In this new classification, *A. evenia* comprises two subspecies: *A. evenia* ssp. *evenia* and *A. evenia* ssp. *serrulata* that are morphologically well differentiated (Fig. 45.3a). The *evenia* subspecies is characterized by mostly glabrate stems, tender green leaves, and flowers with an elliptic standard petal. The *serrulata* subspecies differs being glandular in all parts. Leaflets are consistently ciliate-serrulate and dark green. Flowers present a rounded standard petal. Molecular analyses were performed using either the nuclear ribosomal internal transcribed spacer (ITS) sequence that is usually used for species identification or single nuclear gene-coding sequences. They indicated that accessions of the *evenia* and *serrulata* subspecies form distinct but related clades compared to the other diploid *Aeschynomene* species. In addition, flow cytometry analysis revealed a significant genome size difference between the two subspecies, ranging from 0.82 to 0.87 pg/2C for the *evenia* subspecies and between 0.94 and 0.99 pg/2C for the *serrulata* subspecies (Fig. 45.3a). Finally, using the artificial hybridization protocol successfully developed for *A. evenia*, the two subspecies were tested for their genetic compatibility. Inter-subspecies crossings were only possible when using the *evenia* subspecies as maternal parent. However, the F1 plants obtained, although highly flowering, were almost entirely sterile, producing only occasionally one-seed-bearing pods (Fig. 45.3a).

Each subspecies was, in turn, divided in two varieties (Fig. 45.3b). The *evenia* subspecies groups var. *evenia* and var. *pauciciliata*. The *evenia* variety is characterized by early-flowering accessions that tend to develop one primary axis with small axillary axes bearing the flowers. The *pauciciliata* variety comprises late-flowering accessions with developed secondary axes. Some accessions present moderately denticulate and ciliate leaflets suggesting to Rudd (1955) that they correspond to intergradations with the *serrulata* subspecies. In the latter, the var. *major* that includes the cultivated IRFL6945 line differs from the var. *serrulata* by larger plants developing bigger flowers. The genetic diversity between and within each subspecies was evaluated using RAPD and SSR markers. They gave congruent results in that the *evenia* and *serrulata* profiles were significantly different, and that variety delimitation on the basis of morphological and molecular markers were concordant. Interestingly, the polymorphism levels obtained using 82 EST-SSRs were similar: 24–33% between the two varieties of the *evenia* subspecies and 31–37% between the two varieties of the *serrulata* subspecies, whereas it rose up to 72–82% between the two subspecies (Fig. 45.3a,b). Contrarily to what was observed with the inter-subspecies hybridizations, bidirectional crossings of the two varieties for each subspecies could be efficiently performed and allowed to produce fully fertile hybrids (Fig. 45.3b). This indicates that crossing-compatibility was normal within each subspecies.

This knowledge on the phenotypic and genetic diversities present in *A. evenia* allows its judicious exploitation to develop genetic approaches. In particular, for map development, the use of parental lines belonging to the same subspecies is required, but fortunately the polymorphism level encountered in each subspecies appears to be sufficient. Characteristics found in *A. evenia* ssp. *evenia* such as a smaller genome size, a shorter growth cycle, a uniaxis habit, and interesting symbiotic features make up the difference. We therefore suggest this subspecies to be the most

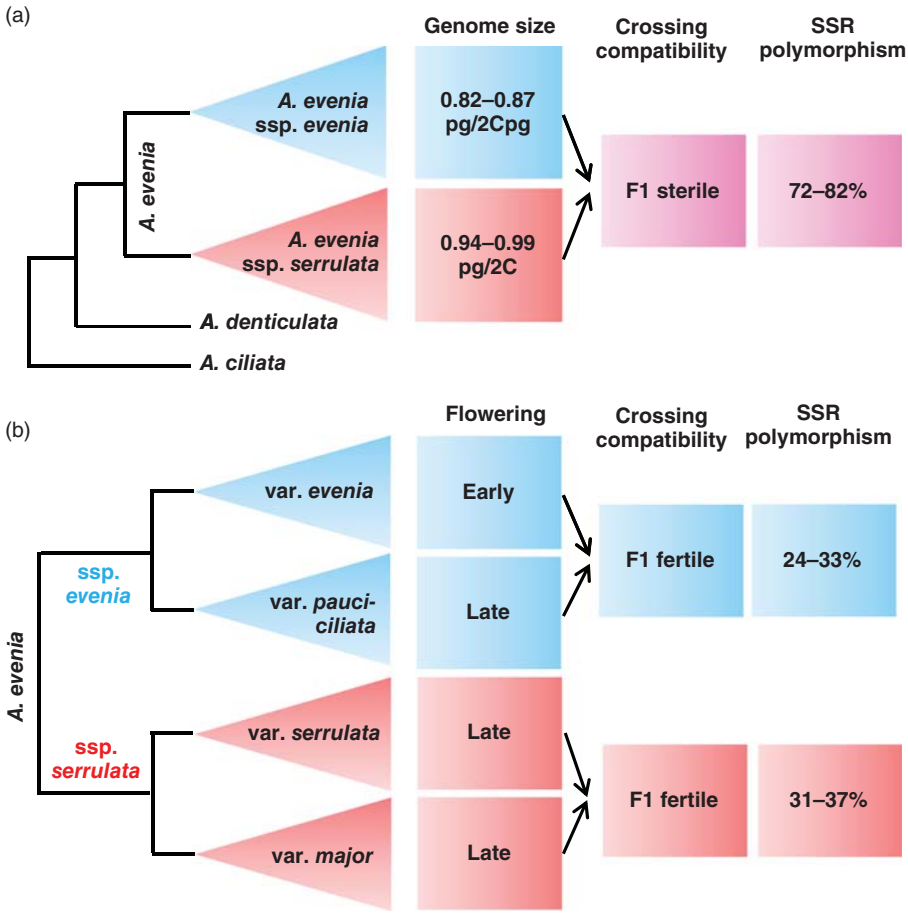

Figure 45.3 Genetic differentiation within the *Aeschynomene evenia* species. Schematic representation of the genetic diversity at the subspecies level (a) and variety level (b) with genome size and flowering characteristics, crossing compatibility, and SSR polymorphism. appropriate for future projects of forward genetics (Arrighi et al., 2013).

45.1.3 Nodulation Characteristics

Similar to other semi-aquatic *Aeschynomene* species, *A. evenia* is endowed with the capacity to develop both root and stem nodules upon inoculation with photosynthetic *Bradyrhizobium*. It is efficiently nodulated with the commonly used laboratory strains ORS278 (using a Nod-independent strategy) and ORS285 (using both Nod-dependent and Nod-independent strategies) (Arrighi et al., 2012). Importantly, the genomes of these two strains have been completely sequenced and extensive collections of *Tn5* mutants have been developed (Bonaldi et al., 2010a; Giraud et al., 2007). In addition, *Bradyrhizobium* strains with reporter genes such as *GFP* and *GUS* are also available, thus facilitating the detailed observation of the symbiotic infection process (Bonaldi et al., 2011).

Stem nodulation has previously been analyzed in different *Aeschynomene* species, in particular *A. afraspera* (Alazard and Duhoux, 1987; 1988; Boivin et al., 1997). Like other *Aeschynomene* lines, accessions of *A. evenia* present stems with vertical rows of dormant root primordia. The ability of the root primordium to develop into an adventitious root can be easily checked by immerging cutting of stems in water (Arrighi et al., 2012). The root primordia on *A. evenia* have been reported to be less developed than those of *A. afraspera*, as they usually do not break the stem epidermis and just underlie it, sometimes at the proximity of lenticels. As a consequence, they are less prone to be infected by *Bradyrhizobium* (Alazard and Duhoux, 1987). But in the condition of high humidity, primordium dormancy can be broken, thus activating some nodulation sites. On *A. evenia* ssp. *evenia* stems, round swellings are rapidly visible (5–7 days) after inoculation with the strain ORS278, leading to hemispherical nodules with a broad attachment to the stem (Fig. 45.4a). Cross sections of mature nodules reveal a dark green peripheral cortex and a red-pigmented inner zone filled with *Bradyrhizobium* that is organized around the central vascular connection of the root primordium. The longevity of such nodules is no more than 9 weeks (Fig. 45.4a). On the contrary, stem nodules of *A. evenia* ssp. *serrulata*, which

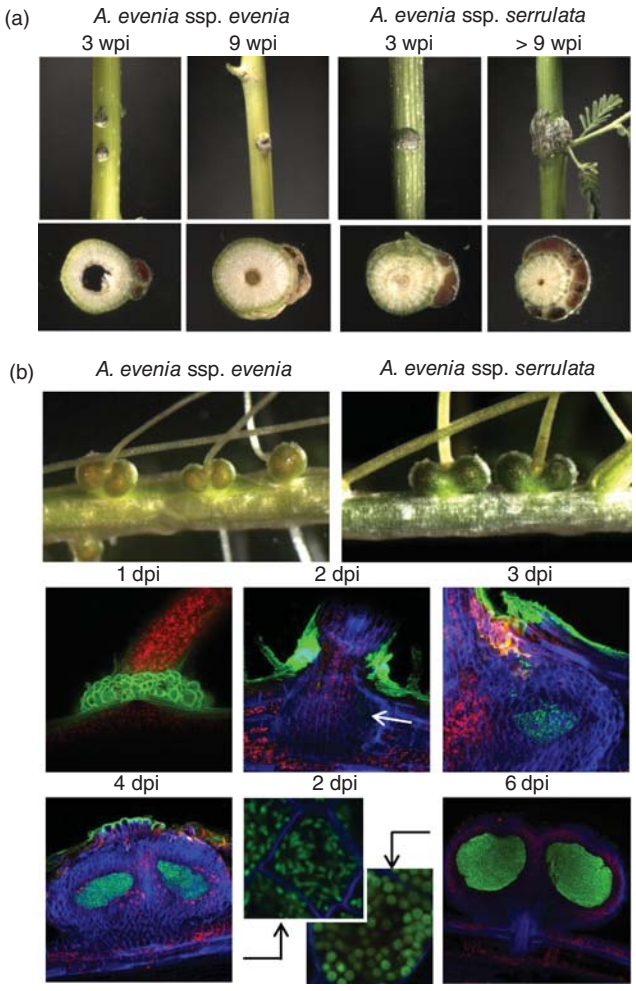

Figure 45.4 Stem and root nodulation in *Aeschynomene evenia*. (a) Stem nodules at two ages (3 and 9 weeks post-inoculation with the *Bradyrhizobium* strain ORS 278) in *A. evenia* ssp. *evenia* and ssp. *serrulata*. Below, cross-sections reveal the structure of the stem nodules. (b) Root nodules (15-day post in post-inoculation with the *Bradyrhizobium* strain ORS 285-*GFP*) showing similar morphology in both *A. evenia* subspecies. Below, kinetics of the infection and nodulation processes detailed for the *serrulata* IRFL6945 line. (*Source*: Confocal pictures reprinted from Arrighi et al. (2012) with permission.)

appear to be less frequent, mostly differ in their organogenesis. They tend to progressively form collars around the stem that embrace several root primordial vascular connections (Fig. 45.4a). These stem collar nodules could result from maintenance of mitotic activity in the peripheral cells of the nodule primordium leading to an important longevity (>3 months). It is therefore worth noting that there are significant variations in the stem nodule organogenesis between the two *A. evenia* subspecies. The *evenia* hemispherical nodules are similar to those of *A. afraspera*, whereas the *serrulata* collar nodules are reminiscent of those observed in *A. sensitiva* (Alazard and Duhoux, 1987; 1988; Boivin et al., 1997, Giraud et al., 2000).

Different from stem nodules, root nodules in both *A. evenia* subspecies were found to develop similarly at the base of lateral roots and to display the same spherical shape (Fig. 45.4b). The nodulation process was analyzed for the *serrulata* line IRFL6945 using the ORS285-*GFP* strain (Fig. 45.4b) (Arrighi et al., 2012). Shortly after inoculation, a strong proliferation of the bacteria was observed, specifically at the surface of the axillary root hairs surrounding the lateral roots. Then they penetrated between root hairs and progressed to the root cortex, most probably by successive collapses of the initially infected cells. At 2 dpi, some deeper infected cortical cells started to divide, giving rise to the nodule primordium. By successive divisions of these founder cells, the bumps rapidly evolved to spherical nodules. Between 5 and 6 dpi, the internalized *Bradyrhizobium* differentiated to bacteroids. This step was marked by a change from a rod to hemispherical shape (Fig. 45.4b) and the apparition of nitrogenase activity. Between 7 and 10 dpi, the nodules reached their mature size and displayed the classical histological organization of the aeschynomenoid nodules, that is, a large central zone of infected tissue surrounded by an uninfected nodule cortex comprising vascular bundles (Fig. 45.4b).

The process of symbiotic infection and of nodule organogenesis was found to be very similar to the one described for the related *A. indica* (Bonaldi et al., 2011). This suggested that the root nodulation process is well conserved among the Nod-independent *Aeschynomene* species, and that the use of *A. evenia* as symbiotic model is relevant to study the Nod-independent infection process.

45.1.4 Tools for Functional Analysis

Plant transformation is a prerequisite for the molecular and physiological analyses of *Aeschynomene* symbiotic gene function. However, transformation with *Agrobacterium tumefaciens* is a difficult and time-consuming approach, which is not suitable for high-throughput analysis of candidate genes. In the case of root tissues, where the nitrogen-fixing symbiosis takes place, the *Agrobacterium rhizogenes*-mediated transformation provides a convenient and rapid alternative and has been successfully developed for a number of legumes, such as *Medicago truncatula*, *Lotus japonicus,* and *Sesbania rostrata* (Boisson-Dernier et al., 2001; Kumagai and Kouchi, 2003; Van de Velde et al., 2003). For these reasons, we retained the option of an *A. rhizogenes*-mediated root transformation protocol for *Aeschynomene* with the goal to gain insights into the host genetic program recruited during the Nod-independent symbiotic association. The capacity to induce transgenic roots was initially investigated on *A. indica* that is used as

a convenient host plant. Two different wild-type *Agrobacterium rhizogenes* strains (A4RS and ARqua1) both carrying the *CaMV35S::GFP* construct and two infection methods were tested (stab inoculation or direct application of *Agrobacterium rhizogenes* on freshly sectioned radicles). The ARqua1 strain and infection by hypocotyl cutoff were retained and were subsequently used to determine the frequency of appearance of transformed roots and nodules in the new model legume *A. evenia* (Fig. 45.5a–c) (Bonaldi et al., 2010b; Arrighi et al., 2012). We are now able to transform *A. indica* and *A. evenia* with efficiencies of cotransformation of 80% and 60%, respectively, and an average nodulation efficiency of over 70% in less than 2 months (for comparison, the nodulation efficiency is 40% of transformed roots of *Casuarina glauca* and 90% of those of *Arachis hypogaea*) (Diouf et al. 1995; Sinharoy et al., 2009). In parallel, the expression pattern of the *CaMV35S* promoter was investigated in transgenic roots and nodules with the goal to determine whether its pattern was suitable for a gene expression downregulation approach in *Aeschynomene* symbiotic tissues. In *A. indica* and *A. evenia* transgenic nodules, the *CaMV35S* promoter was expressed in all cell types, including the infected cells of the central region, while in roots, 35S-driven *GUS* expression was restricted to vascular tissues, root tip, and root cortex (Fig. 45.5d,e) (Bonaldi et al. 2010b; Arrighi et al. 2012). According to *CaMV35S* promoter expression patterns and RNA silencing experiments described in other legumes (Gherbi et al. 2008; Kumagai et al., 2006; Sinharoy et al. 2009), those results are consistent with the achievement of functional analysis of symbiotic candidate genes.

One of the main issues raised by the discovery of the absence of *nodABC* genes in some *Bradyrhizobium* strains naturally associated with *Aeschynomene* species is the existence and nature of the rhizobial signal molecules required for this symbiosis. To address this question, we used a fusion of the *MtENOD11* promoter with a reporter gene as a bioassay. MtENOD11 is an early nodulin whose expression pattern has been widely described and used as marker of pre-infection and infection events occurring either during nitrogen-fixing and AM symbioses (Journet et al., 2001). During the *Medicago truncatula–Sinorhizobium meliloti* interaction the NF produced by *S. meliloti* induce a root hair curling, which is an early-plant response easy to follow. In the case of *Aeschynomene*, no NF are produced, and the rhizobial factors assumed to play an equivalent role do not induce root hair deformation. As a consequence, an early visible plant response is not available for *Aeschynomene* species. To bypass this difficulty, the p*MtENOD11::gusA-int* construct appeared as an appealing molecular marker of infection. ENOD11 symbiotic expression was observed in nodule primordia and later in a cell layer surrounding the infection zone but, unfortunately no early symbiotic expression of *ENOD11* could be detected

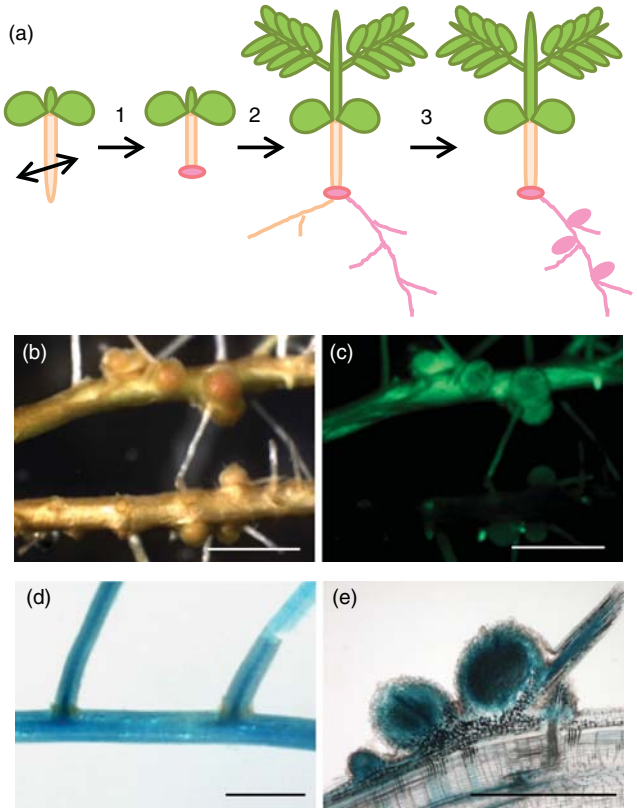

Figure 45.5 *Agrobacterium rhizogenes*-mediated transformation. (a) Steps to obtain transformed and nodulated roots: (1) hypocotyl cutoff and ARqua1 inoculation; (2) development of transformed roots; and (3) inoculation with *Bradyrhizobium* and subsequent development of nitrogen-fixing nodules. Transformed *A. evenia* nodules observed under either (b), white or (c), blue light for epifluorescence of green fluorescent protein (GFP), 35 days after transformation with *Agrobacterium rhizogenes* ARqua1 expressing the p*CaMV35S::GFP* construct. β-Glucuronidase staining in *A. evenia* transformed roots (d) and nodules (e) expressing the p*CaMV35S::gus-int* construct. Scale bars = 1 cm. (*Source*: Pictures reprinted from Arrighi et al. (2012) with permission.)

in *A. indica* (Bonaldi et al., 2010b). This illustrated the need for genomic resources to identify *Aeschynomene* genes differentially expressed during the establishment of the symbiosis that could be used as an early marker of infection in *A. evenia* for the development of bioassay strategies.

For this reason, *A. evenia* massive transcriptomic resources were established and used as a reference transcriptome for transcript profiling during symbiotic interactions (Cartieaux, unpublished data). The analyses of this data set will lead to the identification of candidate genes displaying a specific pattern of expression during the symbiotic interaction with the *Bradyrhizobium* partner. This library of putative new symbiotic genes associated with the ability of root transformation will pave the way for a successful gene candidate analysis in *A. evenia*.

45.2 CONCLUSIONS

The analysis of transcriptomic resources already constituted for *A. evenia* should rapidly allow us to highlight a subset of candidate genes specific to the Nod-independent symbiotic process, and the *Agrobacterium rhizogenes*-mediated transformation will permit to test their role via functional analyses. Moreover, the genetic dissection of the Nod-independent symbiosis, by screening a library of plant mutants altered in the symbiotic process, will constitute an essential approach that is complementary to the transcriptomic studies. It is such an approach that led to the identification of the key symbiotic genes in model legumes, and that could also bring to light specific determinants of the Nod-independent symbiotic infection process in *A. evenia*.

Although the absence of requirement of NF to trigger symbiosis has been identified to date in only 11 species of *Aeschynomene*, the mode of bacterial invasion and nodule organogenesis described in *Aeschynomene* spp. is largely shared by tropical legumes, including species of agronomic importance such as *Arachis hypogaea*. Peanut is the fourth largest oilseed crop in the world and is cultivated in more than 100 countries, with an annual production of 35.5 million tons (FAOSTAT [http://faostat.fao.org]). The phylogenetic proximity of *A. hypogaea* with *Aeschynomene* should allow knowledge transfer to this species with the goal of improving its nodulation efficiency. This work is a part of the valuation of tropical legumes, less studied than their temperate counterparts, while presenting an alternative symbiotic infection process. Understanding these mechanisms is a bottle neck in the current state of research on the ability to transfer the symbiotic nitrogen-fixation to nonlegume plants with the goal to improve agricultural production in a sustainable and environmentally way (Beatty and Good, 2011; Charpentier and Oldroyd, 2010; see also Chapters 5, 108, 109).

46.1 INTRODUCTION

Farmers in most developed countries are recommended to minimize nitrogen fertilization for environmental sake, whereas those in less developed countries cannot afford it in large agricultural areas. Thus, symbiotic nitrogen fixation (SNF) by legumes that already constitute a major input into agricultural and natural ecosystems may provide an ecologically acceptable complement or substitute for mineral nitrogen fertilizers. However, P deficiency is a major limiting factor for legume production where legume N nutrition largely depends on the rhizobial symbiosis, particularly in acidic and calcareous soils. Thus, low-soil P availability is a primary constraint to legume productivity in many low-input systems. It is also a limitation in high-input systems where soil chemistry converts the fertilizer P into less available forms, so that high P fertilization is inefficiently applied.

A possible explanation is that legumes have higher P requirements than nonsymbiotic plants (Vadez et al., 1996). Nevertheless, for common bean, it is possible to improve its SNF potential and expression under P deficiency (Pereira and Bliss, 1987; Vadez et al., 1999). However, the large genetic diversity of growth habits and duration, from bushy determinate to climbing indeterminate types, was not fully explored in the putative nine distinct gene pools of the species (Singh, 1991). In this study, we synthesize recent experiments that were performed in glasshouse hydroaeroponic culture in order to screen for genotypic diversity in P use efficiency (PUE) for SNF in *Phaseolus vulgaris*, *Vigna subterranea*, and *Medicago truncatula* and to search for candidate genes that may contribute to PUE for SNF. The nodulation and growth of the most contrasting recombinant inbred lines (RILs) were measured in field with multilocation participatory testing in various cultural systems of South France and North Africa in relation to soil P availability.

46.2 METHODS

46.2.1 Hydroaeroponic Culture of Nodulated Legume in Glasshouse

Legume seeds were surface-sterilized in 3% Ca hypochlorite for 30 min and subsequently washed with sterile distilled water. They were germinated in a Petri dish with 0.8% YEM Agar media. Selected uniform seedlings of each RIL were inoculated by soaking them 30 min into 100 ml broth containing around 10^8 cells ml^{-1} of one specific reference rhizobial strain as previously described for common bean (Hernandez and Drevon, 1991), cowpea (Alkama et al., 2009), and the *M. truncatula* model legume (Aydi et al., 2004).

Roots of inoculated seedlings were passed carefully through pierced rubber stopper, fixed with cotton fitted around the hypocotyl, and placed upon the topper of a $0.40 \times 0.20 \times 0.20$ m vat receiving 20 plants before transplanting into a temperature-controlled glasshouse. They were transferred during the third week into 1 l serum bottles for individual-plant culture until harvest during the sixth week when they had reached the flowering stage (R6-7). For microsymbiont assessment, nodulated seedlings were immediately placed into a 1 l serum bottle, just after germination and inoculation. The nutrient solution was intensely aerated with 400 ml compressed air per minute per liter solution and maintained around pH 7 through the addition of 1 g $CaCO_3$ per liter solution. The vats and bottles were distributed in a block design.

The symbiotic plants received 1 L $plant^{-1}$ of the nutritive solution from Hernandez and Drevon (1991), complemented with sterile distilled water and renewed every week. The solution contained 1 mmol urea starter N during the first 2 weeks and at transplanting into bottles. Thereafter, plants were grown with N-free nutrient solution. The starter urea concentration depended on legume spp. Every week, the deficient or sufficient P treatments were applied as KH_2PO_4

of which the amount in micromole plant^{-1} depended on legume spp.

46.2.2 Nodule *In Situ* Reverse Transcription and PCR Amplification

Three-millimeter-diameter nodules were harvested from 5-week-old plants in glasshouse and were thoroughly washed with diethyl pyrocarbonate (DEPC) treated water. They were then fixed overnight at 4 °C in tubes containing freshly prepared PFA (2% [v/v] paraformaldehyde, 45% [v/v] ethanol, and 5% [v/v] acetic acid).

Fixed-nodule sections were washed four times with DEPC-treated water under agitation during 5 min followed by 10 min twice to remove PFA. Thereafter, the nodules were included in low-melting agar 9% [m/v], dissolved with filtered phosphate-buffered saline (PBS) solution 1×, and cut into 50 µm sections. The nodule sections were transferred in tubes containing 0.5 ml of DEPC-treated water where the rest of agar was removed by three washings with DEPC-treated water at 60 °C. Then, the sections were added with 40 µl RT mix [8× buffer [5×], 1.25 dNTP [10 mM], 0.4 dig-11-dUTP, 3 Primer rev [10 µM], 6.7 DEPC-treated water], heated at 65 °C for 5 min, and then placed in ice for 2 min before the reverse transcriptase was added to each sample to a final concentration of 5 µmol l^{-1} before incubation at 42 °C for 1 h. Negative controls (NRT) were prepared by omitting the reverse transcription.

After reverse transcription, the RT mix was removed, and the samples were washed three times with 100 µl DEPC-treated water. Then, the PCR reaction was performed in 20 µl of DEPC-treated water and 20 µl of PCR mix [4× PCR buffer [10×], 1.2 $MgCl_2$ [50 mM], 0.8 dNTP [10 mM], 0.4 dig-11-dUTP, 1 Primer dir [10 µM], 1 Primer rev [10 cM], 0.2 Taq Poly [5 U/µl], 10.4 DEPC-treated water] with 30 cycles thermocycling [95 °C for 3 min; 95 °C for 30 s; 55 °C for 30 s; 72 °C for 45 s; 72 °C for 2 min] and at 20 °C for 5 min.

After amplification, the PCR mix was removed and the samples were washed three times with PBS 1×. Before detection of amplified cDNA, the samples were incubated in 100 µl of blocking solution (BSA 2% with triton 0.3% during 30 min under gentle agitation in darkness at 37 °C). Then the blocking buffer was removed and replaced by 100 µl of acid-phosphatase-conjugated anti-dioxygenin diluted 1 : 1000 in BSA [2%]. To remove anti-body excess, the samples were incubated during 90 min at room temperature and then washed during 5 min and 10 min twice with filtered PBS [1×].

Detection was carried out using the enzyme-labeled fluorescent ELF-97 endogenous phosphatase diluted 1 : 40 in the detection buffer, vigorously shaken, and filtered through a 0.22-µm filter. Samples were incubated in 20-µl ELF substrate–buffer solution for 20 min in the dark and transferred to washing buffer for three washings of 1 min, then mounted, and observed immediately with gray-scale view camera using ImageJ software as an image analysis program.

46.2.3 Nodular Diagnosis in Multilocation Participatory Field Assessment

From the screening in the glasshouse, two to six contrasting RILs were chosen for the multilocation field comparison. In each field, a homogeneous 20 by 10 m area was identified as a site. The RILs were sown in 2 m single-row within the local bean field in order to reduce border effects and to expose the RILs to similar environment and practices as the local bean cultivar. Up to 20 sites were chosen in each agroecosystem, constituting a randomized block design with each block being one farmer's site with RILs.

Like in glasshouse, nodulation and growth of the RILs were measured at the flowering stage when the first pod was 2 cm long for 50% of the plant population. Sampling was performed by excavating 20 cm in depth and around the root system of 10 plants per row, per block. Soil and plant samples were transferred in plastic bags and stored in a cold room until further analysis in laboratory.

The soil surrounding the roots was sorted from plants that were subsequently separated into shoot, root, and nodules. The plant parts were dried at 70 °C for 2 days. The available P of the soil was measured by the Olsen method according to standard NF ISO 11263 after extraction by soil agitation with a solution of sodium bicarbonate [0.5 M, pH 8.5].

Standard deviations were determined for all the traits. Analyses of variance and regressions were performed. Fixed effects in the analysis of variance were genotype and treatment or locations.

46.3 RESULTS AND DISCUSSION

46.3.1 Screening for N_2-dependent Growth in Low-P Controlled Environment

Following the initial screening with a common-bean core-collection (Vadez et al., 1999), the search for genotypes contrasting in PUE for SNF was performed in hydroaeroponics under glasshouse conditions with the population of the

cross between BAT477, tolerant to abiotic water-deficit, and DOR364, tolerant to biotic mosaic virus. A large diversity of adaptation to P deficiency was found with RILs 5, 6, 7, 12, 26, 28, 34, 60, 64, 75, 104, and 115 that were tolerant, in contrast with RILs 1, 4, 11, 24, 27, 29, 32, 37, 38, 62, 73, 83, 124, and 147 that were sensitive (Fig. 46.1). P deficiency decreased shoot/root ratio for all RILs (L'taief et al., 2012). Overall the RIL115 has been confirmed to be one of the most efficient genotypes with a mean N_2-dependent growth of 6 g DW $plant^{-1}$ under P deficiency, corresponding to a yield potential higher than 3 t grain ha^{-1}.

With similar methodology, RILs contrasting in PUE for SNF were found for *Vigna subterranea* (Fig. 46.2), *Vigna unguiculata* (Alkama et al., 2009), and *Medicago truncatula* (Mt) (Schulze et al., 2011). For these legume species, the value of optimal P was 75 and 30 µmol KH_2PO_4 pl^{-1} $week^{-1}$, respectively, whereas that for *P vulgaris* was 250 µmol KH_2PO_4 pl^{-1} $week^{-1}$.

Under controlled environment with starter N in hydroaeroponic culture, the growth of shoot could be expressed as a function of nodule growth as illustrated in Figure 46.3. The efficiency in use of the rhizobial symbiosis (EURS) is proposed as the slope of the linear part of the regression between plant growth and root nodulation. Thus, the EURS is the ratio of N_2-dependent growth/nodule mass. Indeed the growth depending on N_2 is the value of shoot biomass minus that corresponding to the growth of the plant without nodulation, that is, the growth exclusively due to the supply of N by the seed and the starter urea. The latter is estimated as the intercept of the curve with *Y* axis. Thus, the additional growth depended on the amount of N_2 fixed and the efficiency of its utilization.

Those genotypes having values above the mean EURS in Figure 46.3 were most efficient in PUE for SNF. They contrasted with those below the mean EURS that were the least adapted to P deficiency, especially those with low nodulation. Whatever the P supply, the mean EURS was higher for *M. truncatula* (Schulze et al., 2011) than, for *Vigna unguiculata* (Fig. 46.3) and for *Vigna subterranea*, meanwhile that for *Phaseolus vulgaris* being the lowest one (Drevon et al., 2011).

46.3.2 Physiological Characterization of Contrasting RILs

As illustrated in Figure 46.4, plants harbor various strategies to adapt to P deficiency. The external strategy links with the various processes involved with P acquisition, whereas the internal strategy links with distribution of P among plant organs and the efficiency of its utilization. For nodules, the internal strategy consists in optimizing the PUE for SNF.

In order to assess whether any phosphatase (APase) would be involved in the PUE for SNF, primers were designed from available sequences of candidate APase in the gene bank of *P. vulgaris* or other legume spp, including *Glycine max* and *M. truncatula*, for localization of the corresponding mRNA on cross nodule sections. The green signal in Figure 46.5a shows that phytase was expressed in nodules, and essentially localized in nodule cortex, both inner and middle. The higher increase in phytase signal (Lazali et al., 2013) and activity (Araújo et al., 2008) under P deficiency for the RIL115 compared to the less-efficient RIL147 suggests that the use of phytate in nodule cortex may contribute to P efficiency for the rhizobial symbiosis.

The expression of trehalose 6P APase in the outer-cortex of the nodule (Fig. 46.5b) might contribute to the control of various abiotic constraints by trehalose release (Bargaz et al., 2013), and that of phosphoenolpyruvate Apase (PEPase) (Fig. 46.5c) suggests inorganic P (Pi) mobilization from senescent cells (Bargaz et al., 2012). In the infected zone, both genes may supply Pi for bacteroidal metabolism. In the middle cortex, surrounding the internal cortex, the PEPase activation under P deficiency would not only supply additional Pi but also reduce active oxygen species through a nonenzymatic oxidative decarboxylation of pyruvate by hydrogen peroxide (Bargaz et al., 2012).

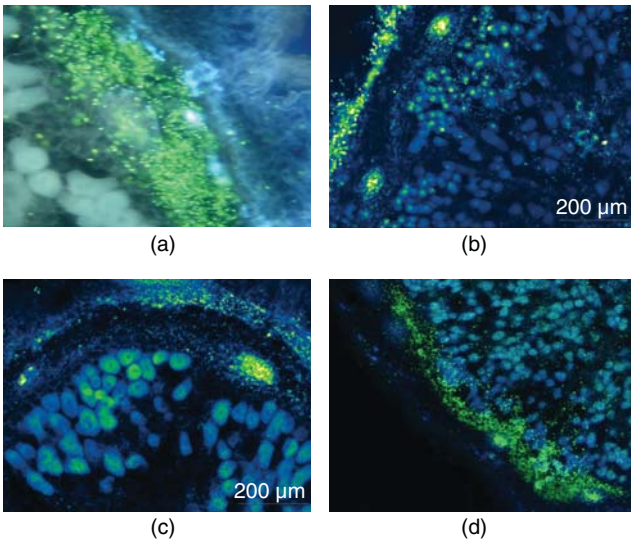

Figure 46.5 Transcript localization of phytase (a), phosphoenolpyruvate phosphatase (b), trehalose-6-phosphate phosphatase (c), and fructose-1,6-bisphosphate phosphatase (d) by *in situ* localization in nodule transversal section of the efficient common-bean RIL115.

All candidate genes of APases were intensely marked by fluorescence in the layers of inner cortex cells, that is, the tissue localized between vascular traces and the infected zone of nodule (Fig. 46.5). This reveals an intense metabolism of organic P in this tissue. It may supply Pi for the catabolism of sucrose from vascular traces into organic acids as the source of energy for bacteroids in the infected zone. Organic acids may also contribute as a source of energy and osmoticum for the turgescence of inner cortex cell that are presumed to be involved in the permeability of nodule cortex to gases (Serraj et al., 1995; Schulze and Drevon, 2005). Indeed this tissue has been suggested to be the oxygen barrier by regulating the entry of gases, in particular the O_2 that is involved in the respiratory synthesis of ATP for bacteroidal nitrogenase activity.

Thus, P deficiency was shown to increase the nodule conductance to O_2 diffusion, and the energetic cost of N_2 fixation under P deficiency in soybean (Ribet and Drevon, 1995)

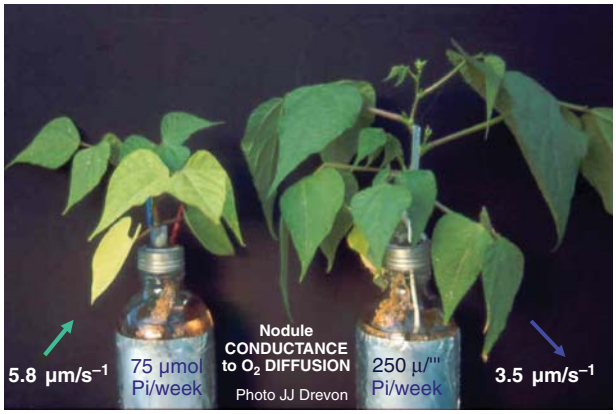

Figure 46.6 Effect of phosphorus deficiency on growth and nodule permeability to O_2 diffusion of common-bean inoculated with *R. tropici* CIAT899.

and *P. vulgaris* (Ribet and Drevon, 1995; Fig. 46.6) with the methodology described in detail in Jebara et al. (2005). This increase was concomitant with increase in gene expression of aquaporins (Fig. 46.7a) and carbonic anhydrase (Fig. 46.7b and c) in addition to APases. These results are consistent with the hypothesis of osmoregulation of the nodule conductance as illustrated in Figure 46.7d.

46.3.3 Field Observation of Contrasting RILs

The contrasting RILs 115 versus 147 were tested in fields in Lauragais (Southern France) during successive years with a participatory approach as described in Drevon et al. (2011). These RILs were also observed in organic horticultural farming of common bean in the Herault valley where, like in Lauragais, large variation in nodulation was found among sites as illustrated in Figure 46.8a. The simultaneous measurement of shoot and nodule biomass made it possible to establish the nodulation threshold for significant N_2 contribution to the growth of the plant, that is, the nodule mass below which no relation between growth of shoot and nodules was found. For the fields where the mean nodulation was above this threshold, a significant regression of shoot growth as a function of nodule mass was found (Fig. 46.8b), showing higher EURS for the efficient RIL115 than for the inefficient RIL147. This suggests that the selection for PUE and SNF may contribute to the improvement of the N_2-dependent growth of legumes in agro-ecosystems where low P in the soil is a limiting factor of SNF.

The contrasting RILs were also compared in agro-ecosystem of Kabylia. Four groups of soils could be identified from the analysis of physicochemical parameters: Group A for soils where N and P contents were high and nodulation was low, suggesting that nodulation was inhibited by high available mineral N that supported high plant growth

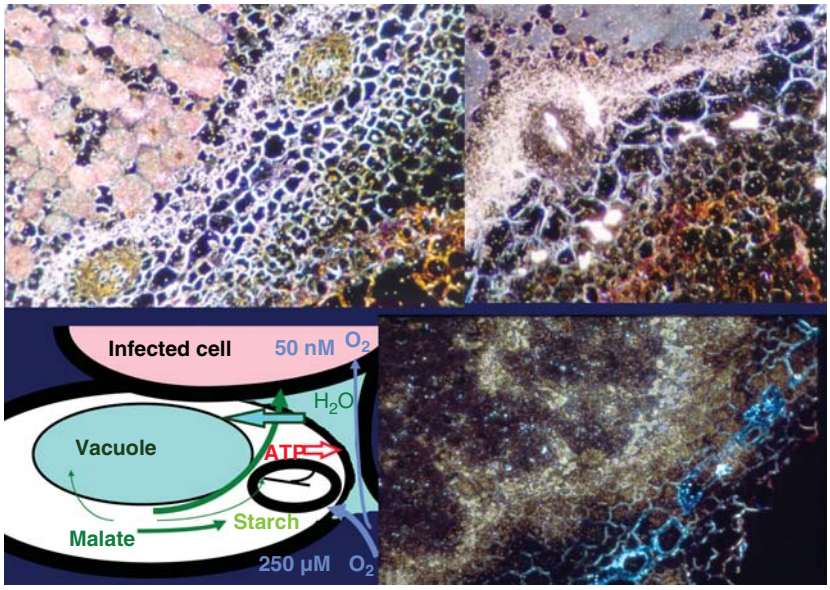

Figure 46.7 Transcript localization by *in situ* hybridization of aquaporin (a) and carbonic anhydrase under sufficient (b) versus deficient (c) phosphorus supply (Schump et al., 2003), and the hypothesis of osmoregulation of the nodule permeability (d) for the efficient common-bean RIL115.

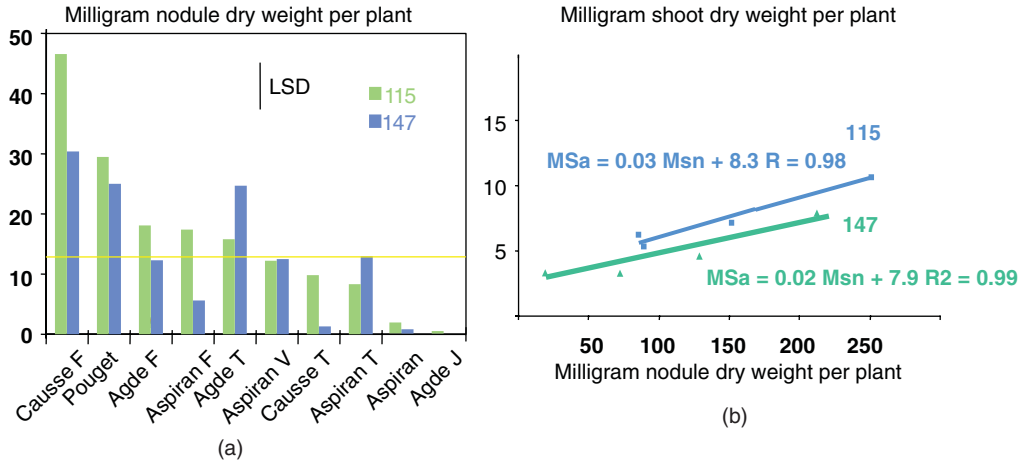

Figure 46.8 Spatial variation of nodulation (a) and the relationship with growth (b) of contrasting RILs 115 and 147 of *P. vulgaris* in Hérault valley in 2006.

without N_2-dependance; Group B for soils where N content and nodulation were low, although soil P content was not particularly low, suggesting that the low nodulation might be attributed to low population of native rhizobia and that rhizobial inoculation could be tested; Groups C for soils with relatively low P and N contents and low plant growth and nodulation, though nodulation was higher than in groups A and B, suggesting that low nodulation might be due to low soil P content; Group D for soils with higher P content than Group C, where nodulation and growth were the highest with relatively low soil N content. For C and D soil groups, a relationship between mean nodulation and Olsen P contents was found (Fig. 46.9).

46.3.4 Interactions with Soil Microorganisms

In order to assess whether the rhizobia may influence the use of P for nitrogen fixation, cross-inoculation trials were performed with rhizobia isolated from agro-ecosystems. Thus, some rhizobia were found to compensate the low PUE for SNF of such genotypes as RIL124 (Fig. 46.10). This suggests that the genotype of not only the macrosymbiont, that is, plant, but also the microsymbiont, that is, rhizobia, may contribute to the PUE for SNF.

In order to assess whether rhizobial phosphatase could be involved in this contribution, primers were designed for

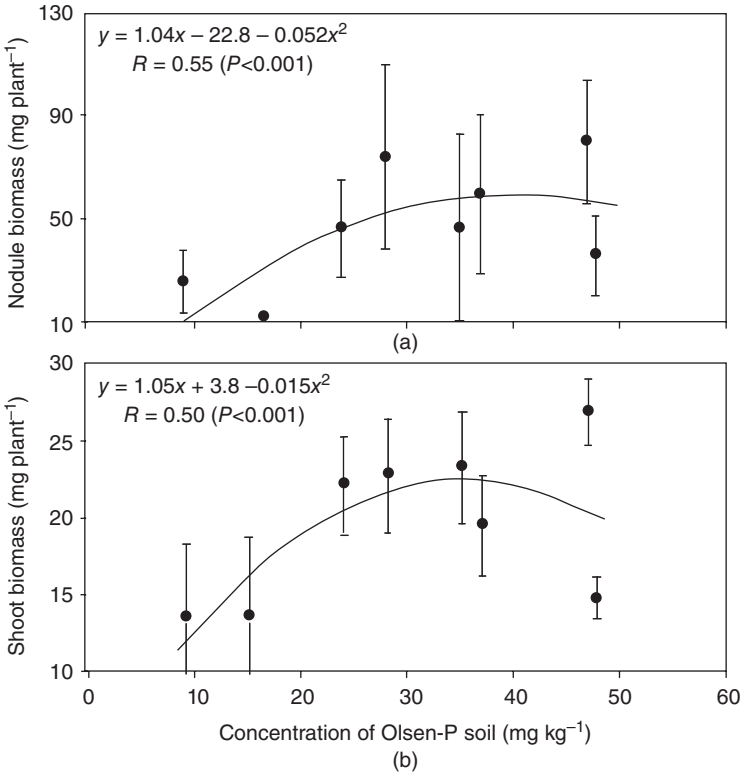

Figure 46.9 Nodule (a) and shoot (b) biomasses, versus concentration of Olsen P in soil, for El Djadida (Dj) and the RILs 147, 124, 115, 104, 83, 75, and 7 through multilocation test in Kabylia (Algeria). Data are means and SD of 10 replicates collected at flowering stage for each line and site.

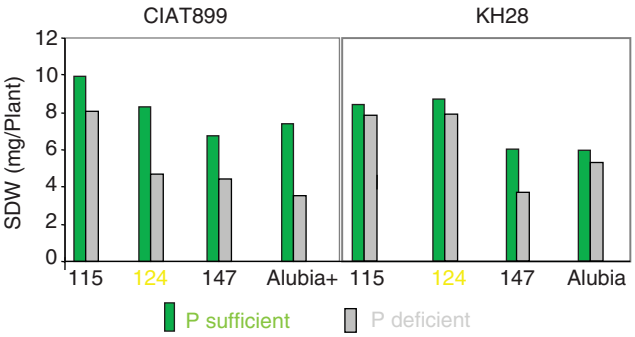

Figure 46.10 Native rhizobia KH28 increases the tolerance to P deficiency for common-bean RIL124 and Alubia (Zaman-Allah et al., 2006).

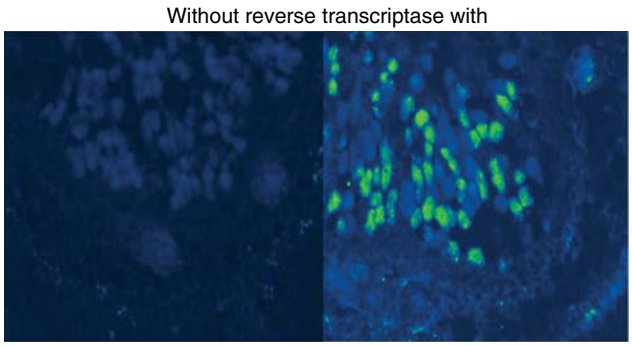

Figure 46.11 Localization of transcripts (green fluorescent signal) of rhizobia acid phosphatase in nodule transverse sections of the efficient common-bean RIL115 (left) versus the deficient common-bean RIL147 (right) as a function of P treatments. bacterial APase from sequences of whole genome of various rhizobia. The green signal in Figure 46.11 shows that the acid phosphatase was expressed in some infected cells of the nodule infected zone.

As the mycorrhizal partner may influence the PUE for SNF, the tripartite symbiosis was examined in hydroaeroponic culture after preculture in sandlike, described in details in Tajini et al. (2009). The effect of mycorrhizal infection on nodulation varied according to species, *Glomus intraradices* being the most efficient whereas *Gigaspora* sp. was detrimental whatever the RILs.

In order to assess whether the variation in PUE for SNF might alter the soil P availability, the Olsen P was measured in the rhizosphere soil separated from the nodulated roots during the nodular diagnosis. Some fields of Herault valley were found with higher P availability in the soil interacting with nodulated roots of RIL115 than in that of RIL147 (Fig. 46.12). This suggests that the high PUE for SNF of RIL115 has stimulated the mechanisms associated with root for transformation of soil organic P and mineral P into soluble Pi as the only source of P that the roots can absorb. Whether those mechanisms would be due to rhizospheric microorganisms, or exclusively due to root excretions, remains to be established in our experiments.

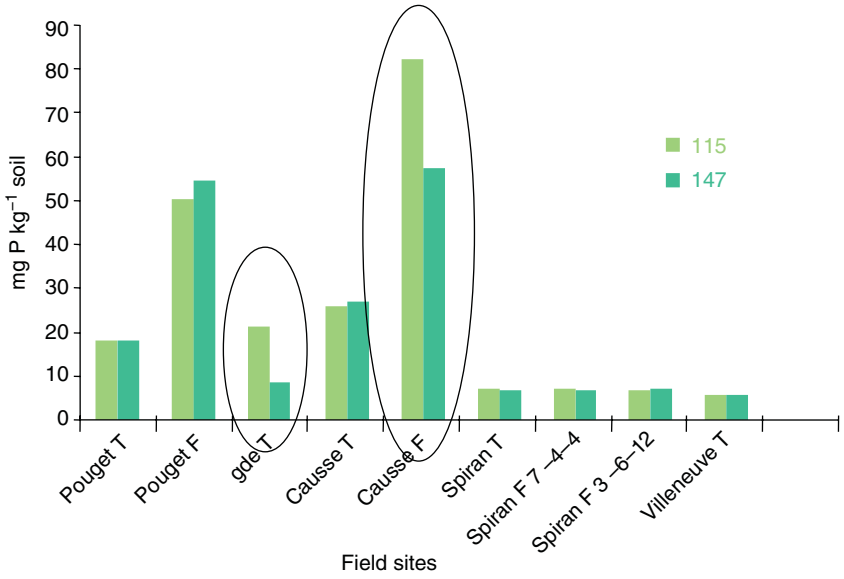

Figure 46.12 Differences in Olsen P among field sites and RIL rhizosphere in Herault valley.

In other fields (Fig. 46.12), Olsen P was comparable for both RILs, suggesting that some soil microbes may have compensated the effects of low PUE on soil P availability for RIL147. Therefore, P-solubilizing rhizospheric bacteria or fungi could be isolated preferentially from those soils in order to test subsequently in hydroaeroponics whether they do contribute to the increase in Olsen P.

46.4 CONCLUSION

Genotypic variations in PUE for SNF could be found in hydroaeroponics among various legume species, including so far *P. vulgaris*, *V. unguiculata*, *V. subterranea*, and the model legume *M. truncatula*. Therefore, this parameter may be suggested to legume breeding in order to ensure that selected legumes have high potential for N_2 fixation and efficient use of P. Thus, the phosphorus is becoming a scarce, nonrenewable resource. Our physiological work suggests that some APases may contribute to P efficiency for SNF in nodules. This is the case of the plant phytase that we recently discovered in common bean nodule. More studies are therefore needed on the diversity of plant phosphatases in nodules and their contribution to the N_2 fixation process and the adaptation of nodulated legumes to P deficiency. Among the mechanisms involved in this adaptation is the regulation of the nodule permeability to O_2 with the following hypothesis of osmoregulation of the FSN: The energy metabolism determining the symbio-rhizobial nitrogen fixation was regulated by the variations of the cellular volume of the inner nodular cortex (parenchyma surrounding the infected zone), which changed the nodular permeability modifying the twisting of the intercellular spaces of the cortex through which O_2 diffuses (Fig. 46.5). The variations in cellular volume would be determined by the internal variations in nitrogen demand of the plant. They could also be affected by the variations in physicochemical environment of the nodules.

The multilocation tests show that the genotypes with high PUE for SNF do better adapt to low-P soils. This confirms that the *in vitro* selection of high PUE and SNF in hydroaeroponics is a methodology to breed for legumes with potentially better adaptation to low-P soils. However, the tests also show some fields where less-efficient genotype may adapt probably because of beneficial interactions with soil microbes. Thus, the fields where the nodulation of the least efficient symbiosis was as high as that of the most efficient symbiosis, as illustrated in Figure 46.8, may be the source of efficient microbes to compensate for low P efficiency of the plant. Therefore, nodules and roots of the plants sampled on these soils have been preserved in order to identify their rhizobia, mycorrhiza, and rhizobacteria.

These microbes will be subsequently tested in hydroaeroponics in order to assess whether they do contribute to the adaptation to P deficiency and whether they harbor candidate phosphatase genes for adaptation to low-P soils. If they would confirm such potential, then these microbes could be considered for inoculation tests in those fields where the genotypes with low PUE for SNF did perform weakly. Such an approach could lead to precision inoculation, consisting of transferring beneficial local microbes to the fields where the requirement for inoculation has been established by the nodular diagnosis.

The earlier assessment of the contribution of soil microorganisms for P efficiency is based on the comparison in hydroaeroponics of their effect on the N_2-dependent growth of genotypes contrasting in PUE for SNF. This environment makes it possible to perform *in situ* open-flow gas

exchange measurements to assess the energetic metabolism supporting SNF as physiological basis of the efficiency. The localization and intensity of the expression of candidate microbial genes for P efficiency is possible by *in situ* RT-PCR, on the basis of our ongoing observation with phytases of rhizobia and *Bacillus subtilis*.

Overall, the earlier observations lead us to postulate the following hypothesis of a virtuous cycle of fertility due to be symbiotic and rhizospheric microorganisms associated with legumes: because legumes require P for their SNF, they would have developed intensive interactions with soil microorganisms for acquiring P from soil and the benefit of this cycle for soil fertility would increase with raising PUE for SNF.

47.1 INTRODUCTION

Nodules are root organs induced by rhizobia on legume roots, following the perception of specific Nod factors by the host. Similarly, actinorhizal plants form nodules in symbiosis with *Frankia* bacteria. It has been argued that because nodulation emerged recently during evolution, approximately 60 million years ago (Sprent, 2007; 2008), it is likely that the mechanisms that regulate nodule development were co-opted from existing developmental processes, most likely those that regulate lateral root development (Hirsch and LaRue, 1997), a process that has existed for approximately 400 million years (Raven and Edwards, 2001).

Nodules and lateral roots are formed post-embryonically from endogenous cell types that are triggered to divide, then form an organ primordium, and later differentiate and elongate. In the case of lateral roots, cell divisions first occur in the pericycle, a lateral root primordium is formed after further divisions, and the primordium differentiates into an organ with a central stele. An apical meristem becomes active and leads to lateral root elongation. Depending on the host species, nodule development can be based on modifications of existing lateral or adventitious roots or involve *de novo* induction of cell divisions in pericycle and cortical cells. Nodule development in the nonlegumes shows similarities to lateral root formation. In actinorhizal plants, *Frankia* first cause cortical cell divisions to form a pre-nodule that is colonized by hyphae, and then trigger pericycle cell divisions to form a lateral root-like nodule. *Frankia* invade the cortical cells of this nodule, which retains a central stele, similar to lateral roots (Pawlowski and Bisseling, 1996; see Chapters 42, 43, 55). In *Parasponia*, the only nonlegume known to

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

nodulate with rhizobia, the symbionts trigger the initiation of a lateral root that they later invade (Trinick, 1979; see Chapter 4). Nodule structures in legumes are diverse, as discussed later, and typically involve the initiation of a nodule from pericycle and/or cortical cells *de novo*, resulting in a nodule with peripheral vascular strands (Hirsch, 1992).

