce metabolites that are bacteriostatic toward rhizobia (see Chapter 101).

Data on contaminated inoculants collected in this point-of-sale survey indicate that high levels of contamination had a significant effect on rhizobial numbers ($P < 0.001$) when compared with medium, low, and no contamination (Fig. 97.2; see Chapter 101). When moist peat is exposed to fluctuations in temperature, growth may be encouraged to a point where other contaminant organisms may be favored. Growth of rhizobia occurred when moist peat inoculants were returned to 25 °C after a period of elevated temperature

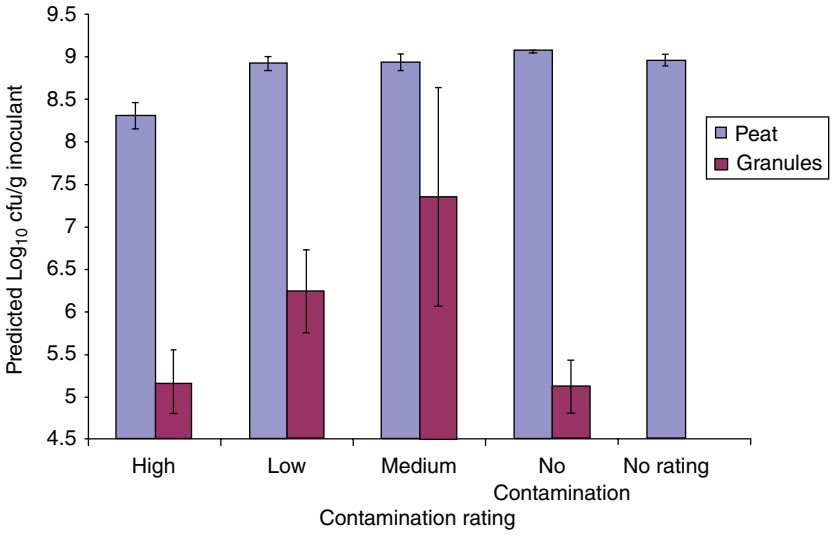

Figure 97.2 Number of rhizobia per gram of peat and granular inoculants at the point of sale as a function of contamination rating. Data were provided by ALIRU and counts of all inoculants were pooled and analyzed in GenStat using a general analysis of variance with unbalanced treatment design, with contamination rating as a factor. There was a significant effect of contamination rating for peat inoculants only [$P < 0.001$] with high levels of contamination resulting in a significant decrease in rhizobial numbers. There was no significant effect of contamination rating on rhizobial numbers in granular inoculants.

(Roughley et al., 1995). Detection of contamination at the point of sale is not generally a cause for action. However, removing the restriction on contamination in moist peat detected at the point of manufacture should not be considered and should therefore continue to be an important criterion for determining inoculant quality of freshly manufactured and re-submitted peat batches.

In a survey of 40 commercial North American rhizobial inoculants, Olsen et al. (1994b) found that in all but one of the inoculants tested contaminant organisms occurred in higher numbers than rhizobia (see Chapter 101) and they listed the potential negative effects of contaminants in peat. Contaminants may be pathogenic to humans, animals, or plants. They may be antagonistic to rhizobia, inhibit legume root nodulation, decrease the potential shelf life of inoculants, and increase the difficulty in performing quality control procedures. Brockwell (1982) suggested that low dilution "skips" in plant infection MPN tests may be due to inhibition of nodulation caused by other organisms such as saprophytic fungi.

The survey data for granular inoculants, while not extensive, do not indicate an interaction between level of contamination and numbers of rhizobia. This is probably due to the lower moisture content of granular inoculants and hence little likelihood that growth inhibition would occur during storage. Moisture status is clearly a major factor determining the potential effect of the level of contaminants within inoculants. In recent research, we found that moist preinoculated lucerne seed [Aw 0.84] had a much higher frequency of contamination (83.3%) than dry seed (38.9%, Aw 0.62) indicating that an increase in growth of contaminants will occur in ideal conditions (Deaker et al., 2012). Consequently, rhizobial survival was better on drier seeds after long-term storage.

While not all contaminants behave the same, it is impossible to determine which contaminants might be present in a carrier given the heterogeneous nature of the natural materials on which they are based. To maintain quality, it is recommended that restrictions on contaminants in moist peat inoculants remain and that contaminants in drier granular products be tolerated provided that rhizobial numbers remain above minimum standards. However, further research is necessary to determine whether high numbers of contaminant organisms in dry granules pose a threat to successful nodulation or affects the predictability of shelf life of the inoculant (see Chapter 101).

97.8 INOCULUM POTENTIAL AND INOCULANT EFFICACY

The minimum standards for rhizobia required for adequate nodulation of legumes have generally been presented as numbers per seed and vary depending on seed size. Globally, there is general agreement that these numbers should be 500 cfu/seed for legumes with very small seeds, 10^3 cfu/seed for small seeds, 10^4 cfu/seed for medium seeds and 10^5 cfu/seed for large seeds (Lupwayi et al., 2000, Herridge et al., 2002). Small seeds, in this case, refer to seeds of the size of subterranean clover [referred to as medium seeds in some texts] and very small seeds refer to seeds the size of white clover.

There is evidence that increasing numbers above these levels can greatly increase nodulation, nitrogen fixation and yield in both competitive (Ireland and Vincent, 1968) and non-competitive soil environments (Hume and Blair 1992; Roughley et al., 1993). Olsen et al. (1994a) suggested that minimum standards for rhizobial number for seeds should be increased 10-fold to 10^4, 10^5, and 10^6 per seed for each seed size category. However, in recent field experiments where faba bean was inoculated with increasing rates of a freeze-dried inoculant, Denton et al. (2013) did not find a yield benefit in competitive soil unless rates were increased 100 fold, which is uneconomical and impractical for peat and granular technologies. However, clear responses to increasing rhizobial numbers were observed in soil with no history of faba bean. Thompson (1991) noted that legume yield is not decreased when rhizobia are applied in excess and therefore there is no conceivable maximum standard for rhizobial inoculants.

We calculated the theoretical inoculum potential for different legumes using minimum standards for peat inoculants at manufacture (data not shown, 10 fold higher than at expiry) and at expiry and using recommended rates of inoculation (Table 97.3). We also calculated the theoretical inoculum potential in soil using the minimum standards for rhizobial number per seed and maximum and minimum published sowing rates. In order to calculate the number applied to seed, the number of seeds per kilogram for each species were averaged across a range of published values and cultivars ranging in size. When the colony-forming units per gram peat at expiry [1×10^8] was used to calculate colony-forming units per seed, only the number on faba bean exceeded the minimum standards for the large-seeded grain legumes. The lowest number was on narrow leaf lupin seed at 2.5 times lower than the standard. Standards were reached for all medium- and small-seeded species. This may suggest a need to increase the minimum standard at expiry or the rate of application of inoculant to seed.

The difference in numbers of rhizobia per seed on faba bean and other grain legumes is diminished when considering the number per hectare delivered at different sowing rates. Except in the case of soybean, the number of rhizobia delivered on large grain legume seed per hectare with the minimum standard of 1×10^5/seed and at the lowest sowing rate, was more than 1.5 times that of faba bean. The number of rhizobia delivered on narrow leaf lupin was more than 2.5 times the number delivered on faba bean. The low sowing rate for soybean of 15 kg ha^{-1} is used in some dryland

Table 97.3 Application of peat-based legume inoculants to seed; inoculum potential on seed and in soil

Legume species	Inoculum potential on seed at expiry (cfu/seed)	Minimum standard (cfu/seed)	Published sowing rates (kg/ha)		Inoculum potential in soil at different sowing rates (rhizobia/ha)	
			Lowest	Highest	Lowest	Highest
Grain legumes						
Faba bean	1.82×10^{5}	1×10^{5}	117	175	1.6×10^{10}	2.4×10^{10}
Chickpea	6.03×10^{4}	1×10^{5}	59	131	2.5×10^{10}	5.5×10^{10}
Pea/vetch	5.50×10^{4}	1×10^{5}	77	165	3.5×10^{10}	7.4×10^{10}
Lupin (angust.)	3.80×10^{4}	1×10^{5}	65	73	4.3×10^{10}	4.8×10^{10}
Lupin (albus)	8.32×10^{4}	1×10^{5}	153	197	4.6×10^{10}	5.9×10^{10}
Soybean	4.68×10^{4}	1×10^{5}	15	40	8.0×10^{9}	2.1×10^{10}
Mungbean	1.35×10^{4}	1×10^{4}	12	30	2.2×10^{10}	5.6×10^{10}
Lentil	2.51×10^{4}	1×10^{4}	50	75	9.9×10^{10}	1.5×10^{11}
Pasture legumes						
Sub. clover	3.89×10^{3}	1×10^{3}	4	10	5.2×10^{8}	1.3×10^{9}
Annual medic	2.24×10^{3}	1×10^{3}	3	8	6.8×10^{8}	1.8×10^{9}
Serradella	1.82×10^{3}	1×10^{3}	0.5	10	1.4×10^{8}	2.8×10^{9}
Lucerne	2.24×10^{3}	1×10^{3}	1	15	4.4×10^{8}	6.7×10^{9}
Red clover	1.86×10^{3}	1×10^{3}	1	4	5.4×10^{8}	2.1×10^{9}
Biserrula	2.88×10^{3}	1×10^{3}	1	3	8.6×10^{8}	2.6×10^{9}
Persian clover	6.76×10^{2}	5×10^{2}	4	10	5.9×10^{9}	1.5×10^{10}
Lotus pedunc.	1.62×10^{3}	5×10^{2}	1	3	1.5×10^{9}	4.6×10^{9}
White clover	6.31×10^{2}	5×10^{2}	0.5	4	8.0×10^{8}	6.4×10^{9}

Inoculum potential on seed is calculated using the recommended inoculant application rates and the number of seeds per kilogram calculated for each legume species as an average across several cultivars (Gemell, unpublished data). Inoculum potential in soil is calculated using minimum standards per seed.

cropping areas and it would be recommended that higher inoculant rates be applied when low sowing rates are used. Interestingly, only lentil at the high sowing rate delivered 10^{11} rhizobia per hectare when calculated using the minimum standards for seed inoculation. This number per hectare was selected as the minimum standard for granular inoculants to be comparable with the number delivered by seed. Although in most cases seed inoculation delivers almost an order of magnitude less rhizobia per hectare when calculated in this way, it is expected that numbers per hectare would be higher in reality as the majority of peat inoculants generally contain several times the minimum number of rhizobia at expiry and numbers per seed would exceed the global standard. However, when rhizobia are delivered on seed, rhizobial death rates can be high.

The question remains whether the numerical standards for legume inoculants are adequate to produce meaningful responses across a broad range of sites. Brockwell and Bottomley (1995) reported that most literature reports numbers of 1×10^{4} indigenous rhizobia/g soil, which is equivalent to 1.5×10^{13} rhizobia/ha if spread evenly through the top 10 cm soil. It is clearly inconceivable that the inoculant strain applied at the standard recommended rate could outnumber indigenous rhizobia. The authors suggest that numbers of indigenous rhizobia between 10 and 1000 rhizobia/g soil are of much more practical concern, particularly if the soil population is poorly effective. In this case, the inoculant strain should be applied in high numbers or be highly competitive; however, seed inoculation may improve competitiveness by localizing inoculant strains around the emerging root.

The number of rhizobia delivered per hectare on pasture legume seed is generally one to two orders of magnitude lower than numbers from grain legumes because of much lower sowing rates. In this case, it would be important to localize rhizobia around the emerging root using seed inoculation, and the number per seed is critical for improved competition by the inoculant strain. Roughley and Walker (1973) recommended farm inoculation of pasture seed where sowing rates were low. The number per hectare is more relevant when inoculants are delivered directly to the soil.

97.9 SOIL VERSUS SEED INOCULATION

The prospect of inoculating legumes by direct application of inoculant to the soil has been investigated for some time. Brockwell et al. (1980) compared application of solid and liquid inoculants directly to the soil with slurry inoculation on seed. The inoculants were evaluated in 16 field experiments over 8 years with soybean, chickpea, sweet lupin, field

pea, and subterranean clover. They listed the inefficiencies associated with seed inoculation as follows:

1. Seeds may be treated with incompatible chemicals for the control of fungal disease, etc.
2. High sowing rates of grain legumes render seed inoculation a major and difficult task.
3. Seeds may be too fragile to be tumbled with the inoculants; such is the case with peanuts.
4. Some legumes lift their seed coats, and hence inoculant rhizobia, out of the soil during emergence.
5. The size of the seeds (particularly small seeds) restricts the number of rhizobia that can be applied.
6. Inoculation of some seeds can mobilize toxic water soluble compounds from the seed coat.

The authors found that under favorable conditions solid and liquid inoculants applied directly to the soil were generally as good as seed inoculation (as measured by nodule occupancy, quality of nodulation, seedling establishment, shoot dry matter production, and seed yield). Soil inoculants outperformed seed-applied inoculants when conditions on the seed were unfavorable for survival (e.g., use of seed-applied chemicals). Brockwell et al. (1980) concluded that while granular inoculants have advantages, their use would require modification of seeding equipment and adequate storage space, and transport costs would be increased because of the need for large quantities.

Several other authors have reported superior performance of soil-applied inoculants with soybean (Chamber, 1983; Hardarson et al., 1989; Gault et al., 1994), field pea (Jensen, 1987; Rice et al., 2000; Kutcher et al., 2002; Clayton et al., 2004), chickpea (Kyei-Boahen et al., 2002; Gan et al., 2005) and to a lesser extend with alfalfa (Knight, 2007). Granular inoculants were particularly advantageous when seed-applied fungicides were used (Kutcher et al., 2002) or where seeds were sown into acid soil (Rice et al., 2000). In most studies, granular inoculants and seed-applied peat slurries outperformed seed-applied liquid inoculants.

Results from field studies over several years on the use of granular inoculants for inoculation of field pea, faba bean, lentil, chickpea, and narrow leaf lupin in Victoria, New South Wales, and South Australia were compiled by Denton et al. (2009). In all experiments, seed inoculation with peat slurries were the same if not better than granular inoculation. The results suggest a strong interaction between rhizobial numbers in granules and nodulation (percentage of plants nodulated). Nodulation percentage increased markedly when rhizobial numbers per gram of inoculant increased from 10^6 to 10^7 (equivalent to 10^{10} to 10^{11} rhizobia/ha when applied at $10\,kg\,ha^{-1}$). The authors concluded that the success of inoculation was also related to particle size distribution of the granules. It is interesting to note that attapulgite granules containing 10^6 rhizobia/g but with a predominantly smaller particle size (highest frequency at 0.5–1.0 mm) were as effective as larger granules with 10 times more rhizobia per gram. Granules with low numbers and larger particle sizes were the least effective. Attapulgite granules were also more effective than peat slurry inoculation when applied to soybean [ALIRU annual report, 2005]. It follows that particle size limits the distribution of granules and hence rhizobia, and thus should be a determinant of inoculant quality.

Inoculant manufacturers recommend application rates for granular inoculants according to row spacing. It is expected that row spacing is the most critical factor as this would affect granular distribution by essentially varying the number of linear meters for application. Increased nodulation would also potentially result from higher plant densities by increasing the probability that granules would be proximal to roots.

Plant density for legume crops (as affected by sowing rate and row spacing) varies for a number of reasons including rainfall, temperature, cultivar and seed yield potential, and disease (Regan et al., 2003). Row spacing of grain legumes may be as wide as 100 cm [NSW DPI Summer Crop Production Guide, 2008]. Wide spacing is an advantage when sowing into stubble or in moisture-limited situations. In this situation, there would be 10,000 linear meters per hectare and granules applied at $10\,kg\,ha^{-1}$ would be distributed at $1\,g\,m^{-1}$. A decrease in row spacing would effectively increase the number of linear meters for application and decrease the number of granules per meter if the same application rate was used. If granule size was large, then there would be considerably less confidence in distribution of granules when narrow row spacing was used. It is suggested that consideration be given to developing a standard for granule size and the minimum number of granules (as well as a minimum number of rhizobia) per linear meter applicable to the lowest plant density.

Clearly, soil applied inoculants can be effective and overcome constraints associated with seed inoculation as well as providing a convenient ready-to-use product. However, their efficacy is dependent on numerical quality and issues relating to supply and application of large quantities of inoculant. While liquid inoculants applied to seed did not have much success in the described studies, they provided a convenient alternative to peat for seed inoculation (Hynes et al., 1995).

Freeze-dried and liquid inoculants applied to seeds are exposed to similar potentially adverse conditions as peat slurries. However, there is evidence of physiological changes in peat improving tolerance (Feng et al., 2002; Casteriano et al., 2013). Conversely, cells in liquid cultures became more membrane-compromised with age (Maurice et al., 2001). Peat also provides additional protection to cells on seed (R. A. Date, unpub. PhD thesis, University of Sydney, 1959). Survival is strain dependent and can be improved by selection of a protective polymer (Deaker

et al., 2007; Deaker et al., 2012; Hartley et al., 2012). McLeod and Roughley (1961) reported the successful use of freeze-dried inoculants in field trials; however, survival on seed after application with polymeric adhesives was poor (Vincent, 1965). Freeze-dried rhizobia generally survive better at high temperatures than peat cultures but the cells must be kept dry to maintain tolerance to high temperatures (Kremer and Peterson, 1982, 1983). Studies on exposure of freeze-dried cultures to high temperatures on seed revealed that survival was poor when relative humidity was increased (McInnes and Date, 2005). However, the ability to apply large quantities of freeze-dried inoculant to seed and increasing rhizobial numbers by orders of magnitude may be an advantage (Denton et al., 2013) but is not currently economically viable.

97.10 QUALITY OF COMMERCIALLY INOCULATED [PREINOCULATED] LEGUME SEED

Surveys of preinoculated seed in Australia between 1972 and 1974 revealed that five (three batches of subterranean clover and two batches of lucerne) of the 48 batches of seed tested had more than 1600 rhizobia/seed (Brockwell et al., 1975). Further six batches had between 640 and 1600 rhizobia/seed, one of which was white clover and the rest were subterranean clover. Therefore, a total of 23% of the batches tested passed or came close to passing current AIRG standards. In the period 1999–2003, of 293 samples tested the results were more promising for lucerne with 73% passing standards (Gemell et al., 2005). However, only 32% of subterranean clover, 3% of white clover, 4% of red clover, and 0% of other species passed the standards. More recently, 287 samples of preinoculated seed were collected and tested between 2005 and 2010 and only 10% of samples passed the AIRG standards (O'Hara et al., 2012).

Our recent research indicates that this decrease in quality is related to changes in the commercial inoculation process, most notably the poor compatibility of selected materials that are incorporated into the seed pellet and the drying rate of inoculated seeds (Deaker et al., 2012; Hartley et al., 2012). It is our understanding that coating materials are generally selected on the basis of processing quality and the physical properties of the final product rather than on compatibility with rhizobia.

Major changes to production are required to improve preinoculated seed quality, and challenges relating to rhizobial survival on seed, in general, need to be addressed if this product is to reach its full potential. Large areas of grazing pasture and rangelands rely almost entirely on inputs of nitrogen fixed by legumes. It is likely that nitrogen fixation is suboptimal in these environments given the now widespread use of an essentially ineffective inoculation technique. In this case, nodulation and nitrogen fixation are dependent of the effectiveness of the resident soil rhizobia population, which may be substantially less effective than selected inoculant strains as demonstrated by Drew et al. (2012).

97.11 CONCLUSIONS

We conclude that true benefits of inoculation of legumes will result from inoculants that are not only of high quality but are also easy to apply in a way that promotes both adoption of the practice and survival of effective rhizobia. Standards should be reviewed for each formulation and modified accordingly so that inoculant properties support the efficacy of application (see Chapter 101).

The efficacy of seed inoculation is dependent on the initial number and physiology of rhizobia in the inoculant, rhizobial strain, method of application including coating procedure and compatibility of polymer adhesives used during seed coating, and length of time on seed before sowing. If these conditions are optimized, placement of rhizobia proximal to the emerging root for prompt colonization and nodulation and the requirement for smaller quantities of inoculant would be advantageous. Clearly, a major development is required to improve the quality of preinoculated pasture legume seed; however, the convenience of this product has resulted in its widespread use. Given the largely unknown but potentially suboptimal effectiveness of resident soil rhizobia, large gains in nitrogen fixation could be made in the vast areas of pasture and rangelands by improving the quality of preinoculated seed.

In the absence of ideal conditions or where there is adequate means, soil inoculation providing adequate distribution of rhizobia could be recommended. However, there is little data on inoculant quality of granular products either at the point of manufacture or in the retail market, and the shelf life has not been confirmed. In addition, the need for high volumes and increased input costs may reduce the adoption of this product.

Chapter 98

Rhizobiophages as a Marker in the Selection of Symbiotically Efficient Rhizobia for Legumes

Sanjay Kumar Jaiswal and Felix D. Dakora

Department of Chemistry, Tshwane University of Technology, Arcadia Campus, Pretoria, South Africa

98.1 INTRODUCTION

The traditional approach for the development of inoculants has consisted of isolation, testing, and selection of a single strain with the desired properties, such as high nitrogen fixation ability in symbiosis with selected host plants. In cases where indigenous rhizobia able to nodulate that host are already present in the soil but are less efficient, the capacity of the inoculant strain to outcompete those rhizobia is important. The selection of efficient strains is still hampered by the fact that, although the genes encoding nodulation and nitrogen fixation in rhizobia are known (e.g., Franche et al., 2009), the precise genetic bases for symbiotic effectiveness, competitiveness, and tolerance to environmental stress factors in soils remain largely unknown.

Various biotic and abiotic factors are known to influence the survival and competitiveness of rhizobia in soils (see Chapter 97). Bacteriophages are one of the potent factors that can affect the outcome of *Rhizobium*–legume symbiosis (Kowalski et al., 2004). Rhizobiophages have been isolated from soils of many countries and they are usually associated with legume cultivation (Amarger, 2001). Identification and selection of efficient *Rhizobium* strains from field-grown soils is a difficult task; there is a need for a dependable screening system of sufficient sensitivity such that each individual may be easily differentiated from other strains of diverse origins.

Phages associated with susceptible rhizobial strains have been isolated from rhizospheric soil and used to characterize indigenous rhizobial population (Schmidt et al., 1986; Appunu and Dhar, 2006a). The occurrence and distribution of phages active against various groups of rhizobia have been reported from India (Dhar et al., 1979; 1980; Singh et al., 1980; Dhar and Ramkrishna, 1987; Dhar et al., 1993), Poland (Staniewski, 1970), New Zealand (Patel, 1976), Canada (Lesley, 1982), and Senegal (De Lajudie and Bogusz, 1984). Recently phages infective on soybean and lentil rhizobia have also been isolated and characterized (Appunu and Dhar, 2008; Jaiswal and Dhar, 2010).

Rhizobia have long been known to differ in phage susceptibility, and recently this feature has been used in diversity studies of rhizobial strains from field soils (Bromfield et al., 2010). Phages could play an important role in the development of ecologically competitive rhizobial strains in soil (Kowalski et al., 2004; Bromfield et al., 2010).

Variation in host specificity of phages has been suggested to be due to the diversity of the host bacterium (Holmberg et al., 1984). The bacterial wall is likely to be significant in determining the host specificity of phages (Defives et al., 1996). Outer membrane-bound lipopolysaccharides (LPSs) and proteins serve as receptors for phages (Werts et al., 1994). Defives et al. (1996) and Sharma et al. (2008) reported that the involvement of the O-antigen of LPS of bacteria help attract phages. So far, there are no publications on the possible biochemical or structural

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

factors underlying the recognition between specific phages and certain highly efficient rhizobial strains. It is assumed that high susceptibility of rhizobia that show the most symbiotic effectiveness with their host to phages may involve repeating units of the O-antigen of lipopolysaccharide. Therefore, phage specificity in conjunction with micro-heterogeneity in LPS profiles (LPS subtypes) can be used to easily discriminate rhizobia within the same species.

98.2 PHAGE TYPING

Phage sensitivity pattern has been suggested as a potent method to differentiate bacteria according to their genotypic and phenotypic traits (Thurman and Bromfield, 1988; Lindstrom and Lehtomaki, 1988; Sharma et al., 2002). In addition, it gives fast and reproducible results to discriminate indigenous rhizobial isolates and proves to be useful enough for monitoring the purity of bacterial germplasm (Lesley, 1982; Lindstrom et al., 1983; Appunu and Dhar, 2006b). Phage typing has been widely used to characterize strains of *Rhizobium trifolii*, *Rhizobium leguminosarum* for pea, vetch, and horse bean, *R. meliloti* strains and one strain of *R. lupini* for lupine (Staniewski, 1970), *Rhizobium meliloti* of alfalfa (Lesley, 1982), *R. leguminosarum* of *Galega oficinalis* (Lindström et al., 1983), *Bradyrhizobium* sps. of soybean (Appunu and Dhar, 2006b), and *R. leguminosarum* bv. *viciae* of lentil (Jaiswal et al., 2012a). Phage typing simplifies the problem of identification of inoculation strains in soil (Lindstrom and Lehtomaki, 1988; Lindstrom et al., 1990; Anand et al., 2012).

Rhizobiophages are very specific to their host strains and have been reported as an authentic genetic marker for differentiating rhizobial strains. This has been used to differentiate the rhizobial strains of chickpea (Dhar and Ramkrishna, 1987), pigeonpea (Dhar and Kumar, 1998), frenchbean (Dhar et al., 1993), cowpea (Singh et al., 1980), soybean (Hashem et al., 1996; Ali et al., 1998; Appunu and Dhar, 2008), pea (Mendum et al., 2001), lentil (Jaiswal and Dhar, 2010), and some other legumes (Novikova et al., 1993). Rhizobiophages could also play an important role in the development of ecologically competitive phage-resistant strains (Bromfield et al., 2010; Kowalski et al., 2004). Phage could have a fundamental role as an indicator of the microdiversity that is required to efficiently exploit ecological resources (Suttle, 2007).

98.3 MATERIALS AND METHODS

The phage typing procedure as described by Lesley (1982) was used invariably to test the host range sensitivity pattern of a bacterial strain. Phage strains specific to their host rhizobia in terms of their lytic activity were utilized for phage typing of indigenous rhizobial isolates. Each rhizobial strain in the stationary growth phase was introduced into soft agar (0.7%) medium and plated by the double agar method. A volume of 50 µl of each phage strain (10^8 pfu ml^{-1}) was spotted on the bacterial lawn shortly after the soft agar layer solidified. Plates were examined for lytic activity on the lawn following 4–5 days of incubation (Fig. 98.1).

Four rhizobial isolates are shown to have different lytic reactions with six phage strains. Rhizobial strain MPSR084 was found susceptible to three phage strains (RT1, RT3, and RT5) while strain UPSR020 showed a clear lytic zone with two phage strains (RT2 and RT4). Isolates MPSR033 and MPSR220 revealed lytic zones only with phage strains RT5 and RT6, respectively (Fig. 98.1).

98.4 RESULTS AND DISCUSSION

On the basis of sensitivity patterns of lentil (*Lens culinaris*) rhizobial strains, 10 phage groups were identified and the number of rhizobial isolates belonging to each phage typed group is given in Table 98.1. The phage strains used showed variation among the susceptible strains for a particular group. Phage group I included three phage-sensitive strains while group VI contained three susceptible strains to phage LRP-20 only. The maximum number of isolates belonging to phage groups VII and VIII were lysed by two phages LRP-4 and LRP-15. Phage isolates were able to infect the rhizobial strains of *Pisum sativum* and *Phaseolous vulgaris* (Jaiswal et al., 2012a).

Although some rhizobiophages have shown a narrow host range (Dhar et al., 1978; Hashem et al., 1986), many have exhibited a wide host range (Barnet, 1972; Dhar and Ramkrishna, 1987). Host range is, however, not an invariant characteristic of a phage strain and can be altered, as bacteriophages can adapt themselves to proliferate on different host cells.

98.5 SYMBIOTIC RESPONSE OF PHAGE-TYPED *Rhizobium* WITH HOST PLANT

The presence of phage in soil may cause selection pressure on sensitive rhizobial strains, and thus their continued coexistence with the sensitive host genotype is important (Hashem and Angle, 1988; Kleczkowaska, 1971; Patel, 1976). Under such selection pressure, a phage-resistant form of *Rhizobium* may create a better fitness in the rhizosphere. The knowledge of associated changes in the symbiotic properties of such variants is important. Symbiotic effectiveness of *Rhizobium* strains belonging to different phage-sensitive and phage-resistant groups was compared on host plants grown in a nitrogen-free culture system. A significant difference in nodule number, ARA, and total dry matter accumulation was observed. Most of the phage-marked

strains displayed significantly higher symbiotic parameters than phage-resistant strains. In lentil (*Lens culinaris*), reported by Jaiswal and Dhar (2011), four phage susceptible strains (BHULR-104, BHULR-113, BHULR-115, and USDA 2431) were found significantly superior than others in terms of symbiotic parameters. The isolate BHULR-115 exhibited the highest nodule number and plant dry weight, whereas the isolate BHULR-113 evidenced superior performance with regard to nodule number, ARA, and plant dry matter production. Overall increase in plant dry weight by phage-susceptible strains was about 12% more than by all phage-resistant strains.

These genetically distant groups may differ in their ability to persist in soil, infect the host cell, or fix nitrogen in the nodule (Appunu and Dhar, 2006c; Meghvanshi et al., 2005; Jaiswal and Dhar, 2011; Jaiswal et al., 2012b). Phage typing has been also used to identify the successful competitor when alfalfa (Lesley, 1982) and soybean (Anand et al., 2012) plant roots were inoculated with phage marked rhizobial strains under axenic and field conditions.

Phages that are used for typing of rhizobia differ in plaque shape, for example, possessing either circular, sharp, or hazy margins (Dhar et al., 1978; 1979; 1980; 1993; Dhar and Kumar, 1998; Sharma et al., 2002; Appunu and Dhar, 2006c; Jaiswal and Dhar, 2010). Plaque type diversity is mainly associated with the host but habitat factors also influence plaque type groups for at least soybean native *Rhizobium* isolates. Perhaps these phages could be used as an indicator for the distribution of a particular type of rhizobia present in the soil. Phages were also used successfully in the characterization of indigenous rhizobia residing in soybean nodules (Schmidt et al., 1986; Thurman and Bromfield, 1988; Ali et al., 1998; Appunu and Dhar, 2006a).

Ahmad and Morgan (1994) reported that when the concentration of phage is increased in comparison to rhizobia in soil, cowpea nodulation is decreased. Hashem and Angle (1988) have also shown that phages of *B. japonicum* cause a significant reduction in nodule number, nodule mass, and shoot dry weight of soybean. Staniewski et al. (1962) suggested that the direct lytic action of the phage on the nodule bacteria depends on the bacteriophage population in soil. And this finding opened the way to select phage-resistant rhizobial strains.

Recently, it has been observed that the phage-resistant soybean bradyrhizobial isolates form nodules and fix nitrogen on a broad host range of legumes (*Vigna mungo, Vigna radiate, Vigna unguiculata and Cajanus cajan*) (Jaiswal et al. 2012b; Appunu et al., 2009).

98.6 CONCLUSION

Phage typing results indicate the great utility of this method to differentiate nodule rhizobial isolates at a strain level. Compared to serological analysis, phage typing is a simple and less time-consuming technique to differentiate the bacterial strains if a number of lytic phages are available. It provides a basis for selection of rhizobia, which may have strategies for application of appropriate inocula to improve legume production and provide information of genetic diversity and functional variability of the legume–*Rhizobium* symbiosis.

Nitrogen Fixation with Soybean: The Perfect Symbiosis?

Mariangela Hungria
Embrapa Soja, Londrina, PR, Brazil

Iêda Carvalho Mendes
Embrapa Cerrados, Planaltina, DF, Brazil

99.1 INTRODUCTION

Soybean [*Glycine max* [L.] Merr.] is the most important legume cropped worldwide. The high protein content of its grains – about 40% – represents a nutritionally important part of the diets of humans and domestic animals. In addition, other seed products have broad industrial and pharmaceutical applications. For example, there is increasing interest in using soybean oil for biodiesel production to replace its fossil-based counterpart.

In 2011, the total area cropped to soybean was estimated at 103 million ha, with a total production of 261 million metric tons (FAO, 2011). The three major producers are the United States, Brazil, and Argentina (Fig. 99.1); South American countries account for 52% of global production. Interestingly, increasing production has been reported in Africa – currently cropping 1.5 million ha – and 12.1 million ha are cropped in "low-income food-deficit countries" (FAO, 2011), indicating that the legume may play an increasingly key role as a protein source for impoverished populations. The increased production in these areas can be attributed to relatively low susceptibility to pests and diseases, better grain-storage quality, high leaf-biomass yield (benefiting soil fertility], and secure commercial markets (Mafangoya et al., 2009).

Despite considerable differences in yield among countries, for example, averages of 2789 and 2862 kg ha^{-1} in North and South America, respectively, and of 1186 and 1220 kg ha^{-1} in Africa and in countries classified as "low-income food-deficit countries," respectively (FAO, 2011), one may conclude that reasonable yields may be achieved even with low-input management practices. Considering the high demand of N by soybean crops, of about 80 kg of N per 1000 kg of grain (on average 65 kg N in the grain and 15 kg N in the vegetative crop residues, including the roots) (Hungria et al., 2007; 2009), and that the great majority of the soybean in South America, Africa, and in some Asian countries is cropped on soils of very low N content and with no application of N-fertilizer, we may conclude that, in a variety of environments, biological nitrogen fixation (BNF] makes significant contributions to soybean crops.

In an exercise to quantify the global contribution of soybean BNF, Herridge et al. (2008) came up with a figure of 16.4 Tg annually, representing 77% of the N fixed by all crop legumes. However, the increasing shift in production from the United States – with high inputs of N-fertilizers to the soybean-maize cropping system – to the low N-fertilizer input agriculture practiced in South America and Africa should soon result in significantly greater contributions from BNF.

In a survey of quantifications of BNF by agricultural legumes, soybean was rated as the highest among the grain producers, with contributions of up to 450 kg N ha^{-1}, surpassed only by the fodder crops bitter lupin (*Lupinus mutabilis* Sweet) and alfalfa (*Medicago sativa* L.), with up to 527 and 470 kg N ha^{-1}, respectively (Ormeño-Orrillo et al., 2013). On the other hand, few reports exist of low contributions of BNF by soybean; there is need for research

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

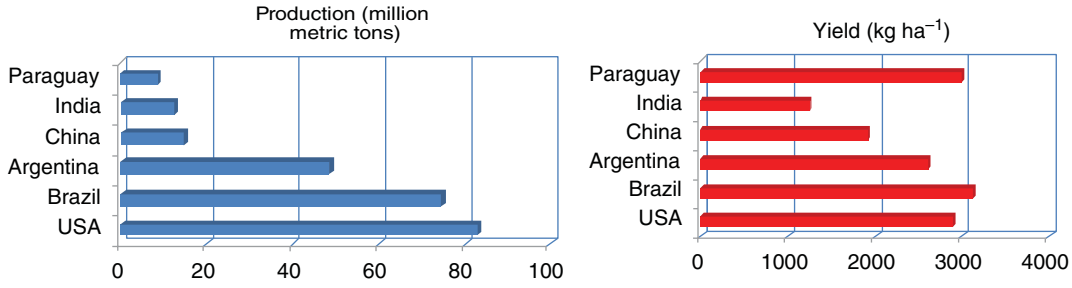

Figure 99.1 Soybean production and yield in the six main producers globally, 2011 (after FAO, 2011).

on limiting factors related to such cases. We hypothesize that the majority of reports of low BNF contributions result from breeding and cropping managements with high inputs of N-fertilizers. Attention should be paid also to global environmental changes, with emphasis on increasing periods of drought that may represent serious limitations to BNF, highlighting the need to identify genotypes with high BNF and high tolerance of moisture deficiency (Chen et al., 2007; Sinclair et al., 2007; Purcell, 2009). Other factors may be critical to the success of the symbiosis, such as treatment of seeds with pesticides (e.g., Campo et al., 2009; Hungria et al., 2009).

99.1.1 Soybean Domestication, Cropping, and Breeding for Nitrogen Fixation

Domesticated soybean emerged in central and northern China in the period 1100–700 B.C., moving before the first millennium A.D. to India, Nepal, Burma, Thailand, Indochina, Korea, Japan, Malaysia, Indonesia, and the Philippines (Hymowitz and Singh, 1987). It arrived in Europe (Germany) in 1712, in Paris in 1740, and in the United States in 1804, probably from seed exchanges with France (reviewed in Hungria et al., 2005). Significant production in the United States and Europe did not occur until the beginning of the twentieth century (Hymowitz, 1970), increasing with the collection and maintenance of germplasms. In South America, *Glycine* spp. was introduced – mainly as seeds from the United States – in 1880 to Argentina, in 1882 to Brazil, and in the 1920s to Paraguay (Hungria et al., 2006a). However, despite the hundreds of accessions available in the main producing countries, it is noteworthy that the genetic base used in occidental breeding programs is narrow. For example, Delannay et al. (1983) reported that, in the United States, 10 introductions provide 80% of the gene pool; similarly for the Brazilian germplasm (Hiromoto and Vello, 1986).

Another limitation is that although N_2-fixation rates of 1–2 kg N ha^{-1} per day should be possible in all legumes, with an emphasis on the efficient symbiosis with soybean (Giller, 2001), the low cost of N-fertilizers in developed countries such as the United States has led to dependence on fertilizers for N, with corresponding reductions in the contributions of BNF to soybean (van Kessel and Hartley, 2000). This helps explain the low interest in breeding for increased BNF in US breeding programs (see Chapter 106). To attend to the demands of high-yield cultivars in the presence of mineral N, supernodulating soybean mutants, tolerant of nitrate (nitrate tolerant symbiotic, *nts*), were developed (Carroll et al., 1985; Gremaud and Harper, 1989; Akao and Kouchi, 1992; see Chapter 106). However, field evaluations of *nts* mutants usually provided lower yields (Wu and Harper, 1991) and some mutants with excessive nodulation show increased sensitivity to environmental stresses. It was suggested that the nodules on *nts* mutants consume extra carbohydrate and, in occupying more root surface, compromise absorption of mineral N (Takahashi et al., 1995).

An early breeding approach in the United States toward increasing the contribution of BNF was based on the identification of soybean genotypes that restrict nodulation by dominant indigenous serogroups of *Bradyrhizobium* that fix N_2 with low efficiency. Some of the genes identified were rj_1, Rj_2, Rj_3, Rj_4, rj_5, rj_6, rj_7, and Rf_{g1}, all distinct in their segregation, which facilitates breeding (Devine, 1984; Sadowsky and Cregan, 1992; Hayashi et al., 2012). In a similar approach, Kvien et al. (1981) and Weiser et al. (1990) sought cultivars with various levels of preference for, or exclusion of, certain serogroups. Using the exclusion approach, Cregan and Keyser (1986) identified, among plant introductions (PIs) and modern genotypes, some with restricted nodulation to serogroup 123, and promising results were obtained with the Rj_4 genotypes (Sadowsky and Cregan, 1992). However, although the presence of indigenous bradyrhizobia of serogroup 123 has been considered a main limiting factor to BNF in midwestern United States (Kvien et al., 1981; Cregan et al., 1989; Weber et al., 1989), breeding programs to restrict nodulation by serogroup 123 strains have been discontinued.

A contrasting approach was taken in Africa – mainly Nigeria – in the 1980s, with the exploitation of cultivars with promiscuous nodulation with indigenous strains (Kueneman et al., 1984; Pulver et al., 1982). The approach was based on the difficulties of producing and applying inoculants in sub-Saharan countries. However, with commercial crops

being increasingly established in several African countries, difficulties in producing and importing inoculants have decreased, and, with the need to grow high yielding cultivars, there has been a change from promiscuous cultivars to those responsive to commercial inoculants. In addition, there are now reports that inoculation can increase the yields of promiscuous cultivars. Important initiatives are in progress, such as N2Africa project (http://www.n2africa.org).

With the exception of the United States, the high cost of N-fertilizers throughout the American continent has necessitated a reliance on BNF. Interestingly, most of the Brazilian genotypes are derived from North America, but the main achievement of the Brazilian soybean program has been that it has always relied exclusively on inoculation, commonly in soils that are limited in N (Hungria et al., 2005; 2006a; 2007; Vieira et al., 2010). However, even under environmental conditions favoring BNF, there are reports of differences among Brazilian soybean cultivars in their symbiotic performances (Hungria and Bohrer, 2000; Hungria et al., 2006a), highlighting the opportunity for improvements in rates of BNF, as well as the need to monitor the BNF capacity of newly released cultivars across environments.

Worthy of consideration are possible adverse effects on BNF of transgenes in genetically modified (GM] soybean cultivars. Commercial use of GM soybean – roundup ready [RR] glyphosate-tolerant lines – was initiated in 1996 in the United States. Soybean now represents the main GM crop, with 75.4 million ha grown worldwide in 2011 (ISAAA, 2011). Greenhouse and field studies evaluating the effect of glyphosate on the *B. japonicum*/*B. elkanii* symbiosis with RR soybean cultivars have shown deleterious effects on nodulation and/or BNF (e.g., Reddy and Zablotowicz, 2003; Zablotowicz and Reddy, 2004; Bohm et al., 2009). Under field conditions, decreases in nodulation, but not in yield, have been demonstrated (Hungria et al., 2014). In general, effects of transgenic soybean changed with glyphosate rate, salt and time of application, soybean variety, and geographical and environmental conditions, and could not be attributed to the transgene. Other generations of GM soybeans are now available, and a recent meta-analysis has shown that they perform better than their conventional counterparts in agronomic and economic terms (Areal et al., 2013). It should be borne in mind that weeds can compete for nutrients, water, and radiation, and insects can severely damage plants; therefore, without proper management of weeds and insects, contributions from BNF can be compromised (Fig. 99.2).

Finally, advances in our knowledge of plant genes related to BNF have been achieved with the help of molecular tools. A first report of a gene associated with nodulation resulted from cloning in *Lotus japonicus*; *nin-1* (a non-nodulating mutant) encoded a transcription factor related to the regulation of gene expression during root infection (Schauser et al., 1999; see Chapter 59). Since then,

(a) (b)

Figure 99.2 Field experiment to evaluate biological nitrogen fixation in (a) transgenic RR soybean managed with glyphosate, and (b) the nearly isogenic parental non-transgenic genotype managed with conventional herbicides. Experiment performed at Embrapa Cerrados, Planaltina, Brazil.

impressive progress has been achieved, with the identification of several genes involved in the root–nodule symbiosis, mostly by using two model legumes, *Lotus japonicus* and *Medicago truncatula*, which have relatively small, simple genomes and are amenable to molecular transformation (Oldroyd et al., 2011; Reid et al., 2011). Outstanding results have also been obtained as a result of the publication of the integrated linkage map of the soybean genome (Cregan et al., 1999; Song et al., 2004); from this map, quantitative trait loci (QTLs) have been broadly used in soybean to identify features of interest, such as yield potential, disease resistance, and contents of protein and oil in seeds (SoyBase, 2012; see Chapter 106); unfortunately, very few groups are including BNF genomic information in this map (Nicolás et al., 2006; Santos et al., 2006; Santos et al., 2013). However, with the outstanding knowledge obtained with the first sequenced genome of soybean (Schumutz et al., 2010), the large EST databases and high density linkage maps have enabled the isolation of several genes, for example, the *Rj* genes, genes related to the perception of Nod factors, early and late nodulins, and the NARK gene (nodule autoregulation receptor kinase] (Reid et al., 2011; Hayashi et al., 2012). Transcription and proteomic profiles of nodulated and non-nodulated soybeans have also identified a variety of genes expressed in the formation and function of the symbiosis (e.g., Brechenmacher et al., 2008; Nguyen et al., 2012; Carvalho et al., 2013), pointing the way to novel studies to elucidate the roles of a number of interesting genes.

In conclusion, soybean breeding has shown spectacular results, for example, average yields in Brazil have increased from 1100 kg ha^{-1} in the 1960s to more than 3000 kg ha^{-1} today. Breeding has focused mainly on increased crop yield, resistance to diseases, and improved seed quality and nutritional traits, in addition to adaptation to edaphoclimatic conditions, such as shorter day length and water-stress tolerance. Transgenic approaches have achieved tolerance of herbicides and resistance to insect predation. Unfortunately, as mentioned above and pointed by Nicolás et al. (2006) and Hayashi et al. (2012), relatively little effort has been

expended in regard to BNF ability, despite the importance of the process to seed productivity and quality.

99.1.2 Selection and Use of Elite Rhizobial Strains

In China, a variety of described and putative species of the genera *Sinorhizobium* and *Bradyrhizobium* nodulating soybean have been identified (e.g., Keyser et al., 1982; Yang et al., 2006; Man et al., 2008), supporting the hypothesis that the original center of the legume is also the center of diversity of compatible rhizobia. However, the need for selecting strains with higher capacity of fixing nitrogen has long been recognized (Baldwin and Fred, 1929; Fred et al., 1932); in the late 1920s, Fred and colleagues commented that native soil strains were not always effective, requiring a screening process to increase productivity by inoculation (Fred et al., 1932).

The most important soybean breeding programs have been in the United States, Brazil, and Argentina, and as these countries do not represent centers of genetic domestication of the host plant, when their soils have not been previously cropped with the legume and in the absence of inoculants, populations of compatible rhizobia are small or absent (e.g., Vargas and Suhet, 1980; Elmore, 1984; Brutti et al., 1998; Ferreira and Hungria, 2002). Therefore, soybean cropped for the first time in soils of low N content show significant responses to inoculation with selected strains (McLoughlin et al., 1990; Hungria et al., 2006a), as exemplified in Figure 99.3.

Interestingly, only a few *Bradyrhizobium* strains have been used in the breeding programs in these countries, resulting in cultivars being highly specific in their strain needs.

One strain broadly used in commercial inoculants is *B. japonicum* USDA (United States Department of Agriculture) 110 (=TAL 102, =BCRC 13528, =JCM 10833, =3I1B110, =ACCC 15034), isolated in 1959 from a nodule on a soybean grown in Florida, USA (Keyser and Griffin, 1987). The strain has been used since then in several commercial inoculants in the United States, and in Europe, Asia, and Africa. It is noteworthy that this strain was recently reclassified and is the type strain of the new species *B. diazoefficiens* (Delamuta et al., 2013).

(a) (b)

Figure 99.3 Soybean grown in first-year areas and soils poor on N. Contrasting effect of green plants inoculated and fixing nitrogen and yellowish non-inoculated plants. Experiments performed in (a) Planaltina, central Brazil, in the 1980s (Photo: Dr. M. A. T. Vargas, Embrapa) and (b) Boa Vista, northern Brazil, in the 2010s (Photo: Dr. J. E. Zilli, Embrapa).

Another strain broadly used is the "improved" 532C (=532), selected by Professor David Hume in 1988 after screening several strains received from the Nitragin Company in the United States; since then, it has been used in inoculants in the United States and, from 1990 also in Canada (Shurtleff and Aoyagi, 2010). Inoculants carrying strain 532C have been exported, and it was probably used in commercial inoculants in Brazil from 1965 to 1966 and in 1976 and 1978 (Santos et al., 1999; Hungria et al, 2006a).

B. japonicum CB 1809 (=USDA 136, =3I1b136, =TAL 379, =SEMIA 585, serogroup 122) (now reclassified as *B. diazoefficiens*, Delamuta et al., 2013) was isolated in United States and sent to Australia, where it was characterized as exceptionally efficient, and thus commercially recommended by the Commonwealth Scientific and Industrial Research Organization (CSIRO) since 1968. The strain is a subculture of USDA 136, which was derived from USDA 122 (Dr. Peter van Berkum, personal communication]. Dr. Don Norris sent the strain from Australia to Dr. Johanna Döbereiner in Brazil in 1966, where its good symbiotic performance was confirmed (Döbereiner et al., 1970), and it was then recommended for use in commercial inoculants in 1977. However, poor nodulation with cultivar IAC-2, which was broadly used at that time, led to withdrawal of this recommendation in the following year (Santos et al., 1999; Hungria et al., 2006a).

In Brazil, with the crop expansion in the late 1960s, strains and commercial inoculants were brought in from the United States and Australia to be tested. *B. japonicum* strain SEMIA 566 was one of the first strains "selected" in Brazil. It was isolated from a nodule on the cultivar Hardee, after inoculation with material distributed by Dixie Inc., probably an inoculant from Nitragin (Milwaukee, USA); the strain belongs to serogroup 123. It was commercially recommended from 1966 to 1978, and greatly contributed to the successful establishment of the crop in the southern region of Brazil (Freire et al., 1983; Santos et al., 1999; Hungria et al., 2006a). A second strain, *B. elkanii* SEMIA 587, was isolated in 1967 from soybean nodules collected at Santa Rosa, Rio Grande do Sul (Professor Jardim Freire, personal communication]; it proved to be effective and competitive in a number of field trials and was used in commercial inoculants from 1968 to 1975, and again since 1979 (Santos et al., 1999; Hungria et al., 2006a). Another promising strain, *B. elkanii* 29W (=SEMIA 5019), was isolated in Brazil in 1979 from a nodule on the soybean line IAC-70-559 (Peres, 1979). Unfortunately, there is no information on the inoculant used in the area (Dr. Jose

Roberto Peres, Embrapa, personal communication]. The strain proved to be efficient and competitive in a newly cultivated area in central Brazil in the 1970s, the Cerrado region, now the main grain-producing region of Brazil. Since 1979, the combination of *B. elkanii* strains SEMIA 587 and 29W has been broadly used in commercial inoculants and represents a major factor in the establishment of soybeans in the Cerrado (Peres, 1979; Peres and Vidor, 1980; Hungria et al., 2006a).

Later, higher N demands of more productive soybean genotypes led to strain-selection programs, with the goal of reaching greater capacity for N_2 fixation, higher competitiveness in soils with established populations of rhizobia, and tolerance of frequently stressful tropical conditions. The approach used in Brazil was successful and may be applied in other countries. Without natural biodiversity from which to select new strains, one approach has been the isolation of efficient and adapted naturalized strains from areas previously inoculated with strain SEMIA 566. The first step in the selection was the isolation of rhizobia from large pink nodules on field-grown soybean plants. Each of these rhizobial isolates was then tested for N_2 fixation capacity under laboratory and greenhouse conditions (plant growth and competitiveness), and then in field trials (Peres et al. 1984). After several cropping seasons, the isolate CPAC 15 (=SEMIA 5079) was identified, and shown to statistically increase soybean yield in comparison with strains SEMIA 587 and 29W, which were used in commercial inoculants (Vargas et al., 1992; Peres et al., 1993; Hungria and Vargas, 2000; Hungria et al., 2006a).

A second strain-selection approach, initiated simultaneously, tested individual colonies from pure cultures of strain CB 1809 for variants that were of greater efficiency in BNF and also highly competitive. When dozens of individual colonies of CB 1809 were separately evaluated for BNF and plant growth under greenhouse conditions, significant variation in these traits was evident and the best strains were taken to field trials, and re-isolated from the nodules of plants showing the best symbiotic performance and grain yield, to improve the adaptability of the isolates to the local edaphoclimatic conditions. This approach led to the identification of *B. japonicum* (now *B. diazoefficiens*) strain CPAC 7 (=SEMIA 5080) (Vargas et al., 1992; Peres et al., 1993; Hungria and Vargas, 2000; Hungria et al., 2006a).

Both CPAC 7 and CPAC 15 were included in the list of strains authorized for use in soybean commercial inoculants in 1992 and are currently very successful and preferentially used by farmers in the Cerrado region. Noteworthy is the natural variability that may be found in each strain (Torres et al., 2012) (Fig. 99.4), which can be used to identify new, elite strains.

As commented before, in Argentina, soils are also devoid of indigenous soybean *Bradyrhizobium*, and imported inoculants and strains were brought for evaluation in areas cropped with soybean for the first time. The search identified *B. japonicum* strain E109 (=USDA 138, =SEMIA 5085, =TAL 377, serogroup 6) as being effective, and this strain has been used for decades in the majority of the commercial inoculants used in Argentina.

In China, an important producer (Fig. 99.1) and the main soybean consumer, inoculants are barely used (Ruiz-Sainz et al., 2005), whereas in Paraguay and other countries of South America imported inoculants carrying Argentinian and Brazilian strains are broadly used. In India, despite the presence of numerous producers of inoculants, information is scarce on their use with soybean; interestingly, more emphasis is given to plant growth-promoting bacteria and to compost use (Patil et al., 2006).

Another interesting recent observation from Canada has shown that indigenous bradyrhizobia symbionts of native legumes can adapt to nodulate soybean, representing a novel source of strains (Tang et al., 2012). High rates of horizontal and vertical transference of nodulation genes to indigenous bradyrhizobia have also been reported (Batista et al., 2007; Barcellos et al., 2007; Tang et al., 2012), resulting in new strains with the capacity of nodulating soybean. However, we are far from understanding the long-term impacts of these genetic events on BNF performance under field conditions.

In addition to slow-growing *Bradyrhizobium* spp., soybean is also nodulated by fast-growing rhizobia found in soils of the People's Republic of China (Keyser et al., 1982; Thomas-Oates et al., 2003), belonging to the genus *Sinorhizobium* (=*Ensifer*). Originally, it was reported that these fast growers were specific for Asian soybean lines (Keyser et al., 1982; Devine, 1985). However, later it was shown that nodulation and BNF with fast growers can occur also in modern soybean genotypes, such as those produced in the United States (Balatti and Pueppke, 1992) and Brazil (Chueire and Hungria, 1997). Advantages of using fast-growing rhizobia with soybean potentially include greater facility of commercial production, more rapid establishment in soils, displacement of indigenous *B. japonicum* strains and easier manipulation of genes; consequently, strain selection took place (Buendía-Clavería and Ruiz-Saínz, 1985; Chatterjee et al., 1990; Buendía-Clavería et al., 1994). However, a main limitation has been that the competitiveness of *S. fredii* is related to pH; *S. fredii* is more competitive than *B. japonicum* in alkaline soils, whereas the converse applies in acid soils (Buendía-Clavería et al., 1994; Hungria et al., 2001). Since most soils cropped to soybean are acidic, the potential utility of fast growers as inoculants is limited.

In several countries, there is no legal requirement for specifying the strains in inoculants (e.g., the United States]. However, DNA fingerprinting of strains isolated from inoculants that do not specify the contents indicates the presence of USDA 110, USDA 122, and 532C. It is also possible, in some countries, to patent strains, and some companies have registered strains with specific superior

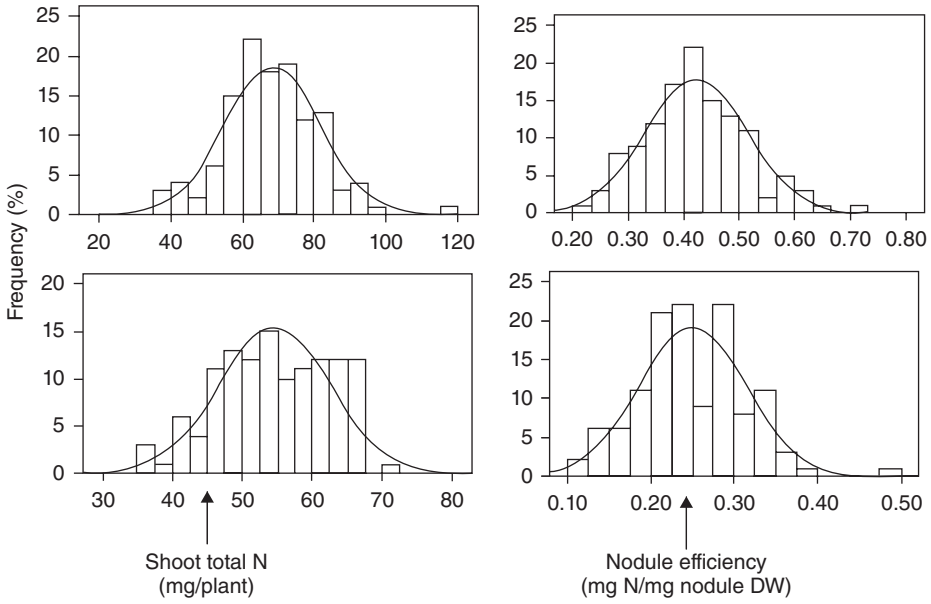

Figure 99.4 Natural variability in shoot total N and nodule efficiency of soybean nodulated by 40 variant and parental strains of *B. japonicum* CIAT 89 and CIAT 104. Arrows indicate the values referring to the parental strain. (Source: Adapted from Torres et al. (2012).

properties. One example is an "improved" *B. japonicum* released by researchers of the Agricultural Research Service [ARS]-USDA in the United States. In 1991, Dr. L. D. Kuykendall and Dr. W. J. Hunter patented a strain with a performance superior to those being used by farmers and licensed it to the Urbana Laboratories of Missouri. They called the process "direct selection," which included simple screening of strains. Nitrous acid was used to trigger gene mutations in a liquid culture of *B. japonicum* strain I-110, and again with "direct selection" they isolated a mutant called TA11 Nod+ in 1994 (USDA-ARS, 2002). Recently in the United States, a patent was granted for a herbicide-resistant inoculant strain (ABM201, =ATCC PTA-10253); this natural mutant – which tolerates glyphosate – was also selected from a "traditional" *B. japonicum* strain (Kuykendall, 2012).

In conclusion, it is noteworthy that the large market for inoculants for soybean relies on very few strains that were identified – or are derived from strains identified – long ago. Probably more than 90% of inoculants produced globally include strains USDA 110 (identified in the late 1950s], 532C [1980s], four "Brazilian" strains [selected or derived from strains selected in the 1960s and 1970s], and the "Argentinian" E109 [derived from USDA 136, also from the 1970s]. These few strains may be variously present in the more than 80 million doses of inoculants produced annually. Possibly, this very narrow bacterial germplasm results from the lack of biodiversity in the main producing and inoculant-consuming countries or from difficulties or lack of interest in exchanging germplasm with domestication centers. It is noteworthy that these "old" strains show high efficacy in conjunction with newly released, more productive soybean cultivars (e.g., Fig. 99.5). Indeed, there are reports of BNF sustaining yields higher than 6000 kg ha^{-1} (Hungria et al., 2006a). The following questions arise: is there a limit to BNF by those strains? Or will the source–sink demand of the soybean–*Bradyrhizobium* symbiosis (Kaschuk et al., 2010) limit BNF rates? Compelling evidence of source–sink control of N supplied by the strains available was obtained in a recent experiment: when soybean density was decreased from 320,000 to 80,000 plants/ha, the rates of BNF were increased four-fold and supported statistically similar total yields de Luca et al. (2014). These strains may have the potential to supply the N demands of soybean realizing their genetic potential, estimated at approximately 8000 kg ha^{-1} (Specht et al., 1999). This implies the potential to supply the astonishing amount of 640 kg N ha^{-1} per growing season. Accordingly, strain-selection programs should be directed not at increased BNF capacity, but at compatibility with fungicides, insecticides, and herbicides that are heavily used in soybean cropping and which can affect rhizobial viability on seeds and in soil (e.g., Campo et al., 2009).

If more efficient strains are needed in the future, new searches in centers of genetic origin or domestication of soybean may be profitable. Indeed, high genetic diversity of soybean rhizobial strains has been reported in China (Keyser et al., 1982; Yang et al., 2006; Man et al., 2008), as well as in other countries including Japan (Minamisawa, 1989) and Thailand (Yokoyama et al., 1999). Certainly, very effective strains are likely to be present within this biodiversity. In addition, microevolution of bradyrhizobia should be considered (Tang et al., 2012).

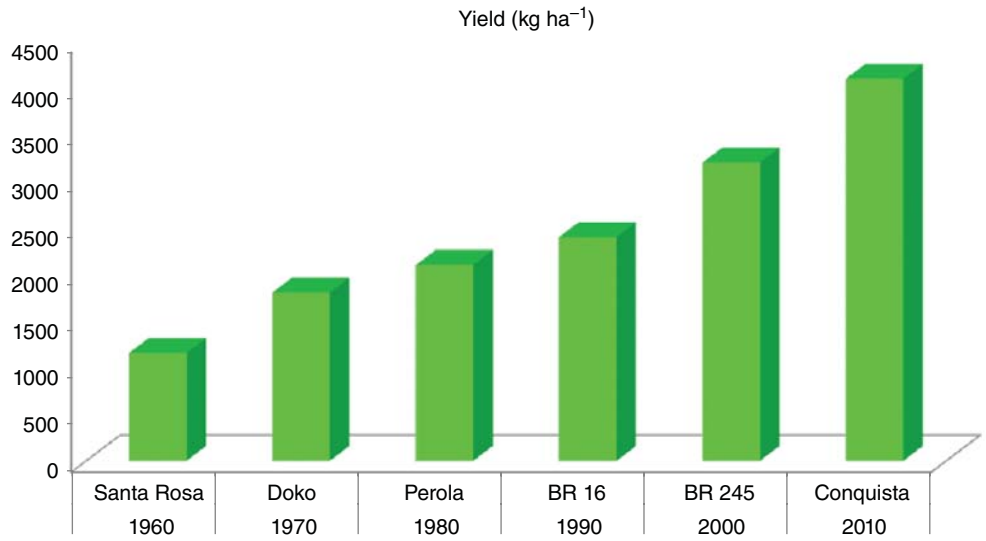

Figure 99.5 Effect of inoculation with *B. elkanii* strain SEMIA 587 in areas void of naturalized population on soybean yield of popular cultivars from each decade in Brazil.

99.1.3 How Limiting is Competitiveness with Soil Populations and How Effective can Reinoculation be?

Competitiveness can be defined as the ratio between the number of bacteria of a particular strain in the inoculum and the percentage of nodules containing the strain on the roots of the host plant. It has been long considered as a major limitation to BNF, where the success of inoculation depends on the ability of the inoculant strain(s) to compete with infective but ineffective strains established in the soil (Nicol and Thornton, 1941).

Through decades, several laboratories have focused their efforts on identifying factors that influence rhizobial competitiveness. These factors include mobility and chemotaxis (e.g., Caetano-Anolles et al., 1988; Catlow et al., 1990; Zdor and Pueppke, 1991), cell-surface polysaccharides (e.g., Bhagwat et al., 1991; Zdor and Pueppke, 1991), bacteriocin production (e.g., Triplett, 1990a,1990b), infection rate (e.g., Hahn and Hennecke, 1988), and the ability to respond to various substrates (e.g., Bottomley et al., 1990). However, the subject is far from being clarified, most probably because superior competitiveness may result from a combination of several bacterial characteristics. It should be mentioned that properties such as early nodulation (Oliveira and Graham, 1990) or adaptation to soil conditions (Hungria and Vargas, 2000; Hungria et al., 2006a) lend competitive ability.

Competitiveness has been considered a serious limitation to the introduction of superior inoculant strains; poor responses to inoculation have been reported even when the numbers of indigenous rhizobia are low (Weaver and Frederick, 1974; Singleton and Tavares, 1986; Thies et al., 1991a,1991b). In the case of soybean, many strains survive saprophytically for prolonged periods, and hence repeated cultivation of the legume promotes long-term establishment of strains introduced via inoculants and on seeds. Accordingly, increased bradyrhizobial populations over time have been reported worldwide, for example, in Australia (Brockwell et al., 1987), the United States (McLoughlin et al., 1990), Argentina (Brutti et al., 1998), and Brazil (Mendes et al., 2004).

The most discussed example of the "competition problem" is that of strains related to the 123 serogroup in the Midwest of the United States (Keyser and Cregan, 1987), with reports of occupations of 60 to 80% of the nodules by indigenous rhizobia (Kvien et al., 1981). Serogroup 123 has also been reported in Canada (Semu and Hume, 1979) and Korea (Kang et al., 1991), and, in Brazil, it is established in practically all cropped areas, due to the introduction of two serologically related inoculant strains, SEMIA 566 and CPAC 15 (Vargas et al., 1994; Ferreira and Hungria, 2002; Mendes et al., 2004; Hungria et al., 2006a). What makes 123-related strains so competitive remains to be elucidated. Gaining an understanding of competitiveness genes in these strains might be of great benefit.

High numbers of cells in inoculants and/or application of highly competitive strains are needed to outcompete resident soil populations. Results from a classical study by Weaver and Frederick (1974) indicate that the concentration of the inoculant strain should be at least 1000 times higher than the soil rhizobial population to result in 50% nodule occupation. Other reports have indicated that, in the presence of populations as low as 10 to 20 cells/g of soil, it is not possible to obtain significant occupancy by a new strain (Singleton and Tavares, 1986; Thies et al., 1991a,1991b).

Consequently, inconsistent responses to inoculation have been attributed to the indigenous or naturalized population, to the enrichment of the indigenous population due to prior cropping of legumes, and/or to a combination of both factors (e.g., Herridge et al., 1987; Sadowsky and Graham, 1998; Thies et al., 1991a,1991b; 1995). This is still the case in the United States. A recent analysis of 73 experiments conducted in Indiana, Iowa, Minnesota, Nebraska, and Wisconsin, by de Bruijin et al. (2010) indicated that inoculation offers limited success for either a yield increase or improved economic return on Midwestern soils previously cropped with soybean.

However, it is intriguing that this is not the case in South America, where more than 150 experiments have consistently proved that annual reinoculation is worthwhile. Edaphoclimatic conditions in Brazil and in many areas of South America commonly include high temperatures, frequent periods of drought, and acidic, infertile soils (Hungria and Vargas, 2000). Therefore, despite showing a high population of soybean bradyrhizobia – reaching up to 10^6 cells/g of soil due to soybean cropping – it is possible that this population is at a low metabolic level and needs some time or another factor to be primed and "ready" for nodulation. A common observation is that, in "old" areas, inoculated soybeans show profuse nodulation at the root crown whereas non-inoculated plants do not, as shown in Figure 99.6. This early root-crown nodulation fosters prompt establishment of more vigorous plants and is responsible for yield increases observed in Brazil, Argentina, and other South American countries when annual reinoculation is practiced. In non-inoculated plants, delayed infection results in nodules present at least 1–2 cm below the crown.

In Brazil, the analysis of 80 field trials, all producing more than 2000 kg ha^{-1} of grain, performed in northern Brazil (Boa Vista, State of Roraima, 02°49'S–60°40'W') to the southern states (Passo Fundo, State of Rio Grande do Sul, 28°15'S–52°24'W) – all in soils previously cropped with soybean and showing 10^3 to 10^6 cells/g of soil – has shown mean increases of 8% in yield due to annual reinoculation. It is remarkable also that no yield gains were obtained with the application of 200 kg N ha^{-1}, highlighting the efficiency of the BNF process (Fig. 99.7). It is also noteworthy that a preliminary analysis of nodule occupancy in several of these trials indicated that, for an efficient strain, nodule occupancy of around 35% can supply the crop's needs, less than the 50% recommended by Frederick and Weaver (1974).

Figure 99.6 Nodulation at the root crown, associated with inoculant applied to seeds in an area "traditionally" cropped with soybean in Brazil.

Similar results have been observed in the analysis of ten consecutive soybean crops (from 2000 to 2010] in "traditional" cropping areas of the State of Mato Grosso do Sul (centrally located Dourados is at 22°13'S and 54°48'W] in western Brazil) (Mercante et al., 2011). By the end of the tenth year, a cumulative yield gain of 2754 kg ha^{-1} resulted from reinoculation. Therefore, as pointed out by the authors, by reinoculating every year, the farmer would garner a profit of 1 crop per every 10 crops (Mercante et al., 2011).

Similar results have been reported in Argentina, and, in an analysis of 62 trials, increases due to reinoculation ranged from 2.1 to 20%. In these trials, the weighted mean yield of the reinoculated treatment was 3133 kg ha^{-1}, and the increase due to reinoculation averaged 11% (Hungria et al., 2006a).

Another important benefit reported from reinoculation in Brazil is the residual nitrogen left for the following crop (Hungria et al., 2005; 2006a; 2007). Experiments were performed to evaluate this contribution in areas "traditionally" cropped with soybean, in Londrina (23°18'S–51°09'W: 10^6 cells of *Bradyrhizobium*/g soil), by comparing two treatments, non-reinoculated and reinoculated. In 9 years, mean increases of wheat [*Triticum aestivum* L.] grain production after reinoculated soybean averaged 14%. For short-season maize [*Zea mays* L.], after 4 years, the mean yield increase averaged 12%.

Finally, another important benefit from reinoculation is the gradual replacement of persistent strains with more efficient counterparts. Mendes et al. (2004) performed an experiment in Planaltina (15°27'S–47°37'W), central Brazil, in which, in the first year, a soil void of soybean bradyrhizobia was inoculated with serologically distinct strains: CPAC 15 (serocluster USDA 123), highly competitive, and CPAC 7 (serogroup of CB 1809), which is less competitive than CPAC 15 but efficient in fixing nitrogen. In the second year, each of the initial plots was subdivided and either inoculated or not, with CPAC 7 or CPAC 15, and in the third year, the entire area was inoculated with CPAC 7. In the treatments where strain CPAC 7 was used as inoculum in each of the 3 years, its representation in nodules increased to 70% in the third year. In the treatment first inoculated with CPAC 15, and the two following years with CPAC 7, nodule occupancy by CPAC 7 in the third year was also high, at 62%. However, in the treatment inoculated with CPAC 7 in the first year

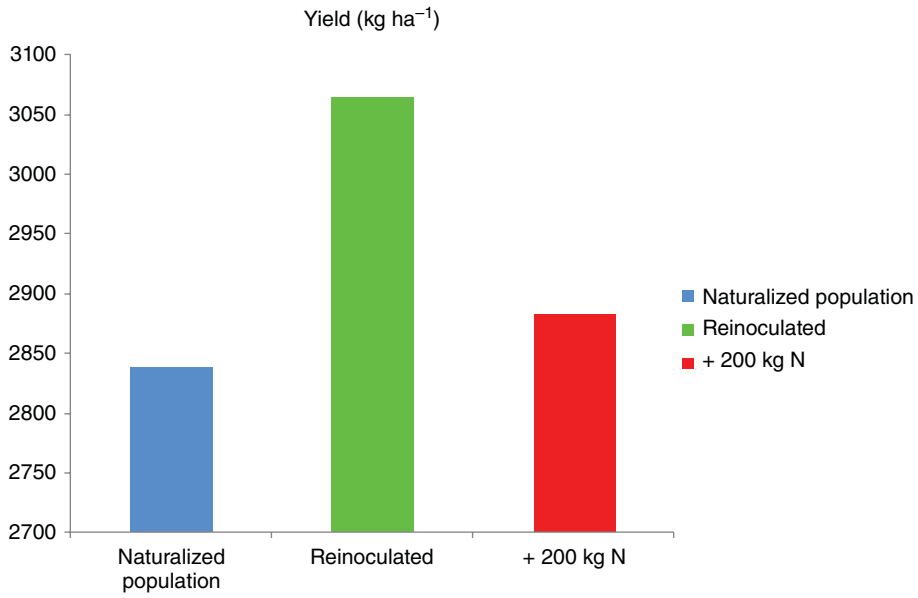

Figure 99.7 Comparison of treatments non-inoculated, inoculated and non-inoculated receiving 200 kg N ha^{-1} [split twice, at sowing and broadcast at flowering]. Mean of 80 field trials performed in Brazil, in soils previously cropped with soybean, and with indigenous bradyrhizobial populations ranging from 10^3 to 10^6 cells/g soil.

and without further reinoculation, nodule occupancy by this strain decreased to only 8%. Therefore, annual reinoculation is key to both the substitution of dominant serogroups and to guaranteeing the persistence of elite strains (Mendes et al., 2004).