Two different nodule types have been studied in detail. Temperate legumes, for example, pea, clover, alfalfa, and the model legume *Medicago truncatula*, usually form indeterminate nodules, which are characterized by nodule initiation in the inner cortex and also usually the pericycle (Timmers et al., 1999). The resulting nodules form a persistent nodule meristem, which allows continuous growth and leads to the formation of elongated nodules. Determinate nodules are formed on many (sub)tropical species, including soybean, bean, and the model legume *Lotus japonicus*, and are initiated in the outer root cortex by cell enlargement and divisions. Cell divisions are later induced in the pericycle and inner cortex, and both cell division sites subsequently merge. These nodules are typically spherical because the nodule meristem differentiates and disappears (Rolfe and Gresshoff, 1988).

There is evidence that auxin is synthesized by the nitrogen-fixing symbionts themselves, including the actinomycete *Frankia* (Wheeler et al., 1984), *Azospirillum* (see Chapters 90, 91) and rhizobia (Kefford et al., 1960). More importantly, the symbiont indirectly alters auxin transport and localization inside the host root (Mathesius, 2008). For a general review on the role of hormones in nodulation (see Chapter 56).

If nodule development has been modified from the process of lateral root formation, it is likely that similar developmental signals regulate both processes. A key regulator of lateral root development is auxin (Casimiro et al., 2003; Fukaki et al., 2007). Auxin patterns in the plant are crucial for determining subsequent developmental patterns (Heisler et al., 2005). Auxin is not only a pattern-determining regulator but also controls cell division, cell elongation, and vascular tissue differentiation (Teale et al., 2006; Woodward and Bartel, 2005). It has long been suggested that auxin is also a regulator of nodule development (Hirsch, 1992; Hirsch and Fang, 1994; Thimann, 1936). There are several possible mechanisms by which rhizobia or *Frankia* symbionts could initiate nodule development through the involvement of auxin in the host, for example, through alteration of auxin synthesis, breakdown, signaling, or transport in the host (Mathesius 2008).

47.1.1 Regulation of Auxin Transport in the Plant

Auxin is thought to be mainly synthesized in young shoot tissues and transported from there to other tissues and organs, although many other tissues can also synthesize auxin (Ljung et al., 2002). Auxin can occur as the free active form, primarily indole acetic acid (IAA), or it can be conjugated for storage. Tracking of radiolabeled auxin indicates that transport of auxin from the shoot to the root tip occurs through the vascular tissue, while transport in the root from its tip to the elongation zone occurs through epidermal cells (Mitchell and Davies, 1975; Tsurumi and Ohwaki, 1978). In addition to long-distance auxin transport, local transport of auxin along and across tissues is important for auxin localization in small groups of cells, for example, in an emerging lateral root (Grieneisen et al., 2007; Jones, 1998). Although auxin can be transported within the plant via the phloem from source to sink tissues, polar auxin transport can be regulated specifically by polar-active transport (PAT) through auxin transport proteins.

Auxin is a weak acid; when present in the acidic cell wall environment, it occurs as the protonated form (IAAH) and can enter cells partially by diffusion. It can also be actively transported into cells by auxin importers of the amino acid permease families AUX1 (auxin resistant 1), LAX (like-AUX1), and PGP4, a member of the MDR/PGP (multidrug resistance/P-glycoprotein) families (Terasaka et al., 2005; Yang et al., 2006). AUX1 has been suggested to play a role in auxin unloading from the phloem and loading into the PAT system (Swarup et al., 2001).

Due to the higher pH inside the cytoplasm, deprotonated auxin (IAA^-) cannot diffuse out of a plant cell but requires active export by transporters of the PIN (Pin-formed) and PGP families (Geisler et al., 2005; Petrasek et al., 2006). The polarity of auxin transport is established by the polar localization of PIN proteins on either the basal or apical side of the cell (Wisniewska et al., 2006). Different members of the PIN family are localized in a cell- and developmental-specific pattern, for example, PIN1 is localized on the apical side of vascular cells in the root and mediates acropetal auxin flow, whereas PIN2 is localized at the basal side of epidermal cells in the root tip where it mediates basipetal auxin flow. Mutations or misexpression of *PIN* genes have been shown to cause changes in local auxin accumulation and plant development (Friml, 2003; Vieten et al., 2007).

Auxin export can be inhibited by synthetic and natural auxin efflux inhibitors, including NPA (1-*N*-naphthylphthalamic acid) and TIBA (2,3,5-triiodobenzoic acid), which bind to the so-called NPA-binding proteins (NBPs). The NBPs have been suggested to interfere with PIN activity through a possible third protein (Muday and DeLong, 2001). AEIs (auxin export inhibitors) also affect auxin transport by inhibiting actin dynamics, which are required for PIN cycling (Dhonukshe et al., 2008). In addition, NPA inhibits auxin export by binding to MDR/PGPs (Geisler et al., 2005; Murphy et al., 2002; Noh et al., 2001). Flavonoids are a class of natural AEIs, some of which have been shown to regulate

PIN activity and localization in *Arabidopsis* (Peer and Murphy, 2007). Flavonoids with specific structures, especially flavonols, have been found to inhibit auxin transport by competing with synthetic AEIs for plasma membrane and microsomal binding sites (Bernasconi, 1996; Jacobs and Rubery, 1988; Stenlid, 1976). Flavonoids are likely to have several targets in plant cells, as they have been shown to interact with PGP auxin transport proteins (Bernasconi, 1996) as well as with an aminopeptidase (Murphy and Taiz, 1999). The flavonol quercetin enhanced auxin uptake by PGP4 in a heterologous system (Terasaka et al., 2005) and reduced auxin export by PGP1 in a manner similar to that of NPA (Geisler et al., 2005). In *Arabidopsis*, the lack of flavonoids alters the expression and localization of certain PIN proteins, and it has been suggested that flavonoids could act by targeting PIN intracellular cycling (Peer et al., 2004). Auxin has also been shown to increase *PIN* gene expression in a positive-feedback loop (Vieten et al., 2005). Studies in flavonoid-deficient *Arabidopsis* mutants confirm that these plants have higher rates of auxin transport, whereas mutants overaccumulating flavonols show decreased auxin transport rates (Brown et al., 2001; Murphy et al., 2000; Peer et al., 2004). Flavonoids are likely to link auxin transport with changes in the environment because flavonoids are accumulated in response to a variety of biotic and abiotic stimuli (Buer and Muday, 2004; Taylor and Grotewold, 2005). The colocalization of flavonoids at sites of high auxin concentration supports their role in auxin transport control (Buer and Muday, 2004; Buer et al., 2006; Murphy et al., 2000; Peer et al., 2001).

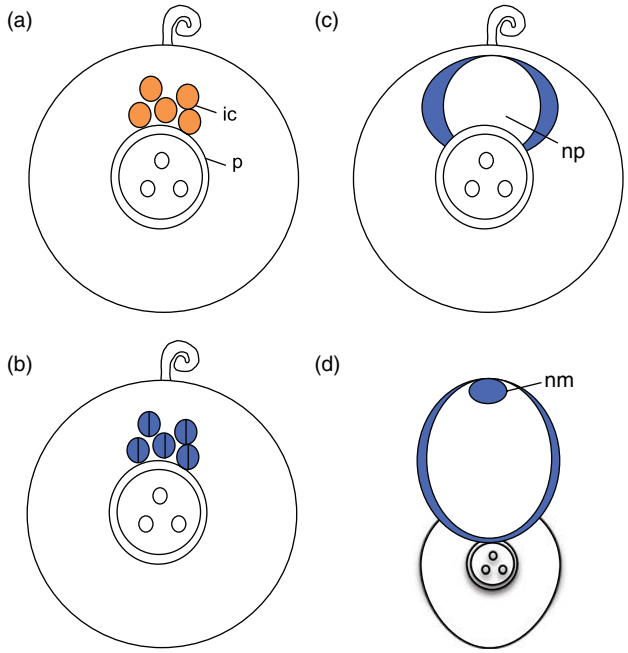

Figure 47.1 Schematic diagram showing areas of auxin accumulation in indeterminate nodule formation. (a) Flavonoid accumulation (orange) in nodule precursor cells preceding cell division. (b) Auxin accumulation (blue) in early dividing cortical cells. (c) Auxin accumulation in young nodule primordia becomes restricted to the nodule periphery. (d) Auxin accumulation in mature nodules is restricted to vascular tissue at the nodule periphery and the nodule meristem. ic = inner cortex; p = pericycle; np = nodule primordium; and nm = nodule meristem. The curled root hair at the top of each section indicates the inoculation site.

47.1.2 Rhizobia Alter Auxin Responses During Nodule Development

Auxin was first connected with the formation of nodule legumes with the discovery of increased auxin concentrations in mature nodules (Thimann, 1936). Since then, auxin response genes, for example, *DR5* and *GH3*, have been used to map the detailed auxin responses, presumably reflecting auxin distribution, during nodule development (Fig. 47.1). In white clover, which forms indeterminate nodules, rhizobia causes a reduction in *GH3* activation at and below the site of infection within 10 h after infection (Mathesius et al., 1998b). This is followed by an increase in expression at the site of nodule initiation 24 h after inoculation. Similarly, *DR5* expression appears to be interrupted below the site of nodule initiation in *M. truncatula*, but increases in a developing nodule (Huo et al., 2006). *GH3:GUS* expression has been observed in the early dividing pericycle and cortical cells of a forming nodule in white clover (Mathesius et al., 1998b) and in *M. truncatula* (van Noorden et al., 2007). *GH3:GUS* expression is high in the early nodule primordium of white clover, but low in the center of a differentiating nodule, remaining only in the nodule meristem and the vascular bundles (Mathesius et al., 1998b). Similarly, high *GH3:GUS* expression has been found in the dividing outer cortex cells in *L. japonicus* (Pacios-Bras et al., 2003; Takanashi et al., 2011), and more recently a sensitive *DR5:GFP* reporter was used to localize auxin responses in the earliest dividing cortical cells in *L. japonicus* (Suzaki et al., 2012). During later stages of determinate nodule development, *GH3:GUS* and *DR5:GFP* expressions are present in peripheral vascular tissue and meristematic cells (Pacios-Bras et al., 2003; Suzaki et al., 2012; Takanashi et al., 2011). Interestingly, *DR5:GUS* expression is altered in *M. truncatula* mutants with altered vascular bundle formation, confirming the idea that auxin localization is important for vascular bundle differentiation in developing nodules (Guan et al., 2013).

The use of nodulation mutants has shown that the auxin responses in early nodule primordia are always associated with the ability to form cell divisions. For example, in spontaneous nodule-forming mutants of *L. japonicus*, auxin responses have been found in the cortex, whereas in nonnodulating mutants no such responses were seen (Suzaki et al., 2012). Computer modeling of the auxin maximum

formed in inner or outer cortical cells of indeterminate and determinate nodule types has been used to investigate whether experimentally observed auxin responses are likely to result from increased auxin synthesis, reduced auxin export, or increased auxin import into the cortical cells. The study concluded that the broad auxin maximum seen in the cortex during nodule initiation is most likely due to decreased auxin efflux from these cells (Deinum et al., 2012; see Chapter 66). In addition, the changes in auxin accumulation in the inner and outer cortex, observed in indeterminate and determinate legumes, respectively, could be explained by slight lateral shifts in auxin exporter localization.

47.1.3 Regulation of Auxin Transport Preceding Nodule Initiation

The observed changes in auxin response, most likely reflecting auxin accumulation, during nodule development are regulated by the plant upon Nod-factor perception and are most likely due to changes in auxin transport. In several legumes, it has been observed that synthetic auxin transport inhibitors can induce nodules spontaneously in the absence of rhizobia (Allen et al., 1953; Rightmyer and Long, 2011; Wu et al., 1996), and this is accompanied by similar expression of certain nodulation genes as in normal nodules (Hirsch et al., 1989). In addition, the reduction of *GH3* expression observed during the early stages of indeterminate nodule formation can be mimicked by Nod factors and the synthetic auxin transport inhibitor NPA (Mathesius et al., 1998b). These findings suggest that rhizobia inhibit auxin transport in legumes forming indeterminate nodules before the onset of cell divisions. This is supported by measurements of radiolabeled auxin transport in roots of *Vicia sativa*, which shows that rhizobia, and specifically functional Nod factors, inhibit polar auxin transport within 24 h of inoculation (Boot et al., 1999). Similarly, a local inhibition of auxin transport has been found in *M. truncatula* following spot-inoculation of the susceptible root zone (van Noorden et al., 2006; Wasson et al., 2006). However, no inhibition of auxin transport was detectable in the legume *L. japonicus*, which forms determinate nodules, before nodule initiation (Pacios-Bras et al., 2003). Known regulators of auxin transport are flavonoids (Jacobs and Rubery, 1988), ethylene (Burg and Burg, 1966), and cytokinin (Laplaze et al., 2007). Rhizobia induce the accumulation of flavonoids (Mathesius et al., 1998a), ethylene (Ligero et al., 1987), and activate cytokinin signaling (Plet et al., 2011) during nodulation.

Flavonoids are induced in the cortical and pericycle precursor cells of a nodule after inoculation of nodulating rhizobia or Nod-factor treatment (Mathesius et al., 1998a). Flavonoids also accumulate in the cortex after treatment of white clover roots with cytokinin, which induces cortical cell divisions (Mathesius et al., 2000). To test if flavonoids are required for auxin transport inhibition by rhizobia, the first enzyme of the flavonoid biosynthetic pathway, chalcone synthase, was silenced using RNA interference in *M. truncatula* (Wasson et al., 2006). The resulting flavonoid-deficient roots do not nodulate and auxin transport inhibition by rhizobia is not observed, confirming that flavonoids are necessary for nodulation and for auxin transport inhibition during indeterminate nodule development in *M. truncatula* (Fig. 47.2). Silencing of sub-branches of the flavonoid pathway in *M. truncatula* suggests that it is most likely the flavonols that are responsible for auxin transport regulation (Zhang et al., 2009). The flavonol kaempferol is upregulated following rhizobia inoculation, and exogenous application of kaempferol is able to restore auxin transport control in flavonoid-deficient roots and rescue nodulation (Zhang et al., 2009). Silencing of the isoflavonoid pathway in soybean has shown that isoflavonoids are crucial for nodulation as Nod gene inducers, but are unlikely to be required for auxin transport regulation in the development of a determinate nodule (Subramanian et al., 2006). As auxin transport inhibition is not detectable after rhizobia inoculation in soybean (Subramanian et al., 2006) or *L. japonicus* (Pacios-Bras et al., 2003), it is possible that the inhibition of auxin transport is unique to legumes forming indeterminate nodules (Subramanian et al., 2007; Wasson et al., 2006).

Ethylene acts as a negative regulator of nodulation (Guinel and Geil, 2002). The effect of ethylene is local, that is, ethylene acts in the root, as established by grafting experiments (Prayitno et al., 2006). The ethylene-insensitive *sickle* mutant of *M. truncatula*, which hypernodulates (Penmetsa and Cook, 1997), still shows auxin transport inhibition at the root tip following inoculation with rhizobia (Prayitno et al., 2006), consistent with the requirement of auxin transport inhibition for nodule initiation. Within 24 h, an increase in auxin transport observed in wild-type roots is exaggerated in *skl*, and this was accompanied by an increased expression of *PIN2* and an increased number of nodules initiated at the site (Prayitno et al., 2006). This suggests that ethylene synthesis and/or perception could downregulate the auxin accumulation at the site of nodule initiation (Fig. 47.2).

Cytokinin is known to interfere with auxin accumulation during lateral root initiation by altering PIN gene expression (Laplaze et al., 2007). In the cytokinin-insensitive and non-nodulating *M. truncatula* mutant *cre1*, auxin transport is elevated and auxin transport inhibition by rhizobia is abolished (Plet et al., 2011). This is accompanied with altered *PIN* gene expression and localization, suggesting that cytokinin signaling acts upstream of auxin transport regulation. This is supported by results from *L. japonicus*, where *DR5:GUS* expression was observed in spontaneous nodules in the *snf2* mutant, which shows constitutive cytokinin signaling (Suzaki et al., 2013; Suzaki et al., 2012). In addition, other Nod-factor signaling components act upstream of auxin transport regulation because synthetic auxin transport

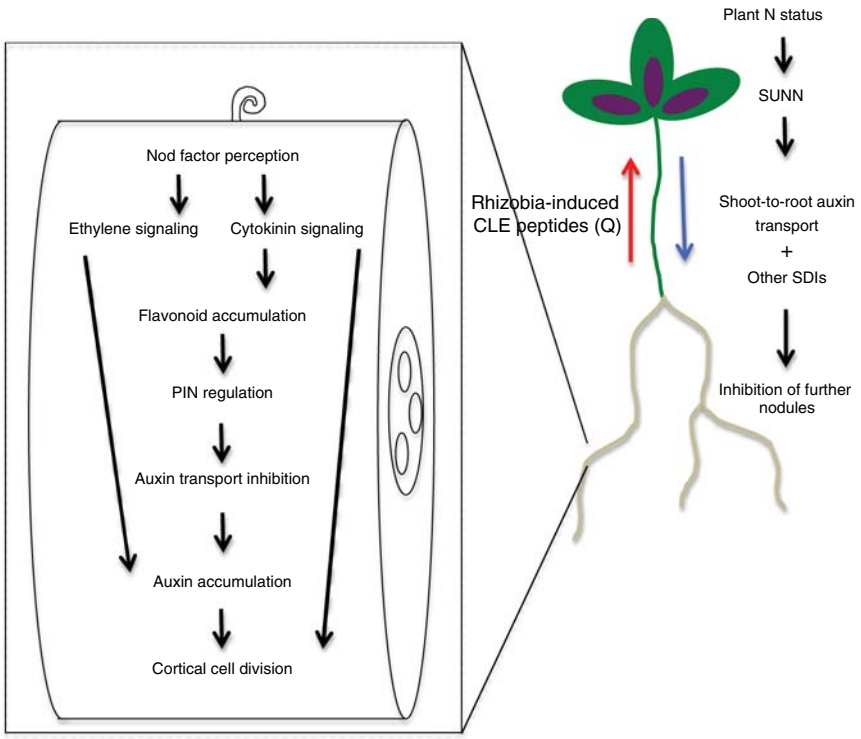

Figure 47.2 Simplified diagram showing the major known steps in local and long-distance auxin transport regulation in indeterminate nodule types. Upon inoculation with rhizobia (curled root hair) and early Nod-factor signaling, both ethylene and cytokinin signalings are activated. Ethylene signaling has been shown to affect auxin accumulation by increasing local auxin transport. Cytokinin signaling most likely acts upstream of auxin transport changes and also most likely upstream of the accumulation of flavonoids, which are hypothesized to regulate auxin transport via changes to PIN protein activity. Following the transient inhibition of auxin export at the inoculation site, auxin accumulates in inner cortical cells, and this is associated with the division of these cortical cells. At a so far undefined step during this local induction of nodulation responses, a signal is sent to the shoot, most likely a CLE-related peptide, which directly or indirectly activates autoregulation via NARK (SUNN in *M. truncatula*). This, together with the plant N status, controls the shoot-to-root auxin transport that is associated with further inhibition of nodulation. Other shoot-derived inhibitors (SDIs) are also likely to be involved in this autoregulation.

inhibitors are able to induce pseudonodules in a range of early nodulation mutants including *nfp, lyk3, dmi1, dmi2, dmi3, nin,* and *rit1,* but not in the ethylene-insensitive mutant *skl* (Rightmyer and Long, 2011).

47.1.4 The Role of Auxin in Nodule Initiation and Differentiation

Auxin transport inhibition preceding nodule initiation is followed by increased auxin transport and increased auxin responses at the site of nodule initiation (Mathesius et al., 1998b). Increased auxin concentrations are also found within 24 h of inoculation in bean (Fedorova et al., 2000), and strong induction of two auxin hydrolases, which release active auxin from conjugate forms, has been found within 24 h of inoculation in *M. truncatula* (Campanella et al., 2008).

Retention of auxin in dividing cells might be mediated by flavonoids in the nodule precursor cells and early primordia. Certain flavonoids and simple phenolics can inhibit the action of peroxidases and auxin oxidases that break down active forms of auxin (Furuya et al., 1962; Grambow and Langenbeck-Schwich, 1983), and it has been shown *in vitro* that those flavonoids accumulating in the inner cortical cells of white clover inhibit auxin breakdown by peroxidase (Mathesius, 2001).

However, modeling suggested auxin transport regulation to be the more likely driver of creating auxin maxima in the cortex (Deinum et al., 2012; see Chapter 66). Localization of members of the auxin import protein family MtLAX showed that this transporter is strongly expressed in young nodule primordia in *M. truncatula* (de Billy et al., 2001). Similarly, the expression of the auxin export proteins PIN1 and PIN2 is localized in early nodule primordia in *M. truncatula*, and their silencing by RNAi leads to a reduction in nodule numbers (Huo et al., 2006). These studies strongly suggest a role of active auxin transport into the initiating nodule.

As the nodule primordium differentiates, auxin responses become restricted to peripheral cell layers of the primordium (see Fig. 47.1d). In mature nodules, auxin

responses are localized in vascular tissues, and the apical meristem and these expression patterns are similar to those in differentiating lateral roots (Mathesius et al., 1998b; Pacios-Bras et al., 2003). The expression pattern of the auxin importer *MtAUX1* is similar to the high expression in peripheral tissues of a nodule and central tissues of lateral roots, indicating that expression overlaps with regions of vascular tissue or endodermal differentiation (de Billy et al., 2001). As in lateral root formation, the changes in auxin responses suggest that auxin concentrations or responses must drop at the differentiation stage relative to the primordium initiation phase (Laskowski et al., 1995). The loss of auxin concentration in central parts of legume nodules could be regulated by peroxidases that destroy auxin accumulating inside the nodule (Fedorova et al., 2000; Mathesius, 2001).

The localization and role of auxin during legume nodulation differs from that in actinorhizal nodules. Examination of *AUX1* in *Casuarina glauca*, which forms nodules with *Frankia*, showed that its expression is localized to infected cells, first in the pre-nodule in cortical cells and later in the nodule (Peret et al., 2007). A possible role of the high auxin levels in infected cells has been suggested to be in controlling cell hypertrophy or cell wall remodeling during infection (Peret et al., 2007). However, *AUX1* expression is absent from nodule primordia, even though the same gene is strongly expressed in lateral root primordia in *Casuarina*. These studies suggest that actinorhizal nodules and lateral roots might require distinct auxin responses for their differentiation. Later studies have shown that a *PIN1*-like gene is specifically expressed in noninfected cells of the actinorhizal nodule (Perrine-Walker et al., 2010). Coupled with computational modeling data, the authors suggested that a PIN1-like and AUX1 protein in *C. glauca* act in concert to actively restrict auxin accumulation in *Frankia*-infected cells. Although isoflavones were found to play a role during *Frankia*-induced nodule formation in *C. glauca*, it remains unclear whether they are necessary for auxin transport regulation (Auguy et al., 2011). In the actinorhizal plant *Eleagnus umbellata*, high levels of an auxin-responsive protein have been found in the nodule-fixation zone, although it remains uncertain whether this expression pattern reflects actual auxin concentrations (Kim et al., 2007). The regulation of auxin transport and accumulation in actinorhizal plants remain unclear, and there might be dual roles of the symbiont and the host in synthesizing auxin as well as controlling auxin transport (Peret et al., 2007).

47.1.5 Auxin as a Long-Distance Regulator of Nodule Numbers

Nodule numbers are regulated by several mechanisms, including nitrogen availability and autoregulation. If sufficient nitrogen is available to the plant, nitrogen uptake from nitrate or ammonium is preferred over the costly establishment of a nitrogen-fixing symbiosis. Both nitrate and ammonium inhibit nodulation at stages of infection, nodule development, and nitrogen fixation (Streeter, 1988). The mechanisms of this inhibition and whether auxin is involved in this inhibition are still unclear. It has been shown that nitrate regulates lateral root initiation and elongation by both local and systemic mechanisms, and that this regulation involves auxin signaling, suggesting that similar mechanisms might be involved in nodulation (Walch-Liu et al., 2006).

The plant also limits nodule numbers on the whole root system by an internal, systemic regulatory mechanism termed autoregulation of nodulation (AON), which is dependent on the action of a leucine-rich repeat receptor-like kinase (NARK, nodulation autoregulation receptor kinase) acting in the shoot (Kinkema et al., 2006). After the root first perceives rhizobia, autoregulation inhibits further formation of nodules on later forming roots, probably to limit the amount of carbon redirected toward nodules. Split-root experiments have shown that an early event during nodule formation sends a signal to the shoot, where it, or a derivative signal, is perceived by NARK and causes a shoot-derived inhibitor (SDI) to move back to the root system to limit further nodulation (Kinkema et al., 2006). Because auxin is transported from the shoot, where most auxin is synthesized, to the root, the role of shoot-to-root transported auxin was investigated for its role in autoregulation. The *M. truncatula* autoregulation mutant *sunn1* (*supernumeric nodules1*) (Schnabel et al., 2005) transports significantly more auxin from the shoot to the root than the wild type (van Noorden et al., 2006), and auxin concentrations in the root zone susceptible to nodule initiation are increased in the *sunn1* mutant. In addition, the auxin-response gene *GH3* is expressed at much higher levels in inoculated *sunn1* than in wild-type roots (Penmetsa et al., 2003). Within 24 h of inoculating the root tip with compatible rhizobia, long-distance auxin transport from the shoot to the root is reduced in wild-type seedlings, at the same time as the start of autoregulation in *M. truncatula* (van Noorden et al., 2006). However, this inhibition of long-distance auxin transport does not occur in the *sunn1* mutant, suggesting that SUNN regulates long-distance auxin transport changes in response to inoculation. Treatment of the shoot–root junction of *sunn1* with NPA causes a reduction in nodule numbers to levels similar to the untreated wild type (van Noorden et al., 2006). Consistent with these findings, *DR5:GFP* expression in *L. japonicus* was reduced in the autoregulation mutant *har1* and also in the overexpression *LjCLE* of roots constitutively, encoding peptides that likely activate NARK signaling (Suzaki et al., 2012).

The long-distance regulation of auxin transport during AON in legumes forming indeterminate nodules is regulated independently of local auxin transport inhibition that occurs

at the root tip within hours of inoculation and is necessary for the initiation of the first nodules on the root (Fig. 47.2). The *sunn1* mutant shows local auxin transport inhibition after inoculation with rhizobia similar to the wild type, despite the difference in long-distance transport (van Noorden et al., 2006).

Nodule numbers are also regulated by ethylene, as demonstrated in the hypernodulation phenotype of the ethylene-insensitive *skl* (*sickle*) mutant (Penmetsa and Cook, 1997). The gene mutated in the *skl* mutant has been shown to encode an ortholog of the *Arabidopsis* ethylene signaling protein EIN2 (Penmetsa et al., 2008). Long-distance auxin transport was similar to that in wild type in uninoculated *skl* plants, whereas the downregulation of auxin transport observed in wild type 24 h after inoculation with rhizobia did not occur in *skl* (Prayitno et al., 2006). The relatively increased long-distance auxin transport in *skl* correlates with a higher number of nodules formed on the root, in a manner similar to the higher long-distance auxin transport in the supernodulating mutant *sunn1*.

The regulation of nodule numbers through AON is linked to the regulation of nodule numbers by nitrogen availability (Fig. 47.2). Studies in *M. truncatula* showed that if sufficient nitrate is available to the plant to inhibit nodule formation, this increases shoot-to-root auxin transport in uninoculated wild-type plants, but not in the *sunn1* mutant (Jin et al., 2012). After inoculation with rhizobia, auxin transport was reduced in plants growing under nitrogen-limiting conditions, but not under nitrogen-sufficient conditions. How the nitrogen status in the plant is "translated" into changes in auxin transport remains unknown. It is possible that auxin transport control by SUNN is a more general mechanism to control root architecture in response to nitrogen, because the *sunn1* mutant is also unable to control lateral root density in response to nitrate through the modulation of auxin transport (Jin et al., 2012).

47.2 CONCLUSIONS AND PERSPECTIVES

Many questions remain in our understanding of how rhizobia control host auxin transport. For example, it is unknown how flavonoids interact with the auxin transport machinery during nodule formation, where flavonoids act, and how they are transported from the site of induction to the site of auxin transport. It also needs to be tested whether flavonoids act in parallel or downstream of cytokinin signaling, and whether ethylene acts independently of cytokinin and flavonoids. Similarly, it is unknown how long-distance auxin transport is controlled through the action of SUNN. In addition, it is unclear how long-distance auxin transport acts in relation to the local auxin transport control. Examination of auxin transport mutants will be imperative for the further dissection of auxin transport control during nodulation. The study of auxin transport in *Arabidopsis* exploded with the characterization of auxin transport mutants; however, most of these are currently not available in legumes. In addition, it would be very interesting to study and compare auxin transport control in different species of legumes, actinorhizal plants, and in *Parasponia*, which all form different types of nodules.

Chapter 48

Functional Analysis of Nitrogen-Fixing Root Nodule Symbioses Induced by *Frankia*: Transport and Metabolic Interactions

Alison M. Berry and Isaac Gifford

Katharina Pawlowski
Department of Ecology, Environment and Plant Sciences, Stockholm University, Stockholm, Sweden

48.1 INTRODUCTION

A diverse group of dicotyledonous plants belonging to 24 genera from eight different families can enter a symbiosis with *Frankia* spp., high G + C, Gram-positive soil Actinobacteria. *Frankia* strains induce the formation of root nodules, functionally complex organs specialized for biological nitrogen fixation (BNF), in symbiosis with the roots of their host plants. In these nodules, the microsymbionts, supplied with carbon by the host plant, fix dinitrogen and export the products of dinitrogen fixation to the host. Nitrogen supplied from symbiotic BNF can provide up to 100% of the host plant nitrogen requirement. Mature actinorhizal nodules are perennial organs consisting of multiple lobes, each of which represents a modified lateral root, with central vascular cylinder and cortex, and superficial periderm. The root nodule lobes retain an apical meristem, but lack a root cap. The microsymbionts are hosted inside expanded cells of the cortical tissue within the nodule lobes (see Chapters 24, 35, 42, 43, 55).

Actinorhizal families belong to three different orders (Fagales: Betulaceae, Casuarinaceae, and Myricaceae; Rosales: Elaeagnaceae, Rhamnaceae, and Rosaceae; Cucurbitales: Coriariaceae and Datiscaceae; see Fig. 48.1). Together with a fourth order, Fabales, which includes the legumes, these plant groups form the so-called nitrogen-fixing clade, a monophyletic subgroup within the Fabidae (Doyle, 2011). With one exception, *Dryas* (Rosaceae), all plants of an actinorhizal genus are symbiotic, but not all genera of an actinorhizal family are symbiotic. For example, within the Betulaceae, *Alnus* spp. are symbiotic but *Betula* spp. are not. There are parallels to this pattern of closely related nodulating and nonnodulating host genera in some basal groupings of the Fabaceae, for example, Cassieae (Caesalpinioideae) and certain members of the Mimosoideae (Sprent, 2009).

The phylogenetic evidence of relatedness (Soltis et al., 1995), together with the discovery that the legumes and actinorhizal plants share common signaling response pathways to inoculation with the microsymbiont (Markmann et al., 2008; Gherbi et al., 2008; see Chapters 42, 43, 55), indicate that the progenitor of this clade gained a unique property or set of properties, which allowed effective root nodule symbiosis (both rhizobial and actinorhizal) to evolve. It has been suggested that the invention of nodulation within the clade likely evolved multiple times (Swensen, 1996; Doyle,

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

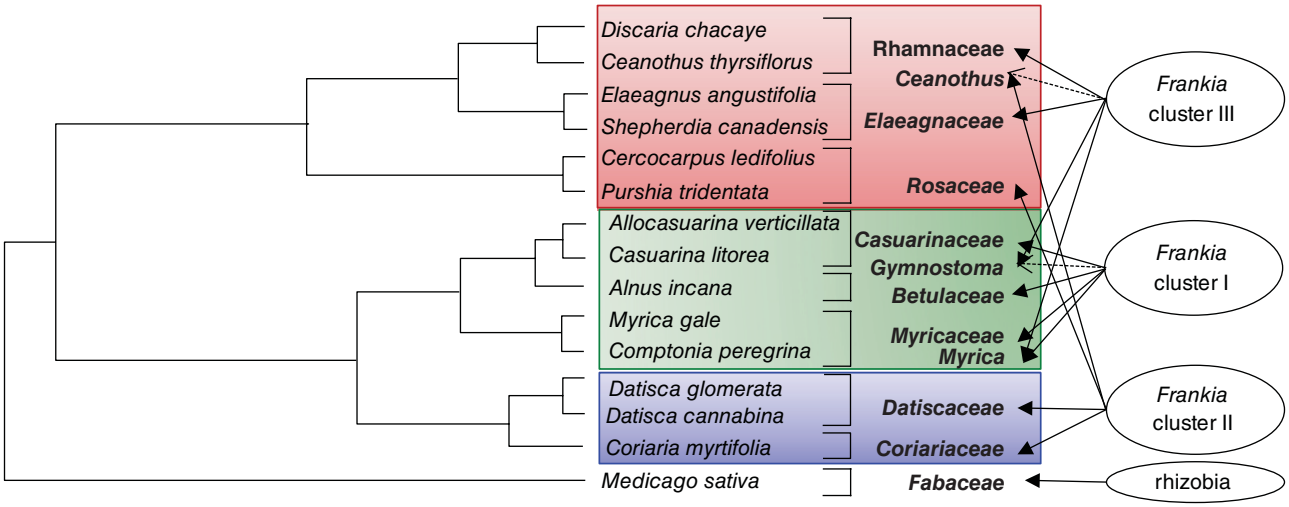

Figure 48.1 Phylogeny of the nitrogen-fixing clade and host specificity in actinorhizal symbioses are depicted in a simplified scheme adapted from Benson and Clawson [2000]. The actinorhizal plant families belong to three orders, Rosales (red box), Fagales (green box), and Cucurbitales (blue box). The numbering of *Frankia* clusters is adapted from Normand et al. [1996]. Thick arrows connecting a *Frankia* cluster with a group of plants indicate that members of this cluster are commonly found in nodules of these plants, while dashed arrows indicate that members of this cluster have been isolated from or detected in an effective or ineffective nodule of a member of this plant group at least once. Not all strains isolated from, or identified in, an actinorhizal nodule can reinfect the corresponding plant species (Ramirez-Saad et al., 1998).

2011). Furthermore, it has become apparent that elements of the evolutionarily much older and more widely distributed arbuscular mycorrhizal (AM) symbiosis between plants and Glomalean fungi were recruited and adapted as a basis for the initial steps in the host signaling pathway leading to root nodule symbiosis (Tromas et al., 2012; Markmann and Parniske, 2009; Oldroyd et al., 2009), although nodulation versus mycorrhizal symbiotic responses diverge after the early signaling steps (see Chapter 110).

Frankia grows vegetatively as septate branching hyphae with a diameter of 0.5–2 µm. Multilocular sporangia can form, containing thick-walled resting-type spores. *Frankia* fixes nitrogen in response to external nitrogen limitation not only in symbiosis but also in the free-living state, even under aerobic conditions, unlike most rhizobia. The reduction of dinitrogen to ammonium is catalyzed by nitrogenase, a highly O_2-sensitive enzyme (see Chapter 2), yet nitrogen fixation requires high amounts of ATP provided by aerobic respiration. This is the so-called "O_2 dilemma of nitrogen fixation." Under aerobic conditions, in response to nitrogen limitation, *Frankia* spp. strains solve this problem by forming vesicles: specialized thick-walled, spherical structures that differentiate on short hyphal stalks, usually side branches. Oxygen tension is regulated within the vesicles by high respiration rates (O_2 consumption). In addition, a multilayered envelope is deposited around the vesicle walls that comprises hopanoids, a class of bacterial sterol lipids (Berry et al., 1993). Such external hopanoid layers are not found in the hyphae. It is assumed that the vesicle envelope acts as a gas-diffusion barrier, supported by the fact that the number of layers comprising an envelope positively correlates with the external O_2 tension (Parsons et al., 1987), and by the packing behavior of artificial membranes containing different hopanoid concentrations (Stroeve et al., 1998). Under conditions of low-oxygen partial pressure, nitrogenase is synthesized in hyphae, and vesicles do not differentiate (Murry et al., 1985). Little is currently understood about the gene regulatory circuitry governing vesicle differentiation, or the biosynthesis of specialized hopanoid mixtures that accompanies vesicle formation. Although partial pressure of oxygen is a key environmental signal, no homologs of NifL–NifA are found in the sequenced *Frankia* genomes.

In symbiosis, within the nodule tissue, the shape, septation, and subcellular localization of *Frankia* vesicles, and whether vesicles are formed at all, depends on the host plant cell environment. In nodules of *Alnus* spp., ovoid septate vesicles are located in the outer parts of the host cytoplasm; in nodules of *Casuarina* spp., no vesicles are formed at all; whereas in nodules of Cucurbitales, long lanceolate vesicles are radially arranged around a central vacuole (Baker and Mullin, 1992; Silvester et al., 1999). Hence, as legumes, actinorhizal plants can direct the differentiation of their intracellular microsymbionts, either through modified environmental conditions (pH, pO_2, carbon, or nitrogen concentration) or possibly by molecular and/or cytoskeletal regulation.

48.1.1 *Frankia* Systematics

Based on phylogenetic analysis, the symbiotic *Frankia* strains can be grouped into three distinct clades or clusters (Normand et al., 1996). The members of one cluster (cluster

Table 48.1 Summary of *Frankia* genomes and selected major transporter groups

Genome	Genome Size (MB)	Total Transporters	Transporters per MB	Transporters % of Genes	ABC Type	Resistance-nodulation-cell division
ACN14a	7.5	559	74.5	8.2	278	11
CcI3	5.43	324	59.7	7	127	9
EAN1pec	8.98	628	69.9	8.7	335	22
EuI1c	8.82	759	86.1	10.4	411	16
Dg1	5.34	354	66.3	7.7	177	8

II) so far have never been cultured (Persson et al., 2011), but numerous isolate strains exist in clusters I and III. These three clusters also correspond to different host specificity groups, as shown in Figure 48.1. For example, members of cluster II are found in actinorhizal nodules of host plants in the Cucurbitales and Rosaceae, and in *Ceanothus* spp. (Rhamnaceae). Members of cluster III nodulate a broad range of host genera and families in Rosales and Fagales, whereas members of cluster I nodulate only within the Fagales. Patterns of host specificity also exist within a given *Frankia* cluster, in that not all members of a cluster can nodulate all plants associated with that cluster. For instance, several cluster I frankiae can only infect Casuarinaceae within the Fagales.

Genome size among the sequenced *Frankia* strains ranges widely, from about 5.3 Mb to over 9 Mb (Table 48.1). The smallest genome reported to date is that of the uncultured symbiont of *Datisca glomerata*, strain Dg1, in cluster II. The members of this cluster so far have never been cultured, so the genome was sequenced from DNA purified from *Frankia* cells derived from nodules (Persson et al., 2011). If cluster II frankiae are obligate symbionts, as they appear to be thus far, the small genome size likely indicates reduction due to loss of function. Otherwise within the frankiae, genome size has been correlated with the saprotrophic potential of *Frankia* strains and with host plant geographical distribution (Normand et al., 2007; see Chapter 24). The cluster III frankiae have the largest genomes, a wide host range, and are ubiquitously found in soils on all continents. In cluster I, the difference in genome size, for example, between ACN14a (host *Alnus* spp.) and CcI3 (host *Casuarina* spp.) may be attributable to the limited native distribution of *Casuarina*, primarily in Australia (Normand et al., 2007).

The availability of an increasing number of sequenced *Frankia* genomes makes it possible to begin comparative analyses pointing to functional properties, within and among the *Frankia* genomic clusters, and more broadly, between *Frankia* and rhizobia in the nitrogen-fixing symbioses.

48.1.2 Nutrient Exchange Between *Frankia* and Its Host Plant: *Frankia* Membrane Transporters

In symbiosis, intracellular bacteria depend on the host plants for many nutrients to support nitrogen fixation and survival within the plant cell environment, as summarized for legume symbioses (Oldroyd et al., 2011). Generally, the plant provides metal ions, sulfate, and carbon sources; the specific transport of host-derived branched-chain amino acids has also been demonstrated as a requirement for *R. leguminosarum* in symbiosis (Prell et al., 2009).

Characterization of transporter genes can provide one line of evidence of interactions between the bacteria and its environment, whether in symbiosis or in the soil (e.g., Young et al., 2006). In this chapter, we compare published genomes of five representative *Frankia* strains from the three clusters to characterize transporters. One set of *Frankia* transcriptomes, for the sequenced genome of ACN14a, has been published to date (Alloisio et al., 2010). This data set, based on microarray comparisons, allows further functional characterization of its transporters in symbiotic and free-living states.

ATP-binding cassette (ABC) transporter proteins are the most abundant class of transporters in the frankiae (Table 48.1). Substrates for identified transporters vary between strains (Table 48.2; transporter genes with substrates identified by annotation in databases BioCyc, KEGG, and IMG) such that many transporters lack a homolog in all sequenced genomes. Transporter types do not necessarily assort directly with clades, as benzoate transporters can be found in Clade II Dg1 (FsymDg_3355) and Clade III EuI1c (FraEuI1c_3834); glycine betaine/choline transporters are found in Clade I ACN14a (FRAAL6726) and EuI1c (FraEuI1c_0106), but not CcI3 and EAN1pec (Clades I and III, respectively). The ineffective strain EuI1c (parent strain EuI1 (Baker et al., 1980) GenBank accession no. ASM16613v1) that cannot form vesicles or fix nitrogen *in planta* has substantially more total transporters, and transporters as a percentage of the genome size, compared with the other four genomes (Table 48.1); this pattern holds across most categories of transporter genes. Many of the

Four-digit numbers represent gene locus tags for each genome. Expression patterns for ACN14a transporter genes in symbiosis with *Alnus glutinosa* (column 8) are derived from GSE18190 (Alloisio et al. 2010) in the NCBI GEO database.

EuI1c transporter genes not found in other *Frankia* genomes appear to be derived from horizontal gene transfer (see Figs. 48.2 and 48.3).

48.1.3 Nutrient Exchange Between Host and Microsymbiont: Primary Nitrogen Metabolism

For legume–rhizobia symbioses, it has been shown that the first enzyme in primary nitrogen assimilation, glutamine synthetase, is repressed in the symbiotic bacteroids. Consequently, the bacteroids do not assimilate the fixed nitrogen themselves, but deliver it to the host plant as ammonium (summarized in Lodwig et al., 2003). In the plant cytosol, this ammonium is assimilated in the host glutamine synthetase–glutamate synthase (GS-GOGAT) cycle. This pattern of primary nitrogen assimilation is confirmed by the observed presence of high levels of plant cytosolic GS in the infected cells of legume nodules, and actinorhizal nodules from hosts in two different orders [*A. glutinosa* in Fagales: Hirel et al., 1982; Guan et al., 1996; and *Discaria trinervis* in Rosales: Valverde and Wall, 2003]. Thus, the dinitrogen fixed by *Frankia* is made available to the plant in the form of ammonium in these symbioses.

Both frankiae and rhizobia have two genes coding for glutamine synthetase (*glnA*, coding for GSI; and *gsII*). The *glnA* gene was strongly repressed in the *Alnus* sp.-infective strain ACN14a in symbiosis; *gsII* was expressed in nodules, but at a much lower level compared to free-living nitrogen-fixing cells (Alloisio et al., 2010). Genes coding for GOGAT were expressed in these nodules at low levels as well. An ammonium transporter was more highly expressed in *A. glutinosa* nodules than in ACN14a cells in culture. These findings indicate an active repression of microsymbiont GS in *A. glutinosa* nodules and ammonium efflux from the microsymbiont, with some low GS-GOGAT activity retained in frankiae *in planta*.

In *Datisca glomerata*, a representative of the Cucurbitales, infected by the cluster II strain *Candidatus* Frankia datiscae Dg1 (Dg1), nodule nitrogen assimilation is strikingly different from all other types of nodules examined thus

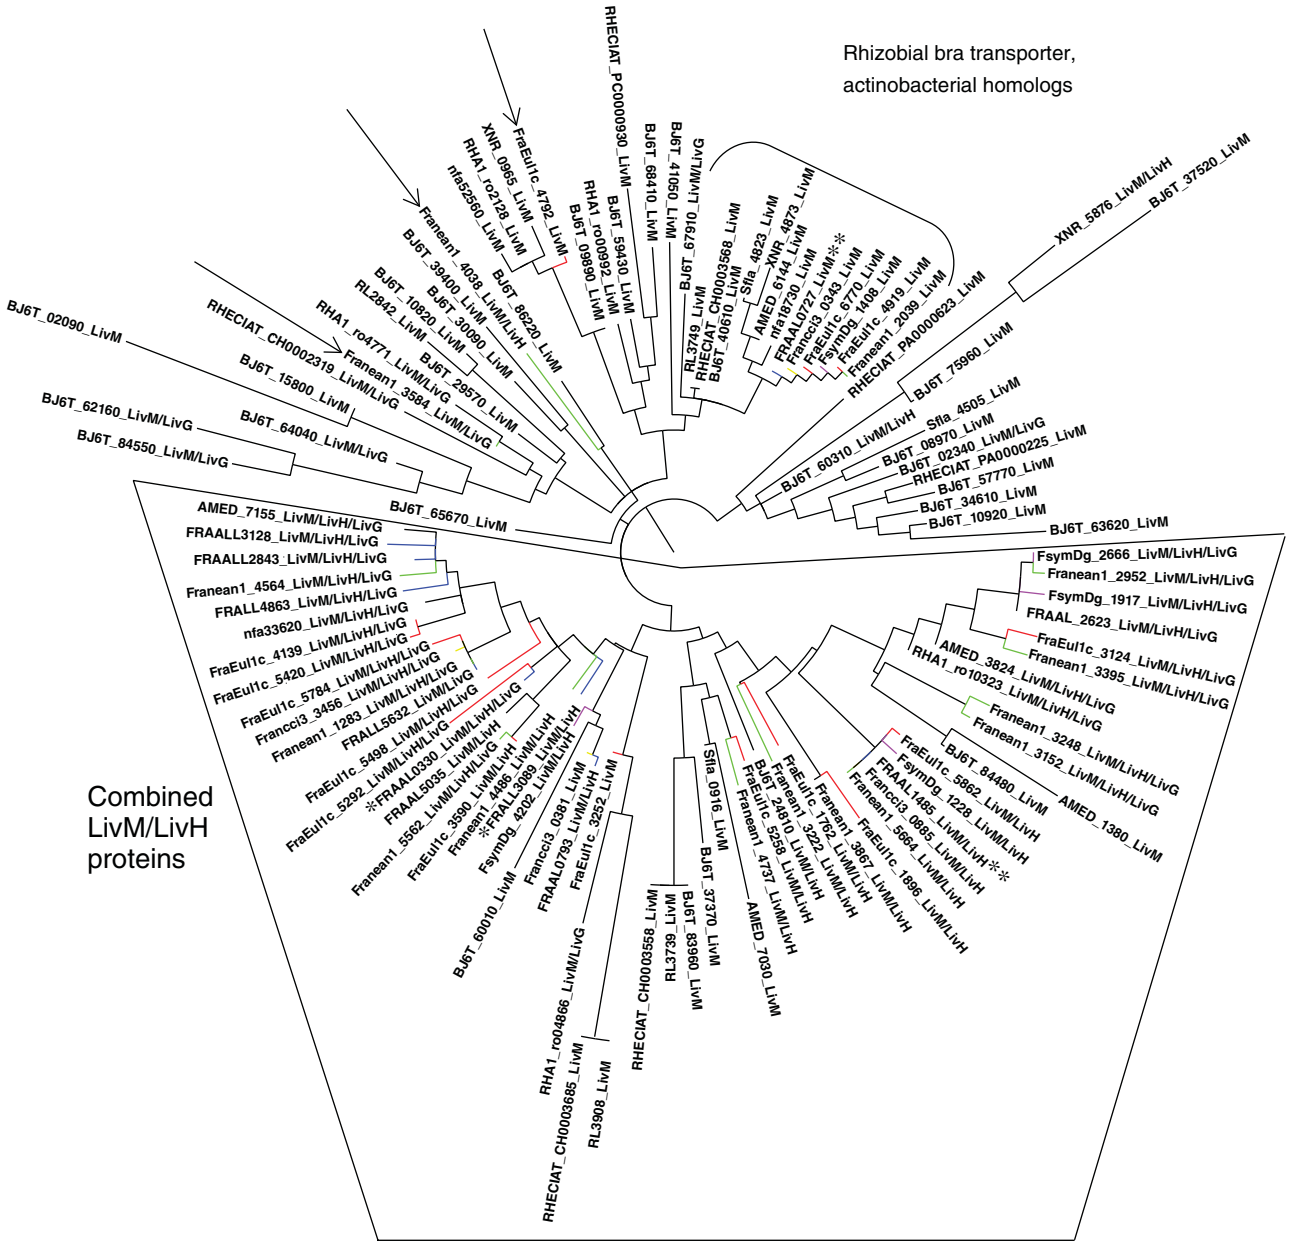

Figure 48.2 Maximum-likelihood protein tree of LivM-domains found in all five *Frankia* genomes and representative related species with full genome sequences. The clade that contains homologs likely related to the Bra transporter is labeled; as is the *Frankia*-dominated clade consisting of combined LIV-domain proteins. Arrows denote proteins that have likely been horizontally acquired in *Frankia*. Asterisks (*) denote FRAAL proteins whose genes are expressed at high levels in *A. glutinosa* symbiosis. Single star (*): Top 50%. Double star (**): Top 25% (GSE18190 in GEO). The tree was constructed using only the LIVM-domain from each protein, but all LIV-domains found in each protein are notated. Organism codes: FRAAL (ACN14a, colored blue), Francci3 (CCI3, colored yellow), Franean1 (EAN1pec, colored green), FraEuI1c (EuI1c, colored red), FsymDg (Dg1, colored pink), AMED (*Amycolatopsis mediterranei*), BJ6T (*Bradyrhizobium japonicum*), nfa (*Nocardia farcinica*), RHA (*Rhodococcus jostii*), RHECIAT (*Rhizobium etli*), RL (*Rhizobium leguminosarum*), Sfla (*Streptomyces flavogriseus*), and XNR (*Streptomyces albus*). Alignment generated in MUSCLE and tree calculated in MEGA v5.2.2.

far. Host plant GS accumulates not in the *Frankia*-infected cortical cells, but in the uninfected cortical cell layers surrounding the uniform patch of infected cells (Berry et al., 2004). A pattern of low relative gene expression was noted for *glnA* and *gsII* in nodules of *D. glomerata* using semiquantitative PCR (Berry et al., 2011), similar to the results for ACN14a, discussed earlier, by comparison with nodule *nifH* expression levels in each experiment. The gene coding for the small subunit of GOGAT was relatively strongly expressed in Dg1. In addition, genes

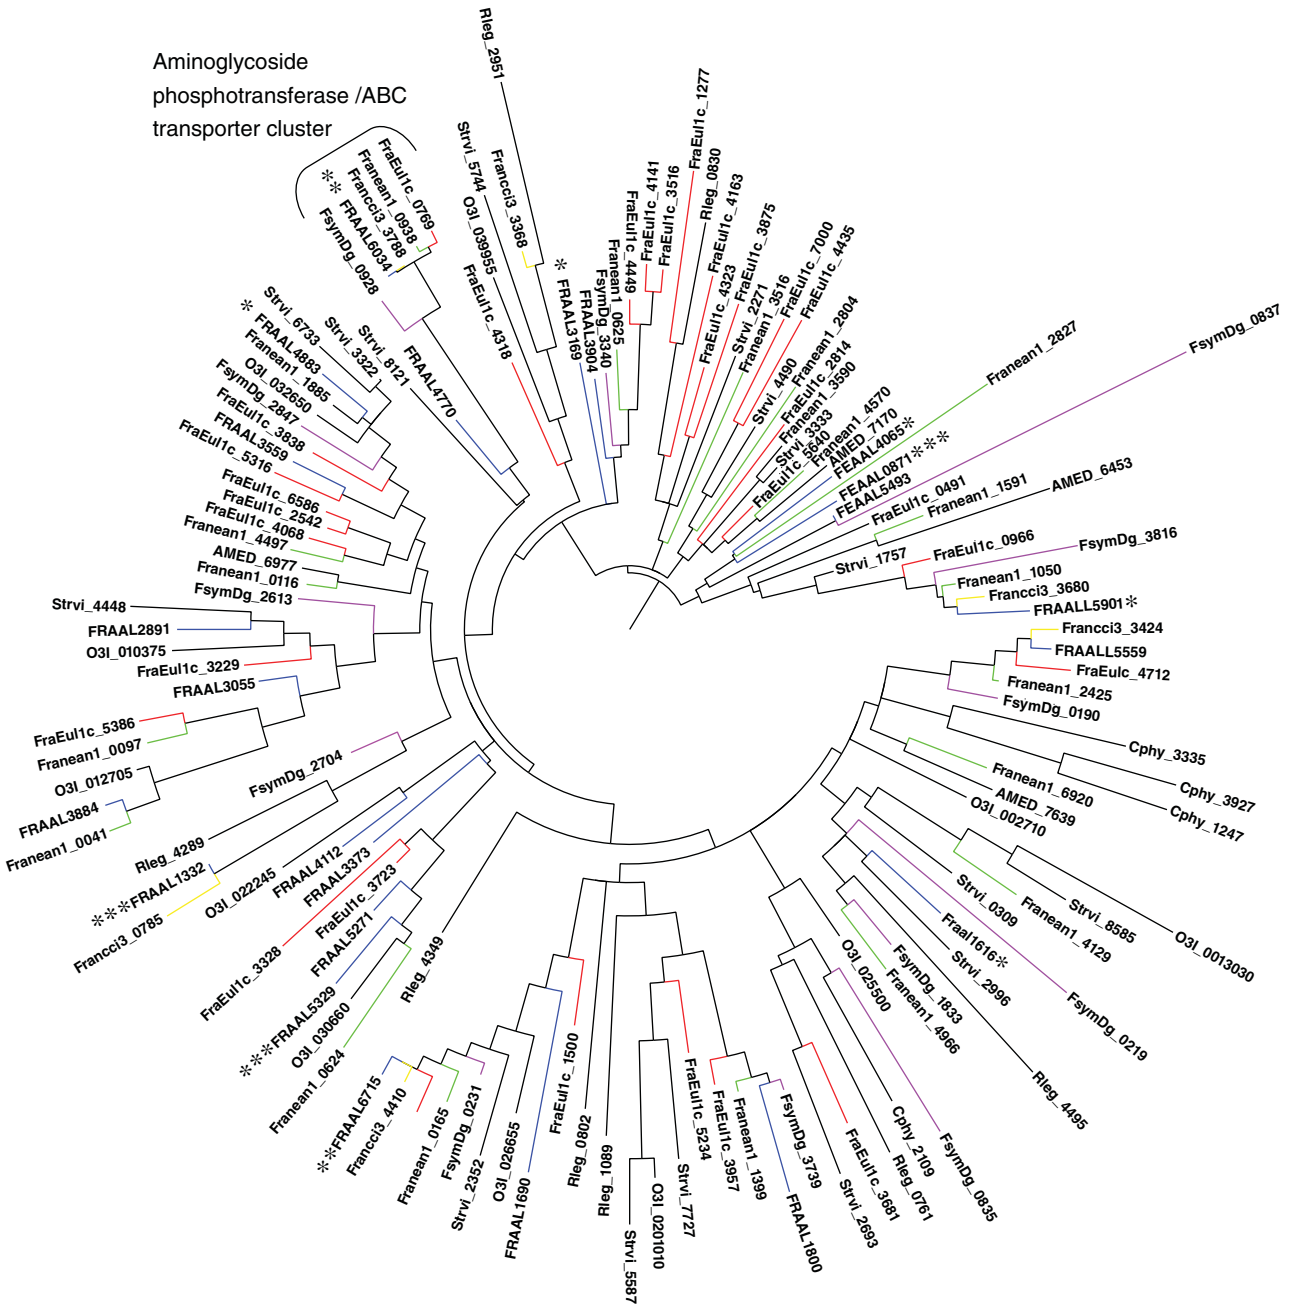

Figure 48.3 Maximum-likelihood protein tree of all putative aminoglycoside phosphotransferases found in all five *Frankia* genomes and representative related species with full genome sequences. The clade of proteins annotated as additionally containing ABC transport ATPase domain is labeled. Asterisks (*) denote FRAAL proteins whose genes are expressed at high levels in *A. glutinosa* symbiosis. Single star (*): Top 50%. Double star (**): Top 25%. Triple star (***): Top 10% (GSE18190 in GEO). Organisms codes: FRAAL (ACN14a, colored blue), Francci3 (CCI3, colored yellow), Franean1 (EAN1pec, colored green), FraEuI1c (EuI1c, colored red), FsymDg (Dg1, colored pink), AMED (*Amycolatopsis mediterranei*), Cphy (*Clostridium phytofermentans*), O3I (*Nocardia brasiliensis*), Rleg (*Rhizobium leguminosarum*), Strvi (*Streptomyces violaceusniger*). Alignment was generated in MUSCLE and the tree was calculated in MEGA v5.2.2.

for key enzymes in arginine biosynthesis were much more highly expressed in Dg1 than in ACN14a in nodules, suggesting that an active amino acid metabolism is operating in Dg1 in symbiosis.

Strikingly, amino acid profiles of the *D. glomerata* nodules revealed a high concentration of arginine (Berry et al., 2004), previously not reported as an abundant nitrogen-containing compound in any root nodule sym-

bioses, except nodules of *Coriaria* sp. (Wheeler and Bond, 1970), the other nodulating genus of the Cucurbitales. Arginine is an efficient temporary storage form of nitrogen, containing four nitrogens per molecule.

These lines of evidence suggest that in the Cucurbitales symbioses, ammonium is assimilated in *Frankia* into amino acids, including arginine, and then transported to the host tissue. The identity of the amine-containing compound or compounds exported from *Frankia* to the host remains to be discovered.

The evidence of high host GS activity in the uninfected cortical tissue likely indicates reassimilation of amino acids derived from *Frankia*. High GS activity implies the presence of free ammonium in the uninfected tissue. It is possible that this reassimilatory step is linked to an arginine–ornithine–urea cycle, a key step in storage-N mobilization in many plant taxa (Goldraij and Polacco, 2000) that produces free ammonium as a by-product; or conceivably free ammonium could result from deamination of glutamate by glutamate dehydrogenase, for TCA carbon skeleton regeneration (Miyashita and Good, 2008).

This specialization of nodule nitrogen metabolism does not seem to be linked to the nitrogen transport form in the xylem: *D. glomerata* transports nitrogen in the xylem in the form of amides, similar to other actinorhizal plants except *Alnus* spp. and certain *Casuarina* spp., who export amides and citrulline to the host xylem (Valverde and Huss-Danell, 2008).

48.1.4 Nutrient Exchange Between Host and Microsymbiont: Transport of Branched-Chain Amino Acids (LIV), Arginine, and Polar Amino Acids

In legume–rhizobia symbioses, the microsymbionts depend on the plant for supply of branched-chain amino acids via the Aap and Bra systems of bacterial transporters (Prell et al., 2009). This auxotrophy is not present in the saprotrophic state; rather, rhizobial genes encoding enzymes involved in the synthesis of branched-chain amino acids are downregulated in symbiosis. Because of the importance of this exchange in nitrogen-fixing symbiosis, we analyzed the LIV genes (leucine–isoleucine–valine), coding for branched-chain amino acid transport, in the *Frankia* genomes. All five of the *Frankia* genomes analyzed, including the symbiotically ineffective strain EuI1c, contain multiple LIV gene systems (Table 48.3). In symbiosis with *A. glutinosa*, one of the LivK (substrate-binding) genes of ACN14a (FRAAL0725) is substantially upregulated, compared with free-living, nitrogen-fixing cells (Alloisio et al., 2010) (GEO DataSet GSE18190 in NCBI); and a LivK protein was detected in nodules of *Alnus glutinosa* (ACN14a) and *Casuarina glauca* (CcI3) by Mastronunzio et al. [2009]. In ACN14a, this gene copy of *livK* is located adjacent to the other genes for the Bra branched-chain amino acid transporter (GI:4231701), which are also highly expressed in symbiosis, suggesting that a Bra operon is important in symbiotic nitrogen exchange in *A. glutinosa* nodules. The Bra transport system is not strictly specific for transport of branched-chain amino acids, but could also be involved in transport of polar amino acids and γ-aminobutyric acid (GABA) (Hosie et al., 2002). Thus, the identity of the LivK substrate(s) of the *Frankia* Bra transporter in actinorhizal symbiotic interactions remains to be demonstrated; nevertheless, in *Rhizobium*, it is the transport of branched-chain amino acids through Bra that seems to be required for symbiosis (Prell et al., 2009).

We further categorized the *Frankia* LIV transporter genes based on the presence of LivM-like and/or LivH-like domains, the two transmembrane domains. In addition, these ABC transporters have LivG and LivF ATPases, and the LivK substrate-binding domain was discussed earlier (Table 48.3). ABC transporters are known to contain fused genes that combine a transmembrane domain with an ATPase domain (Davidson et al., 2008). However, in *Frankia*, most of the LIV gene-encoded proteins are composed of a variety of combinations of LivM, LivH, LivG, and/or LivF domains combined into single proteins by gene fusion, even the two transmembrane domains, an unusual arrangement for ABC transporter gene fusions (Fig. 48.2). LivM and LivH were used to create protein trees either from the single-domain proteins or from the full multidomain protein sequences by taking the individual domains (Fig. 48.2). The multidomain ("combined") LIV genes are the most abundant in the *Frankia* genomes and appear to have originated primarily in Actinobacteria; moreover, ACN14a, EAN1pec, and EuI1c each have more genes with LivM/LivH combined domains than any other sequenced organism in the NCBI database. No LivM/LivH combined genes are annotated among rhizobial transporters. Interestingly, on the other hand, the clade of LivM-only proteins for all five *Frankia* genomes clusters closely with the rhizobial Bra transporter (shown in Fig. 48.2), suggesting horizontal gene transfer events between Actinobacteria and Proteobacteria, and further suggesting the possible identity of this group as the *Frankia* Bra transporters. The LivM-only protein (i.e., the potential Bra transporter permease) in ACN14a (FRAAL0727) is expressed equivalently in both symbiotic and nonsymbiotic conditions (top 25% of genes expressed), although LivK in the same operon is upregulated in symbiosis (top 5% of genes expressed) (Alloisio et al., 2010). Additionally, FRAAL0330 and FRAAL1485 are LIV-transporters (LivH/LivM/LivG and LivH/LivM fusions, respectively) that are expressed at high levels in symbiosis, in the top 40% and 20% of genes (GSE18190 in GEO), respectively.

Exceptions to these two major groups include Francci3_0381, a LivM-only protein that groups in the multidomain

Table 48.3 LIV-domain-containing genes in *Frankia* Genomes

Genome	Genes Containing					Total LIV Genes
	LIVM	LIVH	LIVG	LIVF	LIVK	
ACN14a	11	13	14	12	3	34
CcI3	4	2	4	4	3	13
EAN1pec	15	16	31	31	3	44
EuI1c	15	18	18	16	3	49
Dg1	5	5	5	4	4	17

clade; and a few proteins from EAN1pec and EuI1c that appear to be horizontally transferred from the Gammaproteobacteria (Fig. 48.2).

Other amino acid transporters with database annotations include those for arginine, proline, and polar amino acids. The identified arginine transporters correspond to the ATPase of LAO transporters, responsible for lysine, arginine, and ornithine transport (FRAAL4949, Francci3_3004, Franean1_1945, FraEuI1c_4944, and FsymDg_3821). This transporter is twofold upregulated in ACN14a in symbiosis (in the top 25% of genes in microarray data), compared with free-living conditions (GSE18190 in GEO), implying a role for one of these amino acids in the nutrient exchange between plant and bacterium in *A. glutinosa* nodules. The permease and substrate-binding proteins have not been specifically identified in any of the genomes. The ACN14a proline transporter is expressed in symbiosis in the top 45% of genes (GSE18190 in GEO).

Two major clusters of polar amino acid ABC transporters were found in all five sequenced *Frankia* genomes under discussion here. Based on UniProt characterization, these transporters are responsible for glutamate and glutamine transport (as well as aspartate and asparagine transport). These proteins are apparently primarily vertically derived, forming a tight *Frankia* clade (gene tree not shown). In ACN14a, one of these genes is expressed in symbiosis (FRAAL5715, expressed in the top 40% of genes), although it is downregulated compared with free-living, nitrogen-fixing conditions; the other genes are expressed only at very low levels (GSE18190, in GEO). Other polar amino acid transporters lack more specific annotation (FsymDg_4250, FraEuI1c_3110, FRAAL5987, and FraEuI1c_0815); these appear to have been horizontally transferred from other Actinobacteria based on their scattered distribution in the UniProt-based gene tree (not shown).

48.1.5 Nutrient Exchange Between Host and Microsymbiont: Carbon Metabolism

For legume nodules, it is widely accepted that dicarboxylates are the carbon sources supplied by the plant to the microsymbionts – mostly malate and also fumarate and succinate – although the plant exporter has not been identified yet (summarized by White et al., 2007). Physiological studies on *Frankia* vesicle clusters isolated from *Alnus glutinosa* nodules indicated that malate was likely to be the carbon source for intracellular *Frankia* as well (reviewed by Huss-Danell, 1997). A nodule-specific dicarboxylate exporter from *A. glutinosa* has been identified and located at the symbiotic interface (Jeong et al., 2004). The ACN14a genome contains a dicarboxylate transporter gene, *dctA*, which is expressed in symbiosis, but downregulated relative to free-living conditions (Alloisio et al., 2010; GSE18190 in GEO). A homolog of *dctA* occurs in EAN1pec, but not in CcI3 or Dg1, suggesting that other carbon transport mechanisms may be operating in at least some actinorhizal symbioses. DctA is not the only bacterial dicarboxylate transporter known; yet, so far no homologs of the other known dicarboxylate transporters (Youn et al., 2008; Valentini et al., 2011; Thein et al., 2012) have been identified in the published *Frankia* genomes. At any rate, since *dctA* was not found in CcI3 or Dg1, either the carbon sources supplied in actinorhizal symbioses are very diverse, or some frankiae use a dicarboxylate transporter that has not been characterized yet.

Which other carbon sources could be provided? In the saprotrophic state, clade I frankiae are able to grow well on short-chain fatty acids (acetate and propionate), variably on succinate, malate, or pyruvate, and poorly or not at all on different sugars, while *Elaeagnus*-infective strains grow on sugars as well as organic acids (Benson and Silvester, 1993). Since short-chain fatty acids do not seem to be part of plant exudates or cell–cell carbon exchanges, sugars might be worth an examination. In this context, it is interesting that *D. glomerata*, particularly in the root nodules, utilizes a rather peculiar carbon metabolism: the disaccharides rutinose and methylrutinose – α-L-rhamnopyranoside-(1→6)-D-glucose and α-L-rhamnopyranoside-(1→6)-1-*O*-β-D-methylglucose are used as intermediary carbon storage forms (Schubert et al., 2010). The same disaccharides were also found in *Datisca cannabina*, though not in *Coriaria* sp.; however, since rutinose levels seemed to vary with the growth conditions [Voitsekhovskaja and Pawlowski, unpublished observations], the lack of rutinose in *Coriaria* sp. might

have presented an artifact. So at least two actinorhizal members of the Cucurbitales contain high amounts of rhamnose-containing disaccharides in their roots and nodules.

Two types of disaccharide transporters are found in all five *Frankia* genomes. Genes belonging to COG0395 ("UgpE; ABC-type sugar transport system, permease component [carbohydrate transport and metabolism]") were identified and combined into a tree (data not shown). One cluster of *Frankia* transporters (from ACN14a, EAN1pec, and EuI1c) corresponded to *Mycobacterium* SugB, identified as a trehalose importer (Kalscheuer et al., 2010). The ACN14a homolog was FRAAL3763, which is strongly downregulated in the transcriptome in symbiosis (GSE18190 in GEO).

Additionally, in this COG, there is a clade of transporters in all five genomes with MalK maltose/trehalose/maltodextrin and/or glycerol-3-phosphate transporter annotations. Neither of the two *malK* homologs in ACN14a (FRAAL3201 and FRAAL4369) are highly expressed, either in nodule symbiosis or in free-living conditions; yet, this may be related to the fact that in *Alnus*-nodulating *Frankia*, the main carbon sources are not sugars (Jeong et al., 2004). The other four genomes have two proteins in this clade apiece (Francci3_2254 and Francci3_2838, Franean1_1897 and 3946, FraEuI1c_2623 and 4704, and FsymDg_2865 and 3447). This protein family might represent a candidate for a widespread saccharide uptake transporter in *Frankia*. Altogether, at the present stage, we cannot say whether (a) frankiae contain an as yet unknown class of dicarboxylate transporters or (b) carbon sources provided to frankiae *in planta* differ between host species.

Most rhizobia lack the homocitrate synthase gene [*nifV*; Hakoyama et al., 2009] and therefore have to import homocitrate, an essential part of the FeMo cofactor of nitrogenase, from the plant. So far, all of the sequenced genomes of symbiotic *Frankia* strains contain *nifV*, as would be expected since effective *Frankia* strains can fix nitrogen not only *in planta* but also in the saprotrophic state. Consistent with the function of NifV in nitrogen fixation, only the nonsymbiotic, nonnitrogen fixing strains CN3 (Ghodhbane-Gtari et al., 2013) and the symbiotically ineffective strain EuI1c lack a *nifV* homolog.

48.1.6 Nutrient Exchange Between Plant and Microsymbiont: Secondary Compound Transporters

48.1.6.1 Indole Acetic Acid (IAA). A gene coding for an auxin efflux transporter (IAA transporter) is found in four of the five genomes, absent only in Dg1. In the *A. glutinosa* symbiosis, this gene is upregulated compared to free-living conditions (GSE18190 in GEO). Genes for IAA biosynthesis are found in all four of the IAA transporter-containing genomes, but are absent in Dg1. This suggests that if IAA plays a role in symbiosis, as indicated by gene upregulation in *C. glauca* nodules (Perrine-Walker et al., 2011), there must be an alternative mechanism in the nodules of Cucurbitales. All five genomes encode genes for the enzymes of the biosynthetic pathway for phenylacetic acid (PAA), another type of auxin. PAA, which has been shown to be produced by *Alnus*- and *Elaeagnus*-infective strains (Hammad et al., 2003) and by CcI3 (Perrine-Walker et al., 2011) does not require a transporter since it is membrane-permeable (Simon and Petrášek, 2011).

48.1.6.2 Purine Transporters. A symporter of cytosine and a purine is present in two genomes, ACN14a and EuI1c, but no homolog is present in the other three genomes; it is twofold upregulated in the ACN14a nodule transcriptome, placing it in the top 25% of genes in symbiosis (Alloisio et al., 2010). A second purine transport-related gene, annotated as xanthine/uracil/vitamin C permease, but likely with broader specificity (Loh et al., 2006), occurs in ACN14a, EAN1pec, and EuI1c; it is weakly expressed in ACN14a in either free-living or symbiotic conditions.

48.1.6.3 Polyamine (Putrescine/Spermidine) Transporters. Polyamine production, especially putrescine production, was detected in several *Frankia* strains (Wheeler et al., 1994), and putrescine is commonly found in nodules and roots of some actinorhizal plants (reviewed in Valverde and Huss-Danell, 2008). In the legume *Lotus japonicus*, plant genes involved in polyamine biosynthesis via ornithine decarboxylase (LjODC), but not via arginine decarboxylase (LjADC), are upregulated in the early stages of nodule development (Flemetakis et al., 2004), implying a role in nodulation. All five *Frankia* genomes contain bacterial homologs of the plant protein LjODC, with relatively low e-values. All five genomes have genes coding for the conversion of agmatine to putrescine (the arginine pathway). Three of the five *Frankia* genomes contain annotated polyamine transporters (Dg1 and CcI3 do not). The polyamine transporter in ACN14a is upregulated twofold and highly expressed in symbiosis (top 15% of genes; GSE18190 in GEO), indicating its importance for ACN14a in symbiosis. Since nitrogen assimilation activity in ACN14a *in planta* seems to be very low, this would likely indicate uptake, not export. Yet, the absence of an identifiable polyamine transporter in CcI3, which nodulates the closely related *Casuarina* genus, makes it doubtful that polyamine uptake is essential for *Frankia* in all of the actinorhizal symbioses.

48.1.6.4 Resistance-Nodulation-Cell Division Efflux Pumps. Genes encoding efflux pumps of the resistance-nodulation-cell division family (RND), which

in rhizobia are involved in increasing symbiotic efficiency (Lindemann et al., 2010; Alvarez-Ortega et al., 2013), can be identified in all five genomes. Two out of three RND efflux exporters identified by Alloisio et al. (2010) were strongly upregulated in symbiosis, among the most highly expressed genes, making it likely that the encoded efflux pumps have a symbiotic function in the *A. glutinosa* nodule as well.

48.1.6.5 Aminoglycoside Phosphotransferases/Transporters. A very large family of presumptive aminoglycoside phosphotransferases exists throughout all sequenced *Frankia* genomes (Fig. 48.3), and homologs of the phosphotransferases are abundant in many actinobacterial genomes. Aminoglycosides *sensu stricto* are categorized as a class of antibiotics. Across the five *Frankia* genomes, the number of these proteins varies from 6 (CcI3) to 35 (EuI1c), a result of both gene duplications and horizontal transfer from other Actinobacteria, based on the phylogenetic data (Fig. 48.3). Though the majority of these proteins contain only the phosphotransferase domain, a few larger members (FRAAL6034, Francci3_3788, Franean1_0938, FraEuI1c_0769, and FsymDg_0928) have annotations corresponding to ABC transporter ATPases as well. These proteins form a tight and highly conserved cluster when placed on a tree with the other members of the family, as in Figure 48.3. Unfortunately, the remaining aminoglycoside phosphotransferase genes have been assigned a "transporter" annotation in several databases, based on homology among the phosphotransferase domains, even though most lack evidence of membrane association. In ACN14a, the majority of these genes (including the putative transporter) are downregulated or equally expressed in symbiosis, compared with free-living conditions, with the exception of FRAAL4883 and FRAAL6715, which are in the top 40% and 25% of genes expressed in the *A. glutinosa* symbiosis, respectively (GSE18190 in GEO). Despite the relative lack of upregulation in the ACN14a symbiosis compared with the free-living state, some of the other aminoglycoside phosphotransferases still remain very highly expressed: FRAAL0871, FRAAL1332, and FRAAL5329 are each in the top 10% of gene expression in symbiosis; and the putative transporter is in the top 25% (GSE18190 in GEO). Some homologs of these aminoglycoside phosphotransferases are annotated in genomes of some rhizobia (*R. leguminosarum* proteins are included in Fig. 48.3); however, their distribution varies between species and genera ranging from 1 to 11. Of interest, *Bradyrhizobia* have a homolog of FRAAL4883 (e-value around e-55), FRAAL0871 (e-09), and FRAAL5329 (e-12), but *Rhizobium* and *Sinorhizobium* do not. All three genera have homologs of the putative transporter (e-15 to e-45), but they align only over the transporter domain.

48.2 CONCLUSIONS

In order to understand the nutrient exchange in actinorhizal symbioses, detailed studies of plant and bacterial symbiotic transcriptomes are a logical next step. Although an increasing number of sequenced *Frankia* genomes are available, transporters are not yet fully annotated in existing bacterial genome databases. Biochemical evidence of bacterial transporter specificity is needed, especially for the Actinobacteria. As pointed out for rhizobia {Ramachandran et al., 2011; Udvardi and Poole, 2013], many *Frankia* transporters are likely to be of functional significance in soil and rhizosphere under saprotrophic conditions, to a greater degree than in the specialized exchanges during symbiosis within the nodule. This likelihood is reinforced by the finding of the highest number of transporters in EuI1c, which is symbiotically limited.

The *Frankia* transporters that we have characterized with potential significance in the symbiotic exchange include LAO transporters and LIV transporters. Several aminoglycoside phosphotransferases including the transporter-containing protein appear to play a significant role in nodule symbiotic interactions based on the ACN14a/*Alnus glutinosa* gene expression data. Several genes known to be involved in rhizobial symbioses have close homologs in *Frankia*, which are expressed in symbiosis, at least in *Alnus glutinosa* nodules. An avenue for future inquiry will be the directionality (or directionalities) of horizontal gene transfer to explore how the phylogenetically distant microsymbionts developed the capacity to form the root-nodule symbioses. Arginine metabolism appears to play an important role in symbiotic nitrogen assimilation in the Cucurbitales, but the precise patterns of exchange and functional compartmentalization await further research. The specific substrates for carbon exchange between host and microsymbiont in actinorhizal nodules remain for the most part unknown, and may represent a diversity of adaptations, in both the host and *Frankia* lineages.

49.1 INTRODUCTION

Although a vast majority of the green lineage enters a mycorrhizal symbiosis with soil fungi from the *Glomeromycota* clade (Smith and Read, 2008), the ability to develop specialized symbiotic nitrogen-fixing organs is restricted to a small portion of Angiosperms called the nitrogen-fixing clade (Soltis et al., 1995). The large majority of these symbiotic organs, known as nodules, are root-derived organs characterized by peripheral vasculatures in legume plants or centrally located vasculature in actinorhizal plants and *Parasponia andersonii* (Fig. 49.1). For this reason, legume nodules are often considered as organs *sui generis* in contrast to the root-derived nature of actinorhizal and *P. andersonii* nodules (Hirsch and Larue, 1997).

The anatomy of the different types of symbiotic nodules greatly varies even inside legumes (Sprent, 2007), where two main nodule classes have been defined depending on the presence or absence of a persistent meristem (indeterminate *vs.* determinate nodules, respectively). However, despite this diversity, it appears that conserved signaling modules are triggered and/or necessary for nodule formation in and between the three nodulating groups of plants (Gherbi et al., 2008; Op den Camp et al., 2011a; Tromas et al., 2012). It is now well accepted that nodulation signaling pathway (NSP) evolved by the co-option of mycorrhization molecular machinery, thus defining a common symbiotic signaling pathway (CSP, CSSP or SYM) (Parniske, 2008; Kouchi et al., 2010; Gough and Cullimore, 2011; see Chapters 41–43, 55, 110). The NSP thus allows the infection of host cells by the bacterial partner and also triggers an orig-

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

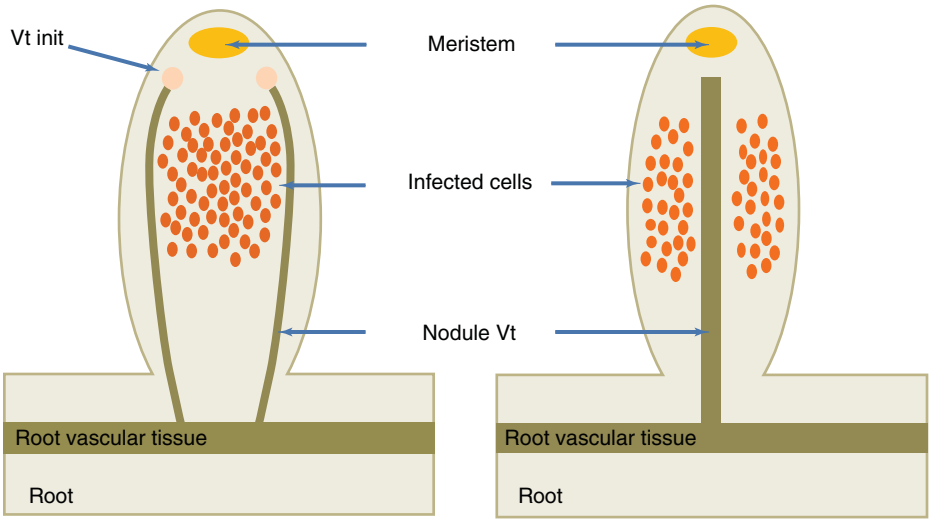

Figure 49.1 Schematic representation of indeterminate-type and actinorhizal nodules. (a) This represents an indeterminate legume nodule with peripheral vasculature (Nodule Vt) and centrally located symbiotic infected cells (red/orange dots). (b) This represents an actinorhizal type of nodule with a central vasculature (Nodule Vt) and peripheral symbiotic cells (red/orange dots). The position of the nodule meristem is indicated for the two nodule types. In the legume nodule, the position of the vascular initials (Vt Init) that can give rise to the roots in the mutant backgrounds is also indicated at the tip of the vascular tissue.

inal developmental program. Although genetically distinct, infection and organogenesis represent two tightly coordinated processes necessary for nodule formation (Oldroyd and Downie, 2008). Over the past decades, a great deal of knowledge has been acquired concerning processes such as infection, early organogenesis, autoregulation of nodulation, bacterial differentiation, and nitrogen fixation (Ferguson et al., 2010; Batut et al., 2011; Desbrosses and Stougaard, 2011; Oldroyd et al., 2011; Mortier et al., 2012). However, we do not know much about the origin of these organs acquired recently in the evolutionary history of land plants (Soltis et al., 1995) and how the nodule(s) developmental program(s) is (are) related to each other and to those of others organs (Hirsch and Larue, 1997).

Plant organs are generally built by the activity of meristems. The shoot apical meristem (SAM) and root apical meristem (RAM) define the main body of the plant (Stahl and Simon, 2010). These meristems fulfill two main functions: (i) self-maintenance and (ii) organogenesis. The organizing center (OC) or quiescent cells (QC) are groups of low mitotically active cells that are centrally located in the SAM and the RAM, respectively. Each is surrounded by a small group of stem cells, defining the stem cell niche (SCN), which combines division and self-maintenance activities. The activity of these SCN is highly regulated and is necessary to furnish all the cell types necessary for building the primary shoot or root. In the SAM, the stem cells are distally located in the meristematic dome, while in the RAM they are subapically located and protected by a root cap in the rootward orientation. The *Arabidopsis thaliana* RAM, which was used to define the model RAM structure, is of the closed type while legume plants have an open RAM (Groot et al., 2004; Heimsch and Seago, 2008). In plants with a closed RAM, each cell type of the root can be connected to one initial stem cell (Dolan et al., 1993). In contrast, in plants with open meristems, the origin of the different cell types of the root cannot be connected to one initial cell. Note that the basic open RAM organization is principally found in Fabaceae and Cucurbitaceae (Rost, 2011), two plant families that are able to generate root nodules. Another important difference in terms of lateral root (LR) formation exists between the model system *A. thaliana* and legume plants such as *L. japonicus* and *M. truncatula*. In *A. thaliana*, LRs exclusively originate from a small group of pericycle founder cells (Malamy and Benfey, 1997; Casimiro et al., 2003). However, this pattern of LR formation is not universal. In legume plants, LRs are also formed predominantly from the pericycle cells (Mallory et al., 1970), but this process also involves other root layers such as the cortex in *L. japonicus* and *M. truncatula* (Op den Camp et al., 2011b).

In contrast to the well-described RAM and SAM model systems in *A. thaliana* (Stahl and Simon, 2010), less is known about the functioning of legume RAM (open type) and even less about the molecular mechanisms governing the functioning, maintenance, and identity of the nodule meristem. If nodule and root organogenesis use common regulatory mechanisms (Hirsch and Larue, 1997), we do not know how the presence of the open-type RAM is of importance for nodule organogenesis. The persistence of an active meristem in the indeterminate nodule (Fig. 49.1) suggests the existence of a SCN(s) in this organ. We can also postulate that the balance between division and differentiation is tightly regulated during nodule organogenesis, as nodules stop developing and enter senescence weeks or months after their initiations depending on the species. However, we do not know how this (these) SCN(s) are distributed and function during nodule development.

Homeotic mutants represent powerful tools to study relationships between different organogenetic pathways. The study of homeotic traits has allowed, for example,

building the floral ABC model in Angiosperms (Coen and Meyerowitz, 1991; Causier et al., 2010) and the Hox-gradient model in *Drosophila melanogaster* (McGinnis et al., 1984; Scott and Weiner, 1984). It has long been suspected that a certain degree of homology exists between roots and nodules (Nutman, 1948; Nutman, 1949; Nutman, 1952; Libbenga and Harkes, 1973). However, the lack of homeotic mutant for the nodule made this question difficult to answer (Hirsch and Larue, 1997), until the first report of nodules converted into roots in the pea *cochleata* mutant (Voroshilova et al., 2003; Ferguson and Reid, 2005).

We have recently characterized the pea *cochleata* and the Medicago *noot* (*nodule root*) recessive mutants as being mutated in orthologous genes (Couzigou et al., 2012). The mutation of a single gene resulting in nodule to root homeosis indicated for the first time that the root is a component of the default identity of the legume nodules, and that this gene acts in repressing (part of) this root identity in the symbiotic organ. In addition to the formation of a root in the apical position of the nodule, the *noot* and *coch* mutants are characterized by enlarged nodule meristems and alteration of stipule and flower developments (Wellensiek, 1963; Gourlay et al., 2000; Yaxley et al., 2001; Couzigou et al., 2012). The legume *NOOT* and *COCH* genes are orthologs of the well-characterized *A. thaliana BLADE-ON-PETIOLE* (*BOP*) genes (Hepworth et al., 2005; Norberg et al., 2005), also necessary for the definition of the leaves and flowers. The identification of the *NOOT* and *COCH* genes as *BOP* orthologs defines a new clade (*NBCL* clade) in the BTB/POZ-ankyrin domain proteins sharing conserved functions in dicot aerial organ development (Couzigou et al., 2012). The monophyletic NBCL clade groups with a sister clade are made of NPR1-LIKE proteins (NPR1 to 4 in *Arabidopsis*) and is supported by a high level of synteny detected between the *NBCL* loci in several plants (Couzigou et al., 2012). This common *NBCL* origin is also supported by their conserved functions (regulation of stipule, flower, inflorescence, foliar senescence, and abscission) in distant Angiosperm species [Arabidopsis, Medicago, Lupin, Tobacco, pea – Hepworth et al., 2005, Norberg et al., 2005, McKim et al., 2008; Khan et al., 2012; Wu et al., 2012; Couzigou and Ratet, unpublished]. In the distant model moss *Physcomitrella patens*, *BOP* genes are also developmental regulators during juvenile-to-adult gametophyte transition (Saleh et al., 2011). In the light of these data, a hypothesis of functional orthology might be favored following a parsimonious hypothesis. Indeed, it is unlikely that all these common functions exerted by NBCLs in distant species are only due to independent convergence mechanisms.

In this chapter, we discuss the role of the *NOOT* and *COCH* genes during nodule organogenesis in Medicago and pea, respectively. Their principal symbiotic functions in indeterminate nodules discussed earlier are (i) the maintenance of a harmonious meristematic growth and (ii) the repression of ectopic root formation from nodule vascular initials (Fig. 49.2a–f). These two symbiotic roles of *NOOT* and *COCH* parallel the *BOP* functions proposed by Norberg et al. (2005) for shoot development in *A. thaliana* and are in agreement with the functional orthology hypothesis. In this study, the authors proposed that the BOP proteins are necessary (i) for the maintenance of a harmonious meristematic activity (e.g., inflorescence architecture) and also (ii) for the repression of ectopic organs formation (e.g., bract suppression). In the following, we also discuss the induction of similar modified nodules from various examples of the literature and a hypothetical cross talk between *NOOT* and *COCH* and plant defense reactions during nodulation.

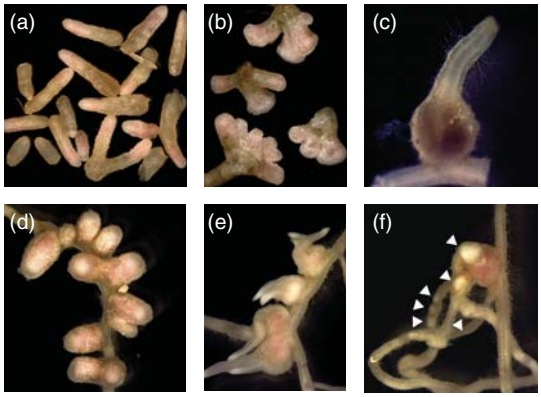

Figure 49.2 Phenotype of the *noot* and *coch* mutant nodules. *M. truncatula* (a) and pea (d) wild-type nodules; *noot* nodules (b, c); *coch* nodules (e, f). The *noot* nodules have increased meristematic activity (b) or show nodule to root conversions (c). The *coch* nodules in (e and f) have multiple roots developing in apical position. The mutant roots originating from the nodule in (f) have root hairs and develop new nodules (asterisk).

49.2 THE NODULE ROOT ORIGINATES FROM NODULE VASCULATURE

The specificity of the *noot* and *coch* mutants among the plant symbiotic mutants is the formation of one to four roots in an apical position of the symbiotic organ. These are genuine roots as they can develop root hairs (Fig. 49.2f) and can themselves bear LR and nodules (Fig. 49.2f). As both mutant roots and nodules are functional, we do not understand at the moment how the plant solves the sink–source functioning in these Russian doll-like structures (root nodule–root nodule). Our work has shown that the roots do not originate from the meristem but are in continuity with the peripheral vascular tissue of the symbiotic organ (Couzigou et al., 2012). This relation to the vascular tissue explains the presence of multiple roots for some nodules (Fig. 49.2c, 2e, and 2f). The

development of these roots can result from the reactivation of the vascular tissue initials present in apical position of these tissues (Fig. 49.1; Osipova et al., 2012). This suggests that one role for NOOT (or COCH) is to suppress the activity of these initials, and that they in fact correspond to silent RAMs. This hypothesis is in agreement with the pattern of expression of the RAM marker *WOX5* and *DR5-RFP* in apical position of the vascular tissue in indeterminate nodules (Osipova et al., 2012; Couzigou et al., 2013).

All these results thus indicate that each nodule vascular element can be considered ontologically homologous to a root. As two vascular traces are detected at early stages of nodule formation (Guinel, 2009), the symbiotic organ is thus initially made of two modified roots surrounding a cortical (symbiotic) tissue. During later steps of nodule development, vascular bundles dichotomize into multiple peripheral vascular tissues.

The conversion from a nodule to a root-like organ can be observed at different stages of the symbiotic organ development as hybrid organs can be formed from very early stages of nodule development to late stages corresponding to mature nitrogen-fixing organs. Conversion from early stages can be sometimes detected only by the presence of a double vascular tissue at the base of the root (Couzigou et al., 2012). When using a GFP-tagged *Rhizobium* strain, discrete foci of infected tissue can be detected at the base of these roots. All intermediates between these early converted roots to mature nodules with one apically developed *noot*-root can be found in the same experiment. This observation suggests that NOOT is acting during the whole nodule organogenesis to maintain the symbiotic organ identity. It remains to determine if its action start after the primordium formation or is already necessary to delimit the primordium territory in the root (see next paragraph). One additional observation is that the penetrance of the mutation is variable in one plant and in between plants species because the *coch* mutants generally develop hybrid organs (Ferguson et al., 2010) in 90% of the nodules in mutant plants, when hybrid structures are generally observed in only 20–40% of the nodules in Medicago *noot* plants (Couzigou et al., 2012). These differences may be explained by the different genetic contexts, resulting in different regulatory mechanisms or may suggest the presence of other actors with similar roles in these plants.

49.3 IS NOOT NECESSARY TO DELIMIT DOMAINS IN THE SYMBIOTIC ORGAN?

In addition to developing a root in nodule apical position, the *noot* and *coch* mutants are characterized by nodules with significantly enlarged meristematic region and increased lobe number (Fig. 49.2b; Ferguson and Reid, 2005; Couzigou et al., 2012). Spots of anisotropic cell divisions are often observed in the meristematic region of these mutant nodules (Fig. 49.3a–c). Some proliferative nodules are also characterized by a callus-like texture in the *noot* and *coch* mutants. *NOOT* and *COCH* are thus necessary for the harmonious growth of the indeterminate nodules, and this suggests an impaired balance between proliferation and differentiation in the mutant backgrounds.

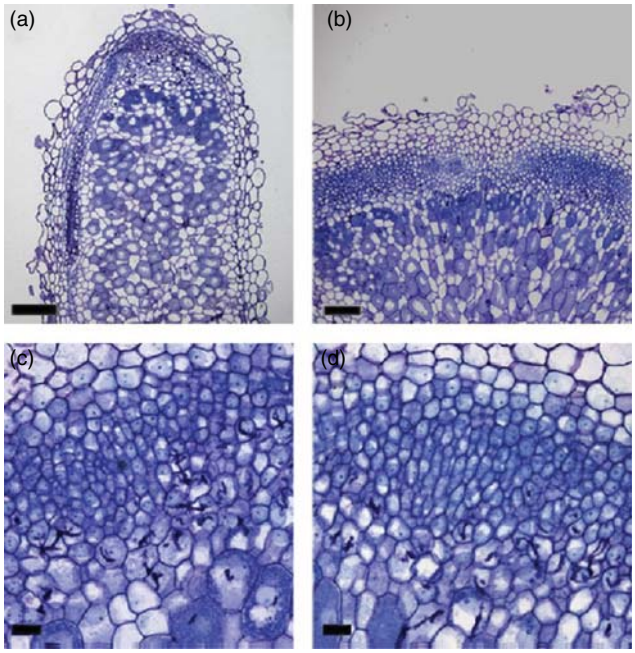

Figure 49.3 Increased meristematic activity in *noot*-mutant nodules. The Technovit section in (a) shows the structure of a wild-type elongated nodule with a small meristem in apical position. The Technovit section in (b and c) shows the meristematic region in a *noot* nodule similar to Fig. 49.2b. The meristem region is enlarged (b) and shows anisotropic cell divisions (c). Scale bar 250 µm in (a and b) and 50 µm in (c).

Plant hormones play an important role in regulating the ratio between division and differentiation in meristems. Auxin and cytokinin were shown to play such roles during nodule formation (Op den Camp et al., 2011b, Deinum et al., 2012, for review see Desbrosses and Stougaard, 2011; Oldroyd et al., 2011; Chapter 56 and Table 49.1) and auxin and cytokinin responsive genes are induced in the nodule meristem (Plet et al., 2011; Couzigou et al., 2013), suggesting that these two hormones might be regulating the nodule meristem activity antagonistically as for the primary meristems (see Chapters 47, 56, 66). Moreover, similar roles for auxin and cytokinin were described for the development of the determinate *Lotus japonicus* nodules (Takanashi et al., 2011; Suzaki et al., 2012), suggesting that part of

the auxin–cytokinin-dependent organogenesis program is conserved between the two types of nodules. The indeterminate nodules of the cytokinin-insensitive *cre1* mutant in *M. truncatula* are characterized by an increased lobe number as we observed in the *noot* and *coch* mutants (Plet et al., 2011). Similarly, an auxin overproducing strain of *Rhizobium leguminosarum* bv. *viciae* induces vetch nodules with an enlarged and more active meristem (Camerini et al., 2008). These results might suggest an interaction between NOOT and the hormone-signaling pathways. However, expression studies (http://mtgea.noble.org, Benedito et al., 2008) do not suggest a direct regulation of *NOOT* expression by auxin or cytokinin. In addition, root elongation is not altered by hormone application in the *noot* mutant (Couzigou et al., 2012).

By contrast, it was shown that the *Arabidopsis BOP* genes are necessary to set boundaries in lateral organs in order to control their development (Ha et al., 2007; Barton, 2010). We can thus hypothesize that *NOOT* and *COCH* fulfill similar functions in boundaries, definitions that will delimit territories and restrict the apical meristem size in the symbiotic organ. The similarities in the *noot* and *bop1bop2* phenotypes in the aerial part of the corresponding mutants (flower and leaf identity) are in agreement with this hypothesis. For example, the *BOP* and *PUCHI* genes are together necessary for bract suppression (Karim et al., 2009), in agreement with the modified and elongated bracts present in *coch* flowers (Gourlay, 1999; Yaxley et al., 2001; Couzigou et al., 2012). In addition, BOP and PUCHI by promoting the expressions of *LEAFY* (*LFY*) and *APETALA1* (*AP1*) (Karim et al., 2009) participate together in the identity of the floral meristem. Similarly, the pea *LFY* ortholog, *UNIFOLIATA* interacts genetically with *COCH* for stipule, flower, and inflorescence development (Gourlay et al., 2000; Kumar et al., 2011; Sharma et al., 2012). These observations thus suggest orthologous functions for the NBCLs present in the different plants.

It remains to determine if the *NBCL* genes play roles during root development. Such role was not described for *BOP* genes, and we did not observe an effect of the *noot* mutation on the root structure but subtle effects cannot be excluded. Using the hypothesis of the orthologous function, it is interesting to note that the *AP2/EREBP* auxin-responsive gene *PUCHI* that interacts genetically with the *BOP* genes (Karim et al., 2009) is required to restrict the zone of proliferation in the lateral root primordia (Hirota et al., 2007). Kang et al. (2013) recently proposed a concerted action of PUCHI with LBD16/ASL18 and LBD18/ASL20 to control lateral root primordium development and size, as well as lateral root emergence, supporting a role for these factors in territory definition. Assuming the functional orthology hypothesis, these results make *PUCHI-LIKE* genes in legumes possible interacting partners. Studying *PUCHI-LIKE* genes expression patterns during nodule and root formation might also be interesting as PUCHI is an early marker for root primordium formation functioning downstream auxin signaling.

49.4 NOOT-LIKE STRUCTURES CAN BE TRIGGERED BY ENVIRONMENT OR MUTANT RHIZOBIA

The formation of roots from indeterminate and determinate nodules (i.e., with or without persistent apical meristem, respectively) was previously reported (Table 49.1). This includes emergence of ectopic roots on (i) *M. sativa* and Trifolium nodules as a result of increased temperature (Day and Dart, 1971; Dart, 1977), (ii) Arachis nodules formed on chimeric plants produced by hairy roots (Akasaka et al., 1998; Sinharoy and DasGupta, 2009), or (iii) after inoculation of Phaseolus, Trifolium, or Soybean plants with *Rhizobium etli*, *R. leguminosarum* bv. *trifolii*, and *Bradyrhizobium japonicum* mutant strains, respectively (McIver et al., 1997; Ferraioli et al., 2004; Morris and Djordjevic, 2006; Gourion et al., 2009). The existence of *noot*-like phenotypes in determinate nodules shows that the conversion of a nodule into a root can be independent of the presence of a persistent meristem in agreement with the vasculature apical origin of the ectopic roots in *noot*. Interestingly enough, these experiments indicate that a bacterial mutant can also induce *noot*-like structure, suggesting a role for the bacterial partner in maintaining the organ identity. The signaling mechanisms underlying the loss of organ identity in presence of a bacterial mutant is still unknown.

It should be noted here that the origin of the root was not precisely determined in all the studies described earlier. Nodules with one central vascular tissue can also be found in some *M. truncatula* mutants or in nodules induced by bacterial mutants (Guan et al., 2013). These hybrid structures are more related to infected roots than to *noot* nodules and seem to be induced after early aborted infections. They may correspond to earlier alterations of the symbiotic organ development, as the vasculature initiation is not altered in *noot*. In agreement with this, a *Rhizobium leguminosarum* purine auxotroph strain induces nodules with a central vasculature in Phaseolus (Newman et al., 1992). If the mutant strain is supplemented with 4-aminoimidazole-5-carboxamide (AICA) riboside for at least 6 days, the nodules have peripheral vascular tissues. These mutant nodules with central vasculature are more similar to the primitive actinorhizal nodules and to rhizobia-induced nodules on the nonlegume *Parasponia andersonii* (Gualtieri and Bisseling, 2000; see Chapter 4). Together with the *noot* (or *coch*) mutant, they will be instrumental in future work to better understand nodule evolution.

49.5 ARE NOOT AND COCH INVOLVED IN NODULE IMMUNITY?

A recent study by Canet et al. (2012) suggests that the *Arabidopsis* BOP proteins can interfere with plant immunity by the interaction with TGA bZIP transcription factors. These TGA transcription factors usually control plant immunity by the interaction with the NPR1 protein that belongs to the group of BTB–POZ ankyrin domain proteins (Canet et al., 2012) including BOPs, COCH, and NOOT.

It will thus be interesting to test the role of the *NOOT* gene in immunity against root and foliar pathogens. In addition, our laboratory has recently shown that immunity might be actively repressed in the symbiotic organ in order to allow an efficient bacterial infection of the symbiotic cells (chronic infection; see Bourcy et al., 2013a,b). NOOT may participate to this process by interacting with a NPR1-like dependent signaling pathway as described by Canet et al. (2012). However, the symbiotic bacterial recognition may also require that the symbiotic cells in the nodule have acquired a NOOT-dependent "symbiotic identity." In other words, a root-like identity of the symbiotic organ may not allow the proper recognition of the bacteria and trigger some defense-like reactions in the invaded cells. In agreement with this hypothesis, some defense-like reactions (phenol

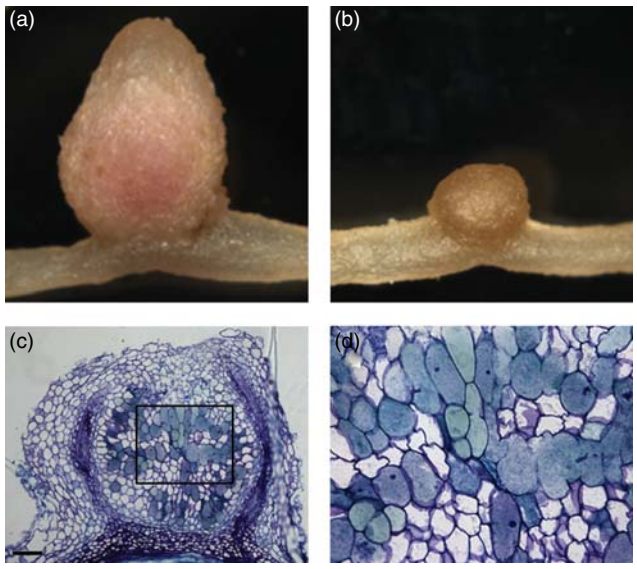

Figure 49.4 Defense-like reactions of the *noot*-mutant nodules. Wild-type nodule (a) and a *noot* nodule showing defense-like symptoms in (b). The toluidine blue stained Technovit section in (c) shows the presence of empty cells that are filled with green material characteristic of phenol accumulation with this staining. (d) Enlargement of a Technovit section showing a symbiotic nodule region showing phenol accumulation. Scale bar 100 µm in (c).

accumulation) were observed sporadically in the *noot* and *coch* mutant backgrounds (Fig. 49.4a–d). Accordingly, these abortive dark nodules show an endoreduplication index more closely related to roots than to wild-type and *noot*-fixing nodules (not shown), probably reflecting an impaired bacteroid differentiation. Future work will be necessary to better define this possible subtle role of NOOT and COCH.

49.6 CONCLUSIONS

Our work (Couzigou et al., 2012) showed that the *NOOT* and *COCH* genes are necessary for the robust persistence of nodule identity. *NOOT* and *COCH* are *Arabidopsis BOP* orthologs, and their functions in the identity of the lateral aerial organs are conserved in *M. truncatula* and *P. sativum* (Hepworth et al., 2005; Norberg et al., 2005; Couzigou et al., 2012). This suggests that *NOOT* and *COCH* were recruited from the aerial developmental programs to repress root identity in the legume symbiotic organ, even if a role in roots cannot be formally excluded. In *Arabidopsis*, the BOP proteins are expressed at the tissue boundaries to define the organ identity and appear to act within the leaf to affect development at the SAM (Barton, 2010). Similar to its *Arabidopsis* orthologs, the *NOOT* expression pattern (Couzigou et al., 2012) suggests a function in the delimitation of the boundaries between the nodule meristem and the vascular tissue initials in the symbiotic organ. In the *noot* and *coch* mutants, the ectopic roots do not derive from the nodule meristem but originate from the vascular initials (Fig. 49.1; Couzigou et al., 2012). This suggests that the nodule vascular strands are ontologically related to roots in agreement with the root-like nature of the nodule vasculature as shown by Osipova et al. (2012) using the WOX5 root identity marker. Thus, similar to their role in the definition of boundaries in Arabidopsis, *NOOT* and *COCH* expressions in the vascular initials may affect the functioning of the nodule meristem and/or regulate the activities of vasculature initials to a level compatible with the coordinated development of these vascular tissues and the nodule meristem.

49.7 PERSPECTIVES

The characterization of the *noot* and *coch* mutants and the identification of the corresponding genes as orthologs of the *BOP* genes allow us to better understand the organogenesis of the temperate legume nodules and may also shed light on their origin(s). However, the known multiple roles of the *Arabidopsis* BOP in interaction with its molecular partners (transcription factors) in root, flower, and leaves do not favor one nodule origin, that is, are they of shoot or root origin (Hirsch and Larue, 1997) even if the phenotype of the mutants point to a root origin of the vascular tissues. Future work will have to identify the NOOT partners and determine their roles in the identity of the whole symbiotic organ. Understanding how NOOT and COCH define territories inside the nodule is also a challenge but will help understanding the structure of this symbiotic organ and possibly how the bacterial symbiotic partner is confined inside the nodule.

It will also be interesting to determine the role of *NOOT* orthologs in other nodule-forming plants. First, we can predict a role for *NOOT* orthologs in determinate nodules as the vascular tissue formation should be similar in these organs (Guinel, 2009), and the nodular roots formed in such nodules are closely linked to vasculature (see references in Table 49.1). The nodules formed in actinorhizal plants and Parasponia have a central vasculature considered as a modified root (Fig. 49.1) and could represent a more ancestral state of the legume symbiotic organ (Gualtieri and Bisseling, 2000). It has been recently proposed that the Parasponia–Rhizobium symbiosis could correspond to a delicate balance between mutualism and parasitism (Op den Camp et al., 2012). The role of *NOOT* orthologs in the identity of these more ancestral symbiotic structures will indicate if the NBCL clade was recruited early for symbiosis or if they are only important for nodules with peripheral vasculature.

The possible complexity of the symbiotic organ with root-like vascular tissue together with shoot-like apical meristem and symbiotic tissue will make these studies challenging but illustrate well the evolutionary tinkering used to recruit pre-existing developmental programs in order to construct new organs (Jacob, 1977).

ACKNOWLEDGMENTS

We would like to thank Dr. Alexei Y. Borisov (ARRIAM, Russia), Vladimir Zhukov (ARRIAM, Russia), Dr. Benjamin Gourion (ISV-CNRS France), and Viviane Jean (ISV-CNRS France) for helpful discussions during this project. We thank Dr. Mick Bourge for expertise and helpful assistance for flow cytometry analysis hosted by Imagif platform (CNRS, Gif-sur-Yvette). This work was supported by the Centre National de la Recherche Scientifique and the grant Blanc International Sciences de la Vie, de la Santé et des Ecosystèmes 6.2010.1 (LEGUMICS) from the Agence National de la Recherche to P.R. as well as by the French and Russian ministries of education and science grants [16.552.11.7085, project no. 8056], and Centre National de la Recherche Scientifique Programme International de Co-opération Scientifique 4902 RFBR 09-04-91054]. JMC was supported by a Ph.D. fellowship from the French Ministry of Research and the French Academy of Agriculture (Dufrenoy Grant, 2011).

Recognition in Nodulation

Chapter 50

Flavonoids Play Multiple Roles in Symbiotic Root–Rhizosphere Interactions

Samira Hassan and Ulrike Mathesius

Division of Plant Science, Research School of Biology, The Australian National University, Canberra, ACT, Australia

50.1 INTRODUCTION

Flavonoids are plant metabolites that are synthesized through the phenylpropanoid pathway. The precursors of the flavonoid pathway, p-coumaroyl-CoA and malonyl-CoA, can be assembled into 10,000 or more diverse flavonoid molecules in plants (Winkel-Shirley, 2001). Flavonoids generally contain two phenyl rings and a three-carbon heterocyclic ring, arranged in different basic structures (Fig. 50.1). However, the diversity of these molecules is largely contributed by modifications to these basal structures such as through glycosylation, methylation, hydroxylation, acylation, malonylation, prenylation, or polymerization (Winkel-Shirley, 2001). The modifications of the flavonoid structures lead to changes in their physical, chemical, and biological properties such as their solubility, mobility across membranes, degradation by rhizosphere organisms, or their functional properties inside the plant or in the rhizosphere.

The biosynthesis of flavonoids has been part of many studies and the majority of the enzymes involved in the processes have been identified (Dixon and Steele, 1999; Winkel-Shirley, 2001). Flavonoid synthesis is thought to initiate at enzyme complexes located on the cytosolic side of the endoplasmic reticulum in plant cells (Jorgensen et al., 2005). The intermediate structures are then transported into the vacuole for storage and are often glycosylated in the process by enzyme complexes on the tonoplast (Aoki et al., 2000; Winkel, 2004).

Inside plant cells, flavonoids have been localized to the cytoplasm, the vacuole, the nucleus, cell walls or cell membranes (Erlejman et al., 2004; Hutzler et al., 1998; Naoumkina and Dixon, 2008; Saslowsky et al., 2005). The differential localization and synthesis of flavonoids is regulated by several transcription factors belonging to the myeloblastosis (MYB) or basic helix-loop-helix (bHLH) families (Verdier et al., 2012). These transcription factors are able to respond to multiple environmental cues (Koes et al., 2005).

Flavonoids can be moved between cells and into the rhizosphere through various transporters, although their function and specificity still remains to be elucidated. It is likely that the cell-to-cell transport of flavonoids occurs through a vesicle-mediated transport or through membrane-bound transporters such as MATE (multidrug and toxin extrusion protein) and ABC (ATP binding cassette)-type transporters (Zhao and Dixon, 2009). The transport of flavonoids also occurs over long distances, as the external application of flavonoids in *Arabidopsis* causes them to move to the more distal parts of the plant (Buer et al., 2007). The mechanism of this transport is thought to be mediated through the members of ABC transporter families or through glutathione complexing.