The question that remains is the reason for the absence of positive effects of reinoculation in North America, as opposed to South America, where significant benefits are observed. As we pointed out earlier (Hungria et al., 2006a), possible explanations for the general lack of response to inoculation in soils containing indigenous bradyrhizobia in the United States may include higher competitiveness of the bradyrhizobial strains established in North American soils, and also lack of emphasis on the need for reinoculation, including the need for care in mixing inoculant cultures and seed protectants. In fact, yield responses to reinoculation of up to 12% were reported in US northern and eastern soybean production states within the Midwest, whereas states from the Great Plains region did not show consistent yield responses to reinoculation of "old" fields (Abendroth et al., 2006). It seems that, in northern states, these responses were more related to cold spring temperatures that limit growth and multiplication of *B. japonicum*, and in eastern states the extensive use of seed-applied fungicides may be partly responsible for the observed yield responses to reinoculation in "old" soybean fields. In South America, the possibility exists that soil rhizobia are less competitive and that environmentally stressful conditions dictate reinoculation to ensure early nodulation and benefit early crop growth. Credit should go to the farmers who believe in and use inoculants every year.

99.1.4 N-fertilizers × Biological Nitrogen Fixation with Soybean: Who Wins?

Contributions of BNF are considerably affected by the availability of mineral N, and as developed countries use more N-fertilizers, the contributions of BNF in these countries are generally lower when compared with those adopting low-N inputs, as in South America.

In an interesting analysis, van Kessel and Hartley (2000) examined results generated in 362 trials – mainly in the United States and Australia over a 25-year period – in which ^{15}N-isotopic dilution or N difference with non-nodulating isolines methods were used to estimate contributions of BNF to soybean. In this data collection, soybean derived an average of 59% of its N from BNF; this value is similar to the 53% reported for 33 commercial soybean fields in Australia (Unkovich and Pate, 2000). A conclusion from the study was that the %N derived from BNF declined from 65% [analysis of 196 trials] to 54% [166 trials] since 1985; the authors attributed the lower symbiotic performance to increased use of N-fertilizers.

In northern and central China, the center of genetic origin of soybean, N-fertilizers are also applied, and the best results were obtained with top dressing [50 kg N ha^{-1}] at the V2 stage, and, especially, at early flowering (R1] (Gan et al., 2002; 2003). These authors mentioned that inefficient use of N-fertilizer often results in high costs, and it is worth mentioning that the yields were lower than in the Americas.

Soybean cropping in Africa is dramatically changing, with adoption of new genotypes, cropping systems, and inoculants; therefore, there is need for new quantification studies. For now, on searching the literature, Ronner and Franke (2012) found contributions of BNF ranging from 3 to 89%, and in some evaluations performed in the N2Africa project (small farmers with low inputs) the average for inoculated soybean was 70%.

In Argentina soybean inoculated with strain E109, without N-fertilizer, achieved 6000 kg ha^{-1} (Hungria et al., 2006a), and in Londrina, Brazil, soybean yielded 5890 kg ha^{-1} again without N-fertilizer (Zotarelli, 2000). Still in Brazil, a survey of studies using ^{15}N isotopic dilution, δ^{15}N, N balance, and the N-ureide technique indicated that the N derived from BNF ranged from 69 to 94%, with estimated rates reaching 300 kg N ha^{-1} (Hungria et al., 2005). The contributions of BNF may be considerably higher, as root N was not considered in these studies; it may represent 30 to 35% of the total plant N (Peoples and Herridge, 2000; Khan et al., 2002).

The comparison made by van Kessel and Hartley (2000) and the results obtained in South America emphasize the importance of management to maximize the contribution of BNF. However, there is strong pressure in South America and in other countries from fertilizer companies to apply chemical N to soybean. The stated objective is to achieve higher yields, or to attend to specific conditions, such as early short season cultivars, indeterminate genotypes, and soils with low-N levels.

One idea that has been discussed for decades has been of the use of "starter" N to overcome problems related with N immobilization, mainly when soybean is cultivated after a non-legume crop, and before BNF is fully established. However, in Brazil dozens of experiments have shown that N doses as low as 20–40 kg N ha^{-1} may drastically decrease nodulation and BNF, with no benefits to yield (e.g., Mendes et al., 2003; Hungria et al., 2005; 2006a,2006b; 2007). Figure 99.8 shows one example of a combination of 20 field trials, with no response to 30 kg N ha^{-1} as starter N.

Experiments have also been performed to confirm that no extra benefits would be obtained by the application of N-fertilizer throughout the plant-growth cycle, because doubts were raised about the capacity of BNF to provide N after flowering, due to nodule senescence (Hungria et al., 2006b; Mendes et al. 2008). Again, no benefits were observed with the supplementary dose of 50 kg N ha^{-1} at the R2 or R4 stages (Fig. 99.8). In the experiments shown in Figure 99.8, BNF contribution evaluated by the N-ureide technique dropped from 84% on the reinoculated treatment to 77 and 78% when N was applied at R2 and R4, respectively, and to 44% with the application of 200 kg N ha^{-1} (Hungria et al., 2006b).

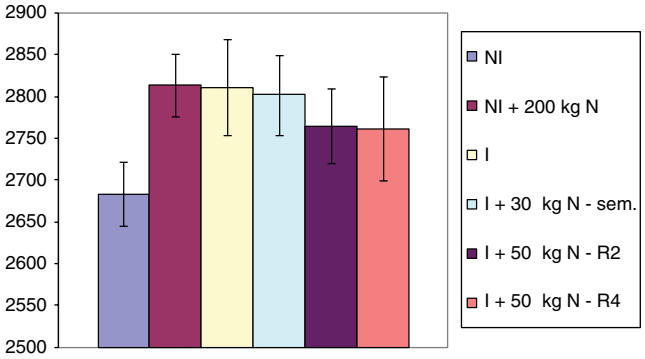

Figure 99.8 Soybean yield (kilogram per hectare) in soils with established populations of *Bradyrhizobium* (>10^3 cells/g) in treatments non-inoculated (NI), non-inoculated receiving 200 kg N ha^{-1} (split at sowing and at flowering – R2), and inoculated (I), with and without N-fertilizer applied at sowing (30 kg N), at full flowering-R2, or at the grain-filling stage-R4 (50 kg N ha^{-1}). Averages of 20 trials performed in the State of Paraná, Brazil. Columns followed by the same letter do not show statistical difference (Duncan, $p \leq 0.05$). Adapted from Hungria et al. (2006b).

First in Argentina and now in Brazil, in the last few years there has been a preference for cultivars of indeterminate habit, in which vegetative growth occurs mainly after flowering. Concerns have been raised about a decrease of BNF after flowering, as two thirds of the plant's growth occurs after this period. But again, in a series of experiments performed for the last 2 years, we have consistently observed that these cultivars also do not need any N-fertilizer supply (e.g., Fig. 99.9). It is noteworthy also that the inhibition of nodulation and BNF, resulting in less yield (Fig. 99.9) by application of chemical N was stronger with cultivars of the indeterminate type. Finally, in a comparison of 20 experiments with cultivars of short- and long-growth cycles, Hungria et al. (2006b) also reported that there was no benefit in yield by adding N-fertilizer at sowing, R2 or R4. Indeed, lack of response to N-fertilizer has been observed in doses of up to 400 kg N ha^{-1}, split 10 times throughout the plant's growth cycle (Nishi and Hungria, 1996; Hungria et al., 2007) Regarding the use of late supplemental N-fertilizers on soybeans it is also important to mention the findings of Mastrodomenico and Purcell (2012) who demonstrated that, under water-replete conditions, BNF can continue late into pod-fill and provide up to 90% of the N content in the seeds. Among soybean isolines for maturity, they did not find differences in seed yield or N content at maturity and also observed that for the later maturing genotypes, a larger reservoir of N in the vegetative tissue was not fully used, and as a consequence, N was not a limitation to yield.

From our discussion in this section we may conclude that the success of BNF with soybean is closely related to soybean breeding programs that rely on inoculation and also to the selection of bradyrhizobial strains with superior

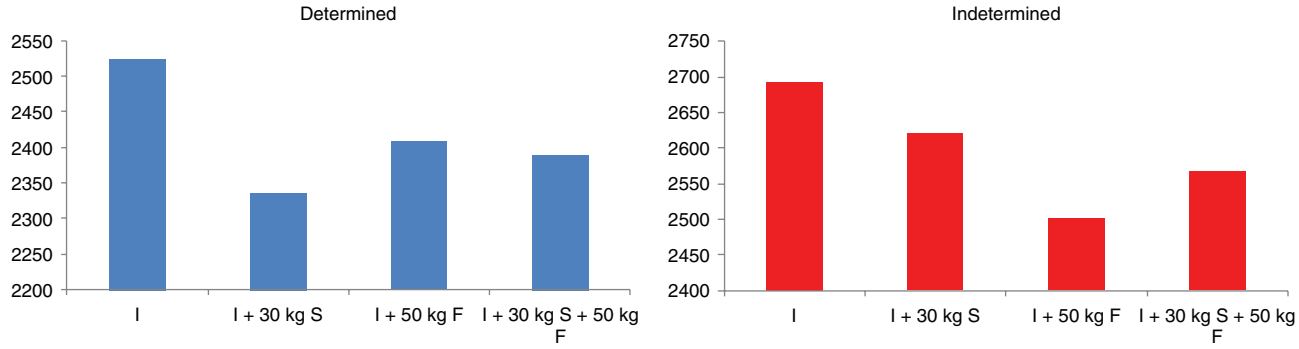

Figure 99.9 Grain yield (kilogram per hectare) of soybean of determinate and indeterminate type of growth when reinoculated with or without a supply of N-fertilizer at sowing (S) and/or at full-flowering stage, R2 (F). Experiment performed in a soil with 10^6 cells of *Bradyrhizobium*/g soil. (M Hungria and M.A. Nogueira, unpublished data).

nitrogen-fixing capacity. In countries where BNF has not been a main goal in breeding programs, yield increases can be obtained with the addition of N-fertilizers. On the contrary, where BNF is continually monitored in breeding programs, the results obtained so far indicate that high yields can be obtained, relying mainly on BNF.

99.1.5 Main Constrains to BNF with Soybean

Several concerns underpin maximizing BNF by soybean in the next decade. Lack of emphasis on BNF in soybean breeding programs is already a reality in many developed countries and may expand to developing countries with the increasing presence of private companies interested in selling N-fertilizers.

Care should also be taken in relation to management practices. Application of fungicides to seeds to which an inoculant is then applied can adversely affect rhizobial cell number (e.g., Hungria et al., 2006a; 2007, Campo et al., 2009). Pre-inoculation of soybean seed, especially when fungicides and/or insecticides are applied, can be disastrous, decreasing nodulation drastically (Fig. 99.10). Attention should also be paid to global climate changes, as the symbiosis is sensitive to high temperatures and water deficiency.

Nutrition and pest control are site-specific problems. A generally applicable constraint is lack of extension outreach to explain the benefits of BNF to farmers.

99.1.6 Economic, Social and Environmental Implications of BNF by Soybean

Economic returns of BNF with soybean in South America are outstanding, with the Brazilian case used here as an example. Considering that for each 1000 kg of soybean produced, the

Figure 99.10 Nodulation of soybean under field conditions when (a) pre-inoculated or (b) inoculated on the same day. Photo: Agronomist José Rogério dos Santos.

plant requires 80 kg of N, the crop needs 240 kg N ha^{-1} to achieve the national mean yield of 3000 kg ha^{-1}. Generally, Brazilian soils are poor in N and usually supply only 15 to 30 kg N/crop, in which case the plants need an additional 210–225 kg N ha^{-1}. As N-utilization efficiency is around 50%, the N application need is doubled, to ≈420 kg N. At US$ 1.4/kg N at the local market(urea, the cheapest source), the cost of applying N-fertilizer would be ≈US$ 15 billion nationally, for the 25 million ha cropped in 2012/2013. A similar picture is found in other countries of South America; clearly, the continent could not produce half of the world's yield of soybean without BNF.

The economy related to soybean agribusiness affects thousands of farmers and attendant industry workers, with far-reaching social implications. Similarly, soybean and BNF profoundly affect small-holding farmers and the economies of several African countries as exemplified in the project N2Africa (http://www.n2africa.org.br). There is no

doubt that, in these countries, there is potential for BNF to play increasingly important roles in ensuring food security and improving life quality.

The environmental effects of using N-fertilizers should not be forgotten. Pollution of aquifers, rivers, reservoirs, and lakes is associated with leaching and run-off of nitrate. In addition, the emission of greenhouse gases related to N-fertilizers is an important issue. Brazil again is a good example, as the government launched a program called "ABC" (Agriculture of Low Carbon Consumption) and among the targets is the adoption of agricultural practices involving BNF, with the commitment of an area expansion of 5.5 million hectares with a mitigation potential of 10 million tons of CO_2. Considering the synthesis, transport, and application of N-fertilizers in Brazil, Hungria et al. (2013) used a rate of 4.5 kg of e-CO_2/kg (CO_2 equivalent) of N-fertilizer and came to the conclusion that if nitrogen-fixing bacteria were not used for the soybean crop, the application of N-fertilizer would result in the emission of about 45 million tons of e-CO_2.

99.2 CONCLUDING REMARKS

High rates of BNF are reported worldwide for the soybean–*Bradyrhizobium* symbiosis, confirming a high capacity to supply N needs to reach high yields. This "perfect" symbiosis should be used as a model in the search for genes related to the efficiency of the biological process. Strategies such as annual reinoculation, plant breeding in the absence of N-fertilizers, and strain selection should be considered in all countries cropping the legume. The results reported in this chapter highlight the fact that BNF by soybean is a key ecological service that contributes billions of dollars to the global economy, increasing farmers' profits and helping to ensure food security. Particularly important is the fact that BNF is applicable and relevant to all kinds of management practices, from large farmers adopting modern technology in the Americas to small-holding farmers in Africa contributing to local economies. Environmental impacts of BNF by soybean are also extremely important, such that if no attention is paid to the contributions of BNF to soybean crops, increases in the applications of N-fertilizers to the 103 million ha cropped worldwide would substantially increase emissions of greenhouse gases.

100.1 INTRODUCTION

Biological N_2 fixation still remains the most sustainable technology to contribute N to both agricultural and natural ecosystems. Members of the plant family Leguminosae have the unique ability to form N_2-fixing symbioses with root-nodule bacteria ("rhizobia") belonging to the genera *Rhizobium*, *Bradyrhizobium*, *Sinorhizobium* (*Ensifer)*, *Mesorhizobium,* and *Azorhizobium*. Inside root nodules, these rhizobial bacteria are able to reduce atmospheric N_2 into NH_3 using the enzyme nitrogenase (Dakora, 1994). The NH_3 produced in excess of the bacterial requirement is secreted into host plant cells, where it is converted into amino acids and other nitrogenous solutes via the GS/GOGAT pathway for plant use. Nitrogenous solutes are thus exchanged by bacteria for photosynthate produced by the host plant, and this forms the basis of the mutualism between root-nodule bacteria and members of the Leguminosae. This review is an attempt to summarize recent data on nodule functioning, root-nodule biodiversity, and symbiotic N contribution of cowpea and soybean used in African agriculture.

100.1.1 Constraints to Cowpea and Soybean Production in Africa

While this symbiotic relationship between soil bacteria and cowpea/soybean plays a major role in sustaining the N economy of agricultural ecosystems, tapping it for increased food security in Africa has remained a challenge. This is due largely to many constraints, which include lack of high yielding legume genotypes/varieties, absence of suitably selected strain/genotype combinations for enhanced N_2 fixation and grain yield, and little information on the biodiversity and N_2-fixing ability of bacteria nodulating African food grain legumes. Eliminating these limitations is crucial for improving N_2 fixation and the agricultural yield of symbiotic legumes.

With 23% protein and 57% carbohydrate in the grain, cowpea is the most important food legume in tropical Africa. Both its leaves and grain are eaten as food, and together they constitute an important part of the African diet. Globally, cowpea is also cultivated for use as food in Brazil (see Chapter 99), India, and the Southern United States.

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

Because of its high N_2 fixation (Makoi et al., 2009; Belane and Dakora, 2009; Pule-Meulenberg and Dakora, 2009, Pule-Meulenberg et al., 2010, Belane and Dakora, 2011; Belane et al., 2011) cowpea leaves and grain are very rich in protein, and are commonly used as feed/fodder for livestock in Australia and the United States. Despite the important value of cowpea as food crop, little is known about the diversity of its nodule bacteria and symbiotic functioning.

Although it has its origin in Asia, soybean is now cultivated worldwide in Australia, Brazil, the United States, Argentina, and China. It is also cultivated in Africa, though it remains unclear when the crop was introduced into the African continent (Mpepereki et al., 2000). Of the 216 million tons of soybean produced worldwide in 2007, only 1.5 million come from Africa, an indication of its limited production. Its promotion as the leading commercial legume stems from the fact that the grain contains 40% protein and 20% oil, making it a high-protein food/feed for humans and livestock (Zarkadas et al., 2007). Increased soybean cultivation in Africa is however, constrained by lack of information on the legume's adaptability to African conditions, especially those bred to nodulate with local soil bacteria.

100.1.2 Nodulation, N_2 Fixation, and N Contribution by Cowpea and Soybean in Africa

Historically, cowpea has been known to form effective symbiosis with only slow-growing root-nodule bacteria (*Bradyrhizobium* species), even though fast growers were frequently isolated as contaminants from cowpea nodules (Dakora and Vincent, 1984). Today, there is evidence (Mpepereki et al., 1996; Zhang et al., 2007; Steenkamp et al., 2008; Pule-Meulenberg et al., 2010) that cowpea is nodulated by both slow- and fast-growing root-nodule bacteria (i.e., *Rhizobium* and *Bradyrhizobium* species). Although Zhang et al. (2007) found cowpea to nodulate with both *Rhizobium* and *Bradyrhizobium* strains in China, a few studies in Africa could detect only *Bradyrhizobium* species in cowpea nodules (Steenkamp et al., 2008; Pule-Meulenberg et al., 2010), indicating that the choice of microsymbiont by cowpea could be environment dependent. Sarr et al. (2009) have also reported the isolation of *Ralstonia* from root nodules of cowpea, although its N_2-fixing status was not clear. Unlike cowpea, soybean is capable of forming effective symbiosis only with strains of *Bradyrhizobium japonicum* (Jordan, 1982; Black et al., 2012), *Bradyrhizobium elkanii* (Kuykendall et al., 1992), *Bradyrhizobium liaoningense* (Xu et al., 1995), and *Sinorhizobium fredii* (Chen et al., 1988; see Chapters 18, 99). Except for South Africa, the soybean material grown by farmers in Africa (e.g., Ghana, Nigeria, Kenya, Zimbabwe, Ethiopia, etc.) is mainly of the TGx type, or tropical glycine crosses (Abaidoo et al. 2007), which have been bred to effectively nodulate with indigenous cowpea-type *Bradyrhizobium* species. As a result, data on the symbiotic performance of soybean in Africa are largely available on the promiscuous nodulating genotypes developed by IITA.

In Africa, these so-called promiscuous soybean genotypes have been found to derive between 46% and 78% of their N nutrition from symbiotic fixation and to contribute about 24 to 260 kg N ha^{-1} under field conditions (Table 100.1). Estimates of N_2 fixation by cowpea range from 4 to 201 kg N ha^{-1} across Africa (Sprent et al., 2010). Both soybean and cowpea are therefore capable of contributing significant amounts of N to the N economy of nutrient-poor soils in Africa, where N-fertilizer use is rare due to high cost, inaccessibility to resource-poor farmers, and its potential to pollute the environment. Furthermore, the greater N contribution by the two legumes also implies increased plant protein production, much needed for the diets of poor rural Africans.

100.1.3 Nodule Occupancy and IGS Type Symbiotic Efficiency in Cowpea and Soybean

The level of N_2 fixation in any legume is determined by the quality of infecting strains, as well as the photosynthate supplied by the host plant. Thus, good nodulation (i.e., high nodule numbers and dry weight) and enhanced N_2 fixation are the sole determinants of greater dry matter accumulation in symbiotic legumes. Studies carried out on six different promiscuous soybean genotypes in Ghana, and nine cowpea cultivars in South Africa, Botswana, and Ghana revealed marked variation in plant growth and grain yield as a result

Table 100.1 Estimates of N_2 fixation and N contribution by promiscuous-nodulating soybean genotypes in Africa

Country	%Ndfa	N-fixed (kg ha^{-1})	Method	References
Ghana	56–63	79–122	^{15}N natural abundance	Pule-Meulenberg et al. (2011)
Nigeria	46–54	51–78	Ureide-N technique	Osunde et al. (2003)
Kenya	47–67	53–82	^{15}N dilution	Kihara et al. (2011)

Nigeria	52–68	60–108	N-difference	Ogoke et al. (2006)

Table 100.2 Diversity of strain IGS types isolated from root-nodules of cowpea genotypes grown at Wa in Ghana, and Taung in South Africa

Cowpea Genotype	Resident Strain IGS Type	
	Wa (Ghana)	Taung (South Africa)
Omondaw	VIII	I, II, VIII
Glenda	II, V, VII	III, V, VIII, XVIII
Apagbaala	III	III, V, VIII, XVIII
IT82D-889	V	III, V, VII, VIII
Bechuana white	V	II, V, VII, VIII
ITH98-46	VIII	III, V, VIII
Fahari		III, IV, VII, XIII, XIV, XVIII

(Source: BMC Microbiology, modified from Pule-Meulenberg et al., 2010)

of differences in symbiotic N_2 fixation (Belane and Dakora, 2009; 2010; Belane et al., 2011; Pule-Meulenberg et al., 2010; 2011).

More interestingly, PCR-RFLP analysis of cowpea nodules from the three countries revealed eighteen strain IGS types, with strong specificity to genotypes and geographical region (Table 100.2). Geographically speaking, strain IGS types I, IV, IX, X, XI, XIII, XIV, XVI, XVII, and XVIII were found only in nodules from Taung in South Africa, IGS types XV and XIX only in nodules from Glenvalley in Botswana, and IGS type XII only in nodules from Wa in Ghana (Pule-Meulenberg et al., 2010; see also Table 100.2). With regard to genotype specificity, strain IGS type I was found only in nodules of Omondaw, strain IGS types XV, XVI, and XVII only in nodules of Fahari, and strain IGS type VIII in all genotypes except Glenda (Pule-Meulenberg et al., 2010; see also Fig. 100.1). In Ghana, eighteen distinct IGS types were similarly found in root nodules of six field-grown promiscuous soybean genotypes (Pule-Meulenberg et al., 2011). There was, however, less strain IGS type/soybean genotype specificity, as strain IGS type II was isolated from all six soybean genotypes, and IGS types X and XI from five soybean genotypes (Pule-Meulenberg et al., 2011). While geographical specificities of strain IGS types can be easily understood, strain IGS type/host plant specificity is difficult to explain, and could be due to molecules involved in the early stages of nodule formation.

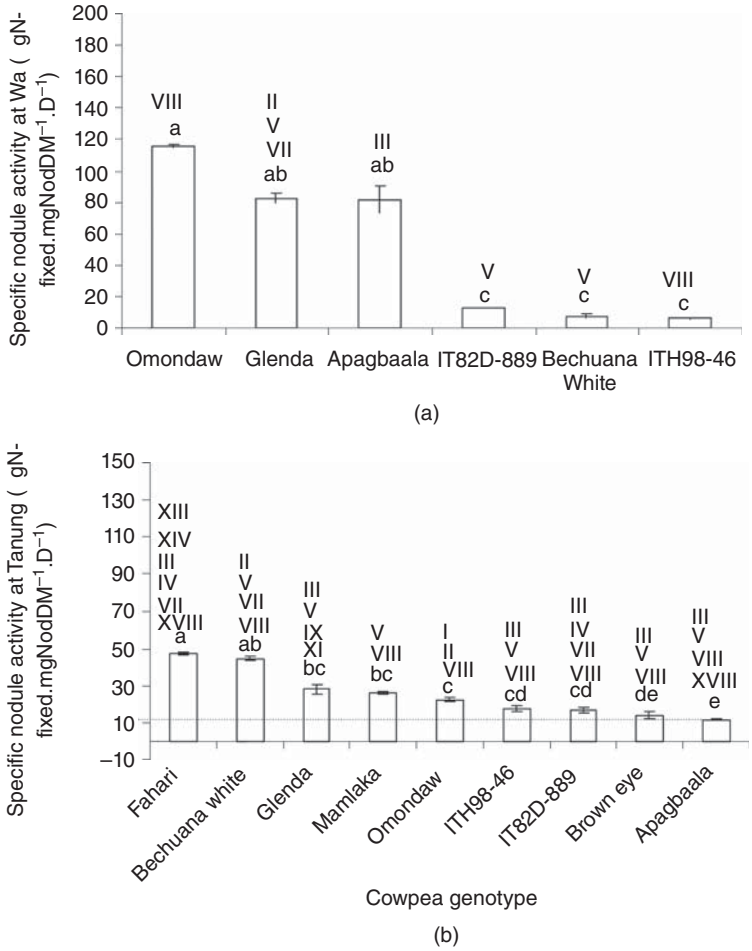

Figure 100.1 Specific nodule activity for nine cowpea genotypes grown at (a) Wa in Ghana, (b) Taung in South Africa. Bars with dissimilar letters indicate significant differences at $p \leq 0.05$. Numerals on the top of each bar represent the different IGS types (strains) that were found in the cowpea nodules from the particular genotype. (Source: BMC Microbiology, see Pule-Meulenberg et al., 2010.)

For the first time, the N_2-fixing efficiency of these IGS types was assessed by relating nodule function to nodule occupancy (i.e., to the identified strain IGS type resident in the nodule; see Pule-Meulenberg et al., 2010). The results showed large differences in symbiotic N produced by strain IGS types. But more importantly, in both soybean and cowpea, symbiotic promiscuity (i.e., multiple nodule occupancy or many strain IGS types in one nodule) appeared not to be a useful trait, as nodules with many bacterial occupants tended to produce less symbiotic N compared to nodules with sole occupants (Pule-Meulenberg et al., 2010; 2011). The differences in IGS type symbiotic efficiency were more likely due to the huge diversity of soil bacteria nodulating cowpea in Africa. For example, gene sequence analysis revealed clustering of cowpea nodule isolates with *Bradyrhizobium yuanmingense*, *Bradyrhizobium* sp. ORS 188, ORS 190 and USDA 3384, *Bradyrhizobium japonicum* USDA 38, and *Bradyrhizobium elkani* (Pule-Meulenberg et al., 2010). Some strain IGS types from Southern Africa also formed a unique group on the phylogenetic tree, which suggests a new *Bradyrhizobium* species (Pule-Meulenberg et al., 2010).

100.2 CONCLUSION

Both cowpea and soybean appear to be very promising grain legumes for food security in Africa. They derive a high percentage of N from symbiotic fixation for their N nutrition, and have the potential to contribute substantial amounts of symbiotic N to cropping systems in Africa. Cowpea seems capable of nodulating with a wide range of root-nodule bacteria in Africa, with some of them being closely related to soybean-nodulating bacteria. Whether with soybean or cowpea, nodulation promiscuity appeared less advantageous to the host plant in terms of symbiotic N yield. For example, one soybean genotype harboring as many as nine IGS types in its nodules in Ghana produced the least biological N.

ACKNOWLEDGMENT

101.1 INTRODUCTION

The inoculation of crop plants is a "success story" of applied soil microbiology to provide a sustainable and effective source of nutrients to plants, particularly with regard to biological nitrogen fixation (BNF) and the development of rhizobial inoculants for legumes (Giller and Cadisch, 1995). Legume inoculation with rhizobia has resulted in improved crop productivity and soil fertility. It has been estimated that 21.5 Tg of N is annually fixed in agricultural systems through BNF (Herridge et al., 2008), and this is especially useful in situations where the natural N fixation is not optimal and/or exogenous N fertilizers are not applied (Kala et al., 2011; Stephens and Rask, 2000).

Plant growth enhancement has also been shown to occur beyond nitrogen fixation, and bacteria such as *Azospirillum* (see Chapter 90), *Azotobacter*, *Bacillus*, *Pseudomonas*, *Agrobacterium*, *Klebsiella*, *Enterobacter*, *Alcaligenes*, *Arthrobacter*, *Streptomyces*, *Burkholderia* (see Chapters 17, 89), or *Serratia* have been shown to be beneficial soil

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

microbes (de Bruijn, 2013). These plant growth – promoting rhizobacteria (PGPR) contribute to plant growth in different ways: some increase N uptake and synthesize phytohormones (auxin, cytokinin) which enhance root growth and facilitate minerals solubilization or iron chelation (Adesemoye et al., 2010; Collavino et al., 2010; Egamberdieva et al., 2010; Robin et al., 2008), while others are able to suppress soilborne pathogens by producing siderophores and antimicrobial metabolites, competing for nutrients and/or niches (Glick et al., 2007), or producing toxins that are inhibitory to the growth and/or activities of fungal and nematode pathogens of plants (Leifert et al., 1995; Pinchuk et al., 2002). As a result, inoculation with PGPR has been performed to improve seed emergence and plant growth and to increase yields of a wide range of crops (Dey et al., 2004; Herman et al., 2008; Minorsky, 2008; Muthaura et al., 2010; Wu et al., 2005), with the aim to decrease the dependence on chemical fertilizers, pesticides and supplements (Ashrafuzzaman et al., 2009; Bhattacharjee et al., 2008; de Bruijn, 2013; Lugtenberg and Kamilova, 2009; Vessey, 2003).

These PGPR include the free-living N-fixing bacteria which have been demonstrated to play an important role in the promotion of plant growth as they can fix significant amounts of atmospheric N (up to 60 kg N per ha and per year) in different cropping systems (Bürgmann et al., 2004). Inoculation of cereals with *Azospirillum* resulted in significant increases in plant biomass, nutrient uptake, tissue N content, plant height, leaf size and root length (Bashan et al., 2004; see Chapter 90). Kloepper and Beauchamp (1992) showed that wheat yield increased by up to 30% with *Azotobacter* inoculation and up to 43% with *Bacillus* inoculation. A number of genera have been identified as being able to convert unavailable P via the production of organic acids (Rashid et al., 2004), and these phosphate-solubilizing bacteria (PSB) will become increasingly important in the face of dwindling global supplies of affordably accessible P. Direct plant growth promotion has also been shown by strains of *Pseudomonas putida* and *P. fluorescens* that increased root and shoot elongation in canola (Glick et al., 1997) as well as in wheat and potato (Frommel et al., 1993).

The increasing demand for rhizobial and PGPR inoculants has resulted in commercial inoculant production facilities worldwide (Brockwell and Bottomley, 1995). New commercial inoculants are proliferating and all claim to substantially enhance the productivity of their various target crops. However, many of these products are sold without robust scientific data supporting their efficacy. Brockwell et al. (1995) reported that as many as 90% of all inoculants produced worldwide have no practical impact on target crop productivity. Ultimately, the efficacy of inoculants depends upon the quality to which they have been produced. If the quality is poor, then everything else is irrelevant (Herridge et al., 2002). Inoculant quality can be evaluated by a number of factors including the nature and effectiveness of the strain(s) it contains (Amarger, 2001), number of viable cells (Brockwell and Bottomley, 1995; Stephens and Rask, 2000), absence of significant contamination, effective and easy to apply formulation, adequate shelf life of the product, proper packaging and clear labeling with instructions for use on each package (Lupwayi et al., 2000; Xavier et al., 2004; see Chapter 97). However, so far, little attention has been paid to the quality of the inoculants during their production, leading to dramatically reduced effectiveness and consequently to a lower adoption by farmers. Since farmers cannot judge the quality of inoculant products at the time of purchase, there is often even less incentive for an inoculant producer to institute a quality control program, with the result that some producers sell poor quality inoculant products (Olsen et al., 1996; Singleton et al., 1997). Without a proper quality control program, the manufacturer is unlikely to have any more concrete information about the quality of his or her product than does the customer. When farmers realize that poor inoculant quality results in limited inoculant response, their confidence in the technology wanes, and both manufacturers and consumers are ultimate losers.

Consequently, the demand for a quality control system of the available commercial inoculants is vital and increasing. This notably involves the verification of the identity of the inoculant strain(s) and a check on the number of living cells in the inoculant (Tas et al., 1995; see Chapter 97). In particular, evaluation of inoculant quality by enumerating the viable cells present has been described as an accurate index of an inoculant's potential and of such significance in determining the effectiveness of inoculant that the need for quality control cell enumeration systems is widely recognized (Brockwell and Bottomley, 1995; Tiesongrusmee, 1991).

This study therefore aims to assess the microbial quality of diverse inoculants already available in the markets in order to verify whether they fulfill the claims of the manufacturer and to give an insight to the quality of current available products. This may significantly contribute to the desired impact of increasing crop productivity as effective and good quality products can be promoted while the proliferation of underperforming products can be prevented.

101.2 MATERIALS AND METHODS

101.2.1 Isolation of the Bacteria Contained in the Products

Sixty-five commercial inoculants were ordered from various private companies worldwide (United States, Argentina, United Kingdom, Australia, etc.). The list of the products is presented in Table 101.1.

The inoculants were serially diluted in sterile saline (0.9% (w/v) NaCl) up to 10^{-8} and 0.1 ml aliquot of each dilution was evenly spread on two culture media: yeast extract mannitol agar (YEMA) (0.5 g l^{-1} K_2HPO_4, 0.2 g l^{-1}

Table 101.1 Analyzed products: origin and claimed content

Name of Inoculant	Claimed Microorganisms	Company
Accelerate	*Bacillus polymyxa, Streptomyces* spp.	Nutritech solutions, Australia
B.Sub	*Bacillus subtilis*	Nutritech solutions, Australia
Bac up	*Bacillus subtilis*	Biological Control Products, South Africa
Biofix (16 different products: chick pea, 4 common bean, cowpea, faba bean, french bean, green grams, 3 groundnuts, 2 pigeon pea, soybean, tepary bean)	Rhizobia	Mea Ltd., Kenya
Bio N	*Azotobacter* spp.	Nutritech solutions, Australia
Bioplant	*Bacillus, Clostridium, Achromobacter, Streptomyces, Aerobacter, Nitrobacter, Nitrosomonas.*	Artemis & Angelio Co. Ltd, Thailand
Bioplex	*Azotobacter* spp.	Nutritech solutions, Australia
Chick Pea Nodulator	*Mesorhizobium ciceri*	Becker Underwood, USA
Cowpea peat inoculant	Rhizobia	Becker Underwood, USA
Defender	*Bacillus subtilis*	Biological Control Products, South Africa
Dry bean Nodulator	*Rhizobium leguminosarum* biovar *phaseoli*	Becker Underwood, USA
Excalibur Gold	Natural bacteria for field seed	America's Best Inoculant, USA
Fertosolflo	No information	Soygro (Pty) Ltd., South Africa
Graph-Ex	*Bradyrhizobium japonicum*	America's Best Inoculant, USA
Green gram peat inoculant	Rhizobia	Becker Underwood, USA
Groundnut peat inoculant	Rhizobia	Becker Underwood, USA
Histick NT	*Bradyrhizobium japonicum, Bacillus subtilis*	Becker Underwood, USA
Integral	*Bacillus subtilis* strain MIB600	Becker Underwood, USA
Legumefix (soybean)	*Bradyrhizobium japonicum*	Legume technologies Ltd., UK
Legumefix (common bean)	*Rhizobium* spp.	Legume Technologies Ltd., UK
Leguspirflo	*Azospirillum brasilense -CD*	Soygro (Pty) Ltd., South Africa
Myco Apply MAXX	*Bacillus licheniformis, B. pumilus, B.amyloliquefaciens, B. megaterium*	Mycorrhizal Applications, Inc. USA
Myco Apply Soluble MAXX	*Bacillus licheniformis, B. azotoformans, B. megaterium, B. coagulans, B. pumilus, B. thuringiensis, B. stearothermophilus, Paenibacillus polymyxa, P. durum, P. gordonae, Azotobacter polymyxa, A. chroococcum, Saccharomyces cerevisiae, Pseudomonas aureofaciens, P. florescence*	Mycorrhizal Applications, Inc. USA
Mazospirflo - 2 different types	*Azospirillum brasilense -CD*	Soygro (Pty) Ltd., South Africa
Myco tea	*Azotobacter chroococcum, Bacillus polymyxa*	Nutritech solutions, Australia
Nemablok	No information	Soygro (Pty) Ltd., South Africa
NIB PGPR peat inoculant	*Pseudomonas* sp.	Murdoch University, Australia
Nodulator (faba bean, pea, lentil)	*Rhizobium leguminosarum* biovar *viceae*	Becker Underwood, USA
Nodulator (soybean)	*Bradyrhizobium japonicum*	Becker Underwood, USA
-Nutrilife 4/20	*Bacillus subtilis, Azotobacter vinelandii, A. chroococcum, Pseudomonas fluorescens, P. putida, P. stutzeri, P. cellulose, Bradyrhizobium japonicum, Azospirillum brasilense*	Nutritech solutions, Australia
Peanutflo	*Bradyrhizobium sp.*	Soygro (Pty) Ltd., South Africa
PHC Biopak	*Bacillus azotofixans, B. licheniformis, B. megaterium, B. polymyxa, B. subtilis, B. thuringiensis*	Plant Health Care, Inc. USA
PHC Colonize AG	*Paenibacillus azotofixans, Bacillus licheniformis, B. megaterium, B. polymyxa, B. subtilis, B. thuringiensis*	Plant Health Care, Inc. USA

Table 101.1 (*Continued*)

Name of Inoculant	Claimed Microorganisms	Company
PHC Complete plus	*Bacillus azotofixans, B. licheniformis, B. megaterium, B. polymyxa, B. subtilis, B. thuringiensis, Streptomyces griseoviridis*	Plant Health Care, Inc. USA
Rhizostim	*Azospirillum* sp.	Soygro (Pty) Ltd., South Africa
Rizo-Liq (5 products: chickpea, common bean, green gram, groundnut, soybean)	*Bradyrhizobium* sp. (green gram, ground nut and soybean, Mani 1), *Mesorhizobium ciceri* (chickpea), *Rhizobium* spp. (common bean)	Rizobacter, Argentina
Rizo-Liq Top - 2 different types	*Bradyrhizobium japonicum*	Rizobacter, Argentina
Root plus growth medium	*Paecilomyces lilacinus*	Biological Control Products, South Africa
Soyflo	*Bradyrhizobium japonicum* strain WB74	Soygro (Pty) Ltd., South Africa
Subtilex	*Bacillus subtilis* MBI 600	Becker Underwood, USA
Twin-N	*Azorhizobium, Azoarcus* and *Azospirillum* spp.	Mapleton Int. Australia
Vault LVL	*Bradyrhizobium japonicum*	Becker Underwood, USA
Vault NP	*Bradyrhizobium japonicum*	Becker Underwood, USA

$MgSO_4 \cdot 7H_2O$, 0.1 g l^{-1} NaCl, 1 g l^{-1} yeast extract, 10 g l^{-1} mannitol, 15 g l^{-1} agar) was used to cultivate the rhizobia, while nutrient agar (NA) (1 g l^{-1} meat extract, 2 g l^{-1} yeast extract, 5 g l^{-1} peptone, 5 g l^{-1} NaCl, 15 g l^{-1} agar) was used as a nonselective media for the growth of most other microorganisms.

The YEMA and NA plates were incubated at 28 and 37 °C, respectively, which are the optimal growth temperatures for most of the targeted microorganisms. Plates were observed daily to record colony growth. Colony morphology including shape, outline, texture, size, color, and opacity was noted each day. Different bacterial colonies identified on the same media were selected and purified three times on the same media using a streak plate technique. Pure bacterial cultures were cultivated in liquid media and stored in 20% glycerol at −80 °C for subsequent analyses.

101.2.2 Bacterial DNA Extraction, Amplification, and Sequencing

Total DNA was extracted from purified bacterial cultures following the protocol described by Wilson (Wilson, 1987) with some modifications. Briefly, liquid culture of each strain was grown at the appropriate temperature until it reached its maximal growth. The culture was then centrifuged and the pellet rinsed with TE buffer (10 mM Tris HCl, 1 mM EDTA pH = 8). The pellet was resuspended in 540 µl of 5× TE (50 mM Tris HCl, 5 mM EDTA pH = 8) and incubated for 15 min at 70 °C before being treated with 2 µl of Proteinase K (10 mg ml^{-1}) and 30 µl of 10% (w/v) SDS at 70 °C for 15 min. DNA was extracted with 600 µl of 25 : 24 : 1 (v/v/v) phenol/chloroform/isoamyl alcohol and residual phenol was removed by adding chloroform/isoamyl alcohol. DNA was precipitated overnight in one volume of cold isopropanol at −20 °C. The pellet was cleaned with 70% ethanol, air-dried, and resuspended in 100 µl of sterile micropure water. The samples were treated with 10 µl of 40 µg ml^{-1} RNase and incubated for 30 min at 37 °C to remove any traces of RNA.

A fragment of the 16S rDNA region was amplified using the primers 27F (5'-AGAGTTTGATCMTGGCTCAG-3') and 1492R (5'-TACGGYTACCTTGTTACGACTT-3') (Lane, 1991; Turner et al., 1999). The 25 µl reaction volume contained 12.5 µl of Faststart PCR Master Mix (Roche), 8.5 µl of sterile micropure water, 10 pmoles of each primer, and 2 µl of template DNA. Amplification conditions were as follows: predenaturation (94 °C for 5 min); 35 cycles of denaturation (94 °C for 1 min), annealing (55 °C for 1 min), and elongation (72 °C for 2 min); and final elongation (72 °C for 15 min). PCR products were purified with 3M sodium acetate and absolute ethanol and 10 µl at a concentration of 50 ng μl^{-1} was submitted for sequencing at SegoliP Unit (BecA, Nairobi).

101.3 RESULTS AND DISCUSSION

A total of 65 inoculant products were classified in three categories based on their claimed contents. Thirty-nine products out of the 65 tested in this study claimed to contain one or several strains of rhizobia; seven products were supposed to contain free-living N-fixing bacteria (e.g., *Azospirillum*, *Azotobacter*); and other 16 claimed to contain various non-N-fixing PGPR (e.g., PSB, biocontrol agents, etc.) such as *Bacillus* or *Pseudomonas*. Three manufacturers refused to give any information about the contents of their products. The microbial content of these three products was analyzed as for the other products, but their quality couldn't be evaluated.

From the 65 products, a total of 259 strains were isolated, purified, and identified. Several colony types were obtained for most of the products, on both culture media. Ninety-two strains were isolated on YEMA and 167 strains on NA. More than 50% of the inoculants analyzed yielded

Table 101.2 Microbial quality of the inoculants for each type of products

Microorganisms Contained in the Products	Category	Number of Products	(%)	Category	Number of Products	(%)
Rhizobia	Pure	18	46.15	Less strains than expected	0	0
	Intermediate	3	7.69	As many strains as expected	18	46.15
	Contaminated	18	46.15	More strains than expected	21	53.85
	Total	39	100	Total	39	100
Free N fixing	Pure	2	28.57	Less strains than expected	0	0
	Intermediate	2	28.57	As many strains as expected	2	28.57
	Contaminated	3	42.86	More strains than expected	5	71.43
	Total	7	100	Total	7	100
Other PGPR	Pure	3	18.75	Less strains than expected	5	31.25
	Intermediate	10	62.50	As many strains as expected	3	18.75
	Contaminated	3	18.75	More strains than expected	8	50.00
	Total	16	100	Total	16	100

Table 101.3 Microbial quality of the inoculants (regardless of the type of products)

Category	Number of Products	(%)
Pure	23	37.10
Intermediate	15	24.19
Contaminated	24	38.71
Total (classified)	62	100
Not classified	3	–
Total (analyzed)	65	–

more strains than expected suggesting high levels of contamination (Table 101.2). Differences in contamination levels were observed between the N-fixing inoculants and the PGPR inoculants. The N-fixing products generally claimed to include one or two strains only and showed a reasonable number of contaminants. In most cases, inoculants acclaimed to contain one single strain had less than 3 contaminants. N-fixing bacteria and rhizobia in particular are known to require specific conditions for their optimal growth. As a result, the carrier for rhizobial products may be more selective than that of other PGPR strains and discourage the growth of other strains that the inoculant might contain.

The non-N-fixing products (PGPR) usually claimed to contain a large number of strains, up to 15 for some of the analyzed products. The competitive ability of indigenous over inoculant strains has caused some authors to advocate mixed inoculant strain formulations (Kyei-Boahen et al., 2002; Sutherland et al., 2000). Sutherland et al. (2000) suggested that inoculation with a single strain could be risky because the rhizosphere competence of a particular strain to establish an effective symbiosis varies within a wide range of environmental factors and, as a result, one strain may not be effective under all environmental conditions. However, most of the products claiming to have a large number of strains yielded fewer strains than claimed. That could be explained by the difficulty in choosing a carrier suitable for all strains. Ideally, a carrier should provide optimal conditions to allow the bacteria to survive in large numbers during formulation, transport and storage (see also Chapter 97). The optimal conditions might be different for each bacterial strain, and the manufacturers must also ensure that the different strains do not compete with each other (Malusa et al., 2012; Stephens and Rask, 2000). For instance, Kellman (2008) showed that some strains contained in an inoculant were able to produce bacteriocins or antibiotics in order to suppress the growth of "competitors" strains in the mixture.

All the strains isolated from the inoculants were identified after partial sequencing of the 16S rDNA. Results showed that in overall, only 37% of the products contained the expected strain(s) without any contamination. These products can thus be considered as "pure" (Table 101.3). About 24% of all the tested inoculants were classified as "intermediate products" since they contained some or all of the expected strains but with also one or more other strains,

Table 101.4 Pathogenicity and occurrence of the bacterial contaminants isolated from the inoculants

Contaminant	Pathogenicity	References	Occurrence (% of Products)
Agrobacterium sp.	Plant pathogen – some cases of septicemia	Freney et al. (1985); Keane et al. (1970)	3.23
Agrobacterium tumefaciens	Plant pathogen (causes crown gall disease = formation of tumors)	Moore et al. (1997); Smith and Townsend (1907)	9.68
Arthrobacter sp.	Nonpathogenic		4.84
Bacillus amyloliquefaciens	Mostly nonpathogenic (but 1 case of pathogenicity on infants)	Huang et al. (2010)	9.68
Bacillus cereus	Responsible for a minority of foodborne illnesses. Toxin production	Kotiranta et al. (2000); Taylor et al. (2005)	11.29
Bacillus circulans	Mostly nonpathogenic (but 1 case of soft rot on Date Palm)	Leary et al. (1986)	3.23
Bacillus firmus	Mainly not pathogenic (but capable of toxin production)	Taylor et al. (2005)	6.45
Bacillus fumarioli	Nonpathogenic		1.61
Bacillus humi	Nonpathogenic		1.61
Bacillus licheniformis	Toxin production	Salkinoja-Salonen et al. (1999)	4.84
Bacillus massiliensis	Isolated from cerebrospinal fluid	Glazunova et al. (2006)	1.61
Bacillus megaterium	Toxin production	Taylor et al. (2005)	1.61
Bacillus nealsonii	Nonpathogenic		1.61
Bacillus simplex	Toxin production	Taylor et al. (2005)	1.61
Bacillus sp.	Pathogens (for some species)	Sliman et al. (1987)	35.48
Bacillus subtilis	Nonpathogenic		8.06
Bacillus thermoamylovorans	Nonpathogenic	Combet-Blanc et al. (1995)	1.61
Bacillus thuringiensis	Nonpathogenic for human but insect pathogen	Bravo et al. (2011); Raymond et al. (2010)	1.61
Bacillus vallismortis	Nonpathogenic	Roberts et al. (1996)	1.61
Brevibacillus borstelensis	Nonpathogenic	Shida et al. (1996)	3.23
Brevibacillus brevis	Nonpathogenic	Shida et al. (1996)	3.23
Cellulosimicrobium sp.	Rare and opportunistic pathogen	Petkar et al. (2011); Rowlinson et al. (2006)	1.61
Chryseobacterium sp.	Opportunistic human pathogen	Bloch et al., 1997; Padmaja et al. (2006)	1.61
Comamonas testosteroni	Human pathogen	Abraham and Simon (2007)	1.61
Cupriavidus sp.	Opportunistic human pathogen	Langevin et al. (2011)	1.61
Enterobacter pulveris	Nonpathogenic	Stephan et al. (2008)	3.23
Enterobacter sp.	Nosocomial pathogen	Gaston (1988)	3.23
Lysinibacillus fusiformis	Toxin production	Wang et al. (2010)	1.61
Lysinibacillus sphaericus	Opportunistic human pathogen, insect pathogen	Berry (2012)	1.61
Microbacterium hydrocarbonoxydans	Opportunistic human pathogen	Gneiding et al. (2008)	1.61
Microbacterium sp.	Opportunistic human pathogen	Gneiding et al. (2008)	3.23
Moraxella osloensis	Rare and opportunistic pathogen	Tan and Grewal (2001)	1.61
Nocardioides dubius	Nonpathogenic	Yoon et al. (2005)	1.61
Ochrobactrum intermedium	Opportunistic human pathogen	Berg et al. (2005)	3.23
Ochrobactrum sp.	Opportunistic human pathogen	Berg et al. (2005)	4.84
Paenibacillus alvei	Nonpathogenic	Ash et al. (1993)	1.61
Paenibacillus barengoltzii	Nonpathogenic	Osman et al. (2006)	1.61
Paenibacillus lactis	Nonpathogenic	Scheldeman et al. (2004)	3.23
Paenibacillus lautus	Nonpathogenic	Heyndrickx et al. (1996)	1.61
Paenibacillus polymyxa	Nonpathogenic	He et al. (2007)	3.23
Paenibacillus sonchi	Nonpathogenic	Hong et al. (2009)	1.61
Pantoea agglomerans	Human and plant pathogen	Delétoile et al. (2009)	1.61
Pseudomonas fluorescens	Potential pathogen	Picot et al. (2001)	3.23
Pseudomonas sp.	Pathogens (for some species)	Stead (1992)	3.23

Table 101.4 (*Continued*)

Contaminant	Pathogenicity	References	Occurrence (% of Products)
Pseudoxanthomonas sp.	Nonpathogenic	Thierry et al. (2004)	3.23
Serratia marcescens	Human pathogen	Kurz et al. (2003)	1.61
Solibacillus silvestris	Non pathogenic	Morohoshi et al. (2011)	1.61
Staphylococcus pasteuri	Potential pathogen. Toxin production	Chesneau et al. (1993)	1.61
Stenotrophomonas maltophilia	Human pathogen	Looney et al. (2009)	4.84
Stenotrophomonas sp.	Opportunistic human pathogen	Berg et al. (2005)	4.84
Total (all products)			53.23
Total (contaminated products)			84.62

considered as contaminants. Finally, almost 40% of the inoculants contained none of the claimed strains by the manufacturers but only contaminations and were referred to as "contaminated products" (Table 101.3). Some of the isolated strains which were not identified by the manufacturers may be shown to also have plant growth-promoting activities. However, for the purposes of this study, if not claimed by the manufacturers, they must be referred to as "contaminants."

Inoculants containing rhizobia were generally of better quality than the rest of the inoculants since almost half of the rhizobial inoculants (46%) tested in this study were classified as pure products, while a further 46% contained none of the expected strain(s) but only contaminants (Table 101.2). It is important to note that 15 out of the 18 rhizobial inoculants classified as "contaminated" were sold by the same company. Indeed, only one product (out of 16) sold by this company actually contained the strain of rhizobia it was claimed to contain (plus some contaminants). It is likely that inappropriate sterilization of the carrier, impurity of the strains before inoculation or contamination of the packaging material may be responsible for the high levels of contamination of these products.

Inoculants containing free-living N-fixing bacteria were generally of poor quality: 43% of them were classified as contaminated products and only 28% were pure. Similar results were obtained with the products claiming to contain non-N-fixing PGPR: only 19% of products were found to be pure, while a majority of the products (62 and 19%, respectively) belonged to the intermediate or contaminated categories (Table 101.2). Moreover, in most cases, when a company did not give the details of the product's microbial content, the same product ended up containing a mix of several strains.

Overall, these results show a remarkably high level of contamination across the range of products. The bulk of "contaminants" found were *Bacillus* sp., but other genera were found such as *Brevibacillus*, *Pseudomonas*, *Moraxella*, or *Staphylococcus*. The list of the contaminants found in the products is given in Table 101.4.

A similar study by Olsen et al. (Olsen et al., 1996) reported on the contaminants found in 60 samples of commercial inoculants: 25% of the inoculants contained opportunistic human pathogens at high levels. Many of these pathogenic strains were also found in our study (such as *Pseudomonas* sp., *Agrobacterium sp.*, *Enterobacter sp.*, *Staphylococcus sp.*), occurring in more than 53% of the products tested (all categories included) and almost 85% of the contaminated products (Table 101.4). Although some of the strains are known to be very rarely pathogenic, our results show that a significant portion of the inoculants are potentially dangerous for humans, plants, or the environment, and this is largely superior to the proportions obtained by Olsen et al. (1996). Other studies have reported bacterial contamination including human pathogens such as *Acinetobacter, Flavobacterium, Alcaligenes, Pseudomonas, Moraxella*, and *Enterobacter* or bacteria inhibiting the growth of rhizobia (Azpilicueta et al., 1996; Gomez et al., 1997; Olsen et al., 1994a). The presence of bacteria which may represent a risk for humans, plants, and the environment poses issues beyond just being contaminants in the inoculant products and should not be ignored (Bashan, 1998; Catroux et al., 2001).

The issue of the quality of inoculants has been raised for many years. Several authors described as a paradox the fact that despite almost 100 years of research and experience, a large portion of the inoculants produced in the world today are still of poor and sometimes extremely poor quality because quality controls are not systematically practiced (Brockwell and Bottomley, 1995; Catroux et al., 2001; Somasegaran, 1991). There have been examples of rhizobial inoculants sold on the markets that did not contain any rhizobia at all (Olsen et al., 1996). In many countries, there is currently neither a system in place nor a set of common international standards to evaluate and ascertain the quality of the products that reach the end user (Olsen et al., 1994b).

To counter this problem, some countries have developed an appropriate legislation supporting systems to control the quality of the products. For instance, in Canada, the quality of all inoculants produced is controlled and an annual

report is prepared (Anonymous, 1997; Catroux et al., 2001). In France, the requirements for inoculant quality are some of the most stringent, with no detectable contaminants admitted (Catroux, 1991). In other countries (e.g., Australia, Thailand, New Zealand), the quality control is voluntary on the part of the inoculant manufacturers (Catroux et al., 2001; Herridge et al., 2002). On the other hand, many countries have not set up or implemented such standards (Brenner, 1996). As a consequence, almost anyone can sell an inoculant without going through the process of quality check. The results obtained in the present study are in accordance with these observations as a majority of the inoculants were not of good quality. This confirms the importance of an effective, regulatory quality control program to ensure a successful production and use of inoculants (see also Chapter 97).

ACKNOWLEDGMENT

This work was funded by the Bill and Melinda Gates Foundation through the Tropical Soil Biology and Fertility Institute of CIAT (TSBF-CIAT) project on commercial microbial products (COMPRO).

102.1 INTRODUCTION

A biofertilizer is an agricultural input, which contains living microorganisms exerting direct or indirect beneficial effects on plant growth and productivity through various mechanisms (Bohlool et al., 1992). It is also a supplement but a sustainable source for replenishing depleted soil microbial community by increasing biodiversity (Seneviratne and Kulasooriya, 2013). It is reported that genera of *Rhizobium, Bradyrhizobium, Azospirillum, Azotobacter, Burkholderia, Enterobacter, Klebsiella, Pseudomonas, Azoarcus, Gluconacetobacter, Herbaspirillum*, and many other rhizobacterial genera enhance the plant growth via supplying essential nutrients and/or providing plant growth-promoting substances (Francesco and Jumpponen, 2006). In general, most of the biofertilizers consist of one or many of the above mentioned bacterial types as "active ingredients" (see Chapter 101).

Many studies have revealed that widely used plant growth-promoting rhizobacteria show specific interactions with their host plants (Saharan and Nehra, 2011; Francesco and Jumpponen, 2006). A typical example is the symbiosis established between bacteria of the Rhizobiaceae and the plant family Leguminosae (Rhijn and

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

Vanderleyden, 1995). Similar interactions are documented within *Azospirillum* (see Chapter 90), *Herbaspirillum* (see Chapter 93), and cereal crops (Baldani, and Dobereiner, 1980). Azotobacter is another example that shows species-based-specific plant interactions (Tilak et al., 2009). Based on those interactions, specific biofertilizers have been formulated for specific crops. Thus, most of the currently available biofertilizers are suitable for one particular or a narrow range of crops. Due to this specificity, plant-specific biofertilizer production creates problems at the industrial level, especially large-scale biofertilizer production. If a few types of biofertilizers could be formulated to a wide range of crops that would certainly provide benefits to commercial biofertilizer industry. Further, the crop response to conventional biofertilizers is also a concern of farmers, due to marginal improvement of yields.

As a recent development in microbiology, surface-attached microbial communities or biofilms are being studied for many biotechnological applications. Biofilms are often complex communities of multiple microbial species that remain attached to surfaces (Seneviratne et al., 2009). They consist of microbial cells and sticky extracellular polymeric substances (EPS; see Chapter 36) which provide structure and protection to the community (Flemming and Wingender, 2010). In this field of research, bacteria in the fungal surface-attached biofilm mode are called fungal-bacterial biofilms [FBBs], which can be developed *in vitro* from microbial monocultures (Seneviratne et al., 2008). These developed biofilms can be applied for various agricultural and biotechnological purposes. As a novel advancement in biofertilizer research, FBBs have been developed and are being tested as biofertilizers, which are now known as biofilmed biofertilizers (BFBFs). It has been shown that plant-associated nitrogenase activity, rhizoremediation, plant and soil carbon sequestration, and plant growth-promoting activities are enhanced by FBBs (Seneviratne et al., 2009). Also, these well-developed biofilms can enhance microbial effectiveness compared to monocultures. It was observed that microbial interactions in the FBBs fixed N_2 biologically, as revealed by nitrogenase activity and N-accumulation, which was not observed when a rhizobial strain was used alone as a monoculture (Jayasinghearachchi and Seneviratne, 2004). Under field conditions, the FBBs have saved 50% of chemical fertilizer use in crop production, with other crop and soil benefits, but without lowering yields (Seneviratne et al., 2011). As such, those observations have made the FBBs more attractive to farmers than the conventional biofertilizers.

The biofilm structures are physiologically and anatomically exclusive and their dynamism and processes are quite different from monocultures (Hancock, 2001). In most biofilms, the microorganisms account for less than 10% of the dry mass, whereas the matrix can account for over 90%. The matrix is the extracellular material, which consists of a conglomeration of different types of biopolymers such as EPS (Flemming and Wingender, 2010; see Chapter 36). As a result, genomic functions and regulations are reasonably diverse in the FBBs. This may cause varied production of different biochemical molecules in the FBBs (Herath et al., 2013) and may lead to break plant-microbe specificity, thus facilitating universal behavior of biofertilizers.

Therefore, *in vitro* development of FBBs with nitrogen fixers and their promotion are essential steps to overcome low acceptance of the biofertilizers by farmers, as well as in the industry. This chapter highlights recent advances in the application of the FBBs, focusing on the potential effects of them on leguminous as well as non-leguminous crops.

102.2 METHODOLOGY

Experiments were conducted at the Institute of Fundamental Studies [IFS], Kandy, Sri Lanka [midcountry wet zone [WM3], 510 m amsl; mean annual temperature, 25.5 °C]. Soil type in the site was Red-Yellow Podzolic with the texture of clay loam, pH 4.1, 1.45% total C, and 0.08% total N. Common bean [*Phaseolus vulgaris L.*], tomato [*Solanum lycopersicum L.*], capsicum [*Capsicum annuum L.*], cabbage [*Brassica oleracea* var. capitata], and rice [*Oryza sativa L.*] crops were employed to evaluate the universality of developed microbial biofilms.

The FBBs used in this study were developed mainly by coculturing of nitrogen-fixing bacteria and a saprophytic fungus (Seneviratne et al., 2011). When they were cocultured *in vitro*, the bacteria attached and colonized on fungal mycelia to form the FBB. The bacterial strains used in this study were *Acetobacter, Azotobacter, Bradyrhizobium*, and *Rhizobium*. *Acremonium* sp. was used as the fungal strain. During bacterial biofilm development process, their maturity at different stages was observed microscopically. Simultaneously, nitrogen-fixing ability was measured using acetylene reduction assay [ARA; Zuberer and Silver, 1978]. To this end, gas samples collected from the headspace of the vial [0.5 ml] were injected into a gas chromatograph [Shimadzu GC 9AM, with a hydrogen flame equipped with flame ionization detector [FID]], a Carboxen™-1010 PLOT capillary column, and helium [99.99%] as the carrier gas at a flow rate of 0.625 ml s^{-1}.

To evaluate the effect of the FBB, three treatments were applied to the four non-legume crops: (i) half of the recommended fertilizer (T1), (ii) developed FBB + half of the recommended fertilizer (T2), and (iii) control (no fertilizer or biofilm). For common bean, treatments were; biofilmed biofertilizers (BFBFs), 100% recommended chemical fertilizers, and no fertilizer control. Each treatment had five replicates, and the experiment was arranged according to completely randomized design CRD.

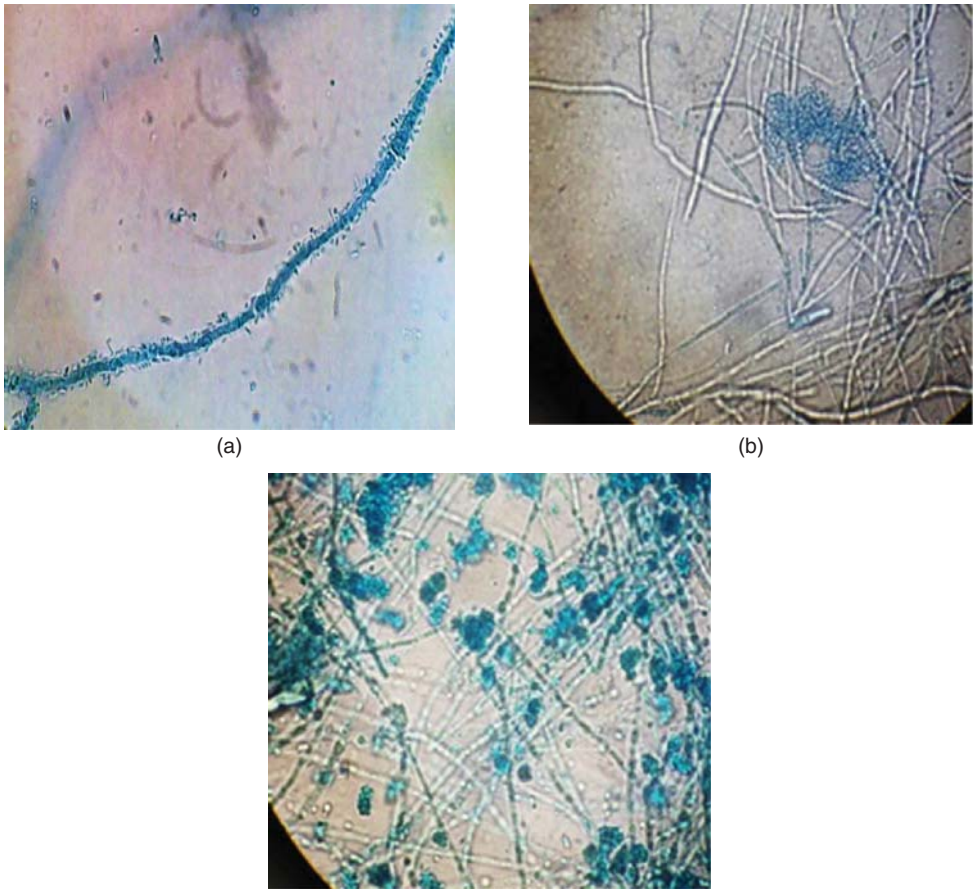

Figure 102.1 *Acremonium* sp. mycelial colonization by N_2-fixing bacteria (*Acetobacter*, *Azotobacter*, *Bradyrhizobium*, and *Rhizobium*) forming fungal-bacterial biofilms, when developed under *in vitro* conditions. (a) Initial colonization of bacteria of the fungal mycelium, (b) a cell cluster formed by multiplication of the colonized bacteria, and (c) matured cell clusters on the mycelium. Darkness is due to cotton blue stain absorbed by exopolysaccharides produced by the biofilms. Magnification, × 400.

Twelve weeks after transplanting, five representative plants were randomly uprooted from each plot. Representative root samples were subjected to ARA. In the case of common bean, roots, and nodules were separately subjected to ARA. After that, all shoots and clean roots were oven dried at 65 °C for total dry weight measurements.

The effects of the treatments were analyzed by ANOVA at 5% probability level, and means were separated by using Tukey's HSD test. SAS® 9.1.3 software was used for all statistical analyses.

102.3 RESULTS

Figure 102.1 shows three stages of FBB development under *in vitro* conditions over time. Initially, *Acremonium* sp. mycelium was colonized by cocultured bacterial species of *Acetobacter, Azotobacter, Bradyrhizobium*, and *Rhizobium* (Fig. 102.1a). Then, cell clusters were formed through multiplication of the colonized bacteria (Fig. 102.1b). At third stage, maturation of the biofilms occurred, as reflected by dark cell clusters on the mycelium, which were stained by cotton blue stain that was absorbed by exopolysaccharides (EPS) produced by the biofilms (Fig. 102.1c). Simultaneously, nitrogenase activity of the developed FBB was measured and found to increase with the maturation stage of FBBs (Fig. 102.2).

Twelve weeks after transplanting, shoot and root dry weights of tomato, capsicum, cabbage, and rice plants treated with the FBB together with half of the recommended fertilizers (T2) were found to be significantly higher than that of 50% recommended chemical fertilizer-added plants (T1) (Fig. 102.3). T1 treatment showed an inconsistent plant growth. Similarly, total dry weight of biofilm-treated common bean plants was significantly higher than that of the chemical fertilizer treated or no fertilized plants (Fig. 102.4).

Root, shoot, and pod dry weights also followed the same trend. However, nodule dry weight did not show significant differences among the treatments [$p > 0.05$].

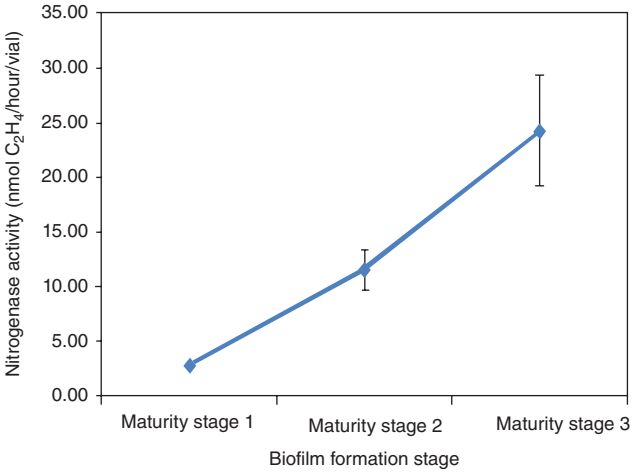

Figure 102.2 Change in nitrogenase activity during fungal mycelial colonization of bacteria and biofilm formation at three stages of maturation, described in Figure 102.1.

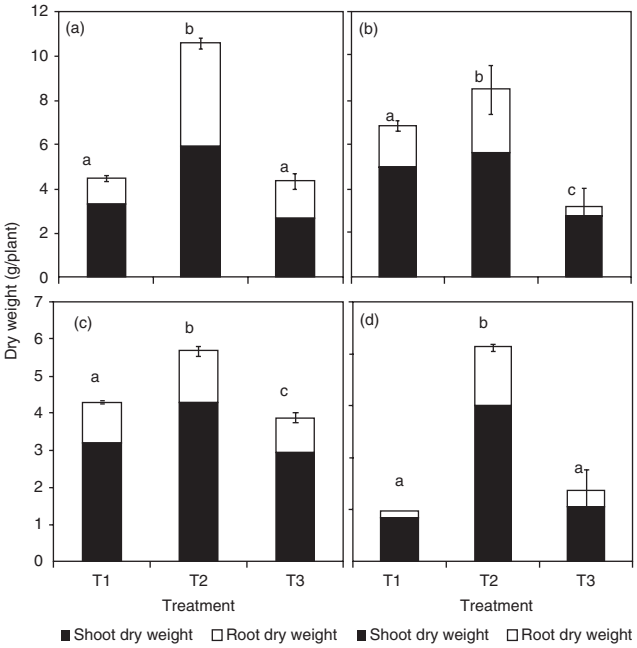

Figure 102.3 Shoot and root dry weights of (a) tomato, (b) capsicum, (c) cabbage, and (d) rice, with half of the recommended fertilizers (T1), FBB + half of the recommended fertilizers (T2), and no fertilizer (T3). Columns sharing a same letter do not significantly differ at 5% probability level. Vertical bars show standard errors.