To reach potential symbionts in the rhizosphere, flavonoids are either actively exuded by the root through transporters (Badri et al., 2008, 2012; Sugiyama et al., 2008)

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

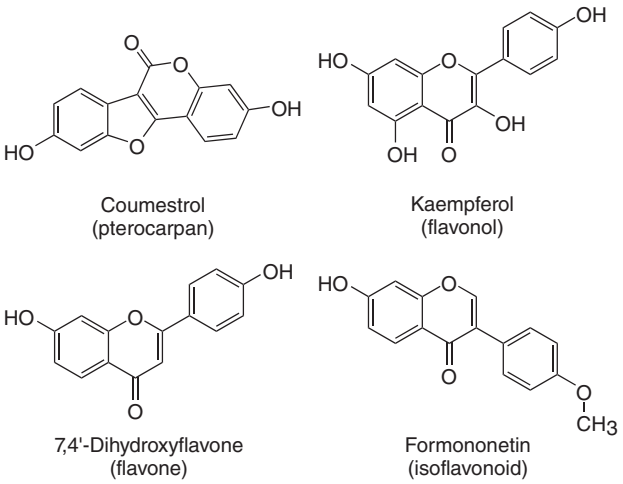

Figure 50.1 Examples of flavonoid structures with roles in root–symbiont interactions.

or released from root border and root cap cells (Hawes et al., 1998; Shaw et al., 2006). The synthesis and exudation of flavonoids are also highly responsive to the presence of biotic elicitors and this is likely to result in fine-tuning of the signaling interaction between plant hosts and symbionts as well as pathogens (Armero et al., 2001; Schmidt et al., 1994).

50.2 ROLES FOR FLAVONOIDS IN THE *RHIZOBIUM*-LEGUME SYMBIOSIS

Most legumes have the ability to form a symbiotic relationship with nitrogen-fixing bacteria collectively known as rhizobia.

The symbiosis requires partner recognition and specificity, which are partially mediated by plant-exuded flavonoids. Nodulation also involves the development of root nodules from root cortical and pericycle cells, which is controlled in part through polar auxin transport and auxin accumulation. Flavonoids control auxin transport and breakdown during nodule development. Thus, flavonoids have roles in the rhizosphere as signals to rhizobia, and in addition act inside the root to control nodule development, as described in the following text (Subramanian et al., 2007).

Flavonoids act in several ways during symbiosis, such as chemically attracting rhizobia, inducing *nod* gene synthesis in rhizobia, acting as determinants of host specificity, as regulators of root development, or by altering plant defence responses (Cooper, 2004).

The regulation of *nod* genes in rhizobia by root-secreted flavonoids has been well studied. The *nod* genes encode enzymes that synthesize species-specific lipochitooligosaccharide molecules known as Nod factors. The Nod factors are required for the formation of nodules and the invasion of rhizobia in the host plant (Spaink, 1995; see Chapter 51). Nod genes are regulated by NodD transcription factors that belong to the LysR family of transcriptional regulators. When an appropriate flavonoid binds to the NodD protein it improves the access of RNA polymerase to the *nod* gene promoter, thereby increasing its transcription (Li et al., 2008; Peck et al., 2006). The transcription factor NodD is also activated by an increase in the concentration of intracellular calcium induced by flavonoids (Moscatiello et al., 2010). The *nod* gene inducing flavones luteolin, isolated from *Medicago sativa,* and 7,4′-dihydroxyflavone (Fig. 50.1) from *Trifolium repens* (Peters et al., 1986; Redmond et al., 1986) were the first flavonoid molecules shown to have an effect. This *nod* gene inducing property has since been discovered for many other flavonoids, although some also function as *nod* gene repressors, as summarized by Cooper (2004). It is thought that a combination of flavonoids is more effective as *nod* gene inducers rather than a single compound (Begum et al., 2001; Bolanos-Vasquez and Warner, 1997). This combination of flavonoids as perceived by the rhizobia is often species-specific and determines which rhizobia are able to successfully establish a symbiotic relationship with the host plant. The affinity of the NodD protein to flavonoids partially determines host range, and it has been shown that NodD proteins from rhizobia with a broad host range, for example, *Rhizobium* sp. NGR234, are activated by a wider range of flavonoids than NodD from narrow host range rhizobia (Gyorgypal et al., 1991; see Chapter 32).

As mentioned previously, not all flavonoids are *nod* gene activators. For example, the isoflavonoids medicarpin and coumesterol (Fig. 50.1) have been shown to negatively regulate *nod* gene expression in *Sinorhizobium meliloti* (Zuanazzi et al., 1998). Together, the combinations of flavonoids maintain an optimal level of Nod factor secretion while also preventing elicitation of defence response by the plant (Savouré et al., 1997; Zuanazzi et al., 1998).

The flavonoid secretion profile from a host root changes during the course of a symbiotic relationship with rhizobia. The flavonoid exudates from different legume species show variation in their composition after inoculation with rhizobia. It is likely that this effect is important to optimize the synthesis of Nod factors during different stages of symbioses. For example, the plant does not secrete high amounts of *nod* gene activating flavonoids after it has formed sufficient numbers of nodules (Dakora et al., 1993; Schmidt et al., 1994). The ability of flavonoids to be metabolized and modified by rhizobia also affects their activity as *nod* gene inducers or inhibitors (Rao and Cooper, 1995).

In addition to *nod* gene activation of their specific symbionts, flavonoid exudation from the root also plays a role in guiding rhizobia to a host root. Some rhizobia display strong chemo-attraction to root-exuded flavones and flavonones such as luteolin and apigenin. The plant also

displays selectivity in attracting different species of rhizobia with variations in their flavonoid exudation profile (Aguilar et al., 1988; Dharmatilake and Bauer, 1992).

The exudation of flavonoids from legume roots can be modified not only in response to rhizobia, but also free-living nitrogen-fixing bacteria. For example, a study by Star et al. (2012) found that co-inoculation of *Vicia sativa* spp. *nigra* with its symbiont *Rhizobium leguminosarum* bv. *viciae* and the free-living nitrogen-fixing bacterium *Azospirillum brasiliense* enhanced flavonoid exudation, and this was dependent on the ability of the *Azospirillum* strain to synthesize auxin (see Chapter 91). Another determinant of flavonoid production is the availability of nitrogen in the growth medium. Flavonoid exudation by legumes remains low under nitrogen-sufficient conditions but is increased in the absence of nitrogen, that is, at a time when the host needs to establish a symbiosis with rhizobia (Coronado et al., 1995).

Legume hosts also exude combinations of flavonoids to select for compatible symbiotic organisms. For example, medicarpin from clover and medic species has an inhibitory effect on incompatible bacterial strains, but does not inhibit the growth of compatible rhizobia (Pankhurst and Biggs, 1980). Low concentrations of isoflavonoids have been reported to induce resistance in compatible symbiotic bacteria to potentially bactericidal phytoalexins from root exudates (Parniske et al., 1991). This suggests additional sites of recognition apart from a *nodD* promoter site and allows the plants to protect the beneficial bacteria while mounting a defence against pathogenic organisms.

Some of the other flavonoid-regulated genes known in rhizobia include genes for exopolysaccharide synthesis (see Chapter 36). The exopolysaccharide layer in rhizobia is important for the regulation of defence response in the host plant (Dunn et al., 1992). Some exuded flavonoids, for example, daidzein and genistein, have been implicated in activating the type III secretion system in rhizobia and thus stimulating the secretion of important nodulation outer proteins (Nops) (de Campos et al., 2011; Krishnan et al., 2003).

The perception of *Nod* factors by the root leads to new initiation of cell division in root cortical and pericycle cells, most likely due to auxin accumulation in those cells (Mathesius, 2008; Suzaki et al., 2012). Flavonoids have also been shown to accumulate specifically in cortical cells before and during the onset of cell division (Mathesius et al., 1998a). Flavonoid accumulation is also spatially distinct in meristematic and vascular tissues of differentiated nodules in a host-species specific manner (Charrier et al., 1998). Those studies suggest specific roles of flavonoids in cell division at both the early and later stages of the symbiosis. Some flavonoids such as the flavonol kaempferol (Fig. 50.1) have been found to act as negative regulators of polar auxin transport in clover, mimicking the action of Nod factors on auxin accumulation in the root (Mathesius et al., 1998b; see Chapter 47). Measurements of polar auxin transport showed that acropetal auxin transport is inhibited during infection with rhizobia, and that this inhibition of auxin transport does not occur when the flavonoid pathway is silenced in *Medicago truncatula* (Wasson et al., 2006). Silencing of specific branches of the flavonoid pathway in *M. truncatula* suggests that it is the flavonol branch that is most likely required for auxin transport control (Zhang et al., 2009). Silencing of the isoflavonoid biosynthesis pathway in soybean also leads to changes in auxin responses in the roots, but this can be overcome by inoculation with a genistein-hypersensitive *Bradyrhizobium* strain or with Nod factor addition (Subramanian et al., 2006), suggesting that indeterminate- and determinate-type nodules have different requirements for auxin transport control by flavonoids. Silencing of isoflavone reductase (IFR) in bean also led to reduced nodule numbers, and this was correlated with reduced expression of the auxin response gene *GH3* (Ripodas et al., 2013). In contrast to chalcone synthase silencing in *M. truncatula*, which showed no significant effects on lateral root development (Wasson et al., 2009), silencing of *IFR* in bean reduced root growth and lateral root emergence, which could be related to an effect on auxin (Ripodas et al., 2013).

The exact mechanism through which flavonoids affect the auxin transport is not known, but evidence from *Arabidopsis* suggests that flavonoids can affect the vesicular cycling of auxin transporters of the PIN family, possibly through interactions with other regulatory proteins such as phosphatases and kinases (Peer et al., 2004; Peer and Murphy, 2007; Santelia et al., 2008; see Chapter 47).

The increase or decrease in auxin in dividing cortical cells may also be caused by the regulation of auxin breakdown by peroxidases. Flavonoids again have been implicated in this role as regulators of peroxidase activity. It has been discovered that the isoflavonoid formononetin (Fig. 50.1) from *Trifolium repens* accelerates auxin breakdown through the activation of peroxidases. Other flavonoids such as 7,4′-dihydroxyflavone and its glycosides accumulate in dividing cortical cells where they can inhibit auxin breakdown by peroxidases (Mathesius, 2001). This differential ability of flavonoids and the availability of a large range of such metabolites ensures that the plant can actively regulate the development of new root organs such as nodules.

Flavonoids could also be playing a role in the systemic regulation of nodule numbers. Split-root experiments have shown that the isoflavonoid formononetin and its glycoside ononin are down-regulated in both rhizobia-induced and mycorrhiza-induced symbioses in a systemic manner, suggesting that a related autoregulation signal affects their synthesis in both processes (Catford et al., 2006). External application of ononin could partially restore the nodulation and mycorrhization of the autoregulated root system, suggesting that flavonoids have an active role in controlling symbiosis (Catford et al., 2006). Similarly, in grafts of

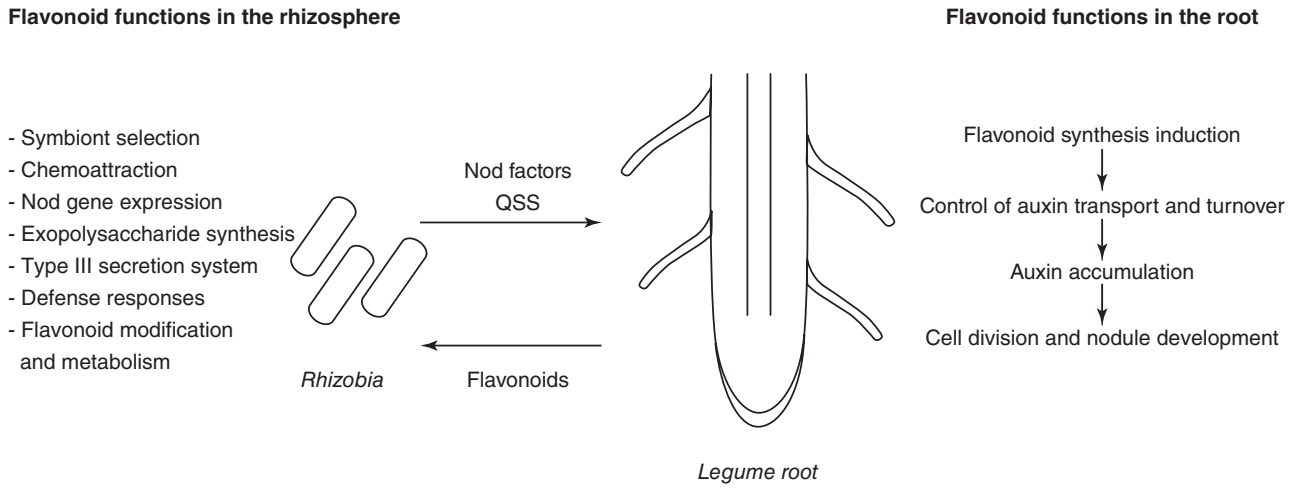

Figure 50.2 Simplified model of the various roles of flavonoids in the *Rhizobium*–legume symbiosis.

supernodulating soybean shoots with wild type bean roots, accumulation of root isoflavonoids is higher in graft combination with a supernodulating shoot than with a wild type shoot (Abd-Alla, 2011). External application of daidzein and coumestrol increases nodule numbers and enhances bacterial growth in culture (Abd-Alla, 2011). It is possible that systemically accumulated flavonoids control auxin transport in the autoregulated roots, as auxin transport has been shown to be modulated during autoregulation in *M. truncatula* (van Noorden et al., 2006). The roles of flavonoids in the *Rhizobium*-legume symbiosis are summarized in Figure 50.2 (see also Chapter 47).

50.3 FLAVONOIDS ARE INVOLVED IN ACTINORHIZAL SYMBIOSES

Apart from the *Rhizobium*-legume symbiosis, nodulation also occurs in several families of non-legumes that form a symbiosis with the actinorhizal bacterium *Frankia*. So far, no *nod* genes have been identified in *Frankia* (Normand et al., 2007) and the early signaling interaction between hosts and *Frankia* are still under investigation (see Chapters 35, 55). There are some indications that flavonoids stimulate the symbiosis. For example, flavonoids present in seed and root exudates have been found to enhance nodulation by *Frankia*, although the mechanism is not understood (Benoit and Berry, 1997; Hughes et al., 1999). Flavonoids might also have a role in bacterial selectivity by the host because the fruits of the plant *Myrica gale* improve the growth and nitrogen fixation ability of the compatible *Frankia* species while repressing incompatible strains (Popovici et al., 2010).

As in legumes, flavonoid biosynthesis genes are differentially expressed during nodulation in actinorhizal plants such as *Casuarina glauca*, and some of the transcripts are up-regulated in the absence of an external nitrogen source (Auguy et al., 2011). Flavans have been found to accumulate in specific compartments of the nodule lobes of actinorhizal plants, where they have been hypothesized to restrict the infection of the symbiont (Laplaze et al., 1999).

50.4 FLAVONOIDS ENHANCE PLANT INTERACTIONS WITH FREE-LIVING NITROGEN-FIXING BACTERIA

Flavonoids appear to play roles not just in legume–rhizobia interactions but also in the colonization of non-legumes with nitrogen-fixing bacteria. Infection of non-legumes with nitrogen-fixing plant-growth promoting bacteria like *Azospirillum* sp. can be host-specific in its effects on plant growth promotion and the induction of flavonoids and other phenolic compounds in the plant (Chamam et al., 2013; see Chapter 90). As in some legumes, for example, *Sesbania rostrata*, which is colonized by *Azorhizobium caulinodans*, infection of non-legumes by rhizobia appears to occur via the so-called crack-entry, mostly at sites of lateral root emergence (Tsien et al., 1983). The colonization of wheat, rice and *Arabidopsis thaliana* by *A. caulinodans* has also been observed around lateral root emergence sites and rhizobia colonize root tissues intercellularly. The frequency of infection is increased in the presence of the *A. caulinodans Nod* gene inducer naringenin, but not with other flavonoids tested (Gough et al., 1997; Jain and Gupta, 2003; Webster et al., 1998). However, this enhanced colonization ability is independent of *nod* gene activation and is unlikely due to the potential of flavonoids to act as a food source for rhizobia in these studies. Interestingly, the colonization of *A. thaliana* by *A. caulinodans* is similar in wild type and flavonoid-deficient mutants, suggesting that plant internal flavonoids are not necessary for the colonization process (O'Callaghan et al.,

2001). While these studies have been carried out under controlled conditions, it has been questioned whether internal colonization of non-legumes with nitrogen-fixing bacteria actually occurs under field conditions and whether the niches occupied by these bacteria in root tissues are viable places for bacterial survival (McCully, 2001). It is currently unknown how externally applied flavonoids could activate colonization of legumes and non-legumes by nitrogen-fixing bacteria, but proteome and transcriptome analysis of rhizobia exposed to flavonoids found multiple protein and transcript accumulation changes, including some related to bacterial stress response, redox control, transport, and biofilm formation (da Silva Batista and Hungria, 2012; de Campos et al., 2011; Guerreiro et al., 1997; Lee et al., 2012). In the endophytic diazotroph *Herbaspirillum seropedicae*, naringenin regulates the synthesis of exopolysaccharides, lipopolysaccharides and auxin, which could be important for regulation of defense responses and developmental changes in the host, for example, lateral root formation by auxin (Tadra-Sfeir et al., 2011; see Chapter 93). Auxin synthesis is also enhanced in the presence of flavonoids in *Rhizobium* sp. NGR234 (Theunis et al., 2004). As naringenin treatment also increases lateral root formation in wheat both in the absence and in the presence of *A. caulinodans* (Webster et al., 1998), it is possible that this effect is via auxin production in the rhizobia or via the interaction of naringenin or downstream flavonoid products with the auxin transport machinery (Wasson et al., 2006).

There is also a possibility that flavonoids such as naringenin interfere with quorum sensing-regulated behaviors in bacteria. Many of the behaviors of bacteria involve cell-to-cell communication signals called quorum sensing signals (QSSs) (Fuqua et al., 2001; see Chapter 37), and this is important for functions including nitrogen fixation and biofilm formation (Gonzalez and Marketon, 2003; von Bodman et al., 2003). Naringenin has been identified as a molecule that interferes with quorum sensing signaling in *Escherichia coli, Vibrio fischeri* (Vikram et al., 2010) and *Pseudomonas aeruginosa* (Vandeputte et al., 2011). However, the effects of naringenin on quorum sensing regulated genes in rhizobia or other rhizosphere bacteria have not been investigated. Flavonoids that induce *nod* gene expression in rhizobia have also been shown to have a stimulatory effect on their QSS synthesis genes (Perez-Montano et al., 2011). Genistein, apigenin, and daidzein have been found to stimulate QSS synthesis, but their activity varies in different species of rhizobia. This suggests that flavonoids could stimulate symbiotic functions in bacteria by influencing their communication.

50.5 ROLES FOR FLAVONOIDS IN MYCORRHIZAL SYMBIOSES

The majority of land plants can be colonized by mycorrhizal fungi that are beneficial contributors in plant phosphorus nutrition. The most studied interaction is the arbuscular mycorrhizal (AM) association. Many of the early signaling steps required for the *Rhizobium*–legume symbiosis are shared in AM symbioses with legumes (see Chapter 108). However, the requirements for flavonoids in nodulation is not shared in mycorrhizal symbioses, as flavonoid-deficient

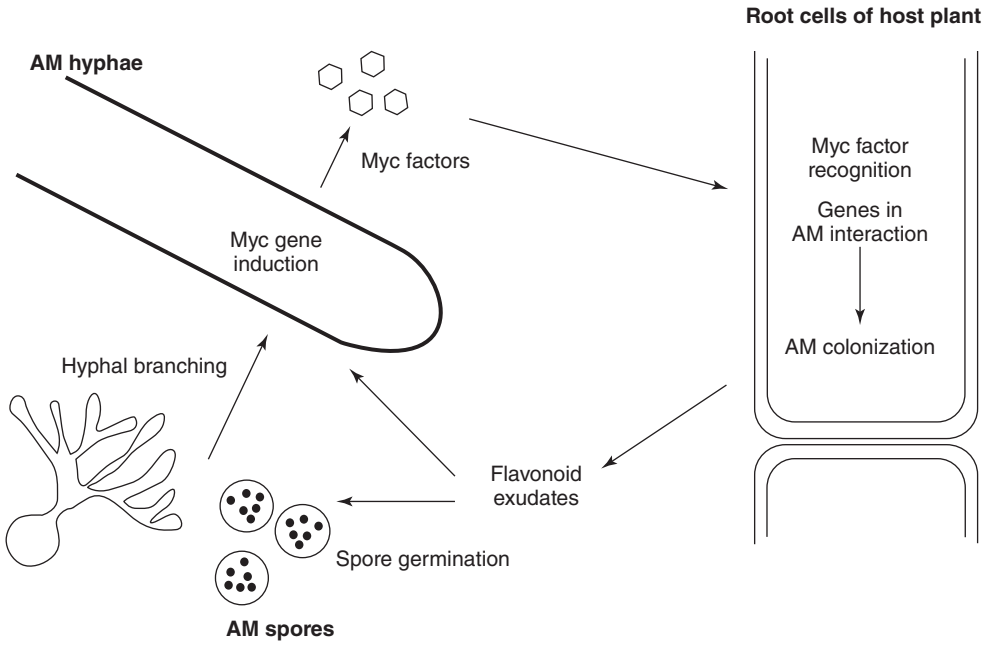

Figure 50.3 Simplified diagram depicting the possible roles for flavonoids in arbuscular mycorrhizal symbioses.

plants have been shown to form functioning AM symbioses (Becard et al., 1995). Nevertheless, flavonoids appear to play stimulating roles that can enhance the symbiosis.

The spores of mycorrhizal fungi germinate in the soil to form hyphae that continue to branch in the presence of specific root exudates (Fig. 50.3). The fungal hyphae are also attracted by the root exudates. As the AM colonization continues, the hyphae form ecto- or endomycorrhizal invasion structures (Harrison, 2005). The flavonoids found in legume root exudates have been reported to stimulate the germination of AM fungal spores, to induce branching of the hyphae, and to regulate the colonization of the roots in a manner that is specific to the symbiont (Kikuchi et al., 2007; Scervino et al., 2005, 2007; Siqueira et al., 1991; Steinkellner et al., 2007). The soil condition also affects the root exudate profile and it has been shown that mycorrhizae-enhancing flavonoids are induced when the plants are deprived of phosphorus in the soil (Akiyama et al., 2002). The isoflavonoid coumesterol (Fig. 50.1) has been identified as an active stimulator of hyphal growth (Morandi et al., 1984). A mutant of *M. truncatula* that overaccumulates coumesterol also showed hyperinfection with its mycorrhizal partner (Morandi et al., 2009).

As the mycorrhizal hyphae invade the root and form arbuscules, the flavonoid profile in the root is altered (Harrison and Dixon, 1994). The flavonoids induced early in this process probably regulate plant defense responses. It has been suggested that there is a temporary up-regulation of flavonoid phytoalexins in the roots in the initial stages, which regulates the invasion of the mycorrhizal fungus. This defense response is used in the later stages as an autoregulation mechanism for the extent of mycorrhizal colonization of the roots (Larose et al., 2002) (Fig. 50.3).

Not all flavonoids may act as stimulators to mycorrhizal growth and colonization. Lupins, when not colonized by AM fungi, secrete pyranoisoflavones that are able to inhibit the branching of mycorrhizal fungi, thereby confirming a duality in the function of flavonoids (Akiyama et al., 2010). Many other host plants also synthesize flavonoids with inhibitory effects on hyphal branching (Tsai and Phillips, 1991). Hence it is possible that host and non-host plants together modify the rhizosphere profile through their root exudates and influence the extent of the symbiotic relationship.

50.6 OUTLOOK

Many of the roles of flavonoids in plant–microbe interactions, particularly between model organisms, have been studied and described in this review. However, most of the interactions have been studied under (semi-) sterile laboratory conditions. Studies under real soil settings will be necessary in the future to determine effective concentrations, stability, and conversions of flavonoids in soil. The ability to modify the flavonoid pathway using RNA interference has proven to be an effective tool for analyzing flavonoid function in legumes and is likely to yield interesting results in future studies in actinorhizal plants.

Further future studies will need to focus on multi-species interactions. The complex nature of the rhizosphere means that the flavonoids exuded by the root may have variable effects on symbionts and pathogens in the soil as well as other plants nearby. Flavonoids may form defence compounds such as phytoalexins or phytoanticipins, in particular against fungal infections (Makoi and Ndakidemi, 2007). Similarly, the chemo-attractant property of flavonoids may attract a number of rhizosphere organisms including symbionts and pathogens. For instance, the isoflavonoid exudates from soybean can attract its compatible symbiont *Bradyrhizobium japonicum* as well as the pathogenic oomycete *Phytophthora sojae* (Morris et al., 1998).

Flavonoids are also able to modify rhizosphere microbial community structures and this is an area that needs further exploration. Some microorganisms are able to use exuded flavonoids as a carbon source and metabolize it. The roots may secrete select flavonoids that these microbes are capable of metabolizing, thus selectively propagating compatible microorganisms. These flavonoids may otherwise act as phytoalexins to inhibit growth of non-compatible microbes (Rao and Cooper, 1994; Walker et al., 2003). An *Arabidopsis* mutant *abcg30* that exhibits higher root phenolics exudation showed extensive changes in bacterial and fungal community structures (Badri et al., 2009). The degradation of flavonoids in the rhizosphere also changes the soil profile and can affect other microbial communities (Shaw et al., 2006). Further studies on the real rhizosphere through techniques such as high throughput sequencing of 16s rRNA to identify bacterial community changes (Peiffer et al., 2013) need to be carried out in order to understand more about the multiple roles flavonoids play in controlling the activities of symbionts and other microbes in the rhizosphere.

51.1 INTRODUCTION

Nod factors, produced by rhizobia, are essential signaling molecules for establishing the root nodule nitrogen-fixing symbiosis with legumes (Dénarié et al., 1996). Nod factors are lipo-chitooligosaccharides (LCOs) composed of a backbone of generally 3 or 4 β-1,4-linked *N*-acetylglucosamine (GlcNAc) units, which is *N*-acylated on the terminal non-reducing glucosaminyl residue and may be decorated with various chemical substitutions that are important for the specific recognition of the symbiont by its host plant. For example, the major Nod factor of *Sinorhizobium meliloti*, the rhizobial symbiont of *Medicago* plants, contains three GlcNAc units, is O6-sulfated on the reducing residue and the glucosamine unit is *N*-acylated with a C16:2 fatty acid and partially O6-acetylated: it is named NodSm-IV(Ac,S,C16:2Δ2,9) and the presence of the sulfate group is the major determinant of host specificity. The recently discovered Myc-LCOs, which stimulate the agronomically and ecologically important root endosymbiosis with arbuscular mycorrhizal fungi, have a chemical structure very close to that of Nod factors, except that they consist of a mixture of simpler sulfated and non-sulfated LCOs (Maillet et al., 2011).

GlcNAc also constitutes the building block of several microbe-associated molecular patterns (MAMPs) derived from fungal chitin (chitooligosaccharides (COs)) or bacterial peptidoglycan (PGN), which are important signaling molecules in parasite–host interactions (Silipo et al., 2010). In plants, several different proteins/protein domains have been implicated as receptors for such GlcNAc containing signals, including the lysin motif (LysM) (Buist et al., 2008; Gust et al., 2012), present in some extracellular receptor-like proteins (LYMs) and transmembrane receptor-like kinases (LysM-RLKs). For chitin, COs, and PGN, a LysM-RLK (CERK1) and LYM proteins have been shown to bind their GlcNAc-containing signals and to be involved in defense responses (Iizasa et al., 2009; Kaku et al., 2006; Miya et al., 2007; Petutschnig et al., 2010; Wan et al., 2008; Willmann et al., 2011). For Nod factor responses, genetic evidence from various legumes implicates the involvement of two LysM-RLKs (NFP and LYK3 from *Medicago truncatula* and NFR5 and NFR1 from *Lotus japonicus*) (Arrighi et al., 2006; Limpens et al., 2003; Radutoiu et al., 2003; Smit et al., 2007). Recently, high-affinity LCO binding to NFR1 and NFR5 was reported (Broghammer et al., 2012).

In *M. truncatula*, no high-affinity binding has been reported for NFP and LYK3 but biochemical studies, using radiolabeled Nod factors, have characterized Nod factor-binding sites (NFBSs) in *M. truncatula* roots and *Medicago* cell cultures, which differ by their affinity and their selectivity toward the *S. meliloti* Nod factor (Bono et al., 1995; Gressent et al., 1999; Hogg et al., 2006). One of them, NFBS2, has recently been identified and corresponds to the LysM-RLK LYR3 (Fliegmann et al., 2013). In this chapter we will summarize our current knowledge on the molecular mechanisms of Nod factor perception in *M. truncatula*.

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

51.2 NFP, A PROTEIN WITH MULTIPLE BIOLOGICAL FUNCTIONS

nfp mutants were first isolated by a genetic screen based on the inability of *M. truncatula* plants to nodulate. Further characterization showed that *NFP* controls all the biological responses triggered by Nod factors during the symbiosis with *S. meliloti* (Ben Amor et al., 2003; Arrighi et al., 2006; El Yahyaoui et al., 2004; Shaw and Long 2003). Both the phenotype of *nfp* mutants and the presence, in the predicted protein, of an extracellular domain with three LysMs known to bind GlcNAc-containing compounds (Bateman and Bycroft 2000), strongly suggested that NFP is the Nod factor receptor. Moreover, complementation experiments of *nfp* mutants using chimeric genes encoding an NFP protein where the LysM domains were replaced by those of PsSYM10, the ortholog of pea, revealed that the second LysM domain of NFP was critical to restore the nodulation and infection processes (Bensmihen et al., 2011; see Chapter 59). Although the extracellular domain of PsSYM10 was expected to interact with non-sulfated Nod factors from *Rhizobium leguminosarum bv viciae*, no change in symbiont specificity was observed, suggesting the presence of an additional component, not yet identified, that is responsible for the perception of sulfated Nod factors in *M. truncatula*.

One of the structural features of NFP is the absence of a catalytically active kinase in the kinase-like intracellular part (Arrighi et al., 2006). Therefore, a ligand-dependent auto-phosphorylation, which is quite a common means for an RLK to activate a signaling pathway, cannot be envisaged for NFP. However, NFP could be trans-phosphorylated by a soluble kinase or another LysM-RLK as reported for NFR5/NFR1 in *L. japonicus* (Madsen et al., 2011). LYK3, a LysM-RLK which possesses an active kinase and which functionally interacts with NFP when expressed in *Nicotiana benthamiana* leaves (Pietraszewska-Bogiel et al., 2013) is an obvious candidate for such a role. However, LYK3 being dispensable for the early responses elicited by Nod factors in the root epidermis, excludes the possibility of an essential role of this protein, at least for this tissue. Alternatively, conformational changes in NFP after ligand binding could result in the activation of the signaling pathway via downstream interacting proteins, which are yet to be identified.

Interestingly, *NFP* is also involved in some of the biological responses elicited by Myc-LCOs, such as lateral root formation, but not in mycorrhization (Maillet et al., 2011). In *Parasponia andersonii*, a non legume plant, the homolog of *NFP* controls both nodulation and mycorrhization (Op den Camp et al., 2011; see Chapter 4). Surprisingly, NFP is also involved in a pathogenic context. Recent studies have reported that, compared to wild-type plants, *nfp* mutants are more susceptible to the root pathogen *Aphanomyces euteiches* (Rey et al., 2013), which causes severe damage in legume crops (Gaulin et al., 2007), as well as to the fungus *Verticilium albo-atrum* (Ben et al., 2013). It could be hypothesized that NFP is involved in the recognition of GlcNAc compounds released from the cell wall of these microorganisms and acting as MAMPs. Indeed, *A. euteiches*, which belongs to the Saprolegniale, contains GlcNAc-based cell wall components organized in a non-crystalline structure (Badreddine et al., 2008) and recently identified as chitosaccharides linked to β-1,6-glucans (Nars et al., 2013). However, the chitosaccharide-enriched fraction, obtained from the *A. euteiches* cell wall, exhibited similar biological effects, in terms of induction of nuclear calcium transients and expression of defence genes, on roots of *M. truncatula* wild-type plants and *nfp* mutants, suggesting a role of NFP in immunity rather than in MAMP perception.

The multi-faceted biological role of NFP questions its biochemical function. The working model proposed by Gough and Jacquet (2013) hypothesized that NFP could participate in different receptor complexes: the perception of a given signal would depend on the interacting partner of NFP within the receptor complex that would lead to the activation of the signaling pathway and the appropriate biological response. This model is reminiscent of the functioning of AtCERK1, the LysM-RLK involved in chitin perception, which, together with the LysM proteins LYM1 and LYM3, participates in PGN perception. If this model is correct it would explain why, despite many efforts and attempts by various approaches, no high-affinity binding to Nod factor has been found for NFP (JJ. Bono et al., unpublished data).

51.3 NOD FACTOR BINDING SITES ARE INDEPENDENT OF NFP

The biochemical approach developed to identify putative Nod factor receptors was based on the use of a radioactive Nod factor to perform ligand-binding experiments on plant extracts. A tritiated Nod factor was first obtained by total chemical synthesis (Bono et al., 1995). Because the specific radioactivity of tritium was relatively low and did not enable the detection of high-affinity binding proteins, a procedure to label the Nod factor to a higher specific radioactivity using ^{35}S was established (Bourdineaud et al., 1995; Gressent et al., 2004). In all cases the chemical structure of the radioactive Nod factor was identical to that of the genuine Nod factor produced by *S. meliloti*. The biochemical approach has allowed the characterization of three NFBSs. Their characteristics are reported in Table 51.1.

All the NFBSs recognize both sulfated and non-sulfated Nod factors with the same affinity and all are independent of *NFP*. NFBS1 and NFBS3 are associated to a high-density root fraction of *M. truncatula*. Because the use of fluorescent derivatives of Nod factors showed that they

Table 51.1 Sub-cellular localization and binding characteristics of the Nod factor binding sites NFBS1, NFBS2, and NFBS3, in *M. truncatula*.

	Low affinity		High affinity	
	NFBS1		NFBS2	NFBS3
	Root	Cell culture	Cell culture	Root
Sub-cellular fraction	3000xg fraction	Microsomal fraction	Microsomal fraction	3000xg fraction
*Affinity (K_d, in nM)	86	107	4	0.45
Abundance (B_{max}, in pmol/mg protein)	2	1	0.5	0.25

*Measured for NodSm-IV(Ac,S,C16:2Δ2,9).

accumulate in the cell wall of root hairs, it is tempting to suggest that these binding sites could be associated to the cell wall compartment (Goedhart et al., 2003). NFBS3 differs from NFBS1 by its affinity for the NodSm factor (K_d of 0.45 nM vs 86 nM for NFBS1) and by the fact that it is not detected in *dmi1* and *dmi2* mutants (Hogg et al., 2006). As DMI1 and DMI2 are respectively located near the nuclear envelope (Riely et al., 2007) and the plasmamembrane or the cytosolic vesicles after Nod factor treatment (Riely et al., 2013), the lack of NFBS3 in *dmi1* and *dmi2* mutants could be due to an indirect effect of these mutations rather than a direct role of DMI1 and DMI2 proteins in the binding site.

NFBS2 was first characterized in cell suspension cultures of *M. varia* and *P. vulgaris* (Gressent et al., 1999, 2002). NFBS2 displays interesting characteristics in terms of Nod factor recognition: it exhibits a high affinity for the Nod factor, it specifically recognizes the lipo-chitoligosaccharidic structure as do NFBS1 and NFBS3 but it differs from these binding sites by its ability to discriminate the length of the chitin backbone and of the fatty acid, which are important for the biological activity of the Nod factors (Demont-Caulet et al., 1999). However, it does not specifically recognize the sulfate group. Nevertheless, it was challenging to identify the protein(s) responsible for such a binding site which, moreover, did not correspond to NFP.

51.4 THE LYSM-RLK LYR3: A NEW PLAYER IN NOD FACTOR PERCEPTION?

In *M. truncatula*, a site similar to NFBS2 was found to be more abundant (at least 5 times) in a cell culture line generated from the roots of a *dmi3* mutant compared to a wild-type line (Hogg et al., 2006). This difference of abundance between the two cell lines offered the opportunity to identify the binding protein by combining photoaffinity labeling experiments with proteomic and transcriptomic approaches (Fliegmann et al., 2013). For that purpose, photoactivatable derivatives of Nod factors, based on the structure of aromatic LCO analogs that tightly bind to NFBS2 (Grenouillat et al., 2004), were first synthesized. The photoreactive group, either an azido or a benzophenone group, was positioned in the vicinity of the non-reducing unit of the oligosaccharidic chain in order to increase the chance to specifically crosslink the binding protein, because binding studies had shown that this part of the molecule was involved in the interaction with NFBS2. Photoaffinity labeling experiments reported in Figure 51.1 enabled to detect a polypeptide specifically crosslinked to the Nod factor derivative for the *dmi3* sample but not for the wild-type, with an apparent molecular mass close to 100 kDa, thus in accordance to the difference in abundance of the binding protein.

Thereafter, proteomic and transcriptomic analyses were used to identify proteins or transcripts more abundant in *dmi3* than in wild-type cell cultures that could correspond to a 100 kDa protein with carbohydrate-binding properties. Based on these criteria, LYR3, LYK9, and LYR4, which were up-regulated at the protein or gene level in *dmi3* compared to wild-type cell cultures, were selected for binding tests.

Nod factor-binding tests performed on LYR3, LYK9, and LYR4, transiently expressed in *N. benthamiana* leaves as fusion proteins with the yellow fluorescent protein (YFP), revealed that only LYR3 exhibited binding. Its binding characteristics were similar to those of NFBS2 in terms of affinity and selectivity toward differentially substituted LCOs (Nod factors and Myc-LCOs) or COs. Therefore, LYR3 was most probably the binding protein in NFBS2. The reason for its higher abundance in the *dmi3* cell culture is unknown but it would be interesting to quantify LYR3 in the roots of wild-type plant and *dmi3* mutant to determine whether the effect observed in cell culture originates from a regulation of *LYR3* by *DMI3* or as a consequence of cell dedifferentiation.

LYR3, similar to other plant LysM-RLKs, has three LysM domains (LysM1, LysM2, LysM3) in the extracellular region, followed by a transmembrane domain and a kinase domain, which, similar to NFP, is predicted to be catalytically inactive. The identification of LYR3 opens the question of the molecular mechanisms involved in the

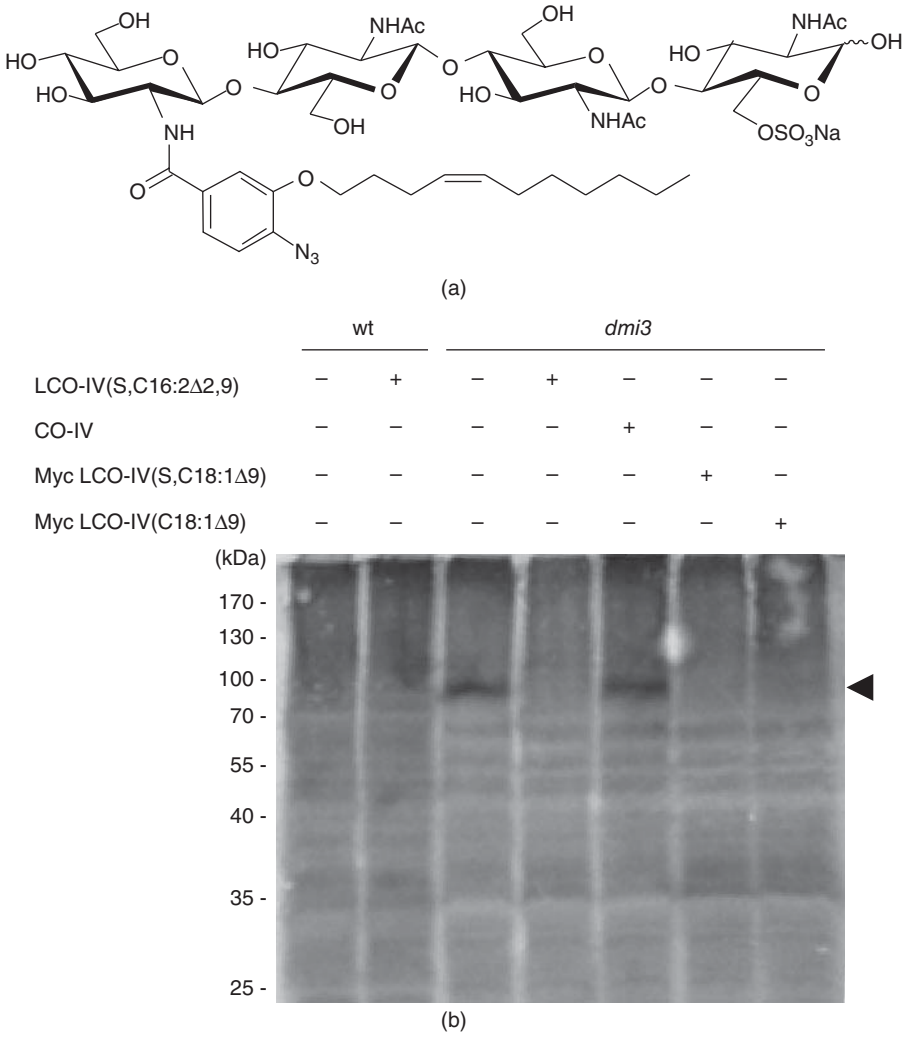

Figure 51.1 Membrane fractions from *M. truncatula* wild-type or *dmi3* cell cultures were incubated with the radioactive aryl-azido photoaffinity probe (a) with or without competing LCOs and COs. After irradiation the proteins were analyzed by SDS-PAGE and autoradiography (b). (Source: Adapted from (Fliegmann et al., 2013) with permission.)

specific recognition of LCOs versus COs. The structure of the extracellular domain of AtCERK1 in complex with chitopentaose, recently solved by X-ray crystallography, showed that the ligand was bound to a groove located on the molecular surface of the second LysM (LysM2) domain, and that the interaction involved three GlcNAc residues via hydrogen bonds with the *N*-acetyl moieties (Liu et al., 2012). Even if the sequence identity between the extracellular domains of LYR3 and AtCERK1 are weak (21.9%), it was sufficient to perform homology modeling and molecular docking with CO and the Nod factor. This approach suggested that the LysM2 domain of LYR3 was structurally close to that of AtCERK1, with the presence of a similar groove able to accommodate CO-IV or sulfated CO-IV. The model predicted that the entire oligosaccharide established contacts with the protein via hydrogen bonds with the *N*-acetyl group of the second and third GlcNAc. The sulfate group was predicted not to interact with the protein surface, which was in accordance with the binding properties of LYR3. This groove is also present in the closest homolog of LYR3 in *A. thaliana*, AtLYK4, involved in chitin perception (Tanaka et al., 2013), suggesting that it is conserved in oligochitin binding proteins. However, it is not present in LYR4, a close homolog of LYR3 in *M. truncatula*, which does not bind the Nod factor. Docking of the Nod factor to the CO binding groove in LYR3 (Fig. 51.2) suggested that the proximal part of the acyl chain may make contact with the LysM2 domain, which was consistent with the photoaffinity labeling of the protein using our probes, in which the photoreactive group was localized in this part of the LCO. However, there was no defined hydrophobic binding pocket for the distal part of the acyl chain that could account for the importance of the length of the fatty acid chain for high-affinity binding of Nod factor to LYR3.

Therefore, this part of the Nod factor could either bind to unknown residues in the LysM2 domain or extend out from the LysM2 domain. The position of the binding groove suggests that it is unlikely to bind to another LysM domain in

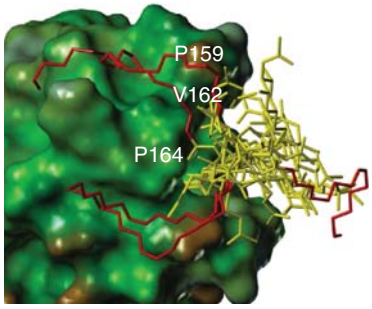

Figure 51.2 Five docking poses for Nod factor interacting with LysM2 of LYR3. Chitin backbone is in yellow and lipid chain is in red. the same molecule but could perhaps bind to a LysM domain in a homodimer. This mechanism would be similar to the recognition of a chitooctamer by AtCERK1 where the ligand spans across two receptor molecules leading to homodimerization (Liu et al., 2012). Alternatively, we cannot exclude that a different binding site is present in LYR3. Interestingly, it has been reported that the chitin-binding site of the LysM fungal effector protein Ecp6 from *Cladosporium fulvum*, is mediated by intrachain interaction of the LysM1 and LysM3 domains (Sánchez-Vallet et al., 2013).

Our main objective now is to determine the biological function of LYR3. As it does not discriminate Nod factors from Myc-LCOs, it could play a role in the perception of both signals. Another challenge will be to identify the binding proteins in NFBS1 and NFBS3 and to determine whether other LysM-RLKs of *M. truncatula* have the ability to bind Nod factors or Myc-LCOs.

51.5 CONCLUSION

Despite the huge breakthrough made 10 years ago using genetic approaches to identify LysM-RLKs as key players in the establishment of root nodule endosymbioses with Rhizobium, the molecular mechanisms of LCO perception is far from being elucidated. Several lines of evidence indicate that probably multiple component receptors are controlling convergent or independent LCO signaling pathways involved in the establishment of the legume-Rhizobium and arbuscular mycorrhizal symbiosis. Because structurally related ligands (LCO and CO) are recognized by structurally related receptors (LysM proteins) in symbiotic or pathogenic contexts, future work will aim to better understand the role of the extracellular LysM domains and of the transmembrane and kinase domains of the LysM-RLK in the selectivity of ligand binding and receptor activation. To decipher these mechanisms, complementary approaches such as molecular genetics, biochemistry, and cell biology will have to be jointly pursued, which might also integrate the evolutionary history of both plants and their interacting microorganisms.

52.1 APYRASE

Apyrases (Adenosine pyrophosphatase; Enzyme Commission number: 3.6.1.5) are calcium- or magnesium-activated non-energy-coupled nucleotide phosphohydrolases that hydrolyze adenosine triphosphate (ATP) or adenosine diphosphate (ADP) to yield adenosine monophosphate (AMP) and inorganic phosphate. Apyrases have been found in many prokaryotes and eukaryotes (Handa and Guidotti, 1996). As the enzyme hydrolyzes a wide range of nucleoside tri- or di-phosphates, the alternative name, nucleoside triphosphate diphosphohydrolase (NTPDase) has been used more commonly in the field of mammalian research over the last decade (Zimmermann et al., 2000). There are five characteristic apyrase conserved regions (ACRs) described in members of the NTPDase/apyrase family across many prokaryotes and eukaryotes (Handa and Guidotti, 1996; Kirley et al., 2006). ACRs form the active site of apyrases, some of which correspond to the β- and γ-phosphate-binding motifs of the actin/Hsp70/hexokinase superfamily (Hurley, 1996).

In mammals, apyrases function in very diverse biological roles, including blood platelet aggregation, neurotransmission, pathogen–host interaction, cell protein and lipid glycosylation, and oncogenesis (Sarkis and Salto, 1991; Edwards and Gibb, 1993; Marcus and Safier, 1993; Knowles, 2011). Likewise, in plants, apyrases are involved in many aspects of plant physiology, including growth of various tissues (Wolf et al., 2007; Wu et al., 2007; Clark et al., 2010a, 2010b), starch synthesis (Handa and Guidotti, 1996), phosphate metabolism (Thomas et al., 1999), pollen germination and growth (Steinebrunner et al., 2003), regulation of stomatal aperture (Clark et al., 2011), plant–insect interaction in entomogenous galls (Detoni et al., 2012), and plant–microbe interactions with pathogens (Kawahara et al., 2003; Toyoda et al., 2012; Shiraishi, 2013) as well as with symbionts (McAlvin and Stacey, 2005; Govindarajulu et al., 2009; Tanaka et al., 2011a, 2011b; Roberts et al., 2013). These reports suggest that apyrases play essential roles in plant growth, development, and stress response.

Apyrases can be grouped into two classes based on the cellular location of their catalytic domain; that is, endo- and ecto-apyrases. Endoapyrases have an intracellular-located catalytic domain while ectoapyrases have an extracellular catalytic domain (Plesner, 1995). Ectoapyrases are well known to regulate the concentration of nucleotides in the extracellular matrix (Todorov et al., 1997; Marcus et al., 2003). Extracellular nucleotides are important signaling molecules in a number of cellular responses in animals (Khakh and Burnstock, 2009), as well as in plants (Tanaka et al., 2010; Clark and Roux, 2011). These signaling molecules act through specific receptors, the so-called purinoceptors in mammals. However, no obvious homologs of the animal purinoceptors have been found in plants and, to date, the mechanism of extracellular nucleotide recognition by plants has not been defined. A plant extracellular ATP receptor has recently been identified (Choi et al., 2014).

52.2 ECTOAPYRASE PLAYS AN IMPORTANT ROLE IN NODULATION

A decade ago, phylogenetic analysis identified a legume-specific apyrase family (Cannon et al., 2003) (Fig. 52.1). The authors of this study suggested that these specific apyrases could function in a biological process specific to legumes, such as nodulation. Very recently, the distinctive difference of this legume-specific apyrase group was shown to be due, at least in part, to the amino acid residues comprising the hydrophobic binding pocket for the adenine ring of the substrate (Tanaka et al., 2011a). Some of the legume-specific apyrases were shown to be ectoapyrases, localized to the plasma membrane, and function in the nodulation process (Etzler et al., 1999; Day et al., 2000; Cohn et al., 2001; Govindarajulu et al., 2009; Tanaka et al., 2011a, 2011b). The best characterized legume-specific apyrases are those present in horse gram (*Dolichos biflorus*), soybean (*Glycine max*), and *Lotus japonicus*.

Originally, the ectoapyrase from the legume horse gram was identified based on its lectin-like properties and was subsequently shown to also possess apyrase activity (Etzler et al., 1999). Hence, this protein was named Dolichos biflorus Lectin Nucleotide Phosphohydrolase (DbLNP). As the rhizobial lipo-chitin nodulation signal, the so-called Nod factor (NF) produced by rhizobia, is a short oligosaccharide, it was possible that DbLNP could bind this molecule via its lectin domain. Indeed, DbLNP was found to bind to NFs and other lipo-chitin oligosaccharides derived from various rhizobia (Etzler et al., 1999). The binding increased the enzymatic activity of DbLNP, suggesting a possible signaling role for this enzyme (Etzler et al., 1999). These results were obtained prior to the identification of the LysM-receptor-like kinase proteins, which are now known to be the primary receptors for the NF (Oldroyd, 2013; see Chapter 51). Therefore, at the time of publication, the paper by Etzler et al. (1999) generated quite a bit of interest and speculation that the DbLNP protein could be the NF receptor. Interestingly, the uniform distribution pattern of DbLNP on the surface of young root hairs changed significantly upon rhizobial inoculation to that of tip-localized; the site in which rhizobial infection occurs (Kalsi and Etzler, 2000). This effect on DbLNP location was not seen when non-rhizobial bacteria, including a root pathogen, were added. Moreover, flooding the roots with specific antibodies against the DbLNP protein blocked root hair deformation and nodule formation upon rhizobial inoculation (Etzler et al., 1999; Kalsi and Etzler, 2000). Taken together, these data argued strongly for an early and essential role for DbLNP in the initiation of the symbiotic interaction.

The soybean ectoapyrase GS52, originally identified in the wild soybean *Glycine soja* as a 52 kDa protein, was shown to be induced early not only during rhizobial infection (Day et al., 2000) but also during the later stages of the nodulation process, for example, nodule development stages (Brechenmacher et al., 2008; Govindarajulu et al., 2009). Strong ectopic expression of the *GS52* gene in *L. japonicus* roots resulted in a significant increase in rhizobial infection events in root hairs, again suggesting an early role for this protein in nodulation. The increase in infection events also led to an approximately twofold higher nodule number (McAlvin and Stacey, 2005). Similarly, nodule numbers increased in transgenic soybean and *Medicago truncatula* roots ectopically expressing GS52 (Fig. 52.2).

However, these effects were not seen when a mutant form of GS52, in which amino acid residues critical for its catalytic activity were mutated, was expressed in transgenic roots (Tanaka et al., 2011a). These results indicate that the catalytic activity of the GS52 apyrase, likely acting on extracellular nucleotides, is essential for the stimulation of rhizobial infection and nodulation seen in these transgenic experiments. Furthermore, RNA interference (RNAi)-mediated gene silencing of the *GS52* gene significantly reduced nodule numbers in transgenic soybean roots (Govindarajulu et al., 2009) (Fig. 52.2). These results are consistent with earlier experiments in which flooding roots with a specific anti-GS52 antibody was shown to inhibit rhizobial infection (Day et al., 2000). The reduction in nodule numbers seen in roots in which GS52 was silenced by RNAi could be partially rescued by addition of ADP (Govindarajulu et al., 2009), suggesting that nucleotide signaling, in part mediated by the catalytic activity of GS52, is important for rhizobial infection. Indeed, extracellular ATP is exuded by the root hair tips of *M. truncatula* and this exudation is stimulated by the addition of the rhizobial NF (Kim et al., 2006).