Nodules of the biofilm-treated bean plants showed about sixfold significant increase in nitrogenase activity compared to 100% recommended chemical fertilizer-added treatment (Fig. 102.5). The biofilm-treated roots without nodules also positively responded to the assay, showing about fourfold significant increase compared to the full chemical fertilizer treatment. Microscopic observations revealed that the root samples that responded positively to nitrogenase activity contained root surface- and root hair-attached biofilm structures (Fig. 102.6). Similar biofilm structures attached to the roots were also observed in capsicum, cabbage, and rice treated with the biofilms.

102.4 DISCUSSION

Biofilm formation generally follows a sequence of steps (Tenke et al., 2004). Initially, planktonic bacteria are deposited on biotic or abiotic surfaces, and subsequently, the cells adhere and anchor to the surface by EPS. Thereafter,

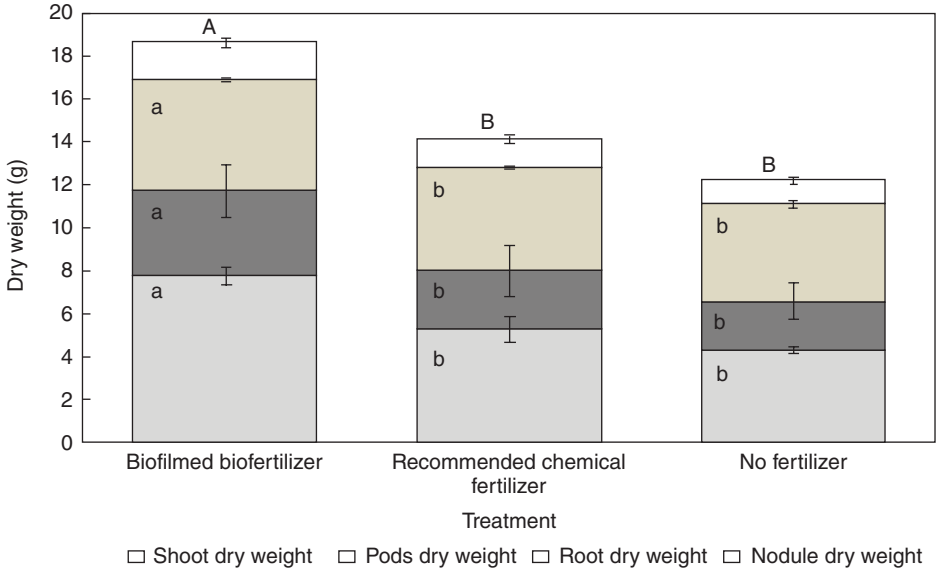

Figure 102.4 Shoot, pod, root, and nodule dry weights of common bean (*Phaseolus vulgaris* L.) treated with the FBB, recommended chemical fertilizer dose, and no fertilizer. Different letters across the columns show significant differences at 5% probability level, whereas the absence of letters indicates absence of significant differences at the same probability level. Vertical bars show standard errors.

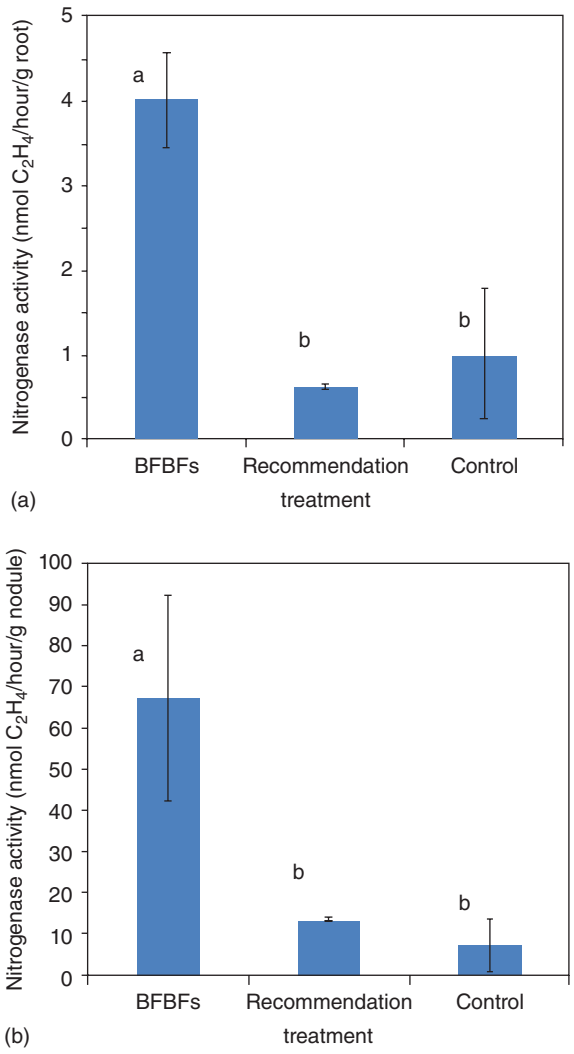

Figure 102.5 (a) Nitrogenase activity of common bean roots (without nodules), and (b) nitrogenase activity of common bean root nodules of the treatments. Columns sharing a same letter do not significantly differ at 5% probability level. Vertical bars show standard errors.

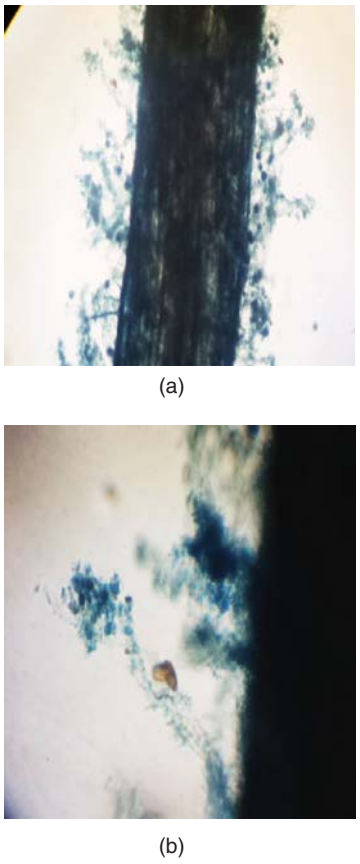

Figure 102.6 (a) and (b) Tomato root surface and root hair colonized by developed microbial biofilms. Stain, lactophenol cotton blue. Magnification, × 400.

the biofilm growth and multiplication occur. In the present study, *Acremonium* sp. mycelium was colonized by nitrogen-fixing bacteria *Rhizobium* sp., *Bradyrhizobium* sp., *Acetobacter* sp., and *Azotobacter* sp., which led to the formation of FBB (Seneviratne and Jayasinghearachchi, 2005). With maturation of biofilms, EPS are accumulated as the matrix (Flemming and Wingender, 2010). Increased nitrogenase activity with maturity could be due to the presence of a higher number of nitrogen fixers in the biofilm or enhancement of nitrogen fixation in the matured community. This needs further investigations.

The FBBs are capable of attaching to plant root system, creating root-biofilm associations, which benefit both plants and biofilms (Seneviratne et al., 2009). The root-attached biofilms with nitrogen fixers have been reported to behave as nodule-like structures or "pseudo nodules", which can fix nitrogen biologically (Jayasinghearachchi and Seneviratne, 2004). These special structures on the root system support non-leguminous plants to supplement their nitrogen requirement more efficiently. It is speculated that the pseudonodules with nitrogen fixers are capable of transferring fixed nitrogen to the root after death and decomposition of the biofilm structures. In return, the root may supply carbon sources to the biofilm (Seneviratne et al., 2009). Release of organic acids by the biofilms helps to increase mineralization of soil nutrients in the rhizosphere (Seneviratne and Jayasinghearachchi, 2005). Increased production of plant growth-promoting hormones like indole acetic acid [IAA] by biofilms helps to enhance plant growth (Bandara et al., 2006). In addition, the FBBs are important in replenishing beneficial microbial communities in depleted agricultural soils due to heavy use of chemical inputs and intensive cropping (Seneviratne et al., 2009). All the aforementioned factors involving the FBBs contribute to increased plant growth, compared to conventional chemical fertilizer application.

Application of moderate levels of inorganic fertilizers helps to increase the composition and biomass of microbes

in the FBBs treated soil. As a result of this, biofilm communities with high cell densities are colonizing root system, which can increase plant growth (Seneviratne, 2009). In the present study, possibility of using only 50% of the chemical fertilizers for the entire crop of such nonlegumes would be a huge economic gain in terms of fertilizer saving.

As observed in the present study, the developed microbial biofilms are also capable of colonizing root system of legume plants enhancing nitrogenase activity of the rhizosphere. As a result, vertical roots can be colonized by the biofilm, which are then able to form the pseudonodules fixing N_2, in addition to proper root nodules. This extra arrangement supplies more nitrogen to the plant, thus resulting in elevated crop growth. It has been also shown that the inoculation of FBBs helps to maintain a higher cell density of rhizobia on the root system than the inoculation of rhizobial monocultures (Seneviratne and Jayasinghearachchi, 2005). Biofilm-based inoculant delivering method may also have a significant effect on common bean nodule production, because biofilm structure provides extra protection and a favorable microenvironment for rhizobia. The root-biofilm association also enhances the legume plant nutrient absorbance from the surrounding soil (Seneviratne et al., 2009). Furthermore, the established microbial communities on the root system may protect the plant from adverse environmental conditions and pathogenic infections (Seneviratne et al., 2010). Importantly, developed microbial biofilms may enhance cell signalling between legume plants and rhizobia, ultimately leading to establish effective symbiosis between them. As a result of all those positive impacts created by the FBBs, common bean showed significantly high plant growth.

102.5 CONCLUSIONS

This study showed that the FBB developed with nitrogen fixers enhanced the plant growth of legumes as well as nonlegumes. Thus, crop specificity of conventional biofertilizers, one constraint in popularizing biofertilizers, can be overcome by using the FBB-based biofertilizers. Further, this eco-friendly and economical biofertilizer technology, due to its reduced use of chemical fertilizers could lead to a sustainable agriculture without hampering yields. Nitrogen-fixing pseudonodules developed on all plant roots may contribute to an increased N budget in the field. However, further laboratory and field studies are required to understand the complete mechanisms and to realize the full potential of the FBBs.

103.1 INTRODUCTION

Phenotypic variation (Pv) is used by several bacterial species to generate intrapopulation diversity that increases bacterial fitness and is important in niche adaptation or to escape host defenses (in the case of pathogens). Pv or phase variation allows that the expression of a given phenotype is either ON or OFF; these events are usually reversible but may be irreversible and result from genetic or epigenetic alterations at specific loci (van der Woude and Baumler, 2004; Wisniewski-Dyé and Vial, 2008). In contrast to spontaneous mutations, occurring at a frequency of approximately 10^{-8} to 10^{-6} mutations per growing cell per generation, Pv occurs at frequencies higher than 10^{-5} events/switches per cell per generation and always affects the same phenotype(s). Pv is extensively studied in animal/human pathogens but has also been reported for plant pathogens and plant beneficial bacteria. In the case of the latter, various phenotypes, such as motility, aggregation, pigmentation, synthesis of antifungal metabolites, and metabolic properties, appear to be regulated through Pv.

In this review, the literature about the occurrence of Pv in different species and strains of the plant growth-promoting diazotrophic genus *Azospirillum* (see Chapter 90) is summarized and complemented with examples of other root-associated and plant growth-promoting bacteria.

103.2 PHENOTYPIC VARIATION IN *Azospirillum* UNDER NORMAL GROWTH CONDITIONS

Azospirillum lipoferum 4B, a strain isolated from a rice rhizosphere in France (Thomas-Bauzon et al., 1982), was reported to generate under normal growth conditions a stable phase variant named $4V_I$ at high frequencies [10^{-4} to 10^{-3} per cell per generation] (Alexandre and Bally, 1999). Variant colonies were distinguishable from wild-type colonies by the differential absorption of dyes (such as bromothymol blue)

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

incorporated into the growth medium: whereas wild-type colonies were blue and opaque, variant colonies appeared nearly white and translucent and usually smaller in diameter (Vial et al., 2004). Under fully aerated conditions at 28 °C, variant cells have been detected only when the parental strain entered the exponential growth phase and their number increased proportionally to the total number of viable cells and reached a maximum of about 2% at the end of the exponential phase (Alexandre and Bally, 1999).

The $4V_I$ variant exhibits pleiotropic modifications compared to the wild-ype. First, it gained the ability to assimilate certain sugars (xylose, galactose, α-methyl-mannoside, 5-ketogluconate) but lost the ability to assimilate others (*N*-acetylglucosamine, tagatose, esculin); fermentation of sorbitol, mannitol, and glucose was also abolished (Alexandre and Bally, 1999). Second, the $4V_I$ variant was no longer able to reduce triphenyl tetrazolium chloride (Alexandre and Bally, 1999). Third, the $4V_I$ variant was unable to swim as it lacked a polar flagellum due to a defect in flagellin synthesis, but it constitutively expressed mechanosensing lateral flagella (Alexandre and Bally, 1999; Alexandre et al., 1999b). Fourth, the $4V_I$ variant could no longer reduce nitrous oxide and deaminate 1-aminocyclopropane-1-carboxylic acid (ACC), the immediate precursor of plant ethylene (Alexandre, 1998; Prigent-Combaret et al., 2008).

From the $4V_I$ variant that was unable to revert to the parental phenotype, a second atypical stable form, named variant $4V_{II}$, appeared under very specific conditions, that is, growth at extremely low oxygen concentrations. This new variant displayed laccase activity and the ability to produce melanin and was also unable to revert to the parental phenotype (Alexandre and Bally, 1999). Laccases or laccase-like multicopper oxidases (EC 1.10.3.2) catalyze the oxidation of various substrates, such as phenols, diamines, and metals, coupled with the reduction of molecular oxygen to water. When oxidizing aromatic substrates, laccases generate reactive species, such as semiquinones and quinones that are powerful inhibitors of the electron transport system in bacteria (Imlay and Fridovich, 1992).

The electron transport systems of the laccase-positive $4V_{II}$ variant and its parental laccase-negative forms have been compared. During exponential (but not stationary) growth under fully aerobic (but not under microaerobic) conditions, the laccase-positive variant lost a respiratory branch that is terminated in a cytochrome *c* oxidase of the aa3 type (Alexandre et al., 1999a); this observation was most likely due to a defect in the biosynthesis of a heme component essential for the oxidase. Moreover, the $4V_{II}$ variant was significantly less sensitive to the inhibitory action of quinone analogs and fully resistant to inhibitors of the bc1 complex, apparently due to the rearrangements of its respiratory system. Thus, loss of the cytochrome *c* oxidase-containing branch in the variant might be an adaptive strategy to the presence of intracellular oxidized quinones, the products of laccase activity (Alexandre et al., 1999b).

The occurrence of Pv under normal growth conditions has been investigated in a collection of *Azospirillum* strains belonging to various species [*amazonense*, *doebereinera*e, *halopraeferens*, *irakense*, and *lipoferum*]. Five strains out of 27 generated variant colonies exhibiting the same phenotypes as the $4V_I$ variant: they could no longer fix bromothymol blue and reduce triphenyl tetrazolium and were nonmotile (Vial et al., 2006). Interestingly, the stabilities of the variants differed: whereas *A. brasilense* WN1, a strain isolated from wheat in Pakistan, engendered a stable phase variant, subculturing variant colonies from *A. brasilense* Wb1 (wheat, Pakistan) and *A. irakense* KBC1 (rice, Iraq) produced a mixture of wild type and variant colonies (at a ratio of about 10 : 1), suggesting that a reversion event had occurred. For strains *A. brasilense* PH1 (rice, France) and *A. lipoferum* MRB16 (rice, Bangladesh), subculturing of variants yielded almost only wild-type colonies, and thus, variants from these strains were considered highly unstable (Vial et al., 2006). The ability to generate variants could not be correlated to a particular *Azospirillum* species or to a specific plant host, and hence, the adaptive significance of Pv in *Azospirillum* remains to be established.

In a recent study, exopolysaccharide overproducing variants of *A. brasilense* Sp7 were examined in further detail (Table 103.1) (Volfson et al., 2013).

Variant colonies with a much increased mucoid morphology occurred spontaneously with a frequency of about 1 in 5000 cells per generation on fructose-based mineral medium. The variants produced exceedingly mucoid colonies [Figure 103.1] that contained about 8 times more exopolysaccharides.

In addition, the exopolysaccharides of the variants were also different in the relative composition of monosaccharides and showed improved tolerance to heat [55 °C] and UV exposure (Volfson et al., 2013).

103.3 PHENOTYPIC VARIATION IN *Azospirillum* UNDER STARVATION AND STRESS CONDITIONS

During exposure of *A. brasilense* Sp7 to NaCl stress, colonies with resistance toward 3,4-dehydroproline (DHP), an antimetabolite of the osmoprotectant proline (Csonka, 1981), could be isolated. In the presence of 80 μg ml^{-1} DHP and salt stress (0.5M NaCl) in mineral medium, DHP-resistant mutants appeared at a frequency of 10^{-1} per generation (Hartmann et al., 1992). These DHP-resistant isolates were then stable in the absence of salt stress and retained their osmotic stress tolerance. A similar high frequent selection of isolates with the ability to grow at severely iron-limiting conditions could be achieved using the

Table 103.1 Exopolysaccharide (EPS) Production, Cell Aggregation, and Partial EPS Monosaccharide Composition of *Azospirillum brasilense* Sp7 and Three of Its Phenotypic Variants

Strain	EPS/Cell Dry Weight* (g g^{-1})	Cell Aggregation (%)*	Monosaccharide Composition of EPS (%)†			
			Glucose	Galactose	Rhamnose	Mannose
Sp7-parental strain	0.20 b	5.0 c	12.7	24.1	17.6	25.5
Variant phv1	1.50 a	18.0 b	57.9	1.5	32.1	8.4
Variant phv2	1.60 a	18.5 b	32.7	56.2	3.5	7.4

*Values represent averages from three independent experiments, each with five replicates for each parameter. Different letters in each column indicate significant differences ($p = 0.05$).

†EPS were purified after 72 h of growth in D-fructose minimal medium. Results represent average ± standard deviation (SD) of the relative presence of each sugar (percentage) from two independent experiments.

(Modified from Volfson et al., 2013).

artificial iron chelator dipyridyl and the fungal siderophores ferrichrysin and coprogen (siderophores which cannot be used by the *A. brasilense* Sp7 wildtype for iron acquisition) (Hartmann, 1988). It has been proven that these isolates were no contaminants, because they showed identical restriction patterns as the wildtype in restriction analysis/pulsed-field gel electrophoresis (Hartmann et al., 1992). Although no detailed studies of genetic alterations were reported on these isolates, they can be considered as phenotypic variants in the light of the present knowledge. These observations indicated very early that there is a potential of considerable phenotypic plasticity in *A. brasilense* Sp7, which may be used applying specific selection pressure conditions to achieve more stress tolerant strains/variants.

More recently, the phenomenon of Pv was studied in more detail in spontaneous aggregation mutants of *A. brasilense* Sp7. This mutant, Sp7-, devoid of aggregation properties, was exposed to carbon starvation for 12 days. Colonies differing in pigmentation (pig), cell aggregation (agg) and EPS overproduction (EPS^{op}) were examined, as these phenotypes have been often associated with increased survival to different stresses in *A. brasilense* (Hartmann and Hurek, 1988; Hartmann et al., 1992; Fibach-Paldi et al., 2012; Lerner et al., 2010). Three different phenotypes were repeatedly observed, although with no indication of frequencies: agg-pig+ (variant $Sp7_2$), agg+pig- (variant $Sp7_3$), and agg-pig+EPS^{op} (variant $Sp7_E$). No differences were observed between LPS patterns of strains Sp7 and Sp7- and the variants $Sp7_2$ and $Sp7_3$; as for variant $Sp7_E$, it lacked the typical high-molecular-weight LPS commonly observed in LPS profiles of *A. brasilense* strains and showed instead modified forms of LPS with lower molecular weights (Lerner et al., 2010). Variant $Sp7_E$ showed significantly higher EPS concentrations (~threefold increase) than the parental strain and the other variants. All variants exhibited modifications in the content of monosaccharide composition of the EPS, the most dramatic changes being observed for $Sp7_E$. Variant $Sp7_E$ formed significantly more biofilm on glass than the parental strain, notably in high C/N ratio. As LPS and EPS contribute to protection against different stresses, variant $Sp7_E$ was further assessed for its ability to respond to several stresses. Variant $Sp7_E$ showed higher survival than the parental strain following exposure to heat (55 °C), osmotic pressure, and desiccation but higher sensitivity to UV radiation and hydrogen peroxide (Lerner et al., 2010). Differences in outer membrane protein (OMP) patterns were noticed between variant $Sp7_E$ and the parental strain Sp7-; interestingly, the OMP pattern of variant $Sp7_E$ displayed similarity with that of a Sp7 mutant altered in LPS biosynthesis (mutated in *noeJ* encoding mannose-6-phosphate isomerase) (Lerner et al., 2009). One can anticipate that such stress-induced events might occur in other *Azospirillum* strains too.

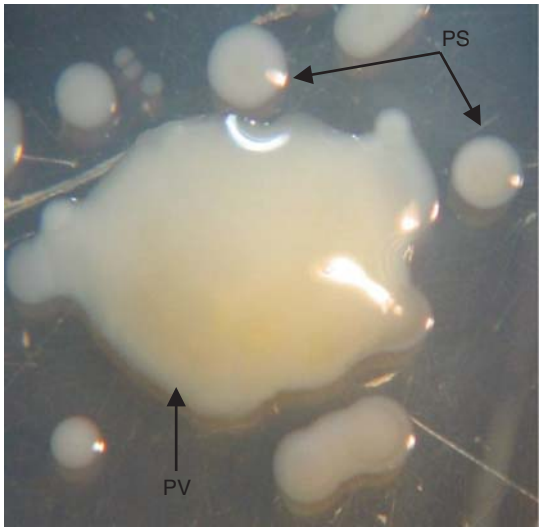

Figure 103.1 Phenotypic variant of *A. brasilense* Sp7. The parental strain (PS) forms a slightly mucoid colony, while isolated phenotypic variants (Pv) generally form exceedingly mucoid colonies as compared with the PS.

103.4 GENOMIC REARRANGEMENTS ASSOCIATED WITH PHENOTYPIC VARIATION IN *Azospirillum*

As Pv is often associated with genomic DNA rearrangements (van der Woude and Baumler, 2004; Wisniewski-Dyé and Vial, 2008), the occurrence of such rearrangements has been investigated in variants obtained from *Azospirillum* strains. Pulsed-field gel electrophoresis (PFGE) following restriction with different enzymes did not reveal any differences between *A. brasilense* Sp7- and its variants (Lerner et al., 2010). However, repetitive PCR (rep-PCR; Rademaker et al., 2000) did reveal differences between wild-type Sp7, Sp7-, and variants obtained from Sp7-. The three rep-PCR techniques (ERIC-, BOX-, and REP-PCR) employed clearly discriminated between strains/variants differing in their aggregation ability but not in pigmentation, suggesting that loss of aggregation involves DNA rearrangements. Variant $Sp7_3$ (agg+pig-) showed identical rep-PCR patterns than that of wild-type Sp7, suggesting that this variant could be a spontaneous revertant of Sp7 (agg-pig-) to Sp7 (agg+pig-) (Lerner et al., 2010). Variant $Sp7_E$ displayed a different plasmid profile from its parental strain, but whether these modifications in plasmid composition are linked to phenotypic alterations of $Sp7_E$ remains to be established. In addition, the genetic elements involved in DNA rearrangements are still to be characterized. In the EPS-overproducing variants of Sp7 obtained on fructose medium, different genetic alterations using ERIC- and BOX-PCR as well as RAPD analysis could also be evidenced (Volfson et al., 2013).

As for variants of *A. lipoferum*, a *recA* mutant of strain *A. lipoferum* 4B was first shown to keep the ability to generate variants *in vitro*. The variants from 4B*recA* exhibited all morphological and biochemical features characteristic of the $4V_I$ variant (Vial et al., 2004). However, the frequency of variants generated by 4B*recA* appeared to be increased by up to 10-fold, contrasting with many studies demonstrating the abolition or a large reduction of the frequency of Pv in *recA* mutants. To assess whether genomic rearrangements take place during Pv of *A. lipoferum* 4B, RAPD profiles were obtained for the parental strain and the $4V_I$ variant: differential bands were obtained, providing the first evidence for DNA rearrangements (Vial et al., 2006). Using probes targeting the differential RAPD bands, it was shown that the genome of the $4V_I$ variant had undergone a deletion event. PFGE analysis with adapted conditions of migration and hybridization experiments revealed that a 750-kb replicon was missing in the $4V_I$ genome. The same rearrangements took place during Pv of 4B*recA*. Large-scale genomic rearrangements during Pv were demonstrated for two additional strains. In *A. brasilense* WN1, generation of stable variants was correlated with the disappearance of a replicon of 260 kb. For *A. irakense* KBC1, emergence of the unstable variant coincided with the formation of a new replicon of 160 kb, whereas the revertant recovered the parental genomic architecture (Vial et al., 2006).

The genome sequence of *A. lipoferum* 4B later revealed that the 750-kb replicon lost in the $4V_I$ variant was a chromid (AZOLI_p2), representing 11% of the genome and harboring 640 genes (Wisniewski-Dyé et al., 2011). Several genes or operons, lost during the process of Pv, can account for the phenotypic modifications observed in the $4V_I$ variant or the strain 4T such as *acdS* encoding ACC deaminase activity and the *nosRDZFYL* operon which catalyzes the reduction of nitrous oxide to dinitrogen (i.e., the last step of denitrification). A gene cluster consisting of five genes (*napABCDE*) which encode a periplasmic nitrate reductase is also present on the 750-kb replicon suggesting that the $4V_I$ variant is also affected in nitrate reduction to nitrite, a feature observed for strain 4T. Interestingly, several genes located within the 750-kb replicon are predicted to be involved in flagellin biosynthesis and are possibly the genetic determinants underlying the difference of motility observed between 4B and $4V_I$ variant. Finally, gene content analysis of the 750-kb replicon highlights numerous clusters of genes likely involved in siderophore production and iron and siderophore transport (e.g., a 14-kb region, AZOLI_p20158 to AZOLI_p20165 is predicted to be involved in pyochelin synthesis) (Wisniewski-Dyé et al., 2012). This observation may explain the slow growth rate of *A. lipoferum* 4T (and probably that of $4V_I$ variant) under low iron concentrations (Alexandre, 1998).

Several other studies have shown that plasmids of *A. brasilense* were involved in frequent and major genomics rearrangements; the resulting strains, although sometimes called variants, might simply be the result of genetic drift or mutations induced by stress. Interestingly, differences in genomic architecture of *A. brasilense* Sp245 strains obtained from different laboratories collections could be attributed to plasmid plasticity (number and size, integration in other replicons) (Pothier et al., 2008; see also Chapter 25). For *A. brasilense* Sp245, spontaneous mutants characterized by the loss of 2 plasmids of 85 and 120 MDa and the generation of a new replicon of more than 300 MDa have also been observed (Katsy et al., 2002). *A. brasilense* Sp7 also generated *in vitro* spontaneous mutants with altered plasmid composition, notably a modification of the size of the pRhico plasmid (Petrova et al., 2005).

103.5 OCCURRENCE OF PHENOTYPIC VARIATION IN NATURAL ENVIRONMENTS AND POTENTIAL IMPACT ON RHIZOSPHERE COMPETENCE AND PLANT GROWTH-PROMOTING PROPERTIES OF *Azospirillum*

It has been discussed almost since the rediscovery of *A. brasilense* in the 1970s by Tarrand et al. (1978) that some of the strains deposited in culture collections are very closely related, like the type strain *A. brasilense* $Sp7^T$, a strain initially isolated from rhizosphere soil of *Digitaria decumbens* in Brazil (Tarrand et al., 1978), with the strain *A. brasilense* Cd. The strain Cd was originally isolated from roots of plants [*Cynodon dactylon*] which had been inoculated with *A. brasilense* Sp7. Strain Cd has a characteristic red pigmentation, while colonies of strain Sp7 are only slightly pink. In the meantime, isolates with different carotenoid pigment content could be quite frequently derived from *A. brasilense* Sp7. The high carotenoid content resulted in increased oxygen tolerance of the variants (Hartmann and Hurek, 1988). It was demonstrated that a point mutation in the antisigma factor (Thirunavukkarasu et al., 2008) is responsible for this phenotypic alterations, which has implications for the oxygen tolerance of the bacterium (Hartmann and Hurek, 1988). Thus, the strain Cd could be a phenotypic variant of Sp7 generated in the rhizosphere.

During the course of isolating variants from strain *A. brasilense* Sp7- (agg-pig-), a variant has been isolated after colonization of maize roots in a gnotobiotic system; this variant displayed the phenotype agg-pig+EPS^{op}, with a significant higher EPS concentrations than the parental strain and a modified pattern for LPS. This indicates that Pv of *A. brasilense* may occur after inoculation and one might anticipate that overproduction of EPS could contribute to improved colonization of plant roots. When EPS-overproducing phenotypic variants of Sp7 were inoculated to maize, wheat, soybean, and peanuts in pot experiments with sterilized and nitrogen-free sand in the greenhouse, the EPS-overproducing variants showed in most cases the same extent of plant growth promotion effects as compared to the Sp7 wild-type strain (Volfson et al., 2013).

A. lipoferum 4B has been isolated simultaneously from the same rice rhizosphere and at the same frequency than *A. lipoferum* 4T, a nonmotile strain displaying laccase activity (Bally et al., 1983), and both strains displayed identical 16S rDNA sequences (Haurat et al., 1994). The plasmid profile of *A. lipoferum* 4T was compared to that of *A. lipoferum* 4B and revealed only two discrepancies: absence of the 750-kb replicon [like in the $4V_I$ variant] and presence of an additional replicon of 400 kb unrelated to the 750-kb replicon (Vial et al., 2006). Thus, *A. lipoferum* 4T could in fact be a variant of strain 4B generated within the soil ecosystem. Interestingly, after inoculation of rice roots with *A. lipoferum* 4B, nonmotile forms appeared in high numbers. However, no analysis of other specific phenotypes has been undertaken to identify these nonmotile forms (Alexandre et al., 1996).

Loss of swimming ability in the $4V_I$ variant and in strain 4T was directly linked to enhanced swarming motility (Alexandre et al., 1999b). Thus, the nonswimming *Azospirillum* strains are expected to keep the ability to move along plant roots. Whereas swimming motility is thought to play a role in chemotaxis of bacteria to plant root exudates, swarming across the surfaces of the roots may be important for long-term colonization. Interestingly, *A. lipoferum* 4T was shown to retain the ability to efficiently colonize rice roots (such a data is not available for the $4V_I$ and $4V_{II}$ variants) (Alexandre et al., 1996).

Bacterial laccases are considered as an advantageous trait for a rhizosphere bacterium as they are involved in various functions such as copper resistance, manganese oxidation, pigmentation, oxidation of toxic compounds, and destruction of reactive oxygen species (Sharma et al., 2007). Interestingly, the first report of a prokaryotic laccase is from the nonmotile isolate *A. lipoferum* 4T (Givaudan et al., 1993), where it was shown to play a role in melanization and utilization of plant phenolic compounds (Faure et al., 1994; 1996). Moreover, laccase-positive strains are less sensitive to the inhibitory action of quinone analogs due to rearrangements of their respiratory chain, a feature that might be a competitive advantage in the rhizosphere (Alexandre et al., 1999a).

The 750-kb chromid lost by the $4V_I$ variant carries genes that are relevant for interaction with plants, notably *acdS* that has been acquired by horizontal gene transfer (Prigent-Combaret et al., 2008; Wisniewski-Dyé et al., 2011). AcdS, by deaminating ACC, the immediate precursor of plant ethylene, is a key activity involved in the modulation of the plant hormonal balance by rhizobacteria. Because ethylene inhibits root growth and may be produced in too large amounts during plant stress response, bacterial ACC deamination can enhance both root system development and plant stress tolerance (Glick et al., 2007). *acdS* elimination might be useful to fine-tune the effect of *Azospirillum* on the plant hormonal balance; however, this hypothesis remains to be investigated. The plant hormonal balance might also be modulated by *nahG*, a gene located onto the 750-kb chromid (AZOLI_p20435) and contributing to the degradation of salicylate into catechol (Wisniewski-Dyé et al., 2012). As for nitrogen fixation, the relevant genes are all located onto the chromosome of strain 4B (see Chapter 25), suggesting the same nitrogen fixation capacity for 4B and $4V_I$ variant.

The question whether Pv modifies soil survival, rhizosphere competence, and plant growth-promoting properties of *Azospirillum* spp. deserves intense attention. Most recently, the EPS-overproducing variants of strain Sp7 were

shown to display higher stress resistance, and its colonization abilities to plant roots and plant growth-promoting effects were not influenced as compared to the wild type (Volfson et al., 2013). Nevertheless, from an applicative point of view, one can wonder if Pv of *Azospirillum* could be associated with some inconsistencies in plant growth promotion observed in the field. Also whether Pv could be manipulated to improve the fitness and thus the quality of the inoculants of this bacterium remains an open question. However, the occurrence of Pv has to be shown convincingly in field situation at many different sites and seasons.

103.6 PHENOTYPIC VARIATION IN NON-DIAZOTROPHIC ROOT-ASSOCIATED BACTERIA

The occurrence of phenotypic and phase variation in rhizosphere colonizing *Pseudomonas* bacteria has been reviewed previously (van den Broek et al., 2005). *Pseudomonas* sp. bacteria show Pv quite frequently, based on spontaneous mutation of the *gacA* and *gacS* genes. It was clearly demonstrated that site-specific recombinases are implicated in the initial genetic event of creating mutations in the *gacA/gacS* genes. In the case of the biocontrol bacterium *Ps. fluorescens* F113, a mutation in site-specific recombinases encoded by the *sss* and *xerD* genes generated phenotypic variants at a very low frequency compared to the wild type strain, both under laboratory conditions and after plant inoculation (Sánchez-Contreras et al., 2002; Martínez-Granero et al., 2005). In addition, these phenotypic variants were severely impaired in competitive root colonization. Most interestingly, it could be demonstrated that the expression of these recombinases was induced in the presence of the plant (Martínez-Granero et al., 2005).

Pv in *Pseudomonas brassicacearum,* a major root-colonizing population in *Arabidopsis thaliana*, has a major role in the root-colonizing strategy. During the colonization of *A. thaliana* and *Brassica napus*, bacteria can be retrieved with different colony appearance (Achouak et al. 2004). While wild-type cells (phase I cells) were located at basal parts of the roots, bacteria from translucent colonies (phase II cells) were essentially localized at young roots and root tips, a result obtained using differentially fluorescence-labeled phase I and phase II cells. Accordingly, phase II cells showed a higher ability to swim and to swarm, due to an overproduction of flagellin (Achouak et al., 2004). Comparison of the transcriptomes of these phase I and II cells revealed several genes relevant for secondary metabolism and small RNAs. In addition, it turned out that point mutations in the *gacA* and *gacS* genes accounted for the observed phenotypic switching to phase II cells. This was accompanied by downregulation of antifungal secondary metabolites, indole acetate, and exoenzyme (lipase and protease) production. Interestingly, also the production of three *N*-acyl-homoserine lactone (AHL; see Chapter 37) molecules was drastically reduced (Lalaouna et al., 2012). Since these are key regulators of the quorum-sensing response, some of the observed differences in phase II cells, like diminished biofilm formation, alginate biosynthesis, or expression of the type VI secretion machinery, could be a consequence of the altered AHL levels. Thus, in many *Pseudomonas*, the GacA/GacS regulatory system is of key importance for phenotypic/phase variation. While screening the published genomes of *Azospirillum*, no indication of a *gacA/gacS* similar genetic system has been found (Wisniewski-Dyé et al., 2011). Therefore, a similar mechanism as basis of phenotypic switching is not expected in *Azospirillum*.

The β-proteobacterium *Acidovorax radicis* N35, which was isolated from surface-sterilized roots of wheat, was shown to have growth-promoting effects on barley (Li et al., 2011). When plated on NB agar, phenotypic variants occurred with a high frequency of 3.2×10^{-3} per cell per generation (Li et al., 2012). While the wild type had a rough colony type, variant colonies (N35v) were characterized by their smooth appearance. Most strikingly, the variants showed almost no cell aggregation and had lost their flagella and swarming ability; moreover, the variants were no longer effective as plant growth-promoting bacteria in barley pot experiments in the greenhouse (Li et al., 2012). Inoculation of roots with a mix of differently fluorescence-labeled wild-type N35 and variant N35v cells demonstrated that the variant had lost its competitive root colonization abilities. When the genome sequences of the N35 wild type and the N35v variant were compared, one deletion could be found in all tested variants. The *mutL* gene which plays a key role in mismatch repair was affected by a 16-nucleotide deletion resulting in the expression of a truncated, nonfunctional MutL protein. The shift from root to laboratory conditions may have triggered this mutation by a hitherto unknown mechanism. This led to increased mutation frequency which resulted in an accumulation of point mutations, as could be shown in the comparison of the genome sequences of the wild type and the variant strain. Thus, this is an example that during laboratory cultivation of root-associated or rhizosphere bacteria, the potential of plant growth promotion can be lost. Therefore, Pv could be considered as one reason for less efficient PGPR performance after cultivation under laboratory conditions or during biotechnological cell mass production to obtain large inoculum biomass. Pv also occurs in plant pathogenic bacteria. Interestingly, in a recent study, Pv was observed in the *A. radicis*-closely related species *A. citrulli*, a serious pathogen of cucurbit plants (Burdman and Walcott, 2012). Pv in this pathogen was shown to be associated with loss of the ability to produce type IV pili [T4P] and with a significant reduction in virulence (Kumar Shrestha et al., 2013).

103.7 CONCLUSIONS

The occurrence of Pv has to be considered, when bacteria are isolated from their natural habitat, like the root environment. While some bacterial isolates may keep their original properties well under laboratory conditions, others undergo quite rapidly major changes, because genetic mutations and rearrangements may occur at high frequency. This genome plasticity may be considered as intrinsic genetic mechanism to improve plant growth promotion as well as challenge to preserve optimized rhizosphere competitivity (Terzaghi and O'Hara, 1990). In laboratory and biotechnological mass production, this dynamics of the genome should be taken into account and kept under control as much as possible. However, the genome plasticity could also be considered as a chance to preselect for strains optimized for specific niches. The "training" of candidate strains for biotechnological applications in the "rhizosphere school" could also be seen as a case of Pv and adaptive mutations towards optimized properties. Future studies in the fields will show whether this adaptation and optimization approach taking advantage of Pv is a possible way for strain improvement to specific plant and soil requirements. Furthermore, extensive comparative genome sequencing experiments of wild type and phenotypic variants will bring much more insights into the underlying molecular and genetic mechanisms in different bacterial species.

Chapter 104

The Physiological Mechanisms of Desiccation Tolerance in Rhizobia

Andrea Casteriano, Meredith A. Wilkes, and Rosalind Deaker
Faculty of Agriculture and Environment, University of Sydney, Sydney, NSW, Australia

104.1 INTRODUCTION

Poor survival of rhizobial inoculants on legume seed has long been recognized and is a result of several factors including desiccation (Deaker et al., 2004; see Chapters 39, 96). Significant losses in viable cell numbers occur during the drying and storage of coated seed with cell survival dependent on the rate of drying, water activity, and relative humidity during storage (Deaker et al., 2012; Hartley et al., 2012). Peat cultures of rhizobia applied to the surface of seeds or beads have a greater rate of survival than cells from agar or liquid cultures (Deaker et al., 2004; Bullard et al., 2005; Albareda et al., 2008). Dart et al. (1969) suggested improved survival was due to cells being partially encapsulated within a protective matrix of peat particles when coated onto seeds. However, cells extracted from peat cultures also survive better than liquid-cultured cells when coated onto plastic beads (Feng et al., 2002). Adaptive changes observed in peat-cultured cells such as cell wall thickening and changes in protein expression, believed to result from nutrient- and oxygen-limiting conditions during growth, have been suggested to contribute to their higher rate of survival (Dart et al., 1969; Feng et al., 2002).

Rhizobia accumulate intracellular compounds referred to as compatible solutes, or osmoprotectants, as a response to both osmotic and desiccation stress (Vriezen et al., 2007; see Chapter 96). Compatible solutes can be either synthesized *de novo* by rhizobia or transported into the cell from the environment via active uptake systems. The intracellular accumulation of trehalose in rhizobia has been observed to significantly improve desiccation tolerance (Streeter, 2003; McIntyre et al., 2007; Streeter, 2007). Trehalose is a nonreducing disaccharide and is believed to maintain membrane structure through the formation of biological glasses which protect proteins and other macromolecules from denaturation during desiccation stress (Crowe et al., 1984).

The biosynthesis of trehalose in *Rhizobium leguminosarum* bv. *trifolii* NZP561 involves the TreYZ and OtsAB pathways, and mutants deficient in either pathway accumulate trehalose in amounts similar to the wild type. However, double mutants fail to accumulate any trehalose and are also more sensitive to desiccation stress (McIntyre et al., 2007). The amount of accumulated intracellular trehalose varies between strains, species, growth stages, and conditions. Streeter (1985) reported that *Rhizobium japonicum* USDA110 and USDA138 accumulated more trehalose than USDA123 when ammonium nitrate was used as a source of nitrogen, compared with urea or glutamate. However, no explanation was given for this variation in trehalose accumulation as a result of the different nitrogen sources in the growth medium. In *R. leguminosarum* bv. *trifolii* NZP561, peak trehalose concentrations are reached in the early stationary phase of growth and decline during stationary phase due to catabolism as carbon in the growth medium becomes depleted (McIntyre et al., 2007).

Previous studies have reported that increasing the osmotic pressure of the growth medium through the addition of solutes such as sodium chloride increases the amount of accumulated trehalose in *R. leguminosarum* bv. *trifolii* TA1 (135 $\mu g\, mg^{-1}$ protein) and *Rhizobium meliloti* SU47 (280 $\mu g\, mg^{-1}$ protein) (Breedveld et al., 1991; Breedveld et al., 1993). Similarly, Streeter (2007) found that adding 40 mM sodium chloride to the medium, increased trehalose accumulation in bradyrhizobia by two- to threefold and

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

that trehalose content gradually increased with further additions of sodium chloride up to 60 mM. However, growth of bradyrhizobia was significantly reduced when grown in basal medium containing 60 mM sodium chloride.

The addition of 3 mM trehalose to the growth medium increased intracellular trehalose concentration by threefold in cultures of *B. japonicum* USDA110. Increasing the exogenous trehalose concentration to 6 or 9 mM increased the trehalose content by five- to sixfold, respectively (Streeter, 2003). It was concluded that although USDA110 does not grow when trehalose is the sole source of carbon, it is able to accumulate the sugar at a slow rate in response to increased external osmotic pressure as a way of maintaining an isosmotic equilibrium. In a subsequent study, Streeter (2007) found that sodium chloride and trehalose had a cumulative effect when added to the medium. The addition of 40 mM sodium chloride and 3 mM trehalose resulted in a fivefold increase in trehalose accumulation in *B. japonicum*.

Evidence suggests that increased amounts of intracellular trehalose, whether synthesized or taken up by the cells from the growth medium, play an important role in desiccation tolerance. Survival of bradyrhizobia was highly correlated to the accumulation of increasing amounts of trehalose (Streeter, 2007). A two- to threefold increase in intracellular trehalose resulted in a 294% increase in survival of USDA110 after 24 h desiccation on soybean seed (Streeter, 2003).

In a separate study using NZP561, there was 70% recovery of cells immediately after air-drying when intracellular trehalose was synthesized by the wildtype. Intracellular trehalose was not detected in the *ots*A and *tre*Y double mutant, and cell recovery was 63%. Twenty-four hours after drying, recovery of viable cells was 39% for the NZP561 wild type and <0.001% for the double mutant, clearly indicating the role of trehalose in improved desiccation tolerance (McIntyre et al., 2007).

This study examined the growth conditions that affect trehalose accumulation in *R. leguminosarum* bv. *trifolii* (TA1) and *B. japonicum* (CB1809) and its role in desiccation tolerance. Physical and biochemical changes in cells exposed to the different growth conditions were then examined using vital staining, electron microscopy, and proteomic techniques.

104.2 METHODS

The osmotic pressure of JMM-defined medium (O'Hara et al., 1989) was altered through the addition of increasing concentrations of sodium chloride and trehalose. Osmotic pressure of the growth medium was estimated using Equation (104.1):

$$\pi = MRT \tag{104.1}$$

where π = osmotic pressure (atm), M = molarity of solutes (mol/L), R = ideal gas constant (0.0821 L atm/K mol), and T = Kelvin temperature (°C + 273) (Zumdahl, 1989).

Aqueous peat extract (50%, w/v) was used as a growth medium and was prepared by suspending gamma-sterilized peat in Milli-Q water. Cells of TA1 and CB1809 were grown aerobically in the different liquid media to early stationary phase and harvested through centrifugation. Desiccation tolerance was assessed by resuspending the harvested cells in water and drying under vacuum (Deaker et al., 2007). Trehalose accumulation at early stationary phase of growth was measured using a trehalose assay kit from Megazyme® according to the manufacturer's instructions. The effect of different growth media on membrane integrity was assessed using a LIVE/DEAD® BacLight™ Bacterial Viability Kit (L7012) according to the manufacturer's instructions. Cell morphology was examined by electron transmission microscopy using a JEOL 1400 electron microscope. SDS-PAGE was performed as described by Laemmli (1970), and peptide analysis carried out by liquid chromatography–mass spectrometry (LC–MS) using a C18 reversed-phase liquid chromatography coupled to a Q-TOF mass spectrometer. Details of the materials and procedures are as previously described by Casteriano et al. (2013).

104.3 RESULTS

104.3.1 Trehalose Accumulation in Rhizobia

Increasing the osmotic pressure of a defined growth medium (JMM) showed that trehalose accumulation increases as osmotic pressure increases (Fig. 104.1). Trehalose accumulation increased by 6- to 12-fold for TA1 and 3- to 5-fold for CB1809 in comparison to the control.

Trehalose accumulation was greater in TA1 and CB1809 cells grown in an aqueous peat extract compared to cells grown in the control medium (JMM). Cells of CB1809 grown in peat extract accumulated 150 ng of trehalose/μg of protein, which was 8-fold greater than that of cells grown in the control medium (JMM). Growing TA1 in crude peat extract increased trehalose accumulation by 5-fold in comparison to the amount accumulated by cells grown in the control medium (3.2 ng/μg protein).

104.3.2 Desiccation Tolerance in Rhizobia

The percentage of viable rhizobia immediately after drying was higher for cells grown at 2.5 atm compared to those grown in the control medium, as shown in Figure 104.2. However, this increase in survival was not found to be significant for either strain after analysis of variance (ANOVA).

Survival of TA1 was significantly improved immediately after drying and after 7 and 21 days in storage

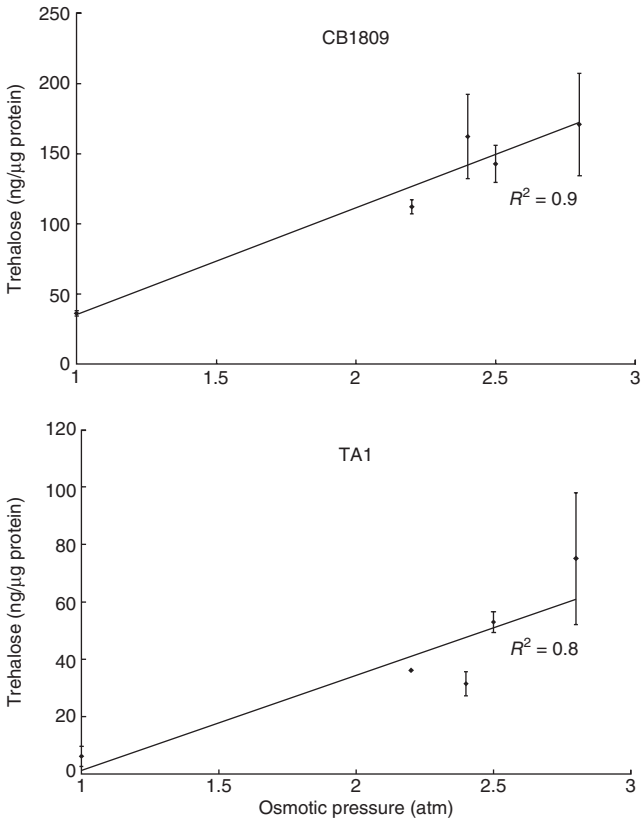

Figure 104.1 The effect of osmotic pressure on trehalose accumulation in rhizobia. Data points are the mean value of three replicate treatments and extractions ± SE (absence of error bars indicates that the error bar was less than the data point).

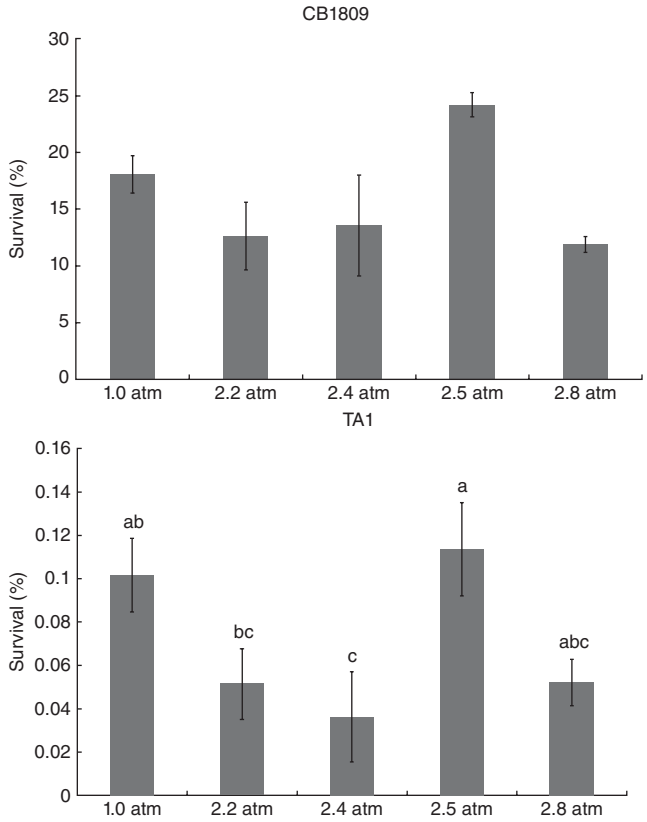

Figure 104.2 Survival of rhizobia immediately after vacuum drying. Cells were grown at increasing osmotic pressure with cells grown at 1.0 atm used as the control. Data shown are mean values of three replicates ± SE. Values with the same letter are not significantly different. Survival of CB1809 was not found to be significantly different ($p > 0.05$).

in 9% relative humidity when cells were grown in peat extract compared to that of the control. Survival of CB1809 grown in peat extract was not significantly improved after drying or during storage when compared to the control (Table 104.1).

104.3.3 The Effect of Growth Media on Membrane Integrity

A comparative analysis of the mean green-to-red fluorescence ratio (G/R_{Ratio}) between the growth media treatments was made using ANOVA for 10^5 cells of TA1 and 10^7 cells of CB1809 (Fig. 104.3). Analysis of the data showed that the ratio of TA1 cells grown in JMM medium (1.0 atm) was significantly higher than that of cells grown in the treatment media. No significant difference in the G/R_{Ratio} was found between cells grown at 2.5 atm and peat extract.

ANOVA of the G/R_{Ratio} for CB1809 showed that the ratio of cells grown at 2.5 atm was significantly higher than that of cells grown in the control and peat extract. The G/R_{Ratio} for cells grown in peat extract was significantly lower than that of cells grown in the control medium.

Table 104.1 The effect of growth medium on survival of Rhizobia after drying and storage

Strain and Growth Media	Initial	After Drying	7 Days in Storage	21 Days in Storage
TA1 (Control)	8.68	5.28	2.77	2.57
TA1 (Peat extract)	8.52	6.38	4.48	4.18
$P < 0.001$; LSD = 0.51				
CB1809 (Control)	9.08	8.36	7.50	7.32
CB1809 (Peat extract)	8.37	7.98	7.38	7.10
$P < 0.05$; LSD = 0.34				

The data are predicted mean values ($\log_{10}$ CFU/mL) of viable cells obtained using Residual Maximum Likelihood (REML) analysis

104.3.4 Changes in Cell Morphology and Protein Expression

Cells of TA1 grown in peat extract were found to be significantly smaller in length (0.87 µm) than cells grown in

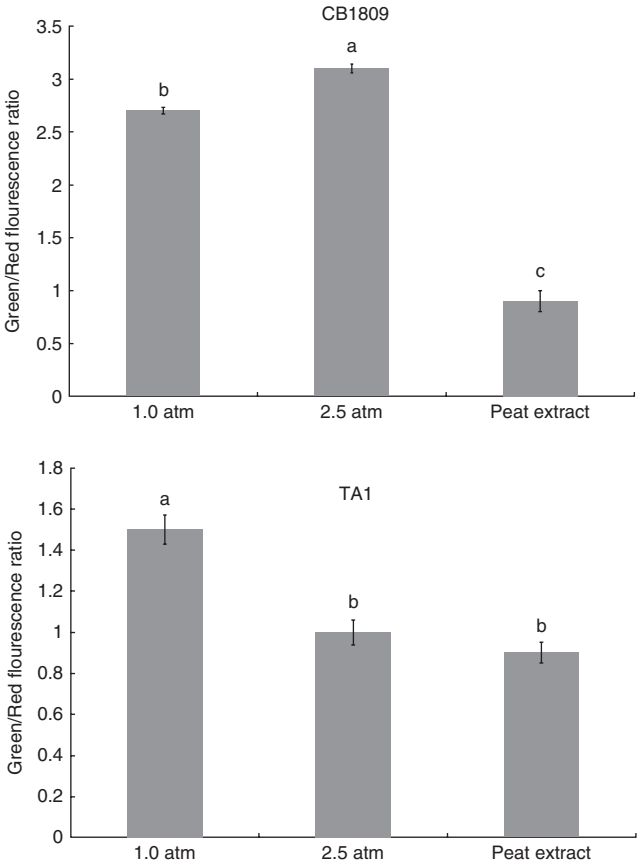

Figure 104.3 Membrane integrity assay using LIVE/DEAD staining. Values are the mean ratio of green-to-red fluorescence of three replicates ± SE. Columns with the same letter are not significantly different.

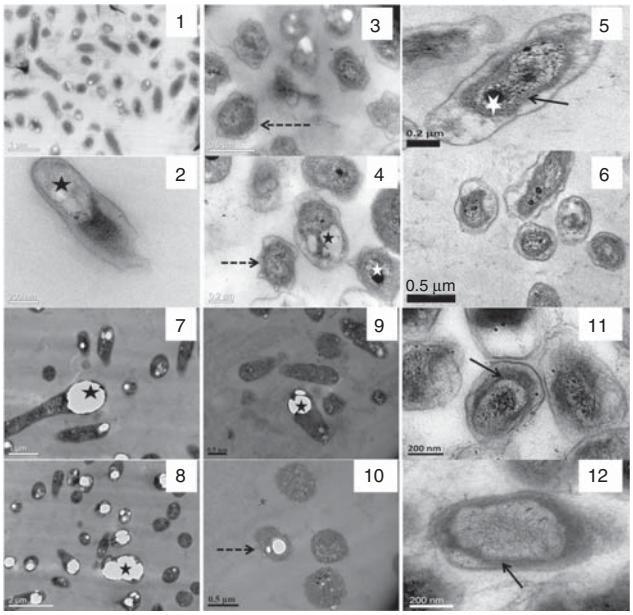

Figure 104.4 Transmission electron micrographs of rhizobia at early stationary phase of growth. 1 and 2 = CB1809 grown in JMM (1.0 atm); 3 and 4 = CB1809 grown in JMM (2.5 atm); 5 and 6 = CB1809 grown in crude peat extract; 7 and 8 = TA1 grown in JMM (1.0atm); 9 and 10 = TA1 grown in JMM (2.5 atm); 11 and 12 = TA1 grown in crude peat extract.

JMM media. The cell size of CB1809 grown in the treatment media was not significantly different to that of the control. The observed cells of rhizobia grown at 2.5 atm had noticeable undulations in the outer membrane, giving them the appearance of plasmolyzed cells, illustrated in Figure 104.4(3),(4),(9), and (10).

The cytoplasm of rhizobia grown in JMM media contained electron-dense inclusion bodies as well as abundant PHB granules (Fig. 104.4(2),(4),(7), and (9)). Although the cytoplasm of cells grown in peat extract was also found to contain electron-dense inclusions, PHB granules were less abundant than in cells grown in JMM media.

A concentration of electron-dense material was observed around the plasma membrane of cells grown in peat extract, giving the plasma membrane a more defined appearance (Fig. 104.4(5)(6)(11), and (12)).

Total protein extracts from cells of TA1 and CB1809 grown to early stationary phase in JMM media (1.0 and 2.5 atm) and peat extract were separated using one-dimensional (1D) SDS-PAGE (Fig. 104.5). Proteomic analysis showed that 25% of the bands analyzed for TA1 were downregulated in cells grown in the treatment media, while 67% were upregulated when compared to the control. Analysis of eight protein bands, differentially expressed in CB1809, showed that 63% of the bands were downregulated and 50% upregulated in the treatment media when compared to the control.

The comigration of proteins was identified in this analysis; therefore, it is difficult to conclude with certainty which protein or proteins are contributing to the observed changes in polypeptide band expression when rhizobia were exposed to stress. However, it is interesting to note the proteins that change in response to growth in the treatment media and to suggest possible mechanisms for their contribution to the observed improvements in desiccation tolerance. Among the peptides identified in the upregulated bands of rhizobia grown in the treatment media were proteins involved in the prevention and repair of oxidative damage, as well as proteins involved in the maintenance of membrane integrity (Table 104.2).

104.4 DISCUSSION

In this study, increased osmotic pressure of the growth medium increased trehalose accumulation in rhizobia which

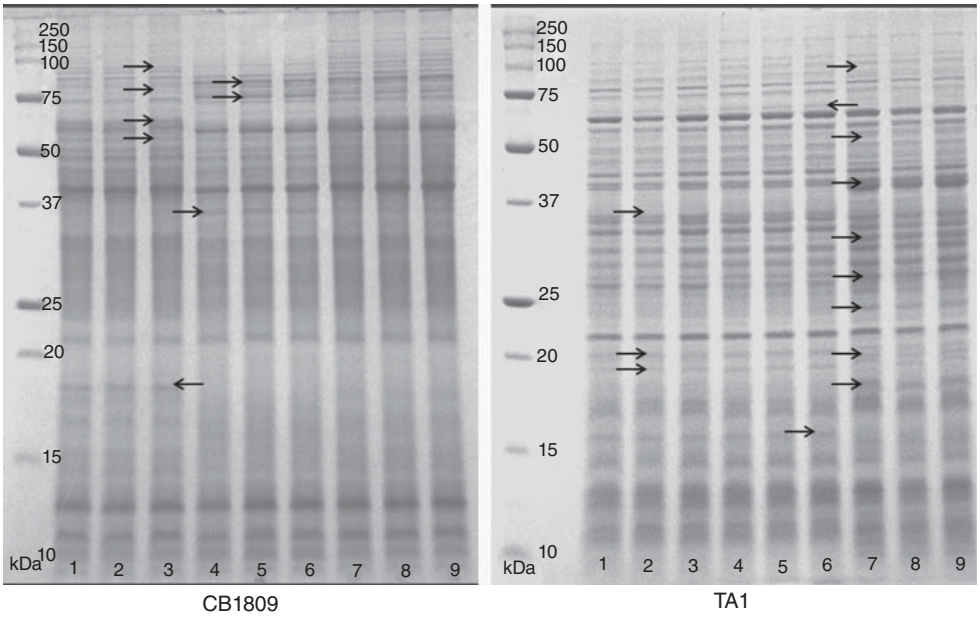

Figure 104.5 SDS-PAGE of total cell protein extracts from CB1809 and TA1 cells grown in different media. Cells of CB1809 were grown in JMM (lanes 4–6), JMM (2.5 atm) (lanes 7–9), and peat extract (lanes 1–3). Cells of TA1 were grown in JMM (lanes 1–3), JMM (2.5 atm) (lanes 4–6), and crude peat extract (lanes 7–9). Each lane corresponds to a single replicate growth treatment and protein extraction.

Table 104.2 Peptides of interest identified in response to growing rhizobia in treatment media (JMM 2.5 atm and crude peat extract) in comparison to the control

	CB1809		TA1	
	Protein	Function	Protein	Function
Upregulated	Lon protease	Protects DNA by degrading abnormal proteins	Phage shock (PspA)	Maintains membrane potential
	DNA-binding Dps family	Protects against oxidative stress	ATP-dependent Clp protease	Proteolytic activity
	60 kDa chaperonin	Prevents misfolding of peptides generated under stress	Thioredoxin	Oxidative stress protection
			Organic solvent Tolerance	Combats periplasmic stress
			60 kDa chaperonin	Prevents misfolding of peptides generated under stress
Downregulated	ABC transporter sugar binding	Transporter	Solute-binding component ABC	Transporter
	TonB receptor Hemin receptor	Iron transport	Ribosome recycling factor	Ribosome recycling after protein synthesis

supports previously published reports that rhizobia accumulate trehalose in response to osmotic stress (Breedveld et al., 1991; Breedveld et al., 1993; Streeter, 2003; Streeter, 2007).

The accumulation of intracellular trehalose by *B. japonicum* USDA110 was increased by supplying trehalose in the growth medium. In turn, the survival of trehalose-loaded cells was significantly greater than that of nonloaded cells 24 h after they were coated onto soybean seeds and air-dried (Streeter, 2003). McIntyre et al. (2007) reported that NZP561 (wild type) survived significantly better than the *ots*A and *tre*Y mutant strain after drying on glass beads and after storage for 24 hours at 5% and 32% relative humidity.

Our findings show that trehalose accumulation did not result in improved desiccation tolerance immediately after vacuum drying when cells were grown in defined medium with altered osmotic pressure. However, trehalose-loaded cells did survive significantly better after 10 days in storage at 9% relative humidity (data not shown).

Growing rhizobia in peat extract increased trehalose accumulation and survival of TA1 when compared to the control. Survival was not significantly improved for CB1809.

Although trehalose appears to play an important role in desiccation tolerance, the variation in survival of trehalose-loaded cells indicates that additional protective mechanisms are required to improve survival.

The results of the membrane integrity study showed that cells of TA1 and CB1809 grown in JMM medium have a greater ability to exclude propidium iodide (PI) than cells grown in peat extract. PI has been widely used in cell viability studies on the assumption that it is excluded from cells by intact membranes. According to this assumption, the results of this study infer that growing cells in peat extract compromises the integrity of membranes as the G/R_{Ratio} is significantly lower than that of the control cells. However, in this current study, growing rhizobia and in particular TA1 in peat extract was found to consistently increase desiccation tolerance.

Salema et al. (1982) reported that the process of drying and rehydration resulted in the rupture of the TA1 cell envelope causing death. Hence, to be able to withstand the process of drying and rehydration, cells must have a healthy cell envelope in order to remain viable. The reliability of PI as an indicator of membrane integrity must therefore be assessed keeping in mind that membrane integrity assays have been optimized for a limited number of bacterial species.

Previous reports on *Saccharomyces cerevisiae* indicate that cells under stress conditions can become more permeable to PI without loss of viability (Davey and Hexley, 2011). They found that exposing *S. cerevisiae* to heat stress resulted in 23% increase in PI uptake. However, removing the stress and allowing cells to recover for 1 hour prior to staining showed that only 14% of the cells remained permeable to PI. Similarly, cells exposed to ethanol and SDS became more permeable to PI, and removing the stressor prior to staining decreased PI uptake. They concluded that environmental stresses can cause reversible changes to membrane function and permeability, demonstrated by the changes in PI uptake.

Osmotic treatment of *S. cerevisiae* has been shown to lead to changes in membrane permeability resulting from the phase separation of phospholipids (Simonin et al., 2007). In this study, the cell envelope of TA1 was more permeable to PI after growth at higher osmotic pressure (2.5 atm). However, that was not the case for cells of CB1809 grown under the same osmotic conditions. It is difficult to suggest with certainty that cells grown in peat extract were also under osmotic stress as the osmotic pressure of that medium was unknown. Other chemical stressors present in peat may have been responsible for the possible changes to membrane permeability in those cells.

Heipieper et al. (1991) found that sublethal concentrations of phenolic compounds not only restricted growth of *E. coli* K12 but could increase membrane permeability. They observed the loss of ATP and nucleotides at both sublethal and lethal concentrations of phenolic compounds. Acidic phenols and tannins have been found to not only delay growth in *Lactobacillus plantarum* but also alter membrane fluidity. When acidic phenols were added to the medium, changes in the fatty acid composition of cells similar to that in response to low temperature and high alcohol concentrations were observed. Conversely, tannins added to the growth medium of *L. plantarum* had an effect on fatty acid composition and membrane fluidity comparable to that of increasing the temperature of the growth medium (Rozes and Peres, 1998). Henis et al. (1964) found that the tannin fraction of carob pod extract inhibited the growth of *C. fulvus*. Tannins are high-molecular-weight substances which form insoluble complexes with proteins. The mechanisms by which tannins inhibit growth were suggested to either be by adsorbing on their surface or by penetrating the cell wall and reacting with its components.

Peat is rich in phenolic compounds and tannins which would be expected to be also found in the extract. It is possible that these chemical constituents of peat affected the membrane permeability of rhizobial cells grown in the extract. PI uptake by rhizobial cells grown at 2.5 atm and in peat extract in this study may not indicate a decrease in membrane integrity as both growth treatments did not reduce their capacity for desiccation tolerance.

Transmission electron microscopy showed distinct changes in the cell morphology of rhizobia grown in peat extract. The accumulation of electron-dense material around the plasma membrane has previously been described in rhizobia extracted from peat (Dart et al., 1969; Feng et al., 2002). Those changes, believed to be an adaptive response to solid-state fermentation, have been suggested to contribute to their greater capacity for survival. Our findings suggest that the observed morphological changes are an adaptive response to the water-extractable constituents of peat.

Cytryn et al. (2007) reported on the genome-wide transcriptional analysis of *B. japonicum* USDA 110 in response to desiccation stress and concluded that trehalose accumulation, together with the expression of polypeptides such as membrane-protective proteins, DNA repair proteins, and oxidative stress responses, was necessary for desiccation tolerance.

Identification of proteins in rhizobia grown in crude peat extract and 2.5 atm showed an increase in proteins generated as a response to environmental stress compared with the control cells. Among several of the proteins identified in rhizobia grown in treatment media were two proteins

regulated by sigma factor o'^{E}, which typically regulates genes required to combat stress in the periplasmic space of *E. coli* (Abe et al., 2003; Aono et al., 1994; Dartigalongue et al., 2001). Phage shock protein A, or PspA, and OstA (organic solvent tolerance protein) are membrane-associated proteins. PspA maintains membrane potential by preventing proton leakage from damaged membranes (Kobayashi et al., 2007). It is expressed under membrane stress conditions such as growing cells in the presence of organic solvents, osmotic and heat stress (Kobayashi et al., 1998). OstA maintains cell envelope structure and is required for cell division, and its absence leads to loss of membrane integrity and consequently cell lysis (Braun and Silhavy, 2002). The increased expression of OstA and PspA may explain the morphological changes observed in the envelope of cells grown in crude peat extract and their increased capacity for desiccation tolerance. It could be suggested that physical damage to the cell envelope during drying and upon rehydration is minimized in peat extract-grown cells as a result of the maintenance of membrane potential and structure by OstA and PspA.

Other proteins induced in rhizobia after growth in crude peat extract and 2.5 atm include proteins which prevent DNA damage such as lon protease, thioredoxin, and DNA-binding stress response protein from the Dps family. Lon protease protects DNA from damage by degrading abnormal proteins, and ATP-dependent protease mutants of *E. coli* have been found to be more sensitive to DNA damage (Torres-Cabassa and Gottesman, 1987). Thioredoxin lowers reactive oxygen species levels (Hübner et al., 1996; Pauly et al., 2006), and DNA-binding stress response protein from the Dps family has been demonstrated to provide protection against oxidative stress (Chen and Helmann, 1995). Feng et al. (2002) also reported that superoxide dismutase was upregulated in peat cultures of rhizobia and suggested that this protein could be involved in improved survival through the protection of cells from oxidative damage.

Cytryn et al. (2007) found that genes induced in *B. japonicum* by desiccation stress encoded sugar transporter proteins and a 60 kDa chaperonin. Chaperonins have been shown to assist in the proper folding of misfolded or unfolded polypeptides generated under stress (Gutsche et al., 1999). These proteins were upregulated in both strains of rhizobia as a result of growth in crude peat extract in this current study, and their presence warrants further investigation in future proteomic or transcriptomic studies.

104.5 CONCLUSION

Desiccation tolerance in rhizobia may be enhanced through the manipulation of the growth medium. Trehalose accumulation, while playing an important role in desiccation tolerance, requires other poorly characterized processes to significantly improve survival. Growing rhizobia in peat extract appears to promote morphological changes and the upregulation of proteins involved in prevention and repair of desiccation-induced damage. This study provides a preliminary insight to the characterization of stress response protein expression which should be targeted through the use of more discriminatory techniques. Future work should also focus on the constituents of peat extract which appear to promote adaptive responses in rhizobia linked to enhanced desiccation tolerance.

105.1 INTRODUCTION

In Africa, many grain legumes (both cultivated and wild) are consumed as food, especially during periods of food insecurity as a result of drought, flooding, or civil strife. The commonly cultivated food grain legumes include cowpea (*Vigna unguiculata* L. Walp.), Bambara groundnut (*Vigna subterranea* Verdc.), groundnut (*Arachis hypogea* L.), soybean (*Glycine max* L.Merr.), Kersting's bean (*Macrotyloma geocarpum* L.), and African yam bean (*Sphenostylis stenocarpa L.*). Many parts of these legumes are eaten as food. For example, the leaves and fresh mature pods of cowpea are eaten as a vegetable, while the dry grain is used in various food preparations. Nutritionally, there is about 35–40% protein in cowpea leaves; the grain also contains about 34% protein and 57% carbohydrate (Dakora, 2013).

Of the undomesticated grain legumes currently used as food security crops in Africa, fourteen are *Vigna* species. The tubers of *V. lobatifolia, V. reticulata*, *V. fischeri*, *V. vexillata, V. ambacensis, V. marina*, and *V. stenophylla* are harvested as food, in addition to the grain of *V. reticuleata*, *V. vexillata*, *V. juncea*, *V. gracilis*, *V. membranacea*, and *V, radiata,* which is consumed as pulse (Dakora, 2013). Nutritionally, the tubers of *V. lobatifolia, V. vexillata* and the African yam bean (*S. stenocarpa*) contain up to 15% protein, a level six times greater than that of cassava and three times than that of Irish potato or sweet potato (Dakora, 2013). Marama bean (*Tylosema esculentum* L.), an unimproved legume native to Southern Africa, produces grain containing 30–39% protein compared with the highly improved soybean with 38–40% protein and 43% oil compared with groundnut which has 48% oil (Dakora, 2013). Food legumes are high in dietary protein and fiber, but low in cholesterol, traits that are nutritionally ideal for good health.

In addition to their role as food in human nutrition, legumes are also used as high-protein feed and forage for livestock production. In many parts of the arid, semiarid and sahelian Africa, residues of food grain legumes are collected

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

after harvest and used as feed for livestock during the dry season. Tree and shrub legumes are of particular importance as forage plants for animal production in arid, semi-arid and sahelian Africa. *Acacia albida, A. senegal*, and *A. karroo* are examples of leguminous species that serve as high-protein forage for livestock and wildlife, the latter being very important for ecotourism in Africa. Grain, shrub and tree legumes do serve as high-protein food and nutriceuticals for human consumption and high-protein fodder/forage for livestock production. This is because they display an ability to fix N_2 in root nodules when in association with specialized soil bacteria belonging to the genera *Rhizobium, Bradyrhizobium, Sinorhizobium* (*Ensife*r), *Azorhizobium*, and *Mesorhizobium*.

105.2 N_2 FIXATION AND N CONTRIBUTION BY FOOD GRAIN LEGUMES IN CROPPING SYSTEMS

In the past, measurements of N_2 fixation in nodulated legumes have largely centered on only a few genotypes or varieties, often leading to over generalization on their symbiotic performance under various agronomic/ecological conditions. As noted with quantification of N fixed, past inoculation studies often involving one or two varieties of grain legumes have also resulted in the generalized view that these species do not respond to inoculation. Today, many estimates of N_2 fixation by nodulated legumes in experimental field plots have tended to use a large number of legume genotypes (Table 105.1) with a greater chance of obtaining more representative results. Recent data on N_2 fixation and N contribution by food grain legumes in Africa, measured using the ^{15}N natural abundance technique, are summarized in Table 105.1.

The quantification of N_2 fixation by up to 32 cowpea varieties in Africa has revealed large differences in symbiotic functioning between and among genotypes. Although the 30 cowpea varieties planted at Taung in South Africa and at Wa and Manga in Ghana in 2005 were the same material, the percent N derived from fixation (%Ndfa) differed between locations and ranged from 8–60% at Manga in Ghana to 50–81% at Taung in South Africa and to 64–87% at Wa in Ghana (Table 105.1). The percent N obtained from fixation in 2005 for 15 genotypes planted at the three locations were 30–67% at Taung, 57–89% at Manga, and 56–96% at Wa. These %Ndfa values suggest that, in Africa, cowpea derives a large proportion of its N nutrition from symbiotic fixation.

Other grain legumes whose symbiotic performance has been assessed in Africa include groundnut, mungbean, pigeonpea, soybean, and chickpea. The evaluation of 25 groundnut varieties at three locations in 2010 revealed %Ndfa values ranging from 33–51% at Mzinti to 41–59% at Nelspruit and to 47–67% at Klipplaatdrift in South Africa. Fifteen field-grown mung bean genotypes also showed high levels of N_2 fixation at two locations, with %Ndfa values varying from 66–80% at Nelspruit to 71–86% at Klipplaatdrift in 2011 (Table 105.1), indicating once again that this species has a high dependency on N_2 fixation for its N nutrition. Similarly high levels of dependency (65–74%) on symbiotic N nutrition were obtained when 15 pigeon pea varieties were assessed for N_2 fixation at Nelspruit in South Africa (Table 105.1). Of the soybean varieties evaluated, the promiscuous-nodulating tropical glycine crosses derived between 54% and 63% of their N nutrition from symbiotic fixation in Ghana, while 13 strict-nodulating genotypes (which require rhizobial inoculation) obtained 39–83% of their N from fixation at Vredefort, 60–96% at Balfour, and 60–96% at Bergville in South Africa (Table 105.1; see also Chapter 99). While more studies are needed to properly compare the performance of the two soybean types in Africa, the promiscuous-nodulating genotypes appear to produce less symbiotic N relative to the strict-nodulating varieties. Twenty-six genotypes of chickpea (kabuli) also exhibited large differences in their dependency on N_2 fixation for N nutrition, with %Ndfa values ranging from 3–91% at Klipplaatdrift to 14–86% at Nelspruit and to 27–72% at Mzinti in the Mpumalanga Province (Table 105.1), indicating genotypic variation in symbiotic response to the different sites.

The variation in N_2 fixation observed between legume species and genotypes in the different experimental environments could relate to biotic and abiotic factors, which include the soil moisture and temperature, the level of mineral nutrients in plant rhizosphere, the soil mineral N, the varietal differences, as well as the presence, size, and efficacy of root nodule bacterial populations in the soil (Dakora and Keya, 1997). There is evidence to show that rhizobial biodiversity is greater where legume diversity is high (Pule-Meulenberg et al., 2010). This was exemplified in a recent study, where we found greater cowpea rhizobial diversity in South Africa compared to Ghana and Botswana, which have a relatively low plant biodiversity compared to the high legume diversity and endemicity in South Africa (Pule-Meulenberg et al., 2010). Furthermore, rhizobial IGS type symbiotic efficiency can differ considerably even within the same location. Estimates of rhizobial strain IGS type symbiotic efficiency revealed marked differences in symbiotic N yield independent of single or multiple nodule occupancies (Pule-Meulenberg et al., 2010). For example, strain IGS type XI produced greater symbiotic N in soybean genotype TGx1445-3E as sole nodule occupant, in contrast with nine strain IGS types in root nodules of the highly promiscuous genotype Salintuya-1 that produced less symbiotic N (Pule-Meulenberg et al., 2010).

As found for %Ndfa, there was a large variation in N contribution by the different genotypes of cowpea, soybean, pigeon pea, groundnut, and mung bean evaluated in field

experiments (Table 105.1). Where 30 cowpea genotypes were assessed at three locations in Ghana and South Africa, in general, the data showed greater symbiotic N yield at Wa in Ghana in 2005 and 2006, followed by Taung in South Africa and then Manga in Ghana (Table 105.1). Some cowpea genotypes such as IT84S-2246, Glenda, Fahari, and IT90K-59 were found to be high grain yielding and high N_2 fixers across the three locations. The genotype IT84S-2246 could, for example, produce as much as 146, 175, and 111 kg N ha^{-1} at Wa, Manga, and Taung, respectively. The genotype Glenda also fixed 109 and 102 kg N ha^{-1} at Wa and Taung, Fahari 105 and 159 kg N ha^{-1} at Manga and Taung, and IT90K-59 106 and 114 kg N ha^{-1} at Wa and Manga, respectively. These high-yielding, high N_2-fixing cowpea genotypes could serve as food security crops as well as biofertilizers for improving soil fertility in African cropping systems. There was a similar pattern in N contribution by 13 soybean, 25 groundnut, 15 mung bean, and 26 chickpea (kabuli) genotypes evaluated at two to three locations in South Africa (Table 105.1). Unlike the other genotypes, soybean and chickpea were inoculated to ensure nodulation and N_2 fixation. Although they exhibited high levels of symbiotic dependency on N_2 fixation for their N nutrition (up to 72, 86, and 92% at the three different experimental sites), the 26 chickpea genotypes evaluated in South Africa recorded the lowest amounts of N fixed (0.1–34 kg N ha^{-1}) when compared to other legume species, indicating that this grain legume is less likely to make a significant contribution to the N economy of cropping systems in Southern African region.

Some studies have also been carried out on N_2 fixation and N contribution by grain legumes in farmers' fields in the African continent. The food legumes studied under farmer conditions include cowpea, Bambara groundnut, soybean, groundnut, and common bean (Table 105.2). On average, Bambara groundnut could derive between 49% and 72% of its N nutrition from symbiosis in farmers' fields in Zambia, 33% to 98% in South Africa, and 36% to 40% in Botswana, while cowpea obtained 31–70% in Zambia and 13–87% in 2005 and 29–92% in 2006 in Botswana (Table 105.2). The proportion of N derived from the atmosphere by soybean for its N nutrition was 32–96% in South Africa and groundnut 32–47%. Despite the relatively high levels of dependency on N_2 fixation for the N nutrition of grain legumes from farmers' fields, their N contribution was generally low (Table 105.2) due to the low legume plant density in the cropping system. With cowpea in Ghana, for example, plants derived as much as 66-90% of their N nutrition from symbiosis in farmers' fields and yet contributed only 17–23 kg N ha^{-1} (Table 105.2). This suggests that the low N contribution is not from poor symbiotic functioning, but

rather from low legume plant density, which affected dry matter yield.

105.3 N_2-FIXING EFFICIENCY AND MINERAL ACCMULATION IN GRAIN LEGUMES

In addition to N_2 fixation, symbiotic legumes are also reported to accumulate greater levels of mineral nutrients in their tissues than cereals (Pederson et al., 2002; Broadley et al., 2003; Fageria, 2004). More recently, Belane and Dakora, 2011a,b, 2012 have shown that cowpea can accumulate more macro-/micronutrients in its leaves compared to spinach, a commercial vegetable grown in South Africa. As a result of these reports (Pederson et al., 2002; Broadley et al., 2003; Fageria, 2004; Belane and Dakora, 2011a,b, 2012), a field study was recently conducted at Wa in Ghana to establish the relationship, if any, between N_2 fixation and mineral accumulation in nodulated cowpea. The data showed that the cowpea genotypes, which produced the largest amounts of symbiotic N, accumulated the most mineral nutrients in organs. For example, the genotypes with superior symbiotic performance consistently exhibited greater accumulation of P, K, Mg, S, Na, Fe, Cu, Zn, Mn, and B in young fully expanded trifoliate leaves (Table 105.3), clearly indicating a link between legume N_2 fixation and mineral accumulation in organs.

Many soil microbes are capable of solubilizing mineral nutrients in plant rhizosphere for increased uptake by roots (Vessey, 2003). There are, for example, reports of bacterial endophytes that promote uptake of mineral nutrients such as P, Fe, and Zn in the rhizosphere (Barretti et al. 2008). Other studies have also found an increase in N, P, K, Ca, Mg, B, Mn, Zn, Fe, Cu, Al, and Na in organs of inoculated groundnut (Howell, 1987). Furthermore, applying a strain of *Mesorhizobium mediterraneum* to the roots of chickpea increased tissue concentration of K, Ca, Mg, P, and N (Peix et al., 2001), a result similar to inoculating *Phaseolus vulgaris* plants with *Burkholderia cepacia* (Peix et al., 2001). An increase in the concentration of trace elements in *Phaseolus vulgaris* was also observed, following inoculation with rhizobial bacteria (Ndakidemi et al., 2011). From these reports, it appears that many nonrhizobial bacteria are capable of solubilizing mineral nutrients in the rhizosphere (Vessey, 2003) and promoting increased mineral uptake. Experiments conducted under strict microbiologically controlled environments are therefore needed to validate these reports of bacteria-induced mineral accumulation (Howell, 1987; Peix et al., 2001; Ndakidemi et al., 2011).

One such experiment was done by applying seven infective rhizobial strains to the seedlings of cowpea (cv. TVu11424) grown in sterile Leonard jars. The results showed marked differences in plant growth and symbiotic efficacy between strains (Table 105.4). Strains TUT53b2vu and TUT33b4vu were more efficient in N_2 fixation, measured as dry matter yield (Table 105.4). A 0.5 mM NO_3-fed treatment also produced significantly higher plant growth than the remaining five rhizobial isolates. ICP-MS analysis of nutrients in the nodulated cowpea plants revealed marked differences in mineral accumulation in shoots. Strains TUT26a1vu and TUT13d1vu, which were symbiotically more efficient (measured as dry matter yield), recorded significantly higher content of P, K, Ca, Mg, S, Fe, Cu, Mn, and B in cowpea shoots (Table 105.5). In contrast, strain TUT25d1vu, which showed the lowest symbiotic efficiency, also induced the least mineral accumulation in host plant shoots (Table 105.5). The 0.5 mM NO_3^--fed cowpea plants exhibited the next higher amounts of minerals after the

105.4 CONTRIBUTION OF LEGUME SYMBIOSIS TO FOOD SECURITY AND ENHANCED HUMAN NUTRITION/HEALTH

The ability of nodulated legumes to reduce atmospheric N_2 into NH_3 in root nodules using the enzyme nitrogenase is crucial to global food security, human nutrition, and health (see Chapter 109). The excess NH_3 produced, following utilization by bacterial cells, is converted into amino acids via the GS/GOGAT pathway inside the host plant. The synthesis of amino acids and other nitrogenous solutes from symbiotic N forms the basis for the high protein levels in grain and leaves of nodulated legumes, and therefore, the higher the N_2 fixation in a legume, the greater the protein concentration/content in plant organs. But more importantly, the higher the N_2 fixation in grain legumes, the greater the plant growth, biomass accumulation, and grain yield (Belane and Dakora, 2009; Pule-Meulenberg and Dakora, 2009; Makoi et al., 2009; Belane and Dakora, 2010; Belane et al., 2011), thus indicating the contribution of N_2 fixation to legume grain yield and ultimately to food security.

However, as indicated earlier, in addition to N_2 fixation, nodulated legumes also accumulate mineral nutrients in organs, a trait much needed in African cropping systems. African agriculture is generally faced with soil infertility, leading to low crop yields, as well as food and nutritional insecurity, which in turn cause protein–calorie malnutrition with components of trace element deficiency, kwashiorkor in children, and diabetes in adults. In our view, symbiotic N_2 fixation in grain legumes is the key to overcoming the food security and human nutrition/health problems in Africa. This is because N_2 fixation can contribute to soil N economy in cropping systems, increase soil fertility (other than N), improve plant/animal protein production, raise yield levels of legume and cereal crops, as well as overcome a host of nutritional disorders, including trace element deficiency. The fact that symbiotic activity in nodulated legumes is linked to mineral accumulation in these species has implications for human nutrition and health, including micronutrient deficiency, which is a major problem in Africa. In addressing this nutritional disorder, the South African government has resorted to exogenous supplementation of maize flour ("mealie meal") with Fe, Zn, and Se in order to reduce trace

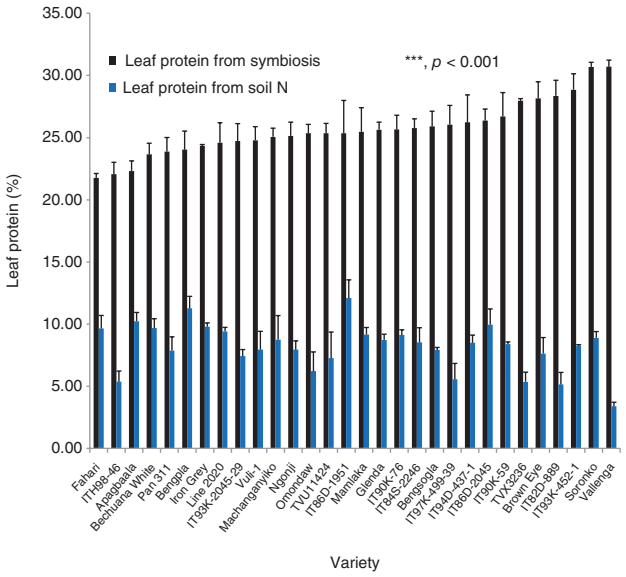

Figure 105.1 Comparison of cowpea protein from symbiosis and soil at Wa, Ghana, in 2003.

element deficiency in the population (Belane and Dakora 2011a). While conventional plant breeding and genomic approaches have been employed elsewhere to promote micronutrient uptake by crop plants, and thus increase mineral nutrients in grain in order to overcome trace element deficiency in consumers (Welch and Graham, 2004; Bouis, 2003), our data (Tables 105.3–105.5) suggest that the same can be achieved by identifying combinations of rhizobia and food grain legumes that fix greater amounts of symbiotic N (Tables 105.1–105.3) and accumulate mineral density in edible plant parts (Table 105.3) for improving human nutrition and health.

As indicated previously, in addition to enhanced mineral supply, the legume/rhizobia symbiosis is also a huge source of dietary protein for human consumption. Figure 105.1 shows a comparison of leaf protein originating from symbiosis and that from soil N in cowpea leaves. To estimate leaf protein from the two sources, symbiotic N and soil N were measured in cowpea leaves using the ^{15}N natural abundance technique and %N fixed (the dividend of N fixed and leaf dry matter) multiplied by 6.25 to obtain leaf protein from symbiotic origin. The leaf protein from soil source was obtained by multiplying %N from soil by 6.25. The data clearly show that where the legume was deriving a high proportion of its N nutrition from symbiosis (85–95% Ndfa and 5.1–6.3% N in cowpea leaves at Wa), most of the leaf protein synthesis was dependent on symbiotic N, with very little coming from soil N.

In this study, nodulated cowpea could produce as much as 22 to 32% of its leaf protein from N_2 fixation, indicating that, with cowpea, rhizobial symbiosis does contribute significantly to food and nutritional security, as well as to improved human nutrition and health. Additionally, by being high in protein and fiber, and low in cholesterol, grain legumes is a source of healthy diet for the rural poor in Africa.

In conclusion, with the selection of high N_2-fixing rhizobia and high-yielding hosts, food grain legumes in Africa have the potential to increase soil fertility and double crop productivity in the continent, eradicate hunger and food poverty, eliminate micronutrient deficiency and kwashiorkor in children, reduce protein–calorie malnutrition in rural communities, and enhance the overall human nutrition and health while creating cash and wealth for farmers. More studies are however needed to intensify the search for both high-yielding legume genotypes and high-performing rhizobial symbionts for the different agroecological zones of Africa, especially with adaptability to climate change. In our view, symbiotic N_2 fixation is the solution to Africa's food and nutritional security problems.

Chapter 106

Plant Breeding for Biological Nitrogen Fixation: A Review

Peter Kennedy, Antonio Leonforte, and Mirella Butsch
Victorian Department of Economic Development, Jobs, Transport and Resources, Horsham, VIC, Australia

106.1 INTRODUCTION

Costs associated with nitrogen fertilizers have increased steadily and are predicted to rise into the future (Tilman, 1999). There are also environmental concerns associated with gaseous emissions, and fertilizer inefficiency has resulted in an increased interest in biological nitrogen fixation (Peoples et al., 1995; see Chapter 108). Nitrogen-fixing crops (crop legumes) naturally replenish soil nitrogen without the use of nitrogenous fertilizers. This ability is facilitated by a complex symbiotic relationship between nitrogen-fixing bacteria, comprising 13 different genera known as rhizobia (Willems, 2006), and a host plant, culminating in the establishment of root nodules.

Plant-related nitrogen fixation is a significant contributor to the global agricultural nitrogen budget, adding 21.45 million tons of fixed N each year (Herridge et al., 2008; see Chapters 5 and 109). Increasing the effectiveness of N fixation in agricultural systems could be a powerful tool in reducing reliance on chemical fertilizers and sustainably increase agricultural production. Nevertheless, while there are various benefits of improved N fixation, attempts at targeted breeding have been minimal (Herridge and Rose, 2000). Genetic diversity for traits related to enhanced N fixation has been identified in soybean (Nicolas et al., 2002; Hungria and Bohrer, 2000), field pea (Buttery et al., 1992), model species *Medicago truncatula* (Rangin et al., 2008), common bean (Redden and Herridge, 1999; Rodino et al., 2005), chickpea (Biabani et al., 2011), and others.

The heritability of symbiotic traits and the resulting opportunity to realistically breed for N fixation have also been documented. Reviewing heritability of N fixation traits on a range of legume crops, Provorov and Tikhonovich (2003) concluded that in many cases the broad-sense heritability of N fixation may be as high as 0.90, narrow-sense heritability as high as 0.76, and realized heritability up to 0.96, all strongly suggesting that breeding for enhanced symbiosis is a realistic target. Nicolas et al. (2002), studying soybean (*Glycine max*) populations derived from four commercial cultivars, found the narrow-sense heritability of nodulation characteristics (nodule number and nodule weight) to range from 0.39 to 0.77, illustrating the potential gains in nodulation when considered parent selection is made. Also studying soybean, Gwata et al. (2004) suggested that the genes controlling indiscriminate or promiscuous nodulation may be relatively few in number. To demonstrate this, soybean cultivars were inoculated in a glasshouse experiment with cowpea (*Vigna unguiculata*) rhizobia strains, where nodulation indicated promiscuity. Promiscuous and nonpromiscuous lines were then crossed to assess heritability based upon nodule dry weight and leaf color score. Their findings suggested that nonpromiscuity was partially dominant [h/d = 0.37] for nodule dry weight and almost completely dominant for leaf color score [h/d = 0.74]. Working with peanut (*Arachis hypogaea*), Sikinarum et al. (2007) crossed high- and low-fixing cultivars and generated six F_5 populations to assess heritability of nodule weight, leaf color score and shoot dry weight. Generally, broad-sense heritability was high (>0.50) for most fixation-associated traits with nodule dry weight ranging from 0.63 to 1.0 and fixed nitrogen ranging from 0.85 to 0.98. However, Herridge and Danso (1995) have suggested that the heavy reliance

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

on the acetylene reduction assay may have compromised accuracy on N fixation heritability studies. Nonetheless, their own conclusions regarding the possibility of enhanced N fixation through breeding in soybean have been positive (Herridge and Danso, 1995; Herridge and Rose, 2000).

Despite the promising diversity and heritability of N fixation, a major obstacle to successful breeding is the complexity of the host plant–rhizobia symbiosis and the difficulty of identifying improved germplasm through conventional screening. Furthermore, modern legume breeding tends to trail other major crops in the majority of agronomically required traits, inevitably pushing nitrogen fixation down the list of priorities and discouraging the introgression of landraces that might destabilize other essential traits.

106.2 POTENTIAL TRAITS AND BREEDING STRATEGIES THAT CONFER ENHANCED FIXATION

Effective advances in N fixation breeding may be realized through a range of approaches.

106.2.1 Host–Symbiont Compatibility

The overall productivity of nitrogen fixation depends largely upon the compatibility of both the legume plant and rhizobia strain, making cultivar–strain interaction an important consideration for breeding. The synergistic relationship between the host and rhizobia strains can be one of the most crucial factors for achieving symbiotic potential (Abi-Ghanem et al., 2011; Santalla et al., 2001).

In their review, Herridge and Rose (2000) suggest two breeding strategies to deal with host–strain specificity, namely, target cultivars that form effective symbioses with a broad range of rhizobia (often referred to as *promiscuous* nodulation) or target cultivars that preferentially nodulate with more productive rhizobia and exclude the less productive lines (selective nodulation). Ultimately, screening for productive symbioses across cultivars needs to take field variation into account as indigenous rhizobia populations can often competitively nodulate legumes but fix nitrogen poorly, potentially confounding the results and frustrating breeding efforts.

Evaluating the compatibility of subterranean clover (*Trifolium subterraneum*) genotypes, Drew and Ballard (2010) inoculated 49 clover genotypes with 4 rhizobial strains isolated from soil extracts. The symbiotic performance (SP) of each cultivar and strain was determined by calculating plant growth as a percentage of shoot dry matter when inoculated with the recommended commercial inoculant. Their findings indicated a significant effect of both cultivar and rhizobia strain on plant growth. Broad variation of SP was also noted across genotypes when inoculated with the commercial strain (WSM1325), with some varieties showing less than half the shoot dry weight of other varieties, indicating the scale of impact that inappropriate inoculation has on N fixation. For further insight, a low SP genotype (cv. Clare) and a high SP genotype (cv. Campeda) were selected based on their comparable optimum dry weight. Both genotypes were inoculated with soil extracts that contained a diverse range of different rhizobia strains. The SP of Campeda across all rhizobia strains was on average 29% higher than that of Clare. Moreover, nodules were generally more efficient at fixing nitrogen in Campeda than Clare (inferred from leghemoglobin being present in nodules). Clare's poor performance was attributed to disruptions at multiple points in the nodulation process as shown by the lower number and less effective nodules. Drew and Ballard (2010) concluded that a wider compatibility range accounted for the superior SP observed, though the authors postulated that the greater SP in Campeda could imply that this genotype had an additional ability to discriminate against less effective rhizobia.

Investigating the cultivar–strain interaction in field pea, Martensson and Rydberg (1996) tested the interaction between 16 commonly grown European cultivars with 7 rhizobia strains. Results were collected at early and advanced plant maturity to differentiate between early symbiotic interactions and nitrogen uptake generally. Their results indicated no significant interaction in early stages of symbiosis initiation, highlighting that early nodulation does not necessarily imply greater N uptake or dry matter accumulation. Interestingly, results collected at advanced maturity showed that from 16 cultivars, Maro, Maxi, and Minnesota exhibited marked cultivar–strain interactions where N uptake ranged from moderately above average to well below average, whereas cultivars Bodil, Bohatyr, Filby, and Imposant showed no variation with moderate to good performance across the board, suggesting two possible N fixation breeding targets. Commenting on the dilemma that this imposed on plant breeders, the authors suggested that the former target of cultivars which form productive symbioses with a narrow range of strains might be the most sensible target due to better marketability to growers.

106.2.2 Selective Nodulation

Glasshouse and field studies have thoroughly demonstrated the pervasiveness of host–strain specificity and the gains to be made with effective coupling of symbionts (Laguerre et al., 2007). However, indigenous rhizobial populations that can competitively nodulate crop legumes but inefficiently fix nitrogen can undermine the benefits of symbiotic compatibility (Denton et al., 2002). Yates et al. (2008) demonstrated the selective nodulation ability of *Trifolium purpureum* and *T. polymorphum*, where both hosts were nodulated with an

effective and an ineffective rhizobia strain. Both hosts nodulated solely with the effective strain even when outnumbered a hundredfold.

It has been suggested that to counteract *free-riding* rhizobia, certain legumes have evolved the ability to impose sanctions on ineffective nitrogen fixers by preferentially supplying nodules with more productive rhizobia or blocking infection altogether (Denison 2000; Yates et al., 2008). However, the prevalence of nitrogenous fertilizers in modern agriculture and breeding programs may have had a deleterious impact on modern cultivars to discriminate between effective and ineffective rhizobia strains. In a field study of soybean cultivars ranging from 1937 to 2001, cultivars were inoculated with fixing and nonfixing rhizobial strains. Kiers et al. (2007) noted a clear trend of newer cultivars nodulating with ineffective strains more commonly than older cultivars, suggesting that contemporary breeding efforts in soybean may be having a retrograde effect on the efficacy of N fixation symbiosis. This finding corroborated the observations made by Van Kessel and Hartley (2000), who reviewed 362 studies of soybean and found a significant drop-off in N fixation according to studies conducted post-1985.

106.2.3 Nitrate-Tolerant Fixation

The inhibitory effect of nitrate on legume nitrogen fixation is a well-documented phenomenon (Voisin et al., 2002; Glyan'ko et al., 2009). A common explanation is that the carbon demand of nodulation exceeds the assimilation costs of mineral nitrogen, culminating in suppressed nodulation (Glyanko et al., 2009]. Nevertheless, the biochemical background to nitrate suppression of nodulation is complex. It cannot be entirely explained as an energy regulation decision by the plant, as it is specifically nitrate that poses the most severe reduction compared to other mineral nitrogen forms such as ammonia (Gibson and Nutman, 1960; Bollman and Vessey, 2006). Nitrate-tolerant symbiosis has been regarded as one of the most important targets for fixation breeding, as it would greatly increase the nitrogen benefits of legumes in high-fertility environments (Evans, 1982).

Two general strategies for targeting nitrate-tolerant symbioses are to select for natural variation within a population or through mutants carrying super- or hypernodulating genes. Looking to develop nitrate-tolerant symbiosis through natural variation, Herridge and Rose (2000) conducted a nitrate-tolerant breeding program of soybean by introducing 32 genotypes that displayed superior nodulation into a mainstream breeding program. Genetic variation for N fixation was first determined through glasshouse screening in low N sand-filled pots. Once selections were made, two subsequent field trials conducted on high nitrate soils in Australia tested the lines for sustained nodulation in response to soil nitrate. Korean cultivars in particular were observed to possess notable nitrate tolerance and nitrogen fixation activity in the field conditions. Postharvest soil tests revealed that on average 34 kg/ha nitrogen was conserved where high N-fixing Korean cultivars were present when compared to the commercial cultivar Bragg. Despite the gain in nitrogen, seed yield for the high N fixers was on average 30% below mainstream cultivars due to poor agronomic features. Nevertheless, correlation matrices suggested that the traits associated with yield loss were independent of the high N-fixing ability, leading to the conclusion that the Korean cultivars could be effective donor parents (Herridge and Rose, 2000). Four high-fixing Korean cultivars [K464, K466, K468, and K469] were subsequently hybridized with four high-yielding cultivars [Valder, Reynolds, Forrest, and Bossier]. From these combinations, 849 F_2 progeny were tested for N uptake, with results suggesting promising segregation for fixation. Single seed descent was used to generate F_5 and F_6 populations to be tested once again in the field for nitrate tolerance. Although these populations produced lines that yielded above some mainstream cultivars, such as Valiant, unfortunately no significant symbiotic advantage could be attributed to lines produced from the N fixation breeding program. Furthermore, the lack of disease resistance necessitated that lines produced from this program be shelved. Nevertheless, the program succeeded in identifying novel germplasm, and the Korean cultivars may well have delivered other benefits to the program such as seed protein content (Herridge and Rose, 2000).

106.2.4 Supernodulation

An intuitive strategy to enhance nitrogen fixation is to increase nodulation: the sites of dinitrogen reduction. The establishment of root nodules is facilitated by a complex signaling process between rhizobia and plant root hairs at the extremities of the root system. The host plant exudes secondary metabolites [flavonoids; see Chapter 50] that attract rhizobia and activate bacterial *nod* genes, eliciting the production of lipochitooligosaccharides also known as Nod factors (see Chapter 51). These factors induce the plant root to allow the infection of rhizobia to commence and ultimately cause the nodule structure to form (Franche et al., 2009; Mortier et al., 2011; see Chapter 59). The specificity between legume species and different rhizobial strains is largely accounted for by the structure of these signaling compounds (Ferguson et al., 2010).

After nodule formation, the production of ammonia from dinitrogen reduction requires sucrose and dicarboxylic acids for energy. This energy is delivered by the photosynthetic activity of the plant shoot (Caetano, 1997). However, the amount of energy partitioned to nodulation is carefully controlled through an autoregulation system similar to other shoot-to-root signaling pathways (Novak et al., 2009). Typically, when nodulation has reached a determined optimum, a substance termed as *Q* [most likely a CLAVATA3/ESR

[CLE]-related peptide] is synthesized by the root and is translocated to the shoot where it is transformed into a shoot-derived inhibitor (SDI) (Okamoto et al., 2009). The SDI is translocated back to the root system and halts the nodulation process (Li et al., 2009). A key gene that controls this pathway in the model species *Lotus japonicus* is *HAR1*, and its product has been identified as a receptor kinase (Krusell et al., 2002). Variants of this gene have been isolated in a number of legume species including soybean (Mortier et al., 2011), pea (Sagan and Duc, 1996), and *M. truncatula* (Searle et al., 2003; Schnabel et al., 2005).

Supernodulation [SN] is caused by a mutation that disrupts the autoregulatory signaling pathways to the root system and encourages an abnormal amount of nodules to form (Li et al., 2009). Generally, an overabundance of nodules has a deleterious effect on plant competitiveness as the increased nodulation demands an excessive carbohydrate supply (Voison et al., 2007). Sidorova et al. (2005) found the *nod4* SN inducing gene in field pea (*Pisum sativum*) to drastically limit plant growth and productivity while also reducing N fixation efficiency despite the large increase in nodulation. Attempting to remedy this effect, the SN mutant was crossed with three conventional cultivars (Torsdag, Truzhenik, and Falensky), and progeny were recurrently selected to the F_6 generation. The conventional cultivars were selected based on their difference in N fixation ability, with Torsdag and Falensky being efficient N fixers and Truzhenik an inefficient fixer. Their findings showed considerable alleviation of the SN effect at the F_6 generation on plant growth productivity while maintaining superior levels of nodulation and nitrogenase activity when compared to the wild-type cultivars. Nevertheless, all of the cultivar–mutant crosses incurred yield loss and growth reduction to some extent with the introduction of *nod4* when compared to the conventional parent. Despite this result, a strong cultivar effect was observed on plant yield and growth, leading to the conclusion that N fixation and photosynthetic ability of the background genotype is a critical consideration when incorporating SN mutations in a breeding program and appropriate genetic background could ultimately justify wider use of SN in breeding programs (Sidorova et al., 2005).

Keeping in mind the carbon demand that SN imposes on the plant, Novak et al. (2009) crossed an SN pea mutant with high-biomass forage pea cultivars, Arvika and Zhodino E9000, in an effort to balance the effect of excessive nodulation with plant ideotypes that conduct higher levels of photosynthesis. Similar to other parallel studies, growth deprivation was noted in the majority of recombinant lines when the SN mutation was introgressed into the wild-type cultivars. Although five lines carrying the SN mutation were found to exceed their forage-type parent in some growth characteristics, this did not translate to a completely successful counteractive of the SN trait (Novak et al., 2009). Nevertheless, the experiment showed that one recombinant line derived from forage cultivar Zhodino E900 possessed the ability to modify the SN mutation so that the number, size, and efficiency of nodules could be brought closer to the wild-type nodulation pattern, though their study stopped short of actually showing the beneficial effect of this modification. The authors suggested that SN modification was an additional counteractive strategy to previous attempts such as mutations to nodule number loci (Sagan and Duc, 1996) and suppressor mutations to the SN allele (Murray et al., 2006).

Theoretically, the seed and biomass yield reduction caused by SN may potentially be overlooked in forage systems where nitrogen nutrition is the primary target, as suggested by Novak et al. (2009). Nonetheless, these circumstances remain in the minority for legume breeding. Ultimately, incorporation of SN mutants into a crop breeding system should be accompanied by traits that can alleviate the growth and yield reduction that SN imposes.

106.2.5 Molecular Breeding Techniques

Given the numerous genetic influences on nitrogen fixation, molecular breeding techniques such as quantitative trait loci [QTL] mapping and marker-assisted selection can potentially help breeding programs that identify N fixation as a breeding target. However, the application of these technologies to N fixation traits remains in its infancy. Studying recombinant inbred line [RIL] populations from the model legume species *L. japonicus*, Tominaga et al. (2012) identified 34 QTLs associated with 10 traits relevant to nitrogen fixation and plant growth. Acetylene reduction activity, nodule number per plant, and stem length all displayed strong QTL correlations. Colocalization was discovered for a variety of trait QTLs and was additive with the sole exception of the acetylene activity per nodule weight trait. Promising discoveries were the detection of a nitrogen fixation regulating loci on chromosome 5 that promoted plant growth through the regulation of nodule development, the detection of an allele on chromosome 4 that influenced yield and plant growth via regulation of nitrogen, and a QTL on chromosome 3 that affected nodule number. As linkage maps and marker identification become available, the application of this knowledge to breeding for N fixation may help unravel the many interacting factors associated with N fixation (see Chapter 78).

Furthermore, utilizing a recently published integrated genetic linkage map of soybean, Nicolas et al. (2006) identified two genomic regions associated with nodule number and nodule dry weight in the F_2 progeny derived from Embrapa 20 × BRS 133, as well as another 13 significant associations between QTL and marker loci relevant to enhanced fixation. For the portion of the genome tested (21 SSR markers, approximately 10%), phenotypic variation

in nodule number and dry weight accounted through linked markers was 2–9% and 3–6%, respectively. This indicated that subsequent studies into the remaining genome will further augment the understanding of phenotypic variation for N fixation (Nicolas et al., 2006).

Working with seven cultivars of field pea (Ballet, Cameor, China, VavD265, K586, Sommette, Terese), Bourion et al. (2010) measured nitrogen acquisition structure as determined by root system size, prolonged nodulation period, and the effect these had on nitrogen nutrition. Significant genotypic variation was observed for both root structure and nodulation traits across all seven cultivars. Nodulation appeared to be particularly variable with certain growth stages showing 10-fold differences between genotypes. Broad-sense heritability was calculated showing that root and nodule traits were found to be highly heritable [0.88 and 0.77, respectively]. To investigate the genetic contribution further, a RIL population of Ballet × Cameor was genotyped based on the dissimilarity in root and nodule traits. 20 QTLs were identified to have an effect, 3 were identified that were associated with the proportion of nitrogen derived through fixation [%Ndfa], 7 were linked to N acquisition, and a further 10 were identified for nitrogen fixation efficiency traits. Of these 10, 5 were located within the same genomic region and correlated with 9–21% of the phenotypic variation. QTLs were also observed in four additional genomic regions contributing between 8% and 12% of the variation. Interestingly, cv. Cameor alleles contributed solely positive effect QTLs for fixation efficiency and solely negative effect for %Ndfa. All QTLs for %Ndfa corresponded to QTLs associated with root and nodule traits, indicating that targeting traits that promote root development prior to seed filling, when nitrogen fixation is most intense, would be an effective breeding target (Bourion et al., 2010).

However, the difficulty in interpreting and implementing large numbers of QTLs for complex traits into breeding programs is a well-recognized phenomenon (Mir et al., 2012). Given the complex of interacting factors that constitute N fixation symbiosis, molecular approaches such as QTL mapping for marker-assisted selection will present their own host of challenges.

106.3 CONCLUSION

The advantages of biological nitrogen fixation will increase as fertilizer costs and environmental concerns become more pressing. However, progress to date in breeding for these traits has been slow due to the trait complexity and competing breeding targets in legume programs. Nevertheless, continued research into Supernodulation, host–strain compatibility, and nitrate-tolerant symbiosis combined with advanced molecular approaches could lead to substantial increases nitrogen fixation within the farming system. However, it is likely that large-scale enhancement will only be delivered as N fixation becomes less of a research subject and more of a priority trait in breeding programs themselves.

107.1 INTRODUCTION

Signal molecules are essential for the penetration into plant roots by beneficial symbiotic microorganisms. Rhizobia are symbiotic nitrogen-fixing bacteria that penetrate legume roots via root hairs and enter the developing root nodules that contain the atmospheric nitrogen-fixing process. Lipochitooligosaccharides (LCOs) are Nod factor signal molecules produced by rhizobia after the legume plant exudes flavonoids that bind to rhizobia and turns on bacterial genes that synthesize the Nod factor molecules (Kamst et al., 1998; see Chapters 50, 51). The basic research and discovery of Nod factor structures (Broughton et al., 1997; Lerouge et al., 1996; Stacey et al., 1992, 1994; D'Haeze and Holsters 2002; Ardourel et al., 1994), specific root hair receptor binding sights (Limpens et al., 2003; see Chapter 51), and plant gene signaling cascade (Gough and Cullimore, 2011; see Chapter 59) leading to rhizobial root hair infection and nodule morphogenesis (Oldroyd and Downie, 2008) have been extensively reported.

Arbuscular mycorrhizae also produce LCOs known as Myc factor signal molecules (Maillet et al., 2011) that act in a similar manner allowing fungal penetration into plant root cells. More than sixty percent of land plants form this symbiotic relationship allowing the fungal mycelium to scavenge for the plant soil nutrients, particularly phosphorus, nitrogen, and sulfur (Harrison, 2005; see also Chapter 108).

Applied research investigating LCO direct plant growth responses in either the greenhouse or field trials has been far less studied and will be reported in this review.

Formulations of Nod factors combined with the rhizobia for the specific legume host, or Nod factors alone, provide several plant growth benefits when applied to seed. The Nod factor of *Bradyrhizobium japonicum* enhances the germination of important agronomic crops, to include legumes [soybean (*Glycine max*) and beans (*Phaseolus vulgaris)*] and nonlegumes (corn (*Zea mays*), rice (*Oryza sativa*), sugar beets (*Beta vulgaris*), and cotton *(Gossypium hirsutum*)] in greenhouse and field conditions (Prithiviraj et al., 2003; Smith et al., 2005). The Nod factor of *Rhizobium leguminosarum* biovar *viciae* increases germination of both peas (*Pisum sativum*) and hairy vetch (*Vicia villosa*) (Kidaj et al., 2011]. Enhanced legume nodulation with Nod factor seed treatments has been reported with *P. sativum* and *V. villosa*

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

[Kidaj et al., 2011], *Medicago truncatula* (Macchiavelli and Brelles-Marino, 2004), and *Trifolium pratense* (Maj et al., 2009). Nod factors and Myc factors are active molecules which also increase mycorrhizal root colonization and stimulate lateral root development (Olah et al., 2005). Evidence of cross talk between the two molecules is suggested by these findings. These two signal molecules produced by either a bacterium (rhizobia providing Nod factors) or a fungus (mycorrhizae producing Myc factors) each have their specific LysM receptor-like kinases on the root that activates a common symbiotic plant gene pathway (Gherbi et al., 2008; known as CSSP, CSP or SYM; see Chapters 42, 54, 55, 108, 110). Downstream genes beyond the common symbiotic pathway provide for rhizobial nodulation or Mycorrhizal root penetration (see Chapter 59).

Nod factors have also been reported to provide improved early growth of both legumes and nonlegumes (Souleimanov et al., 2002; Prithiviraj et al., 2003; Kidaj et al., 2012; Maj et al., 2008]. Growth and plant vigor are most likely responses resulting from more specific Nod factor effects such as enhanced germination, lateral root development, and nutrient supply.

Further LCO plant responses have been reported to include overcoming the stressful effect of low pH on soybean root hair curling with higher levels of LCOs (Miransari et al., 2006), foliar applications of LCOs on soybeans, and corn enhancing photosynthesis (Khan et al., 2008; Smith et al., 2007), plus foliar LCO application with tomatoes increasing both flowering and fruit production (Chen et al., 2007).

The plant benefits of LCOs clearly extend beyond improved nodulation, to include various benefits from seed, in-furrow, or foliar applications.

107.2 METHODS

107.2.1 Lipochitooligosaccharide Formulations

Liquid LCO formulations (Nod factors and Myc factors) were prepared for application studies and commonly analyzed via HPLC and mass spectrum analysis. LCO preparations were formulated by either preincubating a rhizobial Nod gene activating flavonoid (see Chapter 50) (specific molecules are required for the various rhizobial species) with the rhizobium or providing precise concentrations of LCO via direct addition of a purified LCO molecule. Pure LCOs in reported studies by Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc., Salem, VA, unpublished results, were those with structures representing soybean or pea LCOs. Preincubation preparations with *B. japonicum* included genistein, a Nod gene inducer, at concentrations of 5 to 20 µg with 3-day-old *B. japonicum* cultures and incubation for two additional days (Zhang and Smith, 1995).

107.2.2 Root Hair Deformation Assays

Root hair deformation (RHD) is the first plant physical response to LCO molecules (see Chapters 41, 57). A semi-quantitative RHD assay for hairy vetch roots was utilized by replacing plant growth medium with a medium containing Nod factor within Fahraeus slides followed by incubation in Petri dishes at 22 °C for 3 hours. Microscopic examination of deformed root hairs was carried out, and deformation was rated as 0, 1, or 2 corresponding to 0–20%, 20–60%, and greater than 60% deformed root hairs (Heidstra et al., 1994). RHD was also evaluated utilizing 15-cm-long root segments of 5-day-old siratro (*Macroptilium atropurpureum)* roots. Root segments were soaked in 5 ml of a 10^{-8} M LCO solution in glass test tubes for 6 hours. Then the root segments were colored by adding 100 µl of 1% Congo red dye for 15 minutes. Root segments were observed for RHD under a compound microscope (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results).

107.2.3 Seed Germination Assays

Procedures for evaluating the effects of LCO on seed germination are provided by Kidaj et al. (2012). Pea and vetch seeds were surface sterilized, soaked for 30 minutes in serially diluted LCO solutions (from 10^{-10} to 10^{-12} M). Seeds were transferred to Fahraeus agar medium (10 seeds per container) and germinated in darkness at 28^0C. Germination was observed after 3 and 4 days for pea and 4 and 5 days for vetch. Prithiviraj et al. (2003) evaluated the activity of LCO on germination of *Z. mays, B. vulgaris, G. max, G. hirsutum, and P. vulgaris* in a greenhouse maintained at 25 $\pm 2^0$C. Twenty ml of a Nod factor preparation at concentrations of 10^{-6}, 10^{-7}, 10^{-8}, 10^{-9}, 10^{-10}, and 10^{-11} M was irrigated into the pots and percent emergence determined for each concentration after 3 days.

107.2.4 Nodulation Assays

Procedures evaluating nodulation enhancement with the addition of LCOs have been reported in several previous studies with peas and vetch (Kiday et al., 2012), *M. truncatula* (Macchiavelli and Brelles-Morrino, 2004), and *T. pratense* (Maj et al., 2009).

107.2.5 Mycorrhization Assays

Nod factor effects on mycorrhization were evaluated (Olah et al., 2005) utilizing the model legume *M. truncatula* seedlings inoculated with the arbuscular mycorrhizal (AM) fungus *Gigaspora margarita* and then grown in sterile conditions in test tubes with and without Nod factors in the

medium. Nod factors from *Sinorhizobium meliloti* were used at 10^{-9} M and grown for 6 weeks under growth chamber conditions. Plant roots were stained and microscopically screened for mycorrhizal infection.

107.2.6 Root Growth Evaluations

Procedures for evaluating the effects of both Nod factors and Myc factors on lateral root growth and their interactions with auxin are provided by Olah et al. (2005). Root enhancement was also evaluated with LCO on corn seeds (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem VA, unpublished results). Seeds were treated with 10^{-8} M Nod factor solution, placed on moist germination paper in the dark for germination. After 7 days, several root parameters were measured using the WinRhizo^{TM} Scanner.

107.2.7 Plant Growth Evaluations

The effects of LCO on early plant growth has been evaluated and described in several studies. Pea and vetch were evaluated in growth chamber studies using seeds soaked in serially diluted LCOs (from 10^{-10} to 10^{-12}M) and grown for 6 weeks. Further pot studies with two arable soils evaluated early growth for 6 weeks outdoors under a shelter (Kidaj et al., 2012). Seeds of *G. max, Z. mays, B. vulgaris, G. hirsutum, Cucumis sativus*, and *P. vulgaris* were grown in pots within growth chambers (Prithiviraj et al., 2003). Pots were irrigated with 25 ml of LCO solution (10^{-6} to 10^{-11}M) and harvested after 15 days with early growth parameters measured. Further greenhouse studies with corn seeds treated with 10^{-9}M LCO and grown for 3 weeks, cotton seeds treated with 10^{-8}M LCO and grown for 6 weeks, and LCO-treated soybean seeds (10^{-8}M LCO) harvested after 5 weeks evaluated early plant growth parameters (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M , Novozymes Biologicals, Inc, Salem, VA, unpublished results).

Foliar applications of soybean LCO (Nod BjV(C18:1, MeFuc)] were evaluated at concentrations of 10^{-6}, 10^{-8}, and 10^{-10}M on corn and soybeans, and the photosynthetic rate 3 days after application was determined (Kahn et al., 2008). The foliar application of LCO was further evaluated with greenhouse tomatoes (*Solanum lycopersicum*) by spraying the leaves twice with a 5 ml water solution containing LCO concentration of 10, 50, or 100 ng per plant (Chen et al., 2007). The first application was at early flowering stage and the second application 2 weeks later. Field studies were also conducted (Chen et al., 2007) with the LCO dosage ranging from 1 to 1000 ng (1.4×10^{-10} to 1.4×10^{-7}M in a 5 ml solution) per plant once at the onset of flowering and/or fruit set stages. Leaf parameters including chlorophyll content (estimated via a SPAD chlorophyll meter), leaf carbohydrate content by colorimetric assay (Dubois et al., 1956), and leaf NO_3-N were measured from the third fully opened soybean leaf from the top at two weeks after foliar LCO application (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results).

Nod factor field trials with legumes (soybean and peas) and nonlegumes (corn, cotton, and wheat) were conducted through University and third-party research contractors (Smith and Habib, 2009). Soybean (LCO BjV (C18:1,MeFuc)] and pea [LCO Rl V (C18:1)] Nod factors were prepared in liquid formulations at concentrations ranging from 10^{-7} to 10^{-9}M. Seed applications ranged from 5 to 10 ml kg^{-1}, in-furrow applied at 0.1 ml m^{-1} of row, and foliar applications were applied at early growth stage and in combination with glyphosate herbicides. Small field plots had 4–6 replications and were in a randomized complete block design, while large strip plots with 4 replications were randomized. Multiple-site analyses from North and South America and from multiple years were combined and evaluated. Probability that the mean percent yield difference between the treated and control was greater than 0 was tested using the Wilcoxon signed-rank test, JMP10 software SAS Institute, Inc., 2012.

107.3 RESULTS

Direct and indirect plant responses with the application of Nod factors (LCOs from rhizobia) have been widely reported with both legumes and nonlegumes.

107.4 ROOT HAIR DEFORMATION

The first direct effect of Nod factors is the RHD response, which requires 5 to 10 minutes of Nod factor—root hair interaction. The first deformation with *Vicia sativa* was visible within 1 hour, and after 3 hours, about 80% of the root hairs in a small susceptible zone of the root were deformed (Heidstra et al., 1994). Suboptimal temperatures (15 to 17.5° C) delayed the rhizobial Nod factor production because the Nod gene inducing molecule (flavonoids) were not released from the roots (Zhang and Smith, 1995). The time for soybean RHD to begin under these conditions was shortened by inoculating with a *B. japonicum* culture preincubated with genistein to cause Nod factor production (Zhang and Smith, 1995).

107.5 GERMINATION AND EMERGENCE

Seeds treated with Nod factors have provided enhanced seed germination and emergence (Smith et al., 2005). Growth chamber studies with soybean Nod factors (LCO

Table 107.1 Effect of the Nod factor Nod BjV(C18:1, MeFuc) on seedling emergence of four crop species under field conditions measured 10 days after planting (adapted from Prithiviraj et al., 2003)

BjV(C18:1,MeFuc)], inoculated on various economically important plants belonging to diverse botanical families, provided significantly improved emergence with corn (*Z. mays*), sugar beets (*B. vulgaris*), soybean (*G. max*), cotton (*G. hirsutum*), and beans (*P. vulgaris*) (Prithiviraj et al., 2003). Further studies with four crop species under field conditions also provided significantly improved emergence when treated with Nod factor concentrations of 10^{-5}, 10^{-7}, and 10^{-9}M (Table 107.1) (Prithiviraj et al., 2003). Growth chamber studies with extremely low amounts of *R. leguminosarum* bv. *viciae* Nod factors provided significant percent germination increases for pea (control without Nod factors $87\% \pm 13$, 10^{-10} M Nod factors $93\% \pm 11$, 10^{-11} M Nod factors $97\% \pm 13$, and 10^{-12} M Nod factors $96\% \pm 9$) and vetch (control $70\% \pm 9$, 10^{-10} M Nod factors $82\% \pm 11$, 10^{-11} M Nod factors $78\% \pm 6$, and 10^{-12} M Nod factors $73\% \pm 5$) (Kidaj et al., 2012).

107.6 NODULATION

Nodulation occurs when combining an infective rhizobium with its legume host. Studies have reported either earlier or increased nodulation when supplementing the rhizobial inoculum with the required Nod factor. The model legume *M. truncatula* inoculated with *S. meliloti* and the *S. meliloti* Nod factor significantly increased nodulation 15 days after inoculation with Nod factor concentrations of 10^{-8} M (2.20 ± 0.36 nodules plant^{-1}) and 10^{-9} M (2.32 ± 0.38 nodules plant^{-1}), but not with the rate of 10^{-7} M (1.30 ± 0.25 nodules plant^{-1}) (Macchiavelli et al., 2004]. Nodulation was also enhanced with pea seeds treated with *R. leguminosarum* bv. *viciae* Nod factors (control without Nod factors 61.6 ± 0.6 nodules plant^{-1}) as compared to Nod factor-treated seeds (102.6 ± 23.6 nodules plant^{-1}) (Kidaj et al., 2012). Hairy vetch seeds treated in a similar manner with Nod factors provided 87.6 ± 64 nodules plant^{-1} without Nod factors and 107.6 ± 10 nodules plant^{-1} with Nod factors. Nod factor treatments of clover seeds significantly (P<0.05) enhanced clover nodulation and growth of plants (Maj et al., 2009). Soybean seed inoculated with *B. japonicum* cultures preincubated with genistein, causing Nod factor production by the bacteria, increased nodulation at the suboptimal root zone temperatures (RZT) of 15.0 and 17.7 °C, but not at the optimal RZT of 25 °C (Zhang and Smith, 1995).

107.7 Nod FACTOR: Myc FACTOR CROSS TALK

Nod factors and Myc factors utilize a common plant gene pathway before their specific activation leading to nodulation or mycorrhizal root infection, respectively (Olah et al., 2005). Cross talk between these two LCO molecules was illustrated by the observation that Nod factors from *S. meliloti* increased mycorrhizal colonization in *M. truncatula* (Olah et al., 2005).

107.8 ENHANCED ROOT DEVELOPMENT

Further plant responses to LCO include enhanced root development. Both Nod factors and Myc factors provide this response. *S. meliloti* Nod factors very significantly ($P < 0.01$) stimulated *M. truncatula* lateral root formation at concentrations of 10^{-7}, 10^{-8}, and 10^{-9} M. The increase was in the range of 35–40% (Olah et al., 2005). Nonsulfated Myc factors elicited root-branching stimulation (RBS) at concentrations lower than 10 nM. Sulfated Myc factors and the 1:1 mixture with nonsulfated Myc factors elicited RBS at concentrations lower than 0.01 nM. Both sulfated and nonsulfated Myc factors were thus extremely active with RBS, but sulfated molecules were about 100-fold more active (Maillet et al., 2011). Mycorrhizal signal molecules also stimulated root development and plant growth in

nonlegumes (Mukherjee and Ane, 2011). Various root parameters of corn and wheat treated with Nod factors were evaluated with 7-day-old seedlings and analyzed with the WinRhizo™ Root Scanner (Smith and Habib, 2009). Significant ($P < 0.05$) increases in root length (corn, control 40.7 cm vs. 10^{-8} M Nod factor 73.2 cm; wheat, control 18.4 cm vs. 10^{-8} M Nod factor 21.2 cm), root surface area (corn, control 10.5 cm^2 vs. 10^{-8} M Nod factor 19.4 cm^2; wheat, 3.6 cm^2 vs. 10^{-8} M Nod factor 4.0 cm^2), and root volume (corn, 0.2 cm^3 vs. 10^{-8} M Nod factor 0.4 cm^3) were observed.

107.9 EARLY GROWTH

Enhanced early plant growth, following seed treatment of corn with the Nod factor from *B. japonicum*, included shoot dry weight per plant and leaf area over a wide Nod factor application range. Shoot dry weight of the control (30.1 mg $plant^{-1}$) was not significantly different from the highest Nod factor concentration of 10^{-5} M (41.6 mg $plant^{-1}$) nor the lowest rate of 10^{-11}M (38.0 mg $plant^{-1}$). However, all rates in between provided significant differences (P<0.05) in mg $plant^{-1}$ compared with untreated control (10^{-6} M 51.4 $plant^{-1}$, 10^{-7} M 51.6 $plant^{-1}$, 10^{-8} M 66.2 $plant^{-1}$, 10^{-9} M 46.8 $plant^{-1}$, and 10^{-10} M 51.4 $plant^{-1}$) (Prithiviraj et al., 2003). The authors found similar results with leaf area (cm^2) comparing the untreated control (7.63 cm^2 $plant^{-1}$) to Nod factor treatments of 10^{-5} M (11.7 cm^2 $plant^{-1}$), 10^{-6} M (18.2 cm^2 $plant^{-1}$), 10^{-7} M (15.7 cm^2 $plant^{-1}$), 10^{-8} M (19.3 cm^2 $plant^{-1}$), 10^{-9} M (17.0 cm^2 $plant^{-1}$), 10^{-10} M (13.9 cm^2 $plant^{-1}$), and nonsignificance at 10^{-11} M (8.51 cm^2 $plant^{-1}$). Early plant growth enhancement of corn and cotton was observed following the seed treatment with Nod factors. Corn seeds treated with Nod factors at a 10^{-9} M rate provided significant (LSD $P < 0.05$) increases in dry matter production with both root (untreated 0.32 g $plant^{-1}$ vs. Nod factor 0.35 g $plant^{-1}$) and shoot (untreated 0.57 g $plant^{-1}$ vs. Nod factor 0.64 g $plant^{-1}$). Cotton seeds treated with Nod factors also obtained significant (LSD P<0.05) increases in root fresh weight (untreated 0.74 g $plant^{-1}$ vs. Nod factor 1.69 g $plant^{-1}$) and shoot fresh weight (untreated 4.95 g $plant^{-1}$ vs. Nod factor 8.73 g $plant^{-1}$) (Smith and Habib, 2009).

107.10 FOLIAR APPLICATION

Nod factors applied as a foliar treatment have also provided increased plant growth responses (Smith et al., 2005). The foliar application of Nod factor (Nod BjV(C18:1 MeFuc)] enhanced ($P < 0.05$) the photosynthetic rate of corn. The increases were 36%, 23%, and 12% for 10^{-6}, 10^{-8}, and 10^{-10} M treated plants, respectively (Khan et al., 2008). This study indicates that Nod factors can enhance the photosynthetic rate and growth of corn. Foliar treatment of 10^{-8} M Nod factor with greenhouse soybeans at the v3 growth stage (Fehr and Caviness, 1977) provided increases in various plant parameters. Leaf chlorophyll concentration 14 days after application was 30.1 in untreated plants compared to 33.3 (Minolta SPAD meter units) with plants treated with Nod factors. Total leaf sugar content 2 weeks after application was 909.3 µg in untreated plants compared to 1362.2 µg in plants treated with Nod factors. Leaf nitrate concentration 2 weeks after application was also increased from 2.96 mg in untreated plants to 4.26 mg in plants treated with Nod factors (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results).

107.11 YIELD ENHANCEMENT

Yield enhancement with seed applications of Nod factors was first reported for soybeans (Smith et al., 2004). Two field trials were established: a virgin soybean site without *B. japonicum* and a site previously planted to soybeans with indigenous *B. japonicum*. The Nod factor treatment provided a nonsignificant response at the virgin site, while *B. japonicum* alone and the rhizobium combined with Nod factors provided a significant ($P < 0.10$) yield enhancement. At the indigenous site, the Nod factor treatment, the *B. japonicum* alone, and the *B. japonicum* plus Nod factors provided increased seed yield ($P < 0.10$). In both trials, the largest yield was obtained with the *B. japonicum* plus Nod factor treatment (Table 107.2).

Multiple-site and multiple-year field analyses in North and South America show that treatments containing Nod factors from *B. japonicum* provided soybean grain yield increases compared to untreated control (Table 107.3) (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results). The largest yield increase occurred in Argentina

Table 107.2 Soybean grain yield performance with Nod factors, applied with and without *Bradyrhizobium japonicum* seed inoculation, on virgin soil and soil with indigenous *B. japonicum* (Adapted from Smith et al., 2004)

	Yield (kg ha^{-1})	
	Virgin Soil	B.j. Indigenous Soil
Control	3335	2499

and Canada with increases of 8.9% and 25.3%, respectively. Yields greater than control were found in 14 of 17 trials (84.2%) in Canada and in 366 of 476 trials (82.4%) in Argentina. In the United States, treatments containing Nod factors were greater in 346 of 529 trials (65.4%) with an average of 4.3% yield increase. Yield increases in Brazil occurred in 25 of 36 trials (54.3%) with an average of 3.7% yield increase. Pea grain yield was also generally enhanced with treatments containing Nod factors from *R. leguminosarum* bv. *sativa*. In the United States, grain yield increases occurred in 54 of 70 trials (77.1%) with a 15.1% average yield increase. Canadian trials increased in 17 of 21 trials (80.8%) with an 8.9% yield enhancement.

Field trials were also conducted in North and South America with Nod factors as seed treatments on nonlegumes (corn and cotton) providing similar results in the United States, Argentina, and Brazil. Forty of 60 US corn trials (66.7%) increased yields providing an average of 2.1% yield enhancement (Table 107.4) [Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results). Positive corn grain yield responses with Nod factors were found in 25 of 41 trials (61.0%) in Argentina enhancing yields by 2.1%, and in Brazil, 28 of 43 trials (65.1%) had positive results with a 2.9% average increase. Cotton trials in the United States responded in a similar manner with positive yield increases in 23 of 32 trials (71.9%) with an average increase of 1.8% (Table 107.4) [Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results).

Studies with the foliar application of Nod factors also provided improved plant yield responses. Foliar application of *B. japonicum* Nod factors on greenhouse tomatoes increased flower numbers and early fruiting leading to increased tomato fruit yield (Chen et al., 2007). *B. japonicum*-extracted Nod factors foliarly applied to greenhouse tomatoes enhanced fruit weight when harvested 7 weeks after application (control 76.2 g plant^{-1} vs. Nod factor 10 ng 87.1 g plant^{-1}, 50 ng 104.3 g plant^{-1}, and 100 ng rate 88.0 g plant^{-1}) (Chen et al., 2007). Two foliar applications of Nod factors in field-grown tomatoes provided a significant enhancement ($P < 0.05$) in the number of fruit production (control 29.28 fruits plant^{-1} vs. a range of Nod factor rates: 1 ng 33.96 fruits plant^{-1}, 10 ng 42.50 fruits plant^{-1}, 100 ng 36.37 fruits plant^{-1}, and 1000 ng 35.00 fruits plant^{-1}) (Chen et al., 2007). Both fruit number per plant and fruit weight were increased by up to 29.4 and 29.8%, respectively (Chen et al., 2007). These studies indicate that

Table 107.5 Grain yield responses with Nod factor foliar applications on soybean and corn in North and South America field trials

a Nod factor foliar application to tomatoes in the range of 10 to 50 ng plant^{-1} can increase early flowering and fruiting, which results in improved fruit yields. Approximately 350 field trials in North and South America with the foliar application of Nod factors also provided a grain yield increase of soybeans and corn (Table 107.5) (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results). Foliar application of Nod factors increased yield ($P < 0.10$) of soybeans in North America (United States 2.7% and Canada 2.4%) and South America (Argentina 3.9% and Brazil 2.5%). Treatments were applied during early vegetative growth stage and in combination with a glyphosate herbicide, which provided a convenient method for application. The yield increases with Nod factors applied as a foliar treatment to corn were also evaluated in North and South America (Table 107.5). Corn grain yields in the United States were increased by an average of 3.2% and positive yield enhancements occurred in 76.1% of the trials. In Argentina, grain yields were increased an average of 2.1% with 60.0% of the trials providing a yield enhancement. Trials in Brazil provided a greater response with an average of 5.1% yield enhancement with 77.8% of the trials with increased yields.

107.12 DISCUSSION

Plant responses to LCO molecules, both Nod factors and Myc factors, go beyond the well-studied basic understanding of the specific receptors, common pathway of activated plant genes, rhizobial or mycorrhizal infection leading to nodulation, and arbuscule development followed by symbiotic nitrogen fixation and enhanced phosphorus uptake, respectively. Improved seed germination, greater mycorrhization, enhanced root development, better early plant growth, and higher yields frequently result from the LCO application on seeds, and also applications in-furrow, or as a foliar treatment. This review focuses on plant responses to Nod factors; however, Myc factor LCO molecules are also currently providing improved plant development (Olah et al., 2005).

The plant responses to the Nod factor signal molecules begin with RHD, which may be disrupted by environmental stress responses. The study of Zhang and Smith (1995) provides evidence that suboptimal temperatures (15 to 17.5 °C) decreased the release from the plant roots of the rhizobial Nod gene inducing molecules and thereby limited Nod factor production. This suboptimal temperature RHD response and the stress effects of low pH were improved by the addition of Nod factor molecules (Duzan et al., 2004).

The addition of Nod factors on the seed before planting improved the plant seed germination and emergence. The germination response was reported under growth chamber conditions with the application of the soybean Nod factor on important agronomic crops (corn, sugar beets, soybean, cotton, and beans) (Prithiviraj et al., 2003). The authors also found improved seedling emergence under field conditions with Nod factors applied to corn, soybean, cotton, and cucumbers.

Nodulation was the anticipated result of the Nod factor activation of plant genes leading to both rhizobial root hair infection and cortical cell morphogenesis into nodule formation. Supplementing Nod factors with the appropriate legume rhizobial host indeed did improve nodulation with *M. truncatula* (Macchiavelli et al., 2004], pea and vetch (Kidaj et al., 2012), clover (Maj et al., 2009), and soybean (Zhang and Smith, 1995). However, further plant growth parameters are enhanced with the addition of Nod factors. Enhanced root development is reported by the addition of either Nod factors or Myc factors (Olah et al., 2005; Maillet et al., 2011; Smith and Habib, 2009). This early plant root growth is likely the driving force to improved early plant growth leading to increased plant yields, plus the plants improved ability to withstand environmental stresses. Earlier and improved root

systems are likely to provide for better nodulation opportunities leading to enhanced nitrogen fixation and mycorrhization delivering increased phosphorus to the plant. Extending root systems further into the soil will provide the plant with more soil nutrients uptake and access to more soil water to mitigate abiotic stress (i.e., desiccation). Enhanced early plant growth occurred following Nod factor seed treatment with corn (Prithiviraj et al., 2003; Smith and Habib, 2009) and cotton (Smith and Habib, 2009).

Application of Nod factors to plant foliage appears independent from the plant responses to Nod factors delivered on or with the seed at planting. An increase in the photosynthetic rate (Smith et al., 2007; Khan et al., 2008) improved plant leaf parameters (chlorophyll, sugars, and nitrate (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results), and earlier flowering and fruiting (Chen et al., 2007) are reported after the foliar application of Nod factors. These foliar plant responses with Nod factor treatment are reported with legumes and nonlegumes, but the lack of understanding of molecular modes of action warrants further investigation.

Soybean grain yield enhancements with the seed application of Nod factors is reported when comparing sites with and without indigenous populations of *B. japonicum* (Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem VA, unpublished results). Additional multiple-year trials in both North and South America with legumes (soybeans, and peas – North America only) and nonlegumes (corn and cotton) with Nod factors applied on the seeds, in-furrow with the seed, or as foliar application have provided improved yields [Smith S, Habib A, Kang Y, Leggett M, Diaz-Zorita M, Novozymes Biologicals, Inc, Salem, VA, unpublished results). This indicates effective Nod factor plant growth effects under various soils, environmental, and crop management conditions.

Nod factors from different rhizobial genera (*B. japonicum* and *R. leguminosarum* bv. *sativa*) have demonstrated improved plant responses in growth chamber and field studies. With legumes, the appropriate host–rhizobial combinations were utilized, but with nonlegumes, Nod factors from different rhizobial genus may provide plant growth responses.

The direct and indirect plant growth responses with Nod factors have been reported over a broad application range (10^{-6} to 10^{-12} M) (Prithivaraj et al., 2003; Kahn et al, 2008; Chen et al., 2007; Kidaj et al., 2012; Olah, et al., 2005) indicating plant responses at very low amounts of applied molecules. However, the responses are generally reported to be most effective in the midrange from 10^{-7} to 10^{-9} M.

Additions of LCO signal molecules (Nod factors or Myc factors) have demonstrated the activation of plant genes providing for nodulation and mycorrhization, respectively (Gough and Cullimore, 2011). In addition, these signal molecules provide for various improved plant growth parameters. This demonstrates the agronomic value of these LCO molecules leading to generally better crop yields.

Detailed modes of action for the various reported LCO plant effects remain to be identified. However, seed-applied LCOs with both legumes and nonlegumes frequently provide for earlier and season-long enhanced root development in field studies. It is proposed that enhanced root development, providing the plant with better water and nutrient uptake supporting overall plant growth and yields, is a major contributor from the LCO mode of action. The mode of action for foliar LCO applications remains a subject for further research.

Nitrogen Fixation and Cereals

Chapter 108

The Quest for Biological Nitrogen Fixation in Cereals: A Perspective and Prospective

Frans J. de Bruijn
INRA/CNRS Laboratoire des Interactions Plantes-Microorganismes (LIPM) UMR441-2594, Castanet-Tolosan, France

108.1 INTRODUCTION

Recent advances in understanding symbiotic *Rhizobium*–legume and nonlegume interactions, actinorhizal–nonlegume interactions, and widespread arbuscular mycorrhizal (AM)–plant interactions at the molecular level, as described in various sections of this book, have stimulated the quest for biological nitrogen fixation (BNF) in cereals, such as rice. Moreover, the studies on the molecular genetics of the genes required for BNF in free-living diazotrophs such as *Azotobacter vinelandii*, described in this book, and methods to stably transform rice with heterologous genes have further stimulated this quest. The discovery of associative and endophytic diazotrophs in rice has stimulated research in this area, as described in this book as well. These advances will be discussed in this review. For other reviews on this topic, see Beatty and Good (2011) and Charpentier and Oldroyd (2010) and Chapters 5 and 109 of this book.

Rice is the most important staple food for over two billion people in Asia and for hundreds of millions in Africa and Latin America. To feed the ever-increasing populations of these regions, the world's annual rice production must increase from 560 million tons in the year 2000 to 760 million tons by 2020 (IRRI, 1993). If future increases in rice production have to come from the same or even reduced land area, rice productivity (yield ha-1) must be greatly increased to meet these goals (Ladha et al., 1997b). Nitrogen is the major nutrient limiting rice production. Rice requires 1 kg of nitrogen to produce 15–20 kg of grain (Ladha and Reddy, 2003).