An orthologous ectoapyrase of DbLNP and GS52 was identified from *L. japonicus* by the Etzler laboratory and, following the convention of DbLNP, named LjLNP (Roberts et al., 1999). A very recent study shows that antisense-mediated gene silencing of LjLNP expression blocks NF signaling at the very first steps of plant recognition of this molecule (Roberts et al., 2013). Specifically, the NF-induced perinuclear calcium spiking in the root hair and calcium influx at the root hair tip was abolished in the *LjLNP* antisense transgenic lines. As a result, an early nodulin gene, *NIN,* was not induced and no nodules were formed in the antisense lines, which grew less vigorously than in nodulated control plants in the absence of nitrate or ammonia (Roberts et al., 2013). However, NF- or rhizobium-induced root hair deformation was intact in the transgenic lines, indicating that LjLNP likely acts downstream of the Nod factor receptors NFR1 and NFR5, in which mutations block root hair deformation (Radutoiu et al., 2003). These results also suggest that LjLNP acts upstream or in a parallel position to the other genes in the common symbiotic signaling (SYM) pathway for both nodulation and mycorrhization (SYMRK/DMI2, POLLUX/DMI1 and CASTOR, NUP133, NUP85, NENA)

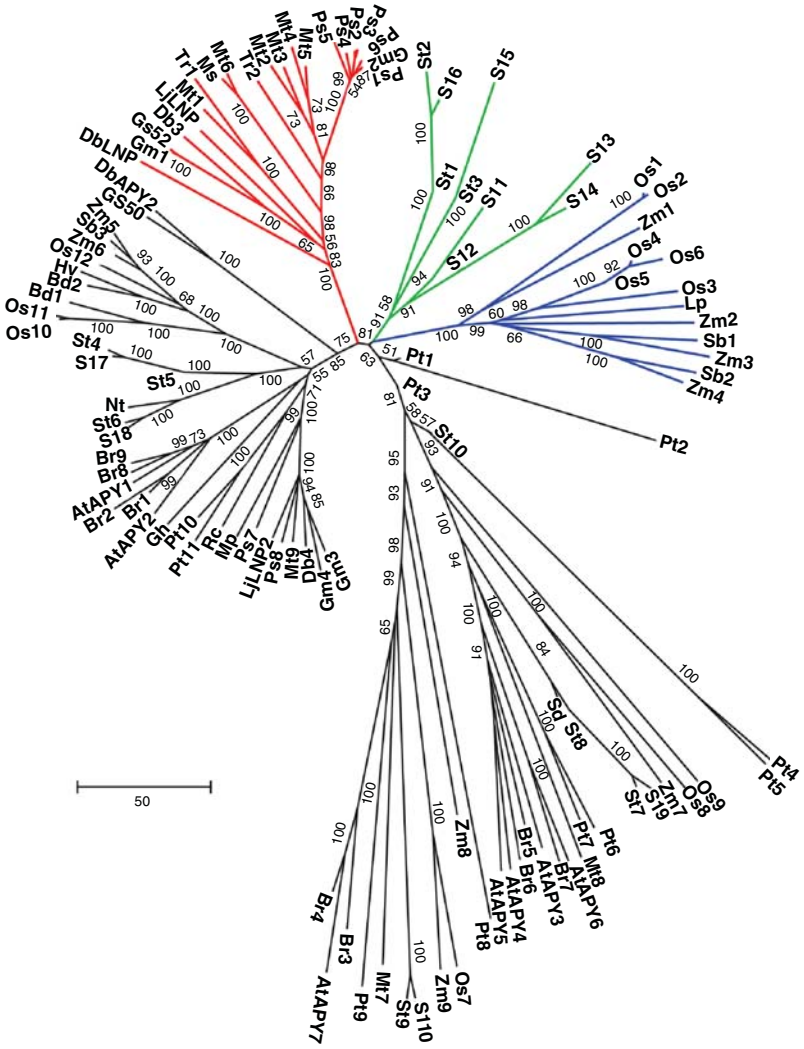

Figure 52.1 Phylogenetic comparison of plant apyrases. The unanchored tree was generated using full length protein sequences of plant apyrases by the neighbor-joining method with 1000 bootstrap replicates. Only bootstrap values >50% are shown in the cladogram at the branching points. Specific apyrase clades, that is, *Fabaceae*-specific clade (red), *Poaceae*-specific clade (blue), and *Solanaceae*-specific clade (green), are indicated in color-highlighted branches. The letters and their associated number correspond to the predicted apyrases with their accession numbers as listed below: **At**: *Arabidopsis thaliana* (AtAPY1, At3g04080; AtAPY2, At5g18280; AtAPY3, At1g14240; AtAPY4, At1g14230; AtAPY5, At1g14250; AtAPY6, At2g02970; AtAPY7, At4g19180), **Bd**: *Brachypodium distachyon* (Bd1, XP_003557997; Bd2, XP_003562437), **Br**: *Brassica rapa* (Br1, Bra002150; Br2, Bra006450; Br3, Bra012554; Br4, Bra013379; Br5, Bra019669; Br6, Bra019670; Br7, Bra024796; Br8, Bra031947; Br9, Bra040151), **Gm**: *Glycine max* (Gm1, XP_003548772; Gm2, BAD13527; Gm3, XP_003548478; Gm4, XP_003553324), **Gs**: *Glycine soja* (GS52, Q9FVC2; GS50, AAG32959), **Gh**: *Gossypium hirsutum* (Gh, ADD09804), **Hv**: *Hordeum vulgare* (Hv, BAJ85095), **Lp**: *Lolium perenne* (Lp, ACB38287), **Lj**: *Lotus japonicus* (LjLNP, AAF00609; LjLNP2, chr1.CM0104.1830.r2.d), **Ms**: *Medicago sativa* (Ms, AAF00611), **Mt**: *Medicago truncatula* (Mt1, Q84UD9; Mt2, Q84UE1; Mt3, Q84UE2; Mt4, MSAF288132; Mt5, Q84UE3; Mt6, XP_003624587; Mt7, XP_003612462; Mt8, XP_003613774; Mt9, AAO23007), **Mp**: *Mimosa pudica* (Mp, BAK78981), **Nt**: *Nicotiana tabacum* (Nt, ABK51386), **Os**: *Oryza sativa* (Os1, NP_001067813; Os2, EAY96392; Os3, EEC67580; Os4, ABA91303; Os5, ABA95699; Os6, NP_001066032; Os7, NP_001064408; Os8, NP_001061886; Os9, AAL82534; Os10, EEC75177; Os11, EAZ26787; Os12, EEC82701), **Ps**: *Pisum sativum* (Ps1, AB038669; Ps2, BAB87182; Ps3, BAB87198; Ps4, BAB87197; Ps5, BAD13517; Ps6, BAD13519; Ps7, AAG22044; Ps8, BAB85978), **Pt**: *Populus trichocarpa* (Pt1, Potri.T151300; Pt2, Potri.019G031200; Pt3, Potri.013G053700; Pt4, Potri.004G195400; Pt5, Potri.009G157500; Pt6, Potri.008G086400; Pt7, Potri.010G169100; Pt8, Potri.015G079900; Pt9, Potri.004G236900; Pt10, Potri.019G031000; Pt11, Potri.013G053500), **Rc**: *Ricinus communis* (Rc, XP_002525470), **Sd**: *Solanum demissum* (Sd, AAT66769), **Sl**: *Solanum lycopersicum* (Sl1, Solyc02g032550; Sl2, Solyc02g032560; Sl3, Solyc12g098540; Sl4, Solyc12g098550; Sl5, Solyc09g092400; Sl6, Solyc02g081980; Sl7, Solyc08g016010; Sl8, Solyc12g096560; Sl9, Solyc05g007670; Sl10, Solyc05g052490), **St**: *Solanum tuberosum* (St1, PGSC0003DMT400018918; St2, PGSC0003DMT400018919; St3, PGSC0003DMT400053021; St4, PGSC0003DMT400019809; St5, PGSC0003DMT400019810; St6, PGSC0003DMT400075516; St7, PGSC0003DMT400047384; St8, PGSC0003DMT400047383; St9, PGSC0003DMT400069878; St10, PGSC0003DMT400093747), **Sb**: *Sorghum bicolour* (Sb1, XP_002442736; Sb2, XP_002448918; Sb3, XP_002461227), **Tr**: *Trifolium repens* (Tr1, ACB38285; Tr2, ACB38286), **Db**: *Dolichos biflorus* (DbLNP, AF139807; DbAPY2, AAF00610; Db3, Q5NT85; Db4, BAD80837), **Zm**: *Zea mays* (Zm1, GRMZM2G349839; Zm2, GRMZM2G085711; Zm3, GRMZM2G431714; Zm4, GRMZM2G006762; Zm5, GRMZM2G131026; Zm6, GRMZM2G003331; Zm7, GRMZM2G152457; Zm8, GRMZM2G106618; Zm9, GRMZM2G140587).

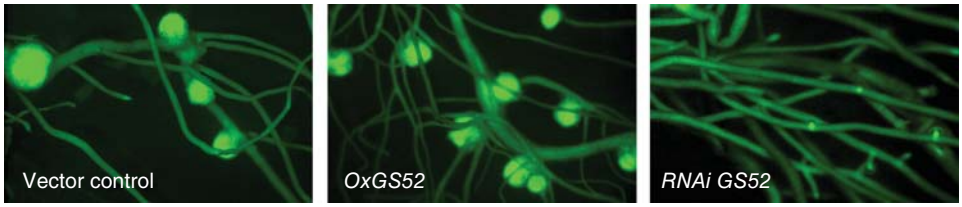

Figure 52.2 Nodule formation on transgenic soybean roots. Each figure shows transgenic soybean roots 4 weeks after inoculation with the soybean symbiont, *Bradyrhizobium japonicum*. The panels represent (a–c) transgenic roots carrying the empty vector (vector control), ectopically expressing *GS52* from a strong, constitutive promoter (*OxGS52*), or expressing an RNAi construct silencing *GS52* expression (*RNAi GS52*). The transgenic roots could be identified due to the constitutive expression of the green fluorescent protein, GFP. Note that, in comparison with the transgenic control roots the transgenic roots ectopically expressing *GS52* produced more nodules, whereas the transgenic roots in which *GS52* expression was silenced showed a severe reduction in nodulation. For more detail, see Govindarajulu et al. (2009) and Tanaka et al. (2011a).

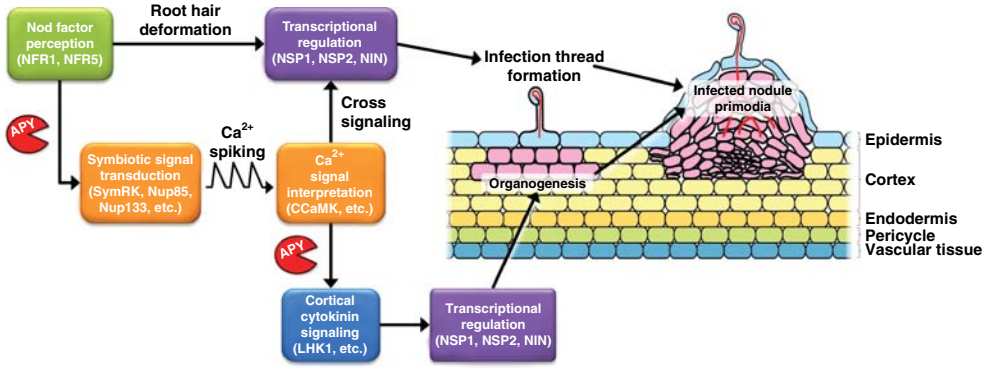

Figure 52.3 Model of ectoapyrase function in the symbiotic signaling pathway during the nodulation process. Regulatory pathways associated with rhizobium infection (root hair deformation, infection thread formation) and nodule organogenesis (cortical cell division) lead to nodule primordium formation as exemplified for determinate nodule formation on *L. japonicus* roots in the figure. Ectoapyrase (APY) is proposed to act upstream of the common SYM pathway (shown in orange box; e.g., SymRK) but downstream of the Nod factor receptors (NFR1 and NFR5). We also propose that ectoapyrase (APY) might be involved in regulating hormonal levels (i.e., cytokinins) for nodule organogenesis, although this hypothesis has to be confirmed by experimental evidence. Research studies performed on the non-legume Arabidopsis suggest that ectoapyrases are involved in signaling/regulation of plant hormones.

(Parniske, 2008; Singh and Parniske, 2012) (Fig. 52.3). Mutations in these genes also block NF-induced calcium spiking but still show NF-induced root hair calcium influx and root hair deformation. A role in the common SYM pathway, which is shared between the rhizobial and mycorrhizal symbioses, is also strongly supported by the demonstration that silencing of LjLNP also blocked infection of arbuscular mycorrhizal (AM) fungi (Roberts et al., 2013).

Collectively, the above-mentioned published data clearly demonstrate an important role for legume-specific ectoapyrases in nodulation and the mycorrhizal symbiosis. It remains to be seen whether ectoapyrases also function in mycorrhizal infection in those non-legume plants, which lack this legume-specific ectoapyrase family, and yet are infected by AM fungi.

52.3 POSSIBLE FUNCTIONS OF ECTOAPYRASE IN NODULATION SIGNALING

As mentioned above, before the identification of the NF receptors NFR1/LYK3 and NFR5/NFP (Nod-factor perception), ectoapyrases were viable candidates for the long-sought NF receptor (Geurts and Bisseling, 2002). Legume ectoapyrases were found to directly bind NFs and plants showed nodulation-deficient phenotypes when the enzyme function was blocked by specific antibodies (Etzler et al., 1999; Day et al., 2000). NF binding by DbLNP increased apyrase activity and, therefore, conceivably, this effect could be essential for subsequent NF-induced cellular signaling. However, other than hydrolysis of extracellular

nucleotides, there remains no solid biochemical connection between ectoapyrase activity and nodulation signaling.

We have previously postulated that ectoapyrase is important in nodulation due to the ability to control the level of extracellular nucleotides at the root hair surface. The addition of NFs, as well as known pathogen elicitors (including chitin), increases extracellular ATP release (Kim et al., 2006; Wu et al., 2008; Tanaka et al., 2011a). Treatment of plants with extracellular ATP was also shown to change their susceptibility to pathogen infection (Song et al., 2006). One hypothesis is that the ectoapyrase enzyme decreases extracellular ATP levels induced upon symbiont infection and thereby prevents the activation of plant defense pathways that could limit symbiont invasion (Fig. 52.4).

Studies in the non-legume *Arabidopsis* have shown that ATP (but not ADP) does induce the production of reactive oxygen species (ROS) in root hairs (Clark et al., 2010b) and epidermal cells (Demidchik et al., 2011). ROS are well-known signals important in plant defense response against pathogens. However, ROS are also important for a variety of other plant processes, including cell wall growth (Brewin, 2004; Jamet et al., 2007; Kopcińska, 2009), which could be important during root hair curling and in the formation of the infection thread, by which the rhizobia gain entry into the interior of the root.

NF control of ectoapyrase function may be complex as this molecule has been shown to induce ectoapyrase gene expression (Day et al., 2000), change the distribution of the ectoapyrase protein on the root hair surface (Kalsi and Etzler, 2000), as well as increase DbLNP enzymatic activity (Etzler et al., 1999). It should be noted that addition of NF to the soybean GS52 apyrase did not result in increased enzymatic activity so it remains to be seen if this is a general property of the legume-specific ectoapyrase family (Tanaka et al., 2011b).

The reduction in nodulation seen upon RNAi silencing of the GS52 ectoapyrase in transgenic soybean roots could be partially restored upon the addition of exogenous ADP. These data suggest that it may be the catalytic products of apyrase action that are critical for the nodulation process, perhaps acting as an extracellularly generated signal (Fig. 52.4). Indeed, as already mentioned, the catalytic domain of the GS52 apyrase was shown to be essential for the ability required to enhance nodulation when the protein was ectopically expressed in transgenic soybean roots (Tanaka et al., 2011a). Consistent with such a notion, the addition of ADP to root hairs was shown to change plasma membrane conductance (Lew and Dearnaley, 2000). ADP treatment was also shown to induce calcium influx in the root epidermal cells (Demidchik et al., 2011). In this case, ADP was more effective than extracellular ATP, for example, half-maximal depolarization is at 0.4 mM for ATP and at 10 μM for ADP (Lew and Dearnaley, 2000). Similar results would be seen during the nodulation process (Fig. 52.4). NF-triggered release of nucleotides may be causal for some of the early, nodulation-related cellular responses, with ectoapyrases acting to modulate the levels of extracellular nucleotides to maximize their effects. It is likely that any test of this hypothesis will require a more detailed understanding of the basic mechanisms of extracellular nucleotide recognition by plants and the subsequent downstream signaling events. For example, the identification of extracellular nucleotide receptors in plants would be a major advance.

It is also possible that ectoapyrases are involved in organogenesis (Fig. 52.3) and in maintaining functional nodules as *GS52* gene expression is continuously upregulated during the entire nodulation process (Brechenmacher et al., 2008; Govindarajulu et al., 2009). Nodule organogenesis is also regulated by plant hormones; for example, cytokinin signaling is especially important (Oldroyd and Downie, 2008). Moreover, asymmetric distribution of auxin has been observed at the onset of organogenesis (Boot et al., 1999; Takanashi et al., 2011). It is interesting to speculate that ectoapyrase might indirectly (mediated through controlling extracellular ATP level) regulate hormonal actions during the nodule organogenesis process. Perhaps consistent with this notion, the transgenic expression of the pea ectoapyrase in Arabidopsis was found to increase the resistance to the toxic levels of cytokinin (Thomas et al., 2000), implying that the hormonal action could be influenced by the activity of this enzyme. In other respects, apyrase was implicated as a positive regulator of polar auxin transport, thereby changing the asymmetric distribution of auxin in *Arabidopsis* roots (Liu et al., 2012). However, there is no direct evidence in legume plants in terms of the relationships between ectoapyrase enzymatic activity, hormonal levels, and nodule organogenesis.

A final role may be that ectoapyrases can supply phosphorus to the plant upon hydrolysis of ATP or other nucleotides. This assumption is supported by numerous reports showing that phosphorus is required for cortical cell division and organogenesis during the nodulation process (de Mooy and Pesek, 1966; Israel, 1987; Tang et al., 2001; Gentili et al., 2006; Miao et al., 2007).

52.4 FUTURE PERSPECTIVES

The recent paper by Roberts et al. (2013) demonstrated that ectoapyrases are essential for both rhizobial and mycorrhizal symbioses. Given that mycorrhizal associations have been documented as early as circa 400 million years ago (Parniske, 2008), it is likely that ectoapyrases initially evolved to play a role in AM signaling, and were then secondarily recruited, along with other members of the common SYM pathway, to play a role in nodulation. Indeed, apyrase genes in AM host plants (*Fabaceae* (legume), *Poaceae* (monocot),

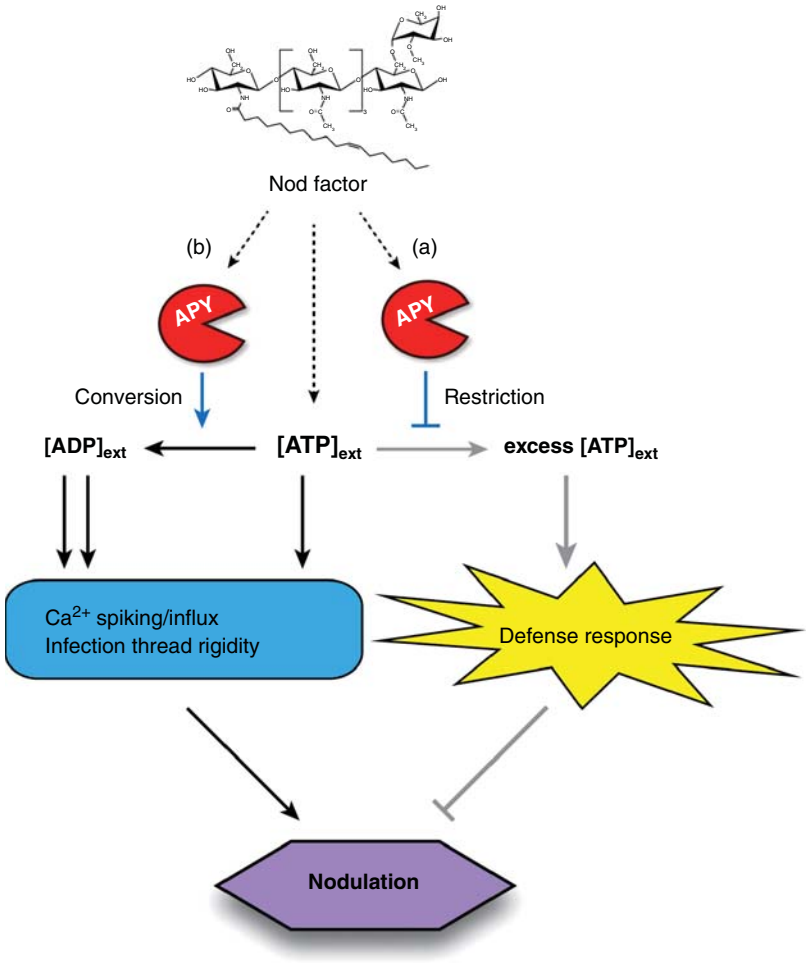

Figure 52.4 Hypothetical role for ectoapyrases in maintaining an optimal extracellular nucleotide concentration to allow rhizobial infection. Ectoapyrase either reduces the extracellular ATP level or increases the level of ATP degradation products (e.g., ADP and others), thereby affecting root symbiotic signaling. (a) Rhizobial infection or Nod factor addition increases the extracellular ATP concentration ($[ATP]_{ext}$) at the root hair surface (Tanaka et al., 2011a). Concurrently, the Nod factor maximizes the ectoapyrase (APY) function by increasing its gene expression (Day et al., 2000), by changing its localization (Kalsi and Etzler, 2000), or by directly affecting its enzymatic activity (Etzler et al., 1999) in the root hair. The ectoapyrase then restricts $[ATP]_{ext}$ at an optimal level to prevent the induction of plant defense responses. For example, the addition of ATP induces excess amount of ROS production in the root hair surface (Kim et al., 2006; Cardenas et al., 2008). (b) Alternatively, the activated ectoapyrase generates degradation products of ATP, for example, ADP and others, that might be important for symbiotic signaling. For example, extracellular ADP was shown to change plasma membrane conductance in root hairs (Lew and Dearnaley, 2000) and induce calcium influx in root epidermal cells (Demidchik et al., 2011). ADP addition could be more effective than ATP in stimulating nodulation.

and *Solanaceae* species) but not non-AM host (e.g., *Brassicaceae* species), are classified in specific clades (Fig. 52.1). This phylogenetic classification fits the symbiotic toolkit model proposed by Delaux et al. (2013); that is, symbiotic ectoapyrases can be molecular components of the symbiotic toolkit, a core set of symbiotic genes conserved in all AM host plants (Delaux et al., 2013). This raises the interesting future possibility that identification of all members of this toolkit could eventually provide the means to transfer mycorrhizal and rhizobial symbiotic capability to those plant species that currently lack these abilities (see Chapter 108). This is clearly more critical for nodulation, given that a large number of plants are mycorrhizal. Very interestingly, transgenic expression of the soybean ectoapyrase GS52 enhanced colonization of rhizobia surrounding the tip area of root hairs in rice plants (Sreevidya et al., 2005). Because many monocots are infected by AM fungi, they must already contain many components of the common SYM pathway (Venkateshwaran et al., 2013). Introducing the legume-specific ectoapyrases into monocot plants may be an essential step toward the ultimate goal of engineering nitrogen-fixing non-legume crop plants. The idea of creating nitrogen-fixing, non-legume crop plants has been a "Holy Grail" of the field of biological nitrogen fixation (see Chapter 108). It is of wider general interest due to the importance of biological nitrogen fixation and its tremendous agronomic potential if we could achieve fixation in non-legumes. Understanding ectoapyrase function, acting on extracellular nucleotides, during the symbiosis process would also aid in the engineering of more efficient associations between crops and microbes for sustainable agriculture in the future.

As described above, recent research findings have provided significant evidence regarding the role of ectoapyrase in plant–symbiont interactions, where the activity of ectoapyrase, controlling extracellular nucleotide levels, is essential for maximizing symbiotic signaling. However, there are still many open questions about the detailed mechanism, that is, how extracellular nucleotide excretion and possible signaling is involved in rhizobium–symbiotic signaling. Although the model we proposed (Figs. 52.3 and 52.4) is consistent with current evidence, key features still lack strong experimental support, for example, what is the extracellular ATP receptor in plants, which will be addressed by ongoing research efforts in many laboratories.

53.1 INTRODUCTION

Among the many factors involved in the development of an effective symbiosis between rhizobia and their host plants, those associated with adherence, colonization, and infection involving entry into the plant have not been fully elucidated at the molecular level (Robledo et al., 2012).

Root attachment and colonization in rhizobia follows the two-step system described in bacteria (Dazzo et al., 1984). During early reversible specific binding events, several bacterial proteins have been proposed to participate, such as bacterial ricahdesin and flagella, and plant lectins (Dazzo et al., 1984, Ausmees et al., 2001; Fujishige et al., 2006; De Hoff et al., 2009), while polysaccharides are the main components involved in the later irreversible attachment stages. Some of these cell surface components include exopolysaccharides, lipopolysaccharides, cyclic β-1,2-glucans (Davey and O'Toole, 2000), and especially cellulose fibrils that mediate aggregation to root hairs and firmly anchor the bacteria to the root surface (Dazzo et al., 1984; Smit et al., 1992; Mateos et al., 1995; Robledo et al., 2012). Attachment to a surface is the initial step in biofilm formation, followed by cooperative colonization behaviors leading to the establishment of microcolonies by clonal propagation and maturation, and formation of three dimensional structures that are embedded in and covered by exopolymers (Costerton et al., 1987; Davey and O'Toole, 2000; Webb et al., 2003; Fujishige et al., 2006). Studies have revealed that *Rhizobium* (Napoli et al., 1975) as well as species of the *Enterobacteriaceae* family, such as *Citrobacter* spp., *Enterobacter* spp., and *Klebsiella* spp., produce cellulose as a crucial component of the bacterial flocs and extracellular matrix (reviewed in Lasa 2006; Robledo et al., 2012).

Infection is a term considered by most to mean the entrance, growth, and multiplication of microorganisms within a host, resulting in the establishment of a disease

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

process. Others define infection as the ability to breach the host barrier and colonize internal host tissues, regardless of whether it leads to detectable disease symptoms or not. This is the case of rhizobia. These beneficial bacteria infect host plants and promote their growth instead of producing disease. For this to occur, there must be full coordination between the macro and microsymbionts (Mateos et al., 2011). Rhizobia invade their plant hosts through colonization of intercellular epidermal spaces, crack entry at emerging lateral roots or penetration into deformed tips of host root hairs to produce tubular walled structures called infection threads (Dazzo and Wopereis, 2000; Goormachtig et al., 2004).

A key event of the primary infection process required for the development of the *Rhizobium*-legume root-nodule symbiosis is the passage of the bacteria across the root hair wall. This process of host wall degradation must be highly localized and delicately balanced in order for the bacterial symbiont to fully penetrate and trigger infection thread formation successfully without killing the root hair and subsequent abortion of the infection process (Peix et al., 2010). Several hypotheses have been proposed to explain how this event occurs. Nutman et al. (1973) proposed that rhizobia redirect growth of the root hair wall from the tip to the localized site of infection, causing invagination of an intact root hair wall rather than bacterial penetration of it. Ljunggren and Fähraeus (1961) proposed that homologous *Rhizobium* strains specifically induce the host plant to produce polygalacturonases, which soften the root hair wall at the site of infection, thus allowing the bacteria to penetrate between microfibrils to the cell membrane and initiate an infection thread. The third model (Hubbell, 1981) proposed that wall-degrading enzymes produce a localized degradation that completely traverses the root hair wall, creating a continuous portal of entry allowing direct penetration by the bacteria. The strongest evidence for involvement of wall hydrolysis in the *Rhizobium leguminosarum* bv trifolii-white clover infection process was obtained by Callaham and Torrey (1981), who reported a localized degradation of the root hair wall coincident with the deposition of a new wall layer, above the site of degradation, which is continuous with the root hair wall. The main point of divergence would be the possibility that the wall-degrading enzymes involved in the process are associated with the bacteria or locally induced in the plant by components of the bacteria (Peix et al., 2010). Plant cell wall-degrading enzymes are predicted to participate in two steps of this infection process: during primary infection of the host root hairs leading to infection thread formation (Inf) and later during bacterial release (Bar) from walled infection threads within host nodule cells (Robledo et al., 2008, 2011a).

Extending the role of hydrolytic enzymes in the active penetration of plant cell walls by some pathogenic microorganisms, McCoy (1932) was the first to investigate the possible involvement of hydrolytic enzymes in the infection of legumes by rhizobia. There was no evidence of these enzymes from rhizobia, though sensitive procedures to detect minute amounts of cell wall-degrading enzymes were not yet available. Later, several studies detected pectinolytic (Hubbell et al., 1978), cellulolytic (Morales et al., 1984), and hemicellulolytic (Martínez-Molina et al., 1979) enzyme activities from pure cultures of rhizobia. In general, the activities of these rhizobial enzymes are very low and at the limit of sensitivity of conventional reducing sugar assays. Using improved, reliable assays of increased sensitivity (Mateos et al., 1992), it was established that cellulases are produced by all type strains of the official species of rhizobia (Jiménez-Zurdo et al., 1996; Robledo et al., 2008). In contrast, polygalacturonase activity is less commonly found in rhizobia (Jiménez-Zurdo et al., 1996). Progression of infection threads across adjacent root cells would require the sequential action of plant enzymes degrading other components of the cell-wall induced upon rhizobia inoculation, such as by plant polygalacturonases in *Medicago sativa* and *Medicago truncatula* (Muñoz et al., 1998; Rodríguez-Llorente et al., 2003) and pectate lyases in *Lotus japonicus* (Xie et al., 2012).

Two key findings in earlier studies were the *in vivo* cell-bound location rather than extracellular secretion of these enzymes, and the substrate requirement of being amorphous rather than non-crystalline (Mateos et al., 1992, 2001). These two characteristics of the rhizobial enzyme have profound implications on their predicted role in primary host infection.

53.2 METHODS

All methods of DNA manipulation, construction of strain derivatives, detection, purification and biological activities of enzymes and substrates, plant microbiology, and determination of biofilm formation are described in (Robledo et al., 2008, 2011a, 2012).

53.3 RESULTS AND DISCUSSION

53.3.1 Cellulases in Rhizobia

The cellulase genes and the cellulolytic enzymes they encode are widespread and commonly expressed among bacteria establishing the root nodule symbiosis (Robledo et al., 2008, 2011b). Among them, the *celC* gene, located near putative cellulose synthase genes in a region of the chromosome (*celABC*), is involved in bacterial cellulose biosynthesis (Robledo et al., 2012) and encodes a cellulase (CelC2) essential for the symbiotic infection of legume host roots in the genus *Rhizobium* fulfilling a very significant

role in infection processes required for the development of the nitrogen-fixation endosymbiosis (Robledo et al., 2008, 2011a). All species in the genus *Rhizobium* analyzed up to date carry a *celC* gene in their chromosome (Robledo et al., 2011b). Furthermore, the phylogeny of the *celC* gene is completely congruent with those based on the chromosomal genes, but not with those based on plasmid-borne genes, in species of the genus *Rhizobium*, and thus *celC* represents a new phylogenetic marker useful for taxonomic studies in this genus (Robledo et al., 2011b).

53.3.2 Role of *Rhizobium* Cellulase CelC2 in Root Colonization

Among the molecules involved in biofilm development are different proteins and some exopolysaccharides, such as cellulose, which is a major component of the biofilm matrix of several bacterial species (Romling, 2002). It is not known how well conserved cellulose production is among all currently known bacterial genera or species that can establish symbiotic nitrogen-fixing root nodules with legumes. Currently, the known diversity of these bacteria mostly resides within the order *Rhizobiales*, which includes about 83 species distributed in different families and genera. We examined most of the official type strains of each of these taxa for cellulose production by Congo red staining, and all were found to be positive to varying degrees (Robledo et al., 2012). We previously used direct *in situ* enzyme cytochemistry at subcellular resolution to detect cellulose microfibrils associated with wild-type *Rhizobium leguminosarum* bv. trifolii ANU843 cells anchored on the roots of its host plant, white clover (Mateos et al., 1995). Timing of their production coincides with the transition from loose to firm adhesion of the bacteria to clover root hairs *in planta* (Dazzo et al., 1984).

By testing cellulose production and biofilm formation by rhizobia on different abiotic *substrata* and examining their attachment to the root epidermis of the host plant clover, we qualitatively and quantitatively compared the biofilm formation ability of the wild type strain ANU843 and its derivatives ANU843ΔC2 (CelC2 knockout) and ANU843C2+ (CelC2 overproducing), illustrated in Figure 53.1.

Aggregation of bacteria, usually mediated by cellulose microfibrils, and dispersion of cell aggregates by exogenously added cellulase are highly suggestive that an excess of extracellular cellulose was being produced (Deinema and Zevenhuizen, 1971; Napoli et al., 1975). The ANU843ΔC2 mutant flocculated heavily into large cell aggregates in yeast mannitol broth (YMB) liquid culture, and these flocs were completely dispersed after treatment with commercial cellulase (Sigma) for 2 h (Robledo et al., 2012). In contrast, flocculation was visually undetectable in the CelC2 overproducing derivative strain ANU843C2+ (Robledo et al., 2012).

Intensity of Congo red staining of ANU843ΔC2 and ANU843C2+ strains was greatly increased or reduced, respectively, as compared to the wild type (Fig. 53.1a). In addition, quantitative image analysis of fluorescence micrographs of cultures stained with the fluorochrome Calcofluor, which binds to β-linked glucans such as cellulose, indicated that the extracellular microfibrils associated with cells of the ANU843ΔC2 mutant were Calcofluor-bright and significantly longer than the average length associated with wild-type cells (Robledo et al., 2012), and that they were not detected in association with the ANU843C2+ derivative strain (Fig. 53.1b).

Thus, the increase in flocculation, enzymatic treatment, Congo red staining, and estimated microfibril length observed in the ANU843ΔC2 mutant are all directly correlated with the overproduction of external cellulose microfibrils. By contrast, the *celC* over-expression derivative strain lost the ability to make extracellular cellulose microfibrils (Robledo et al., 2012). These results suggest that *R. leguminosarum* bv. trifolii cellulase CelC2 is involved in the elongation of cellulose extracellular microfibrils (Robledo et al., 2012).

Biofilm rings of ANU843ΔC2 at the glass–liquid–air interface were thicker, more compact, and more easily

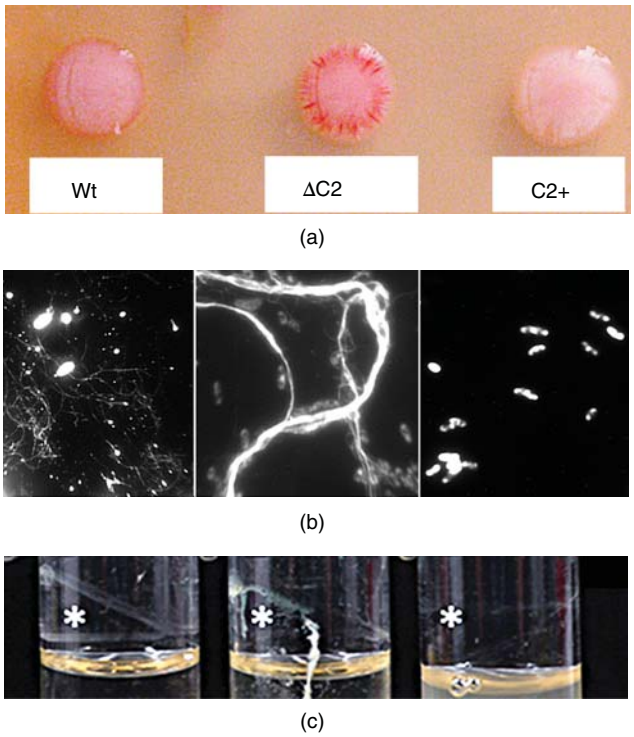

Figure 53.1 Role of *Rhizobium* cellulase CelC2 in cellulose biosynthesis and biofilm formation. (a) Colony uptake of Congo red, (b) calcofluor staining of cells and extracellular microfibrils, and (c) ring formation at the glass–air–liquid interface by wild-type strain of *Rhizobium leguminosarum* bv. trifolii ANU843 (wt) and its derivatives ANU843ΔC2 (ΔC2) and ANU843C2+ (C2+).

dislodged from the glass surface compared to the wild type strain (Fig. 53.1c). In ANU843C2+, the rings were much thinner, suggesting a role for CelC2 in biofilm formation (Robledo et al., 2012).

We also examined biofilm development on a sand substratum representing a more natural environment for these bacteria. Polyvinyl chloride (PVC) tabs were also used to examine the three-dimensional structure of biofilms formed at the edges of inert surfaces. Wild type ANU843 developed microcolonies, which coalesced into a characteristic three-dimensional biofilm (Robledo et al., 2012). In contrast, ANU843ΔC2 established unstable aggregates on surfaces that were easily removed (Robledo et al., 2012). On the other hand, ANU843C2+ bacteria only produced a two-dimensional monolayer biofilm, with just a few bacteria attached to one another (Robledo et al., 2012).

These results confirm the role of external cellulose microfibrils in biofilm attachment and architecture. They further suggest that *R. leguminosarum* bv. trifolii does not develop biofilm normally if production of cellulose microfibrils is altered by elevated or diminished levels of CelC2 endoglucanase (Robledo et al., 2012).

To extend these results found in the abiotic surface tests, we also examined attachment and biofilm formation of *Rhizobium leguminosarum* bv. trifolii and its *celC* derivative strains on roots and root hair tips of the host plant *Trifolium repens* grown in a N-free Fähraeus medium. All strains colonized the root, especially root hair zone II, and remained attached to the root surface even after thorough washing (Robledo et al., 2012). Even strain ANU843C2+ impaired in external cellulose microfibrils biosynthesis attached to plant roots, further confirming that bacterial cellulose does not act alone in plant root attachment (Robledo et al., 2012).

Most root hairs in the growing root hair zone were covered with wild type *R. leguminosarum* bv. trifolii ANU843 cells growing in a three-dimensional biofilm (Robledo et al., 2012) whereas ANU843ΔC2 formed large aggregates that covered the root in an irregular manner (Robledo et al., 2012). In contrast, very few individual cells of the ANU843C2+ derivative strain (cellulose overproducing) were attached to root hairs (Robledo et al., 2012).

The differences in the pattern of root and root hair attachment by the cellulose mutants imply that the cellulose fibrils play a significant role in the stability of the three-dimensional root hair "cap" biofilm (Robledo et al., 2012).

53.3.3 Role of *Rhizobium* Cellulase CelC2 in Root Infection

We have purified the cell-bound cellulase isozymes CelC2 from *R. leguminosarum* bv. trifolii to homogeneity, and analyzed its symbiotic function by a combination of biochemical, reverse genetics and plant microscopy approaches.

Rhizobial CelC2 is a 1,4-ß-D-endoglucanase (EC 3.2.1.4) with high substrate specificity for non-crystalline (amorphous) cellulose. It has an approximate molecular mass of 33.2 kDa, an optimal pH of 5.0, a maximal rate of carboxymethyl-cellulose (CMC) hydrolysis at 40 °C, and an apparent Km of 84.4 mg/ml for CMC as the substrate (Robledo et al., 2008). These biochemical characteristics of CelC2 cellulase restrict its symbiotically relevant activity during primary host infection. The cell-bound location, the high Km value, and the relatively low activity of CelC2 cellulase are all characteristics that would restrain its degradative action on roots, thereby minimizing indiscriminate host cell lyses and death (Mateos et al., 2011). The substrate specificity of CelC2 cellulase for non-crystalline cellulose significantly restricts its *in vivo* site of wall-penetrating erosive action to the highly localized root hair infection sites lacking crystalline wall architecture (Mateos et al., 2001; Robledo et al., 2011a). The pH 5 optimum for CelC2 cellulase is consistent with the slightly acidic pH at the external surface of white clover root hairs. Finally, the specificity in the host plant exhibited by the Hot (Hole on the tip) biological activity of CelC2 cellulase, which includes the compatible white clover legume but excludes the heterologous, non-host legume alfalfa, is consistent with the host specificity of infection thread formation in legume root hairs (Robledo et al., 2008).

Purified CelC2 can completely erode the highly localized non-crystalline tip of the host root hair, forming a complete hole whose geometry and location match the portal of entry point in primary host infection into white clover (Mateos et al., 2001; Robledo et al., 2008). CelC2 knockout mutants are unable to breach the host wall at the root-hair tip or form infection threads within the host root hair and effective nodules (Robledo et al., 2008). Transfer of the cloned wild-type gene into the CelC2 knockout mutant restored these symbiotic phenotypes (Robledo et al., 2008).

Plants grew well in nitrogen-free medium when inoculated with the wild type strain ANU843, indicative of an effective nitrogen-fixing symbiosis. Those plants benefited by symbiotic nitrogen-fixation producing greener leaves and shoots that were significantly longer than plants inoculated with the mutant ANU843ΔC2 or the uninoculated axenic control plants (Robledo et al., 2008). The latter two groups of plants were stunted in development and became chlorotic once the fixed nitrogen from their cotyledons was exhausted, indicative of nitrogen starvation stress without the benefit of nitrogen fixation under these N-free growth conditions (Robledo et al., 2008). Complementation of the mutant strain ANU843ΔC2 with a plasmid expressing the *celC* gene restored the ability to produce the CelC2 cellulase isoenzyme, infect root hairs, and induce effective nitrogen-fixing nodules on white clover roots (Robledo et al., 2008).

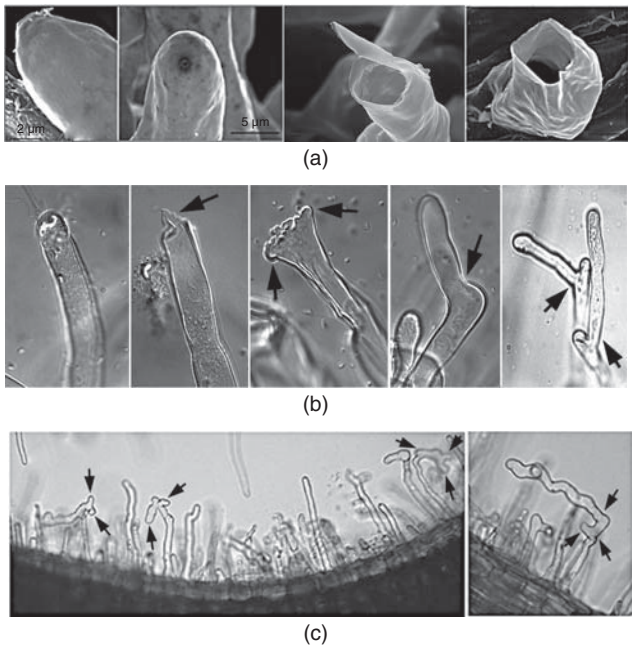

Figure 53.2 Effect of *Rhizobium* cellulase CelC2 overproduction on primary infection. (a) Scanning electron microscope (SEM) images showing the Hot (Hole on the tip) phenotype on root hairs of white clover inoculated with ANU843C2+. (b) The phase-contrast and Nomarski interference contrast micrographs show the deposition of new cell wall material before *transmuro* erosion of the original root hair tip followed by redirection of new tip growth (arrows) resulting in the development of a branch in the root hair that is again susceptible to hydrolysis at its new growing tip. (c) Clover root hairs showing multiple redirections (arrows) after inoculation with ANU843C2+.

These results provide compelling evidence that this enzyme fulfills a very significant role in the primary infection process required for the development of the canonical nitrogen-fixing *R. leguminosarum* bv. trifolii-white clover symbiosis (Robledo et al., 2008).

We have used a gain-of-function approach to further explore the impact of the CelC2 activity on the infection process during the development of the white clover-rhizobia symbiosis (Robledo et al., 2011a). Root hair deformation and infection thread formation assays were performed on white clover plants inoculated with cells of the wild-type strain of *R. leguminosarum* bv. trifolii ANU843, ANU843EV (Empty Vector) control or the recombinant strain that over produces CelC2 (Robledo et al., 2011a). ANU843C2+ cells induced various alterations at the root hair tip that included: (i) canonical primary infection stages as occurs in wild type or ANU843EV with deformations, markedly curled shepherd's crooks and infection thread formation (Robledo et al., 2011a) and (ii) hot phenotype as occurs in response to incubation with purified CelC2 enzyme (Robledo et al., 2011a) where the wall at the tip of some growing root hairs is degraded to produce a hole at this location (Fig. 53.2a) resulting in the extrusion of the root hair protoplast/cytoplasm. Although root hairs without tips can be found at very low frequency in uninoculated plants or after inoculation with the wild type strain, this feature is more frequent after ANU843C2+ inoculation (Robledo et al., 2011a); (iii) sometimes, new cell wall material was deposited before *transmuro* erosion of the original root hair apex, followed by redirection of new tip growth resulting in the development of a branch in the root hair (Fig. 53.2b) that is again susceptible to hydrolysis at its new growing tip (Fig. 53.2c). These branched redirections of root hair growth were also frequently observed on axenic clover roots after 12 h of incubation with purified cellulase CelC2 (Robledo et al., 2011a). These features show that the CelC2 cellulase-overproducing strain evokes severe aberrant phenotypes in clover root hair development, disrupting the balance between biosynthesis and degradation of its cell wall.

Because localized regions of nodular infection threads that develop into infection droplets exhibit a non-crystalline isotropic cell wall (Robledo et al., 2011a), we predicted that CelC2 may be involved in infection droplet development within nodule cells. To examine if CelC2 has a symbiotic function during this event of the secondary infection process, we monitored both ANU843wt and CelC2-overexpressing strains behavior within nodules by transmission electron microscopy (TEM), illustrated in Figure 53.3.

ANU843wt strain followed the normal steps of the infection process: dissemination of bacteria within walled infection threads within plant cells, localized hydrolysis of the infection thread wall, movement of the vegetative bacteria into membrane-enclosed infection droplets that protrude into the host cell cytoplasm, and endocytosis of bacteria from infection droplets followed by their differentiation into nitrogen-fixing competent bacteroids, forming the nitrogen-fixing symbiosomes within host nodule cells (Fig. 53.3a).

Secondary host infection by the recombinant strain ANU843C2+ included steps that were similar to and others that were different from wild type ANU843. Bacterial progression through the infection thread was similar to wild type, except for more frequent areas of localized hydrolysis resulting in an increase in the diameter of the lumen of infection threads, and infection droplets that were larger with prominent multilobed protrusions (Robledo et al., 2011a). Often, vegetative cells of the CelC2 over-producing strain were released into the host cells without being surrounded by a peribacteroid membrane or bacteroid differentiation (Fig. 53.3b). The cell wall of nodule cells containing naked vegetative bacteria showed significant deformation accompanied by thinning and breakage indicating significant disruption of this host barrier (Robledo et al., 2011a). Thus, invasion of host nodule cells by the CelC2 over-producing strain resulted in uncontrolled disorganization of the plant

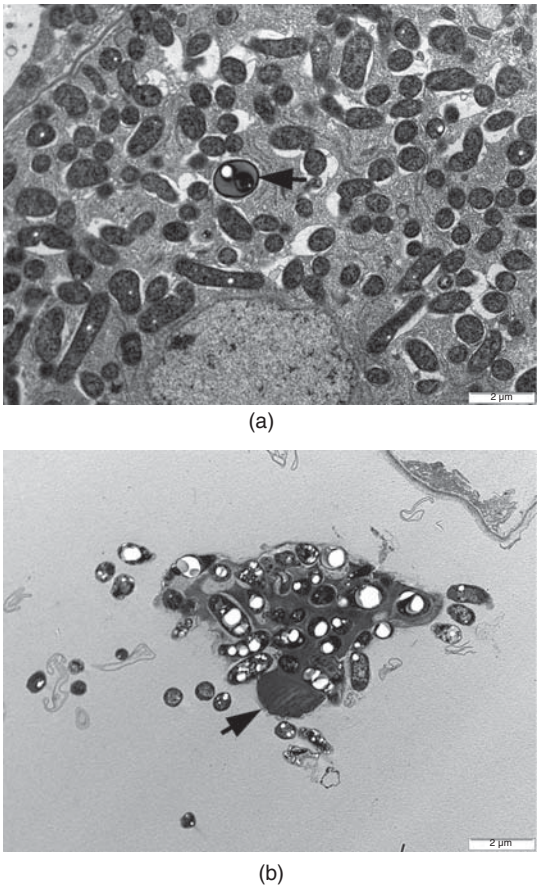

Figure 53.3 Effect of *Rhizobium* cellulase CelC2 overproduction on secondary infection within white clover root nodules. TEM images showing clover nodule cells in the infection zone inoculated with ANU843 (a) or ANU843C2+ (b). Infection threads are marked with arrows.

cell wall and absence of well-defined symbiosome formation, leading to premature senescence of nodules that do not fix nitrogen (Robledo et al., 2011a).

These observations indicate that the CelC2 cellulase could intervene in localized erosion of and bacterial liberation from infection threads within the nodule, and that its *in situ* concentration and activity must be critically regulated to advance successful symbiotic development. Thus, an excess of CelC2 production leads to an aberrant, exaggerated Bar phenotype of bacterial release without peribacteroid membrane enclosure, followed by the induction of nodule premature senescence and eventual abortion of the symbiotic nitrogen-fixing process (Robledo et al., 2011a).

53.4 CONCLUSIONS

Our results support: (i) a key role of the rhizobial CelC2 cellulase in cellulose biosynthesis by modulating the length of the cellulose fibrils that mediate firm adhesion among *Rhizobium* bacteria leading to biofilm formation; (ii) the importance of *Rhizobium* cellulose as an essential component of the biofilm polysaccharidic matrix architecture; (iii) the essential role of rhizobial CelC2 cell wall-degrading enzyme in the primary infection process; and (iv) its importance in secondary symbiotic infection and tight regulation of its production to establish an effective nitrogen-fixing root nodule symbiosis.

Chapter 54

Nod Factor-Induced Calcium Signaling in Legumes

Sarah Shailes and Giles E.D. Oldroyd
John Innes Centre, Norwich Research Park, Norwich, UK

54.1 INTRODUCTION

In plants, calcium is a ubiquitous signal molecule involved in a number of developmental processes including pollen tube and root hair apical growth, regulation of stomatal aperture, and responses to abiotic and biotic stresses (Foreman et al., 2003; Feijo et al., 2001; McAinsh et al., 1995; Dodd et al., 2010). A calcium signal can consist of a single elevation in calcium within a cellular compartment, for example, the sustained elevations of calcium in the cytoplasm and nucleus caused by the recognition of pathogen-associated molecular patterns (PAMPs) during innate plant defense (Dodd et al., 2010). They can also exhibit oscillatory behavior, such as the tip-focused calcium gradients in pollen tubes and root hair cells, which oscillate for the same period as the oscillations in cell growth (Feijo et al., 2001; Monshausen et al., 2008). In *Arabidopsis thaliana* root hairs the oscillations in calcium have a period of about 30 s but calcium oscillations can have a much longer period; for example, oscillations with a period of 24 h are involved in circadian clock regulation (Love et al., 2004). During the establishment of the legume-rhizobial symbiosis (Sym), rhizobia produce lipo-chitooligosaccharides (LCOs) known as Nod factors (NFs). NFs are first perceived by the legume at the root epidermis and are capable of activating two different calcium responses: nuclear-localized calcium oscillations (spiking) and a tip-focused calcium influx. These two calcium responses are associated with the activation of nodule organogenesis and the initiation of bacterial infection.

54.2 CALCIUM SPIKING

Upon NF treatment there is a delay of 10–15 min before calcium spiking starts around the nuclear region of legume root hair cells (Ehrhardt et al., 1996; Miwa et al., 2006b). Use of both nuclear-targeted and nuclear-excluded calcium reporters confirms that the spiking originates from the periphery of the nucleus and can be observed both in the nucleoplasm and the nuclear-associated cytoplasm, suggesting that the nuclear envelope and nuclear-associated endoplasmic reticulum (ER) are the calcium sources (Sieberer et al., 2009; Capoen et al., 2011). The response can be activated by NF concentrations as low as 10^{-12} M and can also be activated by chitin oligomers, NF analogs, and mycorrhizal-produced Lipochitooligosaccharides (Myc-LCOs) (Oldroyd et al., 2001a; Walker et al., 2000; Genre et al., 2013). Once activated by NF, calcium spiking is very robust and can be observed in a root hair cell for many hours (Walker et al., 2000; Miwa et al., 2006a). In the model legume *Medicago truncatula* the spikes have a period of around 90 s, although this can vary over the course of the spiking response and between cells (Kosuta et al., 2008; Sun et al., 2007).

Calcium spiking is central to the common Sym signaling pathway (also known as CSSP) required to form symbioses with rhizobia and mycorrhizal fungi (Fig. 54.1). The pathway has a core set of genetic components required for both symbioses that are involved with generating or "encoding" the calcium spiking response and "decoding" it to lead to the activation of downstream genes. Downstream of

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

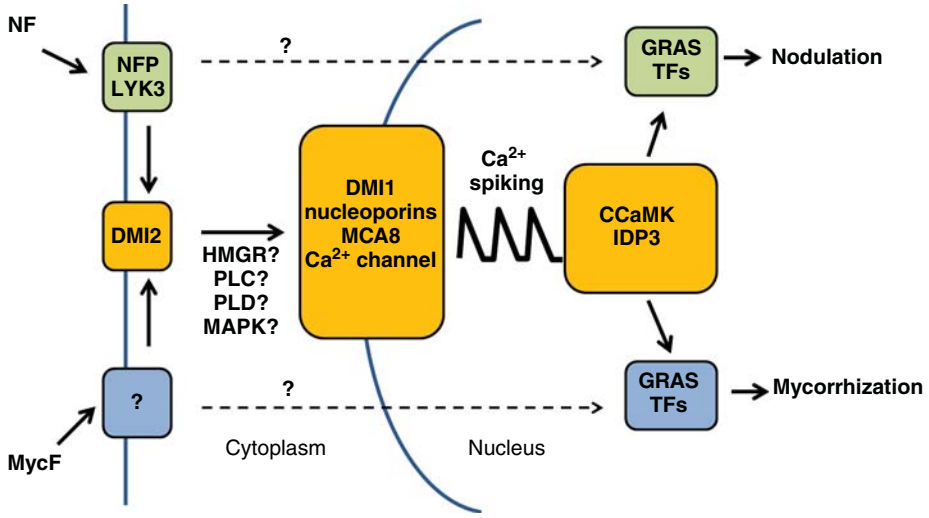

Figure 54.1 The Sym pathway. The Sym pathway (shown in orange) is shared between nodulation and mycorrhization. NFs from rhizobia are perceived by NFP and LYK3 at the plasma membrane and mycorrhization factors (MycFs) are perceived by currently unidentified receptors. The signals from both symbionts activate DMI2 also located at the plasma membrane and then nuclear calcium spiking is mediated by the cation channel DMI1, nucleoporins, the Ca^{2+}-ATPase MCA8 and an unidentified calcium channel. Downstream of calcium spiking CCaMK is activated and with its interacting partner IPD3 promotes appropriate gene expression for either nodulation or mycorrhization via activation of GRAS transcription factors (TFs). Parallel signaling may also be involved.

calcium decoding differential transcription factors (TFs) activate genes required for nodule formation and bacterial infection in the rhizobial Sym, or to facilitate fungal infection during the arbuscular mycorrhizal (AM) Sym. During nodulation, genes induced by the Sym pathway include *ENOD11* and the TFs *NIN* and *ERN* (Journet et al., 2001; Marsh et al., 2007; Schauser et al., 1999; Middleton et al., 2007).

In *Lotus japonicus* calcium spiking is dependent on the NF receptors NFR5 and NFR1 of the LysM receptor kinase-like family (Miwa et al., 2006b). In *M. truncatula* the homologs are Nod factor perception (NFP) and LYK3, but interestingly only NFP is required for NF-induced calcium spiking (Smit et al., 2007; Ben Amor et al., 2003). Another plasma membrane component, a leucine-rich repeat (LRR)-receptor kinase called DMI2/SymRK (does not make infections 2) is required for NF induction of calcium spiking and is required for both rhizobial and mycorrhizal Sym (Wais et al., 2000; Endre et al., 2002; Stracke et al., 2002). It is likely that these receptors act in a complex to bind NF (ref) and activate downstream signaling.

54.3 SECONDARY MESSENGERS: LINKING NF RECOGNITION AT THE PLASMA MEMBRANE WITH NUCLEAR CALCIUM SPIKING

From the plasma membrane the signal generated by NF recognition must be relayed to the nucleus probably by secondary messengers to generate calcium spiking, but the mechanism for this is unclear. There is evidence for the involvement of phospholipase C (PLC) and phospholipase D (PLD) in the Sym pathway. IP_3 along with diacylglycerol (DAG) are the products of phosphatidylinositol 4,5-bisphosphate (PIP-2) hydrolysis by PLC and the PLC inhibitor U73122 blocks NF-induced calcium spiking and pENOD11-GUS expression (Pingret et al., 1998; Engstrom et al., 2002). PLD can catalyze the conversion of DAG to phosphatidic acid, which can also act as a signal molecule. NF activates PLD activity in legumes (den Hartog et al., 2001, 2003) and n-butanol treatment inhibits calcium spiking and pMtENOD11-GUS expression suggesting that PLD may also be involved in the Sym pathway (Charron et al., 2004; Sun et al., 2007).

Interestingly, the G-protein agonist mastoparan (or its synthetic analog Mas7) can activate calcium oscillations similar to NF-induced calcium spiking and can induce pMt-ENOD11-GUS expression (Sun et al., 2007; Pingret et al., 1998). However, there are some differences in NF and Mas7-induced calcium spiking signatures. Mas7 leads to calcium oscillations with a slower initial release of calcium and greater period variability and the oscillations are not confined to the nucleus but can be observed all over the cell (Sun et al., 2007). Unlike the NF response it is independent of *NFP* and *DMI2*, suggesting that it either acts downstream of these receptors or by an independent mechanism. Several G-proteins have been identified as having roles in nodulation including members of the rho of plants guanosine triphosphatase (ROP GTPase) family and a Rab GTPase (Blanco et al., 2009; Ke et al., 2012). *L. japonicus* ROP6 is able

to bind to NFR5 and the gene is expressed in nodules and infection threads after inoculation with *Mesorhizobium loti* (Ke et al., 2012). In *ROP6* RNA interference (RNAi) lines infection thread development into the cortex is impaired and few nodules are formed (Ke et al., 2012). G-proteins can activate multiple signaling pathways including IP_3 production and in pollen tube tips PIP-2 accumulation is dependent on ROP-GTPases (Kost et al., 1999). Mastoparan activates PLC and PLD in the legume *Vicia sativa* (den Hartog et al., 2001). Altogether these results suggest that NF receptor activation could result in the activation of ROP-GTPases leading to the production of IP_3 and DAG to activate calcium spiking in the nucleus. However, there is no direct evidence for IP_3 induction of calcium spiking and mastoparan-induced calcium release during the activation of plant mitogen-activated protein kinase (MAPK) signaling occurs independently of G-proteins (Miles et al., 2004) so care should be taken in interpreting these Mas7 results.

Multiple secondary messengers may be interacting in a signaling pathway so even if IP_3/DAG are involved in generating NF-induced calcium spiking it is possible that other secondary messengers are also required. A MAPK kinase SIP2 interacts with DMI2/SymRK (Chen et al., 2012). In *L. japonicus* SIP2 RNAi plants produced fewer nodules and three nodulation marker genes including *NIN* were downregulated suggesting that an MAPK signaling cascade may be involved in generating calcium spiking. An enzyme known as HMGR1 (3-hydroxy-3-methylglutaryl coenzyme A reductase 1) also interacts with MtDMI2 (Kevei et al., 2007). HMGRs catalyze the production of mevalonate, a precursor required for isoprenoid biosynthesis. Treatment with lovastatin, an HMGR inhibitor, leads to reduced numbers of nodules in *M. truncatula* plants inoculated with *Sinorhizobium meliloti*, and *MtHMGR* RNAi lines produce fewer nodules than the wildtype suggesting that mevalonate is required for nodule formation. It may be that mevalonate is required for the production of isoprenoid compounds such as cytokinins or phytosteroids but it is also possible that mevalonate or a downstream compound is acting as a secondary messenger to relay the NF signal to the nucleus to activate calcium spiking.

54.4 ENCODING CALCIUM SPIKING: THE NUCLEAR ENVELOPE MACHINERY

Once the NF signal reaches the nucleus there are a number of genes that are required to induce calcium spiking. *DMI1* encodes a protein that localizes preferentially to the inner nuclear membrane with structural similarity to the pore domain of MthK, a calcium-activated potassium channel in *Methanobacterium thermoautotrophicum* (Ane et al., 2004; Edwards et al., 2007; Imaizumi-Anraku et al., 2005; Riely et al., 2007; Wais et al., 2000; Charpentier et al., 2008; Venkateshwaran et al., 2008; Capoen et al., 2011; Miwa et al., 2006b). In *L. japonicus* there are two homologs of *DMI1* required for calcium spiking known as *CASTOR* and *POLLUX* (Charpentier et al., 2008). CASTOR has ion channel activity *in vitro* with preferential mobilization of potassium, and POLLUX can complement a potassium-transport-deficient yeast mutant, providing evidence that they are functional potassium-permeable channels (Charpentier et al., 2008). Although *M. truncatula* has a gene orthologous to *CASTOR* it is not required for calcium spiking. *L. japonicus castor* and *pollux* mutants can be complemented by *DMI1* suggesting that *DMI1* in *M. truncatula* can fulfill the roles of both *CASTOR* and *POLLUX* (Venkateshwaran et al., 2012). *NUP85*, *NUP133*, and *NENA* encode subunits of the nucleopore and are also required for NF induction of calcium spiking. These proteins possibly function in the transport of membrane proteins to the inner nuclear membrane (Kanamori et al., 2006; Saito et al., 2007; Groth et al., 2010), and obvious substrates would be DMI1, POLLUX and CASTOR.

For the initiation of a calcium spike, where the calcium concentration in the nucleus and the nuclear-associated cytoplasm increase calcium permeable channels must be present in the nuclear membrane to allow calcium release from the nuclear periplasm. The genetic identity of the channel is still unknown. Its absence among nodulation mutants identified in several forward genetic screens conducted over the last two decades suggests that there may be multiple different genes involved or they may have other roles in development.

To return the calcium released into the nucleus and the nuclear-associated cytoplasm back to its store, a calcium pump is required that actively transports calcium across the nuclear membrane against its electrochemical gradient. A role for plant type IIA (SERCA-type) Ca^{2+}-ATPases has been suggested by an inhibitor cyclopiazonic acid and two activators gingerol and butylated hydroxynanisole that can block calcium spiking (Capoen et al., 2009, 2011; Engstrom et al., 2002). RNAi of a nuclear-localized SERCA Ca^{2+}-ATPase (MCA8) results in a large reduction in the number of root hair cells with NF-induced calcium spiking (Capoen et al., 2011). MtMCA8 is localized to the nuclear membranes, but has no preference for the inner or outer membranes. This location coupled with the phenotype of RNAi suggests that MCA8 acts to return calcium to the nuclear envelope during NF-induced calcium spiking.

54.5 MODELING CALCIUM SPIKING

To further understand how the NF-induced calcium oscillations in the nucleus may be generated Granqvist and colleagues (2012) have developed a mathematical model

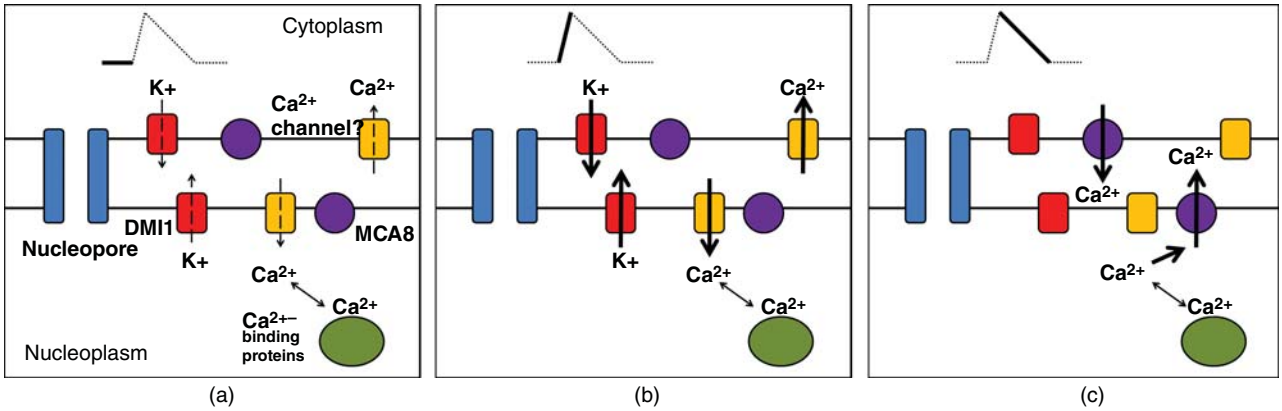

Figure 54.2 A model for calcium spiking. Model of calcium spike generation at the nuclear membranes. (a) Prior to the start of a calcium spike the membrane potential is negative on the nucleoplasmic side close to the potassium resting potential and DMI1 (shown in red) is weakly conducting potassium. This drives a transient influx of calcium ions through the calcium channel (orange) into the nucleoplasm leading to the depolarization of the membrane until it reaches the calcium resting potential. (b) The conductivity of DMI1 increases, resulting in the flow of potassium ions down their electrochemical gradient into the nuclear lumen. This hyperpolarizes the inner nuclear membrane, generating the large calcium flow into the nucleoplasm that forms the upwards part of the calcium spike. (c) Once the membrane returns to the potassium ion resting potential the potassium and calcium currents almost cease and the downwards part of the calcium spike is formed by the action of MCA8 (purple) returning calcium ions to the nuclear envelope lumen. Since the electrochemical gradient of calcium is so large once the membrane potential returns to the starting value the conductance of the voltage-activated calcium channel increases leading to a transient release of calcium that restarts the cycle. The frequency and shape of calcium spikes can be modulated by altering concentrations of calcium-binding proteins (green) in the nucleus.

to simulate the oscillations (Fig. 54.2). It consists of three membrane components: a Ca^{2+}-activated K^+ channel (based on DMI1), a voltage-gated calcium channel and a calcium-pump (based on MCA8). Assuming that the nuclear membrane potential is more negative on the nucleoplasmic side than in the nuclear envelope lumen the model can produce self-sustaining calcium oscillations in the nucleoplasm in the simulation similar to those experimentally observed in *M. truncatula*. However, the calcium oscillations in this model continue indefinitely, suggesting that additional components or activities are required for the cessation of the response.

The addition of Ca^{2+}-binding proteins, which act as Ca^{2+} buffers, improves the ability of the model to simulate calcium spiking. By altering buffer concentrations they can stop the oscillations or alter the period of the oscillations to simulate the observed variation in experimental data. When the model was set up with high levels of unbound calcium-binding proteins at the start, rapid calcium oscillations preceded the regular spiking pattern. This is very similar to experimental observations where, in about 50% of cases calcium spiking appeared to start with a rapid oscillatory phase before the regular spiking pattern can be established (Granqvist et al., 2012). Experimentally adding additional NF after the induction of calcium spiking leads to a short stage of rapid oscillations before the regular spiking pattern resumes in *M. truncatula* root hair cells, suggesting that NF may increase calcium buffering capacity in the nucleus by regulating calcium-binding proteins.

While the model (Fig. 54.2) can simulate calcium oscillation it is not without its limitations. For simplicity only the nucleoplasm and the nuclear membrane lumen are included and within those compartments it does not include any spatial information. Nevertheless, it proposes a mechanism for how a relatively small number of genetic components can generate robust calcium spiking and predicts that calcium-binding proteins are important modulators. It indicates that the currently unidentified calcium channel could be voltage-gated, although a ligand-gated or a dual-regulated channel could also be possible.

The function of the cation channel DMI1 can also be hypothesized using the model. It could be acting to counter balance the flow of the positively charged calcium ions into the nucleoplasm when calcium channels are activated, or alternatively it could directly trigger the activation of a voltage-gated calcium channel by polarizing the inner nuclear membrane potential. Charpentier and colleagues (2013) found that calcium spiking is only initiated when DMI1 and the calcium channel are activated simultaneously with DMI1 conductance dependent on the membrane potential and calcium concentration (Fig. 54.3). It indicates that although the main function of DMI1 is to act as a counter-ion channel, initial low-level potassium ion conductance is required to activate a transient calcium ion flux. In turn, this activates both DMI1 and the calcium channel by depolarization of the nuclear membrane. The conclusions from the model are supported by the following evidence: the homology of DMI1 to a calcium-activated

potassium channel, DMI1 interferes with galactose-induced cytosolic calcium transient increases in yeast cells and when expressed in human embryonic kidney (HEK) cells is sufficient to drive calcium-induced calcium release (Edwards et al., 2007; Venkateshwaran et al., 2008; Peiter et al., 2007). All this indicates the ability of DMI1 to coordinate calcium channels in diverse cell types. From the model it seems possible that the calcium spiking machinery could be primed for activation even in the absence of NF, suggesting that DMI1 or the calcium channel may be negatively regulated and NF perception releases them enabling calcium spiking to be initiated.

It is still not clear whether the calcium spiking in the nucleoplasm and the nuclear-associated cytoplasm is a consequence of calcium fluxes across both the inner and outer nuclear membrane, or is due to calcium fluxes across only one side with calcium ions flowing from the nucleoplasm to the cytoplasm or *vice versa* through nuclear pores to generate the spiking response on the other side. So far, using current imaging techniques, it has not yet been possible to distinguish between these scenarios (Capoen et al., 2011). However, modeling suggests that diffusion through the nuclear pore is insufficient to explain the calcium release inside and outside the nucleus. Calcium spiking in the nucleoplasm has a clear function because this is where the downstream components of the Sym pathway including the calcium/calmodulin-dependent kinase (CCaMK) and TFs such as NSP1 and NSP2 are located (Riely et al., 2007; Mitra et al., 2004; Hirsch et al., 2009; Kalo et al., 2005; Levy et al., 2004). The question remains whether calcium spiking in the nuclear-associated cytoplasm is just a consequence of the presence of machinery on the inner and outer nuclear membranes and/or the permeability of calcium through nuclear pores, or whether it has a biologically relevant function in nodulation.

54.6 DECODING CALCIUM SPIKING IN THE NUCLEUS

Mutants defective for CCaMK retain calcium spiking but lack NF-induced gene expression and nodulation suggesting that CCaMK is positioned downstream of calcium spiking (Levy et al., 2004; Mitra et al., 2004; Miwa et al., 2006b) and likely acts to decode this signal. CCaMK has a kinase domain at the N-terminal end, a calmodulin (CaM)-binding domain/autoinhibitory domain and three calcium-binding EF hand motifs, making it highly unusual as it is capable of perceiving both free calcium ions and calcium bound to CaM (Patil et al., 1995) (see Fig. 54.3). The kinase and CaM binding domains have sequence similarity to calmodulin-dependent protein kinase II (CaMKII) in animals, which is capable of frequency dependent activation by calcium, making CCaMK a good candidate for the decoding of calcium spiking (De Koninck and Schulman, 1998; Patil et al., 1995).

There are several gain-of-function mutations in CCaMK, including truncated "kinase only" and point mutations of the threonine at position 271 in *M. truncatula* (or equivalent in other species), which result in the activation of nodulation gene expression and spontaneous nodule formation even in the absence of rhizobia (Gleason et al., 2006; Hayashi et al., 2010; Takeda et al., 2012; Tirichine et al., 2006). The gain-of-function mutations demonstrate that CCaMK activation is sufficient to activate downstream components of the Sym pathway and also that T271 has a crucial role in the regulation of the protein. CCaMK kinase activity can be regulated by autophosphorylation and mutations of the equivalent threonine residue in *Lilium longiflorum* CCaMK resulted in lower levels of autophosphorylation and substrate phosphorylation, supporting a role for T271 in regulation (Sathyanarayanan et al., 2001). Expression of autoactive CCaMK T265D and T265I (equivalent to T271) variants in *L. japonicus* Sym pathway mutants that are unable to produce calcium spiking, restored nodulation, and AM colonization demonstrating that the primary purpose of generating nuclear calcium spiking is the activation of CCaMK (Hayashi et al., 2010; Madsen et al., 2010). However, the infection process was delayed and was less efficient with fewer functional nodules, probably due to deregulated CCaMK activity and ectopic expression, especially in the case of $CCaMK^{T265D}$, which was expressed under control of a constitutive promoter.

The two calcium-sensing domains appear to play different roles in the activation of CCaMK. CaM binding to CCaMK decreases phosphorylation of CCaMK (Takezawa et al., 1996). The autoinhibitory domain of CCaMK overlaps with the CaM-binding domain, so CaM-binding may release autoinhibition of the protein (Patil et al., 1995). The calcium-binding affinities to CaM and that of CaM binding to CCaMK suggest that CaM binding to CCaMK may only occur at significant levels at the higher concentrations of calcium generated by calcium spiking (Swainsbury et al., 2012). In contrast, the affinities of calcium binding to the EF hands suggests that at basal calcium concentrations before calcium spiking starts some of the EF hands may be occupied by calcium. The EF hands could inhibit CCaMK activation at low calcium concentrations or perhaps prime CCaMK for activation by CaMbinding or both. Therefore, the EF hands and the CaM-binding domain could provide CCaMK with mechanisms for sensing both high and low levels of calcium to facilitate the switch from the inactive to active state during calcium spiking (Fig. 54.3).

Point mutations in T271 and the CaM-binding domain of CCaMK have provided some insights into the mechanism of activation of the protein. Interestingly, both phospho-ablative (T-A) and phospho-mimic (T-D) mutations in T271 result in spontaneous nodule formation in legumes (Gleason

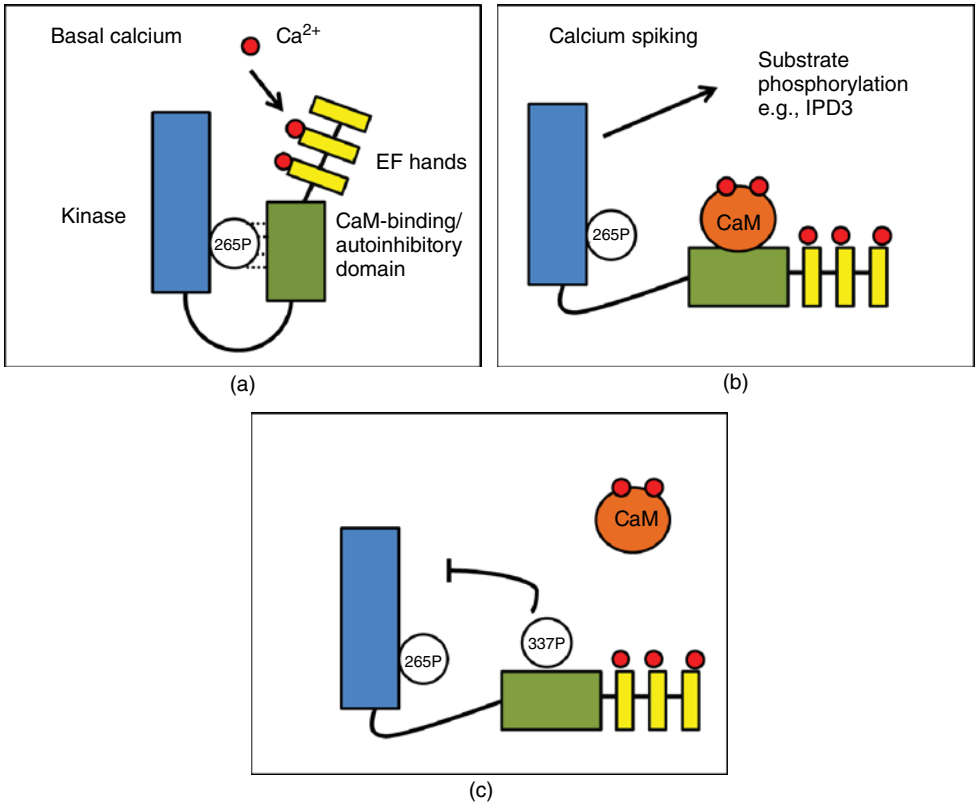

Figure 54.3 Model of CCaMK regulation. (a) Inactive CCaMK with a hydrogen bond network linking the kinase and CaM-binding/autoinhibitory domains. At basal calcium concentrations some of the EF hands are occupied by calcium ions, promoting Threonine 265 phosphorylation to drive the hydrogen-bond network, deactivating CCaMK. (b) At the onset of calcium spiking higher calcium concentrations result in full occupancy of the EF hands and calcium-bound to calmodulin (CaM). CaM binds to the CaM-binding domain, inducing a conformational change that releases the inhibition of the kinase domain, resulting in phosphorylation of CCaMK targets (e.g., IPD3/CYCLOPS). (c) Inactivation of CCaMK by phosphorylation of serine 337 in the CaM-binding domain, which prevents CaM binding and restores autoinhibition of the kinase domain by association with the CaM-binding/autoinhibitory domain.

et al., 2006; Takeda et al., 2012; Tirichine et al., 2006). A possible explanation of how these "opposite" mutations could have the same phenotypes has been provided by homology modeling of CCaMK with *Caenorhabditis elegans* CaMKII (Shimoda et al., 2012). This homology modeling predicts that in *L. japonicus* CCaMK residue T265 forms a hydrogen bond network with neighboring residue R317 in the CaM-binding/autoinhibitory domain. According to the model, mutation or phosphorylation of T265 would disrupt the hydrogen bond network, weakening the link between the kinase and CaM-binding/autoinhibitory domain, thus preventing effective autoinhibition even in the absence of calcium (Shimoda et al., 2012). It is possible that calciumbinding to the EF hands at low calcium concentrations may facilitate autophosphorylation of T271 to prime CCaMK for activation by CaMbinding at higher calcium concentrations (Fig. 54.3).

CCaMK can be negatively regulated by phosphorylation of a residue in the CaM-binding domain (Fig. 54.3). The *ccamk-14* mutant in *L. japonicus* has a serine to asparagine mutation at position 337 (Liao et al., 2012). The mutant is defective in mycorrhizal infection and during rhizobial infection produces more infection threads in the epidermis but the infection threads are impaired in progression through to the cortex, although nodule formation is unaffected. The phospho-mimic variant $CCaMK^{S337D}$ is unable to complement *ccamk-1*, suggesting that $CCaMK^{S337D}$ is not active. These mutations also indicate that negative regulation of CCaMK is required to facilitate bacterial infection, but is not required for nodule development or mycorrhizal infection.

CCaMK interacts with phosphorylates IPD3 (CYCLOPS in *L. japonicus*), a protein of unknown function with two nuclear localization signal motifs and a C-terminal coiled-coil motif thought to mediate protein–protein interactions (Messinese et al., 2007; Yano et al., 2008). *IPD3/CYCLOPS* is required for both rhizobial and AM infection (Yano et al., 2008). Although the mechanisms are currently unclear, CCaMK/IPD3 complex activation and recruitment of several GRAS TFs including *NSP1*, *NSP2*,

and *RAM1* are involved in the activation of specific nodulation or mycorrhizal gene expression (Heckmann et al., 2006; Kalo et al., 2005; Smit et al., 2005; Gobbato et al., 2012).

54.7 DO CALCIUM SPIKING SIGNATURES ENCODE SPECIFICITY BETWEEN NODULATION AND MYCORRHIZATION?

One of the most interesting questions regarding Sym pathway function is how activation of a shared signaling pathway can result in the differential outputs required to establish either the rhizobial or mycorrhizal Sym. Either specificity must be encoded within the pathway itself or a parallel pathway exists that modulates the output of the Sym pathway to induce the appropriate changes in gene expression. If specificity is encoded within the pathway it would be expected that the calcium spiking signatures would be different between the symbioses and CCaMK would be capable of differential activation, as is CaMKII in animal systems (De Koninck and Schulman, 1998).

The concept of different calcium spiking signatures is supported by mathematical analyses of calcium spiking signatures in *M. truncatula* produced by NFs and the mycorrhizal fungus *Rhizophagus irregularis* (previously, *Glomus intraradices*). Kosuta and colleagues (2008) found that the duration of a mycorrhizal-induced calcium spike is shorter than an NF-induced spike and there are also differences in shape. However, this experimental set up was not optimal because when using the fungus it is impossible to determinate when the plant root first perceives the fungus and the concentrations of the then unidentified diffusible signal factors dubbed "Myc factors." Using a different experimental set up Sieberer and colleagues (2012) studied calcium spiking signatures during the progression of infection of rhizobia and mycorrhizal fungi (see also Chapter 57). They found that for both symbioses, cortical cells switched from low frequency calcium oscillations prior to the microbes reaching the cell to high frequency oscillations during apoplastic entry. The high frequency oscillations appeared to be similar in both symbioses so it seems likely during the infection process that atleast calcium oscillations do not encode symbiont specificity. Myc-LCOs and chitin oligomers from fungal exudates that are capable of activating calcium spiking have recently been identified and if mathematical analyses of these calcium spiking signatures with those produced by NFs is carried out it may lead to some clarification (Genre et al., 2013; Maillet et al., 2011).

Instead of spike duration and shape encoding specificity CCaMK could be differentially activated by the number of calcium spikes that occur. In *M. truncatula* NF-induced calcium spiking only leads to *ENOD11* expression after about 36 individual spikes have occurred (Miwa et al., 2006a). It could be possible that during AM colonization a different number of calcium spikes occur, perhaps due to differences in nuclear Ca^{2+}-binding protein concentrations that terminate spiking sooner or later than during nodulation.

CCaMK activation does not appear to be associated with differential induction of symbiotic-specific responses. The autoactive $CCaMK^{1–314}$ (kinase only) variant activated both the nodulation marker *NIN* and the mycorrhizal marker subtilase (*SbtM1*) expression when expressed in *L. japonicus* (Takeda et al., 2012). Interestingly, *SbtM1* is expressed in multiple cell layers in $CCaMK^{1–314}$ expressing plants and is associated with the formation of fungal infection-like structures, whereas *NIN* expression is restricted to the epidermis (Takeda et al., 2012). However, the *snf1* mutant, which expresses autoactive $CCaMK^{T265I}$ induced nodulation-specific gene expression but not AM-specific gene expression, indicating that the phosphorylation status of threonine 265 may be important in activating rhizobial-associated responses (Takeda et al., 2011).

At this stage it seems unlikely that differences in calcium spiking responses can allow CCaMK to discriminate between the rhizobia and AM fungi and, instead, alternative signaling may define the specificity of the response.

54.8 THE CALCIUM INFLUX

In addition to calcium spiking, NF treatment also induces a calcium influx into the cytoplasm that originates in the tip of root hair cells (Miwa et al., 2006b; Shaw and Long, 2003a; Walker et al., 2000). Using ion-selective electrodes, Felle and colleagues (1998) were able to detect the calcium influx occurring within seconds of NF addition with calcium ions moving into the cytoplasm from the extracellular matrix. To initiate the calcium influx response, higher concentrations of NF must be used than those required to initiate calcium spiking, with 10^{-9} M required for half maximal induction and 10^{-8} M typically used to induce the response reliably (Felle et al., 2000; Miwa et al., 2006b; Shaw and Long, 2003a). Non-sulfated NFs and chitin oligomers, which are able to activate calcium spiking, do not activate the calcium influx suggesting that it has higher NF stringency (Felle et al., 1999; Miwa et al., 2006b; Shaw and Long, 2003a; Walker et al., 2000). In addition to being temporally and spatially separate it is also possible to genetically separate calcium spiking and the calcium influx. Both responses are dependent on the NF receptor *NFP* (in *L. japonicus NFR5* and *NFR1*) but the sym pathway mutants *dmi1* and *dmi2* both retain the calcium influx response (Ben Amor et al., 2003; Miwa et al., 2006b). Altogether these results suggest that the calcium influx is involved in a parallel pathway independent of calcium spiking. However, Shaw and Long (2003a) reported that the calcium influxes observed in *dmi1*

and *dmi2* after NF addition appeared to be shorter in duration than in wildtype *M. truncatula*, so it is possible that *DMI1* and *DMI2* can modulate the calcium influx.

The requirement for higher concentrations of NF and the higher stringency suggest that calcium influx may be involved in bacterial infection (Miwa et al., 2006b). In the early stages of establishment of the Sym before rhizobia attach to the root surface, the NF concentrations perceived by the plant are likely to be low, but presumably high enough to activate calcium spiking to induce early nodulation gene expression. During infection rhizobia attach to the surface of the tips of root hair cells, inducing the root hair to curl around the rhizobia entrapping them in infection foci where they continue to divide. The next stage is the development of the infection thread, a plant-produced structure that guides the dividing rhizobia down through the root hair into the root cortex to enable the bacteria to infect the developing nodule. Throughout this process as the rhizobia come into closer contact with the plant cell membranes and the number of "trapped" bacteria increase, the local NF concentration at the plant membranes is expected to increase, perhaps to a threshold where the calcium influx might be activated, and this may be associated with root hair curling or infection thread initiation. The infection process also has more stringent requirements for NF than induction of the Sym pathway, demonstrated by the *nodO/nodE* double mutant of *Rhizobium leguminosaurum* bv. v*iciae*, which induces root hair deformation and many infection foci on vetch but rarely forms infection threads (Walker and Downie, 2000). The *NodO* gene encodes a secreted protein that is capable of forming cation-selective pores in membranes (Sutton et al., 1994) and restoration of it or *NodE* (involved in attachment of acyl groups to NF) rescued infection thread development in the mutant, suggesting that an ion flux across the plant membrane induced by NodO could compensate for defective NF structures.

54.9 A ROLE FOR THE APYRASE LNP IN NF-INDUCED CALCIUM SIGNALING

Calcium spiking and the calcium influx are both dependent on *Lectin Nucleotide Phosphohydrolase (LNP)*. *LNP* antisense lines in *L. japonicus* do not form nodules or infection threads and the lines are defective for calcium spiking and the calcium influx, but maintain root hair deformation (Roberts et al., 2013). LNP has apyrase (hydrolysis of phophoanhydride bonds of nucleoside triphosphates and diphosphates) activity and is able to bind NF (Etzler et al., 1999, 2000). Extracellular adenosine triphosphate (ATP) is a signal molecule involved in a wide range of processes in plants and both ATP and ADP (adenosine diphosphate) are able to induce increases in cytosolic free calcium (Roux and Steinebrunner, 2007; Demidchik et al., 2003, 2009, 2011; Jeter et al., 2004). ADP treatment partially rescued Soybean LNP (GS52) RNAi lines, which are defective for nodule development and infection, suggesting that ADP may have a role in promoting nodulation (Govindarajulu et al., 2009). Perhaps, during nodulation, LNP regulates extracellular ADP/ATP levels to modulate calcium responses (For a more detailed review see Chapter 52: The Role of Apyrases in Nodulation.).

54.10 THE CALCIUM INFLUX IS SPATIALLY AND TEMPORALLY COINCIDENT WITH OTHER NF RESPONSES

After NF addition, there is an efflux of chloride ions, intracellular alkalization, and plasma membrane depolarization at the tip of a legume root hair cell, all occurring a few seconds after the calcium influx (Ehrhardt et al., 1992; Felle et al., 1996, 1998; Kurkdjian, 1995). The calcium inhibitor nifedipine inhibits these responses and the responses can be mimicked by treatment with the calcium ionophore A32187 and the Ca^{2+}-ATPase inhibitor 2,5-di(t-butyl)-1,4-benzohydroquinone (BHQ), providing further evidence that the calcium influx acts upstream of these responses (Felle et al., 1998). After membrane depolarization there is an efflux of potassium ions from the cell and membrane repolarization. Similarly to the calcium influx, the membrane depolarization is not induced by non-sulfated NFs or chitin oligomers and is dose dependent with a maximal response produced at $10^{-8}/10^{-7}$ M NF (Ehrhardt et al., 1992; Felle et al., 1996; Shaw and Long, 2003a). Felle and colleagues (1998) suggested a model where the NF-induced calcium influx acts as a secondary messenger leading to the activation of the chloride efflux and intracellular alkalinization, perhaps by inhibition of proton pumps, to generate the membrane depolarization. They also suggested that membrane repolarization is achieved by the efflux of potassium ions through potassium permeable channels, which is activated once the membrane potential becomes more positive than the potassium equilibrium potential.

Other responses to NF also occur at the tip. Within 3–6 min of NF addition cytoskeletal changes occur in legumes (Cardenas et al., 1998; Weerasinghe et al., 2003). The cytoskeletal changes precede NF-induced root hair deformation. There is also a transient increase in reactive oxygen species (ROS) production starting around 1 min after NF addition with ROS levels restored to normal levels by around 3 min (Cardenas et al., 2008; Shaw and Long, 2003b). Chitin oligomers were unable to produce the response, and the fungal elicitor chitin produced a larger, more sustained increase in ROS production more like the ROS burst seen during PAMP recognition in plant defence. Pretreatment of

root hair cells with DPI (diphenyleneiodonium), an inhibitor of NADPH oxidases and other flavin-containing enzymes, inhibited the response, suggesting that the main source of the ROS may be from NADPH oxidases (Cardenas et al., 2008). During the apical growth of root hair cells and pollen tubes calcium, protons and ROS interact to drive polar growth so it is possible that during nodulation the transient ROS production may be involved with the calcium influx and intracellular alkalinization that lead to membrane depolarization (Foreman et al., 2003; Monshausen et al., 2007, 2008). Although the ROS transient appears to be occurring later than the calcium influx and membrane depolarization, these processes have not been measured concurrently and the differences may be associated with technical differences in the experiments.

ROS can act as signal molecules in plants and there is evidence that ROS levels are regulated throughout the nodulation process (Apel and Hirt, 2004). Increased superoxide production can be detected in infection threads formed during the *M. sativa-S. meliloti* Sym, and there is an accumulation of hydrogen peroxide during nodule development and bacterial infection (Rubio et al., 2004; Santos et al., 2001). A ROS-sensitive peroxidase (RIP1) is induced by NF treatment, suggesting that ROS levels are regulated by NFs (Cook et al., 1995; Ramu et al., 2002). ROS levels in *M. truncatula* roots start to decline 30–60 min after NF treatment (Lohar et al., 2007; Shaw and Long, 2003b). The response can be activated by 100 pM NF but is not activated by sulfated chitotetraose or non-sulfated NFs. The decline was absent in *nfp* mutants but was present in Sym pathway mutants, suggesting that it is involved in a separate signaling process. Exogenous ROS treatment prevented NF-induced root hair swelling and branching, suggesting that the ROS decline is involved in root hair deformation, perhaps by preventing the activation of plant defence responses (Lohar et al., 2007). It seems likely that the transient ROS increase and the later, more gradual decline in ROS may have separate signaling roles in nodulation.

54.11 CALCIUM SIGNALING IN ROOT HAIRS: LESSONS FROM APICAL GROWTH

Gradients of calcium, pH and ROS production are required for apical growth of root hairs (Herrmann and Felle, 1995; Jones et al., 1995; Foreman et al., 2003). These gradients oscillate with the same period but are out of phase with oscillations in the rate of cell expansion (Monshausen et al., 2007, 2008). Calcium ion influxes across the plasma membrane at the tip of cells are responsible for the calcium gradient (Herrmann and Felle, 1995; Very and Davies, 2000). The *A. thaliana rhd2* mutant lacks the tip-focused calcium gradient and tip ROS production and has stunted roots and short root hair cells (Wymer et al., 1997; Schiefelbein and Somerville, 1990). *RHD2* encodes a plasma membrane NADPH oxidase (AtRBOHC) and ROS treatment to *rhd2* roots raised cytoplasmic calcium levels in the root hairs and restored cell expansion but this was not limited to the tip, suggesting that the sub-cellular localization of ROS production is important for appropriate polar cell expansion. Plant NADPH oxidases or RBOHs (respiratory burst oxidative homologs) contain calcium-binding EF-hand motifs and calcium ions have been shown to regulate their activity *in vitro*, suggesting that a positive-feedback loop between calcium and ROS is involved in regulating apical growth (Sagi and Fluhr, 2001; Keller et al., 1998; Takeda et al., 2008). Elevation of the pH of the external medium surrounding *rhd2-1* mutants to 6.0 restored normal root growth along with the tip-focussed calcium gradient (Monshausen et al., 2007). However, the mutants had lower ROS levels in root hairs and lacked the oscillations in ROS production at the tip, suggesting that either pH lies downstream of ROS or that they may act together to regulate root hair growth.

The calcium gradients are thought to provide directional regulation of apical growth by regulating exocytosis and actin reorganization (Rato et al., 2004; He et al., 2006). Alongside any signaling roles, ROS and pH may also directly regulate cell wall structure. ROS are involved in peroxidative-cross linking of cell wall polysaccharides and pH is involved in cell expansion (Cosgrove, 1999; Bibikova et al., 1998; Kjellbom et al., 1997; Kerr and Fry, 2004). Artificially raising the pH of the external medium surrounding *A. thaliana* roots to 8.0 or application of ROS arrests root tip growth, whereas decreasing the external pH to 4.5 or treatment with the ROS scavenger MCLA (methoxylated *Cypridina luciferin* analog) causes root tip bursting, suggesting ROS and a rise in apoplastic pH promote cell wall hardening during the slower growth phases.

Root hair apical growth is co-ordinated by ROP GTPases, which associate with the plasma membrane at the apex of the cell. There are 11 members of the ROP GTPase family in *A. thaliana* and they are involved in processes including abscisic acid (ABA) responses, pollen tube growth, cell shape formation and low oxygen response (Craddock et al., 2012). ROP GTPases switch between an activate state when they are bound to guanosine triphosphate (GTP) and an inactive state when they are bound to guanosine diphosphate (GDP). ROPs are regulated by RopGEFs, which exchange the GDP for GTP to return the ROP to its active state; RopGAPs, which promote the intrinsic GTPase activity of the ROP to inactivate it; and RhoGDIs, which sequester ROPs in the cytosol to prevent them being activated by the RopGEFs (Berken and Wittinghofer, 2008; Bos et al., 2007; Carol et al., 2005; Kost, 2008). The *A. thaliana scn1* mutant is defective in a RhoGDI and develops multiple root hair initials (Carol et al., 2005). *AtROP2* is mislocalized in this mutant demonstrating the importance

of the regulation of ROP GTPase subcellular localization for regulation of polar growth. In *A. thaliana* ROP GTPase genes can have redundant and non-redundant functions and *AtROP2*, *AtROP4*, and *AtROP6* are involved in root hair apical growth (Jones et al., 2002, 2007; Molendijk et al., 2001; Yang et al., 2007; Duan et al., 2010). *AtROP2* and *AtSCN1* (a RhoGDI) are required for AtRBOHC-mediated ROS production during root hair growth (Carol et al., 2005; Jones et al., 2007).

Regulation of polar growth is essential during rhizobial infection to mediate root hair curling around attached bacteria and the development of the infection thread. It seems likely that the mechanisms for regulating the processes for root hair growth may have been co-opted for rhizobial infection. NF treatment induces root hair elongation, but unlike apical growth this is independent of ethylene indicating that if NF can activate the apical growth machinery it does so downstream of the ethylene receptors (Oldroyd et al., 2001b). Spot inoculation of NF to the surface of *M. truncatula* root hairs is sufficient to alter the axis of polar growth to generate root hair curling (Esseling et al., 2003). Recently, evidence of the involvement of ROP GTPase signaling in nodulation has been emerging. Three *M. truncatula* ROP GTPase genes are up-regulated in roots and root hairs after inoculation with *S. melliloti* (Liu et al., 2010). RNAi knockdown of *MtROP9* inhibits an NF-induced ROS response and results in the formation of fewer nodules (Kiirika et al., 2012). In *Lotus japonicus LjROP6* is up-regulated after inoculation with *M. loti* and the protein interacts with the NF receptor NFR5 *in planta* (Ke et al., 2012) (Fig. 54.4). *LjROP6* RNAi lines showed an inhibition of infection thread growth through the cortex suggesting that ROP6 may promote infection thread development from the epidermis into the cortex, perhaps through regulation of the cytoskeleton (Ke et al., 2012). The RNAi lines also produced fewer nodules and the early nodulation genes *NIN* and *ENOD40* are down-regulated compared to wildtype after inoculation with *S. meliloti.* These results indicate that either *LjROP6* may be involved in the Sym pathway or it may lie in a parallel pathway, perhaps primarily involved in regulating infection but with a role in the positive feedback of the Sym pathway as part of the co-ordination of nodule development and bacterial infection.

Part of the function of ROP GTPases in nodulation may involve the regulation of NADPH-dependent ROS production. The *MtRbohA* gene is up-regulated in nodules during the *M.truncatula-S. melliloti* Sym and expression of *MtRbohA* appears to be restricted to the nitrogen-fixing zone of the nodules (Marino et al., 2011). Plants inoculated with *S. meliloti* mutant strains *nifH* and *bacA*, which are unable to form functioning nodules, had lower *MtRbohA* expression and *MtRbohA* RNAi lines had lower nitrogen fixation activity in nodules (Marino et al., 2011). Coinciding with the decline in ROS after NF treatment, *MtRBOH2* and *MtRBOH3* are transiently down-regulated at 1 h in an NFP-dependent manner in *M. truncatula* (Lohar et al., 2007). Another member, *PvRbohB* is expressed in several tissues including developing nodules and in infected root hairs in *P. vulgaris* (Montiel et al., 2012). RNAi lines have reduced ROS production, fewer nodules and the infection threads are impaired in progression from the epidermal cells into the cortex. The few nodules that form in the *PvRbohB* RNAi lines have infection threads that are wider and more irregular in shape, indicating that *PvRbohB* is involved in infection thread development. It would be very interesting to know if any of

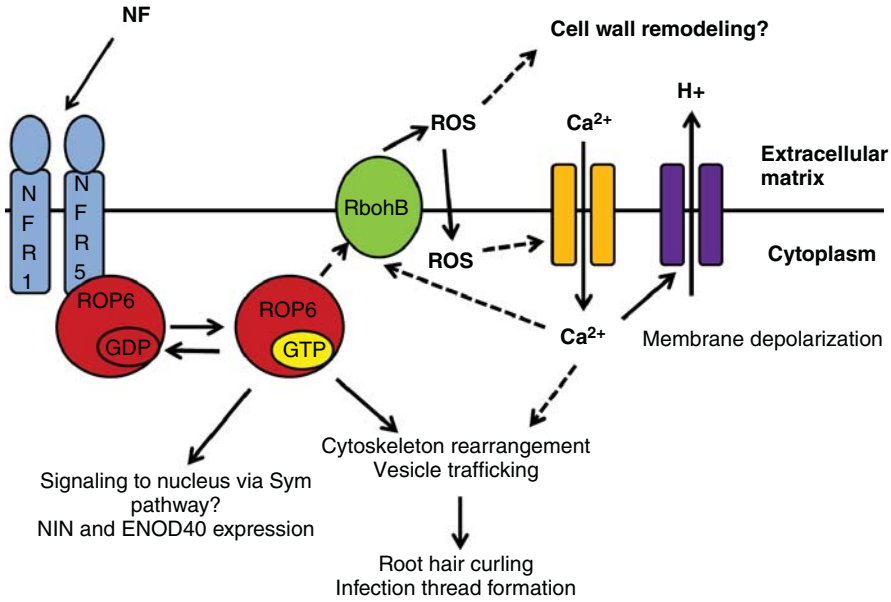

Figure 54.4 Initiation of the NF-induced calcium influx. ROP6 signaling is activated by NF binding to ROP6-interacting partner NFR5. ROP6 activates Rboh activity producing ROS, promoting cell wall remodeling and activating a calcium influx. Calcium ions and ROP GTPases regulate cytoskeleton rearrangement and vesicle trafficking to generate root hair curling around attached rhizobia and regulate infection thread formation. ROP6 also induces *NIN* and *ENOD40* gene expression, perhaps via the Sym pathway. Cycling of ROP GTPases between GDP and GTP bound states by RopGEFs and RopGAPS (not shown) and sequestering in the cytoplasm by RhoGDIs ensure ROP activity can be appropriately localized to drive new membrane formation in the appropriate location and direction.

the ROP GTPases or Rbohs that are involved in bacterial infection are required for the induction of the calcium influx.

In summary, drawing on parallels between rhizobial infection in legumes and polar root hair growth in *A. thaliana* it seems likely that NF induction of the calcium influx is mediated by ROP GTPase signaling (Fig. 54.4). At the root hair tip, perception of NFs by the NF receptors NFR5/NFR1 leads to the activation of ROP6, which could promote Rboh-dependent ROS production. The ROS production may promote cell wall remodeling and/or the activation of the calcium influx and membrane depolarization. In *A. thaliana* ROP GTPases are master regulators of polar growth, so in legumes the calcium influx may be involved in ROP GTPase regulation of cytoskeletal rearrangement and vesicle trafficking leading to root hair curling and infection thread formation.

54.12 CONCLUDING REMARKS

The NF-induced calcium spiking and calcium influx responses are spatially and genetically separable. Mathematical modeling is providing insight as to how calcium spiking can be generated by ion fluxes across the nuclear membranes and detailed studies of CCaMK are gradually unraveling the regulation of this unique protein. However, there are still several major gaps in our understanding of the generation of calcium spikes and how they are decoded to activate nodulation gene expression. Identification of the calcium channel responsible for calcium release from the nuclear lumen would be a major advance and may also provide insight as to how the NF signal is relayed by secondary messengers from the plasma membrane to the nucleus to activate calcium spiking. An outstanding question is whether the calcium spiking signal itself encodes rhizobial or mycorrhizal-specific information, or is a more general Sym signal with downstream Sym pathway signaling modulated by parallel pathways that determines specificity. As CCaMK seems to be at the point of divergence of the two pathways it is likely that understanding how it is regulated will provide further insight into how the specificity is achieved.

What role the NF-induced calcium influx plays in nodulation is still a mystery. Analogy with apical growth of root hairs suggest that the calcium influx may be interacting with spatially and temporally co-incident NF-induced ROS and pH changes to signal alterations in polar growth of the root hair required to generate root hair curling and infection thread formation. Consistent with this several ROP GTPase and NADPH oxidases involved in bacterial infection have been identified, and in the future it will be interesting to find out whether they are required to generate the calcium influx. If any ROP GTPase or NADPH oxidases are required for the activation of the calcium flux it would provide a missing link between the perception of NF and the calcium influx, and strengthen evidence for a role of the calcium influx in bacterial infection.

Chapter 55

Signaling and Communication between Actinorhizal Plants and *Frankia* during the Intracellular Symbiotic Process

Didier Bogusz and Claudine Franche
Institut de Recherche pour le Développement, UMR DIADE, Montpellier, France

55.1 INTRODUCTION

Actinorhizal root nodules are specialized organs that result from the interaction between the gram-positive nitrogen-fixing actinomycete *Frankia* and roots of dicotyledonous plants collectively called actinorhizal plants. Inside the infected cells of the nodule, *Frankia* reduces atmospheric nitrogen to ammonium for the benefit of the host plant that in return provides reduced carbon to the microsymbiont (Chaia et al., 2010; Franche and Bogusz, 2012; Pawlowski and Demchenko, 2012; see also Chapters 42, 43). The actinorhizal symbiosis is found among 25 genera of plants, mainly trees and shrubs, belonging to eight plant families in the orders Fagales (*Betulaceae*, *Casuarinaceae*, and *Myricaceae*), Rosales (*Rosaceae*, *Eleagnaceae*, and *Rhamnaceae*) and Cucurbitales (*Datiscaceae* and *Coriariaceae*). The symbiotic process occurs in conditions of nitrogen deficiency and results in high rates of nitrogen fixation comparable to those found in legumes (Diem and Dommergues, 1990). Besides their contribution to the global biological nitrogen fixation process, some actinorhizal species such as *Alnus glutinosa* and *Casuarina equisetifolia* have great economic value as timber and fuel wood, and also contribute to land reclamation and protection of coastal areas (Diouf et al., 2008; Dawson, 2008; Zhong et al., 2010).

Actinorhizal nodulation can occur by an intercellular penetration mechanism in the orders Rosales and Cucurbitales (Miller and Baker, 1985) or by intracellular penetration via root hair infection in the order Fagales (Callaham et al., 1979). It should be noted that a single *Frankia* strain can exhibit different infection mechanisms, whereas the host plant has the capability for only one mode of infection (Miller and Baker, 1986). First identified in *Eleagnaceae* (Miller and Baker, 1985), the intercellular infection process does not involve the infection of root hairs. Current knowledge on this infection process is described in the chapter dedicated to *Discaria trinervis* (Chapter 43), while this chapter will focus on the molecular mechanisms underlying intracellular infection by *Frankia*.

Four major stages can be distinguished during the intracellular infection process: the presymbiotic stage that involves perception and recognition of specific and still unknown plant and *Frankia* signal molecules, the infection of root hairs by *Frankia* hyphae, the induction and infection of a prenodule resulting from the division of root cortical cells, and the induction and invasion of a nodule primordium initiated from divisions in the root pericycle (Berry and Sunnel, 1990; Wall and Berry, 2008; Santi et al., 2013). The resulting actinorhizal nodule is a coralloid cluster of small lobes; each of them possess a central vascular system and *Frankia* infected cells (fic) in the expanded cortex. Behind the nodule meristem, there is a progression in the stage of infection, with the youngest stages being closest to the apex.

The development of the actinorhizal symbiosis is associated with major changes in *Frankia* (Alloisio et al., 2010; Beauchemin et al., 2012) and plant gene expression (Hocher et al., 2006, 2011; see Chapter 42). Recent detailed cytological analyses in RNAi plants as well as the

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

characterization of promoters from symbiotic genes, have proved valuable in revealing the function of genes involved in the symbiotic process with the actinomycete (Svistoonoff et al., 2010a; Franche and Bogusz, 2012; see Chapter 43). This chapter will report on the recent advances in deciphering the molecular dialog during the intracellular infection process, with an emphasis on the data obtained with the tropical tree *Casuarina glauca* where genetic transformation tools are available (Franche et al., 1997, Smouni et al., 2002), together with transcriptomic resources (Hocher et al., 2011; Tromas et al., 2012).

55.2 THE PRESYMBIOTIC DIALOG

55.2.1 Host-*Frankia* Specificity

Successful actinobacterial symbiosis requires a compatibility between the host plant and its symbiont. Phylogenetic analyses reveal that *Frankiae* form a coherent clade within the actinobacteria, and that strains generally fall into three major groups or clusters (Normand et al., 1996, Benson and Clawson, 2000; Hahn, 2008). Cluster I consists of strains isolated from plants belonging to the order Fagales; they have the most specific host range and are only able to interact with plants belonging to this clade. A subgroup of cluster I infects the family *Casuarinaceae*, and appears to have evolved even higher levels of specificity, as some *Frankia* are only able to nodulate *Casuarina* and *Allocasuarina* in natural conditions. Strains belonging to cluster III have a wider host range and can interact with plants belonging to five families within the two distant plant orders Rosales and Fagales. No strain belonging to cluster II has yet been cultured (see Chapter 43).

The molecular basis for host specifity of interaction between *Frankia* and the plant hosts remains unknown due to the difficulty to develop genetic tools for the actinomycete.

55.2.2 *Frankia* Signals

The initiation of the actinorhizal symbiotic relationship involves a molecular dialog between the plant and its bacterial partner. Bacteria-free filtrates from exponentially growing cultures of *Frankia* contain a factor(s) that induces root hair deformation (RHD) in the host (Fig. 55.1), thus indicating the presence of specific diffusible molecule(s) (see also Chapter 43). The susceptible root zone remains confined to a region of the root just behind the root tip, from the location of young emerging root hairs to the location of mature root hairs.

The chemical structure of *Frankia* factors involved in the symbiotic process remains unknown so far. However, some biochemical properties have been established for the strain ACoN24d nodulating *A. glutinosa*. The RHD factor(s) has a molecular weight of about 5 kDa and, whereas in

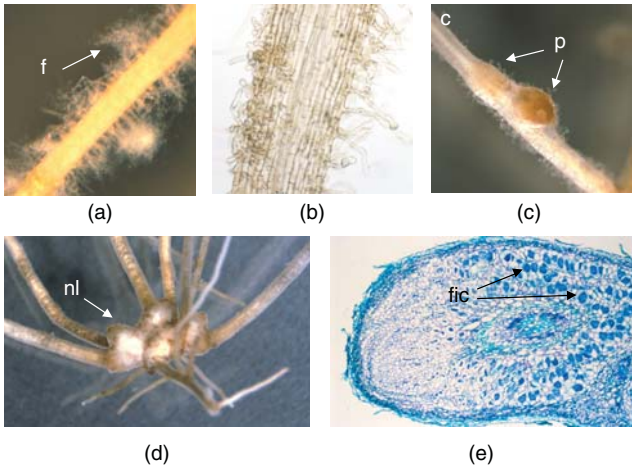

Figure 55.1 Nodulation of *Casuarina glauca* by the actinomycete *Frankia*. (a) Chemoattraction of *Frankia* (f) hyphae observed 24 h after inoculation of *C. glauca* plants deprived of nitrogen. (b) Root hair curling on lateral roots of *C. glauca*. (c) Prenodules (p) resulting from root hair infection. (d) Two-month-old nodule of *C. glauca* exhibiting several nodular lobes (nl). (e) Longitudinal section of an actinorhizal nodular lobe with *Frankia*-infected cells (fic).

legumes Nod factors are amphiphilic and chitinase sensitive (Dénarié et al., 1996), *Frankia* factors from the symbiotic strain ACoN24d of *Alnus* were found to be hydrophilic and resistant to endochitinase and exochitinase from *Streptomyces griseus*. However, *N*-acetyl-glucosamine, the subunit of the Nod factor backbone, has been detected in the *Alnus* root hair deforming fraction, leaving open the existence of a Nod-factor-related *Frankia* compound (Cérémonie et al., 1999). The recent identification of *C. glauca* promoters from symbiotic genes that are specifically induced by the supernatant of *Frankia* CcI3 provides a valuable tool for the future purification of the corresponding molecules (Rhizogenesis, Montpellier, France).

55.2.3 Plant Signals

Plants have recruited phenolics as signal molecules to facilitate interactions with other organisms (Weston and Mathesius, 2013; see Chapters 42, 50). In Legumes, the host plant secretes phenolic compounds, essentially flavonoids, that attract symbiotic rhizobia and further activate the transcription of the *nod* genes that are essential for both host range and nodulation (Wasson et al., 2006; Zhang et al., 2009). Several studies have shown that flavonoid-like compounds also contribute to influence nodulation of actinorhizal plants by *Frankia* (Abdel-Lateif et al., 2012). In *Alnus* sp., nodulation was enhanced by the addition of flavonones (Benoit and Berry, 1997) or flavonols compounds (Hughes et al., 1999). A general reorganization of protein biosynthesis was also observed when three *Frankia* strains, ACN14a, M16467, and Ea112, were treated with seed

phenolic extracts from the actinorhizal plant *Myrica gale* (Bagnarol et al., 2007). Additional studies in *Myricaceae* suggested that the interaction between root flavonoids and actinobacteria was strain specific (Popovici et al., 2010).