Enhancing rice production from the present 8 to 12 ton per hectare by 2020 would require an increased application of 400 kg per hectare, doubling the amount of N fertilizer applied (Ladha and Reddy, 2003). The industrial production of nitrogen fertilizer comes at a cost of more than $100 billion per year and requires the use of large amount of fossil fuel, including petroleum, which, in turn, is highly vulnerable to political and economic fluctuations in the oil markets. Thus, fertilizer costs are high and this affects especially resource-poor farmers worldwide. In addition, the use of fertilizer has severe environmental impacts, due to runoff of excess nonassimilated nitrate, and concomitant eutrophication of rivers, lakes, and the ocean, as well as contamination of the drinking water. Moreover, carbon dioxide which is released during fossil fuel combustion to produce chemical fertilizer contributes to the greenhouse effect, as does the decomposition of nitrogen fertilizer, which releases nitrous oxide, itself about 292 times more active as a greenhouse gas than carbon dioxide (Ferguson et al, 2010; Crutzen et al., 2007). This obviates the need for alternative approaches, namely, BNF (see Chapter 109).

Diazotrophs in rice cultivation can be broadly grouped into two existing BNF systems, with the possibility of an additional two novel systems: (i) Indigenous BNF

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

systems comprised of heterotrophic and phototrophic bacteria, endophytes, as well as native cyanobacteria; (ii) Exogenous BNF systems including *Azolla* harboring symbiotic N_2-fixing cyanobacteria and aquatic legumes like *Sesbania* and *Aeschynomene* forming symbioses with heterotrophic and phototrophic rhizobia (green manures). These systems need to be applied/inoculated into rice fields and involve additional labor, which is not preferred by farmers; (iii) Endogenous (*in planta*) BNF resulting from a rice plant transformed with the nitrogen fixation (*nif*) genes (Ladha and Reddy, 2003; Chapters 5 and 109); (iv) Symbiotic (nodular) endogenous BNF by rhizobia. The BNF systems 1, 3, and 4 will be discussed here. For further discussion, see Ladha and Reddy (2003).

Rice suffers from a mismatch of its N-demand and N supplied as fertilizer, resulting in a 50–70% loss of applied N fertilizer (see Chapter 5). Two basic approaches may be employed to solve this problem. One is to regulate the timing and level of N-application based on the need of the plant (see chapter by Kronzucker and Coskun (Chapter 5] and Beatty et al. [Chapter 109] of this book). The other is to increase the ability of the rice system to fix its own nitrogen. The latter approach is a long-term strategy, but it would have enormous environmental benefits while helping resource-poor farmers. Furthermore, farmers more easily adopt a (genetically modified) genotype or variety with useful traits than they do crop and soil management that are associated with additional costs (labor) (Ladha et al., 1997a). Recent advances in understanding the symbiotic Rhizobium–legume and AM–plant interactions at the molecular level, the structure and function of the nitrogen fixation (*nif*) genes, and the ability to introduce new genes into rice via transformation have created a new opportunity to incorporate BNF capability into rice.

108.2 PAST INVESTIGATIONS (PERSPECTIVE)

During a think-tank workshop organized by the International Rice Research Institute (IRRI) in 1992, the participants reaffirmed the existence of these possibilities and subsequently IRRI developed a New Frontier Project to coordinate a concerted international effort and constituted an International Rice Biological Nitrogen Fixation Working Group to review, to share research results and materials, and to catalyze research in this area (Ladha et al., 1997a). The second meeting of the Working Group took place in October 1996 at the National Institute of Biotechnology and Genetic Engineering in Faisalabad, Pakistan, and the proceedings of this meeting are summarized in Ladha et al. (1997a) and the potential research approaches for achieving improved nitrogen fixation and N use efficiency discussed at that time are summarized in Figure 108.1 (Ladha et al., 1997b).

The majority of the contributions in the latter volume deal with the isolation and characterization of associative and endophytic diazotrophs from rice and the interaction of rhizobia with rice (e.g., see Stoltzfus et al., 1997). *Nif* gene transfer to rice was also discussed (Dixon et al., 1997).

This trend continued at the Third Working Group Meeting held at the IRRI in August 1999, although at this meeting the genetic predisposition of rice for symbiotic nitrogen fixation was addressed in several chapters of the proceedings of the meeting (Laddha and Reddy, 2000), setting an important trend that continues today (see following text). In addition, participants of the meeting pointed out that rice, similar to most angiosperms, but unlike *Arabidopsis*, is capable of developing a symbiotic relationship with AM fungi and that rice has the ability to respond to mycorrhizal signals that trigger plant cortical cell division and the formation of symbiotic intracellular membrane structures. Moreover, it was pointed out that many of the legume plant early nodulin genes described at that time are present in rice (Reddy et al., 2000; Reddy et al., 1998, 1999; Kouchi et al., 1999; 2000) and selected ones induced upon mycorrhizal infection and that a subset of legume plant mutants defective in nodulation are also defective in the mycorrhizal symbiosis (Laddha and Reddy, 2000; Gough and Denarié, 2000). Thus, the rice mycorrhizal endosymbiosis was considered to be a good starting point for thinking about a nitrogen-fixing endosymbiosis in rice. Indeed, this important prediction was borne out in subsequent studies on the similarities between rhizobial and mycorrhizal symbioses with plants and the discovery of the common symbiotic signaling pathway (CSSP; SYM; see Chapters 42, 55, 110; see also following text).

In addition, at the meeting, the first demonstration of the engineering of a eukaryotic alga (e.g., *Chlamydomonas*), in which the *Klebsiella pneumoniae* NifH protein functions to complement a dark-dependent chlorophyll biosynthesis mutant, was reported (Dixon et al., 2000; see also Cheng et al., 2005).

The *nif* gene transfer to cereals such as rice was thus brought back to the forefront, and further research on *nif* gene structure and regulation was stimulated (see following text).

108.3 MORE RECENT INVESTIGATIONS (PERSPECTIVE AND PROSPECTIVE)

108.3.1 Associative and Endophytic Diazotrophs

Indigenous free-living and associative BNF systems are ubiquitous in paddy soils and offer an alternative to the fertilizer input-based technologies. Indigenous diazotrophs and soil organic N together meet more than half of the N-requirement of rice and often are sufficient for sizable

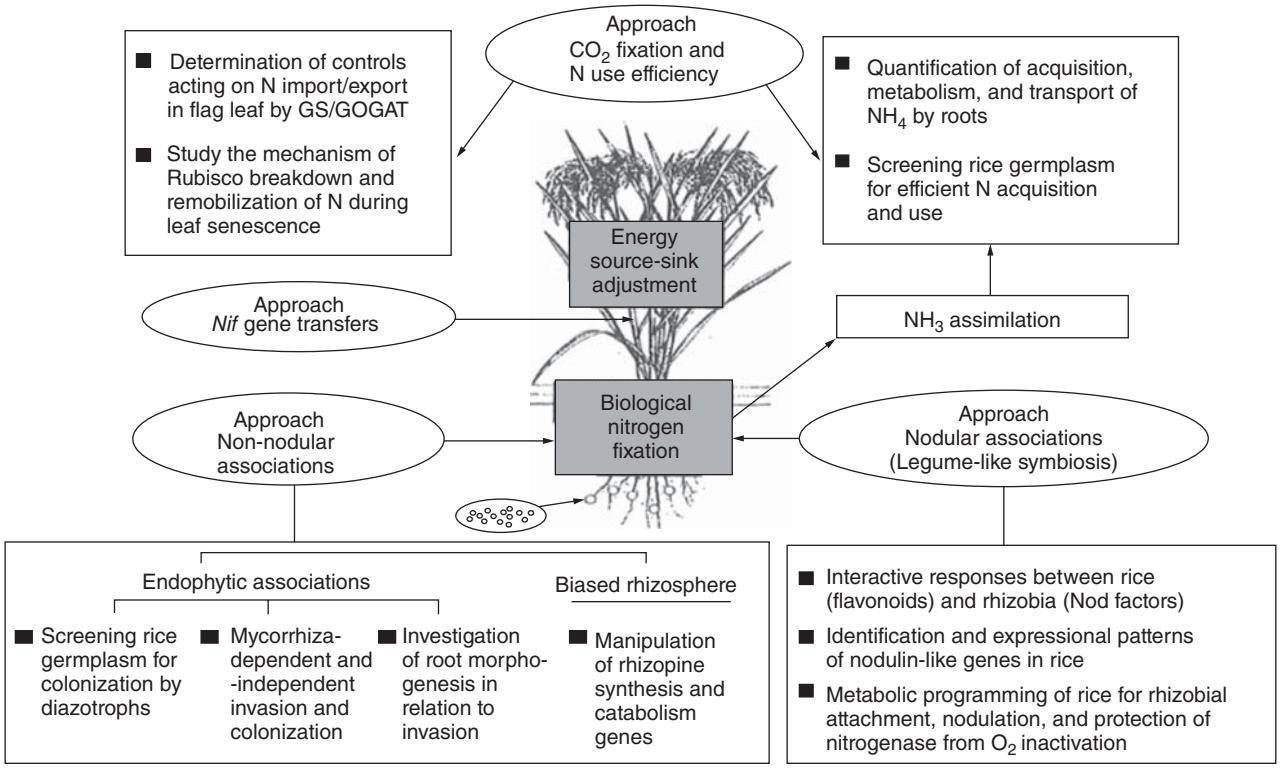

Figure 108.1 Potential research approaches for improving nitrogen fixation and N use efficiency in rice. (Reprinted with permission from Springer; Ladha et al. 1997a.)

yields, sometimes equivalent to yields obtained from using moderate amounts of fertilizer N (Ladha and Reddy 2003). The aquatic environment in rice fields provides an optimum environment for BNF by diverse free-living autotrophs and heterotrophs. The major BNF systems are cyanobacteria and photosynthetic bacteria that inhabit floodwaters and soil surfaces, as well as heterotrophic bacteria in the root zone and free-living in the soil. Multiple studies have reported the isolation and characterization of diazotrophic bacteria from rice and other cereals. However, their actual contribution of fixed nitrogen to the rice plant is difficult to measure (Ladha and Reddy, 2003), and the physiological and biochemical mechanisms that operate in these associations remain to be elucidated (Ladha, 1986). Moreover, the variability observed with different rice varieties remains unexplained. One study reported the mapping of seven genes underlying rice genotypic variability to stimulate BNF, suggesting that the ability of rice to enhance BNF in the rhizosphere is controlled by multiple genes (Wu et al., 1995; Ladha and Reddy, 2003).

In addition to associative diazotrophs, there has been an increasing interest in endogenous BNF systems, particularly nitrogen-fixing endophytic bacteria (e.g., see Stoltzfus and de Bruijn, 2000). Endophytic bacteria are defined as bacteria detected inside surface-sterilized plants or extracted from inside plants and having no visibly harmful effects on the host plant (Hallman et al., 1997; Mano and Morisaki, 2008; Reinhold-Hurek and Hurek, 2011; see also Chapter 114]. The potential of diazotrophic endophytes for BNF in plants was already recognized by the BNF Working Group (Ladha et al., 1997a; Laddha and Reddy, 2000). Various diazotrophic endophytes have been isolated from rice (for a listing, see Mano and Morisaki, 2008, and references therein). They were identified as BNF bacteria on nitrogen-free medium or as rhizobia using a legume trap. However, as in most cases thus far, an actual BNF-based growth advantage of the diazotrophic endophytes for the host rice plants has not yet been clearly demonstrated. Moreover, as is the case for many, if not most, associative or endophytic diazotrophs, growth promotion of the plant may not be due to BNF but to other factors, such as the production of hormones (e.g. *Azospirillum*; Chapters 90, 91). Thus, they should be labeled as plant-growth-promoting (PGP) bacteria (Lugtenberg et al., 2013; de Bruijn, 2013). A historical perspective on PGPR (rhizobacteria) by Elmerich can be found in Chapter 88 of this book. In this review, the extensive Brazilian experience with associative and endophytic diazotrophs and PGPR on sugarcane, rice, and other grasses is highlighted. This experience is further discussed in a special issue of plant and soil (E.K. James and J.I. Baldani, Eds. 2012, Issue 356], based on the BNF with non-Legumes International Symposium of 2010 in Brazil. In the case of sugarcane and other biofuel crops, the location of the meeting in Brazil was

particularly pertinent since the highly advanced Brazilian bioethanol program, which produces over 27 billion liters of ethanol per year, is based on the cultivation of sugarcane, deriving much of its N-requirements via BNF (James and Baldani, 2012). Field-based BNF quantitative studies revealed very substantial inputs into sugarcane and elephant grass of at least 40 kg N per ha per year for sugarcane and up to 132 kg N per ha per year for elephant grass (Urquiaga et al., 2012; De Morais et al., 2012).

Several studies in this special issue on PGPR have focussed on *Azospirillum* which has long been known to be an effective (diazotrophic) PGPR on rice and other cereals. Papers by Castro-Guerrero et al. (2012), Walker et al. (2012), and Vargas et al. (2012) have examined in detail at the biochemical and/or molecular level the mechanisms by which cereals such as rice respond to inoculation by *Azospirillum* strains and how the bacteria respond to their host. Similarly, Brusamarello-Santos et al. (2012) have examined the molecular response of rice to inoculation with another endophytic diazotroph, *Herbaspirillum seropedicae* (James and Baldani, 2012). Moreover, in Chapter 90 in this book, Yaacov Okon describes the agronomic application of *Azospirillum* inocula on maize and rice and reports the positive PGP results of extensive field experiments. The effects of the inoculation of *Burkholderia vietnamiensis* and related diazotrophic bacteria on grain yield of rice are described by Govindarajan et al. (2008), and the beneficial properties of plant-associated *Burkholderia* species are discussed by Hirsch et al. (Chapter 89 and in Chapter 17).

One of the most promising of the endophytic diazotrophic bacterial genera both as a "Model" and a prospective inoculant is *Herbaspirillum* (James and Baldani, 2012). Chubatsu et al. (2012) and Monteiro et al. (2012) have explored how *H. seropedicae* regulates N fixation and the (generally beneficial interactions between the members of this interesting and diverse genus and their various Poaceous hosts (James and Baldani, 2012). The reader is referred to these articles for further details. Infection and colonization of seedlings of two rice varieties by *H. seropedicae* Z67 were also investigated by James et al. (2002). These authors reported that CV IR42 showed a significant (approximately 30%) increase in N content above that of the inoculated controls, and it also incorporated a significant amount of 15N2 (James et al., 2002). *Herbaspirillum* attachment to maize roots is discussed in Chapter 93 of this book. The genetic and functional characterization of another PGP bacterium, *Paenibacillus riograndensis*, isolated from wheat plants, is presented in Chapter 92.

Another model endophyte which stably infects grasses such as kallar grass and rice is *Azoarcus* sp. strain BH72, studied by Reinhold-Hurek and colleagues (Krause et al., 2007). *Azoarcus* is of agrobiotechnological interest because it supplies biologically fixed nitrogen to its host and colonizes plants in remarkably high numbers without eliciting disease symptoms (Krause et al., 2007). Its ability to fix nitrogen contributes to plant growth of its original host kallar grass, and it stably colonizes rice, as well as expresses its *nifH* gene and produces nitrogenase *in situ* (Egener et al., 1999), although its BNF-mediated growth stimulation of rice plants remains to be shown.

A highly researched natural endophytic *Rhizobium*–rice association has been described by Yanni, Dazzo, and colleagues. An extensive treatise on its occurrence and ecophysiology, as well as a translational assessment of its biofertilizer performance within the Egypt Nile Delta, is presented in Chapter 111. Their studies indicate that the promotion of this association by inoculation using certain endophytic rhizobial strains can significantly enhance vegetative growth and grain yield of rice over what can be contributed by full application of N fertilizers and other plant nutrients.

The molecular biology and ecology of associative and endophytic diazotrophs have been advanced considerably by genomic and metagenomic (see de Bruijn, 2011a,b) studies. The genomes of some of the most prominent members *Azoarcus*, *Azospirillum* spp., *Burkholderia* spp., *Gluconacetobacter diazotrophicus*, *H. seropedicae*, *P. riograndensis*, and others have been determined. Moreover, the functional characteristics of an endophyte community colonizing rice roots as revealed by metagenomic analysis have been reported (Sessitsch et al., 2012). These studies will reveal more details of the molecular basis of plant–microbe interactions and the observed PGP effects of the diazotrophs and other PGPRs under study.

108.3.2 Transfer of *nif* Genes to Cereals Such as Rice

The transfer of the nitrogen fixation *nif* genes to nonlegumes has been a holy grail for decades and has been discussed as a way to obtain nitrogen-fixing rice plants in the IRRI Frontier Project Working Group Meetings since their inception in 1992 and before those (Ladha et al., 1997a; Laddha and Reddy, 2000; Chapters 5 and 109). The main result of the research to date has been the seminal paper by Dixon and colleagues showing that the *K. pneumoniae* nitrogenase Fe protein gene *(nifH*) functionally substitutes for the chlorophyll biosynthetic gene *chlL* in *Chlamydomonas reinhardtii* (Dixon et al., 2000; Cheng et al., 2005). At the third meeting of the IRRI Working Group, the hope was expressed that the announcement of this advance would remove barriers to funding in this area (Ladha and Reddy, 2000]. Indeed, 12 years later, the Bill & Melinda Gates Foundation provided a large grant to advance research in the area of *nif* gene transfer to cereals, funding specifically the work by Rubio and colleagues on *A. vinelandii nif* genes summarized in the following [see also Beatty et al., Chapter 109] and the work of Oldroyd on transferring the ability to symbiotically

fix nitrogen to Maize (see following text; Oldroyd, 2013). The BBSRC (United Kingdom) and NSF (United States) have also provided funding for projects on nitrogen fixation and cereals.

More recent work has focussed on the nitrogen fixation genes of *A. vinelandii*. For a general discussion of the biochemistry of nitrogenase, see Chapter 2. The biosynthesis of the iron–molybdenum cofactor (FeMo-co) of nitrogenase has been studied in detail by Hu and Ribbe (2011, 2013) and Rubio and colleagues (Rubio and Ludden, 2008; Jimenez-Vicente et al., Chapter 7; see also references therein]. Jimenez-Vicente et al. concluded that FeMo-co synthesis is a complex process involving a number of *nif* genes that function as molecular scaffolds, metallocluster carriers, or substrate providers. The findings from their and other biochemical and genetic studies using model systems should be taken into account when designing a strategy to transfer *nif* genes into cereals such as rice. They stated that the products of at least six genes *(nifB*, *nifEN*, *nifH*, and *nifDK*) are absolutely required for FeMo-co biosynthesis and nitrogenase activity both *in vivo* and *in vitro* [Jimenez-Vicente et al., Chapter 7]. They further concluded that it is likely that the products of some genes (NifU, NifS, FdxN, NifQ, and NifV) that are required for FeMo-co biosynthesis *in vivo* could be replaced by the activities of plant counterparts. Moreover, the metallocluster carrier proteins NifX, NifY, and NafY aid in FeMo-co synthesis and insertion, but are certainly not essential and could be removed from the equation in initial approaches to carry out *nif* gene transfer [Jimenez-Vicente et al., Chapter 7]. These findings and conclusions would certainly simplify any initial attempts to transfer BNF to rice, since substantially less of the multiple canonical *nif* genes would need to be engineered into plants.

The expression pattern of the nitrogen fixation genes is another factor to be considered when contemplating *nif* gene transfer to plants. Due to the extreme oxygen sensitivity of the nitrogenase enzyme complex and energy-intensive nature of the nitrogenase-catalyzed reaction, most diazotrophs will only carry out nitrogen fixation under anoxic or microaerobic conditions and in the absence of another nitrogen source, respectively. Thus, the process is highly regulated in all diazotrophs examined in detail thus far. Examples of the regulatory circuits and proteins involved are included in this book (see Chapter 11 by Masepohl et al. on *Rhodobacter capsulatus*, Chapter 12 by Nordlund et al. on *Rhodospirillum rubrum*, Chapter 15 by Girard et al. on *Rhizobium etli*, and Chapter 10 by Lin Min on *Pseudomonas stutzeri*). Common themes and differences are discussed in these chapters. However, probably the most studied diazotroph with respect to structure and regulation of the nitrogen fixation genes (proteins) has been *K. pneumoniae* (Dixon and Kahn, 2004; Wang et al., 2013; Huergo et al., 2013). A cluster of 21 genes, organized in seven operons and carried by a sequenced 24,206 bp DNA fragment (Arnold et al., 1988) and regulated by a cascade mechanism, consisting of the NtrBC regulatory system, which responds to the nitrogen availability and modulates the expression of the *nifLA* operon. The NifLA products, in turn, control the expression of the other *nif* genes. NifL controls the activity of NifA in response to both nitrogen and oxygen status, and NifA in concert with the integration host factor (IHF) and the sigma54 holoenzyme form of RNA polymerase initiates the transcription at the other *nif* promoters (Dixon and Kahn, 2004; Wang et al., 2013]. In addition, the PII signal transduction protein plays a role in nitrogen regulation (Huergo et al., 2013).

In any case, in order to transfer the essential *nif* genes to plants, it may be necessary to remove all regulatory circuits and promoter elements, as well as intragenic or intraoperon regulatory sequences. This has been approached by two groups (Temme et al., 2012; Wang et al., 2013] using synthetic biology. In this process carried out by Temme et al. (2012), all native noncoding DNA, regulatory proteins, and nonessential genes were removed. The genes were synthesized using a new codon usage to create a divergent sequence from the wild-type genes. Recoded genes were organized into operons and placed under the control of synthetic promoters, ribosome binding sites, and terminators. In addition, a controller consisting of genetic sensors and regulatory circuits regulated the conditions and dynamics of expression of the refactored genes (operons) (Temme et al., 2012). The latter authors used the nitrogen fixation cluster from *Klebsiella oxytoca*, a *Klebsiella* isolate virtually identical to *K. pneumoniae*, and showed that the refactored *nif* gene cluster recovered 7.4% ± 2.4% nitrogenase activity of the wild-type strain, when introduced into a strain in which the full cluster was deleted.

A similar approach was used by Wang et al. (2013a) to use synthetic biology to distinguish and overcome regulatory barriers related to nitrogen fixation employing the *nif* gene cluster from *K. pneumoniae*. They stated that the expression patterns of the nif operons reconstructed were critical to the maximum activity of the nitrogen-fixing system in *Escherichia coli* and that by mimicking these expression levels with variable strength T7-dependent promoters, approximately 42% of the nitrogenase activity of the wild-type *nif* system could be detected in *E. coli* (Wang et al., 2013a). Moreover, the T7-dependent *nif* system bypassed the involvement of native regulatory factors and gave rise to substantial nitrogenase activity when cultures were grown in the presence of ammonium or glutamine (Wang et al., 2013a). The presence of oxygen was not found to inhibit *nifH* gene expression, although, as expected, nitrogenase activity was not detected in the presence of oxygen. They concluded that their manufactured *nif* cluster may provide the first step for further research into the introduction of *nif* genes into eukaryotic organelles, such as those of plants,

which has considerable potentials in agrobiotechnology (Wang et al., 2013a).

The *nif* gene cluster is not always as complex as in *K. pneumoniae*. Recently, a minimal nitrogen fixation gene cluster from *Paenibacillus* sp. WLY78 containing only 9 *nif* genes (*nifB*, *nifH*, *nifD*, *nifK*, *nifE*, *nifN*, *nifX*, *hesA,* and *nifV*) has been identified and shown to enable expression of active nitrogenase in *E. coli* (Wang et al., 2013b). This would greatly facilitate the engineering of nitrogen fixation in non-nitrogen-fixing organisms such as plants.

The other diazotroph studied extensively for its regulation of *nif* gene expression is *A. vinelandii* (see preceding text). One of the main reasons for its emergence as a model system for the biochemistry and genetics of diazotrophy is its ability to grow on N2 aerobically, its genetic tractability, and the great quantity of and quality of nitrogenase enzymes produced (Dos Santos, 2011; Dingler et al., 1988; Poza-Carrion et al. Chapter 9]. Moreover, its entire genome has been sequenced (Setubal et al., 2009; see also Chapter 22), and extensive transcriptional profiling of nitrogen fixation has been performed (Hamilton et al., 2011a, 2011b). *A. vinelandii nif* gene regulation has been studied in detail also by Rubio and colleagues (see Poza-Carrion et al., Chapter 9]. The regulatory circuits in *A. vinelandii* resemble those in *K. pneumoniae* to a large extent (see preceding text). The specific regulatory elements NifA and NifL, in concert with nitrogen control proteins GlnD and GlnK, constitute a system that integrates redox, energy, and nitrogen signals to modulate the initiation of *nif* gene expression by a sigma54 containing RNA polymerase (for details, see Poza-Carrion et al. Chapter 9 and references therein). The authors concluded that when considering the transfer of *nif* genes to a new organism, such as a plant, a decision must be made to either completely imitate the regulatory circuitry of a model diazotroph, such as *A. vinelandii*, or to abolish all intrinsic regulatory sequences and use the synthetic "refactoring" biology approach described earlier (Temme et al., 2012; Wang et al., 2013).

108.3.3 Transfer of the Ability to "NODULATE" and Fix Nitrogen Symbiotically to Cereals, Such as Rice: The "CSSP" (SYM) Pathway

It has been a long-standing goal in the field of nitrogen fixation to extend nitrogen-fixing symbioses to presently nonnodulated cereal plants such as rice (e.g., de Bruijn et al., 1995; Markmann and Parniske, 2009). Eighty percent of the stable, biologically fixed nitrogen is a direct result of the symbiotic interaction of members of the Rhizobiaceae and selected actinomycetes with leguminous, as well as nonleguminous plants. The potential of symbiotic nitrogen fixation with rice was also discussed by the IRRI Working Group in 1997 and 2000 (Ladha et al., 1997a; Laddha and Reddy, 2000). As pointed out earlier, at the latter meeting, the rice AM symbiosis was reported to share genetic elements in common with the legume–*Rhizobium* symbiosis, and therefore, the former was considered be a good starting point for thinking about a nitrogen-fixing endosymbiosis in rice (Ladha and Reddy, 2000]. This issue will be discussed in the following section.

108.3.3.1 The AM Symbiosis and the Common SYM Pathway.

The AM symbiosis is formed by plants and fungi from the Glomeromycota. The AM symbiosis dates back to about 450 million years ago and is formed by about 80% of land plants, including cereals such as rice (Harrison, 2012; Parniske, 2008; Gutjahr et al., 2008). As a result of its widespread distribution, the AM symbiosis has a global impact on plant phosphorus nutrition and on the carbon cycle. The AM symbiosis is an endosymbiosis, and during AM symbiosis, the fungus enters the root through epidermal cells and grows into the cortex where it establishes highly branched hyphae called arbuscules within the cortical cells (Harrison, 2012). At all stages of development, the hyphae growing through or differentiating within the plant cells are always surrounded by a plant membrane. This is referred to as the perifungal membrane around intracellular hyphae or the periarbuscular membrane around the arbuscule (Harrison, 2012; see also Parniske, 2008). The arbuscule is the site of phosphate delivery to the plant. Diffusible signals initiate the symbiosis before physical contact between the symbiotic partners. Strigolactones activate AM fungal metabolism and this results in hyphal branching (Harrison, 2012; Akiyama et al., 2005). This is similar to the symbiotic nodulation process where flavonoids secreted by the plant activate the nodulation genes (see following text; Chapter 50]. AM fungi secrete a mixture of sulfated and nonsulfated lipooligosaccharides (Myc-LCOs; Maillet et al., 2011) with structures similar to the product of the nodulation genes in rhizobia (lipochitooligosaccharide (LCOs) or Nod factors; Denarie et al., 1996; see also Chapters 51 and 107). In addition, active COs are produced (Genre et al., 2013), which trigger nuclear Ca2+ spiking in *Medicago truncatula* and whose production is enhanced by strigolactone. Both Myc-LCOs and rhizobial Nod factors activate genes involved in the Common Symbiotic Signalling Pathway (CSSP or SYM), leading to AM infection/colonization and nodulation (see Oldroyd, 2013; Venkateshwaran et al., 2013; see also Chapters 54, 55, 59, 110 and in the following text, Figure 108.2).

Myc factors are thought to be perceived by LysM receptor kinases in plants (Maillet et al., 2011; Venkateshwaran et al., 2013; see Chapter 51). According to this model, the binding of Myc factors to these currently unknown receptors triggers rapid responses in the plant, including calcium spiking (Chabaud et al., 2011; 2013; Oldroyd, 2013; see Chapter 54]. The perception of Myc-LCOs by these yet to be identified receptor(s) sets off the AM signaling pathway

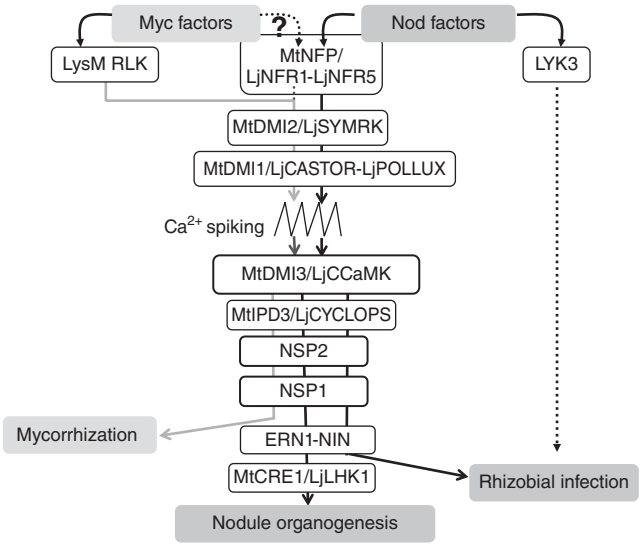

Figure 108.2 Scheme of the genetic control of AM and RL symbiotic pathways. (Reprinted from Chapter 110 by Charles Rosenberg.)

which includes an LRR receptor kinase, nuclear cation channels, nucleoporins, a calcium pump, a calcium-dependent and calmodulin-dependent protein kinase, its interacting protein, and two GRAS-family transcription factors (Venkateshwaran et al., 2013, and references therein; see also Figure 108.2). Mutant plants defective in these genes are defective for the AM symbiosis, as well as symbiotic legume-*Rhizobium* and in some cases Actinorhiza-*Frankia* interactions (see Chapters 55, 59).

108.3.3.2 The Legume–Rhizobium Symbiosis and the SYM Pathway. In addition to establishing an AM symbiosis, legumes establish an efficient symbiosis with nitrogen-fixing bacteria (rhizobia) resulting in the formation of root or stem nodules inside of which rhizobia fix nitrogen in exchange for a plant-derived carbon source (see Sections 8–10 of this book). The *Rhizobium*–legume symbiosis appeared about 60 million years ago (Ferguson et al., 2010). The induction of nitrogen-fixing root and stem nodules on leguminous plants by soil bacteria belonging to the Rhizobiaceae involves a fine-tuned interaction between the two symbiotic partners, including multiple regulatory signals produced by the bacterium and the plant to coordinate the expression of gene sets in both partners. The first step in the plant–microbe signaling pathway leading up to nodulation is the production/secretion of flavonoids, chalcones, and conjugated isoflavonoids by the plant host (see Chapter 50). These host-specific compounds are responsible for activating the nodulation (*nod, noe*) genes of the microbial symbiont. Once the rhizobial *nod* genes are activated, their gene products are involved in the synthesis of a class of compounds (Nod factors), which serve as the first return signal from the bacteria to their host plant. This class of compounds has been shown to consist of LCOs of varying lengths, carrying different side groups and substituents that play major roles in conferring host specificity (Denarie et al., 1996). Nod factors are highly similar in structure to the Myc factors discussed earlier. Nod factors, like Myc factors, have been postulated to be perceived by LysM-type receptor kinases in the host plant (Madsen et al., 2003; Radutoiu et al., 2003; 2007; Ben Amor et al., 2003; Rival et al., 2012; Smit et al., 2007; Limpens et al., 2003; Venkateshwaran et al., 2013; see Chapter 51). In the model legume *M. truncatula* the NFP/LYK3 and in *Lotus japonicus* the NFR5/NFR1 are required for nodulation and have been proposed to function as receptor pairs (see Figure 108.2; Venkateshwaran et al., 2013). Recently, in *L. japonicus* (Lj), NFR5 and NFR1 have been shown to bind Nod factor (Broghammer et al., 2012). However, in *M. truncatula* (Mt), the situation seems to be different and the LysM-RLK LYR3 has been identified, a high-affinity Nod factor and MYC-LCO binding protein (Fliegmann et al., 2013; see also Chapter 51]. The Myc factor receptor remains elusive to date probably because of genetic redundancy in the LysM-RLK family. The perception of Nod factors in legume roots induces a series of responses, including ion flux changes and membrane depolarization, rhythmic calcium spiking, cytoskeletal modification and root hair curling, and activation of cortical cell divisions (Oldroyd, 2013). A signal transduction pathway starting with the MtDMI2/LjSYMRK gene is set in motion (see Figure 108.2; Chapters 5, 110). SymRK has been shown to define a common genetic basis for plant root endosymbioses with AM fungi, rhizobia, and *Frankia* bacteria. A *Casuarina glauca CgSymRK* gene was isolated and its role in root endosymbiosis was analyzed. The results revealed that SymRK was required for both AM and actinorhiza formation in *C. glauca*, indicating shared genetic mechanisms between fungal and bacterial root endosymbioses in *C. glauca* and legumes (Gherbi et al., 2008; see also Chapter 42, 43, and 55]. It is interesting to note that in the nonlegume *Parasponia*, which acquired the ability to establish a symbiotic relationship with *Rhizobium* relatively recently, there exists a LysM-RLK-like gene, *PaNFP*, controlling the formation of a symbiotic interface with rhizobia as well as mycorrhizal fungi (Op den Camp et al., 2011; see Chapter 4]. These are all indications of a common symbiotic pathway (SYM; CSSP; Venkateshwaran et al., 2013; Oldroyd, 2013; see preceding text; Figures 108.2 and 108.3). A transcriptional analysis confirmed a conserved genetic program among AM, actinorhizal, and legume–rhizobial symbioses (Tromas et al., 2012; see Chapter 42]. A comparison with genes induced by AM fungi in *M. truncatula* and rice (*Oryza sativa*) revealed a common set of genes. A comparison with genes induced in nitrogen-fixing nodules in *M. truncatula* and *C. glauca* also made it possible to define a common set of genes induced in these symbioses. The existence of this core set is in accordance with the proposed

adaptation of ancient AMF genes for new functions related to nodulation in legumes and actinorhizal plants (Tromas et al., 2012; see Chapters 42, 55, 110).

After SYMRK, the (common) signaling pathway in legumes proceeds through MtDMI1/LjCASTOR–LJPOLLUX to calcium spiking transduced by MtDMI3/LjCCaMK (Capoen et al., 2011; Oldroyd, 2013; see Chapter 54; Figure 108.2). It is interesting to note that the specific removal of the autoinhibition domain of CCaMK leads to the autoactivation of the nodulation signaling pathway in *M. truncatula*, resulting in the induction of nodules and nodulation genes in the absence of bacterial elicitation (Gleason et al., 2006). Thus, the release of autoinhibition from CCaMK after calmodulin binding is a central switch that is sufficient for the activation of nodule morphogenesis. This, in turn, has implications for the possibility of transferring this process to nonlegumes (Gleason et al., 2006).

Subsequent steps via MtIPD3/LjCYCLOPS, NSP2, and NSP1 lead to a branch point in the Sym pathway between AM fungi and rhizobial infection and nodule organogenesis (see Figure 108.2; see Chapter 59). Details of the generation of the pathway and genes downstream of NSP1 can be found in Venkateshwaran et al. (2013) and Oldroyd (2013), as well as Chapter 59, and will not be reviewed here. The most relevant observations for the purpose of this review are shown in Figure 108.3 (Venkateshwaran et al., 2013), where the common SYM pathways between legumes and monocots such as rice are compared. Clearly, monocots (rice) capable of engaging in a symbiotic interaction with AM fungi possess equivalents of many of the common SYM pathway genes found in legumes. The functionality of the rice orthologous of the SYM pathway has been tested in various ways. One way has consisted of cross-species complementation experiments, for example, testing whether full functional root nodule functioning in a SYM pathway mutant can be restored by introducing the corresponding orthologue from a nonlegume, such as rice (see Rosenberg, Chapter 110). For example, the rice (shorter) form of SymRK, *OsSYMRK*, is sufficient to restore the AM symbiosis to a *L. japonicus symRK* mutant, but not a functional *Rhizobium*–legume symbiosis (see Chapter 110). Thus, a potential specialization of legume symbiotic genes during evolution to fulfill nodulation-specific constraints may have occurred (see Chapter 110]. DMI1 in *M. truncatula* and both CASTOR and POLLUX in *L. japonicus* (see Figures 108.2 and 108.3; Venkateshwaran et al., 2013) are essential for Nod factor-induced nuclear calcium spiking, and the orthologous genes in rice play indispensable roles in rice for the AM symbiosis (Banba et al., 2008; Chen et al., 2009). The OsCASTOR gene was found to restore both the *Rhizobium*–legume and the AM symbioses in a *L. japonicus castor* mutant (Banba et al., 2008; see also Chapter 110], suggesting that this gene is functionally conserved between legumes and rice. In contrast, OsPOLLUX could not fully restore the symbiosis-defective phenotype of *L. japonicus pollux* mutants, suggesting again a functional specialization of POLLUX specific to legumes (Chen et al., 2009; see Chapter 110). For other examples of cross-complementation studies with rice SYM pathway genes, see Chapter 110 and Godfrey et al., 2006. Thus, rice, although a monocot plant species phylogenetically distant from legumes, seems to possess the counterparts of most of the known legume SYM pathway genes (see Figure 108.3). In rice as in legumes, inactivation of these genes results in the loss or alteration of the symbiotic interaction with AM fungi. In spite of these similarities, rhizobial infection cannot be fully rescued by the orthologous rice genes in some legume mutants of the SYM pathway (see Chapter 110). The fact that some of the SYM pathway genes are functionally conserved for nodule formation but not for rhizobial entry is a new illustration of the strict genetic control of rhizobial infection. In spite of this tight control of microbial infection by the host plant, the fact that most of the SYM pathway genes have a counterpart in rice suggests that engineering cereals to form nodules hosting nitrogen-fixing rhizobia might not be an unrealistic goal, provided that the key components missing in rice are identified (Chapter 110).

Gain of symbiotic gene function experiments in rice has also been carried out. Metabolic engineering of rice with the soybean isoflavone synthase IFS gene in order to achieve rhizobial nodulation gene expression was achieved by Sreevidya et al. (2006). Studies with rhizobia demonstrated that the expression of isoflavone synthase conferred transgenic rice plants with the capacity to produce flavonoids which were able to induce rhizobial *nod* gene expression, albeit to varied degrees (Sreevidya et al., 2006; see also Chapter 50]. Moreover, transgenic rice plants harboring the pea (PSL) or wild-soybean lectin-nucleotide phosphohydrolase (GS52) genes were generated and infected with *Rhizobium leguminosarum* bv. *viciae* or *Bradyrhizobium japonicum* USDA110 (Sreevidya et al., 2005). The authors concluded that the presence of lectins, such as PSL and GS52, leads to structural modifications in cell wall organization of the root hair/epidermal cells, making them prone to localized dissolution by the hydrolytic activity of compatible rhizobia to permit invasion of the root cells (Sreevidya et al., 2005). Expression of PSL and GS52 promoted rhizobial colonization of rice plants, although no evidence of infection thread formation in the rice root hairs was observed. Thus, the genetic mechanisms enabling rhizobia-triggered infection thread formation appear to be lacking in rice (Sreevidya et al., 2005).

Thus, genetic analyses in the model legumes *M. truncatula* and *L. japonicus* support the model that legumes usurped the ancestral SYM signaling pathway to carry out the nodulation process (Venkateshwaran et al., 2013). Indeed, the majority of AM SYM pathway genes are conserved in

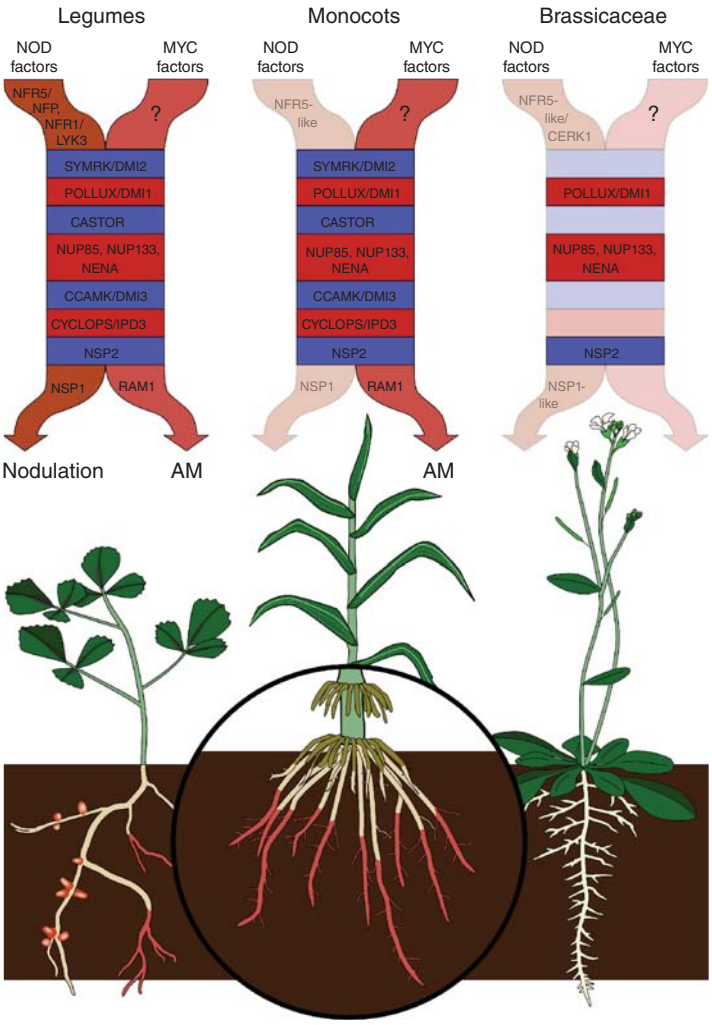

Figure 108.3 Host genetic composition decides the "social network" of plants with major root endosymbionts, such as rhizobia and AM fungi. (Reprinted with permission from Elsevier; Venkateshwaran et al., 2013.)

extant lower land plants, as well as nonleguminous plants, such as rice, suggesting an ancient origin of this signaling pathway, as well as its extraordinary degree of conservation (Venkateshwaran et al., 2013; see Figure 108.3).

Several model legume mutants mentioned earlier which are defective for AM symbiosis are also affected in nodulation, showing that these plants use the same SYM pathway for both root endosymbioses (Kistner et al., 2005; Venkateshwaran et al., 2013).

As pointed out earlier, one of the main objectives of understanding the molecular machinery of the AM fungal and rhizobial symbioses present in leguminous plants is to transfer the ability to symbiotically fix nitrogen to cereals, such as rice. One promising strategy is to use the SYM pathway machinery, which is present already in most land plants and in particular cereals, to recruit additional symbionts, such as rhizobia (Venkateshwaran et al., 2013; Oldroyd, 2013; Charpentier and Oldroyd, 2010; Geurts et al., 2012).

The choice of the *Rhizobium* (rhizobia) for these recruitment studies is under study. A number of naturally occurring nitrogen-fixing rhizobial endophytes of rice have been identified (Mano and Monsaki, 2008]. One of these diazotrophic endophytes could be chosen for rice infection studies. One could also envision choosing one of the *R. trifolii* isolates endophytic to rice described by Yanni and Dazzo (Chapter 111). In addition, a *Rhizobium* species capable of free-living and symbiotic nitrogen fixation, such as the stem- and root-nodulating *Azorhizobium caulinodans* ORS571 (Ratet et al., 1988; de Bruijn et al., 1987, 1989), could be considered. Of course, the rhizobia infecting the model legume species *M. truncatula* (*Sinorhizobium meliloti*; itself a model system for rhizobia) or *L. japonicus* (*Rhizobium loti*) are good candidates, especially since the putative Nod factor receptors (binding proteins) are being characterized (see preceding text) and the corresponding genes could be transformed into rice. Alternatively, one could choose the bacterial partners of the unusual symbiosis between photosynthetic bradyrhizobia and tropical aquatic legumes (Strains ORS278 and BTAi1; Giraud and Fleischman, 2004; Evans et al., 1990; see Chapters 28

and 45]. Besides being photosynthetic, which could provide additional energy for the symbiotic plant–microbe interaction, these strains nodulate the stem and the root of the host plant *Aeschynomene* (see Chapter 28). Moreover, they fix nitrogen in the free-living state and are found as endophytic diazotrophs associated with wild rice (*Oryza breviligulata*; Chaintreuil et al., 2000). But these strains are the most unique because they lack the canonical *nodABC* genes required for Nod factor biosynthesis (see preceding text) but maintain the ability to elicit efficient nodules on their host plant (Giraud et al., 2007; Bonaldi et al., 2011; see Chapters 28 and 45]. This revealed the existence of a Nod factor-independent nodulation process, which could be uniquely suitable to bypass a NF-dependent SYM pathway and its NF receptor in rice (Chapter 28).

In general, nonlegumes have been assumed to lack the ability to respond to rhizobial lipochitin Nod factors. However, very recent data presented by Liang et al. (2013) indicate that *Arabidopsis thaliana* plants, as well as other nonlegumes, such as tomato or corn, recognize the rhizobial Nod factor via a mechanism that results in a strong suppression of microbe-associated molecular pattern (MAMP)-triggered immunity (Liang et al., 2013). To study the interaction between symbiosis and pathogenesis, Liang et al. (2013) added both the strong MAMP flagellin 22 (flg22) and purified Nod factor from *Bradyrhizobium japonicum* to soybean leaves and showed a 25% reduction in flg22-triggered reactive oxygen species (ROS) production, the latter being a strong marker of defense response. Moreover, Nod factor or chitotetraose pretreatment decreased the activation of mitogen-activated protein kinase (MAPK), another marker for defense response downstream of flg22 recognition (David, 2013; Liang et al., 2013). Surprisingly, Nod factor pretreatment also reduced flg22-induced ROS production and MAPK activation in the leaves of the nonlegume *A. thaliana*, as well as tomato (dicot) and corn (monocot) (Liang et al., 2013; David, 2013). Similarly to legumes which recognize Nod factors through specific LysM-type receptors (see preceding text), *A. thaliana* required the LysM receptor kinase LYK3 for Nod factor recognition and plants with a mutated LYK3 gene failed to suppress flg22-mediated ROS production and MAPK activation (David, 2013; Liang et al., 2013). It is possible that Nod factor-mediated suppression of MAMP-induced immunity is universal in plants (David, 2013). Taking advantage of such potential symbiotic relationships might further the cause of establishing symbiotic nitrogen fixation in nonlegume plants, such as rice.

Otherwise, since cereals have most of the necessary components required for AM fungi infection, engineering the perception of rhizobial signals by nonlegumes is a means by which the SYM pathway could be activated to lead to preparation for infection by rhizobia (Venkateshwaran et al., 2013). Work in the only nonlegume nodulated by rhizobia, *Parasponia*, demonstrates that it is not necessary to have a complex nodule organogenesis to have symbiotic nitrogen fixation. In fact, intercellular colonization of modified lateral roots can eventually lead to intracellular fixation threads (Geurts et al., 2012; see Chapter 4]. The cross talk observed between Nod factors and the Myc factor signaling pathways already suggests that it would be possible to modify the receptor machinery to perceive rhizobial signals in cereal plants, such as rice. However, the receptors involved in Myc factor perception have not yet been identified. The transfer of the rhizobial nitrogen-fixing symbiosis to cereals mandates comparative genomic studies between plants forming nodules and those that do not. *Parasponia* is the only nonleguminous plant which associates with rhizobia and is thus available for comparative genomics with its nonnodulating close relative *Trema* [Molling and Bisseling, Chapter 4]. Such comparative studies should shed light on the genetic components which are present in nodulating *Parasponia* and missing in its nonnodulating close relative *Trema* (Venkateshwaran et al., 2013). Venkateshwaran et al. (2013) concluded that engineering important nonleguminous crops, such as rice, to accommodate nitrogen-fixing rhizobia may be an achievable goal that will have a huge impact on the sustainability of food, feed, and biofuel production. Knowledge on the ancestral and widespread CSSP or SYM pathway that has been used repeatedly in plant evolution to accommodate nitrogen-fixing bacteria suggests that this goal is quite possibly within our reach. However, ever-advancing high-throughput studies combined with in-depth genetic analyses will be critical for engineering nitrogen-fixing associations in nonleguminous crops and particularly in cereals such as rice.

ACKNOWLEDGMENTS

The author would like to thank Charles Rosenberg and Jean-Michel Ané for their permission to use Figures 108.2 and 108.3 in this review, respectively. Julie Cullimore is thanked for her critical review of the chapter. The authors' editorial work is supported by the LIPM, INRA, and CNRS and the Labex Tulip.

109.1 INTRODUCTION

109.1.1 The Tragedy of the Commons

In 2011, we published a review of the economic and ecological impacts of excessive nitrogen (N) fertilizer use from the global perspective, comparing regions that have reduced N fertilizer consumption with regions that have not (Good and Beatty, 2011a). N pollution resulting from excessive use of N fertilizers is an example of what the late Garret Hardin described as the "tragedy of the commons" (Hardin, 1968). Farmers, particularly in the developed world, apply high amounts of N fertilizer to maximize crop yields for economic gain. However, when this excess N fertilizer is applied to low nitrogen use efficient (NUE) cereal crops (those that take up only 30 to 50% of applied N), the remaining N is susceptible to loss by soil microbial denitrification, volatilization into the atmosphere, and leaching into waterways (Good and Beatty, 2011a; see also Chapter 108). This excess lost N fertilizer represents a direct cost to the farmers. The larger cost of using excess N fertilizer, either synthetic or organic, is represented by the damage done to aquatic and atmospheric environments. Therefore, the overall cost of excess nitrogen fertilizer use is reflected not only by the monetary cost of applying N fertilizer but also by the loss of marine biodiversity and global climate change. The severe ecological consequences of excess N use will be borne by present and future populations.

However, the knowledge that excess N fertilizer application will damage the environment is insufficient to curb fertilizer consumption for two reasons. First, producers prefer the "insurance" of having sufficient N available for maximum yield, and second, they rarely see the effects of excess N and even less often do they pay any of the associated costs. On a global scale, the incentive to continue using large amounts of N fertilizer on cereal crops is high due to our increasing human global population, livestock populations, and biofuel industry. This is compounded by the decreasing amount of arable land available for agriculture, such that maintaining or increasing crop production in available land is essential (Godfray et al., 2010; Conway, 2012).

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

109.1.2 We Need Another Green Revolution, but This Time Greener

During his speech at the World Hunger Prize in 2009, Bill Gates emphasized that we need another revolution in agriculture, similar to the late Dr. Norman Borlaug's green revolution of 40 years ago, only this time greener. Such an effort must be guided by smallholder farmers and be adaptable to their localities while being sustainable to both economy and environment. Dr. Borlaug bred semidwarf wheat varieties that were resistant to rust and adapted for growth in a variety of different latitudes. These wheat varieties dramatically increased crop yields by over 150% per acre in Mexico, India, Pakistan, China, and parts of South America (Miller, 2012). Dr. Borlaug was awarded the Nobel Peace Prize for helping to avert malnutrition, hunger, and the premature death of millions of people. However, these crop varieties were selected to grow by taking advantage of the high N available when using fertilizers, and since these and other cereal crops tend to have low NUE, this means that the N that is not taken up by the plants can be lost into the environment.

There have been many calls by the United Nations, government, philanthropic funding agencies, scientists, and others for a revolution in the way we manage N fertilization of our cereal crops (EPA-SAB report, 2011; Den Herder et al., 2010; Long and Ort, 2010; ENA 2011; Sutton et al., 2012; The Montpellier Panel, 2013). We need to continue growing cereals at high yields to ensure our food security and biofuel production but in a way that is economically and environmentally sustainable. In his book "One Billion Hungry," Gordon Conway, professor of international development at Imperial College, London, optimistically wrote that we can feed the world's one billion chronically hungry people by 2050. Many of the world's hungry are smallholder farmers in developing countries (see Chapter 105). But to accomplish the goal to feed them, we will need a doubly green revolution - one that embraces both productivity and environmental sustainability. He also outlined the importance of people acknowledging that biotechnology is essential to obtain this goal. Clearly, we need to aim for an agricultural system that is stable, resilient to climate change, productive, and equitable (Conway, 2012).

109.1.3 Excess N Fertilizers and Global Climate Change

Ammonia volatilization and microbial nitrification/denitrification are N loss pathways that can have a significant impact on global warming. Urea fertilizers can be volatized to ammonia gas, especially when the urea is near or on moist, warm soil surfaces. In the nitrification pathway, bacteria oxidize ammonia fertilizer first to nitrite (NO_2) and then nitrate (NO_3), while during denitrification, other soil microbes sequentially reduces NO_3 to NO_2 and then nitric oxide (NO), which can then be oxidized to nitrous oxide (N_2O) and ultimately back to N_2 (Alberta Environment, 2010). All of these forms of nitrogen can be released in gaseous form into the atmosphere and travel large distances. N_2O, for example, is a key greenhouse gas emitted from agricultural soils and is approximately 300-fold more potent a greenhouse gas than CO_2 (Good and Beatty, 2011a). As well, N_2O has an ozone depletion potential similar to hydrochlorofluorocarbons, making this atmospheric pollutant a double threat to the environment as both a greenhouse gas and an ozone depletion catalyst (Ng et al., 2013). Loss of NH_3 from applied N fertilizers can cause soil acidification and eutrophication and when combined with NO_x in the atmosphere forms NO_3^- particulates that can affect human health and reduce visibility (Ianniello et al., 2011).

There is a need to lessen N_2O emissions and NH_3 volatilization from agricultural sources in order to mitigate global warming. Many developed countries have begun to implement plans to do this. For example, in Alberta, Canada, farmers are encouraged to lower their N_2O emissions by using the "Consistent 4R Nitrogen Stewardship" program that, if fully implemented, will generate offset credits for the farmers (Alberta Environment, 2010). This program aims to reduce N_2O emissions by optimizing the amount of N applied to the crop to lessen the opportunity for N to accumulate and persist in the soil. The program uses the 4Rs of N Stewardship (right source at the right rate, right time, and right place) and can include the use of slow-release N fertilizers, nitrification inhibitors, urease inhibitors, and variable N fertilization rates using real-time crop sensors that measure greenness and correlate this to crop N demand (please access http://www.nutrientstewardship.com/what-are-4rs for more information on the 4R N Stewardship program).

Managing N fertilizer use in cereal production has been shown to reduce N_2O emissions and NH_3 volatilization (Cui et al., 2010; Snyder and Melsinger, 2012). However, N management could be made simpler by growing cereal crops that can supply their own internal source of N fertilizer, similar to how legumes are supplied with N from diazotrophic bacteria living as bacteroids within root nodules. Cereals that have been coerced to form efficient partnerships with endophytic or symbiotic diazotrophic bacteria responsible for fixing atmospheric N_2 or that are engineered with the nitrogenase enzyme complex responsible for this catalysis could in principle supply their own fixed N, greatly reducing the need for farmers to apply external N fertilizers (see Chapter 108).

109.1.4 Why Should We Enhance and/or Introduce N Fixation in Cereal Crops?

The importance of improving both crop yield and NUE so we can meet our food needs and protect our environment

from N pollution is clear. There are many reports in the literature, from on-farm and research trials that outline N fertilizer best management practices (BMP) such as the 4Rs and variations of this depending on location (Shanahan et al., 2008; Cui et al., 2010; Alberta Environment, 2010). Cereal crop NUE has been shown to improve in research trials when BMPs have been implemented (Ladha et al., 2005). However, these improved efficiencies rarely reflect the NUE of crops on farms, which tend to remain lower (Dobermann, 2005; McIntyre et al., 2009). This discrepancy is explained as being due to lower management quality on working farms, the use of excessive N fertilizer, and more variability in the factors affecting NUE on working farms versus test plots (Cui et al., 2010). For example, Cui et al. (2010) found that N recovery efficiency was improved from 18% to 44% by using an appropriate in-season N management strategy (see also Chapter 5).

Large yield increases have been due to crop genetic modifications through plant breeding and genetic engineering. Crop improvements such as the semidwarfism, disease resistance, NUE, and tolerance to temperature, drought, and salinity have all brought about yield increases (Good and Beatty, 2011b; McAllister et al., 2012; Schroeder et al., 2013). In recent years, we have begun to see a reduction in the rate of yield increases due to plant breeding, especially in certain regions of developed countries such as the US intensive-farming corn belt where BMPs are generally followed and modern plant bred and engineered varieties are grown (Long and Ort, 2010). This suggests we may have reached the limits of what yield improvements can be bestowed by traditional breeding programs (see also Chapter 106). In order to make a breakthrough and increase crop yields further, we need to use genetic engineering to match crop N demand with crop N supply (Beatty and Good, 2011).

109.1.5 The Global Interest in Reducing N Overuse

Many government-funded technical reports have been recently written that address the increase of biologically reactive N to the N cycle from anthropogenic sources and the negative consequences this has to the environment and list methods to reduce the overuse of reactive N (EPA-SAB, 2011; ENA, 2011; Sutton et al., 2012). One of the most comprehensive is the 2011 European Nitrogen Assessment (ENA) report which was presented at the international conference "Nitrogen and Global Change" held in Edinburgh in April 2011. The report summarizes findings on the effects of excessive human-derived reactive N release into the environment on the climate, environment, biodiversity, and human health and estimates that the societal damage cost of this excess N in the EU alone ranges from €70 to 320B per year (ENA, 2011; Sutton et al., 2012).

In the United States in 2002, 65% of the human-released fixed N was from agriculture, 20% was from fossil fuels, and 15% was from industry [EPA-SAB, 2011]. This makes agriculture an obvious target for reducing the amount of human-made fixed N released into the ecosphere. The EPA Scientific Advisory Board (SAB) estimated that there could be a 25% reduction in fixed N lost to the environment over the next 10 to 20 years using existing technologies aimed at, among other targets, improving N uptake efficiency by crops and decreasing N loss pathways from agricultural lands [EPA-SAB, 2011]. We argue that further reductions in the amount of fixed N lost to the environment could be achieved by improving the synchrony between crop N supply and crop N demand (see also Chapter 5).

109.1.6 Learning from Nature

Symbiotic nitrogen (N_2) fixation by nodulating bacteria in legumes was discovered in 1886 and was closely followed by isolation of the first bacterium (*Rhizobium leguminosarum*) from a root nodule in 1888 (Franche et al., 2008; see Chapter 88). Less than 30 years later, the American scientists Burrill and Hansen asked the question, "*Is symbiosis possible between legume bacteria and non-legume plants?*" (Burrill and Hansen, 1917).

The only organisms known to fix nitrogen biologically are diazotrophic bacteria. N_2 fixation occurs through the action of an iron–sulfur–molybdenum–enzyme complex called nitrogenase. Nitrogenase catalyzes the reduction of N_2 gas (comprising approximately 78% of the atmosphere) to NH_3 (Franche et al., 2008; Lindstrom and Mousavi, 2010). The nitrogenase complex is made up of three structural proteins (NifH, D, and K). NifH (also called Fe protein) carries an iron–sulfur cluster (Fe_4S_4), and NifDK carries two iron–sulfur clusters: a P cluster and an M cluster cofactor (co) that is part of the active site and is unique to diazotrophic bacteria (Rubio and Ludden, 2008; see Chapters 2, 7). The M cluster also contains an atom of either molybdenum (FeMoco), vanadium (FeVco), or iron (FeFeco), depending on the type of nitrogenase (Eady, 1996). The nitrogenase complex is sensitive to oxygen mainly due to the Fe_4S_4 and P clusters that are irreversibly oxidized by oxygen (Bothe et al., 2010).

Aerobic–diazotrophic bacteria have developed many different ways to overcome the oxygen sensitivity of their nitrogenase complexes. For example, some Cyanobacteria (which also photosynthesize and generate O_2 as a by-product) form heterocysts where N_2 fixation occurs, which are separate from the main cells where photosynthesis takes place (see Chapter 86). Other Cyanobacteria separate photosynthesis and N_2 fixation temporally by regulating the functioning of nitrogenase so that it occurs in the dark (Bothe et al., 2010). *Azotobacter* species have the highest rate of respiratory metabolism known in bacteria. This means that

the cell is using oxygen in respiration so rapidly that there is a very low level of free oxygen within the cell. Some *Azotobacter* species also make the Shethna protein (also called FeSII) which protects the conformational shape of nitrogenase, while still others make a polysaccharide called alginate that forms a capsule around the cell and limits the diffusion rate of oxygen (Moshiri et al., 1994; Maier and Moshiri, 2000).

Depending on the species of diazotrophic bacteria, there have been up to 82 nitrogenase genes found. However, the number of genes essential for nitrogenase activity was recently shown to range from 12 to 20 in *in vitro* and *in vivo* studies (Curatti et al., 2006; Curatti et al., 2007; Curatti et al., 2008; Temme et al., 2012; see Chapter 108).

Diazotrophic bacteria have been found as free-living bacteria in low-N environments, associative bacteria that grow within plant rhizospheres, and endophytic bacteria that colonize the interior of plant roots or stems. They are also found as symbiotic bacteria that infect specific plants such as legumes, actinorhizal plants, and *Parasponia*, forming specialized bacteroids that provide fixed nitrogen to the plant host in exchange for photosynthates (Franche et al., 2008). Symbiotic biological N_2 fixation (BNF) can also provide significant amounts of the required supply of N to the plant. Symbiotic fixed N that is taken up by plants has been measured to be as high as 300 kg N/ha, which matches the synthetic N fertilizer rates of intensive wheat–maize farmers in the North China Plains (Ju et al., 2009; Cui et al., 2010).

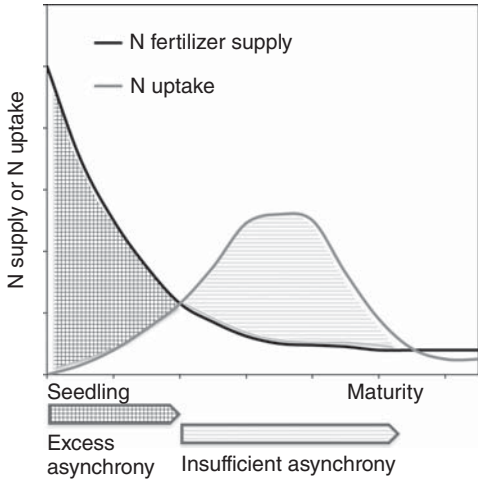

Figure 109.1 Asynchrony of N supply with N uptake. At the seedling stage, N fertilizer tends to be applied at a rate that is higher than the N demand and uptake of the seedlings, leading to an excess of N fertilizer. By midgrowth stage, the N fertilizer supply still available to the crops tends to be lower than the N uptake rate, leading to insufficient N supply.

109.2 DISCUSSION

109.2.1 Asynchrony, Excess, and Insufficient N Supply

Two reasons for low worldwide cereal NUE are, first, uniformly applying N fertilizer regardless of the actual N needs of the crop, which will often vary due to localized soil N levels, and, second, the fact that the crops' N needs increase over time (Shanahan et al, 2008). Asynchrony is the mismatch between N supply to crop N demand, leading to significant potential losses of N to the environment (Figure 109.1; see Chapter 5).

A key reason (from an N fertilizer management perspective) for the low NUE of cereal crops worldwide is poorly synchronized N fertilization management, which is often dictated by other reasons (such as when it is easiest to apply N fertilizers). In many parts of the world, the majority of N fertilizer is applied prior to planting, resulting in the largest supply of N to the plant when it is taking up a small amount (or zero) of N, representing excess N synchrony (Figure 109.1, Shanahan et al., 2008; see Chapter 5). What would be considered excess N at the preplant or sowing stage can quickly become insufficient N at a later stage of plant development. Insufficient N occurs when the crop biomass, and subsequently crop N uptake, is rapidly increasing but there is insufficient N available in the soil to meet this demand. This is because the preplant or seed stage applied N has leached down to a soil level that the crop roots cannot reach, has been lost as runoff, or has been denitrified and released back to the atmosphere as NOx, N_2O, or N_2 gases or volatized to NH_3 gas.

109.2.2 N Leaching from Various Cropping Systems and Mitigation Methods

One agronomic method to reduce N leaching further down the soil profile and into waterways, especially after a drought year, is to grow winter cereal cover crops to act as N scavengers that will take up (capture) residual soil N between growing seasons (Snyder and Melsinger, 2012). Numerous studies using rye, ryegrass, and winter wheat as cover crops show a range in the reduction of NO_3^- leaching from the field soils of 13 to 94%, with an average of 58% reduction in nitrate–N leaching. This method of conservation also has the added benefits of retaining moisture levels in the field, increasing soil carbon content, and reducing the phosphorus (P) surface runoff. However, there are limitations to this approach to mitigate N losses. For example, many farms are in geographical locations where the soil and cover crops will freeze in the winter. In addition, there needs to be enough rainfall to allow for the winter crop to mature in a timely manner so that planting of the cash crop is not delayed. In addition to these challenges, farmers would need to pay the

initial investment costs of winter cover crop growth (Snyder and Melsinger, 2012).

109.2.3 Methods to Fix and/or Avoid Asynchrony

There are methods to mitigate both excess and insufficient N asynchrony in cereal crop production such as improved agronomic management of N fertilizers, plant breeding/variety selection, and genetic engineering, as described in the following (Dobermann and Cassman, 2005; Crew and Peoples, 2005; Cui et al., 2010).

Using best nutrient management strategies, such as the 4Rs, can allow for N supply to be close to N demand. The European Union (EU) adopted the Nitrate Directive in 1987 to reduce the amount of N pollution via runoff and leaching into drinking water. In this directive, EU farmers need to show that they are using BMP by reporting detailed farm N budgets before they can receive "Common Agricultural Policy" (CAP) subsidy payments (EU Nitrates Directive, 2010).

Another method to synchronize N supply with N demand is to use symbiotic rhizobia–legumes in cropping rotations as a source of green manure (Drinkwater et al., 1998; Crews and Peoples, 2005). Legume N residues tend to mineralize N and make it slowly available for plants. This suggests that there will be some N available for the plants during all growth stages (Figure 109.2).

Adding perennial varieties that have much longer roots than cereal crops into the agricultural cropping system could reduce loss of N from the soil by leaching down the soil profile (Crews and Peoples, 2005). The long roots can uptake N from soil depths that the annual crop root systems cannot.

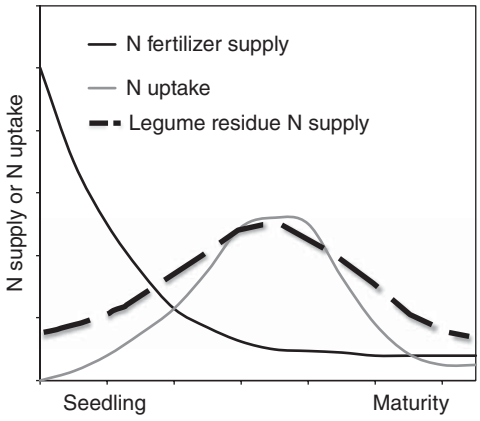

Figure 109.2 The legume residue N supply overlaid onto the N fertilizer supply and N uptake lines showing that legume residue N remains available in the soil to crop plants at a higher level than synthetic N fertilizers and can substantially reduce insufficient asynchrony between the supply and uptake of crop plants in midgrowth.

Improving the NUE of the cereal crop plants would allow for less N fertilizer application, and there are some transgenic plants that have shown NUE phenotypes (Giller et al., 2004; for a review, see McAllister et al., 2012). However, improving NUE does not address the key problem of asynchrony of N demand to N supply.

109.2.4 Development of a New System: The Introduction of BNF to Cereal Crops

The goal of BNF cereals is to synthesize biologically active N within the plant, so that N supply is tightly coupled to growth. Given the economic importance of fixed N_2 and the significant environmental damage caused by excessive N, it is time to refocus our efforts and resources on making crop plants that can fix N_2, either independently or in association with bacteria (Saikia and Jain, 2007; Cheng, 2008; see Chapter 108). If successful, these advances will start a truly "green" revolution, one that addresses the increasing demand for N in agriculture while also dramatically reducing the environmental costs associated with application of N-based fertilizers (New Scientist, 2011).

Engineering cereal crops to fix their own N could relieve the application of N fertilizers and allow the crops to synchronize their supply of N with their own demand (Figure 109.3; see Chapter 108).

While many promises of generating N_2-fixing cereal plants have been made, there has been little progress in this area from either the public or private sectors. This has

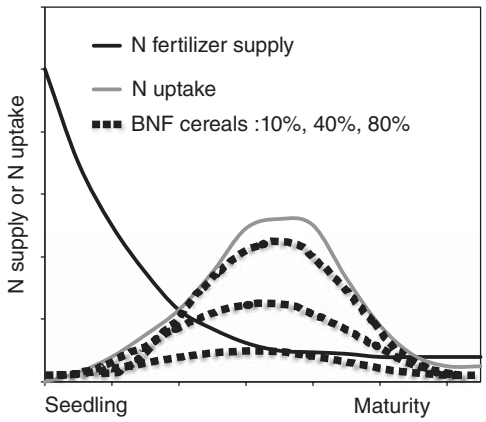

Figure 109.3 Potential for asynchrony between N uptake needs of the cereals with the supply of N available for the cereals with the development of cereal plants that can fix their own nitrogen using atmospheric unreactive N as the N source. Even a modest rate of cereal-sourced BNF would benefit the plant during the midgrowth stage where there is generally less N supply available to the plants in the soil from N fertilizers applied at the seedling stage. The economy and environment would also benefit from less leached and volatized N released into the ecosystem.

resulted in skepticism that N_2 fixation could be introduced into cereals and stalled funding in this field despite the increasing need for this trait in the major cereal crops. During 1994–2000, the International Rice Research Institute (IRRI) conducted a frontier research program on assessing opportunities for nitrogen fixation in rice and generated some valuable information on rice endophytic associations and symbiosis with rhizobia (Ladha and Reddy, 2000; see Chapter 108). However, due to the long-term nature of the experiments and the lack of long-term funding, this project was discontinued.

109.2.5 Three Approaches to Develop BNF Cereal Crops

Three different approaches to introducing BNF into cereal crops have been outlined in the literature (Table 109.1; Ladha and Reddy, 2000; Beatty and Good, 2011; see Chapter 108).