In *C. glauca*, several genes involved in the flavonoid pathway have been identified and shown up-regulated following plant inoculation by *Frankia* Cci3 (Auguy et al., 2011; Hocher et al., 2011). Transcript analysis suggested an increase in expression of the chalcone synthase isomerase and the isoflavone reductase genes after inoculation by *Frankia*, whereas isoflavone reductase and flavonoid-3′,5′-hydroxylase transcripts accumulated in mature nodules. To further investigate the role of flavonoids during actinorhizal symbiosis, the chalcone synthase gene *CgCHS1* (Laplaze et al., 1999) was down-regulated in *C. glauca* using an RNA interference approach. This enzyme was chosen as a target as it is the first enzyme of the flavonoid pathway, catalyzing the synthesis of naringenin chalcone and naringenin flavanon, from which diverse flavonoids are derived. Data obtained in RNAi-*CgCHS1* roots showed that knockdown of chalcone synthase expression reduced the level of specific flavonoids and resulted in severely impaired nodulation (see also Chapter 42). A 1-month delay in nodulation was observed in RNAi plants and 12 weeks after inoculation, 56% of control plants were nodulated, while only 30% of *CgCHS1*-silenced roots contained nodules; furthermore, the number of nodules per RNAi-*CgCHS1* plant was reduced by about twofold. Nodule formation was rescued by supplementing the RNAi-*CgCHS1* plants with naringenin, which is an upstream intermediate in flavonoid biosynthesis. These data resulting from the functional analysis of *CgCHS1* in the actinorhizal tree *C. glauca* provide a direct evidence for the role of flavonoids during the infection process by *Frankia*.

55.3 PLANT RESPONSE TO *FRANKIA* IN THE INTRACELLULAR PATHWAY

55.3.1 Root Hair Deformation (RHD) and Infection

The earliest visible event in intracellular infection process is the infection of root hairs by *Frankia* hyphae (Callaham et al., 1979; Prin and Rougier, 1987). Epidermal cells located in the zone of root hair growth constitute a privileged site of interaction with the actinomycete. Within 8–24 h, hyphae are attracted by root hairs and, following their colonization by *Frankia*, root hair branching or curling is observed (Miller and Baker, 1986; Berry and Sunnel, 1990) (Fig. 55.1a,b). Some hyphae captured within a curled root hair partly dissolve the plant cell wall and enter the root hair by invagination of the plant plasma membrane. When the bacterium penetrates the cell wall, it becomes an intracellular endophyte. The host deposits new cell wall material at the site of infection, forming a so-called infection thread that is able to grow toward the base of the trichoblast. Infection threads penetrate further into cortical cells by local degradation of the cell wall.

55.3.2 Prenodule and Nodular Primordium

Besides RHD, some responses are also observed in root cortical cells and pericycle cells (Callaham and Torrey, 1977). Some cell divisions are observed in the root cortex, close to the *Frankia* infected root hair, leading to the development of a small protuberance called the prenodule (Fig. 55.1c; see also Chapter 42). Hyphae encapsulated in the infection threads progress toward the mitotically active zone and then further invade some cells of the prenodule. *Frankia* proliferates in the infected prenodule cells that undergo considerable hypertrophy. When multiple root hair infection occur, several prenodules can be observed on a same root (Fig. 55.1c). The prenodule stage is neither observed during the intercellular actinorhizal infection process nor the intracellular symbiotic process between legumes and rhizobia. Once the prenodule is established, one or more primordium are initiated from the pericycle. As the prenodule stage appears as an obligatory step for nodule organogenesis in the intracellular infection process, it is likely that specific signals are necessary to induce cell divisions in the pericycle cells.

Although the function of the prenodule remains to be elucidated, *in situ* hybridizations experiments together with studies of transcriptional fusions between promoters from symbiotic genes and reporter genes have provided some preliminary information concerning gene expression in the prenodule (Laplaze et al., 2000a). In *C. glauca*, fic were found to express the *nifH* gene encoding the iron protein subunit of the nitrogenase complex, and the symbiotic hemoglobin gene, thus suggesting that *Frankia* hyphae in hypertrophied cells of the prenodule can fix nitrogen. These data are further confirmed by the differentiation of nitrogen-fixing vesicles in the prenodules of *A. glutinosa* (Berry and Sunnel, 1990). So far, actinorhizal promoters conferring gene expression in nodule-infected cells exhibit a similar pattern of expression in prenodule-infected cells. In *Casuarinaceae* plants genetically transformed with a ß-glucuronidase (GUS) gene driven by the promoters from the genes *Cg12* and *CgAUX1*, encoding an infection-associated serine protease (Svistoonoff et al., 2004) and an auxin influx carrier protein (Péret et al., 2007) from *C. glauca*, respectively, GUS activity was observed in both prenodule and nodule cells infected by the actinobacteria. Interestingly, similar data were observed with the promoter from the early symbiotic gene *MtEnod11* from *Medicago truncatula* encoding a putative cell wall

repetitive proline-rich protein (Svistoonoff et al., 2010b), and more recently, with the promoter from *MtDMI2* coding a leucine-rich-repeat receptor kinase (Bersoult et al., 2005) involved in the Nod-factor signaling cascade (Rhizogenesis, IRD Montpellier, France). All these data lead to the hypothesis that the prenodule could be a primitive form of a nitrogen-fixing symbiotic organ. In the future, further transcriptome analyses targeted to the prenodule tissue will help clarify the role of this obligatory developmental step in the actinorhizal infection process.

55.3.3 Actinorhizal Nodule Development

The nodular primordium arise from divisions in pericycle cells opposite to a protoxylem pole and close to the prenodule (Berry and Sunnel, 1990). This nodule primordium will grow and become infected by *Frankia* that advances by cell wall penetration through the prenodule and the nodule protoperiderm, toward the nodule meristem. After penetration into cortical cells, the endophytic hyphae proliferate, leading to the enlargment of the infected cells. When the infected cell matures, the tips of the hyphae eventually differentiate into vesicles that will fix nitrogen (Newcomb and Wood, 1987). The mature actinorhizal nodule consists of multiple lobes, each of which is a modified lateral root with a central vascular bundle (Fig. 55.1d,e).

Within the cortex, infected cells occur in layers surrounded by smaller non-infected cell layers that contain heavy deposits of phenolic compounds. It was believed that the high amounts of phenolics in uninfected cells may represent a defense response to *Frankia* infection and could contribute to restrict the endophyte to certain regions in the cortex, preventing its spread in the vascular tissue, periderm and meristem. However, recent data arising from the histological analysis of the RNAi-*CgCHS1* nodules from *C. glauca* are not in favor of this hypothesis. Although the amount of phenolic compounds was drastically reduced in uninfected cells of the RNAi nodules, fic still occurred in layers surrounded by uninfected cells and the compartmentation of the cortex of the nodule lobe was conserved.

55.4 PLANT GENES EXPRESSED IN *FRANKIA*-INFECTED CELLS

55.4.1 Functional Analysis of Genes from the Common Symbiotic Pathway

The understanding of the molecular mechanisms involved in the actinorhizal symbiosis has benefited from the recent breakthroughs obtained on the model Legumes *Medicago* and *Lotus*. Symbiotic legume mutants unable to form nodules have contributed to the identification of genes controlling early stages of the perception and signal transduction pathway of the Nod factors (Madsen et al., 2010; Oldroyd et al., 2011; see Chapters 59, 63). Their analysis revealed that some of them were also affected in the arbuscular mycorrhizae (AM) symbiosis, thus indicating that the two symbiotic interactions overlap in the early steps of the symbiotic interactions. Among this shared "common SYM pathway," (also known as CSSP; see Chapters 42, 54, 110) the homologs of the symbiotic genes *DMI2/SymRK* and *DMI3*/*CCaMK* from legumes have been characterized in *C. glauca* using an RNAi approach and the spatiotemporal analysis conferred by the promoter region.

In Legumes, the receptor kinase DMI2/SymRK encodes a leucine-rich-repeat receptor kinase that is highly expressed during the infection process by Rhizobium and also required for endomycorrhization (Endre et al., 2002; Stracke et al., 2002). Downregulation of *CgSymRK* resulting from an RNA interference approach revealed that the frequency of nodulated RNAi-*CgSymRK* plants was reduced twofold compared to *C. glauca* control plants. In addition, a range of morphological alterations was observed in the down-regulated *CgSymRK*-nodules (Gherbi et al., 2008; Benabdoun et al., 2011). Additional experiments revealed that CgSymRK was also necessary for the establishment of the symbiosis with the arbuscular mycorrhiza *Glomus intraradices*. The knockdown of *CgSymRK* was seen to strongly affect penetration of the fungal hyphae into the root cortex, thus revealing the key role of CgSymRK in root endosymbioses in *Casuarina*, and the conservation of SymRK function between legumes and actinorhizal plants (Gherbi et al., 2008). Similar results were obtained following the functional analysis of *DtSymRK*, a *SYMRK* sequence isolated from the actinorhizal plant *Datisca glomerata* (Markmann et al., 2008). The most recently targeted gene is *CgCCaMK* that encodes a Calcium and Calmodulin-dependant kinase homolog to the *DMI3*/*CCaMK* gene from legumes (Lévy et al., 2004; Mitra et al., 2004; see Chapter 54). Functional analysis of the RNAi plants also indicate that this gene is necessary for appropriate root infection by *Frankia* and nodule development in *C. glauca*, thus suggesting that the entire common SYM pathway could be conserved in actinorhizal plants (see also Chapters 59, 110).

55.4.2 Other Genes Expressed during the Infection Process

cg12 was one of the first actinorhizal symbiotic gene isolated from *C. glauca* (Laplaze et al., 2000b). It encodes a subtilisin-like serine protease (subtilases). Subtilases are a super-family of proteases and are thought to play a role in several different aspects of plant development, response to pathogens and lateral root development (Schaller et al.,

2012). The regulation of *cg12* expression and its possible role during actinorhizal nodule infection was investigated following the analysis of transgenic *cg12-gus* and *cg12-gfp* transgenic plants of *C. glauca*. Expression of the reporter genes was observed when *Frankia* hyphae invaded deformed root hairs and in root prenodule and nodule cortical cells containing growing infection threads (Svistoonoff et al., 2004). The correlation of *cg12* expression with plant cell invasion lead to suggest that CG12 could participate in cell wall weakening during *Frankia* infection; it might also be involved in the maturation of a polypeptide as part of a signaling cascade in response to infection.

A clone for type I metallothionein (MT) (*cgMT1*) was then isolated from a *C. glauca* nodule cDNA library (Laplaze et al., 2002). MTs are defined as low molecular weight cysteine-rich proteins that can bind heavy metals and may play a role in their intracellular sequestration and transportation. They are also involved in response to stresses like wounding, pathogen infection and leaf senescence and function as antioxidants (Hassinen et al., 2011). In transgenic *Casuarinaceae* plants, the *cgMT1* promoter was shown to be primarily active in large fic of the nodule nitrogen-fixing zone, roots and the oldest parts of the shoots. Induction experiments revealed that the promoter P*cgMT1* responded to wounding, oxidative stress and pathogen infection, thus suggesting that *cgMT1* could be involved in antioxidant defence against reactive oxygen species induced during the symbiotic process (Obertello et al., 2007).

In 2007, the auxin influx carrier *CgAUX1* was studied. Using the *GUS* gene driven by the *CgAUX1* promoter, it was clearly shown that auxin plays an important role during plant cell infection in actinorhizal symbiosis (Péret et al., 2007; see also Chapter 47). *CgAUX1-GUS* was found to be strongly expressed both during root hair infection and cortical cell invasion by *Frankia*. It was also reported that *CgAUX1-GUS* was highly expressed in the root primordium, whereas no reporter gene activity was observed in the nodule primordium. This result further indicates that, although the actinorhizal nodule is comparable with a symbiotic lateral root, the molecular mechanisms involved in primordia initiation in lateral roots may differ from those in actinorhizal nodules.

55.5 CONCLUSIONS

Progress in the knowledge of the actinorhizal symbiosis has been hampered by the difficulties to develop functional analysis of candidate symbiotic genes in *Frankia*, together with the lack of green fluorescent protein (GFP) tagged *Frankia* strains to easily follow the infection process in wildtype and RNAi actinorhizal plants. The complete genome sequences that are currently available for various *Frankia* strains, combined with the data arising from transcriptomic and proteomic analyses, provide a vast amount of information (Alloisio et al., 2007, 2010; Normand et al., 2007a, 2007b; Benson et al., 2011). Genes that are induced or repressed during the different stages of the symbiotic process can now be identified, while new attempts to develop targeted mutagenesis in *Frankia* are still in progress.

The sucessful functional analysis of symbiotic genes in the actinorhizal plants *C. glauca* and *D. glomerata* has revealed a common symbiotic signaling pathway in actinorhizal, legume and arbuscular mycorrhization (Gherbi et al., 2008, Markmann et al., 2008). There are still indeed many mechanisms unknown in the plant–*Frankia* interactions. In the next years, challenging aspects of actinorhizal research will be the identification of the signaling molecules involved in the control of host specificity, infection and nodulation, as well as the mechanisms by which these factors are perceived and transduced in the host plant. The understanding of the signals and genes that enable an actinorhizal plant to enter into symbiotic association with *Frankia* may help in the future to extend the ability to fix nitrogen outside the legume and actinorhizal plant families (see Chapter 108).

ACKNOWLEDGMENTS

Research conducted in the Rhizogenesis laboratory on actinorhizal plants was supported by the Institut de Recherche pour le Développement (IRD), Montpellier University 2, the Agence Nationale de la Recherche (ANR) Blanc project NewNod (ANR-06-BLAN-0095) and SESAM (BLAN-1708-01), the ECOS-Sud and the PHC-IMHOTEP. We thank Jocelyne Bonneau (IRD) for help with the manuscript.

Infection and Nodule Ontogeny

Chapter 56

The Role of Hormones in Rhizobial Infection

Andrew Breakspear, Chengwu Liu, Donna R. Cousins, Sonali Roy, Dian Guan, and Jeremy D. Murray

John Innes Centre, Norwich Research Park, Norwich, UK

56.1 INTRODUCTION

Nodulation involves the local perception of a rhizobial signaling molecule called Nod factor (NF, see Chapter 51). These lipochitooligosaccharides induce two principal developmental outcomes, infection thread formation by rhizobia and nodule organogenesis, which depend on changes in the production, transport, and sensing of plant hormones (reviewed in (Oldroyd et al., 2011; Guinel and Geil, 2002)). Hormones are defined as regulatory substances produced in a cell and transported externally to elicit responses in specific cells or tissues. In plants this includes auxin, gibberellic acid (GA), jasmonic acid (JA) and, more recently, strigolactones (SLs). Nodulation is a multi-stage developmental process, and plant hormones are involved at every stage, from influencing the initial NF production by rhizobia to the formation of nodules. During nodulation, rhizobia typically attach near the tip of a growing root hair, which curls around the attached rhizobia to entrap them, creating the so-called infection pocket. The infection thread initiates from this infection pocket as a narrow tube around 1 μM in diameter. The infection thread then grows through the root hair cell as it becomes colonized by the rhizobia. The infection thread subsequently grows into the subtended outer cortical cells and finally into the cells of the growing nodule primordium, where it branches and eventually releases bacteria enclosed by the host membrane into nodule cells where they fix nitrogen. Although considerable effort has been directed at determining the role of hormones in nodulation, much of this work has been focused on nodule organogenesis, and, consequently, relatively little is known about hormonal involvement in rhizobial infection. Here, we review the role of SLs, JA, auxin, and GA in this process and consider their potential interactions.

56.2 STRIGOLACTONES ARE PHYTOHORMONES AND PLANT-MICROBE SIGNALS

SLs are carotenoid-derived terpenoids that act as endogenous plant hormones and as secreted signals to other organisms in the rhizosphere. Originally, it was discovered as a seed germination stimulant of the parasitic plant witchweed (Cook et al., 1966), and later as a component of root exudate that can induce hyphal branching in arbuscular mycorrhizal fungi (Akiyama et al., 2005), a process required for normal colonization of the host (Gomez-Roldan et al., 2008). SLs were shown to inhibit shoot branching and have been classified as phytohormones in 2008 (Gomez-Roldan et al., 2008; Umehara et al., 2008). Since then, SLs have been associated with a growing array of endogenous functions, influencing both shoot and root architecture (Ruyter-Spira et al., 2013). While the role of SLs in the arbuscular mycorrhizal symbiosis continues to expand (Yoshida et al., 2012), a new role in the legume-rhizobia symbiosis is beginning to emerge (Soto et al., 2010; Foo and Davies, 2011; et al., 2013).

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

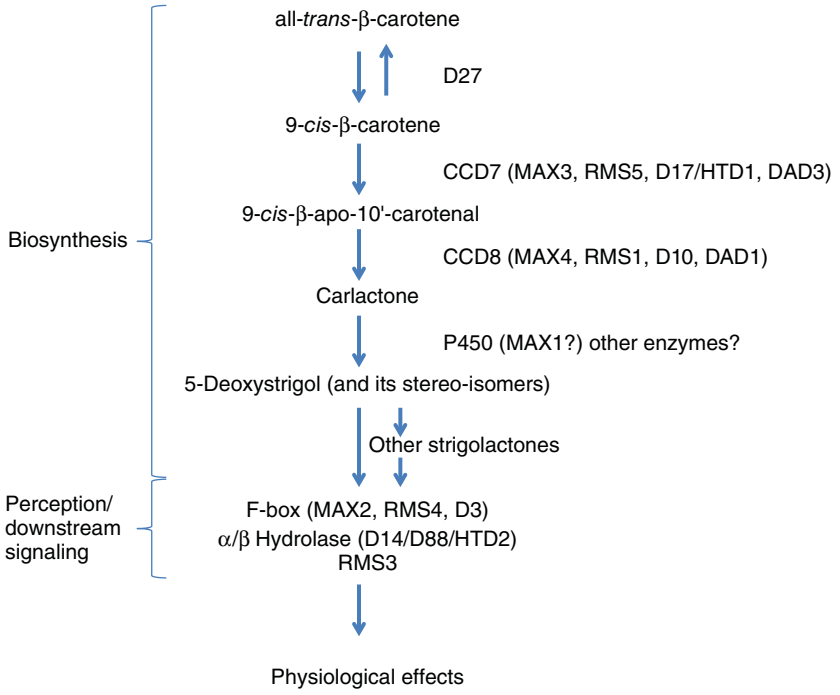

Figure 56.1 Strigolactone biosynthesis and downstream signaling. (*Source:* Figure adapted from (Ruyter-Spira et al., 2013.))

Functional diversity is accompanied by an expanding catalog of SL compounds, which now includes at least 15 members (Ruyter-Spira et al., 2013). SLs are synthesized from β-carotene using at least four biosynthetic steps, as shown in Figure 56.1 (Alder et al., 2012).

The sequential action of a β-carotene isomerase (DWARF27; D27) and two carotenoid cleavage dioxygenases (CCD7 and CCD8) produce a compound called carlactone that is able to stimulate seed germination in parasitic plants (Alder *et al*., 2012). At least one further step, perhaps involving a cytochrome P450 (MAX1) (Booker et al., 2005), is required to produce 5-deoxystrigol, an SL and likely precursor of other SLs (Ruyter-Spira et al., 2013). Additionally, several other genes have been implicated in SL perception or signaling (Fig. 56.1) including an F-box protein (Johnson et al., 2006; Stirnberg et al., 2007; Yoshida et al., 2012) and an α/β hydrolase (Arite et al., 2009; Hamiaux et al., 2012; Waters et al., 2012).

Much of our knowledge of SL biosynthesis and downstream signaling comes from mutants that display increased branching of the shoot. Cloning such mutants in rice (*dwarf*, *d*); pea (*ramosus*, *rms*); petunia (*decreased apical dominance*, *dad*) and *Arabidopsis* (*more axillary growth*, *max*) have revealed components of both SL biosynthesis and perception (Table 56.1). Reciprocal BLAST searches of the *Medicago truncatula* genome have revealed homologs of all previously characterized SL biosynthetic and perception/signaling genes (Liu et al., 2011; Challis et al., 2013), (Table 56.1).

56.3 STRIGOLACTONES IN NODULATION

The first evidence of a role for SLs in nodulation came from alfalfa (Soto et al., 2010). Treatment of *Sinorhizobium meliloti* inoculated plants with the synthetic SL GR24, stimulated a 30–40% increase in nodule number compared to untreated controls (Soto et al., 2010). In pea, the SL deficient *rms1* (orthologous to *ccd8*) displayed a significant reduction (approximately 40%) in nodule number, which could be rescued by GR24 treatment (Foo and Davies, 2011). Although the phenotype was reported for only a single allele of *rms1*, a significant decrease in nodule number was observed for another SL biosynthesis mutant, *rms5* (orthologous to *ccd7*) (Foo et al., 2013). SLs have also been shown to be required for normal numbers of nodules in *Lotus japonicus* where significantly fewer nodules were observed on a *Mesorhizobium loti* inoculated *ccd7*-silenced transgenic line (Liu et al., 2013). In contrast, nodule number was significantly increased (although nodules were significantly smaller than those on water-treated (WT) plants) in a pea SL-insensitive F-box (*rms4*) mutant (Foo et al., 2013). Notably, SL-insensitive mutants *d3* and *d14* have been shown to have increased SL production (Umehara et al., 2008; Arite et al., 2009), so one possible explanation is that the increased nodulation in the mutant is a consequence of higher SL levels. This appears consistent with a role of SLs in signaling to rhizobia in the rhizosphere, and suggests that endogenous perception of SLs is not required for infection

Table 56.1 Strigolactone genes and their *M. truncatula* homologs

Gene	Description	Characterized genes (Rice, Pea, Petunia, *Arabidopsis*)	*M. truncatula* homolog(s)*
D27	Carotene isomerase	*D27*, –, –, *AtD27*	Medtr1g471050†
CCD7	Carotenoid cleavage dioxygenase 7	*D17*, *RMS5*, *DAD3*, *MAX3*	Medtr7g045370
CCD8	Carotenoid cleavage dioxygenase 8	*D10*, *RMS1*, *DAD1*, *MAX4*	Medtr3g109610
MAX1	Cytochrome P450	–, –, –, *MAX1*	Medtr3g104560 Medtr1g015860
MAX2	F-box	*D3*, *RMS4*, –, *MAX2*	Medtr4g080020
D14	α-β hydrolase	*D14*, –, *DAD2*, *AtD14*	Medtr1g018320

*Established *M. truncatula* homolog or reciprocal BLASTP hit to Mt4.0v1 (http://blast.jcvi.org/Medicago-Blast/index.cgi) using characterized *Arabidopsis* protein sequence as the query.

†Described in Liu *et al*., 2011.

and initiation of nodule formation. However, treatment of *S. meliloti* with GR24 failed to induce a change in growth rate or induction of *nodC* (Soto et al., 2010).

Interestingly, the rice *d3* mutant shows strongly reduced mycorrhizal colonization while in *d14* mutants mycorrhizal colonization is increased (Yoshida et al., 2012). It seems clear from this that although D3 and D14 may be required for SL responses, they may also have additional roles. Along this vein, the D3 ortholog RMS4 has also been implicated in karrikin signaling (Nelson et al., 2011).

It is now clear that SLs influence nodulation. Whether the phytohormone acts as a signal to rhizobia, functions endogenously in the plant, or a combination of both, remains to be determined. If acting endogenously, it will be important to understand how SLs are perceived and how the downstream signaling pathway(s) influences nodulation. It will also be important to explore the potential crosstalk between SL signaling and other plant hormones. SLs have been shown to interact with auxin, ethylene, abscisic acid (ABA) and GA (reviewed in (Foo and Reid, 2012)) all of which have been associated with nodulation. Interestingly, their interaction with auxin and ethylene has been reported in the regulation of root hair elongation in *Arabidopsis* (Kapulnik et al., 2011). The positive influence of SLs on root hair growth was found to be dependent on MAX2 and to be mediated through ethylene. However, because NF-induced root hair growth is ethylene independent (Heidstra et al., 1997), and ethylene has strong repressive effects on infection and nodulation (reviewed in (Murray 2011)), it seems extremely unlikely that SLs are involved in the root hair growth that occurs during rhizobial infection. On the other hand, it has been shown that GR24 increases the GA/ABA ratio in *Arabidopsis* and witchweed seeds (Toh et al., 2012). Because GA has a positive role in nodulation (discussed below) and ABA inhibits nodulation (Suzuki et al., 2004) this seems a promising lead to understand the role of SLs in nodulation.

In summary, it is still uncertain whether SLs serve as an external or internal signal or both to enhance nodulation. SL biosynthetic and signaling mutants in model legume species are needed to help elucidate the role of this hormone.

56.4 JASMONIC ACID ACTS AS A PLANT HORMONE AND A LONG DISTANCE SIGNAL FOR RHIZOBIA

JA is a plant hormone that is widely known for its roles in plant defense to both necrotrophic pathogens and herbivores. JA is synthesized through what is commonly referred to as the octadecanoid pathway due to its 18 carbon precursor, linolenic acid. It is also implicated in other processes such as abiotic stress responses, pollen development, vegetative growth and senescence. Studies have shown that JA also has an important function in legume nodulation. It has a role in the dialogue that initially occurs between rhizobia and the host plant, and may also have a role in nodule development in the context of autoregulation of nodulation (AON).

56.5 A ROLE IN SIGNALING TO RHIZOBIA

The most recognized and studied plant-rhizobia signaling compounds are flavonoids that legumes exude from the root into the rhizosphere stimulating the expression of *nodD* genes in soil-borne rhizobia (see Chapter 50). This results in the expression of other *nod* genes and subsequently to NF production (Mulligan and Long, 1985). However, perhaps less well recognized is that JA and methyl jasmonate (MeJA) can also induce *nod* genes in *Rhizobium leguminosarum* (Rosas et al., 1998). Genistein is the main flavonoid secreted by soybean roots which is a powerful inducer of *nod* genes in *Bradyrhizobium japonicum* (Kosslak et al., 1987). However, JA and MeJA are more potent *nod* gene inducers than genistein on soybean roots, and the NFs activated by them are just as effective. This was measured using high-performance

liquid chromatography to determine the lipochitooligosaccharide (LCO) profiles of bacterial cultures after treatment. Also, the cumulative effects of JA/MeJA and genistein produce more LCOs than either alone (Mabood et al., 2006). Remarkably, when pre-inoculating *B. japonicum* with JA or MeJA, it was found that soybean plants produce an increased number of nodules in a concentration-dependent manner (Mabood and Smith, 2005).

In addition to its role in the induction of *nod* gene expression, JA appears to also have a role in plant flavonoid biosynthesis. The *M. truncatula* flavone synthase gene (*MtFNSII*) is induced both by *S. meliloti* and exogenous JA application (Zhang et al., 2007). Notably, flavonoids also serve as signals to another important root symbiont, arbuscular mycorrhizal fungi (Nair et al., 1991; Steinkellner et al., 2007). It has been suggested that the NF response to JA may reflect a more ancient form of the symbiosis where rhizobia entered via cracks in legume roots (Sun et al., 2006). The close relationship of rhizobia to *Agrobacterium* (Sawada et al., 2003), which are attracted to plant wounds, adds weight to this idea.

56.6 JA INHIBITS NF-SIGNALING

Whilst JA has a positive role in the signal exchange between rhizobia and the plant host, it appears to actively inhibit the plant's ability to positively respond to the NFs. Calcium spiking in and around the nucleus of rhizobia infected cells, in response to NF, is a crucial step in early signaling events during nodulation (see Chapter 54). JA was found to affect the maintenance of spiking, the spike period, and the responsiveness to NF (Sun et al., 2006). Application of 100 μM JA after the start of NF-induced calcium spiking resulted in the rapid suppression of spiking which was subsequently recovered when the JA source was removed and replaced with more NF. Lower concentrations of JA (10–50 μM) did not block calcium spiking, but increased the period between the spikes. From this observation that JA can inhibit NF signaling, we would predict a corresponding reduction of expression of nodulation genes. Indeed, JA has been shown to inhibit the expression of the early marker genes of NF response, *RIP1* and *ENOD11* in plants inoculated with *S. meliloti* (Miwa et al., 2006; Sun et al., 2006; Zhang et al., 2012). Exogenous MeJA also negatively affects the early stages of rhizobial infection. At concentrations of 10^{-4} M, it greatly reduces root hair curling and infection thread formation. The gene encoding the nodulation transcription factor (TF) *Nodule Inception* (*NIN*) has reduced expression at this concentration, suggesting that the effects of MeJA are upstream of *NIN*, which is consistent with a defect in early NF-signaling. Indeed, since mutants with deficient calcium spiking still have some root hair responses, a role for JA at the level of NF perception is indicated.

Evidence suggests that some of the effects of JA on nodulation may be through the production of ethylene which is a strong inhibitor of infection and nodulation (the effects of ethylene on nodulation are reviewed by (Murray, 2011)). A concentration of 1 μM JA was found to strongly inhibit nodulation, but this reduction did not occur when the JA was applied in combination with the ethylene biosynthesis inhibitor L-α-(2-aminoethoxyvinyl)-glycine (AVG) or if the ethylene insensitive *sickle* (*skl*) mutant was used. However, a higher concentration (10 μM) of JA inhibited nodulation independent of ethylene. The higher concentration of JA was also found to reduce the percentage of cells that showed calcium spiking in response to NF (Sun et al., 2006).

56.7 JA HAS A ROLE IN THE AUTOREGULATION OF NODULATION

Nodule development places high demands on plant metabolism, making the control of nodulation events crucial for plant success. The plant host does this through the process of AON (Ferguson et al., 2010). Signals from the root travel to the shoot after rhizobial inoculation (Delves et al., 1986). This is perceived by a leucine rich repeat receptor-like kinase called Nodule Autoregulation Receptor Kinase (NARK) in soybean (Krusell et al., 2002), Hypernodulation Aberrant Root Formation 1 (HAR1) in *L. japonicus* (Nishimura et al., 2002), and Super Numeric Nodules (SUNN) in *M. truncatula* (Schnabel et al., 2005). The phenotypes of *Gmnark*, *Ljhar1* and *Mtsunn* mutants feature hypernodulation.

There are many putative JA-biosynthesis/responsive genes that are regulated by *GmNARK*. This includes an allene oxide cyclase, a lipoxygenase and an allene oxide synthase (Kinkema and Gresshoff, 2008). Although *Gmnark* mutants have high levels of endogenous JA (Seo et al., 2007) and show an increase in JA biosynthesis/responsive genes, when inoculated with rhizobia, the expression of these genes is reduced (Kinkema and Gresshoff, 2008). Also, treatment with a chemical JA inhibitor (n-propyl gallate) generates a significant reduction in nodulation in *Gmnark* mutants, but not in wildtype plants. These results indicate a positive role for JA in nodulation (Kinkema and Gresshoff, 2008). Contrasting results are provided by work using *L. japonicus* where exogenous JA inhibited nodulation and the *Ljhar1* mutant showed enhanced sensitivity compared to WT (Nakagawa and Kawaguchi, 2006).

Does JA promote or suppress nodulation? It is possible that exogenous JA application has a strong negative impact on NF signaling as discussed above, while endogenous production of JA does not, possibly due to distribution of the active hormone.

Evidence has emerged recently that further indicates a positive role for JA in nodulation. The gene *PhyB* is

important for detecting low red:far-red (R/FR) light, a condition generally unfavorable for nodulation. In *phyB* mutants, or in WT plants grown in these suboptimal conditions, nodule numbers are strongly reduced (Suzuki et al., 2011). Both were also accompanied by a decrease in JA-responsive genes. When treated with JA, all the plants showed increases in both infection thread formation and nodule formation.

Overall, work in this area suggests that JA promotes nodulation. Rhizosphere signaling to rhizobia may be directly affected by JA, or by JA-induced increases in flavonoids. Alternatively, the induction of flavonoids by JA may serve to alter polar auxin transport (PAT), which may in turn influence infection. In addition, high levels of JA may have local negative effects on nodulation signaling. Host mutants for JA perception will help clarify whether JA acts mainly through its effects on rhizobia or if it also affects the host plant directly.

56.8 AUXIN'S ROLE IN NODULATION

Went (1926) originally showed that asymmetric application of the plant hormone auxin on decapitated Avena coleoptile causes it to bend in proportion to the amount of auxin applied (Went, 1926). Using this principle, in 1936, Thimann showed that sections of young pea nodules, both, from the base and the meristematic apex, cause significant bending of the avena coleoptile. As the activity was not only ascribed to the nodule meristem but to the entire nodule cortex, he hypothesized that auxin in nodules was perhaps related to tissue infected with rhizobia (Thimann, 1936). Auxin was thus established to play a role in symbiosis (see also Chapter 47). However, it was not until 1989 that Hirsch et al. showed that nodule-like structures could be initiated in the absence of bacterial symbionts (Hirsch et al., 1989). Further evidence that changes in auxin transport were important for nodulation was provided by studies using the promoter of soybean *GH3*, an auxin responsive gene, fused to a β-glucuronidase (*GUS*) reporter. Using this tool, Mathesius et al. noted a striking but transient arrest in transport at the site of infection as early as 24 h post infection followed by a strong increase at the same position where the nodule later initiated (Mathesius et al., 1998; see Chapter 47). Remarkably, purified NFs were shown to disrupt auxin transport in a similar manner to naphthylphthalamic acid (NPA) (Boot et al., 1999; Pacios-Bras et al., 2003).

Directional or "PAT" refers to the cell to cell movement of auxin mediated by members of the AUX-LAX family of influx carriers and efflux transporters like the PIN-formed (PIN), P-glycoprotein (PGP) family proteins (Friml, 2003). The PGPs are members of the B subfamily of the ABC transporters. To date, four members of the family have been shown to transport auxin in *Arabidopsis* (Noh et al., 2001; Noh et al., 2003; Geisler et al., 2005; Terasaka et al., 2005; Kamimoto et al., 2012). In *M. truncatula*, there are ten *MtPIN* genes, five *AUX-LAX* genes (Schnabel and Frugoli, 2004) and based on the latest release of the *Medicago* genome Mt3.5, we have found at least 35 genes encoding full ABC subfamily B type transporters.

Auxin acts as a developmental trigger primarily by creating local cellular gradients in the existing auxin stream using this PAT machinery. Both in *Medicago* and *Lotus*, within the first 50 h post infection the soybean auxin marker *GH3* expression accumulates at the site of inoculation (Mathesius et al., 1998; Pacios-Bras et al., 2003; see Chapter 47). Upon infection, both the stably transformed *GH3* marker and the synthetic auxin marker DR5 in *Medicago* hairy roots (Huo et al., 2006) show an arrest in auxin transport at the inoculation site. In determinate nodules of stably transformed *DR5*:*GFP* (green fluorescence protein) lines of *Lotus*, 72 h post infection, marker activity is observed in a few cells just below the infected root hair cell. As nodule development progresses, the actively dividing cortical cells of the nodule maintain this *DR5* expression until the rhizobia enter the cortex (Suzaki et al., 2012). By 6 days post infection, *DR5* marker expression is restricted to the outer cortex of the nodule (Takanashi et al., 2011). The authors suggest that as the DR5 expression pattern seems to mimic meristem activity within the nodule, restriction of the marker expression to the periphery of a determinate nodule occurs because the parenchymatic cells in this region retain meristematic activity. In *Medicago*, DR5 expression in mature nodules is especially strong in the vascular bundles (Guan et al., 2013).

Plant flavonoids act as natural auxin transport inhibitors (ATIs) by competing with NPA binding sites (Jacobs and Rubery, 1988) and are also referred to as natural ATIs. Interestingly, a screen for NPA binding proteins, a synthetic ATI, identified members of the ABCB sub-family B type auxin efflux transporters (Noh et al., 2001; Murphy et al., 2002). Since the inhibition of auxin transport by NPA was shown to initiate nodule like organs (Hirsch et al., 1989), it follows that in the absence of endogenous ATIs, nodule number should be affected. Wasson et al. showed that in *M. truncatula*, by silencing the enzyme chalcone synthase which catalyses the first step of the flavonoid biosynthesis pathway, nodulation can be eliminated (Wasson et al., 2006). Conversely, in the hyper-nodulating mutant of *L. japonicus har1*, a stronger *DR5* expression was associated with a wider cortical area of expression and excessive cell division in comparison to the wild type (Suzaki et al., 2012). Auxin can thus be conclusively ascribed to have a positive role in nodule organogenesis. Moreover, observations that in the *M. truncatula* hypernodulating mutants *sickle* and *sunn*, auxin transport is enhanced (Prayitno et al., 2006; van Noorden et al., 2006) points at a specific role for auxin transport in nodule organogenesis.

56.9 AUXIN AND RHIZOBIAL INFECTION

Over the past few years, growing evidence seems to point at a direct relation between rhizobia containing infected cells and auxin activity. Most of the research so far has focused on the involvement of auxin transport in nodule organogenesis rather than its role in infection (Mathesius, 2008; see Chapter 47). Interestingly, transcripts of *LjABCB1*, a *L. japonicus* homolog of the *Arabidopsis ABCB4* gene, were found to be nodule-specific. The promoter *GUS* fusion further showed that its expression was limited to the uninfected cells of the nodule (Takanashi et al., 2011). A chloride channel (CLC) yeast mutant (*gef1*) expressing *LjABCB1* accumulated less indole-3-acetic acid (IAA) than a control strain transformed with the empty vector control, suggesting that LjABCB1 functions as an auxin exporter. In another model symbiosis – between the actinomycete Frankia and the actinorhizal plant *Casuarina glauca*, the gene encoding the *Casuarina* homolog of the *Arabidopsis AUX1* permease *CgAux1* was found to be expressed only in infected cells of the nodule (Peret et al., 2007). Moreover, they showed that *CgAUX1* is specifically increased in infected root hairs. Using antibodies it was further shown that auxin accumulates in the infected cells of the nodule (Perrine-Walker et al., 2010). What role might auxin play in infected cells? Auxin has a well-established role in cell wall expansion/loosening and it can be expected that it may be important for the growth of the giant cells of the nodule, and possibly the redirection of root hair growth that occurs during actinorhizal infection. Although a general expression pattern of members of the *MtLAX* family was studied by *in situ* hybridization in *Medicago* (de Billy et al., 2001), it is not clear whether infection by rhizobia is similarly associated with *AUX1* expression, and studies in model legumes would provide insight into whether this feature is evolutionarily conserved.

56.10 THE ROLE OF GIBBERELLINS IN NODULATION

Gibberellins or GAs are very important plant hormones that are involved in many plant developmental processes. The GA signaling pathway (Fig. 56.2) includes perception of bioactive GA, the interaction of the GA receptor with DELLA proteins and the degradation of DELLAs leading to GA responses (Daviere and Archard, 2013). In the current model GA acts as an "inhibitor of an inhibitor," where GA derepresses DELLA proteins, which are central repressors of GA-dependent process (Harberd et al., 2009).

The function of GA in nodulation has been studied in pea (*Pisum sativum*), *L. japonicus* and *Sesbania rostrata* by using exogenous application of bioactive GA and GA biosynthesis inhibitors, examination of the expression pattern of GA-related genes, and different mutants involved in either GA biosynthesis or signaling.

GA plays a negative role during rhizobial infection and nodule formation in *L. japonicus,* which forms determinate nodules (Maekawa et al., 2009). Both the number of infection threads and the number of nodules are reduced by exogenous application of bioactive GA_3 at concentrations between 10^{-9} and 10^{-6} M. Spontaneous nodule formation in hairy root plants carrying gain-of-function of *LjCCaMK* (see Chapter 54) is also inhibited by application of GA_3. In plants overexpressing a gain-of-function allele of *LjSLY1*, which results in an increase in GA signaling, the number of nodules is reduced. It was also shown that application of GA repressed both the NF-induced and cytokinin-induced expression of *Nodulation Signaling Pathway 2* (*NSP2*) and *NIN* TFs

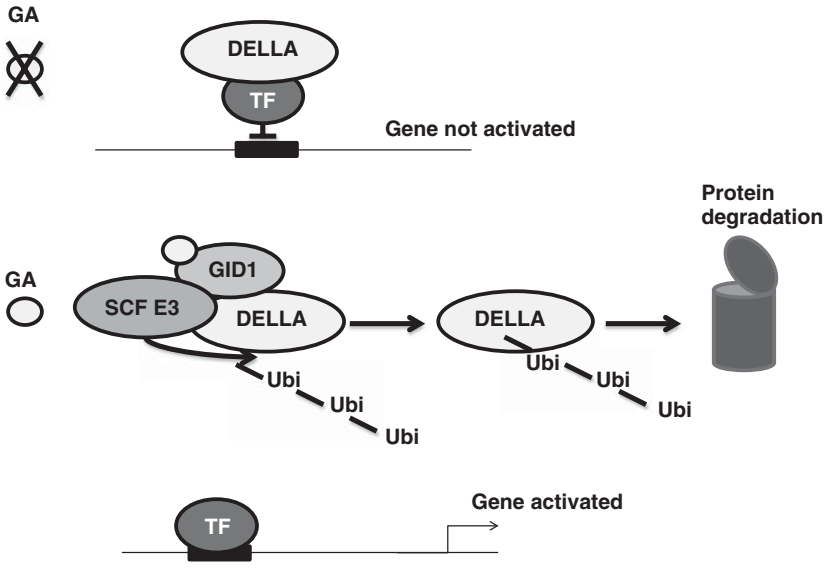

Figure 56.2 GA acts through its receptor to regulate gene expression. In the absence of GA, DELLA proteins interact with TFs (transcription factors), interfering TFs interaction with genes, and this inhibits TFs to activate genes expression. In the presence of GA, GID1 (GA receptor) binds GA, this interaction promotes GID1 interaction with DELLA proteins. The GA-GID1-DELLA complex formation stimulates substrate recognition by the SCF E3 ubiquitin ligase. This leads to DELLA proteins ubiquitination and protein degradation in the proteasome. GA-GID1-DELLA protein complex formation releases TFs which bind DNA and activate gene expression.

(Maekawa et al., 2009). It was shown that the *la cry-s* double mutant of pea exhibited a constitutive GA response due to a lack of repression by the DELLA proteins. Fewer nodules were found in the *la cry-s* mutant, suggesting that GA also inhibits nodulation in the indeterminate nodulators (Ferguson et al., 2011).

In contrast, Kawaguchi et al. found that exogenous application of GA_3 at a concentration of 10^{-7} to 10^{-4} M to *L. japonicus* could induce nodule-like structures, which arise from pericycle cell divisions (Kawaguchi et al., 1996). Similarly, exogenous application of GA_3 at concentrations between 10^{-9} and 10^{-6} to pea promotes nodule formation (Ferguson et al., 2005). Furthermore, in *L. japonicus*, enhanced GA signaling by overexpression of a gain-of-function allele of *LjSLY1* causes the formation of small nodules (Maekawa et al., 2009) and nodules from the pea GA deficient mutant *na* are aberrant and have poorly developed nodule meristems (Ferguson et al., 2011). Together these findings suggest a positive role for GA in nodulation which is consistent with its role in cell expansion, and that experiments using externally supplied GA need to be interpreted with caution. Future research directed at determining the location and timing of GA biosynthesis in nodulation, as well as additional genetic studies, are needed to better understand the role of this phytohormone.

56.11 GA IS NEEDED FOR NODULATION INVOLVING CRACK ENTRY

The *S. rostrata-Azorhizobium caulinodans* symbiosis presents an interesting case. Fernández-López et al. showed that this semi-aquatic legume can form both determinate and indeterminate nodules, depending on the conditions (Fernández-López et al., 1998). In aerated conditions *Sesbania* forms nodules by root hair curling, like most legumes. In this case indeterminate nodules are formed. In these conditions the application of GA_3 at 10^{-5} M dramatically reduced nodule number (Lievens et al., 2005), which is consistent with GA's negative role in nodulation of *L. japonicus* and pea. However, in hydroponic conditions where rhizobia invade via crack entry at lateral root bases, GA plays an opposite role. Both the NF-dependent expression pattern of a GA biosynthesis gene and pharmacological treatment with a GA biosynthesis inhibitor suggest that GA is important for infection pocket and infection thread formation; hence, the nodule primordium development during lateral root base nodulation in *S. rostrata* (Lievens et al., 2005). Interestingly, crack entry nodulation is dependent on ethylene, which in *Arabidopsis* appears to stabilize DELLA proteins and thereby antagonize GA-mediated growth (Achard et al., 2003). It seems possible then, that *Sesbania* has evolved ethylene independent GA-responses in context of waterlogged nodulation.

Such crosstalk between GA and ethylene, and possibly other plant hormones adds complexity to the investigation of GA's role during nodulation. For example, the pea *na* mutant forms fewer nodules than wild type (Ferguson et al., 2005). But later it was found that this GA deficient mutant accumulated more ethylene, which inhibits nodule formation in *na* (Ferguson et al., 2011).

What roles might GA play in nodulation? Given GA's role in cell expansion, it seems plausible that it may be involved in both infection and nodule development. During infection, root hairs expand in response to rhizobial NFs, and, in the presence of rhizobia, this leads to the development of root hair curls. The effects of GA on cell expansion in the root are dependent on auxin (Fu and Harberd, 2003), so a scenario in which these two hormones are elevated (possibly through the actions of SLs and flavonoids) and work together to facilitate root hair curling and/or infection thread growth seems plausible (Fig. 56.3).

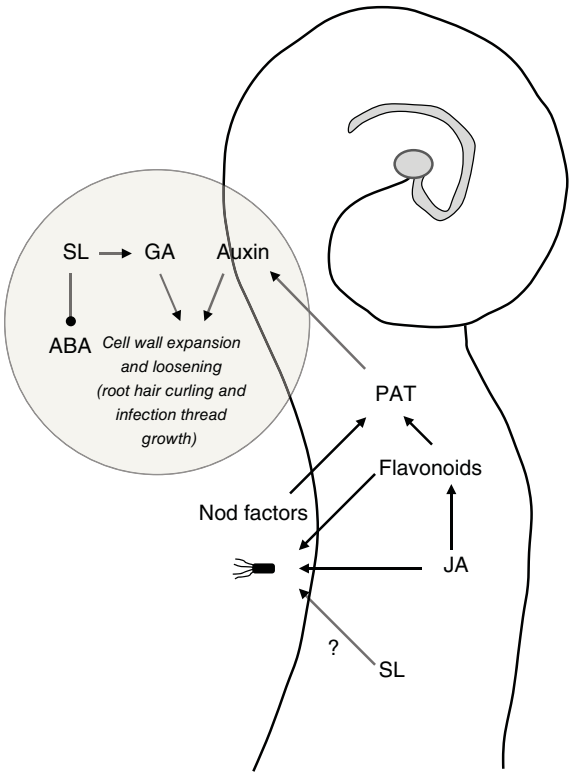

Figure 56.3 A speculative model on the role of hormones in rhizobial infection. Jasmonic acid (JA) and flavonoids induce Nod factor production in rhizobia. JA also induces the production of flavonoids. Strigolactones (SL) are also secreted into the soil, but it is unclear whether they act as a signal to rhizobia. Nod factors influence polar auxin transport (PAT) through an unknown mechanism. In seeds, SL increases gibberellic acid (GA) levels and lowers ABA levels. If GA were similarly enhanced by SL in roots during rhizobial infection, it could act together with auxin to facilitate the remodeling and growth of the root hair. In this scenario, sufficient levels of auxin would be needed within infected root hairs to promote the effects of GA.

56.12 FUTURE DIRECTIONS

The central role of hormones in rhizobial infection is unequivocal. Studies in this area will be greatly facilitated by the isolation of hormone signaling and biosynthesis mutants through forward or reverse genetics. Once the key players have been identified, it will be necessary to map out their expression during nodulation to better understand their roles and their potential interactions. Transcriptomic studies of root hairs from *S. meliloti* infected *Medicago* plants indicate that genes for auxin signaling, GA, and SL biosynthesis are enhanced, suggesting that these hormones may play key roles in the infection process. Identification of the transcriptional regulators that control these genes will help identify the intersection between the modulation of hormones and the NF signaling pathway.

57.1 INTRODUCTION

The beneficial symbiotic association between nitrogen-fixing soil rhizobia and temperate legumes such as the model plant *Medicago truncatula* initiates at the root surface when the motile bacterium binds to the growing root hairs of the host. The rhizobia respond to secreted root flavonoids by synthesizing specific lipochito-oligosaccharides (LCOs) (Nod factors), which are perceived by the host and trigger a range of co-ordinated molecular and cellular responses required for both rhizobial root infection and the formation of the nodule primordium within the root cortex (for recent reviews see Oldroyd and Downie, 2008; Madsen et al., 2010; Murray, 2011; see also Chapter 51). These responses include the re-orientation of root hair tip growth leading to tip curling and the physical enclosure of the bound rhizobia between cell walls of the root hair. Interestingly, this tip-growth re-orientation can be mimicked by the localized application of Nod factors, suggesting that the curling is a direct response to Nod factor secretion at the site of rhizobial attachment (Esseling et al., 2003).

Following rhizobial enclosure within the curl, localized remodeling of the host cell wall then leads to invagination and the progressive formation of the rhizobial infection tube known as the infection thread (IT) (reviewed in Kijne, 1992; Brewin, 2004; Gage, 2004; Jones et al., 2007). The IT comprises a specialized cell wall/membrane interface which creates an apoplastic compartment into which a small number of bacteria enter from within the curled root hair. As the IT extends toward the base of the hair via a nucleus-driven tip growth mechanism the bacteria both divide and physically move in a series of successive head-to-tail files along and within the IT (Fournier et al., 2008). This complex process is discontinuous, with significant variations in IT growth rate and accompanying rhizobial colonization, and gaps are frequently present both between adjacent bacterial files and also between the growing IT tip and the leading file (Fournier et al., 2008). Once infection has been established in the root hair, a major cellular reprogramming is set in motion within the underlying cortical cells leading to the formation of the pre-infection thread (PIT) (Van Brussel et al., 1992), a polarized cytoplasmic column that traverses the cell and which serves to direct future transcellular infection. Thus, once the IT reaches the base of the root hair, apoplastic infection is continued across the underlying cortical cell, and this entire process is then repeated in

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

subsequent cortical layers until membrane-bound rhizobia are delivered into the cells of the developing nodule. Finally, concomitant differentiation of the nodule tissues and of the membrane-enclosed rhizobia into bacteroids are required to generate the functional N-fixing root organ.

In addition to triggering root hair curling, Nod factors also activate the common symbiotic signaling pathway (CSSP; also knows as CSP or SYM), a key signaling pathway common to both rhizobial and arbuscular mycorrhizal symbioses (see Chapters 42, 54, 55, 110). CSSP activation leads to the transcriptional activation of symbiosis-specific genes involved in rhizobial infection/nodulation (reviewed in Kistner and Parniske, 2002; Oldroyd and Downie, 2008; Madsen et al., 2010; Murray, 2011). A unique mode of Ca^{2+} signaling lies at the heart of the CSSP, involving the initiation of sustained and regular Ca^{2+} spiking responses within both the nuclear and cytoplasmic (perinuclear) compartments (Ehrhardt et al., 1996; Shaw and Long, 2003; Oldroyd and Downie, 2006; Sieberer et al., 2009; see Chapter 54). Thus, the activation of the CSSP in root tissues can be followed *in vivo* by means of genetically engineered calcium reporters known as cameleons (Miyawaki et al., 1997), which can be expressed in specific host cell compartments (Miwa et al., 2006; Sieberer et al., 2009). The recent development of live-tissue imaging strategies for the model legume *M. truncatula* has made it possible not only to visualize the subcellular rearrangements described earlier (Fournier et al., 2008), but also to monitor cellular signaling during progressive stages of rhizobial colonization in intact roots. In this context, the use of cameleon reporters for *in vivo* calcium imaging has revealed two distinct nuclear Ca^{2+} oscillation profiles during specific stages of rhizobial infection in the root outer cortex (Sieberer et al., 2012). Low-frequency irregular Ca^{2+} spiking is initially observed in outer cortical cells preceding infection, and is associated with the characteristic cell remodeling leading to the formation of PITs. This is then followed by a rapid switch to a phase of regular high-frequency spiking concomitant with the initiation of transcellular infection of the cell. This high frequency spiking resembles that observed when exogenous Nod factors are applied to the root epidermis, suggesting that symbiotic signals generated by the rhizobia within the IT can be perceived by the host cortical cell undergoing infection (Sieberer et al., 2012). Interestingly, the high frequency spiking phase lasts for less than 1 h, and then progressively attenuates. Thus, spiking is no longer detectable during the remaining 2–3 h of transcellular infection. This very characteristic pattern of Ca^{2+} signaling is then repeated in the underlying cortical cell layers as the IT progresses toward the nodule primordium.

Having shown that cortical cell infection is accompanied by major changes in host Ca^{2+} signaling responses, we wanted to know whether similar spiking profiles could also be observed during root hair infection. This question is important because there are a number of significant differences between apoplastic infection in the epidermal and cortical cell layers. Firstly, root hair infection initiates from within the closed chamber created by tip curling around the attached rhizobia, whereas cortical infection is prepared in advance via the formation of the PIT cytoplasmic column. This means that the cell remodeling processes which precede IT initiation differ in the two tissues. Secondly, root hairs can be up to 200–500 μm in length, as compared to a typical width of only 20–50 μm for the cortical cell. And finally, as discussed earlier, root hair IT growth is a discontinuous process, alternating rapid and slow elongation rates (ranging from 1 to 12 μm/h) with occasional phases of transient growth arrest (Fournier et al., 2008). Indeed, all these characteristics have made it particularly difficult to monitor intracellular Ca^{2+} signaling throughout the various stages of root hair infection. Here we report the use of the nuclear-localized cameleon Nup-YC2.1 to follow calcium responses in root hairs during pre-infection, IT initiation, and IT elongation stages. Our results reveal similarities and differences as compared with cortical cell infection, and we discuss these in the light of the nature of the root cell undergoing rhizobial colonization.

57.2 METHODS

57.2.1 Plant Material and Rhizobial Inoculation

Agrobacterium rhizogenes-transformed composite plants of the *M. truncatula sunn-2* mutant expressing the Nup:YC2.1 cameleon (see below) were used for all the rhizobial infection studies presented in this chapter. The *sunn-2* mutant (Schnabel et al., 2005) has a supernodulation and enhanced infection phenotype, greatly facilitating the identification of root hair infection. Composite plants were grown and inoculated with *Sinorhizobium meliloti* 2011 strains constitutively expressing green fluorescent protein (GFP) in order to visualize the initiation and progression of the ITs as described in Fournier et al. (2008).

57.2.2 Cameleon Calcium Reporters and *M. truncatula* Root Transformation

To study host Ca^{2+} signaling both prior to and during rhizobial infection we made use of the 35S-driven nucleoplasmin:YC2.1 (Nup:YC2.1) cameleon that specifically targets the plant cell nucleus (Sieberer et al., 2009). Roots expressing cameleons were obtained via *A. rhizogenes*-mediated transformation (Boisson-Dernier et al., 2001) and selected according to their fluorescence levels (Sieberer et al., 2009). In addition to evaluating Ca^{2+}

responses within the nucleus, the cameleon fluorescence also facilitated the imaging of nuclear position throughout infection.