These approaches either involve the plant receiving fixed N from a diazotrophic partner in either an associative, endophytic, or endosymbiotic relationship or producing fixed N *in planta* using a stably inherited nitrogenase enzyme complex (see Chapter 108). If we engineer cereals to fix their own N, we could greatly reduce or eliminate the need for N fertilizer applications in countries with access to N fertilizers. Furthermore, we could greatly increase yields for smallholder farmers in developing countries who grow crops on poor soils with low to no N fertilizer available to them. N supply and cereal crop N demand would be synchronized. The specific challenges inherent to these approaches, the current state of knowledge in these areas, and the funding granted to these approaches are briefly discussed.

109.2.6 Enhance Endophytic Relationships with Cereals

Diazotrophic bacteria can partner with cereal crops to form surface associations or colonize the roots or stems and grow endophytically (Mahdi et al., 2010; Reinhold-Hurek and Hurek, 2011; Santi et al., 2013). These partnerships can provide some fixed N to the plant from the associated bacteria, and increases in cereal yields from diazotrophic associative and endophytic nitrogen fixation have been reported (Bhattacharya and Jha, 2012; Santi et al., 2013). Bacteria that colonize the plant rhizosphere, called rhizobacteria, have been shown to promote plant growth by various means, including N fixation, and are often described as associative plant growth-promoting rhizobacteria (PGPR)

Table 109.1 Comparison of the 3 major BNF systems evaluated and the relative benefits and challenges of each approach (see also Chapter 108)

System	BNF Potential	Amount Fixed N (kg/ha/yr)	Advantages	Disadvantages	Time	Probability of Success	Potential Returns
Endophytic diazotrophic–cereal plant enhancement	Low to medium	1–25,~ 50	Many known endophytic and diazotrophic bacteria–cereal crop partnerships in nature	Nonspecific, low population of endophytes, poor active transfer of fixed N to plants, difficult to manage, seasonal reinoculation needed	Short to medium	Medium to high	Low/medium
Endosymbiosis with diazotrophic–cereal plant partners	High	75–300	High BNF levels in nodules, symbiosis with rhizobia a well-known system, N supply synchronized to N demand	Complex genetic engineering, requires interactions between two partners, some steps in symbiosis not yet understood	Medium to long term	Low to medium	Medium/high
Stable introduction of nitrogenase in plant organelle	High	ND	Technology in the seed, broad application to crops, N supply synchronized to N demand	Complex genetic engineering into a plant organelle, challenges with oxygen levels and energy requirements	Long term	Low to medium	Medium/high

Original Sources: Ladha and Reddy, 1995, Reddy et al., 2002.

(see Chapters 88, 108). Other diazotrophic bacteria colonize the inside of the plant and live endophytically, possibly as a means to protect their nitrogenase enzyme from oxygen. N_2-fixing endophytic bacteria forming associations with some cereal crops have been found in numbers as high as 10^8 colony-forming units in roots and can provide the plants with fixed N at rates of 1–25 kg N ha^{-1} (Stoltzfus et al., 1997, Yanni and Dazzo, 2010; see Chapter 111). PGPR can also provide additional benefits by supplying other molecules such as phytohormones to their hosts. Many different PGPR are used in biofertilizer (bioinoculant) formulations that are on the market as yield enhancers (Santi et al., 2013). One approach to make BNF cereals would be to improve diazotrophic, endophytic bacteria–cereal plant associations (Beatty and Good, 2011; Santi et al., 2013). This method has the benefit that the interactions are already present in nature and these bacteria are known to promote plant growth. Farmers could include the enhanced endophytic N-fixing bacteria with the seeds at planting time.

The enhancement of these associations would need to address such factors as increasing the stability of the association by optimizing the plant and bacteria interaction and encouraging the bacterial partner to share its fixed N with the plant. There have been numerous genomic and transcriptomic studies performed on both the associative diazotrophic PGPR bacteria and cereal plants that have shown the responses to partnership from both sides (Santi et al., 2013). This information can be used to enhance these partnerships. However, the limitation of this approach to make BNF-enhanced cereals is that currently the low rate of N fixation from these associative bacteria may not be able to be increased enough to allow for a substantial reduction in N fertilizer application in intensive farming. Conversely, even modest increases in BNF capability within cereals would greatly increase crop yields in chronically N-poor regions such as Sub-Saharan Africa.

109.2.7 Symbiotic Diazotroph–Cereals

Several rhizobia and *Frankia* bacterial species have independently evolved productive nitrogen-fixing symbioses with more than 14,000 Leguminosae species, several *Parasponia* species, and approximately 200 *Actinorhizal* species (Lindstrom and Mousavi, 2010; Santi et al., 2013). These symbioses result from nitrogen-fixing bacteria colonizing the plant root cells and forming a plant nodule. Another approach to BNF cereals is to engineer cereal crop plants and/or nodulating diazotrophic bacteria to form symbiotic partnerships (Charpentier and Oldroyd, 2010; Beatty and Good, 2011; see Chapter 108). There have been significant advances in understanding how these symbioses are established, which can help us determine how to engineer this process in cereals. There are four basic steps that need to be either co-opted or introduced into cereals for cereal–diazotrophic bacteria endosymbiosis to occur. The plant and bacterial partners need to locate each other, nodulation needs to occur, the plant needs to be stably infected with the bacterial partner, and the nitrogenase complex within the bacteria needs to be protected from free oxygen. BNF researchers have recently discovered that all plants have the capacity to attract, interact, and form symbiotic partnerships with arbuscular mycorrhizal (AM) fungi (Maillet et al., 2011) via a dialog with plant-derived and fungi-derived macromolecules. It appears that rhizobia adopted or mimicked the macromolecules from AM fungi to form their own symbioses with plants at some point during their evolution (Gherbi et al., 2008; Op den Camp et al., 2011). For nodule formation, some of the genes necessary for this already exist in cereals (see Chapter 108). However, they may not be expressed in the right concentration, at the right time, or in the right place to allow for nodules to form currently (Charpentier and Oldroyd, 2010). The promoter–gene combinations for production of the correct hormones and transcription factors required for nodulation would need to be genetically engineered into the cereal.

There are endosymbiotic relationships between plants and diazotrophs that use prenodules instead of rhizobial/legume-like nodules. This type of primitive structure may be easier to introduce to cereals initially (Laplaze et al., 2000). Infection of the plant host by the endosymbiotic bacterial partner has been seen to occur in simple to very complex ways (Madsen et al., 2010). Many *Rhizobia* and *Frankia* species use a highly specialized plant-derived structure called an infection thread to colonize plant roots. A simpler infection method, called intercellular infection, is carried out by the bacterial partners of some legume species, all *Parasponia* species, and most actinorhizal plants (see Chapter 4). Mutant legumes that cannot form infection threads can still be colonized by rhizobia by the simplest method, called crack entry. All of these infection methods still allow for N fixation; therefore, the less genetically complex intercellular or crack entry methods may be more successful (Madsen et al., 2010). The nitrogenase enzyme needs to be protected from oxygen in order to function. In the rhizobial–legume symbiosis, the intracellular rhizobia develop into organelle-like bacteroids that are packed into microaerobic nodules containing leghemoglobin that sequesters free oxygen (Soupene et al., 1995). By contrast, *Frankia* fix nitrogen *in planta* in specialized vesicles that provide the oxygen protection needed for nitrogenase to function (see Chapters 35, 43). Endosymbiotic N fixation rates are often comparable to the N fertilizer rates used in intensive farming, suggesting that if cereals could be engineered to allow for diazotrophic colonization and nodulation, they could have a high level of *in planta*-sourced N to use in biomass and yield. The benefits of this BNF cereal crop approach to farmers would be that they could grow

cereal crops like legumes. N fertilizer applications to the growing crop could be greatly reduced or even eliminated provided the correct symbiotic bacterial partner was used to inoculate the cereal crop (Ng et al., 2013).

Researchers at the John Innes Centre in the United Kingdom have recently received a grant of over $9 million USD from the Bill & Melinda Gates Foundation (B&MGF) to study the feasibility of developing diazotrophic symbiosis with traditionally grown Sub-Saharan maize (www.foundationcenter.org/gpf/foodsecurity; see also Chapter 108).

109.2.8 Introduce BNF Genes Directly into Plants

Why don't plants fix atmospheric nitrogen themselves? Perhaps, it is because plants can "easily" harness bacteria to do it for them, for the price of providing photosynthate to the bacteria. Or maybe, there is a fitness-related issue inhibiting plant BNF. Whatever the reason, plants do not fix their own nitrogen, although there are thousands of different species of plants that can form endosymbiotic relationships with many different species of diazotrophic bacteria. Moreover, these plants have developed the ability to deliver C to the nodule and transport and utilize the N that is fixed in that organelle. Unfortunately, many of the crops that the world population relies on for food, such as maize, rice, wheat, and barley, do not form endosymbiotic relationships.

The third approach to engineering BNF cereals that would address many of the issues associated with excessive N applications but would be just as challenging and as lengthy a research process as engineering symbiotic cereals would be to introduce the genes encoding nitrogenase directly into plants (Merrick and Dixon, 1984; Beatty and Good, 2011; Ng et al., 2013; see Chapter 108).

The 10 to 20 bacterial genes that are essential for producing a functional N_2-fixing enzyme complex could be used to stably transform cereal crops so they could fix their own N using freely available N_2 from air (see Chapters 7, 108). There are three known types of nitrogenase that differ in the type of transition metal atom present in the active site M cluster cofactor: molybdate (Mo, with *nif* genes), vanadium (V, with *vnf* genes), or iron (Fe, with *anf* genes)(Schwarz and Mendel, 2006; Rubio and Ludden, 2008; see Chapter 2). The nitrogenase complex is made of three structural proteins (HDK) encoded by three genes *(*e.g., *nifHDK* for Mo–nitrogenase) (Dixon and Kahn, 2004; Dos Santos and Dean, 2011). Although nitrogenase is unique to bacteria, there are Fe–S containing enzymes found in the nucleus, cytoplasm, chloroplasts, and mitochondria of plant cells (see Chapter 6). For example, many plant mitochondrial enzymes function with Fe–S–P clusters. Although the M cluster cofactor (e.g., FeMoco) is unique to bacteria, plant mitochondria do make cofactors containing molybdenum (Moco). Thus, mitochondria are known to take part in the import of Fe, S, and Mo into the mitochondria, although the identity of these transporters is currently unknown. Plants are poised to be the model organism of choice to study these transporters since the single-celled eukaryotic model organism *Saccharomyces cerevisiae* does not have the Moco biosynthetic pathway (Balk and Pilon, 2011).

There are several main challenges to engineering BNF directly into cereal crops that must be overcome: first, determining which *nif* genes are essential for production of a functional nitrogenase and from which diazotrophic bacterial source; second, engineering optimal transcription, translation, and assembly of the bacterial gene-encoded metalloproteins to allow for functioning N_2 fixation within the plant; third, protecting the nitrogenase complex from free oxygen that would disable BNF function; and, finally but by no means insignificant, providing enough reducing power and energy, in the form of electrons and ATP, for the N_2 fixation reaction to occur.

Most of the genetic complexity of nitrogenase originates with the M cluster cofactor which is exclusive to nitrogenase. The sequenced, mapped, and annotated *Azotobacter vinelandii* genome has 82 nitrogen fixation (*nif*) genes located in four separate locations on the genome that encode the three types of nitrogenase (Dos Santos and Dean, 2011; Hamilton et al., 2011). This suggests a high level of genetic complexity. However, Curatti *et al*. (2007) has synthesized FeMoco *in vitro*, showing that this complex cofactor can be made using three Nif proteins plus iron, molybdate, sulfur, homocitrate, and S-adenosylmethionine (see also Chapter 7). Therefore, although the N fixation genetics appears to be made up of a large number of genes, only a small portion of these genes may need to be transferred to a plant organelle to have a functional nitrogenase enzyme complex present. Synthetic biology approaches have been used to modify the nitrogen fixation gene cluster from *Klebsiella oxytoca* (Temme et al., 2012; see Chapter 108). Certain structural features of the gene cluster were altered; all regulation, noncoding sequences, and nonessential genes were removed, and codons were modified to distinguish the modified DNA sequence from the native sequence. The genes were then placed under the control of synthetic promoters, ribosome binding sites, and terminators. This modification simplified the regulation and allowed a specific function to be assigned to each genetic component (Temme et al., 2012). This refactoring of the gene clusters from *K. oxytoca* showed that 12 *nif* genes were essential to form a functional nitrogenase in the non-N-fixing bacteria, *E. coli*, to allow it to fix N. The rapid advances in synthetic biology means we can now synthesize novel genes, regulatory components, and pathways; introduce them into the organisms of our choice; as well as target them to the appropriate cellular compartment.

Due to the oxygen sensitivity of the nitrogenase enzyme, it would need to be stably introduced into a microaerobic environment in the plant to ensure functionality, such as an organelle. Chloroplasts and mitochondria are two logical places to transfer nitrogenase genes to for many reasons; their bacterial origins may allow for a more "prokaryotic-like" transcription and translation of the genes into functional gene products, and both generate enough ATP and reducing power for nitrogenase function. As well, the chloroplast genomes of ferns, mosses, and gymnosperms encode protochlorophyllide reductase, an oxygen-sensitive enzyme that is structurally and functionally related to nitrogenase (Fujita and Bauer, 2000, Muraki *et al.*, 2010).

Although the potential rate of cereal crop BNF is unknown, the goal would be to make it possible to match the rate seen in legume symbiosis. Fundamentally, the key benefit of this approach to farmers would be that the plant itself can meet its own N demand so there would be no need to introduce an N-fixing partner at the time of sowing and N fertilizer application could be greatly reduced or eliminated (Ng et al., 2013).

109.2.9 Why Develop BNF Cereal Crops?

There has been renewed interest in bioengineering N_2-fixing cereals, and significant advances in our understanding of the biology of N_2 fixation have been made in the last two decades (Godfray et al., 2010, Oldroyd et al., 2009, Den Herder et al., 2010). The advances in different experimental model systems, including several N_2-fixing bacteria (various rhizobia and *Frankia* species), legumes (*Medicago truncatula* and *Lotus japonicus*), and crop plants (*Brachypodium distachyon*, *Zea mays*, *Oryza sativa*), are important drivers for furthering N_2 fixation in nonlegume plants. Scientific and technological advances that are critical for moving toward N_2-fixing cereals include efficient cereal transformation protocols, development of model organisms that are efficient in terms of molecular biology protocols, and genome sequencing. Access to complete genome information allows researchers to identify homologous genes across species and to identify novel genes. We also now understand nitrogenase biosynthesis from the gene to the protein level (see Chapter 2).

Why should we push ahead now when in the past we failed? We are well aware that projects of this nature are challenging and that success will come in small steps. For example, the first step in many of these concepts will be to initially demonstrate N_2 fixation in the cereal without being concerned about the amount of N_2 fixation. A small increase in available N to a plant can still have a significant effect and would be particularly valuable in areas such as sub-Saharan Africa where N fertilizer application rates are low due to cost and poor infrastructure (see Chapter 105). As well, if one could closely couple N and C metabolism, excess N would not be lost from the roots into the environment. While there is clearly a significant risk of failure of any one of these approaches, the potential benefits are enormous. Even if unsuccessful, the fundamental knowledge gained from such an attempt may prove crucial to further understanding other crop processes, such as root–pathogen interactions and nitrogen metabolism in general.

109.2.10 Is There a Yield Hit from BNF?

The idea of trying to engineer cereal crops to fix their own nitrogen is not a new one. One of the arguments against developing associative/endophytic or symbiotic BNF cereal crops is the question of whether there would be a yield penalty. In a diazotrophic bacteria–plant partnership, the plant receives fixed N but in turn supplies carbon from photosynthesis to the bacteria. Studies have shown that photosynthate C is transferred to the bacteroids in the nodules of legumes within one hour of CO_2 fixation (Voisin et al., 2003). This shows the tight connection between the two symbiotic partners for C and N production and transfer. Symbiotic nitrogen fixation specific activity is dependent on photosynthesis and nitrate availability and will correlate with both of these factors, along with oxygen levels (Voisin et al., 2003). The calculated C costs to pea plants that were directly attributed to nitrogenase activity were 1.5–4 grams C per gram of fixed N (Voisin et al., 2003). However, there have been many reports in the literature showing shoot biomass increases, seed biomass increases, and yield increases in rice, maize, and wheat grown in field and controlled conditions from inoculation with diazotrophic PGPR such as *Azoarcus*, *Azotobacter*, *Pseudomonas*, *Burkholderia*, and other bacterial species (for a review, see Santi et al., 2013). This would suggest that although a plant–diazotrophic bacterial partnership will cost the plant C, the plant gains fixed N and potentially other beneficial molecules that increases yield instead of costing yield. Second, the whole concept of N limitation is based on the fact that when N is applied to crops, they are clearly not C limited, in that they can quickly grow and increase both size and yield. Third, recent efforts underway to improve the rate of C fixation in plants may provide any needed boast in the fixed C required to allow increased growth (Parikh et al., 2006). However, the question of whether there would be an energy deficit in the BNF cereal plants remains to be studied once the nitrogenase genes are engineered into cereal plants.

109.2.11 Economic Benefits of BNF Cereal Crops

Conservation and resource management specialists discuss achieving the equity, economic, and environmental triple bottom line as the ideal outcome of conservation (Halpern et al.,

2013). This is where social outcome, equity, and conservation goals are maximized, while costs to reach those goals are minimized. Conservation studies have shown that the degree of success in environmental protection is highly correlated to the level of perceived or real equity (or compliance) of the participants (Halpern et al., 2013). When equity is low, the probability of success in the conservation project is also low. Providing equity to the participants who have a significant stake in the outcome of a conservation plan, by involving them in the decision making, greatly increases the motivation to adhere to a plan, which in turn increases the success rate. The need to reduce N fertilizer use while continuing to increase yields, in order to minimize the external costs from loss of excess fixed N into the environment, could be analyzed using triple bottom-line conservation models to help determine how best to approach this problem. The equity issues for N pollution from excess N fertilizer use involve the inequitable availability of N fertilizers to farmers and the inequitable cost of N pollution from excess N fertilizer use to the *global commons*. Some farmers cannot access or afford to buy N fertilizers (such as smallholder farmers in developing countries), while other farmers (such as intensive farmers in developed countries) have readily available access, although it is an expensive commodity. Equity, in the case of N loss and environmental damage, is complicated because N loss is difficult to quantify since it fluctuates depending on climate and soil conditions. The source of N pollution is difficult to trace as it enters fast-moving environments such as air and water such that N pollution causes environmental damage that is both spatially and temporally separate from the initial source. Farmers are the initial economic stakeholders in decision about the application of N fertilizers in terms of a simple use/not use and subsequent high/low yields. However, we all become stakeholders in the outcomes of farming, which include food security and the environmental damage caused by excess nutrients. Introducing cereal varieties to farmers on a sliding cost scale that matches their economic resources that have built-in N fertilizer reduction potential could help address the complex equity problems that threaten to derail the goal of decreasing N pollution.

We previously calculated the external costs associated with excess N fertilizer consumption to be a minimum of 44% of the direct costs associated with excess N fertilizer application (Table 109.2; Good and Beatty, 2011a).

This is based on expenses associated with global warming from N_2O emissions, soil acidification and eutrophication costs from ammonia volatilization, and maritime industry and property losses from nitrate runoff and leaching. The ENA (2011) calculated the external costs of excess N fertilizer use for the EU to be much higher, with the annual EU environmental costs ranging from €70B to 320B euro. These two costs were used to calculate the lower and upper limits of the total environmental costs associated with the N fertilizer amount determined to be excess in Table 109.2. These calculations predict the global environmental costs in 2020 to range from $8.7B USD to $251B USD if the status quo is maintained. However, if we could introduce BNF to cereal crops, we believe that with sufficient efficiency enhancements, it may be able to possibly supply from 25 kg N per hectare up to 300 kg N per hectare to the cereal crops from an *in planta* source. This could reduce N fertilizer consumption from the developed world cereal farms and increase cereal crop yields from the developing world farms. If we assume 150 kg N per hectare as an average N fertilizer application to cereals, then supplying a range of 25 to 300 Kg N per hectare as *in planta* N would let farmers reduce their N fertilizer application by 17–100%. If we optimistically suggest that BNF cereals could reduce world N fertilizer use from 2007 levels by 10% by 2020, then we would reduce our N usage by 20 MMt. This would correspond to a direct fertilizer cost savings of $19.8B USD and reduced N_2O emissions of 0.2 MMt (taking the IPCC Tier 1 N_2O–N emissions level), corresponding to a further savings of $0.91B USD in CO_{2eq}. This would cumulate in potential total environmental cost savings of $8.7B USD to $251B USD (Table 109.2). Even for a country like the United States that uses BNMPs and technology in their intensive cereal crop farming, there would be significant cost savings by growing BNF cereals. For a country such as China that uses high levels of N fertilizers in cereal crop production, the savings from reduced N use due to BNF cereals could be very large.

109.2.12 Targeted Projects Funded to Date

Nongovernment philanthropic foundations have granted significant sums of money to improve food security for the hungry and poor; many of these people are women who are also smallholder farmers. These grants have gone to a wide range of agricultural-related projects in countries such as Sub-Saharan Africa, India, and the Philippines. Philanthropic organizations have also given grants for projects based in developed countries, such as improving agricultural education in the rural United States. A few of these philanthropic foundations, such as the B&MGF and the Howard G. Buffett Foundation, have given large grants to research organizations in various countries to improve certain crop traits such as drought and salt tolerance. They have invested approximately $1.8B USD into agricultural programs aimed at improving the lives of smallholder farmers in Sub-Saharan African countries by reducing poverty and hunger (http://www.gatesfoundation.org/Media-Center/Press-Releases/2011/11) (Table 109.3).

Many of these grants are aimed at helping women, since agricultural researchers and the B&MGF have recognized women as the main smallholder farmer in these countries and as the people most likely to be responsible for children's

nutrition. These grants have allowed for the implementation of programs to increase crop yields so these farmers can both feed their family and produce enough market product. A subset of these grants are aimed at increasing the yields of crops that are traditionally grown in these regions by improving the availability of N to these crops. Table 109.3 outlines six projects funded by B&MGF (totaling over $52M USD) that involve N and agriculture in Sub-Saharan Africa. These include improvement of N fertilizer, development of NUE maize, improvement of the BNF capacity of legume crops grown, introduction of BNF directly to cereals, and development of N_2-fixing symbiotic cereals. These funded projects show a commitment to improving crop yields using both existing technologies, such as plant breeding and symbiotic legume crops, and using highly experimental emerging technologies such as N_2-fixing plant biotechnologies. The B&MGF granted nearly $10M USD to researchers at the John Innes Centre in the United Kingdom to test the feasibility of developing diazotrophic symbiosis with traditionally grown Sub-Saharan maize. They also granted over $2M USD to researchers at the Technical University of Madrid to research engineering cereals that can fix their own N_2 (see Chapter 108).

Government funding of agricultural development programs in the G20 countries have generally decreased since the 1980s, falling from 17% in 1980 to 3.8% in 2006 (Sasson, 2012). This reduction in money going to agriculture, along with other factors including grain production going to biofuel stocks and animal feed, climate change, and reduction in available arable land and fresh water, has resulted in food security crises for many countries. The G8 and G20 countries have recently recognized this deficit in agriculture funding and have made pledges to increase spending in agriculture and food-related programs in order to reduce the rising number of impoverished, malnourished, and hungry people in the world. At the Millennium Summit of the United Nations in 2000, the 193 member states and approximately 23 international organizations agreed to achieve eight international millennium development goals (MDG) by 2015. The goals were to (i) eradicate extreme poverty and hunger, (ii) ensure universal primary education, (iii) promote gender equality and empower women, (iv) reduce

Table 109.3 Agricultural and global development projects funded by nongovernment foundations that involve N, crop yields, and sustainability (for information on other projects related to food security, please see www.foundationcenter.org/gpf/foodsecurity)

Year	Granting Agency	Grantee	Project Description	Amount in USD
2012	B&MGF	John Innes Centre, United Kingdom	Test the feasibility of developing cereal crops capable of fixing nitrogen as an environmentally sustainable approach for small farmers in sub-Saharan Africa to increase maize yields	$9,872,613
2011	B&MGF	Technical University of Madrid, Spain	Support the introduction of biological nitrogen fixation in cereals in Sub-Saharan Africa and South Asia	$2,927,139
2010	B&MGF	Columbia University, United States	Support the Earth Institute's International Nitrogen Conference	$50,000
2009 and before	B&MGF and Howard G. Buffet Foundation	Wageningen University, the Netherlands	N2Africa: increases legume productivity, family nutrition, soil health, cropping systems, and farm income for small farmers in Burkina Faso, Mali, Nigeria, Ghana, Kenya, Rwanda, and Malawi Extended to Liberia and Sierra Leone	$20,506,733 (over $2 million from HGBF)
2009 and before	B&MGF	Centro Internacional de Mejoramiento de Maiz y Trigo, Mexico	Develop improved varieties of maize for higher yields on the low-nitrogen soils prevalent in Africa	$18,307,621
2009 and before	B&MGF	Massachusetts Institute of Technology, United States	Improve the chemistry of nitrogen catalysts	$393,706
	B&MGF	International Center for Tropical Agriculture	Evaluate and scale up new chemical and biological commercial products for improving and sustaining crop yields	$4,825,343
Total				$52,057,812

child mortality rates, (v) improve maternal health, (vi) combat HIV/AIDS and malaria, (vii) ensure environmental sustainability, and (viii) develop global partners for development (http://www.un.org/millenniumgoals/). Goals (i) and (vii), to eradicate extreme poverty and hunger and ensure environmental sustainability, pertain closely to agriculture development such as improving NUE and introducing BNF to cereals to increase crop yields in a sustainable way. However, it could be argued that implementing research and agricultural strategies to sustainably improve crop yields in traditionally low-yielding, developing nations would also help to achieve the rest of the goals as well. Unfortunately, meeting these goals is proving to be very challenging. In 2010, 13.5% of the world population was in extreme poverty and hunger. Achieving goal 1 would require that value to be 8% or less by 2015. The G8 countries state that they want to address global hunger, and in 2008, during the G8 summit in Italy, they pledged to raise $22B USD to combat food insecurity issues. However, achieving this level of support has proven very difficult. In 2010, a global food security program was funded ($900M USD) by the United States, Canada, Spain, South Korea, and the B&MGF. Presently,

$224M USD of this has gone to five different countries for food security issues (Sasson 2012).

109.3 CONCLUSIONS

In addressing the challenges to food production that we face now and in the future, we need to consider methods that will allow for increased crop yields but that are economical and universally available and do not add N pollutants to our ecosphere. One method that would address the need for fixed N in both developed and underdeveloped regions would be to grow BNF cereal crops (see Chapter 108). Cereals that can fix their own N from atmospheric N_2 would have their N supply matched to their N demand. In the areas of the world that have little to no access to N fertilizers, this would increase yields and result in decreased malnutrition, hunger, and poverty. In areas that have access to N fertilizers, reducing N fertilizer applications would reduce environmental damage from N pollution and directly reduce farmers' costs.

Chapter 110

Conservation of the Symbiotic Signaling Pathway between Legumes and Cereals: Did Nodulation Constraints Drive Legume Symbiotic Genes to Become Specialized during Evolution?

Charles Rosenberg

INRA, Laboratoire des Interactions Plantes-Microorganismes (LIPM), UMR441, Castanet-Tolosan, France; CNRS, Laboratoire des Interactions Plantes-Microorganismes (LIPM), UMR441, Castanet-Tolosan, France

110.1 INTRODUCTION

Root endosymbioses play an important role in plant nutrition. Arbuscular mycorrhizal (AM) fungi of the Glomeromycota phylum provide improved nutrient uptake to plants and protection against stress. The AM symbiosis dates back to about 450 MY and is formed by about 80% of terrestrial plant species, including cereals (Parniske, 2008). The *Rhizobium*–legume (RL) symbiosis, which supplies combined nitrogen to the plant partner, appeared about 60 MY ago and is basically restricted to the legume family (Ferguson et al., 2010). Though these two root endosymbioses differ in numerous aspects, both rhizobial and fungal microsymbionts have to enter host root tissues and reach cortical cells to establish a functional symbiotic interaction.

The establishment of both the RL and the AM endosymbioses is coordinated by signal exchanges between plants and their microbial symbionts. Rhizobia produce diffusible lipochitooligosaccharidic (LCO) signals called Nod factors (Dénarié et al., 1996; see Chapter 51). Perception and transduction of these symbiotic signals through a specific signaling pathway play a central role in nodule organogenesis and bacterial infection, the two prerequisites for functional nitrogen-fixing symbiotic interaction (Gough and Cullimoren, 2011; Oldroyd, 2013; see Chapter 59). Similarly, AM fungi produce diffusible signals, including Myc-LCOs (Maillet et al., 2011) and also short-chain chitooligosaccharides (COs) (Genre et al., 2013) that are perceived by host plants (see also Chapter 108).

Genetic studies on the model legumes *Medicago truncatula* and *Lotus japonicus* have shown that after an initial perception step, the subsequent transduction of the symbiotic signals is controlled by a set of genes that are necessary for the establishment of both RL and AM symbioses (Venkateshwaran, et al. 2013), thus defining a common symbiotic signaling pathway (CSSP; also known as CSP or SYM), illustrated in Figure 110.1 (see also Chapters 42, 43, 54, 55). These observations support the hypothesis of the recruitment by the more recent RL symbiosis of elements of the preexisting AM symbiotic signaling pathway (Geurts et al., 2012;

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

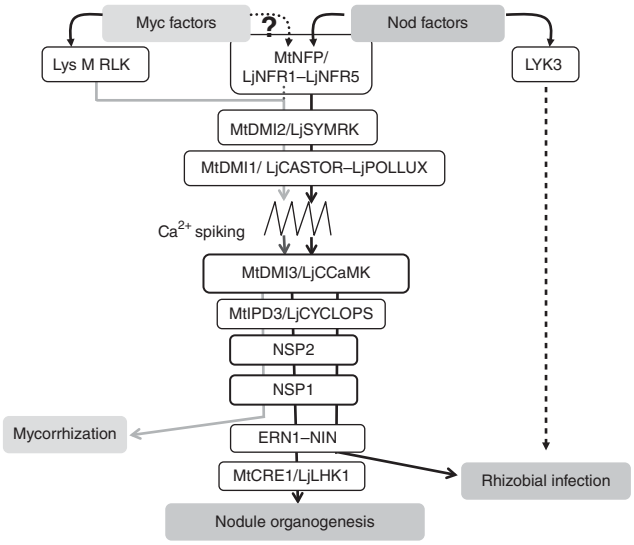

Figure 110.1 Scheme of the genetic control of AM and RL symbiotic pathways.

Markmann et al., 2008; Parniske, 2008, Venkateshwaran et al., 2012). One question arising from this hypothesis is whether functional specialization of the CSSP genes occurred during evolution of the RL symbiosis from the AM symbiosis.

To address this question, one approach has consisted in cross-species complementation experiments, that is, testing whether full functional RL symbiosis can be restored in a CSSP legume mutant by introducing the corresponding gene from a nonlegume species. Because they are nonnodulating and phylogenetically distant from legume plants, but able to establish the AM symbiosis, cereals are a convenient source for nonlegume CSSP genes, and rice (*Oryza sativa*), one of the most extensively studied cereal species, has generally been chosen for these studies.

The scope of this chapter is to summarize and discuss the results obtained by this approach to evaluate the level of specialization that could result from constraints associated with establishment of the RL symbiosis.

110.2 PERCEPTION OF THE SYMBIOTIC SIGNALS

The initial step of perception of rhizobial symbiotic signals by legume host plants, though not yet completely understood, involves lysin motif receptor-like kinases (LysM-RLKs; see Chapter 51). In *L. japonicus*, LjNFR1 and LjNFR5 are able to bind Nod factors and form a receptor complex localized in the plasma membrane (Broghammer et al., 2012; Madsen et al., 2011; Radutoiu et al., 2007). In *M. truncatula*, MtNFP, the LjNFR5 orthologue, though never shown to be able to bind NFs, is absolutely required for Nod factor perception, whereas MtLYK3, the LjNFR1 orthologue, is specifically required for rhizobial infection (Catoira et al., 2001; Gough and Cullimore, 2011; see Chapters 51, 59). Though Nod and Myc factors are structurally very similar, legumes carrying mutations in *NFP/NFR5* or *LYK3/NFR1* are still able to establish a functional AM symbiotic interaction, suggesting that they are not required for the perception of AM symbiotic signals. However, Maillet and coworkers reported that the root branching stimulation observed in response to the addition of purified Myc-LCOs was largely affected in *M. truncatula nfp* mutants (Maillet et al., 2011). Also, transcriptomic responses induced by Myc-LCOs are largely controlled by *NFP* (Czaja et al., 2012). Thus, NFP, though not essential for the AM symbiosis, could play a role in AM symbiotic signal perception. The main receptor(s) of these AM symbiotic signals could be other LysM-RLK(s), since this protein family is known to be involved both in LCO and CO perception (Gough and Cullimore, 2011). This hypothesis is further supported by studies on *Parasponia*, a nonlegume genus that acquired the ability to establish a symbiotic interaction with rhizobium relatively recently (see Chapter 4). In this plant, genetic analysis revealed that the same LysM-RLK gene, *PaNFP*, has a dual symbiotic function, controlling the formation of the symbiotic interface with rhizobium as well as mycorrhizal fungi (Op den Camp et al., 2010). Thus, the rhizobial Nod factor perception mechanism is likely to have been recruited from that used by plants to perceive AM fungi, but could have rapidly evolved into forms specific to legumes, because of particular constraints for nodulation. Because of this early specialization of RLS specific receptors in legumes, it is not expected that LysM-RLK genes from nonnodulating plant species could restore nodulation in *M. truncatula nfp/lyk3* or *L. japonicus nfr1/nfr5* mutants. However, it could be of interest to test whether the *PaNFP* gene, though not yet specialized only for nodulation, could support nodulation in legume mutants.

110.3 GENERATION OF CALCIUM SPIKING

One of the earliest cellular responses of legumes following perception of microbial symbiotic signals is the triggering of nuclear and perinuclear periodic calcium oscillations. This so-called "calcium spiking" response (see Chapters 54, 57) is induced by both Nod and Myc signals and relies on a particular subset of the CSSP genes, namely, *DMI1* and *DMI2* (DOES NOT MAKE INFECTIONS) in *M. truncatula* (Gough and Cullimore, 2011; Wais et al., 2000).

M. truncatula DMI2 (*SYMRK* in *Lotus*) is a leucine-rich repeat (LRR) receptor-like kinase (Endre et al., 2002; Stracke et al., 2002). This gene is not only essential for the establishment of the AM and RL symbioses in legumes but is also required for establishment of actinorhiza, a

nitrogen-fixing symbiotic association formed by members of the Fagales, Rosales, and Cucurbitales with Gram-positive bacteria of the genus *Frankia*. Actinorhizal plants, such as *Casuarina* or *Datisca,* carrying mutations in the *SYMRK* gene are affected for the establishment of both AM and actinorhizal symbioses (Gherbi et al., 2008; Markmann et al., 2008; see Chapters 42, 43, 55), suggesting that the actinorhizal symbiosis also evolved by recruiting genes from the preexisting AM signaling pathway. Markmann and coworkers observed that the extracellular domain of SYMRK from various land plant lineages exists in at least three different structural versions, differing by their exon composition. The "full-length" version is present in the eurosid clade, which includes all nodulating lineages, while shorter versions are found outside this clade (Markmann et al., 2008). Interestingly, in contrast to the full-length versions containing three LRR motifs, which fully restore the symbiotic properties of a *L. japonicus symRK* mutant, the rice or tomato shorter forms are sufficient to restore the AM symbiosis but fail to restore a functional RL symbiosis. When inoculated with their rhizobial symbiont *Mesorhizobium loti*, the *L. japonicus* mutant roots transformed with *OsSYMRK* exhibit primordial swellings generally devoid of bacteria. Thus, only the "full-length" version of SYMRK, the presence of which is restricted to the nodulating clade, seems to satisfy molecular constraints for bacterial penetration through infection threads (Markmann et al., 2008). The DMI2/SYMRK receptor kinases containing only one or two LRR motifs cannot support this functional specialization.

L. japonicus CASTOR and *POLLUX* and *M. truncatula DMI1* are predicted to encode nuclear potassium channels (Ane et al., 2004; Imaizumi-Anraku et al., 2005). *M. truncatula dmi1* mutants and *L. japonicus* mutants affected either for CASTOR or POLLUX are blocked at an early stage of both the RL and the AM symbioses (Catoira et al., 2000), and do not show calcium spiking in response to Nod factors (Oldroyd, 2013; Wais et al., 2000; see Chapter 54). Thus, DMI1 in *M. truncatula* and both CASTOR and POLLUX in *L. japonicus* are indispensable for NF-induced nuclear calcium spiking. The orthologous genes in rice, *OsCASTOR* and *OsPOLLUX*, have been shown to play indispensable roles in rice for the AM symbiosis (Banba et al., 2008; Chen et al., 2009). Cross-species complementation experiments showed that *OsCASTOR* restores both the RL and the AM symbioses in *L. japonicus castor* mutants (Banba et al., 2008), indicating that this gene is functionally conserved between legumes and cereals. In contrast, *OsPOLLUX* could not fully restore the symbiosis-defective phenotypes of *L. japonicus pollux* mutants, suggesting a functional specialization of *POLLUX* specific to the legume family (Chen et al., 2009). Furthermore, Venkateshwaran and coworkers showed that a *dmi1* mutant of *M. truncatula* requires both *CASTOR* and *POLLUX* from *L. japonicus* for symbioses to be restored (Venkateshwaran et al., 2012). The authors propose that DMI1 could derive from POLLUX by one critical amino acid replacement conferring reduced conductance with a long open state, making DMI1 sufficient by itself for symbiosis. Thus, POLLUX could have undergone a first functional specialization step to adapt to nodulation constraints in legumes, and then subsequent specialization within the legume family would have led to DMI1 taking over the role of both POLLUX and CASTOR in *M. truncatula*.

110.4 DECODING OF THE CALCIUM SPIKING

M. truncatula dmi3 mutants cannot establish symbiotic interactions with their microsymbionts (Catoira et al., 2000), but, in contrast to *dmi1* and *dmi2* mutants, they still show calcium spiking in response to symbiotic signals (Wais et al. 2000). MtDMI3 and its orthologue LjCCaMK are calcium/calmodulin-dependent protein kinases (CCaMKs) (Levy et al., 2004; Mitra et al., 2004), the role of which is to perceive the calcium spikes and activate downstream signaling pathways (see Chapters 54, 59).

Gain-of-function mutations of CCaMK induce spontaneous nodulation without rhizobia (Gleason et al., 2006; Tirichine et al., 2007; see Chapter 54). Some of these gain-of-function CCaMK mutations can fully restore not only nodule organogenesis but also successful infection of rhizobia and AM fungi in *L. japonicus* plants carrying mutations in the CSSP genes required for the generation of calcium spiking, for example, *L. japonicus CASTOR* and *POLLUX* mutants. These results demonstrate the central role of CCaMK and that the CSSP genes upstream of calcium spiking are required solely to activate CCaMK (Hayashi et al., 2010). Because of this key role in the CSSP, it has been proposed that MtDMI3/LjCCaMK could act as a switch, distinguishing bacterial and fungal microsymbionts and triggering respective downstream signaling pathways appropriately (Levy et al., 2004; see Chapter 59). This supposes that rhizobia and AM fungi can induce calcium spiking responses with different patterns and, according to the nature of the specific calcium signature, MtDMI3/LjCCaMK would trigger either the nodulation or the mycorrhization genetic program via the activation of specific targets. According to this hypothesis, the CCaMK of legume plants would have evolved to acquire properties that are absent in the orthologous proteins of nonlegumes. As a consequence, it would be expected that orthologues from nonnodulating species such as cereals could restore AM symbiosis, but not nodulation by rhizobia in legume *MtDMI3/LjCCaMK* mutants. To address this question, cross-species complementation experiments were performed using *OsCCaMK*, the rice orthologue of *MtDMI3*, which has been shown to be required for mycorrhizal symbiosis in rice (Chen et al., 2007; Gutjahr et al., 2008). *OsCCaMK* restores mycorrhization (Chen et al.,

2007), but also nodule formation (Godfroy et al., 2006), in *M. truncatula dmi3* mutants. This demonstrates that rice CCaMK can perceive the calcium spiking signal induced by rhizobia and activate the appropriate downstream targets controlling nodule organogenesis. However, restoration of the RL symbiosis is not complete since infection threads were aborted and nodules did not contain bacteria (Godfroy et al., 2006). The inability of *OsCCaMK* to restore rhizobial infection could suggest that this process requires particular functionalities specific to legume CCaMKs. However, the fact that a CCaMK from lily, another nonlegume species, restores both nodulation and rhizobial infection in a *M. truncatula dmi3* mutant (Gleason et al., 2006) is not in favor of such a hypothesis. Furthermore, Banba and coworkers reported that *OsCCaMK* could fully complement symbiosis defects in *L. japonicus ccamk* mutant lines both for AM and RL symbioses (Banba et al., 2008). Thus, the lack of restoration of rhizobial infection by *OsCCaMK* in *M. truncatula* mutants does not reflect the acquisition of a new functionality specific to legume CCaMKs.

This CCaMK has been shown to interact *in planta* with another nuclear-localized protein of the CSSP, called IPD3 (DMI3 Interacting Protein; see Chapter 59) in *M. truncatula* (Messinese et al., 2007) or CYCLOPS (Yano et al., 2008) in *L. japonicus*. As IPD3/CYCLOPS was found to be a substrate of the CCaMK kinase *in vitro*, it has been proposed that the phosphorylation status of MtIPD3/CYCLOPS controls the transcription of infection-related plant genes (Yano et al., 2008). *OsCYCLOPS* from rice was used for cross-species complementation of *L. japonicus cyclops* mutants. Both the AM symbiosis and nodulation by *M. loti* were fully restored, demonstrating that the *CYCLOPS* gene of a nonnodulating cereal can support not only AM fungal but also bacterial endosymbiosis (Yano et al., 2008).

110.5 SYMBIOTIC TRANSCRIPTION FACTORS

The symbiotic pathways intervening downstream of *DMI3* and *IPD3* comprise a set of transcription regulators, including two GRAS-domain transcription factor genes, *NSP1* and *NSP2* (nodulation signaling pathway) (Kalo et al., 2005; Smit et al., 2005; see Chapter 59). These genes were initially reported to be required for the RL symbiosis but not for the AM symbiosis, but in fact, both of them intervene in the CSSP (Delraux et al., 2013; Maillet et al., 2011). Yokota and coworkers demonstrated that *OsNSP1* and *OsNSP2*, the homologues of these genes in rice, are able to fully rescue the RL symbiosis-defective phenotypes of *nsp1* and *nsp2* mutants of *L. japonicus* (Yokota et al., 2010). This functional conservation shows that *NSP1* and *NSP2* from nonlegume plants can fulfill dual regulatory functions, controlling the activation of the RL symbiotic pathway as well as the ancestral role in strigolactone biosynthesis (Liu et al., 2011). Thus, these genes do not appear to have undergone any legume-specific specialization associated with nodulation.

In legume plants, the inactivation of nodule inception (*NIN*), another transcription factor gene, results in the abortion of rhizobial infection (Schauser et al., 1999; see Chapter 59). In contrast to *nsp1* and *nsp2* mutants, this infection defect is not rescued in *L. japonicus nin* mutants by the introduction of *OsNLP1*, the closest homologue of *NIN* in rice (Yokota et al., 2010). These results indicate that the *LjNIN* gene results from the recruitment and specialization of a preexisting gene, and since *NIN* is apparently not required for establishment of the AM symbiosis, this recruitment probably did not come from the mycorrhizal signaling pathway.

110.6 DISCUSSION

Although rice is a monocot plant species phylogenetically distant from legumes, it seems to possess the counterparts of all the legume CSSP genes. In rice as in legumes, inactivation of these genes results in the loss or the alteration of the symbiotic interaction with AM fungi. These observations support the hypothesis that part of the AM symbiotic signaling pathway has been recruited by legumes for nodulation with rhizobia (see also Chapter 108).

Surprisingly, the nodule organogenesis process, which represents a major innovation of the RL symbiosis compared to the AM symbiosis, does not seem to have required any specialization of the CSSP genes, since this process can be fully restored in legume mutants by the corresponding homologous genes from rice. Thus, the acquisition by legume plants of the ability to form nodules could result from the coupling of this signaling pathway with the downstream element *MtCRE1/LjLHK1*, a cytokinin receptor histidine kinase playing an essential role in nodule organogenesis (Gonzalez-Rizzo et al., 2006; Tirichine, et al. 2007).

In contrast to nodule organogenesis, colonization of root tissues occurs in both AM and RL symbioses through infection processes which share common characteristics. Both microsymbionts invade the cells of the root cortex where they develop intracellular structures allowing metabolic exchanges with the plant host. It seems that the ancient exocytotic pathway forming the periarbuscular membrane compartment in the AM symbiosis has been recruited for the symbiosome formation in the RL symbiosis (Ivanov et al., 2012). In spite of these similarities shared by the two symbioses, rhizobial infection cannot be fully rescued by the homologous rice genes in some legume mutants of the CSSP. This is the case for the *OsDMI2/SYMRK* gene that restores nodule organogenesis, but not bacterial infection and symbiosome formation. For *DMI2* genes, only those

versions possessing three LRR domains are able to support the constraints relative to rhizobial infection. Similarly, these constraints could have led to a specialization of the *POLLUX* gene in legume species. Since the roles of these two genes are solely to activate CCaMK via the generation of calcium oscillations (Hayashi et al., 2010; Madsen et al., 2010; see Chapters 54, 57), a parallel specialization of legume CCaMKs would have been expected. However, CCaMKs from nonlegume species are generally able to perceive rhizobium-induced symbiotic signals and to activate downstream targets.

This apparent absence of specialization of DMI3/CCaMK makes it unlikely that legumes can discriminate between rhizobia and fungi on the basis of specific calcium signatures. Furthermore, whereas early observations suggested that different calcium signatures were generated between the RL and the AM interactions (Kosuta et al., 2008), a more recent work using a cameleon calcium sensor showed that the spiking pattern induced in *M. truncatula* during infection by AM fungi or by rhizobia was highly similar (Sieberer et al., 2012; see Chapter 57). However, there are technical limitations in the analysis of calcium spiking that make it difficult to determine whether rhizobia and AM fungal-induced calcium oscillations have exactly the same profiles or not (Sieberer et al., 2012; Singh and Parniske, 2012). Thus, it cannot be ruled out that the two microsymbionts generate slightly different calcium signatures that can be distinguished by legume CCaMKs, which consequently open the appropriate gate to the microsymbiont. In contrast, it can be speculated that CCaMKs from nonlegumes would not have acquired the ability to discriminate between the AM and the RL calcium signatures. This hypothesis could be tested by determining whether legume *ccamk* mutants complemented with *OsCCaMK* are able to selectively trigger the appropriate genetic program or activate both symbiotic pathways, whatever the nature of the microsymbiont.

Alternatively, information on the nature of the microsymbiont could be provided to the host plant by one or more parallel signaling pathway(s), as proposed by Hayashi and coworkers (Hayashi et al., 2010; Madsen et al., 2010). This parallel pathway, though not involving calcium spiking, could nevertheless rely on differential activation of CCaMK through its regulatory domains. It has indeed been shown that truncated variants of CCaMK lacking the autoregulatory domain and the EF hands activate both AM and RL specific genes in the absence of symbiotic partners, whereas autoactive full-length forms of *L. japonicus* CCaMK solely induced nodulation-specific gene expression patterns and no AM-specific genes (Shimoda et al., 2012; Singh and Parniske, 2012; Takeda et al., 2012). Thus, the presence of the autoregulatory domain seems important to define the identity of the downstream pathway. Whether the ability to discriminate between bacterial and fungal parallel pathways reflects a specialization of legume CCaMK, regulatory domains could be studied by complementation experiments using cross-species chimerical CCaMK constructs.

The fact that some CSSP genes are functionally conserved for nodule formation but not for rhizobial entry is a new illustration of the very strict genetic control of rhizobial infection. This stringent genetic control of rhizobium entry in root tissues was previously reported by Ardourel and coworkers (Ardourel et al., 1994), who showed that rhizobial mutants producing modified Nod factors were not able to penetrate the root tissues, but still induced nodule formation.

Similarly, experimental evolution experiments showed that nonsymbiotic bacteria acquire more easily the ability to induce nodule formation on a legume host than the ability to infect this host (Marchetti et al., 2010).

In spite of this tight control of microbial infection by the host plant, the fact that most of the genes of the CSSP have a functional counterpart in rice suggests that engineering cereals to form nodules hosting nitrogen-fixing rhizobia might not be an unrealistic goal, provided that key components missing in rice are identified (see Chapters 108, 109).

Chapter 111

Occurrence and Ecophysiology of the Natural Endophytic *Rhizobium*–Rice Association and Translational Assessment of Its Biofertilizer Performance within the Egypt Nile Delta

Youssef G. Yanni
Sakha Agricultural Research Station, Kafr El-Sheikh, Egypt

Frank B. Dazzo

111.1 INTRODUCTION

111.1.1 Historical Perspective of the Discovery of the Natural Rhizobia–Cereal Association

In the mid-1990s, we began a collaborative research project on novel, beneficial plant–microbe associations involving major cereal crops (Yanni et al., 1995). We wanted to assess their potential for promoting crop productivity with the eventual development of new, improved biofertilizers. Our work focused originally on rhizobia and rice, with a more recent expansion that has included the rhizobia–wheat association.

Our guiding hypothesis was that natural endophytic associations between rhizobia and cereal roots would most likely occur where these cereals are successfully rotated with a legume crop that could enhance and sustain the soil population of the corresponding rhizobial symbionts. Such natural *Rhizobium*–cereal associations would be perpetuated if they were mutually beneficial. If this hypothesis were correct, the cereal roots growing at these sites should harbor, along with other microbes, populations of endophytic rhizobia that are already highly competitive for colonization of the interior habitats of crop roots, being protected from stiff competition with other soil–rhizosphere microorganisms under field conditions. Establishing an endophytic niche is a strategic ecophysiology because a more rapid and intimate metabolic exchange is possible within host plant tissues rather than amidst a larger diverse community at the root epidermal–soil interface.

An ideal place to test this hypothesis was in the Egypt Nile Delta. For more than seven centuries of recorded history, rice there has been rotated with the forage legume Egyptian berseem clover (*Trifolium alexandrinum* L.). In this area, Japonica and (more recently) Indica and hybrid rice cultivars

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

are cultivated by transplantation in flooded rice fields, a practice also referred to as "lowland rice cultivation".

An interesting enigma for this conventional farming management is that the clover rotation with rice can replace 25–33% of the N-fertilizer amount recommended for optimal rice production when rice follows a leguminous rather than nonleguminous crop. N-balance data accumulated over decades on Egypt rice farming systems indicated a repeated misconception statement that related the benefit of rice rotation with clover solely to increases in available soil N contributed by mineralization of the N symbiotically fixed, N-rich clover roots and root-nodule residues that are left after the clover's last cut. However, N-balance calculations do not support this explanation. This raised the possibility in our minds that the rhizobial symbiont of clover (*Rhizobium leguminosarum* bv. trifolii) may participate in a natural endophytic association with rice and possibly contribute to this added benefit of the rotation.

111.1.2 Confirmation of the Natural *Rhizobium*–Rice Association

We undertook an ecological approach that involved multiple cycles of field and laboratory studies to detect, enumerate, and isolate rhizobial endophytes from surface-sterilized roots of field-grown rice (Yanni et al., 1997, 2001). Rice plants were sampled at five different field sites during two seasonal rotations with berseem clover in the Nile Delta. The first field sampling was from vegetative regrowth of residual **ratoon** rice surviving rice harvest and grew intermingled among clover plants that followed rice in the same field area in which clover seeds were broadcasted on the soil surface without tillage after rice harvest. The majority of farmers do that to save costs of clover cultivation, with an additional benefit that the first clover cut will contain a balanced mixture of the N-rich clover plant plus some residual cellulose-rich ratoon rice. The second sampling of rice roots was from four different sites in flooded fields of transplanted rice during the next rice growing season. For both samplings, the roots were washed and surface-sterilized until bacteria on the root surface could no longer be cultured. Diluted macerates of the surface-sterilized roots were then inoculated directly on axenic seedling roots of berseem clover growing on N-free medium in closed glass tubes under gnotobiotic conditions. After one month of clover growth in the greenhouse, the inoculated clover plant replicates were examined for root nodulation, and their positively nodulated replicates were scored and subjected to most probable number (MPN) calculations.

This simple experimental design took advantage of the strong positive selection provided by the clover **trap** host to detect and enumerate any endophytic rice root inhabitants of clover-nodulating rhizobia that are naturally present among other microbial endophytes that survived surface sterilization of the rice root and to isolate the numerically dominant strains from nodules of clover plants inoculated with the highest dilutions in the MPN plant infection test. The results from all five sample sites provided a solid confirmation of our guiding hypothesis that clover-nodulating rhizobia do intimately colonize the rice root interior in those fields of the Egypt Nile Delta (Yanni et al., 1997, 2001). The MPN analysis indicated that the population density of clover-nodulating rhizobia was 2–3 logs higher inside the roots of the ratoon rice growing among the clover plants than inside the transplanted rice roots growing in the flooded fields. These results suggested that rice root interiors provide more favorable growth conditions for rhizobia when present in close physical proximity to clover in nonflooded, more aerobic fields. This highlighted a long-term benefit of the rice–legume rotation in promoting this intimate plant–microbe association.

Next, we created a culture collection of pure culture isolates of these rhizobial nodule occupants representing the numerically dominant rhizobial endophytes of rice roots. We verified that they were authentic strains of *R. leguminosarum* bv. trifolii by confirming their ability to nodulate berseem clover in gnotobiotic culture, expressing and demonstrating their N_2-fixing activities on their natural clover host, and comparing the complete nucleotide sequence of their 16S rRNA-encoding gene with other bacteria (Yanni et al., 1997, 2001). The plant tests indicated both effective and ineffective biological N_2-fixing isolates. This was followed by fulfilling stringent tests of molecular Koch's postulates using BOX-PCR genetic fingerprinting and plasmid profiling methods, proving that pure cultures of selected isolates of rice root inhabitant rhizobia can invade rice roots under gnotobiotic culture conditions and be isolated back into pure culture with proof that they are the same authentic inoculant strains (Yanni et al., 1997).

The strain diversity of the isolates was evaluated to gain a better understanding of the breadth of this ecological niche for rhizobia and to guide us in selecting isolates that can represent the genomic diversity of our culture collection for various studies on this association (Yanni et al., 2001). The molecular fingerprint methods indicated that our culture collection of rice-adapted rhizobia contained ten different strain genotypes, representing sufficient variation to define their range in ability to evoke growth responses in rice. It also indicated that diverse populations of *R. leguminosarum* bv. trifolii colonize rice root interiors in flooded and nonflooded rice soils under the rotation of rice and berseem clover in the Nile Delta (Yanni et al., 2001).

Initially by serendipity and later by direct experimentation, we found that some of the rice endophyte strains of clover rhizobia would promote the growth of rice (Yanni et al. 1997, 2001). These results under microbiologically controlled conditions in the laboratory were corroborated by field inoculation trials in the Nile Delta (Yanni et al.

1997, 2001). It became clear that the rhizobial root-nodule symbiont of clover does participate in a natural, beneficial endophytic association with rice without root-nodule formation or biological N_2 fixation.

Since that novel discovery, many tests of the generality of our original finding have indicated that the natural *Rhizobium*–cereal association is much more widespread than just for the rice–clover rotation found and described in the Nile Delta. Following our initial publication, other examples of rhizobia forming natural endophytic associations with nonlegume hosts in rotation with legumes have been reported, including rhizobial associations with wild and domesticated rice, wheat, maize, barley, sorghum, and millet that are growing in agronomic rotations with legumes in Senegal, Venezuela, Canada, Mexico, Morocco, Kenya, India, Pakistan, China, and elsewhere (Chaintreuil et al., 2000; Dazzo et al., 2000; Matiru et al., 2000; Gutierrez-Zamora and Martinez-Romero, 2001; Hilali et al., 2001; Tan et al., 2001; Lupway et al., 2004; Matiru and Dakora, 2004; Mishra et al., 2004; Singh et al., 2006; Mano and Morisaki, 2008; Mishra et al., 2008; Peng et al., 2008; Sun et al., 2008; Singh et al., 2009; Jha et al., 2009; Y. Jing, personal communication; Prabhat Jha, personal communication). In addition to these, other reports also confirm that rhizobial inoculation can provide growth-promoting benefits on rice and other nonlegume crops through various direct and indirect mechanisms (Haque et al., 1993; Höflich et al., 1994; Chabot et al., 1996; Schloter et al. 1997; Webster et al., 1997; Antoun et al., 1998; Prayitno et al., 1999; Antoun and Prévost, 2000; Biswas et al., 2000a; Biswas et al., 2000b; Yanni et al., 2001; Perrine et al., 2001; Hafeez et al., 2004; Chi et al., 2005; Afzal and Bano 2008; Mehboob et al., 2012; Prabhat Jha, personal communication). Thus, rhizobia are now well known for their ability to occupy a third agriculturally important ecological niche as endophytic colonizers of cereal roots and can promote their growth in agroecosystems that host legume–cereal rotations. This creates a *novel triangle of rhizobia's life cycle and natural history* (Figure 111.1) that replaced the textbook version of a mutual 2-component life cycle that contains only the free-living saprophytic growth state (Gram-negative non-N-fixing short rods) in soil outside the roots of the natural legume host, followed by the N_2-fixing endosymbiotic bacteroid state inside the infected legume host cells within the root nodules.

Although originally met with skepticism, there is no longer any scientific basis to doubt that the natural relationship exists, opening the field for other investigators to assess this endophytic association between many other rhizobial strains belonging to different species and various varieties of different cereal crops growing on all continents worldwide that have agroecosystems containing cereal–legume rotations.

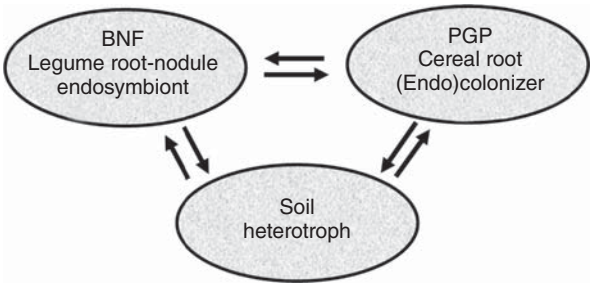

Figure 111.1 Three-component natural lifestyles of ecological niches for rhizobia. Note the newly added niche of plant growth-promoting cereal root (endo)colonizer.

111.1.3 Initiation of Multinational Collaboration Network

By sharing our strains, we established a major multinational network of investigators to cooperate in the creation of a broad-based understanding of the physiology of plant growth promotion (PGP) by our strains and the plant–microbe ecology of this rhizobia–rice association. We envision that the most important long-range impact of this research will be the development and implementation of new microbial biofertilizers that can reduce the major real-world constraint of limited biologically available nitrogen to increase rice productivity in an environmentally friendly way (see Chapters 108, 109). These contributions advanced scientific knowledge on beneficial plant–microbe associations, inevitably assisting marginal low-income farmers who produce rice on N deficit soils that are mostly accompanied by inavailability of many other nutrients, in addition to benefiting manufacturers of agricultural biofertilizer inoculants in the private sector.

111.1.4 Ecophysiology of the *Rhizobium*–Cereal Association

Questions that have interested us most are: what developmental stages of this association are important to provide the enhancement effect and nature of the mechanism(s) that control this enhancement process, and most importantly, what is this N-fixing legume symbiotic micropartner doing on and inside rice roots? Answers to these questions were completely unknown as we began to explore what is happening in this beneficial association.

111.1.4.1 Colonization and Infection. Microscopy has helped to define the infection process in the *Rhizobium*–cereal association. Early studies on the colonization of rice roots by azorhizobia indicated the "crack entry" mode of primary host infection in natural wounds of separated epidermal cells and fissure sites where lateral roots have emerged, followed by colonization within intercellular spaces and host cells of the outer root cortex (Reddy et al., 1997).

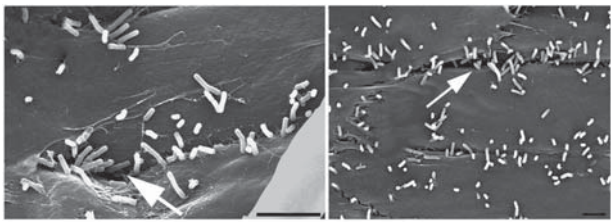

Figure 111.2 Scanning electron micrographs illustrating two examples of crack entry (arrows) of a wild-type endophytic strain of *Rhizobium leguminosarum* bv. trifolii between root epidermal cells of rice. Bar scales equal 10 μm.

The width of these portals of entry can vary considerably but only needs to be ~1 μm for vegetative rods of rhizobia. Two examples of crack entry by an endophytic strain of rhizobia are provided in Figure 111.2. Transmission electron microscopy of well-preserved rice root tissue provided the definitive evidence that confirmed with high magnification/resolution the endophytic colonization of rhizobia within dead host cells adjacent to intact cells of the root cortex (Reddy et al., 1997). Other studies using selected strains of our rice-adapted rhizobia tagged with the green fluorescent protein (Gfp) indicated the crack entry of these bacteria at sites of lateral root emergence, followed by their intercellular multiplication within lateral rootlets and also their ascending migration from these sites of primary host infection to form long fluorescent rows of bacteria inside roots (Prayitno et al., 1999).

More recently, comprehensive microscopy studies of rice plants inoculated with multiple *gfp*-tagged rhizobial strains indicated that the infection process in this association is very dynamic, beginning with bacterial colonization of the rhizoplane especially at lateral root emergence and crack entry into the root interior through separated epidermal cells, followed by *endophytic ascending migration* of the bacteria from the roots up into the stem base and leaf sheath and within lower leaves where they multiply transiently to high local population densities (Chi et al., 2005). *In situ* image analysis indicated that *local* endophytic population densities commonly occur at $\sim 10^8$ per cm^3, but are present in some infected rice tissues at local densities as high as 9×10^{10} rhizobia per cm^3. Thus, this endophytic plant–microbe association is far more invasive than previously thought and includes internal colonization of rhizobia in both belowground and aboveground host tissues. Comparisons of viable plate counts versus direct microscopy indicate that these *gfp*-tagged bacteria remain active for long periods within the rice plant and continue to promote plant growth even after their culturable population densities have declined (Chi et al., 2005).

We are using quantitative computer-assisted microscopy to evaluate spatial patterns of rhizobial distribution on rice roots grown in gnotobiotic culture and under field inoculation conditions in order to better understand the dynamics of their early colonization behavior during this infection process. Our first approach has involved scanning electron microscopy of rice roots inoculated with a candidate biofertilizer strain of *R. leguminosarum* bv. trifolii followed by quantitative image analysis of their spatial patterns of colonization at single-cell resolution using our Center for Microbial Ecology Image Analysis System (CMEIAS©) software (Liu et al. (2001)) and continuously developed thereafter (Dazzo, 2010; Gross et al., 2010; Dazzo, 2012; Dazzo and Yanni, 2013). The results commonly reject the null hypothesis that the spatial pattern of rhizobial colonization of rice is due to random chance, with statistical p values being as low as 10^{-5}. Instead, our spatial ecology analyses indicate that rhizobia form aggregated spatial patterns on the rice rhizoplane, reflecting their highly structured colonization behavior involving cooperative cell–cell interactions of *in situ* ecophysiology (Dazzo et al., 2013; Dazzo and Yanni, 2013). This outcome is a sign of the elegantly symphonic nature of rhizobial interactions during their early colonization of rice roots that ultimately results in this beneficial plant–bacteria association of significant agricultural importance.

111.1.4.2 PGP of Rice by Rhizobial Endophytes.

Our early studies on the natural, endophytic rhizobia–rice association indicated that some strains promote the shoot and root growth of certain rice varieties in gnotobiotic culture (Yanni et al., 1997). Later, more extensive tests established the range of growth responses of Japonica, Indica, and hybrid rice varieties from Egypt, the Philippines, the United States, India, and Australia when these cultivars were inoculated with various rhizobial inhabitants of rice roots. As briefly mentioned above, the results indicated that the diverse rhizobial endophytes evoked a full spectrum (positive, neutral, and sometimes even negative) of growth responses in rice, often exhibiting a high level of strain/variety specificity (Prayitno et al., 1999; Biswas et al., 2000a, 2000b; Yanni et al., 1997, 2001). On the positive side, a chronology of Pgp^+ responses of rice to rhizobia manifests as increased seedling vigor (faster seed germination followed by increased root elongation, shoot height, leaf area, chlorophyll content, photosynthetic capacity, root length, branching, and biomass). Figure 111.3 illustrates the aboveground growth response of rice to inoculation with *R. leguminosarum* bv. trifolii and a low dose of supplemental N-fertilizer and, most importantly, the synergistic positive growth response when both treatments are included that extends beyond either treatment alone. These growth-promoting responses carry over to produce increased yield and N content of the straw and grain at maturity. More information on these synergistic benefits of significant agronomic importance is covered later.

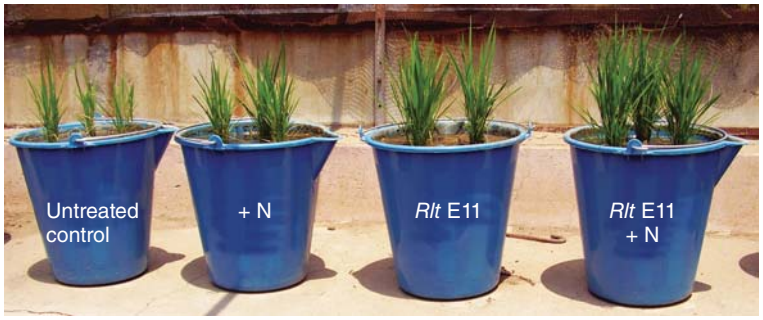

Figure 111.3 Pot experiment showing early, aboveground growth response of the *Giza-178* variety of rice to inoculation with *R. leguminosarum* bv. trifolii with and without a low-dose (48 ppm N) supplemental N-fertilizer treatment. Note the outstanding positive growth response of rice when receiving both treatments. This synergistic result recurs repeatedly in field inoculation experiments.

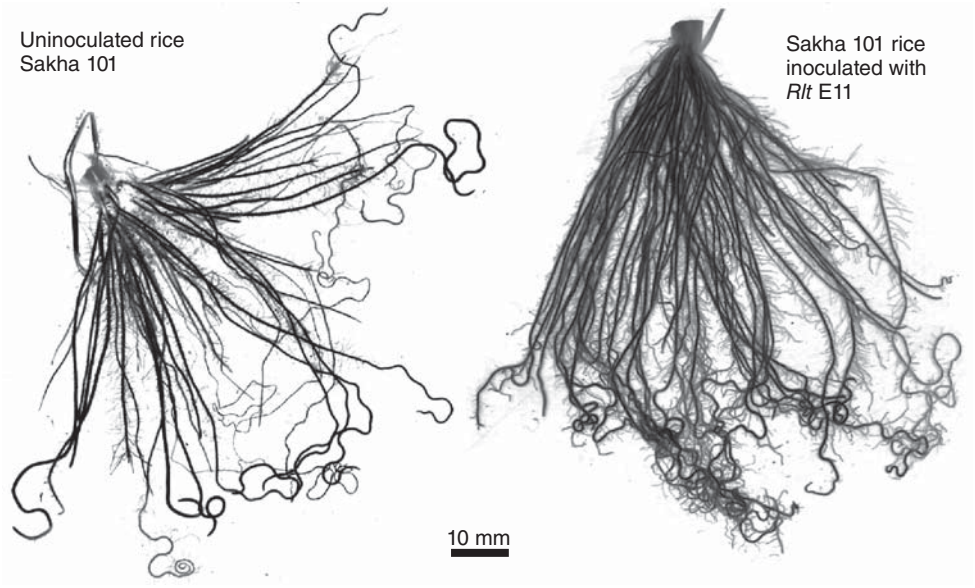

Figure 111.4 Architecture of Sakha-101 rice roots after gnotobiotic growth without (a) and with (b) *R. leguminosarum* bv. trifolii inoculation.

111.1.4.3 Underlying Mechanisms of PGP. The ability of some endophytic rhizobial strains to promote the growth of rice prompted follow-up studies to identify possible mechanisms operative in this beneficial plant–microbe interaction. These studies have addressed the following possibilities: (i) rhizobial induction of an expansive root architecture with enhanced efficiency in plant mineral nutrient uptake; (ii) rhizobial production (or host activation) of extracellular growth-regulating phytohormones; (iii) rhizobial solubilization of precipitated inorganic and organic phosphate complexes, thereby increasing the bioavailability of this important plant nutrient; (iv) associative nitrogen fixation by rhizobia; and (v) rhizobial production of siderophores that increase the bioavailability of iron.

Although biological control of phytopathogens (via direct antagonism or induction of systemic disease resistance) is traditionally recognized as another important mechanism of PGP by rhizobacteria (Kloepper et al., 1980; Haque and Ghaffar, 1993), we have not tested whether this mechanism is operative in our system because our rhizobial inoculants can promote rice growth in gnotobiotic culture (independent of phytopathology) and because the (already blast-resistant) uninoculated control plants lack any disease symptoms in our field inoculation trials in Egypt (Yanni and Dazzo, unpublished observations).

Stimulation of Root Growth and Nutrient Uptake Efficiency. The responsive rice varieties commonly develop expanded root architectures when inoculated with selected biofertilizer strains of rhizobia. An example is presented in Figure 111.4.

This suggests that these rhizobial endophytes alter root development in ways that could make them better "miners" more capable of exploiting a larger reservoir of plant nutrients from existing resources in the rhizosphere soil. This possibility was suggested in early studies showing significantly increased production of root biomass in plants that had been inoculated (Prayitno et al., 1999; Biswas

et al., 2000a; Yanni et al., 1997, 2001) and by studies using greenhouse potted soil indicating significant increases in N, P, K, and Fe uptake by rice plants inoculated with selected rhizobia, including our test strains (Biswas et al., 2000b). More recent studies have confirmed this hypothesis using plants grown gnotobiotically with rhizobia in nutrient-limited medium (50% Hoagland's), followed by measurements of root architecture and mineral nutrient composition using image analysis and atomic absorption spectrophotometry, respectively (Yanni et al., 2001). In these latter studies, inoculated plants developed a more expanded root architecture and accumulated higher concentrations of N, P, K, Ca, Mg, Na, Zn, and Mo than did their uninoculated counterparts.

Interestingly, the levels of Fe, Cu, B, and Mn were not statistically different in the same inoculated versus uninoculated plants under these microbiologically controlled experimental conditions (Yanni et al., 2001). This selectivity in terms of which plant nutrients exhibit increased accumulation as a result of inoculation argues against an across-the-board general enhancement of mineral accumulation due just to expanded root architecture with increased absorptive biosurface area. The results indicate, quite interestingly, that bacteria can modulate the rice plant's plasticity that enables it to control the adaptability of its root architecture and also the physiological processes for more efficient acquisition of selected nutrient resources *when they become limiting*. This same mechanism is largely responsible for the beneficial growth promotion effect of *Azospirillum brasilense* on grasses (Tien et al., 1979; Umali-Garcia et al., 1980; Okon and Kapulnik, 1986; Bashan et al., 1990; Okon and Labandera-Gonzalez, 1994; see Chapter 90). Rhizobacteria can thus control the ecophysiology of mineral nutrient uptake by plant roots.

These *Rhizobium*-induced increases in the accumulated mineral composition of rice plants raise new possibilities regarding their potential impact on the human nutritional value of this world's most important crop. A potential value-added benefit resulting from rhizobial inoculation is their ability to increase the nutritional value of resulting rice grain, not only for increased N (mostly in the form of storage protein) but several other macro- and micronutrients as well. For instance, rice is an important and indeed even the major bioavailable source of some essential minerals, for example, zinc, in the human diet, particularly in developing countries (IRRI, 1999). Zinc is considered an essential supermicronutrient that is important for the maturation of the reproductive organs in women and the developing fetus. Our rhizobial inoculants have the capacity to increase the zinc content of rice grain in the field (Yanni et al., 2001).

Enhanced efficiency in the uptake of nutrient resources by inoculated rice could be a two-edged sword if accompanied by their enhanced bioaccumulation of toxic heavy metals. We, therefore, analyzed other rice grain samples from this same field inoculation experiment for their heavy metal content (Hg, Se, Pb, Al, and Ag). The results indicated no significant differences in the low levels of these toxic heavy metals in the rice grain of uninoculated versus rhizobial endophyte-inoculated treatments (Yanni et al., 2001).

SDS-PAGE and RP-HPLC analyses of the protein composition of field-grown Giza-177 rice grains indicated no discernible differences in the *ratios* of their major nutritionally important storage proteins, particularly glutelin, albumin, and globulin, as a result of inoculation with the rhizobial endophyte strain E11 (Yanni et al., 2001). Field inoculation with this rhizobial endocolonizer thus did not qualitatively alter rice grain protein, as all nutritionally important proteins were present in the treated and control samples in similar ratios. However, since inoculation with rhizobia causes a significant increase in total grain nitrogen per hectare of crop (in protein form), the benefits of inoculation to small farmers will include an increase in the *quantity* of rice grain protein produced per unit of land used for cultivation. This increases the nutritional value of the harvested grain as a whole in comparison with uninoculated rice produced.

Considered collectively, these studies indicate that rice plants inoculated with our rhizobial biofertilizers produce rice grain whose human nutritional value is equal to or improved (depending on the nutrient considered) as compared to uninoculated plants.

Secretion of Plant Growth Regulators. Early studies suggested that rhizobial endophyte strain E11 produced the auxin indole acetic acid (IAA) in pure culture and in gnotobiotic culture with rice (Biswas et al., 2000a, 2000b), as has been observed with *Azospirillum* (see Chapters 90, 91). Further studies indicated that production of IAA equivalents by strain E11 was tryptophan dependent. We developed a simple defined medium to optimize production of IAA by fast-growing rhizobia, and axenic bioassays of filter-sterilized culture supernatant from strain E11 grown in this defined medium showed an ability to stimulate rice root growth (Yanni et al., 2001). These results suggest that endophytic strains of rhizobia can boost rice growth by producing extracellular bioactive metabolites that promote the development of more expansive root architecture.

These results logically led us to identify the growth-regulating phytohormones produced and secreted by strain E11 in pure culture. Analysis of its culture supernatant using electrospray ionization/gas chromatography/mass spectrometry indicated the presence of IAA and a gibberellin (consistent with GA_7) (Yanni et al., 2001). These represent two different major classes of plant growth regulators that play key roles in plant development.

Rhizobial Solubilization of Precipitated Phosphate Complexes. Most Nile Delta soils used for rice cultivation contain around 1000 ppm phosphorus, primarily in the

unavailable form of precipitated tricalcium phosphate [$Ca_3(PO_4)_2$]. Although the submergence conditions normally prevail in rice fields, less than 8 ppm (Olsen) P is available to rice. Therefore, any significant solubilization of precipitated phosphates by rhizobacteria *in situ* would enhance phosphate availability to rice in these soils, representing another possible mechanism of PGP for rice under these field conditions. We tested the diversity of rice-adapted rhizobia for phosphate-solubilizing activity on culture media impregnated with insoluble organic and inorganic phosphate complexes. Our improved, double-layer plate assay indicated that some strains are active in solubilizing insoluble P complexes, both the inorganic form (calcium phosphate) that normally dominates the rice rhizosphere area and the organic form (inositol hexaphosphate = phytate) that accumulates inside the root system (Yanni et al., 2001). These positive results indicate the ability of rhizobial inoculants to perform extracellular acidification that can solubilize the inorganic phosphate complex(es) in the rhizosphere and also produce phosphatase enzymes (phytase) for solubilization of the stored organic forms accumulated inside the root tissue during the early stages of plant growth. This extracellular PGP^+ activity would potentially increase the availability of phosphorus for rice in its nutrient-depletion zone of rhizosphere soil and thereby promote rice growth when soil phosphorus is limiting.

Associative Nitrogen Fixation. Rice plants accumulate more N-shoot and N-grain when inoculated with selected strains of rhizobial endophytes (Biswas et al., 2000b; Yanni et al., 1997, 2001). However, this additional combined nitrogen is mainly derived from soil mineral N rather than from BNF. This conclusion is based on several lines of evidence:

1. The growth benefits to rice by rhizobial inoculation are enhanced rather than suppressed when N-fertilizer is provided (Prayitno et al., 1999; Biswas et al., 2000a, 2000b; Yanni et al., 1997, 2001; Yanni and Dazzo, 2010). This contrasts with the well-known suppressive effect of mineral N application on development of the N_2-fixing *Rhizobium*–legume root-nodule symbiosis.
2. The degree of rice growth benefit linked to inoculation with rhizobial endophyte biofertilizers does not correlate with their degree of nitrogen-fixing activity when in symbiosis with their normal legume host (in our case, the berseem clover), since some rice endophyte strains of rhizobia that are Fix-minus on berseem clover are nevertheless Pgp^+ on rice (Yanni et al., 2001), and therefore, field inoculation with those N fix^- forms is purposely avoided to prevent negative agronomic consequences.
3. Acetylene reduction tests for BNF did not detect associative nitrogenase activity on rice plants whose growth had been promoted gnotobiotically by inoculation with rhizobial endophytes (Yanni et al., 1997; Biswas et al., 2000a).
4. Greenhouse studies using the ^{15}N-based isotope dilution method indicated that most of the increased N uptake in inoculated plants is not derived from BNF (Biswas et al., 2000b).
5. Measurements of the natural abundance of nitrogen isotope ratios ($\delta^{15}N$) on field-grown plants indicated that their greater proportion of N resulting from inoculation with rhizobial strain E11 is not derived from BNF (Yanni et al., 2001). The proportion of rice plant N derived from BNF was approximately the same (~10%) with versus without inoculation.

Considered collectively, these results indicate that biological nitrogen fixation is not a major mechanism responsible for the significantly positive growth response of selected rice cultivars to inoculation with these rhizobial endophytes of rice.

Production of Fe-Chelating Siderophores. Siderophore production potentially provides a dual mechanism of PGP: enhancing bioavailability and uptake of Fe for the plant and suppression of rhizosphere pathogens unable to utilize the Fe–siderophore complex. However, none of the genotypes of rhizobial endophyte strains in our culture collection produced detectable siderophores (Yanni et al., 2001), so this mechanism seems not to be applicable for them. Nevertheless, other rhizobial strains may enhance Fe uptake in rice (Biswas et al., 2000a).

111.1.4.4 Proteomic Analysis of Rice Inoculated with Rhizobia. Proteomic analysis has provided fundamentally new information showing that inoculation of rice plants grown gnotobiotically with certain beneficial, endophytic rhizobia induces the production of identifiable plant proteins that contribute to better plant performance and health (Chi et al., 2010). Energy-associated proteins that enhance both light and dark reactions of photosynthesis in chloroplasts are upregulated in leaf sheathes and leaves. Proteins involved in phytohormone metabolism (e.g., IAA biosynthesis) are upregulated in aboveground plant tissues and downregulated in roots. Several defense-related proteins are upregulated in root and shoot tissues. Considered collectively, these plant molecular biology results predict that certain endophytic rhizobia promote rice growth by (i) enhancing photosynthesis to build plant biomass more efficiently, (ii) regulating phytohormone status *in planta* to promote vegetative growth, and (iii) activating defense responses to minimize the negative effects of environmental and pathogenic factors.

111.1.5 Extension of *Rhizobium* Benefits to Other Rice Varieties

For agronomical reasons, it is important to examine whether the various desirable interactions of these rhizobial endophytes can be extended to cereal varieties that are preferred by farmers in cropping systems throughout the world. Because many characteristics of this association exhibit high strain/variety specificity, tests of their compatibility at the lab bench are necessary before they are tested in the field. Our studies so far have included rice genotypes commonly used in Egypt (Sakha-101, Sakha-102, Sakha-103, Sakha-104, Giza-175, Giza-177, Giza-178, Giza-181, and Jasmine rice), the United States (M202 and L204), Australia (Calrose and Pelde), and India (Pankaj).

But what about rice varieties preferred by low-income farmers who cultivate rice on marginally fertile soils and who cannot afford to purchase fertilizers? To address this question, a study was done to measure how well the rhizobial endophyte strain E11 can colonize the root environment of four rice genotypes (Sinandomeng, PSBRC 74, PSBRC 58, and PSBRC 18) preferred by Filipino peasant farmers because of their good yielding ability and grain characteristics. Cells were inoculated on axenic seedling roots and then grown gnotobiotically in hydroponic tube culture, and the resultant populations were enumerated by viable plate counts. For comparison, seedlings of equal size received an equivalent inoculum of a local, unidentified isolate BSS 202 from *Saccharum spontaneum* used as a Pgp^+ biofertilizer inoculant for rice in the Philippines.

The results indicated significant colonization potential of strain E11 on roots of all four rice genotypes (Yanni et al., 2001). The implications of this experiment are significant: strain E11 exhibits no obvious difficulty in its potential to intimately colonize roots of not only the "superior" rice varieties that have undergone significant breeding development but require high N inputs for maximum yield but also with other rice varieties preferred by peasant farmers because they perform acceptably on marginally fertile soil without significant N-fertilizer inputs. The latter type of rice production could derive significant benefit from the biofertilizer inoculants that our research is developing.

111.1.6 Translational Research on Rice Biofertilization Using *Rhizobium* under Field Conditions

Our strategy to maximize the benefits of rice biofertilization was to initiate a translational research/technology program for enhancement of its production in the Egypt Nile Delta based on our findings that strains of rice-colonizing rhizobial endophytes positively contributed to higher paddy yields and N-fertilizer use efficiencies. This translates to significantly reduced need for additional N-fertilizer applications for increased rice yields, fully consistent with sustainable agriculture and environmental soundness.

The production of rice up to a level of global food security is currently not possible without major nutrient inputs, especially N. Indirectly, rice is able to utilize a basal level of fixed N through N_2-fixing activities of diverse diazotrophs in its agroecosystem. Our measurement of that process in the Nile Delta using $^{15}N/^{14}N$ natural abundance methods indicates that roughly 10% of the N in mature rice plants is derived from BNF (Yanni et al., 2001). Serious economic and environmental problems associated with excessive use of fertilizer application to enhance rice production could then be mitigated if cereal crops could establish a more direct and intimate association with beneficial bacteria that promote its growth and increase grain yield with less dependence on chemical N-fertilizer input. This natural association can significantly improve rice plant growth, resulting in an increase in its grain productivity and agronomic N-fertilizer use efficiency (kilogram grain yield/kilogram N-fertilizer), making it possible to increase rice grain yields with less dependence on nitrogen fertilizer inputs (Yanni et al., 2001; see Chapter 109).

In situations exemplified by our field experiments at the Kafr El-Sheikh Governorate in Egypt (Yanni et al., 1997, 2001), inoculation of rice with rhizobia followed rather than replaced crop rotation with the berseem clover legume crop. Rice could then gain benefits from both biological associations of rhizobia: indirectly as the N_2-fixing root-nodule occupant of clover and directly as an active plant growth promoter in rice roots. This strategy is intended to augment the anticipatory colonization potential of superior inoculant strains in competition with other rhizosphere microorganisms for endophytic niches in rice above the natural level of inoculum potential carried over from decay of residues of the previous clover crop. The strategy is appealing from the environmental impact standpoint since it makes greater use of the natural resource of beneficial plant–microbe interactions.

We have tested selected rhizobial isolates representing a diversity of strain genotypes in a total of 38 field inoculation trials, with earlier studies conducted on small (20 m^2) replicated plots (Yanni et al., 1997, 2001) and later in trials on large upscaled farmers' field locations in the Nile Delta (Yanni and Dazzo, 2010). These experiments were designed and conducted in areas where rice and legumes have been adopted in crop rotation since the beginning of recorded history. This distinctively enabled us to assess the agronomic performance of rhizobia in rice biofertilization under a broad range of soil characteristics and landscapes and, most importantly, to compare it to real-world, present-day on-farm baselines in rice grain production.

In the same set of experiments, replicate plots were also included to measure how much N-fertilizer application could be replaced and/or how much more grain yield could be obtained from the same field area with application of

biofertilizer inoculants even when N-fertilizer expressed its maximum potential in enhancement of rice growth and performance. The experiments included N-fertilizer application at three ascending quantities: 1/3, 2/3, and the full recommended N-fertilizer dose assessed and recommended by the Agricultural Research Center, Egypt (http://www.arc.sci.eg/), for maximum grain yield without biofertilizer application. The N-fertilizer was added as urea (46% N) in two equal doses at 15 and 30 days after transplantation of the rice seedlings.

Three initial field trials were done in 20 m^2 subplots with four replications. Integrated field management practices are fully described in Yanni et al. (1997, 2001). Results of the three field inoculation trials indicated that some rhizobial strains/rice varieties combinations significantly increased rice grain yield, straw production, agronomic N-fertilizer use efficiency, and harvest index. The results further indicate the potential opportunity to exploit this plant–rhizobia association by developing biofertilizer inoculants that may assist low-income farmers in increasing cereal production with no further additions of chemical N-fertilizer beyond the recommended amount for the rice variety, fully consistent with both sustainable agriculture and environmental biosafety.

Interestingly, rice grain yield in the first experiment (Yanni et al., 1997) negatively responded to excessive N-fertilizer application over the recommended (included for comparison reasons) along with biofertilization. This (unrecommended fertilization practice) results in the well-known phenomenon in rice agronomy called "lodging", which is a consequence of overacquisition of N in plant tissue, leading to excessive vegetation in the later growth stage in which the plant must go to panicle initiation rather than excessive production of vegetative parts, producing semierect shoots that are vulnerable to wind damage and have increased spikelet sterility and production of late nonproductive tillers. This adverse growth response was intensified further by biofertilization that led to overabsorption of available N that exceeded the plant's need to complete its natural life cycle (seed to seed).

Later (Yanni and Dazzo, 2010), we conducted 24 large-scale inoculation trials using our selected endophytic strains of rice-colonizing rhizobia in farmer's fields in nine counties of the Kafr El-Sheikh Governorate located in the north–west–central regions of the Nile Delta (Figure 111.5). The rice cultivation area in this governorate represents approximately 18–25 % of the total area used annually for rice cultivation in Egypt. In this massive field experimentation program, we tested the performances of seven genotypically distinct inoculant strains of *R. leguminosarum* bv. trifolii, used individually or in consortia, for inoculation of five rice varieties along five rice growing seasons (May through October) during 2000, 2002, 2003, 2004, and 2005, in which 1, 4, 5, 6, and 8 experiments were conducted, respectively. The field experimentation directory in

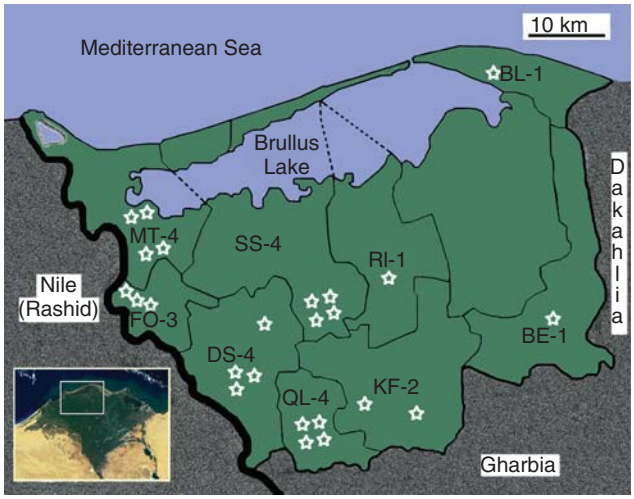

Figure 111.5 Twenty-four sites in nine counties of the Egyptian Nile Delta where large-scale field inoculation trials of the rhizobia–rice association were conducted. County abbreviations are as follows: MT, Metobas; SS, Sidi Salem; RI, Riad; Fo, Fowa; DS, Desouk; QL, Qalein; BE, Biala; BL, Baltem; KF, Kafr El-Sheikh city (including Sakha). The framed insert in the lower left corner is a satellite image showing the portion of the Nile Delta represented by this map.

Table 111.1 presents pertinent information on the location, year, previous crop, rice variety, rhizobial inoculant strain(s), field soil salinity, texture, important chemical properties, and area of the replicated subplots.

111.2 METHODOLOGY

Properties of the used rice varieties, soil sampling, soil tillage, preparation of rice nurseries, transplantation processes, field stand density, amounts, sources, and times of application of phosphatic and potash fertilizers and irrigation regime, experiment follow-up, harvest, yield and yield components, and other agronomic parameters are all described in Yanni and Dazzo (2010). To assess the nitrogen fertilization economy in the presence and absence of bacterial inoculation, three N-fertilizer amounts were placed as the main plot treatments. These 24 large-scale field experiments plus the previously mentioned three small-scale field experiments performed at the experimental farm of the Sakha Agricultural Research Station represent a total of 27 field inoculation trials in which 9 rice varieties and 7 genotypically distinct, indigenous rhizobial endophyte strains were used. Samples for yield comparison were taken from the identical, noninoculated area cultivated with the same rice variety during the same period in the adjacent fields that were managed by the farmer while recalling his own conventional farming practices that he acquired himself or by transfer from his ancestors. We located our experimental plots directly adjacent to the farmer's conducted

area so that he and we could easily recognize differences in the crop growth features along the cultivation season and also calculate together differences in the gained yield and N-fertilizer use efficiency in the two adjacent field areas.

111.2.1 Grain Yields in Our Scaled-Up Field Experiments Compared to the Farmer's Yields

Table 111.2 indicates the best performance obtained with field inoculation treatments using our strains and the three tested N-fertilization rates on the scaled-up, researcher-supervised experimental plots versus yields of the same variety obtained simultaneously by the farmer using the recommended rate of N-fertilizer (mostly more) without inoculation or supervision by the research personnel. The results indicate the synergistic beneficial effects of rhizobial inoculation and N-fertilization on increased grain yield for all rice varieties. The means of percentage increases due to inoculation over all the 24 field experiments ranged from 4.4% to 18.4%, 6.4% to 14.0%, and 4.6% to 11.1% with application of N-fertilizer at 48, 96, and 144 kg/ha, respectively. The results also indicated how the rice varieties differed in magnitude of response to biofertilization. Maximum rice production of 9.404, 10.008, 11.231, 10.770, and 11.102 ton paddy yield/ha for the rice varieties Jasmine, Giza-177, Giza-178, Sakha-101, and Sakha-104, respectively, were obtained with fertilization by 144 kg N/ha along with biofertilizer application. The corresponding figures obtained without biofertilization were 8.725, 9.008, 10.736, 10.294, and 10.611, respectively, registering mean increases of 0.679, 1.000, 0.495, 0.476, and 0.491 ton/ha attributed to biofertilization. This confirms our earlier results (Yanni et. al., 1997, 2001) that strain/variety specificity is controlling this beneficial cereal–strain endophytic association. Higher percentage increases in rice yields (not necessarily the maximum yields) of the five varieties were obtained using biofertilization along with the 48 and 96 kg N-fertilizer/ha, indicating better crop performance when biofertilization was used along with low rather than high N application doses and that inoculation can significantly reduce, but not completely eliminate, the need for chemical N-fertilizer to accomplish maximum grain yield.

111.2.2 Performance of Biofertilization in Salt-Affected Soils

In Egypt, saline soils are very common in the northern coastal region of the Nile Delta that borders the Mediterranean Sea (Figure 111.5) where we have been conducting this translational research program. Submerged rice is predominantly grown not only for its importance as an economically staple cereal crop but also because reclamation of salt-affected soils in those areas can be facilitated by percolation of Nile freshwater through the saline soil profile, which can wash the high salt content downward to drainage canals.

Data in Table 111.3 report the performance of rhizobial biofertilization in different salt-affected soils. Increasing N application rate resulted in concomitant increases in paddy yield. Maximum yields were obtained by biofertilization along with application of 144 kg N/ha when used in soils having salinity levels of up to 7500 ppm and with only 96 kg N/ha added under a salinity level of 8609 ppm. The means of

Table 111.3 Mean of paddy yields obtained under the different salinity levels dominated the experimental locations as affected by inoculation and N-fertilization, when produced under supervision of the research team and under the farmer's conventional practices in their adjacent fields

Soil Salinity (ppm)	Expt.	N (kg N/ha)	Mean of Paddy Yields (ton/ha)		Mean of Increases by Inoculation (%)	Mean of Yields in the Adjacent Farmer's Fields (ton/ha)	Increase by the Best Experimental Treatment over the Farmer's Yield (%)
			Noninoculated	Inoculated			
0–2500	A	48	9.204	9.680	5.2	9.426	18.0
		96	10.002	10.671	6.7		
		144	10.662	**11.122**	4.3		
2501–5000	B	48	9.763	10.627	8.5	9.946	13.0
		96	9.885	10.815	9.4		
		144	10.519	**11.241**	6.9		
5001–7500	C	48	9.154	9.857	7.6	7.140	46.2
		96	9.826	10.309	4.9		
		144	10.056	**10.439**	3.8		
>7500	D	48	6.959	8.134	16.9	8.330	3.5
		96	6.424	**8.623**	34.2		
		144	6.881	8.305	20.7		

maximum paddy yields obtained with inoculation under the salinity levels (ppm) of up to 2500, up to 5000, up to 7500, and >7500 were 11.122, 11.241, 10.439, and 8.623 ton/ha, obtained using application of 144, 144, 144, and 96 kg N/ha, respectively, comparing to 10.662, 10.519, 10.056, and 6.959 obtained with no inoculation and application of 144, 144, 144, and 48 kg N/ha in the same respective order. Moreover, the comparison between means of yields of the best experimental treatments adopted by the research team and those of the farmers (Table 111.3) indicated 18.0, 13.0, 46.2, and 3.5 % yield increases, respectively.

These results highlight the benefit of biofertilization as the mean of grain yield obtained with inoculation exceeded what could be obtained in the corresponding noninoculated controls under all the soil salinity levels. The percentage increases in grain yield due to inoculation followed a special tendency in which – with few exceptions – it increased proportionally with salinity intensification. The higher soil salinity in the county (Figure 111.5) that includes the northern city of Baltem (experiment #2) most likely contributed to the lower grain yield of the variety Giza-178 obtained in the noninoculated treatments when compared to the higher grain yield of the same rice variety obtained in noninoculated treatments at other locations that had less soil salinity. This indicates that rice was only able to tolerate the high salinity stress when inoculated with and receiving the benefit(s) of the rice-colonizing rhizobia. Interestingly, the mean increase in yields resulting from inoculation was highest at that same location, suggesting that *inoculation of rice with certain endophytic rhizobial strains may help to alleviate the adverse effects of salinity stress on rice grain production*. Similar trends have been previously found for the root-nodule symbiosis between *Bradyrhizobium* spp. with pigeon pea (*Cajanus*) and *Rhizobium loti* with chickpea (Rao and Sharma 1995; Subbarao et al., 1990). This raises the interesting possibility that rhizobial inoculation may help farmers obtain higher rice yields during and just after performing primary reclamation processes to saline soils (as long as the benefit-to-cost ratio is acceptable).

111.2.3 Plant Growth Tendencies and Biomass Production as Affected by Biofertilization

The harvest index (grain yield/aboveground harvested grain plus straw biomass, expressed as a percentage) is an important unitless agronomic parameter for plant breeders. It reflects the portion of plant growth directed to reproductive production of grain versus vegetative production of aboveground shoot and leaf biomass, mostly at the expense of grain production. Calculating this parameter at harvest can indicate whether there was an imbalanced growth due to excessive vegetative growth that consumed large amounts of nutrients rather than mobilized them for grain production. This mostly takes place when the plant was supplemented with excessive unnecessary amounts of N-fertilizer during the panicle initiation and flowering stages. This leads to production of extra nonreproductive tillers (tillers bearing no panicles) with soft plant tissues that are more susceptible and easily invaded by bacterial, viral, and insect pests, leading to decreased grain production from fewer panicles and/or lower grain weight.

The harvest indices in our field experiments (Table 111.4) confirmed that for all three levels of N-fertilizer applications, rice straw at harvest was higher than the corresponding

Table 111.4 Influence of *Rhizobium* inoculation on harvest index at eight locations in the Nile delta

Harvest index: % of grain yield/grain + straw yields. Means superscripted by different letters in the same column (for N-fertilization rates) or highlighted in bold (for inoculation) for each experiment are statistically different at the 95% confidence level.

noninoculated counterparts. The tables in Yanni and Dazzo (2010) show the results of eight experiments (#s 1, 2, 6, 10, 11, 12, 13, and 14) in which significant increases in the harvest index resulted from inoculation while increasing the N dose significantly and typically decreased the harvest index, indicating that unlike for inoculation, N-fertilization increased vegetative straw production more so than increased grain production. In the remaining 16 experiments, no significant changes in harvest index were observed due to inoculation or increasing the N application dose, indicating that the recommended N dose used in those experiments was within (did not exceed) the acceptable range that balanced vegetative and reproductive growth.

The results here indicate that this parameter is mostly a plant genetic property that is only slightly affected by agronomic factors like fertilization, inoculation, field location, soil texture, salinity, etc. In this translational research/technology study, inoculation and the N-fertilization doses, in most cases, worked together synergistically in providing the plant's demand for N and other nutrient requirements without seriously decreasing the harvest index values. This beneficial result is consistent with our previous work (Yanni et al., 1997, 2001) showing that rhizobial inoculation and N-fertilization contributed to rice vegetative growth and grain yield in parallel.

111.2.4 Inoculation and N Economy in Rice Agroecosystems

Increases in the N-fertilizer use efficiency (kilogram grain yield/kilogram N-fertilizer) translate to higher production of grain yield with less dependence on additional amounts of N-fertilizer inputs. It does not represent the absolute values of the N-fertilizer use efficiency, which requires ^{15}N analyses to measure how much of the plant nitrogen was derived from the applied N-fertilizer.

As anticipated, the "agronomic" N-fertilizer use efficiency decreased sharply with increased applications of N-fertilizer for both the inoculated and noninoculated treatments and for all the rice varieties under the different soil salinities encountered, with significantly higher mean differences for the inoculated versus the noninoculated treatments (Table 111.5). Its values were significantly higher for inoculated treatments in 18 (75%) of the 24 field experiments (Yanni et. al., 2010). By extrapolation, the rice grain yield of field plots inoculated with rhizobia plus intermediate doses of N-fertilizer was close or equal to that obtained with application of the full N-fertilizer dose without inoculation. This very significant experimental result clearly indicates that rhizobial inoculation can significantly improve rice grain production by counterbalancing the trade-off in reduced agronomic use efficiency of N-fertilizer with increasing the fertilizer doses, producing the desired result that rhizobial inoculation can reduce the need for additional N-fertilizer for production of higher grain yield or obtain the same grain yield from less field area.

Unlike the well-known suppression of symbiotic nitrogen fixation resulting from application of N-fertilizers in fields of nodulated legumes, the results here indicate that the degree of benefit to rice by inoculation with rhizobia was enhanced rather than suppressed by N-fertilizer application. That result means also that inoculation with rice

Table 111.5 The agronomic fertilizer N-use efficiency* in the experimental fields and adjacent farmer's fields as affected by rice varieties, soil salinity, inoculation, and N-fertilization doses

Rice Var.	N (kg/ha)	Noninoculated Control	Inoculated	N-Fertilizer Use in Farmer's Fields	Salinity Level (ppm)	N (kg/ha)	Noninoculated Control	Inoculated	N-Fertilizer Use in Farmer's Fields

rhizobial endophytes increased grain yield even when N was no longer the major limiting factor for grain production, clearly indicating that inoculation transforms the plant to make better use of the available N and other plant nutrient resources in the root zone that are not readily accessible by the plant without inoculation. The outcome of this experimentation program supports our previous studies showing benefits of inoculation in expanding the plant root architecture (biovolume, biomass and cumulative root length, and surface area), increased absorption and acquisition of nutrients by the plant, enhanced production of plant growth regulators, efficient use of insoluble inorganic phosphates in the rhizosphere area and organic phosphates inside the root system (Yanni et al., 1997, 2001), and probably other mechanisms by which this growth promotion was obtained.

111.2.5 Different Performance of Single- and Multistrain Inocula Preparations

A detailed comparison of each of the 24 experiments (Yanni and Dazzo, 2010) indicates that inoculants of certain rhizobial consortia perform better than with only a single rhizobial strain. Inoculation scored a mean increase in grain production of 0.706 ton/ha with multistrain inocula preparations versus 0.635 ton/ha with single-strain inocula, that is, 11.2% more grain yield when certain multistrain consortia were used.

111.2.6 Experimental Rice Productivity as Compared to National Figures of Rice Production in Egypt during 25 Annual Growing Seasons

Another benefit of rhizobial inoculation found in our studies was its ability to increase the potential of paddy yield production for certain rice varieties that exceed the maximum Egypt national rice productivity of 10.071 ton/ha scored in season 2006 (over 25 rice growing seasons extended from 1984 through 2011 and around 21.008 million h cultivated with rice during this quarter century period) when cultivated using the recommended amounts of N-fertilizers without inoculation (http://www.arc.sci.eg/BasicDataReport.aspx?OID=63&lang=en). Concerning mean yields of the rice varieties in the 24-experiment program (Table 111.2), the mean percentage increases were 11.5, 6.9, and 10.2 % for the rice varieties Giza-178, Sakha-101, and Sakha-104, respectively. The increased rice production capacity occurred in 20 of the 24 inoculation experiments when it could not be achieved by N-fertilizer application alone. Inoculation with rhizobia promoted grain yield to levels that exceeded that national production figure in 7 experiments with application of 48 kg N-fertilizer/ha, increased to 15 experiments with 96 kg N-fertilizer/ha, and in 21 experiments with the full recommended application rate of 144 kg N/ha. However, this variation cannot be attributed solely to contributions to grain yields related to the biofertilization practice, as the national production figures were calculated using results

obtained from a wide range of rice cultivation areas with a minimum of 453.6 thousand ha cultivated in season 1991 to a maximum of 743.0 thousand ha cultivated in 2008, under uncountable agronomic variables involved.

111.2.7 Comparison of Rhizobia with Other Biofertilizer Candidates for Rice

Previous field inoculation studies on rice have used N_2-fixing cyanobacteria, *Azospirillum* (see Chapter 90) and *Azotobacter* as biofertilizer inoculants (Subrahmanyan et al., 1965; Venkataraman 1966; Arora 1969; Jack and Roger, 1977; Rajarmamohan et al., 1978; Roger and Kulasooriya, 1980; Gupta et al., 1989; Yanni and Abdallah, 1990; Yanni and Osman, 1990; Yanni and Hegazy, 1990; Yanni 1991, 1992a, 1992b, 1996; Omar et al., 1993; Shahaby et al., 1993; Yanni and Abd El-Rahman, 1993; Yanni et al., 1996). Like with rhizobia, N-fertilizer supplements are required to obtain maximum grain yields even when rice is inoculated with the above mentioned diazotrophs, individually or in consortia containing two or all three of them (Yanni and Abd El-Fattah, 1999 and references therein). However, the performance of rhizobial inoculants differs from those other plant growth-promoting rhizobacteria in two major ways. First, the appropriate rhizobia can benefit both the legume and the cereal sharing the same crop rotation, a phenomenon quite exemplified and easy concluded from results in this research program, whereas the other inoculants are only used for the cereal crops. In Egypt, ~ 67% of rice is cultivated as a summer crop in rotation with berseem clover. The other winter legume crops used in rotation with rice include legumes like faba bean, lentil, bean, lupines, fenugreek, and alfalfa that may also be rotated with rice as a summer crop in the same fields, so that rotation can help to maintain and perpetuate the populations of clover rhizobia involved in both clover–microbe and rice–microbe interactions. Second, the benefits of the rhizobial inoculants to rice occur at each stage of its development, beginning with seed germination and extending through grain maturity (Dazzo et al., 1999; Biswas et al., 2000a; Biswas et al., 2000b; Yanni et al., 2001, 1997; Dazzo and Yanni, 2006), whereas the benefits to rice provided by the other biofertilizer inoculants mentioned earlier are expressed only during its maximum "N-limitation stress period" when an external source of N is required at the tillering stage that extends from 15 to ~40 days post rice seedling transplantation (Yanni and Abd El-Fattah, 1999 and references therein).

111.2.8 Biosafety: A Pertinent Issue in the Biofertilization Technology

The importance of this issue is illustrated in some of our earlier gnotobiotic culture studies (Yanni et al., 1997, 2001). We found that some natural rice endophyte strains of clover rhizobia were active root nodulators and efficient N fixers on berseem clover, some others were inhibitory to rice growth, and a few of those natural rice endophyte strains of rhizobia in our collection were efficient PGP+ on rice but *lethal* pathogens on berseem clover! Since all these beneficial, neutral, and harmful types of endophytic rhizobia–rice interactions exist in nature, it is important to screen for and identify possible detrimental plant–bacteria symbiotic or associative combinations beforehand to avoid catastrophic inoculation outcomes to either crop under field conditions. We made sure beforehand that each of the seven strains of rhizobia that were included in our experimental field program was pretested under gnotobiotic conditions and found to be Nod+ and Fix+ on berseem clover and PGPR+ on many rice varieties (Yanni et al., 2001). Strains belonging to three of the 10 strain genotypes were excluded from field experiments based on these (in)compatibility screen tests in the lab.

111.2.9 Justification of Conclusive Recommendations Derived from the Studies

The translational research/technology program exemplified here can serve as a successful example of how deployment of well-selected biofertilizers can represent an integral component of sustainable nutrient management for rice production and can help farmers grow better, more productive rice crops in an environmentally safe way when soil fertility (especially available N) is a limiting factor. Thus, in addition to its well-known use as a micropartner in the N_2-fixing root-nodule symbiosis with legumes, rhizobia can be used as a microbial biofertilizer that can significantly enhance rice production through a different pathway of rice–rhizobia endophytic association. The benefit provided by the rhizobial biofertilizer is enhanced rather than suppressed with N-fertilizer supplementation, consistent with a mechanism that involve bacterial induction of an increased ability of the plant to sequester and utilize N from the available soil N pool rather than from de novo, *in planta* biological nitrogen fixation. They are not intended to replace the recommended rice farming practices for N-fertilizer management (amounts, N-fertilizer source, and timing of application), which were defined through a significant amount of multidisciplinary teamworks involving soil, water management, and plant nutrition scientists (http://www.arc.sci.eg/InstsLabs/Default.aspx?OrgID=1&lang=en), agronomists (http://www.arc.sci.eg/ResearchStations.aspx?&lang=en#S307), plant pathologists (http://www.arc.sci.eg/InstsLabs/Default.aspx?OrgID=6&lang=en), climate specialists (http://www.arc.sci.eg/InstsLabs/Default.aspx?OrgID=23&lang=en), entomologists (http://www.arc.sci.eg/InstsLabs/Default.aspx?OrgID

=5&lang=en), field experimentation and agroeconomy specialists (http://www.arc.sci.eg/InstsLabs/Default.aspx?OrgID=9&lang=en), agriculture engineering specialists (http://www.arc.sci.eg/InstsLabs/Default.aspx?OrgID=12&lang=en), and extension experts (http://www.arc.sci.eg/InstsLabs/Default.aspx?OrgID=10&lang=en). Instead, it complements those recommendations by providing an additional tool to enhance better plant growth and performance and N-fertilizer use efficiency in an environmentally friendly way that increases crop productivity without excessive use of additional N-fertilizer applications. However, cases where inoculation increased grain production despite no statistically significant increase obtained in response to the maximum recommended dose of N-fertilizer (Yanni and Dazzo 2010) indicate that the benefits of rhizobial inoculation on grain production extend beyond its alleviation of N-limitation.

These translational studies indicate that use of these environmentally friendly biofertilizer inoculants can now be recommended with sufficient supporting data to improve agriculture economy and sustainable agroecosystem maintenance of rice grain production where the benefits of such biotechnology are most urgently needed. However, because rice production often remains "N responsive" even when combined with rhizobial inoculation, further efforts must be exerted to reach the ultimate goal of fully eliminating the need for N-fertilizer inputs to obtain reasonable economic rice grain production. Perhaps the solution to achieve that goal is a critically tested/formulated biofertilizer(s) containing a mixed inoculant consortium that includes our best-performing rhizobial strains plus highly selected free-living N fixers like cyanobacteria, "associative" diazotrophs like azospirilla, and other plant growth-promoting rhizobacteria like *Pseudomonas*. We have been exploring that proposed updated plan and have obtained some very promising outputs through another translational large-scale biofertilization program in further experimentation fields in and outside the Nile Delta. Reports of those studies are forthcoming.

111.3 TAKE-HOME LESSONS OF THIS RESEARCH PROGRAM

Assuming that the results summarized here accurately reflect the potential benefits of this new agricultural biotechnology based on exploitation of a natural resource (natural rhizobial endophytes of cereals), the following outcomes can be expected:

1. Increased cereal crop yields above what is reached using organic and inorganic fertilizers alone, with a reduction in the amount of currently recommended fertilizer input without biofertilization. Economically, this can assist farmers to increase their yield figures while reducing the dependence on additional N-fertilizer inputs to achieve higher yields from important rice varieties, including under a wide range of soil salinity stresses. The farmers then do not need to increase the used land area to obtain similar yields as those reached by biofertilization with the tested strains.
2. Improvements in human nutrition by the increased production of rice with its multiple nutritional values.
3. Decreased environmental pollution and health risks originating from excessive use of inorganic N-fertilizers. However, further studies are needed to verify the reduction in costs of disease treatments associated with excessive use of agrochemicals and the economic benefits from increasing individuals' work abilities.
4. Decreased energy needed for production, transportation, and distribution of fertilizers and directing it to other socioeconomic and industrial uses.
5. A better understanding of how farmers can practice sustainable agriculture by utilizing biofertilizers as a safe and effective alternative to synthetic fertilizers.
6. Promotion of cooperation between research institutions on one side and private sectors represented by farmers and agricultural biotechnology industries on the other.

One of the many lessons we have learned from this study was stated well by Leonardo da Vinci: "Look first to Nature for the best design before invention." Although it is also a huge challenge, the research presented here has shown that the exploitation of naturally selected and significantly screened beneficial plant–bacterial associations is the sound and environmentally friendly way that has high probability for success. This is particularly relevant for the design of strategies derived from the use of genetic engineering for sustainable agriculture. By implementing these words of wisdom, biotechnology can capitalize upon such understanding in efforts to enhance agricultural production in ways that are consistent with complex, evolved biological relationships ascending from the foundation of natural microbial populations associating with crop plants on Earth.

ACKNOWLEDGMENT

We acknowledge the contributions presented by our cooperated farmers, the agronomists, plant nutritionist, and field experimentation and extension specialists who made performance of this research/translational program possible. We also thank all of our collaborators indicated in our publications cited here. Portions of this work were supported by Projects BIO2-001-017-98, BIO5-001-015, BIO10-001-011,

and 58-3148-1-140 from the US–Egypt Science and Technology Joint Program Fund.

N Fixation in Insects: Its Potential Contribution to N Cycling in Ecosystems and Insect Biomass

Domancar orona Tamayo and Martin Heil

Departamento de Ingeniería Genética, Centro de Investigación y de Estudios Avanzados [CINVESTAV], Irapuato, Guanajuato, México

112.1 INTRODUCTION

Nitrogen plays a central role in most metabolic processes and therefore represents a critical element in the growth of all organisms (Mattson, 1980). However, whereas many prokaryotes can assimilate atmospheric N_2 and then are autotrophs for this nutrient, the higher organisms such as plants, animals, and fungi do not harbor this important physiological process. Although gaseous N_2 covers each centimeter of the land and N cycles through the ecosystems, organically bound nitrogen represents a limiting factor in many ecosystems and for many species. The main source of an additional supply of organic N to the ecosystems is the biological fixation of N from the atmosphere by a selected group of prokaryotes (i.e., Rhizobiales and green sulfur bacteria) (Young, 1992) which possess the complex enzymatic nitrogenase machinery (LeBauer and Treseder, 2008; see Chapter 2). These prokaryotes reduce N_2 and convert it into forms that can be utilized by animals, plants, and fungi (Nardi et al., 2002). The global biological nitrogen fixation amounts to ≈ 110 and 140 teragrams in terrestrial and oceanic ecosystems, respectively (Fowler et al., 2013; Gruber and Galloway, 2008; Nardi et al., 2002; Vitousek et al., 2013; see also Chapter 84).

Plants like the legumes establish nutritive mutualisms with prokaryotes (rhizobia), which allow them to have direct access to the *de novo* fixed N. By contrast, the survival, development, maintenance, and growth of arthropods are believed to depend on organic diets with their content of organically bound N, and N often limits their development (Douglas, 2009). When arthropods feed on a nonbalanced diet, they must obtain additional N from other food sources. Here, we present evidence in favor of the existence of N fixation by endosymbiotic prokaryotes that reside in insect midguts: insect–prokaryote mutualisms might be as important for the N balance in many terrestrial ecosystems as the well-known legume–rhizobia mutualism.

112.2 NITROGEN ACQUISITION BY INSECTS

Insects have rather uniform nutrient requirements but live on very diverse diets. Therefore, the development, behavior, and reproduction of herbivorous insects in particular critically depend on the quality of the plant parts on which they feed and the content in limiting nutrients in these diets (Awmack and Leather, 2002; Scriber and Slansky Jr, 1981). In particular, while animals consist mainly of proteins (≈50%) (Mattson, 1980), most diets of herbivorous insects (such as wood, leaves, fruits, phloem sap, or nectar and other plant exudates) are very low in nitrogen. The average N content of an insect is usually 10–20 times higher than the N content of the autotrophic organisms that represent its diet. An exception appears to be only those parts of plants that have particularly evolved to serve as food source for animal mutualists, such as certain fruits, elaiosomes, and the food

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

bodies of specific ant plants (Heil et al., 2004; Heil et al., 1998; Orona-Tamayo et al., 2013). For this reason, even in some human cultures, insects are the most important food source (Barker et al., 1998; Fagan et al., 2002; Finke, 2005).

Likewise, many of those insects that feed on a mainly or strictly vegetarian diet must dramatically alter the relative composition of nutrients in their diet, upgrade some nutrients, and discriminate against others in order to reach the balanced composition in their alimentation (Douglas, 2009; Mayr et al., 2010). Low nitrogen content in the diet can cause severe problems with the physiology of an insect (Benemann, 1973; Wyatt et al., 1956) and, in fact, of all herbivorous animals. For example, the fecundity of the aphid (*Drepanosiphum platanoidis*) is limited directly by the availability of amino acids in the phloem (Dixon, 1970; Douglas, 1993). The Colorado potato beetle (*Leptinotarsa decemlineata*) can use sugars and fatty acids as energy source during flight, but this species also oxidizes the amino acid proline as the main fuel for flight (Arrese and Soulages, 2010; Brouwers and de Kort, 1979; Mordue and de Kort, 1978), as do many other insects such as honeybees, which depend on proline as the main energy source during the early phases of flight (Carter et al., 2006). Whereas adult bees collect nectar and pollen and convert it to honey that provides the energy for flight, pollen provides the N compounds for larval development (Camazine, 1993; Seeley, 1989). In other social insects, such as leaf-cutter ants (*Atta* or *Acromyrmex*), pieces of leaves are used to cultivate a fungus that is the food source for the colony (Craven et al., 1970; Haeder et al., 2009; Weber, 1966; Abril and Bucher, 2004; Bass and Cherrett, 1995). However, neither pollen nor fungal mycelia seem to contain sufficient protein to provide growing larvae with all their nitrogen needs.

This general imbalance between the biomass of herbivorous insects and the availability of their food plants has been expressed in "Tobin's ant-biomass paradox": according to normal quantitative ratios among different trophic levels, the nitrogen contained in what is considered food available to tropical arboreal ants seems not to be sufficient to maintain the ant biomass that exists in nature (Davidson et al., 2003; Tobin, 1995). The solution appears to be that many insects that live on low-N diets depend on associations with microbes that contribute to their nutrition. For example, termites and some wood-feeding beetles have been reported to fix N_2 from the atmosphere (Breznak et al., 1973; French et al., 1976; Kuranouchi et al., 2006; Morales-Jiménez et al., 2009; Morales-Jiménez et al., 2013). Because insects lack the enzymatic machinery for the reduction of N_2, the conclusion was that the insects gained this capacity via the establishment of an "endosymbiosis": a mutualism with resident N-fixing bacteria that live inside the host, allowing particular direct interactions between the partners (Kikuchi, 2009).

Cyanobacteria are the most widespread and major N fixers in freshwater or marine systems (Vitousek et al., 2002; see Chapter 84). These versatile organisms combine photosynthesis and N fixation in the same cell (Berman-Frank et al., 2001; Berman-Frank et al., 2003). In soil, microbes that biologically fix atmospheric N can either live freely in the substrate or interact with plant roots to establish nodular symbiotic relationships (Nardi et al., 2002; Sprent and Sprent, 1990; Vitousek et al., 2002). Surprisingly, evidence is now accumulating that the same prokaryotic taxa can also be found in insects, where they might fulfill the same function: to supply their host with organically bound N.

112.3 WHY ENDOSYMBIONTS RESIDE IN INSECTS?

Xylophagous insects such as termites and bark beetles represent a paramount example of insects with a low-N diet, because they feed on woody material that is rich in cellulose, hemicelluloses, and lignin but usually contains only ≈0.03–0.1% nitrogen (Breznak, 1982; Nardi et al., 2002; Prestwich et al., 1980). To enable protein synthesis and growth, these insects must have physiological adaptations to maintain their internal N pool by dietary supplementation or internal cycling of N (La Fage and Nutting, 1978; Prestwich et al., 1980; Wood, 1978). Interestingly, microbial endosymbionts contribute significantly to these essential processes.

In fact, many insects depend on gut endosymbiotic bacteria to balance their nutrition (Chandler et al., 2008; Eilmus and Heil, 2009; Nardi et al., 2002). For example, the evolution of herbivory in ants has been suggested to have been facilitated dramatically by the establishment of mutualistic interactions with gut endosymbiotic bacteria (Russell et al., 2009). Endosymbiotic bacteria in general aid with processes as diverse as the digestion of complex and difficult-to-digest types of food, detoxification, the synthesis of vitamins and amino acids, and the defense against pathogens (Brownlie and Johnson, 2009; de Souza et al., 2009; Douglas, 1998; Douglas, 2006; Engel and Moran, 2013; Ishak et al., 2011; Lai et al., 1996; Scott et al., 2008; Shi et al., 2013; Zientz et al., 2006; Zientz et al., 2004). The class Insecta is composed of more than 1,200,000 species, and approximately half of them are estimated to harbor endosymbiotic bacteria (Buchner, 1965; Douglas, 1989; Kikuchi, 2009). The most specialized of these bacteria are located in the cytosol of specialized cell structures, the so-called bacteriocytes (Moran and Telang, 1998; Swiatoniowska et al., 2013; Zientz et al., 2005).

Why have these interactions been established? In the end, numerous examples of free-living taxa demonstrate that to survive, N-fixing prokaryotes do not necessarily require any mutualism with a plant or animal. In this context, the predictability of the abiotic and biotic environment (temperature, salinity, humidity, pH, nutrient supply) that

the arthropod gut offers might be an important factor that favors endosymbiosis. As in the case of the legume–rhizobia mutualism, the symbionts can acquire energy for their reproduction in a very reliable way and are protected from most hazardous environmental threats (Nardi et al., 2002). The insects, by contrast, gain access to the biosynthetic diversity that is represented by the prokaryotes. Moreover, in the case of vertically transmitted endosymbionts, the direct interdependency of fitness of both partners helps to maintain mutualistic behavior (Gibson and Hunter, 2010).

112.4 BACTERIAL COMMUNITIES ASSOCIATED WITH INSECTS

Insect endosymbionts are extremely diverse and stem from different phyla that comprise the protists, fungi, archaea, and bacteria (Anderson et al., 2012; Engel and Moran, 2013). Their coevolution with insects has allowed these endosymbionts to colonize the digestive tracts of virtually all insects and in exchange to offer different functions to the host insect. The diet on which the host lives can clearly influence the persistence of endosymbionts, and the proportion of taxa is very different among arthropods (Engel and Moran, 2013). Whereas some taxa of endosymbionts are commonly reported and are universally found in the digestive tracts of insects, others represent specific bacterial residents of certain insect hosts (Anderson et al., 2012).

In some insects, microbial residents are considered as obligate, because they are required for specific vital events in the host; often are transmitted vertically; and then usually live as intracellular symbionts. Examples for this highly special class of endosymbionts are *Buchnera* and *Wigglesworthia* (Akman et al., 2002; Brownlie and Johnson, 2009; Koga et al., 2003). The second group of commonly reported endosymbionts comprises intestinal bacteria that commonly live in the gut lumen, that is, within the insect but outside its cells. These extracellular endosymbionts are considered as facultative symbionts and are usually not required for vital events (Moran et al., 2008). However, the composition of symbionts differs even among closely related species of arthropods, which indicates a certain degree of specificity in these interactions (Fukatsu and Nikoh, 2000; von Dohlen et al., 2001).

Phylogenetic analyses based on the sequencing of the 16S ribosomal DNA indicate that the majority of insect endosymbionts are β- and γ-proteobacteria (Brauman et al., 2001; Breznak, 2000; Degnan et al., 2004; Dillon and Dillon, 2004; Dohlen et al., 2013; Gruwell et al., 2012; Morales-Jiménez et al., 2009; von Dohlen et al., 2001; Wernegreen, 2002; Wernegreen et al., 2009). Social insects such as ants have motivated particular scientific scrutiny due to their abundance in tropical regions (Davidson et al., 2003; Hölldobler and Wilson, 1990; Wilson and Hölldobler, 2005), and the presence of endosymbionts was first reported from *Formica* and *Camponotus* ants (Baumann et al., 2006). Later studies on other ant species found a number of specialized gut bacteria, among which β- and γ-proteobacteria and Rhizobiales were dominating, and significantly increased the number of microbial taxa that are known to be associated with ants (Eilmus and Heil, 2009; Lee et al., 2008; Martinez-Rodriguez et al., 2013; Rey et al., 2013; Stoll et al., 2007). Interestingly, the taxonomic composition of the typical bacterial communities in ants was very similar to those of termites, although ants in general possess bacteria at lower abundance (Engel and Moran, 2013).

Other arthropods for which intestinal bacteria are frequently being reported are phloem sap-feeding insects such as aphids, whiteflies, psyllids, and mealybugs (Baumann et al., 2006). The shared nutritional features of their diet comprise high content of carbohydrates and very low contents of amino acids and other N-based compounds (Sandström and Moran, 1999). Therefore, these insects are loaded with different endosymbionts in their midguts, most commonly from the β- and γ-proteobacteria, although the specific taxa differ from those reported for ants (Baumann et al., 2006; Gosalbes et al., 2010). Moreover, *Buchnera aphidicola*, *Candidatus* (*Ca.*) *Carsonella ruddii*, *Ca. Portiera*, and *Ca. Tremblaya* are frequently reported to be present in phloem-feeding insects (Clark et al., 1992; Gosalbes et al., 2010; Jiang et al., 2013; Munson et al., 1991; Tamames et al., 2007; Thao et al., 2000). In fact, *B. aphidicola* and its aphid host are the best-studied example of an insect–endosymbiont association (Munson et al., 1991; Sasaki and Ishikawa, 1995; Shigenobu et al., 2000). Here, the endosymbiont is involved in the biosynthesis of essential amino acids, a function that has also been suggested for the prokaryotes residing in other insects that feed on phloem (Gosalbes et al., 2010; Tamames et al., 2007).

That gut endosymbionts are selected in adaption to the nutrition of their host can also be exemplified observing the case of termites. The midgut of termites is charged with cellulases that apparently are of fungal origin, and these are involved in the digestion of lignocelluloses and, thus, in the acquisition of carbon from woody material (Hyodo et al., 2000; Martin and Martin, 1979). However, other endosymbionts in termites have been reported to support the fixation or recycling of nitrogen (Ohkuma et al., 1999; Potrikus and Breznak, 1980c).

Like termites, bark beetles live on an N-poor diet, and their endosymbiotic fauna indeed is similar to that found in termites (Adams et al., 2010; Bois et al., 1999). For example, the turpentine bark beetle (*Dendroctonus valens*) is associated with a diverse bacterial community. Interestingly, some well-characterized endosymbionts in these beetles are genera such as *Cellulomonas* and *Cellulosimicrobium*, which show cellulase activity in the beetle midgut (Morales-Jiménez et al., 2009). Furthermore, nitrogen fixation was found both

in larvae and adult beetles, although the first enterobacteria that were isolated from these beetles yielded negative results concerning N fixation *in vitro* (Morales-Jiménez et al., 2009). However, a diazotrophic bacterium [*Raoultella terrigena*] was isolated from *Dendroctonus rhizophagus* and *D. valens* recently and was found to be involved in N fixation and recycling (Morales-Jiménez et al., 2013). Even the aforementioned (Section 112.2) insects commonly consume solutions that are rich in carbohydrates but comparably poor in N, such as extrafloral nectar (Heil et al., 2005; Hölldobler and Wilson, 1990; Janzen, 1974), plant wound secretions, and insect honeydew (Delabie, 2001; Douglas, 2006). Consequently, several studies discovered bacteria in ants whose phylogenetic affiliation indicated their possible involvement in the supplementation of essential nutrients via N fixing and N recycling (Breznak et al., 1973; Eilmus and Heil, 2009; Feldhaar et al., 2007; Potrikus and Breznak, 1981).

112.5 NITROGEN FIXATION AND RECYCLING AS SUPPORT FOR INSECT NUTRITION

One main function of endosymbionts in host insects appears to be the upgrading of the N composition of their diet, although these bacteria also supplement unbalanced diets with essential amino acids and other vitally important compounds such as vitamins (Fan and Wernegreen, 2013). With the introduction of the acetylene reduction (AR) assay, researchers gained a sensitive, rapid, and economic method to estimate the N fixation by nitrogenase activity (Hardy et al., 1973; Stewart et al., 1967). The first class of insects for which this assay was employed was termites. Breznak et al. (1973) and Benemann (1973) applied the AR assay to intact termites and animals from which the guts had been removed and found that N fixation depended on the presence of the gut content. Consequently, they speculated that gut endosymbionts are involved in this process. Then, other wood-feeding insects were evaluated with similar results, for example, bark beetles (Bridges, 1981), cockroaches (Breznak et al., 1974), and soil beetles (Citernesi et al., 1977). Based on the positive results of these screenings, the researchers concluded that endosymbionts are involved in the nitrogen metabolism of the insect.

The development of further molecular tools – and in particular the detection of the nitrogenase gene *nifH* – allowed for more detailed studies (Kneip et al., 2007). For example, various endosymbionts that were isolated from *D. valens* (a bark beetle in pine) were found to fulfill different metabolic functions such as the detoxification of secondary plant compounds and the fixation of N (Morales-Jiménez et al., 2009; Morales-Jiménez et al., 2013). Similarly, certain ant species such as *Tetraponera* are loaded with bacteria that were identified as *Burkholderia*, *Flavobacteria*, and Rhizobiales, that is, in part with taxa known from root nodules of legumes and known to fix nitrogen (Lee et al., 2008), and also, the endosymbiont community of *Pseudomyrmex ferrugineus*, an obligate ant plant inhabiting *Acacia* myrmecophytes, contained multiple taxa that are known as N fixers (Eilmus and Heil, 2009).

The acquisition of nitrogen from food and the supplementation via the assimilation of atmospheric N could be a primary function of endosymbionts in the insects. However, insects lose, by excretion, *ca*. 55–80% of their nitrogen (Bursell, 1970) in the form of uric acid (Nation and Patton, 1961) or urea (Feldhaar et al., 2007) or of primary degradation products such as allantoin (Gaines et al., 2004), allantoic acid (Wadano and Miura, 1976), and ammonia (Scaraffia et al., 2005). Therefore, obtaining nitrogen from these wastes can provide a further rich source of this limited resource in insects (Sabree et al., 2009). Indeed, several insects are capable of storing nitrogen in various inorganic forms and have developed relationships with microbes that can make this N reaccessible to the insect host (Cochran, 1985; Morales-Jiménez et al., 2013; Weihrauch et al., 2012). In *Periplaneta americana*, an omnivorous cockroach, uric acid is stored in the fat body, which serves as metabolic reserve and can release the nitrogen when the insect is deprived of food protein (Cochran, 1985; Sabree et al., 2009). Interestingly, the fat body of this insect harbors *Blattabacterium* (López-Sánchez et al., 2009), which can recycle ammonia and urea although it is unable to assimilate uric acid, because it lacks genes encoding the uricases that are involved in uric acid catabolism (Sabree et al., 2009). In this case, the uricases may be expressed by the insect host or by other endobacteria, which can metabolize uric acid to form the ammonium that *Blattabacterium* then uses to synthesize amino acids (López-Sánchez et al., 2009; Sabree et al., 2009). Apart from cockroaches, *Blattabacterium* is found also in primitive termites such as *Mastotermes darwiniensis*, where it contributes a similar function to the insect host (Bandi et al., 1995). Termites are known to store uric acid in the fat body (Potrikus and Breznak, 1981), but they lack uricase activity and endosymbiont bacteria in their fat body (Potrikus and Breznak, 1980a). However, the uric acid can be transported to the insect gut where it is converted by uricolytic microorganisms (Sabree et al., 2009). For example, in termites such as *Reticulitermes* sp., uric acid is transported from the hemolymph to the hindgut, where *Bacteroides* and *Streptococcus* strains are responsible to convert uric acid to ammonia (Potrikus and Breznak, 1980a; Potrikus and Breznak, 1980b, 1980c; Potrikus and Breznak, 1981). The shield bug, *Parastrachia japonensis*, produces uric acid and other waste nitrogenous compounds such as allantoin, allantoic acid, and urea. Here, the microbial endosymbiont *Erwinia*, which was detected in the midgut, synthesizes uricolytic enzymes such as uricase, allantoinase, and allantoicase, which convert these waste products to

ammonium. Ammonium, in turn, serves as substrate for other bacteria that synthesize and finally excrete amino acids to the insect gut (Kashima et al., 2006). Also, other insects such as *D. valens* or *D. rhizophagus* beetles or the planthopper (*Nilaparvata lugens*) contain gut microbes involved in the conversion of uric acid to maintain the N requirements of the insects (Hongoh and Ishikawa, 1997; Morales-Jiménez et al., 2009; Morales-Jiménez et al., 2013), as it has also been described for *Camponotus* ants, which harbor intracellular *Blochmannia* strains. This endosymbiont contains a complete urease cluster and thus should be able to hydrolyze urea into CO_2 and ammonium, the latter of which then can serve as substrate to produce amino acids in the ant host (Feldhaar et al., 2007). Therefore, several *Camponotus* species are attracted to natural aqueous solution of urea (bird feces or human urine] (Feldhaar et al., 2007; Shetty, 1982). Finally, the endosymbionts in many social insects can upgrade the quality of the diet of their host by utilizing nonessential constituents and transforming them into compounds that are essential for the host (Cook and Davidson, 2006; Feldhaar et al., 2010).

112.6 THE IMPORTANCE OF N FIXATION BY INSECTS IN ECOSYSTEMS

Nitrogen is a limited compound in all ecosystems. Arthropods that harbor nitrogen-fixing endosymbionts might represent an as yet underestimated source of additional N (Nardi et al., 2002). Considering their great abundance and ecological importance, the ability of termites to fix atmospheric N might play a particularly important role in the fertilization of ecosystems with organic nitrogen (Ohkuma et al., 1999). Estimated mean rates of N fixation by an intact termite colony in rain forest are about 0.12 kg/ha/day (Breznak, 1984), which would amount to 43.8 kg/kg//ha/year. For insects such as beetles and millipedes, their N fixation was estimated to be around 0.02 kg/ha//year (Hackstein and Stumm, 1994). In summary, the fixation of N in the guts of arthropods was estimated to represent 10–40 kg/ha/year and, thus, might indeed represent a significant contribution to the N balance of certain ecosystems (Nardi et al., 2002). However, much more research will be required before this mechanism can be considered a quantitatively important source of N.

112.7 CONCLUSIONS

Nitrogen fixation is restricted to specific prokaryotes that contain nitrogenase, an enzyme complex that catalyzes the reduction of atmospheric N_2 to ammonia. However, multiple insects have established interactions with endosymbiotic prokaryotes. In these interactions, the insect host benefits from the metabolic capabilities of certain bacteria to fix N and obtains N-containing organic compounds from the endobacteria. In return, the bacteria obtain a specific and stable habitat for their protection, including reliable supply of the required nutrients for their reproduction. Besides the fixation of atmospheric N_2, the recycling of N represents a further mechanism by which endosymbiotic bacteria in arthropods contribute to the optimization of the N balance of their hosts. The insects release different N waste products that bacteria use as substrates for the biosynthesis of essential amino acids, which fulfill the nutritional requirements of the host. The fixation or recycling of N by endosymbionts of insects might represent an important and as yet underestimated source of organic N in many ecosystems. However, the successful fixation of N depends on multiple environmental factors and has seldom been quantitatively demonstrated *in vivo* for the prokaryotes that reside in insects. Determining the significance of N fixation by insect endosymbionts will require much more quantitative work that includes multiple taxa of insects and studies of them in their natural environment.

113.1 INTRODUCTION

The Leguminosae family includes more than 19,000 species of plants (Lewis et al., 2005), the majority of which may form nitrogen-fixing associations with diverse soil bacteria generically known as rhizobia (Masson-Boivin et al., 2009). Efficient reduction of atmospheric nitrogen (N_2) by the symbiotic forms of rhizobia known as bacteroids occurs mostly inside plant cells of specialized root or more rarely stem organs called nodules. Within each of these N_2-fixing nodules, rhizobia establish long-lasting intracellular colonies of up to thousands of bacteroids per infected plant cell (Batut et al., 2004). To direct free-living rhizobia to nodule cells, most legume crops form transcellular infection threads (IT) that initiate at the tip of receptive root hairs, cross several layers of the root epidermis and cortex, and ultimately reach the newly established nodule primordia (Gage, 2004). As a single bacterium entrapped in a curled root hair is sufficient to initiate IT formation, most N_2-fixing nodules harbor clonal-like bacteroid populations. Throughout the infection process, host plants and rhizobia exchange a number of molecular signals that coordinate IT development and nodule morphogenesis as well as prevent [or minimize] infection by pathogenic bacteria or ineffective strains (Gibson et al., 2008; Perret et al., 2000; Ryu et al., 2012). In spite of the apparent complexity of the infection processes that lead to functional N_2-fixing nodules and the selective screening for proficient bacteroids implemented by most legume hosts, rhizobia form a surprisingly heterogeneous collection of bacteria (Gyaneshwar et al., 2011; Masson-Boivin et al., 2009). Lateral transfer between unrelated soil bacteria of the genes required for nodulation and nitrogen fixation has been highlighted as one of the reasons for such diversity of microbial solutions to the legumes' need for symbiotically reduced forms of nitrogen (Rogel et al., 2011).

Developments in molecular techniques and a renewed interest in probing native legumes collected throughout the world for novel symbiotic strains have led to the identification of "unusual" rhizobia, such as members of the beta subdivision of proteobacteria (now known as ß-rhizobia) (Chen et al., 2001; see Chapters 17, 89) or bradyrhizobia that do not produce nodulation factors (Giraud et al., 2007; see Chapter 28). DNA–DNA hybridization techniques

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

and sequence analyses of 16S rRNA genes have been the predominant molecular tools for bacterial taxonomic studies. Both techniques show intrinsic limitations, however. DNA–DNA hybridization results have been reported to vary between laboratories and were labor-intensive to acquire (Rosselló-Mora, 2006), while 16S rRNA-based analyses (see Chapter 3) have been found to be inadequate for distinguishing closely related species/strains or describing the complex evolution of rhizobial genomes that are prone to genetic recombination and horizontal gene transfer (Broughton, 2003; Freiberg et al., 1997; Sullivan and Ronson, 1998; van Berkum et al., 2003). Multilocus sequence analysis (MLSA) of faster-evolving protein-encoding genes has thus been proposed as an alternative genotyping method that provides adequate delineation of species, including those within distantly related genera such as *Bradyrhizobium* or *Sinorhizobium* (Martens et al., 2008; Nzoué et al., 2009). Often used as markers in MLSA-based population studies (van Berkum et al., 2006, Aserse et al., 2011), the selection of *dnaK*, *glnA*, *gyrB*, *recA*, and/or *rpoB* as reference housekeeping genes (see Chapter 3) has been questioned recently following a comparative analysis of more than 20 complete rhizobial genomes (Tian et al., 2012; Zhang et al., 2012). Regardless of the genetic markers selected for MLSA studies or the molecular tools chosen for describing the unknown nodule isolates, all DNA-based methods of identification require the isolation and amplification of pure bacterial cultures *in vitro*, followed by preparations of genomic DNA samples for each of these strains.

In addition, the isolation of symbiotic strains from soil samples or plant nodules collected in fields can be a tedious process. Like other root surfaces, nodule epithelia are colonized by diverse rhizospheric bacteria, some of which can resist standard surface sterilization procedures (e.g., spore-forming microbes) or find protection against sterilizing agents within the nodule epidermis or cortex. Once plated on growth media, these contaminants often outgrow symbiotic strains, thus necessitating further time-consuming purification steps to enrich and ultimately cultivate isolated colonies of true rhizobia. As some bradyrhizobia have been reported to be particularly slow growers (Xu et al., 1995), weeks if not months can be required to obtain a definitive strain identification from the time nodules are harvested or soil samples collected. These labor-intensive isolation procedures combined with time-consuming identification protocols prompted us to assess the potential of mass spectrometry (MS) in typing nodule bacteria.

In many diagnostic laboratories, matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) MS has replaced the more costly and laborious DNA-based procedures for the identification of clinical isolates (Seng et al., 2009). In procedures involving intact cell MS, small samples taken from single colonies are deposited on a target plate and mixed with a crystalline matrix (e.g., sinapinic acid) that facilitates the ionization of cellular components. When exposed to a laser beam, the matrix-embedded cells are vaporized and the cellular components released and ionized. The resulting charged molecules are accelerated in an electric field and targeted toward a detector that measures their time of flight: lighter molecules flying faster than heavier ones. The vast majority of molecules documented in this way are single-charged cellular proteins that are recorded as peaks with distinct mass/charge (m/z) values. Together, these recorded peaks form complex spectra or fingerprints that have been shown to be specific to the groups of cells deposited on the target plates. For strain identification, each MALDI-TOF MS spectrum is ultimately matched against a database of reference spectra that has been established for bacteria, yeasts, or fungi grown in standardized conditions [for a review, see Bader (2013)]. Archived reference spectra [also called SuperSpectra^{TM} in the Spectral Archive and Microbial Identification System (SARAMIS^{TM}) database] include lists of selected m/z biomarkers that are family, genus, or species specific. Accurate identification of clinical or environmental isolates depends upon the robustness of the database and the choice of strains used to compute the reference spectra (Benagli et al., 2012). When compared against other molecular methods routinely used for the identification of pathogenic strains in the field of medical diagnostics, MALDI-TOF MS has been found to be faster, cost-effective, and less prone to false positives (Cherkaoui et al., 2010). In addition, a number of studies have shown that clustering analyses of MALDI-TOF MS spectra are often congruent with phylogenies based on 16S rRNA, *rpoB*, *gyrB*, and/or *nifH* genes (Benagli et al., 2012; Hahn et al., 2011).

113.2 FROM DNA- TO PROTEIN-BASED MOLECULAR SIGNATURES FOR RHIZOBIA

Initially, the possibility to reliably identify symbiotic rhizobia via MALDI-TOF MS was examined using 50 selected strains belonging to the *Ensifer* and *Rhizobium* genera (Ferreira et al., 2011). Although this study confirmed that fast-growing rhizobia cultivated on media plates could be correctly and reliably identified by MALDI-TOF MS, two important limitations remained: (i) the procedure still needed well-purified strains as starting materials, and (ii) commercially available databases of reference spectra were mostly designed for typing pathogenic bacteria and do not include type strains for all of the known rhizobia genera. Taking advantage of the natural amplification of endosymbiotic rhizobia that occurs inside plant nodules, we have shown that MALDI-TOF MS-based identification of bacteroids found inside crude nodule extracts is both accurate and sufficiently discriminative to distinguish strains belonging to the same

Sinorhizobium fredii species (Ziegler et al., 2012). Thus, MALDI-TOF MS-based identification of nodule bacteria effectively bypasses the time-consuming and labor-intensive steps of purifying nodule isolates followed by preparations of genomic DNA. Incremental results on these premises are discussed in the following sections.

113.3 METHODS

113.3.1 Microbiological Techniques

The identity of all strains of rhizobia used in this work was confirmed by 16S rDNA sequencing. Unless specified otherwise, bacterial cells were grown for several days at 28°C in/on TY or YM media, using antibiotics at final concentrations of 50 µg ml^{-1}.

113.3.2 Preparation of Bacterial Samples for MALDI-TOF MS Analyses

To isolate bacteroids, nodules (either fresh or frozen) were crushed into 400 µl of sterile ddH_2O, and the resulting homogenates free of nodule debris were centrifuged at 20,000 *g* to collect bacteroids. To remove plant leghemoglobins, bacterial pellets were washed three times with 200 µl of sterile ddH_2O prior to spotting MALDI steel target plates. Free-living rhizobia were spotted directly from media plates. Each bacterial spot was then overlaid with 1 µl of matrix consisting of a saturated solution of alpha-cyano-4-hydroxycinnamic acid (Sigma-Aldrich, Buchs, Switzerland) in 33% acetonitrile (Sigma-Aldrich) and 33% ethanol, supplemented with 3% trifluoroacetic acid, and air-dried for a few minutes at room temperature.

113.3.3 MALDI-TOF MS Fingerprinting

Rhizobial identification was carried out on a MALDI-TOF MS Axima™ Confidence machine [Shimadzu-Biotech Corp., Kyoto, Japan], with a detection in the linear positive mode at a laser frequency of 50 Hz and a mass range from 3,000 to 20,000 Da. Acceleration voltage was 20 kV, and the extraction delay time was 200 ns. A minimum of 10 laser shots per sample was used to generate each ion spectrum. For each sample, a total of 50 protein mass fingerprint profiles were averaged and processed using the Launchpad™ 2.8 software [Shimadzu-Biotech Corp., Kyoto, Japan]. Raw spectra were processed with Launchpad™ 2.8 using as settings the advanced scenario from the Parent Peak Cleanup menu, a peak width of 80 chans, a smoothing filter width set at 50 chans, a baseline filter width of 500 chans, and a threshold apex method set to dynamic. The threshold offset was set at 0.020 mV, with a threshold response factor of 1.2. Each target plate was first externally calibrated using spectra of the reference strain *Escherichia coli* DH5a.

113.3.4 Cluster Analyses

MALDI-TOF MS spectra were analyzed with SARAMIS™ [AnagnosTec, Potsdam-Golm, Germany]. For cluster analysis of protein mass fingerprints, binary matrixes were generated using the SARAMIS™ SuperSpectra tool and exported as text files. Datasets were imported into the PAST software [Natural History Museum, University of Oslo, Norway], and multivariate cluster analysis was performed using the Simpson algorithm in order to calculate distance matrixes. For the generation of dendrogram illustrations, distance matrixes formatted as nexus files were imported and processed using FigTree v1.3.1 software (http://tree.bio.ed.ac.uk/software/figtree/).

113.4 RESULTS AND DISCUSSION

One of the initial questions in using MALDI-TOF MS as a tool for typing rhizobia was whether spectra of free-living and endosymbiotic bacteria differed so much as to prevent their accurate identification. The answer was difficult to predict since metabolism and in some instances DNA content of bacteroids and free-living rhizobia differ considerably.

113.4.1 Typing Bacteroids versus Free-Living Rhizobia

Although nodules vary greatly in size and shape within the Leguminosae, most crops form root nitrogen-fixing nodules of either determinate or indeterminate types (Masson-Boivin et al., 2009; Sprent and James, 2007). Determinate nodules lack a persistent meristem, are spherical in shape, and contain mostly homogeneous populations of rhizobia found in developmentally synchronized infected plant cells. After a few weeks of symbiotic activity, these determinate nodules senesce and are replaced by new nodules formed elsewhere on younger root sections. In contrast, a nodule of indeterminate type has a longer lifespan, mostly because a persistent apical meristem provides a continuous source of new plant cells that become infected by bacteria. Once mature, indeterminate nodules are elongated and characterized by a gradient of developmental stages in which senescent plant and bacterial cells are replaced by those that divide in the apical meristem.

Regardless of the nodule type, nitrogen-fixing bacteroids and their free-living counterparts differ significantly. Mature (i.e., N_2-fixing) bacteroids are nondividing entities which metabolism is focused on securing the activity of

the nitrogenase enzyme and the transport of the resulting ammonium to the host (for reviews, see Prell et al. 2009 and White et al. 2007). In exchange for reduced forms of nitrogen, plants feed bacteroids with dicarboxylic acids as carbon source and, at least in a number of symbiotic systems, with branched-chain amino acids such as isoleucine, leucine, and valine for which bacteroids have become symbiotic auxotrophs (Prell et al., 2010). In several indeterminate nodule-forming legumes of the galegoid clade such as *Medicago* or *Vicia*, differentiation into N_2-fixing bacteroids has been shown to be irreversible and to result in the formation of enlarged endosymbiotic bacteria with endoreduplicated genomes (Mergaert et al., 2006). Terminal bacteroid differentiation is not necessarily a characteristic of indeterminate nodules however, as most bacteria isolated from nodules of *Mimosa pudica* have been shown to be capable of resuming free-living growth (Marchetti et al., 2011). In contrast to nondividing bacteroids, rhizobia that colonize the rhizoplane of host plants divide actively using as nutrients the abundant and chemically diverse root exudates. These free-living rhizobia are generally prototrophs for all amino acids, and their metabolism is not constrained to dicarboxylates as sole carbon source. In spite of these significant differences in lifestyles, the MALDI-TOF MS spectra of endosymbiotic and free-living forms of rhizobia were sufficiently similar to obtain an accurate identification (Ziegler et al., 2012).

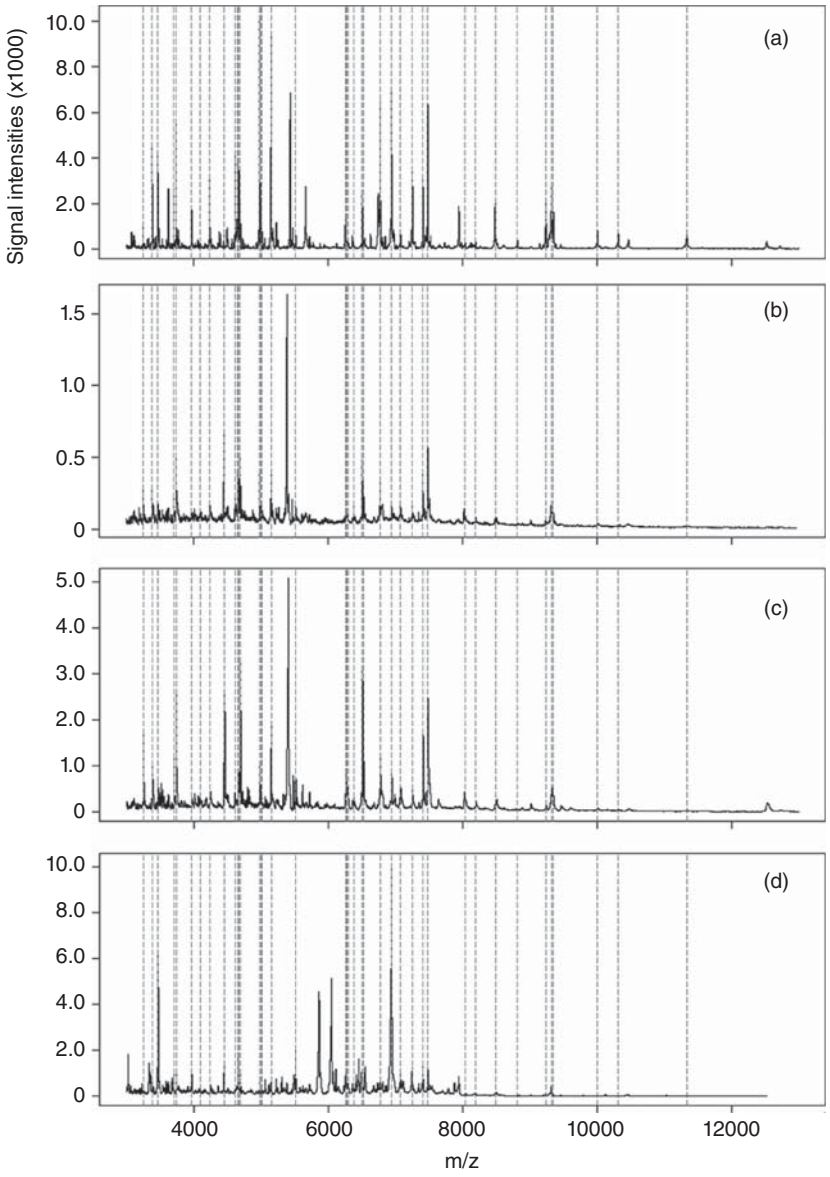

Figure 113.1 *Representative MALDI-TOF mass spectra of free-living or endosymbiotic cells* S. fredii *strain NGR234*. Recorded masses ranged from m/z 3000 to m/z 13,000, with the positions of biomarkers selected for computing the superspectrum of NGR234 shown as dashed lines. Cells of NGR234 were isolated from (a) a colony grown for 2 days on a TY plate at 28°C or nodules of (b) *V. unguiculata*, (c) *M. atropurpureum*, or *L. leucocephala* (d) collected, respectively, 42, 49, and 56 days postinoculation.

113.4.2 Identification of Bacteroids Isolated from Distinct Nodule Types

Initial results obtained with strains *S. fredii* NGR234, *S. fredii* USDA257, and *Bradyrhizobium japonicum* G49 indicated that MALDI-TOF MS-based identification of bacteroids was not compromised by the bacteroid-specific synthesis of the nitrogenase and accessory proteins that occurred inside *Vigna unguiculata*, *Macroptilium atropurpureum*, or *Glycine max* nodules of the determinate type (Ziegler et al., 2012). To test whether MALDI-TOF MS could reliably identify bacteroids found inside indeterminate nodules, plants of *Leucaena leucocephala* [Lam.] de Wit were inoculated with NGR234 and nodules collected 56 days postinoculation [dpi]. *L. leucocephala* is a small tropical tree native of Mexico that is cultivated for production of firewood and fibers as well as for its beneficial properties as green manure (Brewbaker, 1989). Analysis of the morphological and physiological characteristics of NGR234 cells isolated from nitrogen-fixing nodules of *L. leucocephala* using Percoll gradients showed that bacteroids [i] were of size and shape similar to free-living cells of NGR234, [ii] were actively respiring, [iii] had membranes that were permeable to propidium iodide [PI], and [iv] were in the vast majority [ca. 98%] incapable of resuming free-living growth (Bakkou, 2011). As shown in Figure 113.1, spectra generated from cells of NGR234 that were isolated from nodules of *V. unguiculata* (Fig. 113.1b), *M. atropurpureum* (Fig. 113.1c), or *L. leucocephala* (Fig.113.1d) shared a sufficient number of reference biomarkers (dotted lines in Fig. 113.1) for reaching a correct identification of bacteroids in the automatic mode. Thus, typing of NGR234 bacteroids was reliable independently of the host plant or nodule type. Unlike bacteroids of *Rhizobium leguminosarum* bv. *viciae* and *Sinorhizobium meliloti* which DNA contents

Table 113.1 The main characteristics of the rhizobial strains used in this study

Strain	Properties	Reference
1021	Str^R derivative of *Sinorhizobium meliloti* strain 2011	(Meade *et al.*, 1982)
3841	Str^R derivative of *Rhizobium leguminosarum* bv. *viciae* strain 300	(Johnston & Beringer, 1975)
AK83	*S. meliloti* strain isolated from *Medicago falcata* in Kazakhstan	(Giuntini *et al.*, 2005)
ANU265	Derivative strain of *Sinorhizobium fredii* NGR234 cured of pNGR234a	(Morrison et al., 1983)
BL225C	*S. meliloti* strain isolated from *Medicago sativa* in Italy	(Giuntini *et al.*, 2005)
BtAi1	Photosynthetic *Bradyrhizobium* strain isolated from a stem nodule of *Aeschynomene indica*	(Eaglesham & Szalay, 1983)
C58	*Agrobacterium tumefaciens* strain isolated in 1958 from a cherry tree tumor in New York State, USA	(Slater *et al.*, 2013)
CFN42	*Rhizobium etli* strain that forms N_2-fixing symbioses *Phaseolus vulgaris* isolated in Mexico	(Quinto *et al.*, 1982)
CIAT652	*R. etli* strain isolated in Costa Rica	(González *et al.*, 2010)
HH103	*S. fredii* strain that forms N_2-fixing symbioses with soybean and was isolated in China	(Dowdle & Bohlool, 1985)
LMG19424	*Cupriavidus taiwanensis* strain isolated from a nodule of *Mimosa pudica* in Taiwan	(Chen et al., 2001)
MAFF303099	*Mesorhizobium loti* strain isolated from *Lotus japonicus* in Japan	(Saeki & Kouchi, 2000)
ORS278	Strain of *Bradyrhizobium* sp. found in a stem nodule of *Aeschynomene sensitiva* in Senegal	(Lorquin *et al.*, 1997)
ORS571	*Azorhizobium caulinodans* strain from a stem nodule of *Sesbania rostrata* in West Africa	(Dreyfus & Dommergues, 1981)
ORS2060	*Methylobacterium nodulans* strain isolated from a nodule of *Crotalaria podocarpa* in Senegal	(Samba *et al.*, 1999)
NGR234	Rif^R derivative of the promiscuous *S. fredii* strain initially isolated from *Lablab* by M. J. Trinick	(Stanley *et al.*, 1988)
S4	*Agrobacterium vitis* strain isolated in 1981 by E. Szegedi from *Vitis vinifera* in Hungary	(Slater *et al.*, 2009)
USDA110	*Bradyrhizobium japonicum* strain isolated in 1959 from a nodule of soybean grown in Florida, USA	(Mathis *et al.*, 1997)
WSM419	Acid-tolerant strain of *S. meliloti*	(Howieson & Ewing, 1986)
WSM1325	*Rhizobium leguminosarum* bv. *trifolii* strain isolated from clover roots in Serifos, Greece	(Howieson *et al.*, 2005)
WSM2304	*R. leguminosarum* bv. *trifolii* strain from a nodule of *Trifolium polymorphum* in Uruguay	(Howieson *et al.*, 2005)

reached 18C and 24C, respectively (Mergaert et al., 2006), NGR234 bacteroids found inside *L. leucocephala* were 2C (Bakkou, 2011). This finding suggested that although a terminal differentiation process occurred inside nodules of *L. leucocephala*, it did not involve endoreduplication. Whether the endoreduplication process experienced by rhizobia inside *Medicago*, *Pisum*, or *Vicia* plants (Mergaert et al., 2006) affects the quality of MALDI-TOF MS spectra and the subsequent identification of bacteroids remains to be examined.

113.4.3 Toward a Rhizobia-Specific SARAMIS Database

The ability to correctly identify a bacterial strain via MALDI-TOF MS is influenced by a number of factors including the quality of the sample analyzed, the number of entries in the reference database, and the choice of biomarkers that together constitute the reference spectra (e.g., the so-called superspectra in the SARAMIS database) (Table 113.2). As discussed previously, current databases have been primarily designed and built for typing pathogenic bacteria (Martiny et al., 2012). With the aim to develop a database susceptible to facilitate the identification of rhizobia found inside plant nodules, we have begun to collect a number of well-characterized strains, selected to represent each of the genera of α- and β-proteobacteria that include symbiotic bacteria (Masson-Boivin et al., 2009). Figure 113.2 shows a cluster analysis of fingerprint spectra from 20 plant-interacting bacterial strains of the *Agrobacterium*, *Azorhizobium*, *Bradyrhizobium*, *Cupriavidus*, *Mesorhizobium*, *Methylobacterium*, *Rhizobium,* and *Sinorhizobium* genera. Although the structure of the resulting tree is not necessarily concordant with that of a phylogenetic tree based on 16S rDNA sequences, strains that belonged to the same species (e.g., S. *fredii* strains HH103 and NGR234 or the *S. meliloti* strains AK83, BL225C, and 1021) clustered together. This suggests that even though a fully exhaustive rhizobial database is unlikely to be assembled in the near future, unknown strains isolated from nodules are likely to be correctly typed provided spectra from a few members of the corresponding species are included in the reference MALDI-TOF MS database. In this respect, strains from the GEBA-RNB project are in the process of being integrated into the SARAMIS database. While the Genomic Encyclopedia of Bacteria and Archaea

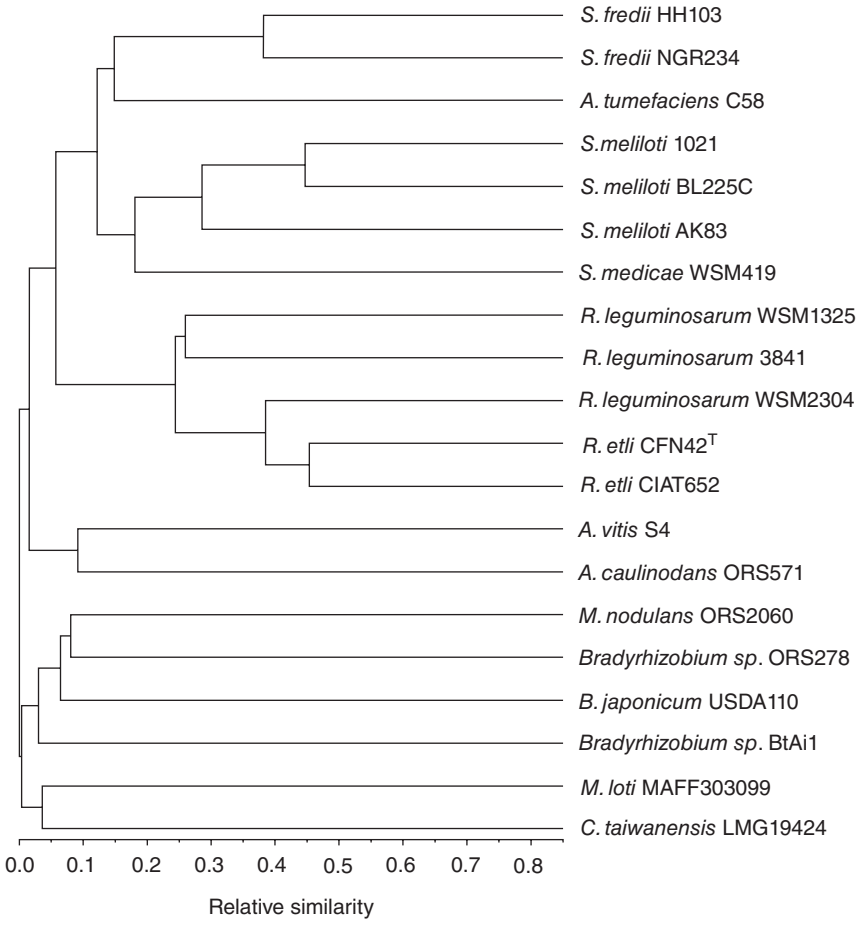

Figure 113.2 *Unsupervised hierarchical cluster analysis of spectra from 20 reference plant-interacting bacterial strains*. Spectra for each individual strain were obtained as described in the methods section, using free-living cells grown on TYA or YMA for one to five days at 28°C. Fingerprint spectra were subsequently assembled from this dataset and analyzed for similarity. Characteristics and origins of the listed strains are summarized in Table 113.1.

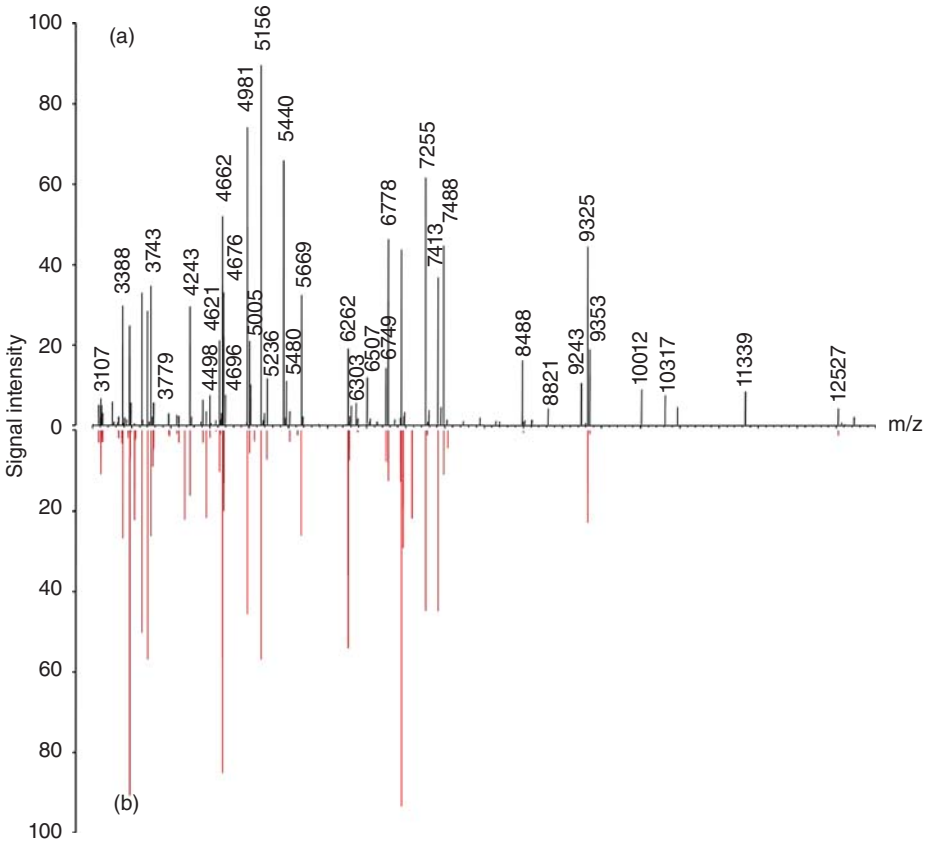

Figure 113.3 *Comparing the MALDI-TOF MS spectra of* S. fredii *strains NGR234 and ANU265*. Mirror display of representative spectra of two-day-old cells of NGR234 (a) or ANU265 (b) grown on TYA at 28°C. Recurrent masses in the range of 3000–13000 m/z that were selected as discriminative biomarkers for NGR234 were labeled according to their respective m/z. In the automatic mode, the matching spectra of ANU265 (one of which is shown in red) was identified as that of NGR234.

(GEBA) aims at sequencing many bacterial and archaeal genomes from diverse branches of the tree of life (see http://genome.jgi.doe.gov/programs/bacteria-archaea/GEBA.jsf), the root-nodulating bacteria (RNB) initiative that is coordinated by Wayne Reeve from Murdoch University has assembled more than 100 rhizobia from 15 different countries. That the genomes of these selected rhizobia will be completed soon is bound to facilitate the *in silico* analysis and validation of the MALDI-TOF MS reference spectra generated for each of these strains.

113.4.4 MALDI-TOF MS-Based Typing of Bacteroids: Strengths, Limitations, and Future Prospects

Together, these results confirm that identification of nodule bacteria via MALDI-TOF MS is rapid and accurate and successfully bypasses the time-consuming steps of isolating pure cultures and genomic DNA of rhizobia. In addition, resolution of MALDI-TOF MS is sufficient to reliably distinguish between the *S. fredii* strains NGR234, USDA257, and HH103, the genomes of which have been shown to be

remarkably similar (Schuldes et al., 2012, Weidner et al., 2012). Although a MALDI-TOF MS-based signature of a strain consists of a specific combination of more than 25 m/z biomarkers, it is unlikely to fully characterize the complexity of the 5,000 to 9,000 protein-coding genes of an average rhizobial genome. For example, we were not able to discriminate between *S. fredii* strains ANU265 and NGR234 using MALDI-TOF MS in the automatic mode (see Fig. 113.3). Derivative strain ANU265 was obtained by heat curing the 536 kb symbiotic plasmid pNGR234a (Morrison et al., 1983), thus deleting the NGR234 genome of ca. 8% of its coding capacity. ANU265 is incapable of nodulating host plants (Morrison et al., 1983) because it lacks the nodulation genes encoded by pNGR234a (Freiberg et al., 1997). RNA-Seq analyses confirmed that in cells of NGR234 grown in *Rhizobium* minimal medium supplemented with succinate (RMS), less than 10 of the >400 annotated genes of pNGR234a were transcribed (for more details, see Chapter 65 by A. Huyghe N. Bakkou and X. Perret). As none of these RMS-expressed genes of pNGR234a coded for proteins of 3 to 13 kDa, MALDI-TOF MS spectra of NGR234 did not include pNGR234a-specific biomarkers, and cells of ANU265 and NGR234 were not recognized as having distinct genomes. Most DNA-based genotyping protocols such as MLSA would not discriminate between NGR234 and ANU265 either, since the commonly used marker genes (e.g., *dnaK*, *glnA*, *gyrB*, *recA,* and/or *rpoB*) are chromosome born in both of the strains and of many other rhizobia.

Current protocols for preparing bacteroids for MALDI-TOF MS analysis include centrifugation and washing steps for removing leghemoglobins (Ziegler et al., 2012). Symbiotic leghemoglobins are small proteins of 12–16 kDa (see Table 113.2) that constitute up to 30% of the total content of soluble proteins in N_2-fixing nodules (Baulcombe and Verma, 1978). Together with a cortical oxygen diffusion barrier that surrounds the infected tissue of a functional nodule, leghemoglobins help regulate the oxygen tension within infected plant cells, and their synthesis is essential for an effective nitrogen fixation (Ott et al., 2009, 2005). Because of their abundance inside nodules and predominant protonation during sample ionization, symbiotic leghemoglobins mask other biomarkers in MALDI-TOF MS spectra unless removed from bacteroid preparations. Leghemoglobins should not be necessarily considered as undesirable contaminants, however. Instead, these abundant nodule proteins can be used as another set of biomarkers in MALDI-TOF MS analyses of nodules in order to confirm the identity of the legume host. In field studies, the roots of selected host plants generally need to be carefully exposed and cleared of soil before nodules that are still attached to these roots can be collected. This practice that reduces the chances of collecting nodules from a neighboring host makes current field studies slow, labor-intensive, and often difficult to conduct on a large scale. By combining the successive MALDI-TOF MS signatures of leghemoglobins and bacteroids, a binary nodule-typing method would make large-scale field studies of detached nodules both faster and easier to conduct. Together with an improved and robust rhizobial-specific SARAMIS^{TM} database, such a protocol of identification for both plant and microbial symbionts should improve our understanding of rhizobia–legume interactions and evolutions in ecological niches as diverse as inoculated soybean fields, natural prairies, or rain forests.

ACKNOWLEDGMENTS

We are grateful to Julie Ardley, Susana Brom, Sofie Goormachtig, Eric Giraud, Alessio Mengoni, Philip Poole, José Enrique Ruiz-Sainz, and Maged Saad for providing many of the rhizobial strains used in this work. Financial support for this project was provided by the University of Geneva, the University of Applied Sciences and Arts of Southern Switzerland, Mabritec AG, and the Swiss National Science Foundation (grant n°31003A-116591).

Chapter 114

The Microbe-Free Plant: Fact or Artifact

Martin Heil
Departamento de Ingeniería Genética, Centro de Investigación y de Estudios Avanzados [CINVESTAV], Irapuato, Guanajuato, México

114.1 INTRODUCTION

114.1.1 Endophytes: A Hidden Diversity

Two of the most well-known and most intensively studied plant–microbe interactions are the mutualistic associations that are formed by plant roots with mycorrhizal fungi and rhizobia. Besides these nutritional mutualisms, however, most plant–microbe interactions are considered detrimental for the host. Roots, shoots, leaves, flowers, and fruits of all plants are regularly infected by bacteria, fungi, and viruses, which act as pathogens and cause disease when not successfully controlled by the host resistance system. Plant pathogens can considerably decrease the fitness of their host or, when it comes to crops, yield. Although pathogens can increase plant diversity in natural ecosystems due to their "Janzen–Connell" effects (Janzen, 1970; Connell, 1971; Garcia Guzmán and Heil, 2014), we perceive them usually like an agronomist or medical doctor: microbial infection in a plant is considered as undesirable.

However, like we just begin to realize the ubiquity and beneficial role of the human microbiome (e.g., intestinal bacteria), research over the last decade has discovered that plants are full of fungi, bacteria, and viruses even when they look phenotypically healthy, that is, express no symptoms of disease (Wilson, 1995; Arnold et al., 2000; Yuan et al., 2010; Partida-Martinez and Heil, 2011; Porras-Alfaro and Bayman, 2011). The so-called endophytic fungi have been isolated from all plant organs and are usually found in 80–100% of the investigated samples. Multiple taxa can commonly be isolated from a single host species or even a single leaf. For example, fungal species representing 18 taxonomic orders were reported from symptomless and surface-sterilized switchgrass (*Panicum virgatum* L.) (Ghimire et al., 2011), 100 morphologically distinct groups in 33 taxa of endophytic fungi were discovered in leaves of European aspen (*Populus tremula*) (Albrectsen et al., 2010), 60 taxa were reported from leaves and twigs of *Quercus ilex* (Fisher et al., 1994), 58 operational taxonomic units (OTUs) were isolated from leaves of wild rubber trees (*Hevea brasiliensis*) in Peru (Gazis and Chaverri, 2010), more than 100 morphospecies of endophytes were found to be associated with tropical palms (Frohlich et al., 2000), and 418 fungal morphospecies could be isolated from 83 leaves from different tropical tree species (Arnold et al., 2000). Whereas most studies on fungal endophytes focused on broad-leaved plants from tropical and temperate systems, many other types and growth forms and habitats remain to be screened. Recent studies reported, for example, 64 species of fungal endophytes from marine algae (Flewelling et al., 2013) and 59 taxa from the cactus *Cereus jamacaru* (Bezerra et al., 2013).

Besides fungi, bacteria represent the second largest group of plant endophytes. Bacterial endophytes seemingly are at least as diverse and widespread as fungal endophytes. Traditionally, symbiotic bacteria are mainly investigated in the context of the rhizosphere, and thus, most reports focus on soil-derived bacteria (Pieterse et al., 2001; Pineda et al., 2010; 2013; de Bruijn, 2013). Many of these bacteria colonize the root tissue and then live as endophytes. For example, 256 strains of root-colonizing bacteria were found

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

in surface-disinfected root tissues of six plant species in Korea (Bibi et al., 2012). However, endophytic bacteria are not restricted to the root but rather infect all parts of a plant and can be found in all types of plants. For example, 283 endophytic bacterial isolates were obtained by culture-based methods from *Sphagnum fallax* (Shcherbakov et al., 2013), most of which were identified as *Burkholderia*, *Pseudomonas*, *Flavobacterium*, *Serratia*, and *Collimonas* (Shcherbakov *et al.*, 2013). A nonculture-based approach (pyrosequencing of 16S rRNA gene amplicons) detected >850 bacterial OTUs in leaves of spinach (*Spinacia oleracea*) (Lopez-Velasco et al., 2013). Because the seeds in this study contained "only" *ca.* 250 different OTUs from the Proteobacteria, Firmicutes, and Actinobacteria, the authors conclude that horizontal acquisition plays an important part in the assembly of this rich bacterial community. Like endophytic fungi, endophytic bacteria seemingly have been detected in all plants that have been screened for them, including desert plants such as *Plectranthus tenuiflorus* [28 bacterial endophytic isolates from different organs comprised *Bacillus*, *Micrococcus*, *Paenibacillus*, *Pseudomonas*, and *Acinetobacter*; see El-Deeb et al., 2013], the arctic moss (*Sanionia uncinata*) (Park et al., 2013), and the arctic higher plants *Oxyria digyna*, *Diapensia lapponica*, and *Juncus trifidus* (Nissinen et al., 2012). Finally, bacteria can also inhabit the hyphae of fungal endophytes and then live as "endo-endophytes" (Hoffman and Arnold, 2010).

Species saturation curves demonstrate that all these studies were unlikely to discover all endophytes present in the investigated host plants (Arnold et al., 2000; Frohlich et al., 2000; Higgins et al., 2011). Even new investigations of standard model plants such as *Arabidopsis* and maize reveal an as-yet-unknown diversity of endophytes (Liu et al., 2012; Bodenhausen et al., 2013). Thus, we must assume that we significantly underestimate the diversity of endophytes and, hence, their potential importance in natural ecosystems. Many more datasets will be required to obtain insights into the general association patterns among endophytes and their host plants and to formulate testable hypotheses concerning the underlying mechanisms of colonization.

114.1.2 Defining "Endophytes"

Endophytes have been defined by Wilson (1995) as "fungi that are present in host plant tissues, during at least part of their life cycle, without causing visible symptoms." Unfortunately, recent evidence has revealed some major drawbacks of this definition. First, microorganisms that develop within living plant tissue without causing visible symptoms are not restricted to fungi but also comprise bacteria and viruses. Second, the net effects of infection on the host are highly conditional and can shift from mutualism to antagonism for virtually any type of plant–microbe interaction (see discussion and references in Partida-Martinez and Heil, 2011). Multiple strains of classical endophytes have been reported to shift at an ecological or evolutionary timescale from endophytic to pathogenic behavior and then usually act as necrotrophs (Delaye et al., 2013). Thus, the term "endophyte" does not necessarily describe a fixed life history trait but refers to a specific microorganism in a specific host under a specific set of environmental conditions.

In this chapter, I use the term **symptomless endophyte** to denominate all microorganisms that develop within living plant tissue and cause no disease. This definition is highly conditional. Furthermore, **symptoms** in this context refer explicitly to **symptoms of disease**. Although symptomless endophytes cause no disease symptoms, they influence the phenotype and epigenome of their host plant (Gilbert et al., 2010). In fact, significant parts of the plant phenotype can represent the **extended phenotype** sensu Dawkins (1999) of one or several microorganisms (Porras-Alfaro and Bayman, 2011). For example, even the production of essential oils in medicinal plants can depend on the colonization by specific endophytes (Ren and Dai, 2012), and Taxol, a **classical** defensive metabolite of Pacific yew (*Taxus brevifolia*), is synthesized by an endophytic fungus rather than by the host plant itself (Stierle et al., 1993). An endophyte-free plant looks and functions differently from an endophyte-infected one under most natural growing conditions (Figure 114.1). It is their omnipresence rather than the lack of visible effects which led earlier researchers to the conclusion that

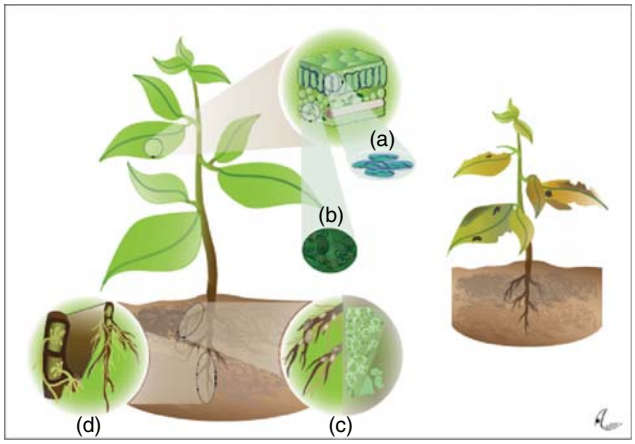

Figure 114.1 *Phenotypic effects of "symptomless" endophytes.* Endophytes such as fungal leaf endophytes (a), bacterial leaf endophytes (b), rhizobia (c), and arbuscular mycorrhizal fungi (d) can colonize all organs of a plant. Due to the ubiquity of these endophytes, the phenotype that we usually know as the normal phenotype of the plant (left panel) represents in fact the phenotype of the halobiont. Endophytes affect so many vitally important traits of their host that a completely endophyte-free plant would suffer from chlorosis and lowered photosynthetic rates due to nutritional shortcomings, lowered resistance to abiotic stress and lowered resistance to both pathogens and herbivores, and, in consequence, lowered competitive abilities and lower survival rates in nature (right panel). Figure from Partida-Martinez and Heil (2011).

endophytes do not cause visible symptoms (Wilson, 1995). The extended phenotype of the endophytes is easily overseen because it represents an integrative, ubiquitous part of the plant phenotype that we usually see (Partida-Martinez and Heil, 2011). Here, I summarize the most commonly reported effects that endophytes have on the resistance in their host plants to biotic stress. Considering their frequently positive effects on the resistance level of their host, I then will discuss the potential of phenotypes in agriculture.

114.1.3 Classes of Endophytes

The first fungal endophytes were discovered in certain cultivars of tall fescue (*Lolium arundinaceum*) and of related grasses (mainly of the genera *Festuca* and *Lolium*) that cause livestock disorders. In these grasses, asexual, alkaloid-producing fungi of the genus *Neotyphodium* could be identified as the causal agent of their negative effects on mammal and insect herbivores (see Clay, 1990, and references cited therein). These "type I fungal endophytes" sensu Yuan et al. (2010) are a taxonomically well-defined group in the family Clavicipitaceae that are vertically transmitted via the seeds of their hosts and therefore cause systemic infection of certain grasses. They directly contribute to the resistance of their host plants to herbivores, but numerous studies have also reported effects on drought and flooding tolerance, biomass production, and – in consequence – the competitive ability of the host grass (see Lehtonen et al., 2005; Schulz and Boyle, 2005, for references).

Less studied but perhaps much more diverse and ubiquitous are the so-called type II fungal endophytes (Yuan et al., 2010). These fungi normally are nonsystemic, horizontally transmitted species that colonize de novo every single leaf. Numerous studies reported surprisingly high numbers of taxa and infection rates by these **nonclavicipitaceous** fungal endophytes. Type II fungal endophytes comprise species from both Ascomycota and Basidiomycota, although Ascomycota are usually dominating (Fisher, 1992; Frohlich et al., 2000; Arnold and Herre, 2003; Albrectsen et al., 2010).

Bacterial endophytes represent a taxonomically and functionally highly diverse group that infects roots and shoots (Weyens et al., 2009). Together with rhizosphere bacteria, these bacteria form the large functional group of "plant growth-promoting bacteria (PGPB)" (see de Bruijn, 2013), although evidence is accumulating that they might contribute to the resistance of their host as commonly as do fungal endophytes.

114.2 PHENOTYPIC EFFECTS OF ENDOPHYTES

114.2.1 Growth Promotion

A very rich literature has described the positive effects on plant growth of PGPB (Pieterse et al., 2001; Zehnder et al., 2001a, 2001b; Brock et al., 2013; de Bruijn, 2013). Having been isolated originally from the rhizosphere, many of these bacteria also colonize the root tissue and then must be considered as endophytes, just as it is true for rhizobia and most mycorrhizal fungi (arbuscular mycorrhiza and endomycorrhiza). Whereas plant–microbe interactions are, thus, most commonly studied belowground, many diazotrophic endophytic bacteria such as *Acetobacter*, *Azospirillum*, *Azoarcus*, *Herbaspirillum*, *Klebsiella*, *Nostoc*, and *Pantoea* can colonize the aerial parts of a plant (leaves and shoots) and are commonly reported to fix nitrogen (Dobereiner, 1992; James and Olivares, 1998; Remus et al., 2000; Krause et al., 2006; Schreiner et al., 2009; Yasuda et al., 2009; Brock et al., 2013; Santi et al., 2013). In fact, N-fixation by endophytic plants "outside the legumes" appears to be a severely underestimated process that readily contributes to the N-supply of natural and agronomic ecosystems (Santi et al., 2013). Endophytic bacteria that colonize root tissues secrete compounds that enhance nutrient uptake by phosphate solubilization or act as siderophores and thus enhance iron chelation. In fact, a single endophyte strain can exert multiple functions. For example, the PGPB *Pseudomonas stutzeri* RP1, which colonized roots of sunflower (*Helianthus annuus*), showed antibacterial activity against *E. coli*, *Xanthomonas* sp., *Serratia* sp., *Bacillus* sp., and *Pseudomonas* sp. and also had growth-promoting attributes such as phosphate solubilization and the production of indole acetic acid and NH_3 and antiherbivore defensive potential via the production of HCN (Pandey et al., 2013). The growth-promoting effects of endophytes can also reduce any negative effects on fitness that might result from damage caused by pathogens or herbivores. In this case, endophytes cause **tolerance** to biotic stressors. For example, clavicipitaceous endophytes might reduce the negative effects of viral infection via changing biomass allocation to roots (Rúa et al., 2013).

114.2.2 Resistance to Infection

An increased resistance to pathogens appears to be a common consequence of plant infection or association with PGPB (Pieterse et al., 2001; Pieterse and Dicke, 2007) but is also reported for plants that are infected with rhizobia or mycorrhiza (Borowicz, 2001; Pozo and Azcón-Aguilar, 2007; Hartley and Gange, 2009; Pineda et al., 2010). Root-colonizing PGPB commonly mediates the plant's own resistance traits (i.e., systemic signaling; see Pieterse et al., 2001), but also the colonization of the aerial parts of a plant by endophytes can enhance the resistance in leaves to pathogens. The first report on pathogen resistance mediated by type II endophytes appears to be the observation that inoculation of leaves of cacao (*Theobroma cacao*) seedlings with fungal endophytes, which had been isolated from naturally colonized asymptomatic hosts, significantly decreased

Table 114.1 Effects of type II endophytes on the resistance in their host plant to biotic stress*

Endophyte Group	Stress Type	Endophyte	Host	Effect	Type of Pathogen	Reference
Fungi	*Pathogens*	*Stachybotrys* sp., *Trichoderma atroviride*, *Ulocladium atrum,* or *Truncatella angustata*	*Populus* sp.	Local resistance to rust caused by *Melampsora x columbiana*	Basidiomycota [biotroph]	(Raghavendra and Newcombe, 2013)
		Fusarium verticillioides	*Zea mays*	Resistance to corn smut disease when endophyte is coinoculated with *Ustilago maydis*	Basidiomycota [biotroph]	(Lee et al., 2009)
		Trichoderma stromaticum	*Theobroma cacao*	Resistance in seedlings to the witches' broom pathogen [*Moniliophthora perniciosa*]	Basidiomycota [hemibiotroph]	(De Souza et al., 2008)
		Mixture of seven endophyte strains	*T. cacao*	Reduced symptoms caused by *Phytophthora* sp.	Oomycota [necrotroph]	(Arnold et al., 2003)
	Herbivores	*Glomerella cingulata*	*Merremia umbellata*	Reduced reproduction by adult *Chelymorpha alternans* beetles, which as larvae had fed on leaves with high endophyte load	Coleoptera	(Van Bael et al., 2009)
		Acremonium strictum	*Vicia faba*	Impaired fitness of *Helicoverpa armigera*	Lepidoptera	(Jaber and Vidal, 2010)
		Chaetomium cochliodes	*Cirsium arvense*	Reduced feeding by the generalist herbivore *Mamestra brassicae*	Lepidoptera	(Gange et al., 2012).
		Nigrospora sp. and *Cladosporium* sp.	*Brassica oleracea*	Enhanced mortality of the generalist *Spodoptera litura*	Lepidoptera	(Thakur et al., 2013)
		Fusarium oxysporum Fo162	*Cucurbita pepo*	Enhanced resistance to *Aphis gossypii*	Hemiptera	(Martinuz et al., 2012)
Bacteria	*Pathogens*	*Bacillus megaterium*, *Salmonella enterica*, *Brevibacillus choshinensis*, *Cedecea davisae*, *Microbacterium testaceum*, *Pectobacterium carotovorum*	*Coffea arabica*	Resistance in leaf disks to leaf rust caused by *Hemileia vastatrix*	Basidiomycota [biotroph]	(Silva et al., 2012)
		Bacillus sp.	*T. cacao*	Black pod rot [*Phytophthora capsici*], oomycete	Oomycota [hemibiotroph]	(Melnick et al., 2008)
		Azospirillum sp. B510	*Oryza sativa*	*Magnaporthe oryzae* [fungus]	Ascomycota [hemibiotroph]	(Yasuda et al., 2009)
		Azospirillum sp. B510	*O. sativa*	*Xanthomonas oryzae* [bacterium]	Proteobacteria [biotroph]	(Yasuda et al., 2009)
	Herbivores					
		Rhizobium etli G12	*C. pepo*	Enhanced resistance to *A. gossypii*	Hemiptera	(Martinuz et al., 2012)

*I present a noncomprehensive list of recent examples of how colonization by nonclavicipitaceous (type II) fungal endophytes or by bacterial leaf endophytes can affect the resistance of their host plants at the phenotypic level. Please see Saikkonen et al. (1998, 2010) for reviews on effects on clavicipitaceous endophytes; Gao et al. (2010), Ownley et al. (2010), and Yuan et al. (2010) for reviews on effects of nonclavicipitaceous fungal endophytes; and Sturz et al. (2000) and Pineda et al. (2010) for reviews on resistance-enhancing effects of soilborne endophytic bacteria.

both necrosis and mortality of the leaf when the seedlings were challenged with a pathogenic *Phytophthora* sp. (Arnold et al., 2003). Reports published over the following years indicate that an enhanced resistance to pathogens might be a common outcome of the colonization of plants by fungal or bacterial symptomless endophytes (van der Lelie et al., 2009; Weyens et al., 2009; Gao et al., 2010; Ownley et al., 2010) (Table 114.1).

114.2.3 Resistance to Herbivores

The ecological role of the clavicipitaceous endophytes has been discovered via their lethal effects on herbivorous mammals (Bacon et al., 1977; Saikkonen et al., 1998; Faeth, 2002). Subsequent studies demonstrated that the colonization of grasses by these fungi also enhances their resistance to multiple chewing and sucking insects (Kuldau and Bacon, 2008), and a recent meta-analysis revealed that colonization of host grasses by these fungi usually enhances their resistance to herbivores (Saikkonen et al., 2010). However, the species and the feeding mode of the herbivore clearly matter in this context. For example, experiments using the grass *Festuca subverticillata* and the type I endophyte *Neotyphodium* sp. revealed that the long-horned grasshopper *Pterophylla camellifolia*, the caterpillar *Spodoptera frugiperda*, and the aphid *Rhopalosiphum padi* preferred endophyte-free plants, whereas the short-horned grasshoppers *Encoptolophus costalis* and *Romalea guttata* preferred plants with the endophyte (Afkhami and Rudgers, 2009).

Whereas there exist numerous reports on antiherbivore effects of these type I endophytes (for reviews, see Saikkonen et al., 1998, 2006; Faeth, 2002; Rudgers et al., 2009; Porras-Alfaro and Bayman, 2011), much less is known on type II endophytes. Females of tropical beetles exhibited impaired reproduction when they had to feed on endophyte-colonized leaves as larvae (Van Bael et al., 2009). Similarly, broad bean *Vicia faba* plants that were colonized with the root endophytic fungus *Acremonium strictum* exhibited enhanced resistance to the generalist leaf herbivore *Helicoverpa armigera*. The endophyte could not be reisolated from the leaves, which makes a systemic effect likely (Jaber and Vidal, 2010). Colonization of cauliflower (*Brassica oleracea*) with the fungal endophytes *Nigrospora* sp. and *Cladosporium* sp. caused higher mortality of the generalist caterpillar *Spodoptera litura*, although these endophytes had been isolated from a different plant species (Thakur et al., 2013). Finally, even seemingly well-defended plants like thistle (*Cirsium arvense*) might benefit from reduced feeding by a generalist insect when their leaves are colonized by specific endophytic fungi (Gange et al., 2012).

By contrast, observations of mountain birches (*Betula pubescens* ssp. *czerepanovii*) over a 3-year period revealed little support for a direct relation between the frequencies of endophytic fungi and the performance of invertebrate herbivores (Ahlholm et al., 2002). In fact, evidence for antiherbivore effects in a meta-analysis was much less convincing for type II endophytes than for type I endophytes (Saikkonen et al., 2010). This observation can be interpreted in different ways. (i) The most conservative explanation would simply be that horizontally transmitted type II endophytes less frequently enhance host resistance to herbivores than type I endophytes. Because most of these endophytes are closely related to necrotrophs or even can shift to necrotrophic behavior (Delaye et al., 2013), the shared JA-dependent resistance pathways that are used by plants to fend off necrotrophic pathogens and chewing herbivores might be a causal explanation for this observation. (ii) Second, type II endophytes usually form diverse communities and no strain achieves domination (Arnold and Herre, 2003; Porras-Alfaro and Bayman, 2011). Therefore, each single fungal train might not reach sufficient density to exert any detectable effect on insects. (iii) Third, effects of high endophyte loads might differently affect the different developmental stages of insects, and of course, they vary among strains of endophytes and species of insects. For example, larvae of the beetle *Chelymorpha alternans* showed no preference for host leaves with low endophyte loads and did not suffer from any detectable effects in development or survival. However, female beetles that as larvae fed on host leaves with high endophyte loads produced 80% less offspring (Van Bael et al., 2009). The negative effect of endophytes on the fitness of *H. armigera* was even carried to a second generation that was maintained completely on an endophyte-free artificial diet (Jaber and Vidal, 2010). However, caterpillars in the first generation had to feed on intact plants, because no negative effects of endophyte colonization on the fitness of the insect were observed when the experiments were performed with leaf disks (Jaber and Vidal, 2010). In the study by Gange and colleagues, colonization by two out of the four endophyte strains tested increased rather than decreased feeding by a specialist insect herbivore (*Cassida rubiginosa*), and only one out of four endophytes tested (*Chaetomium cochliodes*) significantly reduced feeding by the generalist herbivore *Mamestra brassicae* (Gange et al., 2012). Effects of these types are likely to remain undiscovered in most assays, in which we usually focus on choice behavior or on immediate effects on consumption rates or larval growth rate and commonly use leaf disks rather than entire plants.

114.3 MECHANISMS: WHAT DO WE KNOW?

114.3.1 Growth Promotion

The growth-promoting effects of bacteria that colonize plant root or shoots as epiphytes or endophytes result from

multiple mechanisms such as (i) the direct acquisition and provision of nutrients (via N-fixation, the solubilization of inorganic phosphates, the production of siderophores that facilitate iron uptake, etc.), (ii) the production of plant hormones, (iii) the induction of resistance-related plant genes, and (iv) direct antibiosis against pathogens (Weyens et al., 2009; Dudeja et al., 2012; de Bruijn, 2013). Taxa that are frequently reported in this context are the genera *Pseudomonas* (in particular multiple strains of *Pseudomonas fluorescens*), *Bradyrhizobium*, *Azorhizobium*, *Azospirillum*, and *Bacillus* (commonly *Bacillus thuringiensis*). Different mechanisms commonly are exerted by the same microbial strain. For example, the growth-promoting endophytic bacterium *Enterobacter radicincitans* DSM 16656 fixes atmospheric nitrogen, solubilizes phosphate, produces phytohormones, and induces several resistance-related plant genes (Brock et al., 2013).

114.3.2 Resistance to Infection

Although different endophytes often cause phenotypically similar resistance to pathogen infection, this effect can be achieved by numerous direct and indirect mechanisms. Direct effects are particularly likely to exist when the resistance effect is locally restricted to the infected tissue. For example, *T. cacao* leaves that were infected with type II fungal endophytes showed a locally enhanced resistance to pathogens only in the infected areas, and direct *in vitro* confrontation assays demonstrated strong antagonisms between certain strains of endophytes and the pathogen (Arnold et al., 2003). Direct effects of endophytes on the phenotypic resistance of their host can result from the production of antibiotics; of extracellular lytic enzymes such as chitinases, cellulases, proteases, and ß-1,3-glucanases; and of secondary compounds, when endophytes act as mycoparasites and directly parasitize plant pathogenic fungi or when nonsymptomatic endophytes outcompete the pathogens (Weyens et al., 2009; Gao et al., 2010; Ownley et al., 2010; de Bruijn, 2013).

Belowground microorganisms are also very commonly reported to locally enhance the resistance in the roots (Borowicz, 2001; Pozo and Azcón-Aguilar, 2007; Elsen et al., 2008; Pineda et al., 2010), which makes it likely that similar mechanisms are involved. Root-colonizing bacteria or fungi might prevent pathogen invasion directly, for example, by outcompeting pathogens on the root surface or within the tissue or by the production of antifungal or antibacterial compounds (Haggag, 2010; de Bruijn, 2013). For example, 9% of the 256 strains of root-colonizing endophytic bacteria that were isolated from six plant species in tidal flats in Korea showed antagonistic behavior against plant pathogenic oomycetes *in vitro*, and many of these bacteria were found to produce ß-1,3-gucanases, chitinases, cellulases, and proteases (Bibi et al., 2012). Most of these traits have evolved in the context of antagonistic interactions among microorganisms and thus are unlikely to represent a specific adaptation of endophytes to their potential role as mutualists of their host. However, they invariably can benefit any host plant that is colonized by a competitively dominant microorganism with low virulence.

As a second mechanism, the infection of plants with endophytes that enhance the nutritional status of their host (mycorrhiza, rhizobia, and other PGPB) can decrease the plant internal competition among different traits for limited nutrients (Herms and Mattson, 1992). This effect alone might allow for systemically enhanced resistance levels (Van Dam and Heil, 2011). As a consequence, mycorrhiza can improve resistance to leaf pathogens (Fritz et al., 2006; Pozo and Azcón-Aguilar, 2007; Alejo-Iturvide et al., 2008), and also, plants whose roots are infected with rhizobia commonly show enhanced resistance levels in their aboveground parts. For a short overview on ecologically relevant resistance-enhancing effects of mycorrhiza and nodulation on aboveground communities, see Van Dam and Heil (2011).

Furthermore, indirect – and commonly systemic – effects result when endophytes trigger unspecific responses of the plant's own immune system. For example, the colonization by symptomless fungal endophytes induces the expression of resistance-related genes in their host (Mithöfer, 2002; Pozo and Azcón-Aguilar, 2007; Ownley et al., 2010). Similarly, the colonization of roots by mycorrhizal fungi commonly enhances resistance to necrotrophic leaf pathogens, whereas the resistance to biotrophic pathogens is often impaired. The most likely reason for this mycorrhiza-induced systemic resistance is a mycorrhiza-induced shift between the different signaling pathways that control plant resistance to necrotrophic versus biotrophic pathogens: these functional groups of pathogens are controlled by different signaling pathways that are subject to a negative trade-off. The mycorrhizal fungus, which itself lives as a biotroph, must suppress the resistance to biotrophs in order to colonize the plant and thereby enhance resistance to necrotrophs (Pozo and Azcón-Aguilar, 2007).

Also, PGPB that infect the aerial parts of plants can induce or prime resistance-related genes (Pieterse et al., 2001; Pineda et al., 2010). The endophytic bacterium *Pseudomonas putida* MGY2 enhanced gene expression (and also activity at the enzymatic level) of phenylalanine ammonia lyase, catalase, and peroxidase in the tissue of the host (Shi et al., 2011), another *Pseudomonas* strain induced both basal resistance and induced resistance dependent on SA and JA/ethylene signaling in potato (Pavlo et al., 2011), and the N-fixing and growth-promoting bacterium *E. radicincitans* induced various SA- and JA-dependent resistance genes in *Arabidopsis*, including PR1, PR2, PR5, and PDF1.2 (Brock et al., 2013). Thus, the induction of JA- or SA-dependent resistance genes appears a common effect of PGPB that colonize plant tissues. By contrast, colonization of rice (*Oryza*

sativa) with the N-fixing endophytic bacterium, *Azospirillum* sp. B510, enhanced resistance to rice blast disease caused by the fungus *Magnaporthe oryzae* without measurably affecting endogenous SA accumulation or PR gene expression and thus might function via an SA-independent pathway (Yasuda et al., 2009).

Due to the systemic nature of most resistance responses, it might not matter too much whether the resistance-inducing agent is colonizing belowground or aboveground tissues. Most importantly, all these phenomena are mediated by effects of the endophytes on host gene expression patterns and therefore represent the "extended phenotype" of the microorganisms, although they are likely to depend more strongly on host genotype than the direct effects by, for example, toxic fungal metabolites or fungal mycoparasites.

114.3.3 Resistance to Herbivores

From the day of their discovery as the causal reason of livestock disease, fungal endophytes were related to the antiherbivore defense of their host plant (see in the preceding text). The toxic effect on livestock of fungal alkaloids represents a direct antiherbivore defensive mechanism that the plants gain when being colonized by a type I endophyte. However, as described previously for pathogens, the enhanced resistance of endophyte-colonized host plants to herbivores can result from multiple direct and indirect mechanisms.

Although one might expect a positive effect due to the enhanced nutrient contents of mycorrhized plants, the performance of herbivorous insects on AMF-inoculated plants usually is often lower than on unmycorrhized plants (Hartley and Gange, 2009; Kempel et al., 2010; Pineda et al., 2010). Similarly, the colonization of roots by rhizobia can increase resistance in the aboveground parts of soybean to aphids (Dean et al., 2009). As explained previously, the suppression of the host's SA-dependent resistance to biotrophs and the resulting enhanced expression of JA-dependent resistance to herbivores and necrotrophs are likely to contribute to this effect.

Fungal symptomless leaf endophytes are likely to enhance the resistance to herbivores of their host plant via four distinct mechanisms: (i) via the production of alkaloids and other toxic compounds, (ii) due to their function as entomopathogens, (iii) via the induction or priming of resistance-related genes, and (iv) by enhancing the genetic and biochemical diversity of their host. As described previously for bacteria, these modes of action are not necessarily exclusive. For example, entomopathogenic fungal endophytes can also associate with the rhizosphere, act as antagonists of plant pathogens, and might possibly even function as plant growth-promoting agents (Vega et al., 2009).

A recent meta-analysis revealed that alkaloid-producing type I endophytes in general slightly enhance host resistance to insects, although this result might be biased due to the concentration of the experimental effort on few agronomically important model systems (Saikkonen et al., 2010). For type II endophytes, by contrast, the situation appears to be less clear. Beyond doubt, *in vitro* cultures of many type II endophytic fungi produce compounds with antibacterial, fungicidal, and herbicidal effects (for references, see Schulz and Boyle, 2005; Gao et al., 2010; Ownley et al., 2010), and these compounds could exert a direct resistance effect. Type II endophytes, however, in general reach much lower densities in their host than do type I endophytes. In European aspen (*P. tremula*), the phenotypic resistance to herbivores of different clones was positively correlated to their load of endophytic fungi (Albrectsen et al., 2010), which makes a direct effect likely that is mediated by some fungal metabolites. A very specific case of antiherbivore effect exerted by type II endophytes is represented by the discrimination exhibited by leaf-cutter ants (*Atta colombica*) against leaves with higher endophyte colonization rates. In this case, the most likely explanation is a negative effect of the endophytes on the growth of the fungus in the ants' gardens (Van Bael et al., 2012).

Second, several plant endophytic fungi also live as entomopathogens and thereby exert a direct negative effect on herbivores (Vega et al., 2009; Ownley et al., 2010). Interestingly, the lifestyle as an insect parasite might be the ancestral state of many plant endophytic fungi, including type I endophytes (Rodriguez et al., 2009). In fact, parasitic fungi can often infect a wide spectrum of hosts including plants, animals, and other fungi. For example, the ubiquitous fungus *Beauveria bassiana* (Ascomycota) has been found as an endophyte in banana, corn, cotton, potato, tomato, common cocklebur, opium poppy, coffee, and cocoa (for references, see Gurulingappa et al., 2010) but is also known to occur naturally in hundreds of insect hosts (Vega et al., 2009; Ownley et al., 2010). Because the effects on the various hosts can be highly different, a surprisingly high number of fungi cause no symptoms in plants but act as severe pathogens when infecting an insect host (Ownley et al., 2010). A likely scenario appears to be that the fungus uses the plant as a vector, that is, to enhance its transmission rate among different insect hosts.

Whereas the direct effect of entomopathogenic fungi on herbivores happens outside the plant, a third, indirect mechanism results from effects of endophytes on the expression levels of host resistance genes. An infection with the root endophytic fungus *A. strictum* enhanced resistance of broad bean (*V. faba*) to the generalist herbivore *H. armigera*. Because the fungus could not be reisolated from the leaves, the authors suggested that it caused a systemic resistance effect and that the antiherbivore effect did not depend on a direct contact between fungus and herbivore (Jaber and Vidal, 2010). It appears to be likely that in most of these cases, the enhanced resistance, at least in part, results from changed expression patterns of resistance genes of the host plant (Ownley et al., 2010). Indeed, the colonization of

plants with fungal endophytes can increase the production of endogenous JA in the host (Ren and Dai, 2012).

Finally, the presence of endophytes enhances the genetic and, consequently, biochemical diversity of the leaf tissue, which should represent per se a beneficial effect in evolutionary terms, because this increased diversity can make the adaptation of herbivores to certain plants more difficult (Schulz and Boyle, 2005; Albrectsen et al., 2010).

114.4 THE POTENTIAL OF ENDOPHYTES IN BIOCONTROL

Fungal entomopathogens and mycoparasites are used as tools in biocontrol. Many commercial "biocontrol" entomopathogens were isolated originally from symptomless plant tissues (Ownley et al., 2010) and thus can be considered as endophytes, at least during a part of their life cycle. Likewise, the resistance-enhancing effects of multiple fungal and bacterial endophytes have recently attracted much research interest due to their potential in biocontrol (Table 114.1; see de Bruijn, 2013). Colonization by these endophytes comes at no measureable cost to the host and can significantly enhance the resistance to pests and pathogens. Recent reports on a resistance-enhancing effect of the treatment of crops with endophytes comprise *Bacillus* sp. enhancing resistance in cacao to black pod rot caused by the oomycete *Phytophthora capsici* (Melnick et al., 2008), *Trichoderma* fungal endophytes protecting cacao from the witches' broom pathogen *Moniliophthora perniciosa* (De Souza et al., 2008), the protection of tomato against pathogenic *Verticillium* strains by the colonization of a nonvirulent strain of the same species (Shittu et al., 2009), and the protection of rice colonized by an endophytic *Azospirillum* strain against the bacterial pathogen *Xanthomonas oryzae* and the rice blast fungus *M. oryzae* (Yasuda et al., 2009). Likewise, treating harvested papaya fruits with the endophytic bacterium *P. putida* MGY2 enhanced their resistance to anthracnose caused by *Colletotrichum gloeosporioides* (Shi et al., 2011), whereas a *Pseudomonas* strain enhanced resistance of potato to soft rot disease caused by the necrotrophic pathogen *Pectobacterium atrospeticum* (Pavlo et al., 2011). In consequence, endophytes that colonize the roots or aerial parts of crop plants are increasingly considered as highly promising means of environmentally friendly crop protection.

However, much more research will be required before certain strains of endophytes can be considered reliable biocontrol agents for certain crops (see de Bruijn, 2013). First, knowledge on the ecology of the entomopathogens is limited (Rodriguez et al., 2009; Vega et al., 2009; Roy et al., 2010), and it remains to be proven whether their negative effects on their insect hosts can positively feed back to plant fitness. Second, as discussed previously, many endophytes realize their resistance-enhancing effect via their influence on the expression of host resistance genes. Therefore, it depends on the detailed type of interaction of a given endophyte with the immune system of its host to which pathogen the host will become resistant. In this respect, endophytes with direct effects on the plant enemies such as entomopathogens, mycoparasites, and endophytes that produce hydrolytic enzymes such as chitinases and ß-glucanases or secondary compounds might be more promising than endophytes that mainly enhance host resistance via interactions with the host immune system. Third, although costs of the colonization by endophytes are rarely reported, these costs are likely to exist: in the end, the endophyte receives all its nutrients from the host plant. This diversion of nutrients to the endophyte might not cause visible effects under high-nutrient conditions, but it will significantly affect plant growth when a nutrient becomes limiting that is shared among host and endophyte. PGPRs with their positive effects on plant nutrition and growth might represent the most promising candidates to circumvent or at least minimize this problem.

Finally, many endophytes can shift from an endophytic to a pathogenic lifestyle. Both lifestyles (endophyte and necrotrophic pathogen) have been reported for *Alternaria alternata* (Huang et al. 2009; Yu et al. 2011; Park et al. 2012), *Colletotrichum acutatum* (Than et al. 2008; Glenn and Bodri, 2012), *C. gloeosporioides* (Promputtha et al. 2007; Than et al. 2008; Yan et al. 2011; Choi et al. 2012), *Colletotrichum musae* (Photita et al. 2005; Promputtha et al. 2007), *Exserohilum rostratum* (Lin et al. 2011; Loro et al. 2012), and *Glomerella cingulata* (Sette et al. 2006; Kwon et al. 2012). Whether some of these reports might refer to cryptic species comprising distinct strains with different ecologies, both lifestyles have been reported for the same strain in the case of *Deightoniella torulosa* (Photita et al. 2004), *Leptosphaeria maculans* (Junker et al. 2012), *Diplodia mutila* (Álvarez-Loayza et al., 2011), and *Lasiodiplodia theobromae* (Sakalidis et al. 2011). Climatic conditions determined whether *Discula quercina* behaved as a pathogen or an endophyte in oak (Moricca and Ragazzi 2011) and high light intensity caused *D. mutila*, which represents a common symptomless endophyte of the tropical palm (*Iriartea deltoidea*), to switch to pathogenicity and cause necrosis (Alvarez-Loayza et al. 2011). A recent phylogenetic analysis demonstrates that this situation is likely to represent the rule rather than the exception (Delaye et al., 2013).

As exemplified elsewhere (Partida-Martinez and Heil, 2011), the outcome of the colonization of a plant with a certain endophyte is highly conditional and depends on the genotype of the endophyte and of the host as well as on abiotic conditions. Thus, the same endophyte might, or might not, cause resistance against a certain pathogen in a certain host plant species depending on inoculum density, host cultivar, and abiotic conditions (Ardanov et al., 2012).

In conclusion, we will need much more detailed understanding of the mechanisms via which endophytes affect the resistance phenotype of their host and of the conditions under which colonization by them harms rather than helps the host plant before endophytes can be considered a safe tool in biocontrol. However, based on the existing knowledge, one might predict that endophytes with direct effects on the enemies of the plant appear in general to be the more promising candidates than those that "only" trigger host resistance genes.

114.5 ENDOPHYTE OR PATHOGEN: WHO CONTROLS?

As defined previously, endophytes are microorganisms that colonize the living tissue of their host without causing symptoms of disease. However, endophytes do infect their host and extract nutrients. Why are endophytes, then, not perceived as pathogens and cause disease? Indeed, several fungi do shift along the mutualist–parasite continuum and behave as pathogens under certain circumstances. Can endophytes escape from the host pathogen perception machinery, do they actively suppress host resistance (just like many successful pathogens do), or are they involved in specific signaling processes to chemically identify themselves to the host as mutualists, as it has been described for mycorrhiza and rhizobia?

First, we have to realize that many endophytes indeed are perceived as pathogens and readily induce host resistance responses, an effect that appears to be the general mechanism that underlies their "indirect" effects. Due to the operational nature of the definition of "endophyte", any microorganism that actually does not cause symptoms of disease qualifies as an endophyte, although the lack of visible disease symptoms might be the outcome of a delicate balance between host resistance responses maintaining the growth rate of the microorganisms at a tolerable magnitude and the microorganisms suppressing host resistance just enough to enable colonization.

Distinguishing that strictly between symptomless endophytes and "not very virulent pathogens" is somewhat artificial because, for the plant, the effect on its net fitness is way more important than whether or not the colonization by the microorganisms locally causes symptoms of disease. Even pathogens can positively affect the net fitness of their host, for example, in the case of the ergot fungus (*Claviceps purpurea*), which produces alkaloids that cause severe toxicity in mammals (Wäli et al., 2013). The frequency of ergot-infected grasses was much higher in sheep pastures than in surrounding ungrazed areas, which makes a positive selection by grazing on the preservation of this infection highly likely (Wäli et al., 2013). In summary, the net effects of the colonization of a plant by a specific endophytic microorganism are not defined by whether or not this microorganism causes visible symptoms of disease. Rather, it is the net sum of all its (often conditional) positive effects (growth promotion, resistance enhancement, etc.) and of all its negative effects (which invariably comprise the usage of nutrients but also might include the suppression of certain defense signaling pathways) that decides whether the colonization of a plant by a microorganism can be considered a mutualism, parasitism, or commensalism under a defined set of environmental conditions. However, it remains an intriguing phenomenon that some microorganisms do not cause any visible resistance response by the host, whereas others cause disease, and future comparative studies will have to identify the factors that decide where on the "fine line" (Junker et al., 2012) from parasite to mutualist a given endophyte–host combination will be most likely to be found.

114.6 SUMMARY AND OUTLOOK

Bacterial and fungal endophytes have been isolated from all parts of all plants that have been searched for them so far and thus can be considered to be ubiquitous. Although per definition they produce no symptoms of disease, endophytes affect multiple phenotypic traits of their host plants, being the most commonly reported effects: (i) resistance to herbivores caused by type I fungal endophytes, (ii) resistance to pathogens by type II fungal endophytes and (iii) growth promotion, and (iv) resistance to pathogens caused by bacterial endophytes. These effects are achieved via multiple different mechanisms which to different degrees depend on the genotype of both host and endophyte. Type II endophytes usually grow at low densities in their host, and thus, no single strain reaches dominance (Lodge et al., 1996; Porras-Alfaro and Bayman, 2011). By contrast, type I endophytes are transmitted vertically, and usually, a single strain colonizes and dominates a given host. Endophytes with their multiple growth-promoting and resistance-enhancing effects are likely to affect multiple plant traits in natural ecosystems and bear potential for a regular use in biocontrol. However, generalizations are still difficult. We lack reliable lists of endophytes that are naturally colonizing a specific host. The complete contribution that endophytes make to the phenotype of their host as we see it in a given environment has never been evaluated. Petri dish assays findings, for example, antibacterial or antifungal effects, do not always predict the behavior of the endophyte *in planta*, let alone its net effect on the phenotype and, ultimately, the fitness of the host. Finally, many endophytes can shift to pathogenic behavior under certain environmental conditions. In summary, inoculating crops with specific endophytes are certainly a highly interesting perspective, but more research will be required before we understand the true contribution of endophytes to

the phenotypes of plants in nature and before endophytes can be used as reliable tools in biocontrol.