57.2.3 Microscopic Analysis of Infection Sites and Ca^{2+} Imaging in Root Cells

Infection sites were identified and imaged with a Leica TCS SP2 acousto-optical beam splitter (AOBS) confocal laser scanning microscope equipped with a long-distance 40× HCX Apo L NA 0.80 water-immersion objective. The fluorescent-labeled bacteria were imaged using fluorescence excitation at 488 nm (argon laser) and emission detection in the 500–540 nm range. Images were pseudo-colored in green using Leica Confocal Software. Fluorescence resonance energy transfer (FRET)-based ratio imaging was used for detecting the relative changes of Ca^{2+} levels corresponding to changes in YC-fluorescence of the cameleon probes (Miyawaki et al., 1997). Argon laser excitation was set to 458 nm and emissions were collected simultaneously in the 470–500 nm range (cyan fluorescent protein, CFP) and the 530–570 nm range (yellow fluorescent protein, YFP). The pinhole was set to 4 airy units (corresponding to an optical slice thickness of approximately 6 µm in order to image the entire nucleus) and images collected every 5 s. The cameleon YFP-to-CFP ratios were calculated and plotted over time using Microsoft Office Excel 2003 SP3 (Microsoft Corporation) after importing data from regions of interest drawn over cell nuclei using Leica confocal software. Relative changes in cellular Ca^{2+} levels are presented as YFP:CFP ratios (arbitrary units).

For the *Rhizobium* infection studies, data were obtained from a total of 18 experiments and the observation of 39 independent *M. truncatula* roots expressing Nup:YC2.1. Ca^{2+} spiking responses were recorded at regular intervals over 2–5 h periods during IT progression for a total of 12 independent root hairs (e.g., see Fig. 57.3). Results were obtained for an additional 17 infecting root hairs followed over shorter time periods. For the reasons discussed in the results section, recordings were difficult to obtain for Ca^{2+} signaling during the initial stages of rhizobial IT colonization (total of four root hairs: e.g., see Fig. 57.2).

57.3 RESULTS

57.3.1 *Rhizobium*-Elicited Ca^{2+} Spiking in *M. truncatula* Root Hairs Prior to Infection

In order to monitor calcium signaling responses in the host legume epidermis throughout the different phases of rhizobial infection, we exploited *M. truncatula* composite plants expressing the nuclear-localized cameleon reporter Nup:YC2.1 in *A. rhizogenes*-transformed roots, as previously described in Sieberer et al. (2009, 2012). Nuclear-associated Ca^{2+} signaling during root hair infection is difficult to monitor using conventional cytoplasmic probes, because the highly dynamic structure of the cell cytoplasm often results in low-level reporter fluorescence and limited FRET (Fournier et al., 2008; Sieberer et al., 2009). Thus, the use of the Nup:YC2.1 Ca^{2+} reporter turned out to be of crucial importance for the success of the root hair infection studies described in the following text.

M. truncatula plants were inoculated with the GFP-labeled *S. meliloti* strain 2011 and the initial pre-infection stages of the interaction were monitored using light microscopy. *Rhizobium*-elicited root hair curling was observed in growing hairs from 12 h post-inoculation onwards, and Figure 57.1a illustrates three consecutive stages of tip curling in an individual root hair. Observations of numerous such curlings suggest that a single bacterium attached close to the hair tip is sufficient to activate tip growth re-orientation toward the site of attachment, and that the entire curling around the attached *Rhizobium* is completed within approximately 4–5 h (results not shown).

It has already been shown that Ca^{2+} spiking in legume root hairs is triggered within minutes following rhizobial inoculation and is dependent on Nod factor synthesis (Wais et al., 2002; Harris et al., 2003). Our live-tissue confocal FRET imaging experiments performed with cameleon calcium reporters have revealed that the capacity of growing root hairs to respond to rhizobial signals is maintained for many hours post-inoculation. Furthermore, the results presented in Figure 57.1a show that regular high frequency spiking is still present in root hairs throughout tip curling and we presume that this very characteristic response is also the result of the perception of rhizobial-secreted Nod factors.

Although root hair curling is a relatively rapid process resulting in the physical enclosure of the rhizobia within a space surrounded by host cell walls (referred to hereafter as the "infection chamber"), continuous live-cell imaging has shown that there is always a lengthy delay (12–20 h) before the initiation of IT growth from within the curl. Using a variety of cellular markers, we now have strong evidence that major host cell wall remodeling takes place within the infection chamber during this period (Fournier et al., 2015). Strikingly, our *in vivo* imaging experiments have revealed that Ca^{2+} oscillations can no longer be detected in the majority of fully curled root hairs, and in the remaining curled hairs spiking is both infrequent and irregular (Fig. 57.1b,c). In contrast, non-deformed growing root hairs present in the vicinity of the curled hairs continue to show typical Nod factor-elicited spiking. This suggests that once the closed infection chamber has been formed, the root hair temporarily loses its capacity

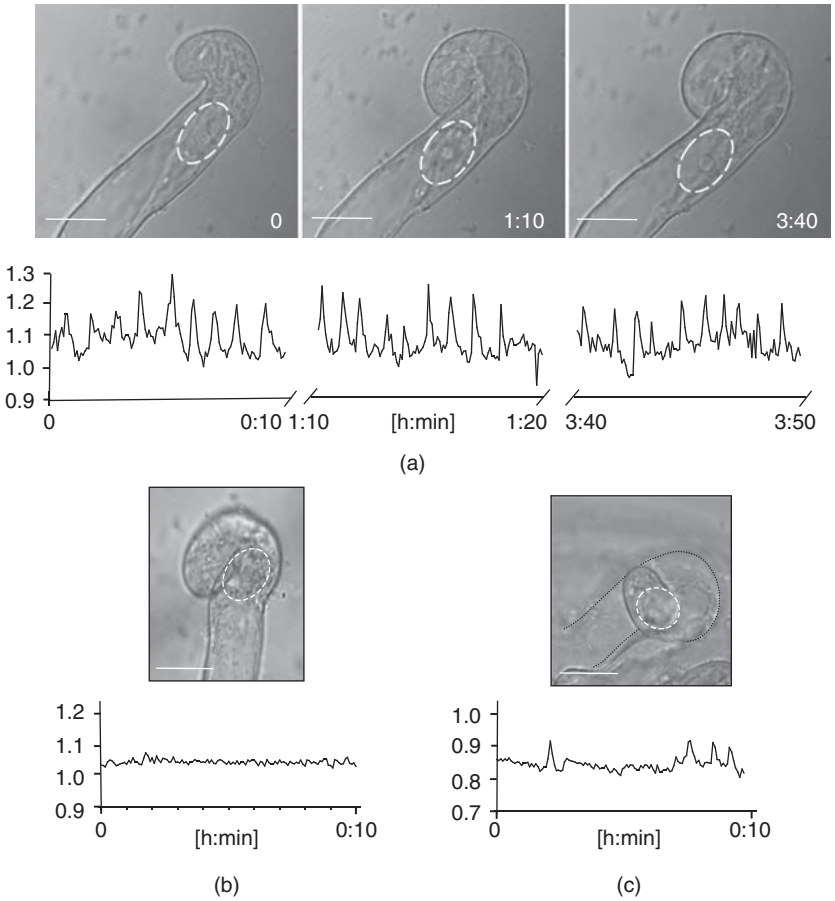

Figure 57.1 Ca^{2+} spiking in *M. truncatula* root hairs during different stages of rhizobial-elicited hair curling. (a) Three consecutive stages of root hair curling over a 4 h period are illustrated, and underneath each image the corresponding high frequency Ca^{2+} spiking profiles observed within the hair nucleus (dashed outlines). (b,c) Nuclear Ca^{2+} spiking is severely attenuated in root hairs once the 360° curl is completed and the rhizobia fully enclosed in a chamber surrounded by host cell walls. The fact that the nuclei are positioned in very close proximity to the infection chamber shows that the loss of spiking is not due to the migration of the nucleus away from the entrapped rhizobia. Scale bars = 10 μm.

to respond to rhizobial Nod factor LCO signals and to activate the CSSP.

57.3.2 Infection Thread Initiation in Root Hairs Correlates with Reactivation of Ca^{2+} Spiking

Throughout root hair curling and the formation of the infection chamber, rhizobial multiplication within the enclosed curl leads to the formation of a microcolony generally comprising less than 20 bacteria. The initiation of the IT corresponds to the localized invagination of the host membrane that surrounds the infection chamber toward the base of the root hair, following a path which is defined by the broad cytoplasmic column linking the chamber to the migrating cell nucleus (Fournier et al., 2008). The bright-field image in Figure 57.2a illustrates a root hair just prior to IT initiation, and shows the relative positioning of the cell nucleus and cytoplasmic bridge to the infection chamber within the curl. The corresponding fluorescence confocal image (Fig. 57.2b) reveals both the GFP-labeled bacterial microcolony present within the chamber and the intense fluorescence in the nucleus corresponding to the Nup:YC2.1 cameleon.

Unfortunately, it is extremely difficult to anticipate the precise moment of IT initiation within the curled root hair for two reasons. Firstly, as stated earlier, there is a lengthy and variable period of time associated with the cell wall remodeling, which takes place within the infection chamber. Secondly, a majority of curled *M. truncatula* root hairs do not progress beyond this stage and never initiate ITs. The reason for this is unclear, but has also been reported for other legume plants (e.g., Callaham and Torrey, 1981 in the case of clover root hair infection). As a result, we have only been able to observe a limited number of IT initiation events, of which a typical example is shown in Figure 57.2c. A comparison with Figure 57.2b shows that rhizobia have entered the newly formed IT during the 3 h period between the two images. When the Ca^{2+} status in the root hair nucleus was evaluated using the fluorescent cameleon reporter, well-defined spiking was present both prior to and immediately following rhizobial entry into the newly formed IT (Fig. 57.2). These findings were confirmed for at least three other root hairs, and lead to the proposition that Ca^{2+} spiking is reactivated in the root hair nucleus at a stage which accompanies IT initiation.

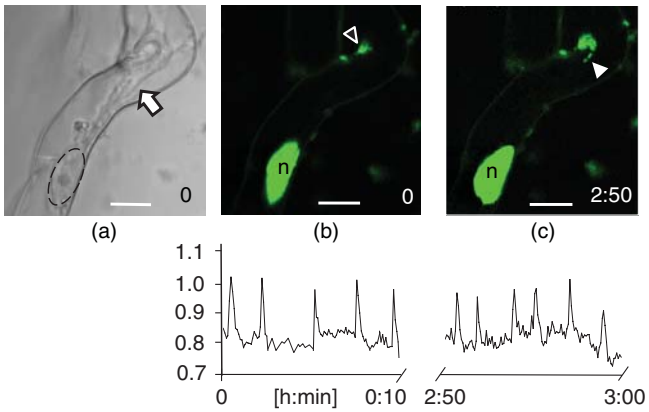

Figure 57.2 Reactivation of Ca^{2+} spiking during infection thread initiation. (a,b) Bright field (a) and corresponding fluorescence (b) images of a root hair during IT initiation at a stage preceding rhizobial entry. The position of the nucleus is outlined in (a) and indicated by "n" in (b), the arrow in (a) indicates the position of the broad cytoplasmic bridge linking the nucleus to the infection chamber and the dark arrowhead in (b) shows the position of the bacterial microcolony. The Ca^{2+} spiking profile shown underneath image (b), derived from FRET-based confocal imaging of the nuclear-localized fluorescent cameleon Nup:YC2.1, shows that spiking has been reactivated at this pre-infection stage. (c) Sustained spiking is still present in the nucleus (n) when the first fluorescent rhizobia can be seen entering the IT compartment (white arrowhead) approximately 3 h later. Scale bars = 10 µm.

57.3.3 Ca^{2+} Signaling is Associated with Active Phases of IT Growth during Root Hair Infection

As outlined in the introduction, a similar *in vivo* imaging approach previously revealed that the initiation of IT growth in the underlying root cortical cell tissues is concomitant with a rapid switch to high frequency nuclear Ca^{2+} spiking in the target cell (Sieberer et al., 2012). However, this spiking response is only of limited duration (<1 h), and is absent during the remaining period of IT growth across the cortical cell. For this reason, it was important to determine to what extent Ca^{2+} spiking is maintained throughout the lengthy period of infection in the root hair, especially because IT growth within this specialized epidermal cell is a highly irregular process, alternating between periods of rapid and slow tip growth and occasional temporary arrest (Fournier et al., 2008).

The four consecutive images presented in Figure 57.3 cover a total period of 3 h and perfectly illustrate the variable nature of IT growth within an individual root hair. During the 40 min period between the first two images (Fig. 57.3a,b), the rhizobial file has progressed at an average rate of 12.6 µm/h. This corresponds to the maximal rate of IT progression observed in *M. truncatula* root hairs (Fournier et al., 2008). Nuclear Ca^{2+} spiking responses can be clearly observed both at the beginning and the end of this phase of

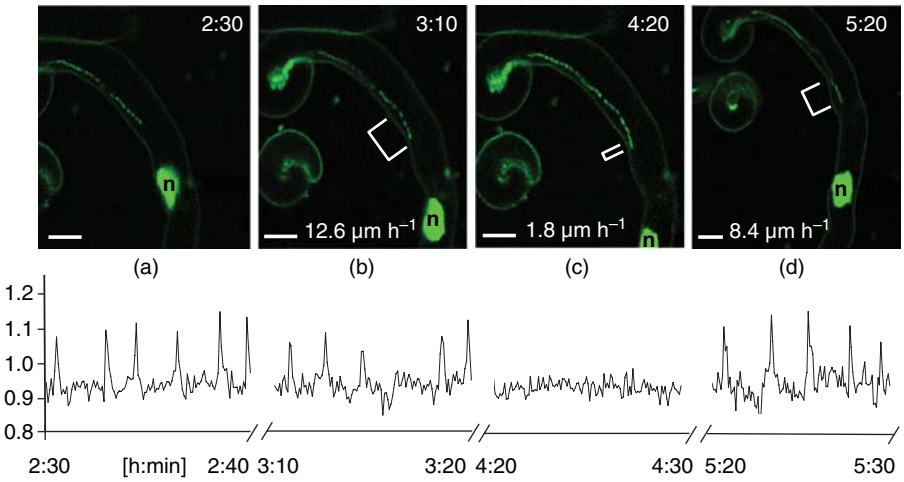

Figure 57.3 Ca^{2+} spiking in infected root hairs correlates with phases of pronounced IT growth. (a–d) The four confocal images covering a total period of 3 h illustrate typical discontinuous IT growth within a root hair which was monitored regularly over a 5 h 30 min period. The fluorescent-labeled nuclei are marked by "n" and the individual fluorescent rhizobia can be identified within the advancing thread. The distance moved by the leading bacteria within the IT between successive images is indicated by the bracket and the corresponding average speed of rhizobial colonization over these periods (40, 70, and 60 min respectively) is indicated at the bottom of images (b–d). The 10 min-duration Ca^{2+} spiking profiles which correspond to each time-point are shown underneath each image and reveal that spiking is present during this entire period of IT growth with the exception of the 4 h 20 min time-point (c). It is striking that this absence of spiking correlates with the slowest phase of bacterial progression (7 and 5× slower than in b and d respectively), most likely corresponding to a slow phase of IT tip growth. Scale bars = 10 µm.

rapid bacterial colonization. However, during the following hour (Fig. 57.3b,c), file progression has slowed to an average of only 1.8 μm/h, and it is striking that there is a concomitant loss of nuclear spiking at the end of this period. During the final hour of imaging, the bacterial colonization rate re-accelerates (Fig. 57.3c,d) to reach an average speed of 8.4 μm/h and this increased growth rate is accompanied by a reactivation of Ca^{2+} spiking within the root hair nucleus. Time-course observations performed on at least 10 other *M. truncatula* root hair infections (see Section 57.2) have revealed a similar positive correlation between high IT growth rates and active nuclear Ca^{2+} signaling. Finally, it should be underlined that spiking was never observed in an infected root hair in which the IT had permanently stopped growth. In conclusion, these findings clearly demonstrate that, in contrast to cortical cell infection, the Ca^{2+} spiking response in root hairs is not shut down shortly after IT initiation and the likely significance for this difference will be discussed below.

57.4 DISCUSSION

57.4.1 Studying Calcium Signaling in Root Hairs Throughout Apoplastic Rhizobial Infection

For the majority of temperate legumes, including the two model species *M. truncatula* and *Lotus japonicus*, initial *Rhizobium* root entry occurs via a unique cellular process involving the creation of a novel apoplastic compartment within tip-growing root hair cells. In order to obtain information about the dynamics of microbe-host signaling throughout root hair infection we have used confocal microscopy to monitor Ca^{2+} signaling in *M. truncatula* root hairs during the various stages which both precede and accompany IT growth. The nuclear-expressed cameleon Nup:YC2.1 has proved to be an ideal calcium reporter for these studies, greatly facilitating time-lapse observations during the highly irregular phases of IT growth along the root hair.

Following rhizobial inoculation, at least two morphologically distinct pre-infection phases can be distinguished in *M. truncatula* roots. Firstly, root hair tip curling around attached rhizobia is observed approximately 12–24 h post-inoculation. The 360° tip-curling which generates the so-called shepherd's crook is relatively rapid and usually completed within 4–6 h (Fig. 57.1). However, IT initiation from within the closed curl was only observed in our experiments following an additional 12–20 h. As commented earlier, we now have strong evidence that major host cell wall remodeling is taking place around the enclosed rhizobia during this second pre-infection phase (Fournier et al., 2015). This phenomenon is not limited to *M. truncatula*, since Callaham and Torrey (1981) previously reported, using light microscopic observation, that ITs are only initiated in clover root hairs 12–16 h after the completion of root hair curling. Together, these findings underline the fact that IT initiation is not simply the result of a switch in polarity from the outward tip-growing root hair to the inward tip-growing IT, as has frequently been suggested (e.g., Jones et al., 2007).

The results presented in Figure 57.1a show clearly that high frequency nuclear Ca^{2+} spiking is present in *M. truncatula* root hairs undergoing tip-curling. This spiking profile is very similar to that observed in root hair nuclei in response to purified Nod factors (Sieberer et al., 2009), suggesting that these cells are responding to the rhizobia-secreted LCO signals. It was previously shown that Nod factor-like Ca^{2+} spiking in *M. truncatula* root hairs could be elicited within minutes following *S. meliloti* inoculation (Wais et al., 2002), and indeed our time-lapse imaging has shown that this highly characteristic spiking is maintained in actively tip-growing root hairs for many hours following inoculation, including in those adjacent to fully curled hairs. It is therefore unclear whether the spiking response present in tip curling hairs is being elicited by LCOs generated locally by the attached rhizobia or by LCOs that have accumulated in the medium surrounding the root following inoculation. Whatever the source of rhizobial Nod factors, we can conclude that root hairs undergoing 360° curling are fully responsive to these symbiotic signals.

In contrast, root hairs that have completed curling to form what we have termed the "infection chamber" appear to have a modified capacity to respond to the rhizobial elicitors, as nuclear spiking is either totally absent or severely attenuated in these hairs (Fig. 57.1b,c). The limited spiking in these cells is unlikely to be due to a lack of exogenous Nod factors as adjacent tip-growing root hairs show normal Ca^{2+} spiking responses. We therefore favor the hypothesis that this transient loss of LCO responsiveness is a consequence of the cell wall/membrane remodeling that accompanies this particular pre-infection phase.

57.4.2 Nuclear Ca^{2+} Spiking is Reactivated and Maintained Throughout IT Growth Phases within the Root Hair

For the reasons described earlier it turned out to be particularly difficult to capture the earliest stages of IT formation in the *Medicago* root hair. Nevertheless, our data-set (e.g., Fig. 57.2) indicates that sustained Ca^{2+} spiking has been reactivated prior to and during the entry of rhizobia into the newly created apoplastic compartment. This is consistent with the results obtained previously for outer cortical cell infection, where regular high frequency spiking is rapidly switched on during the earliest infection stages

(Sieberer et al., 2012). Of course, additional experiments using cellular markers that specifically label the IT cell wall/membrane interface will now be required to determine precisely when Ca^{2+} spiking is activated with respect to IT initiation in the root hair.

As shown previously (Fournier et al., 2008), subsequent IT extension within the root hair shaft is a non-regular process involving a complex interplay between nuclear migration, the dynamics of the cytoplasmic column connecting the nucleus to the growing IT tip, and the progressive bacterial colonization of the newly-formed thread. By monitoring IT growth in a number of root hairs over lengthy 2–3 h periods and in different parts of the root hair, we have been able to draw a number of preliminary conclusions. Firstly, nuclear Ca^{2+} spiking can be observed throughout different stages of IT growth within the root hair, a process which can last for up to 20 h. Thus, in contrast to the situation for outer cortical cell infection (Sieberer et al., 2012), spiking in root hairs is neither attenuated nor switched off within the 1–2 h period that follows IT initiation. Secondly, the spiking response appears to vary as a function of the IT growth rate, with periods of active spiking alternating with a partial or even complete loss of nuclear Ca^{2+} oscillations. This is well illustrated in Figure 57.3, where a transient loss of spiking in the root hair nucleus is concomitant with a major reduction in the rate of rhizobial progression within the thread. Similar transient spiking arrests were observed in other root hair infections monitored over several hour periods, and in each case this coincided with a phase of reduced bacterial progression. Although we assume that these periods of slow rhizobial progression correlate with phases of reduced IT tip-growth, additional studies using IT-specific markers will be required to determine whether the absence of nuclear spiking is directly linked to reduced rates of IT extension and/or other parameters such as the IT tip-to-nuclear distance (Fournier et al., 2008). This information is important if we wish to understand the precise relationship between the activation of the Ca^{2+}-mediated host signal transduction pathway and sustained IT tip growth in the root hair.

In conclusion, these findings underline the requirement for active rhizobial-host signaling throughout root hair infection. As for cortical cell infection (Sieberer et al., 2012), the regular sustained Ca^{2+} spiking observed within the root hair nucleus (Figs. 57.2 and 57.3) resembles Nod factor-induced spiking profiles and this is therefore totally consistent with the perception of rhizobial signals by plant receptors located in the IT membrane. Indeed, the well-characterized infection-related MtLYK3 "entry" receptor (Limpens et al., 2003; Smit et al., 2007) recently localized to the IT periphery (Haney et al., 2011) would be an excellent candidate for perceiving these symbiotic LCOs.

57.4.3 Different Modes of Ca^{2+} Signaling during Root Hair Versus Cortical Cell Infection

The findings reported here have revealed a striking difference between root hair and cortical cell infection in relation to the maintenance of Ca^{2+} spiking throughout transcellular IT growth. Could this reflect fundamental differences in the mode of IT progression between the two cell types? In the case of variable-length root hairs, the infection compartment construction depends both on the relative positioning of the migrating nucleus and the organization of the interconnecting cytoplasmic bridge. The highly variable nature of these two parameters no doubt contributes to the characteristically irregular IT growth dynamics observed in root hairs. In contrast, infection of the underlying cortical cells is programmed in advance via the formation of the transcellular PIT, which guides subsequent IT growth. We can thus speculate that the continued perception/transduction of symbiotic signals generated by the colonizing rhizobia within the growing IT is required for successful root hair infection, whereas the activation of this same signaling pathway leading to Ca^{2+} spiking is only necessary for the initial stages of cortical infection.

In a recent article, Liao et al. (2012) have described a novel and particularly interesting mutation in the *L. japonicus CCaMK* gene (*ccamk-14*), which results in the premature abortion of rhizobial infection in the host outer root cortex. CCaMK is the nuclear-localized calcium and calmodulin-dependent kinase which plays a central role in the CSSP pathway decoding intracellular oscillatory Ca^{2+} signaling elicited by rhizobial Nod factors (Lévy et al., 2004; Gleason et al., 2006; see Chapter 54). *In vitro* studies indicated that the *ccamk-14* mutation (S337N) occurs at a putative auto-phosphorylation site within the CaM-binding domain of CCaMK (Liao et al., 2012). Furthermore, the authors have provided good evidence that the auto-phosphorylation of S337 interferes with CaM binding and that this is involved in the negative regulation of CCaMK activity. Finally, an intriguing feature of the *ccamk-14* mutation is that while rhizobial infection aborts in the outer cortex, infection appears to proceed normally in the overlying root hairs. This suggests that the negative regulation of CCaMK and the consequent inactivation of the CSSP pathway is essential for the successful completion of cortical infection but not for epidermal root hair infection. By analogy, the differences that we have observed in relation to Ca^{2+} spiking between the two outer root tissues in *Medicago* could indeed be the result of different requirements for an active CSSP once infection has been initiated. Future research now needs to be focused on the possible interplay between the negative regulation of Ca^{2+} signaling and the negative autoregulation of CCaMK during cortical cell infection in both *Medicago* and *Lotus,* with the goal of

understanding why the inactivation of the CSSP is crucial for successful cortical infection.

Chapter 58

A Pectate Lyase Required for Plant Cell-Wall Remodeling During Infection of Legumes by Rhizobia

J. Allan Downie

58.1 INTRODUCTION

In order to infect legume roots and nodules, rhizobia induce the plants to form infection threads (ITs), which are established by the initiation of an inward growth of the plant cell wall and membrane. The resulting IT structure resembles an intracellular tube that is lined with newly synthesised plant cell wall and membrane (see Chapter 57). Within the space lined by the plant cell wall there is an apoplastic-like compartment that contains glycoproteins, carbohydrates, and extensins within the matrix (Brewin, 2004).

Rhizobia grow and have some sliding movement near the growing tip of ITs (Fournier et al., 2008) and the elongation of the ITs is usually preceded by nuclear movements that direct their growth (Fahraeus, 1957; Nutman, 1959; Fournier et al., 2008; see Chapter 57). In most temperate legumes, initiation of IT growth occurs from infection foci, formed after the root hairs grow back on themselves entrapping rhizobia that divide in the closed pocket that is formed. However, in some legumes infection does not occur via root hairs, but can be initiated from pockets of bacterial growth formed after rhizobia colonize intercellularly (Boogerd and van Rossum, 1997; Capoen et al., 2010). Indeed it has recently become apparent that, even in legumes in which root-hair infection is the norm, nodule infections can be initiated via a pathway that does not involve epidermal ITs (Karas et al., 2005; Madsen et al., 2010)

Irrespective of whether ITs are initiated in root hairs or in deeper layers of the root, the initiation of IT growth requires remodeling of the plant cell wall. Even before rhizobia had been identified as the infecting micro-organisms in legume nodules, growth of ITs had been observed and it had been deduced that there must be some degradation of plant-cell walls to allow the infection to occur (Ward, 1887).

As the IT initiates and grows down through the root hair, new cell-wall material must be synthesised and this will require delivery of cell-wall synthesis enzymes, structural proteins and cell wall precursors to the growing IT tip. As the growing IT approaches the base of the root-hair cell, the newly synthesized IT cell wall must become cross-linked with the existing root-hair cell wall. In parallel, for the IT to cross between the root-hair cell and the next sub-epidermal cell, there must be a localized degradation of the cell wall at the base of the root hair and opposing sub-epidermal cell wall. Prior to this cell-wall loosening and the arrival of the growing IT tip, the cytoskeleton of the sub-epidermal cell is rearranged and establishes the direction of growth of the IT (van Brussel et al., 1992).

In this short review we will consider the events that will be required to occur at the cell wall to initiate the growth

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

of ITs and their continued growth through adjacent cells to allow nodule infection to occur. This requires localized cell wall loosening/degradation that is coordinated with new cell-wall synthesis.

58.2 CELL WALL COMPONENTS

To understand what may be required to remodel the primary cell walls during initiation of infection, it is important to understand the principle components. Cellulose microfibrils form a structural scaffold that is tied together and given rigidity by crosslinks to xyloglucans and pectins. Xyloglucans can bind to and be entrapped within the cellulose microfibrils, acting as crosslinking tethers that stabilize the cellulose scaffold (Cosgrove, 2005). Pectins come in different major forms all based on α1–4 linked galacturonic acid. These forms include homogalacturonan (which can constitute up to 60% of the pectin in primary cell walls and contains some residues that are methyl esterified), and more complex substituted forms of homogalacturonan including the rhamnogalacturonans RG-I and RG-II, xylogalacturonan and apiogalacturonan (Mohnen, 2008). The different pectins confer physical strength to the cell wall and contribute to the formation of a barrier to the external environment, especially with regard to strengthening the plant cell wall (Caffall and Mohnen, 2009).

When considering infection by rhizobia, it may useful to consider which cell-wall components are targeted by cell-wall-degrading enzymes secreted by plant pathogens. Based on the diversity and range of virulence-associated enzymes that are involved with pectin degradation (pectate lyases, polygalacturonases, and pectin methyl esterases), it is clear that this polymer is the main target for degradation by pathogens (Cantu et al., 2008). Although both pectate lyases and polygalacturonases can degrade the same substrate, they are very different enzymes; polygalacturonases hydrolyse the glycosidic bond, whereas pectate lyases catalyse a β-elimination reaction that cleaves the glycosidic bond. In addition to these pectin-degrading enzymes, xylanases are important for plant cell-wall degradation by some pathogens (Rajeshwari et al., 2005; Brito et al., 2006). Necrotrophic pathogens tend to macerate the plant cell wall and usually have higher numbers of genes encoding cell-wall degrading enzymes than biotrophic fungi. For example, the genomes of the necrotrophic pathogens *Botryris cinerea* and *Sclerotia sclerotiorum* genomes appear to be specially adapted for pectin decomposition (Amselem et al., 2011).

Biotrophic fungi such as *Puccinia graminis* gain access to plant cellular nutrients by locally degrading the plant cell wall adjacent to the appresorium; the associated fungal penetration leads to the production of the haustorium complex which is a fungal intracellular feeding structure (Ehrlich and Ehrlich, 1962). The biotrophic ergot fungus *Claviceps purpurea* has two polygalacturonases that are needed for virulence and growth between cells (Oeser et al., 2002). Such localized cell-wall degradation by biotrophic pathogens points to a specific role for pectin degradation in locally penetrating the plant cell wall; possibly this can be seen as being analogous to the cell-wall remodeling that occurs during rhizobial infection. However, the products of pectin degradation by plant pathogens activate a plant defence cascade (Kohorn et al., 2009) and such a defence response could be a significant problem during rhizobial infection. During cell division, plant cells must locally degrade some pectins and probably other cell-wall components and this seems usually to occur without the strong induction of plant defences (otherwise plant defences would constantly be activated during cell division). So it seems likely that plants have evolved ways of inducing some cell-wall degrading enzymes to allow remodeling of their cell walls without inducing defence responses. Harnessing such plant enzymes during the initiation of infection by rhizobia would be an appropriate way of promoting cell-wall remodeling to allow IT growth initiation without inducing plant defences from products of limited cell-wall degradation.

58.3 INFECTION THREAD INITIATION

Initiation of ITs requires rhizobially produced Nod factors and the consequent activation of the nodulation signaling pathway in legumes (Murray, 2011). Mutations in Nod-factor-receptor genes block Nod-factor-induced responses such as root-hair deformation and perinuclear calcium spiking. However, mutations that block the calcium spiking signaling pathway do not block all root hair responses: for example, mutants blocked in the Nod-factor-induced calcium-spiking pathway retain some root-hair deformation, although in those mutants, the characteristic full root-hair curling that causes rhizobial entrapment did not occur (Miwa et al., 2006). It is the bacterial micro-colonies that develop after the rhizobia are entrapped by the curled root hairs that form infection foci; these foci of entrapped rhizobia define where the plants will initiate the growth of ITs.

The sites of initiation of IT growth in root hairs and the locations where ITs will extend into cortical cells are marked by nuclear relocalisation to the vicinity of new sites of cellular penetration (see Chapter 57). The cytoskeletal rearrangements set up by the nucleus (Timmers, 2008) result in structures called pre infection threads (PITs) and these can be induced by rhizobiallymade Nod factors (van Brussel et al., 1992). Different genes contributing to changes in the assembly of the cytoskeleton have been identified as being required for IT growth, because mutations in these genes block early infection events. Thus, mutations in *NAP1* and *PIR1* block infection; they encode components of the major class 1 actin

nucleation promoting complex (Yokota et al., 2009; Miyahara et al., 2010). Similarly, mutation of the *ARPC1* gene blocks infection; *ARPC1* encodes actin- related protein component 1, which is a component of the major nucleator of Y-branched actin filaments in plants (Hossain et al., 2012).

The rearranged positioning of the actin cytoskeleton at likely infection foci provides a framework, which could be used to deliver plant-cell-wall degradation and cell-wall synthesis enzymes to localized sites. Vesicle trafficking can be directed along the actin cytoskeleton (Samaj et al., 2006) and so there is the potential to deliver glycanases, cellulases, pectinases, polygalacturonases and pectin esterases to the localized region of the cell wall adjacent to the cytoskeletal components that contribute to the PIT. Specific exocytotic-vesicle-associated membrane proteins (VAMPs) have recently been identified as being important for the delivery of proteins to developing symbiosomes (Ivanov et al., 2012). Although no such symbiosis-specific pathway has yet been identified for targeting of plant cell-wall degrading enzymes to the sites of IT initiation, it seems likely that some such targeting must occur.

What is the evidence for a requirement for plant-made cell-wall degradation localized at the sites of initiation of infections by rhizobia? Electron microscopy of such sites revealed localized degradation of the plant cell wall close to rhizobial infection sites. These sites of infection initiation and cell-wall softening were associated with large numbers of plant-made vesicular bodies (Ridge and Rolfe, 1985). At these sites of infection, the rhizobia appeared to be appressed against the cell wall (Ridge and Rolfe, 1985), suggesting that the bacteria may exert a pressure that distorts the cell wall. However, once the IT starts to grow, it is evident that there is frequently a bacteria-free zone near the IT tip, demonstrating that the bacteria need not be adjacent to the growing tip during its progression (Fournier et al., 2008; see Chapter 57). This is consistent with a model in which IT growth and extension is controlled and maintained by the plant. However, after PIT formation, fullyformed ITs are not formed unless bacteria are growing within them implying that IT growth and elongation must be very closely coordinated with rhizobial growth.

It is now evident that one plant enzyme required for infection is a pectate lyase that is specifically induced in legumes in response to the signaling cascade induced by the rhizobially made Nod factors (Xie et al., 2012). Mutation of this Nod-factor induced pectate lyase gene (*NPL*) in *Lotus japonicus* resulted in the blocking of rhizobial infection at the sites of infection foci in root hairs as illustrated by the blocked infection in Figure 58.1b compared with the normal infection shown in Figure 58.1a. The *npl* mutant produced

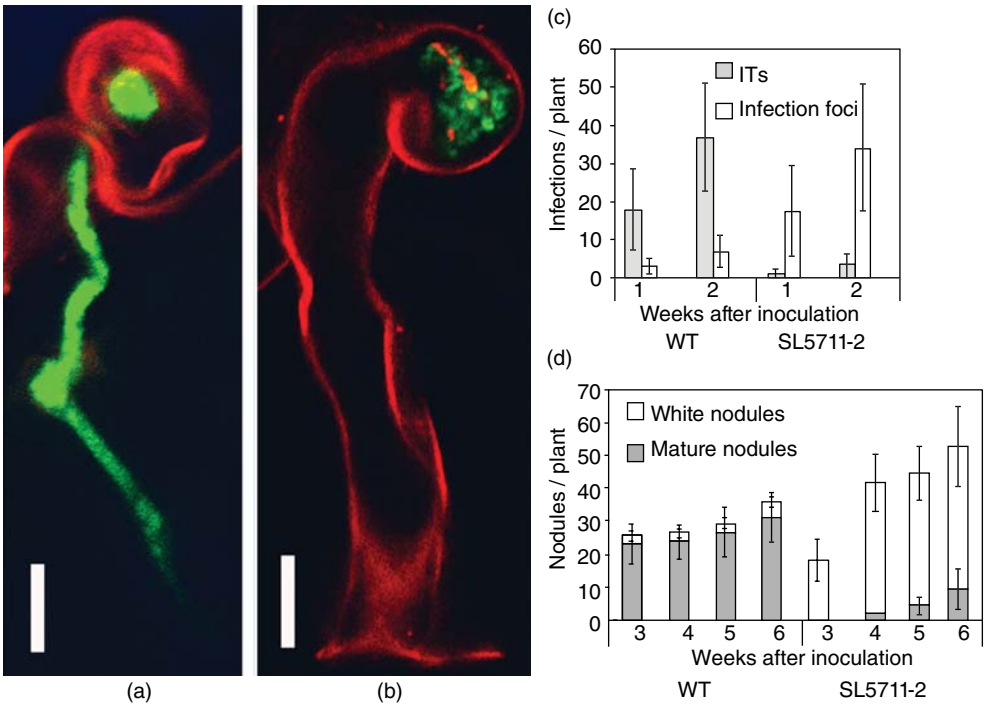

Figure 58.1 Nodulation and infection defects of a *Lotus japonicus* nodulation pectate lyase (*npl-1*) mutant. Panels (a) and (b) show confocal laser scanning fluorescence microscope images of root hairs of WT (a) and the npl-1 mutant SL5711-2 (b) seedlings inoculated with *M. loti* carrying GFP. An infection focus without an associated IT is shown in a root hair of the *npl-1* mutant. Panel (c) shows the average numbers (±SE) of ITs and infection foci in WT and the *npl-1* mutant SL5711-2, 1 and 2 weeks after inoculation with *lacZ*-marked *M. loti*. Panel (d) shows the average numbers (±SE) of mature nodules and white nodules on WT and *npl1-1* mutant scored 3–6 weeks after inoculation (±SE N > 20). Scale bars in (a) and (b) are 12 µm. (*Source*: Adapted from (Xie et al., 2012).)

many infection foci, most of which did not progress to form ITs (Fig. 58.1c). In a few cases infections did occur in the mutant but these appeared to be arrested when the IT reached the next cell wall. The net result was that the mutants produced white nodules, most of which were uninfected (Fig. 58.1d).

The mutated gene was identified by positional cloning and DNA sequencing revealed that one *L. japonicus npl* mutant had a predicted premature stop codon and the other had a missesnse mutation in a region conserved in other pectate lyases. The wildtype and missense mutant form of the pectate lyase were purified, whereas the WT NPL was active on both polygalacturonic acid and its methyl esterified form (pectin), the missense mutation abolished most or all of this activity (Xie et al., 2012).

The *NPL* gene was strongly induced in roots by Nod factors produced by *Mesorhizobium loti* and this induction was blocked by mutations in genes in the Nod-factor signaling cascade (Fig. 58.2a). Normal induction of *NPL* also requires the NIN transcription factor which bound to the *NPL* promoter (Xie et al., 2012). To assay the pattern of *NPL* expression in roots, the promoter of *NPL* was fused to the GUS (β-glucuronidase)-encoding reporter gene (Xie et al., 2012); this gene fusion was strongly induced in curled root hairs inoculated with *M. loti* (Fig. 58.2b, c) and this pattern is similar to the pattern of *NIN* induction (Kosuta et al., 2008).

The *Medicago truncatula* orthologue of *L. japonicus NPL* was identified and it was one of two very similar pectate lyase genes that are closely linked on *M. truncatula* linkage group 3 (Xie et al., 2012). As shown from the phylogeny in Figure 58.3, these two predicted pectate lyases cluster together with *L. japonicus* NPL and two other predicted pectate lyases from *Glycine max*. This group forms a phylogenetically distinct subgroup that does not contain a representative pectate lyase from *Arabidopsis thaliana*.

It has long been recognized that the initiation of legume infection was associated with increased production of clover root-hair polygalacturonase (Ljunggren and Fahraeus, 1959, 1961). Previously a rhizobially-induced polygalacturonase gene (*MsPG3*) was identified in *Medicago sativa*; this gene was strongly induced in nodule primordia and in the infection zone of nodules (Munoz et al., 1998). It was not reported if this gene was expressed in root hairs, but its pattern of expression seems to be somewhat different from that seen with the *L. japonicus NPL* gene, indicating that there may be different pectin/polygalacturonic acid degrading enzymes induced during nodulation. It was reported (Xie et al., 2012) that at least two polygalacturonases are also induced during nodulation, based on an analysis of gene expression in the *M. truncatula* Gene Atlas Expression (MtGEA) database (Benedito et al., 2008).

Taking into account the structure of the plant cell wall, it seems likely that other polysaccharide degradation enzymes will be induced by plants. Pectin methylesterase genes

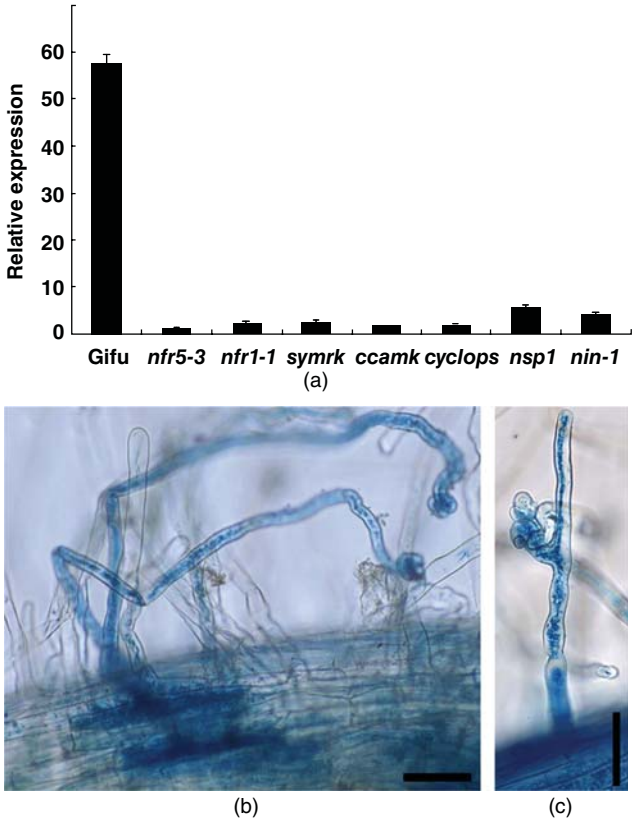

Figure 58.2 *LjNPL* induction requires Nod-factor signaling and *NIN*. Panel (a) shows induction of *LjNPL* by M. loti Nod factor (10 nM) relative to untreated controls, measured by quantitative RT-PCR using RNA isolated from WT and the nodulation mutants indicated. Panels (b) and (c) show *Agrobacterium rhizogenes*-induced hairy roots on chimaeric seedlings of *L. japonicus* WT transformed with the promoter region of *LjNP* upstream of the β-glucuronidase gene. The roots were inoculated with *M. loti* and 8 days after inoculation the roots were stained for 3 h using X-gluc as described (Xie et al., 2012). The curled root hairs stained strongly. The scale bars are 50 μm.

have been identified as being specifically induced during nodulation (Lievens et al., 2002); based on the analysis of the *M. truncatula* gene atlas database a pectin methylesterase was also found to be induced during nodulation (Xie et al., 2012).

Our analysis of the *M. truncatula* GeneAtlas database (http://mtgea.noble.org/v3/) identified several predicted glycanases that are expressed during nodulation as are some predicted cellulases. However, none of these genes has been identified as having the highly specific pattern of expression of the *M. truncatula NPL* gene. This of course does not necessarily mean that such enzymes do not function in legume infection. The regulation of other cell-wall degrading enzymes could for example be less specific than that of NPL, or their activity could depend more on the regulation of their delivery, for example, via targeting to a vesicle-dependent exocytotic pathway.

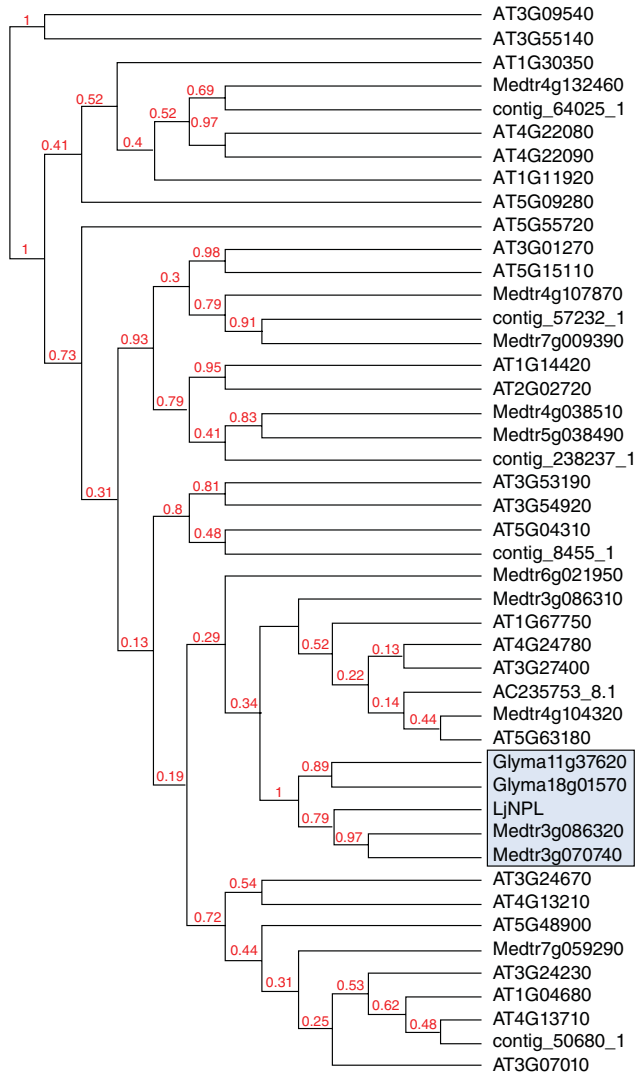

Figure 58.3 Identification of a legume-specific clade of pectate lyases. The phylogeny shows LjNPL and pectate lyase sequences from *Arabidopsis thaliana* and *Medicago truncatula*. *A. thaliana* protein sequences (AT) are from TAIR (http://www.arabidopsis.org/); *M. truncatula* proteins (prefixed 'Medtr' 'AC' or contig) are predicted from IMGAG version 3.5 (http://www.jcvi.org/cgi-bin/medicago/annotation.cgi). The pectate lyases from soybean (SoyBase http://soybase.org/; Glyma11g37620 and Glyma18g01570) are included because they are symbiotically induced; they cluster with LjNPL and with *M. truncatula* Medtr3g086320 (nodulespecific isoform), forming a distinct clade with strong support (blue box). The phylogenetic tree is as presented previously (Xie et al., 2012) and was constructed using a maximum likelihood method, assessing the reliability of branches using the bootstrapping method (100 bootstrap replicates).

It is possible that targeted degradation caused by pectate lyases and polygalacturonases, along with changes in the methylation status of pectin induced by pectin methylesterase, could allow sufficient cell-wall softening that could permit initiation of infection. One way in which this could occur is by the growing colonies of rhizobia in infection foci pushing against the weakened cell wall, followed by cell wall and membrane synthesis coordinated via the rearranged cytoskeleton. The observation that with the *L. japonicus npl* mutant some infections appear to initiate after unusually large numbers of bacteria accumulate in infection foci (Xie et al., 2012) gives some support to this hypothesis if one takes the view that larger accumulations of rhizobia can exert greater pressure. Possibly, such stretching of the cell wall could activate localized cell wall loosening that is associated with the growth of new cell walls. Cell walls expand their cell walls by a carefully controlled process of controlled 'polymer creep' in which the actions of expansins and glucosylases allow movements of polymers that can allow the cellulose microfibrils to move apart (Cosgrove, 2005). Induction of an expansin gene has been observed to be induced in *Melilotus alba* within hours of rhizobial inoculation (Giordano and Hirsch, 2004).

The pectin is clearly one of the components of the wall matrix that must be cleaved, but it is not yet clear what other degradative enzymes will be required. It is evident that the normal process of cell wall synthesis (Cosgrove, 2005) must be activated in order to extend the IT. In some regards, making the connection between the existing plant cell wall and the initiating IT cell wall may be analogous to the process by which a newly synthesised cell wall in a dividing plant cell joins up with the existing cell wall. Both situations require remodeling of the walls to allow the new synthesis and polysaccharide linkages that must be made.

58.4 RHIZOBIAL ENZYMES THAT DEGRADE PLANT CELL WALLS

Several rhizobia have genes that are predicted to encode pectin or cellulose degrading enzymes (Fauvart et al., 2009) although in *Rhizobium leguminosarum* bv. *trifolii*, neither activity was found extracellularly (Mateos et al., 1992). One secreted pectin-degrading enzyme (HrpW) identified in *Rhizobium etli* was found to be induced in bacteria on the root surface and is likely to be secreted via a Type 3 secretion system. However, mutation of the *hrpW* gene did not affect nodule infection (Fauvart et al., 2009). Possible pectin-degrading enzymes may enable rhizobia to access pectin-based components during saprophyic growth or may even allow the rhizobia to become more embedded in roots by promoting some pectin degradation. Critical for such activity would be a mechanism of secretion across both rhizobial membranes, but the predicted polygalacturonase in *R. leguminosarum* bv. *viciae* (Fauvart et al., 2009) was not identified as one of the proteins secreted by *R. leguminosarum* bv. *viciae* (Krehenbrink and Downie, 2008).

There is evidence that a rhizobial cellulase in *R. leguminosarum* bv. *trifolii* may play a role in infection

(Robledo et al., 2008) because an in-frame deletion removing the cellulase gene (*celC2*) blocked clover infection. However, the *celC2* gene is located within a cluster of genes involved in cellulose synthesis and cellulose synthesis in bacteria requires cleavage of the cellulose that is made. Indeed, the CelC2 cellulase is required for the normal processing of the rhizobiallymade cellulose (Robledo et al., 2012; see Chapter 53). So the question arises as to whether the infection defect in the *celC2* mutant is due to its anomalous production of extended (uncleaved) cellulose filaments, because cellulose synthesis in the mutant is retained. There is good evidence that cellulose production can impair rhizobial infection of root hairs (Laus et al., 2005) and that completely blocking expression of the cellulose synthesis operon does not affect nodulation by different biovars of *R. leguminosarum* (Ausmees et al., 2001; Laus et al., 2005; Williams et al., 2008). These observations suggest that the loss of infection by the *celC2* mutant could be due to altered bacterial cellulose synthesis rather than a lack of plant cellulose degradation. Nevertheless, it is evident that over-expression of the CelC2 cellulase can cause degradation of root-hair cell walls (Robledo et al., 2011) and so the role of CelC2 in the degradation of plant cell wall cellulose cannot be ruled out.

59.1 INTRODUCTION

Establishment of the Rhizobium–legume symbiosis (RLS) involves both an intracellular infection process whereby rhizobial bacteria enter the host roots from the soil, and a process of cell division in the cortex of roots, termed nodule organogenesis. Rhizobia subsequently fix atmospheric nitrogen in the newly formed root organs called nodules, to the benefit of the host plant. Before these processes occur, there is a molecular dialog between a host plant and its symbiont in the rhizosphere. In this dialog, rhizobia perceive signals secreted from host roots and, in return, produce and secrete signals that are recognized by the plant. These latter signals are lipo-chitooligosaccharide (LCO) molecules called Nod factors (see Chapter 51). Perception of Nod factors by epidermal plant root cells is an essential first step in the symbiotic process, triggering signaling pathways for the establishment of symbiosis. Understanding the developmental pathways involved in the formation of an intracellularly infected new root organ, and how these pathways are activated by Nod factors, is of fundamental and ecological interest. Several legume species have been exploited to study these questions, notably the model plants *Medicago truncatula* and *Lotus japonicus*, together with their corresponding rhizobial symbionts, *Sinorhizobium meliloti* and *Mesorhizobium loti*, respectively. The genetic tools available in these systems have enabled the dissection of both bacterial and plant determinants of nodulation.

59.2 RHIZOBIAL INFECTION AND NODULE ORGANOGENESIS ARE COORDINATED PROCESSES OCCURRING IN DIFFERENT CELL LAYERS OF THE ROOT

Rhizobial mutants that cannot produce Nod factors are completely deficient for both the epidermal infection process and nodule organogenesis in the root cortex (Denarie et al., 1996). However, while rhizobial infection always depends on Nod factor-producing bacteria, the necessity of rhizobia for the induction of nodule organogenesis depends on the plant species (pure Nod factors are active in certain species, while Nod factor-producing rhizobia are required in others). Studies addressing the role of Nod factor structure in these processes have shown that the infection process is generally more reliant on correct Nod factor structures than nodule organogenesis (Ardourel et al. 1994; Oldroyd and Downie, 2008). That is, rhizobial mutants producing slightly modified Nod factors are generally deficient for infection, but are still able to induce nodule organogenesis.

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

However, in such cases, the uninfected nodules that are formed are usually relatively small and often disorganized. One study in *M. truncatula* involving a cortical marker gene, *MtENOD20*, observed cortical cell activation without further nodule organogenesis in response to a certain rhizobial Nod factor mutant, but this mutant induced no epidermal root hair deformation, again showing that cortical responses are less stringent than epidermal ones (Vernoud et al., 1999).

Symbiotic plant genes have been identified that control either rhizobial infection and nodule organogenesis, more specifically just the rhizobial infection process, or just nodule organogenesis. This latter type of gene, together with results from the analysis of rhizobial Nod factor mutants, indicates that epidermal and cortical symbiotic programmes can be uncoupled, with the epidermal infection process apparently being more stringent for Nod factor structure than the process of nodule organogenesis in the root cortex. Plant mutants in the first type of gene are completely deficient for the symbiotic interaction with rhizobia and show very limited or no response to pure Nod factors. Plant mutants in genes that intervene specifically either in the rhizobial infection process or in nodule organogenesis still respond to Nod factors, and although they are primarily blocked either in infection or in nodule organogenesis, these blocks have repercussions on other symbiotic processes such that only small nodules or formed with infection-deficient mutants and infection does not proceed very far in nodulation-deficient mutants. Therefore, these data have not only led to the characterization of epidermal and cortical symbiotic programmes, but have also underlined the necessity of tight coordination between these programmes for a successful interaction. Considering that infection and nodule organogenesis occur simultaneously in different cell layers of the root, with infection then progressing into the nodule primordium formed by cortical cell divisions, it is clear that these processes are interdependent and that there must be mechanisms by which the inner and outer cell layers are coordinated (Oldroyd and Downie, 2008). A recent study has highlighted the coordinating role that bacterial infection exerts on the developing nodule, by describing plant mutants in which defective rhizobial infection is correlated with nodules having central rather than peripheral vascular bundles (Guan et al., 2013). In terms of signaling between the inner and outer cell layers of the root in the early steps of nodulation, the fact that nodule primordium formation precedes infection thread formation indicates an early event of signaling from the epidermis to the inner cell layers of the root. Also, gradients of cell differentiation have been described that show additional waves of signaling, both from the epidermis to inner cells of the root, and for an opposite wave of signaling that travels out from the inner to outer cell layers of the root (Timmers et al., 1999). Indeed, a detailed description of cellular changes occurring during the establishment of nodulation showed that an outward gradient of cell differentiation starts in the pericycle and leads to the formation of a nodule primordium extending from the inner to the middle cortex, while an inward gradient of cell differentiation starts in the outer cortex and results in infection-related cytoskeleton changes that guide the progression of an infection thread into the nodule primordium (Timmers et al., 1999).

59.3 THE NOD FACTOR SIGNALING PATHWAY

The analysis of plant responses to pure Nod factors has shown that many processes are activated, and this has led to a characterization of the different responses as a function of Nod factor concentration and Nod factor structure (D'Haeze and Holsters, 2002). In this way, many, but not all, Nod factor responses are induced by very low Nod factor concentrations, and the majority of responses rely on the same Nod factor structural features that control host specificity. Most responses are detected in epidermal cells, but some can be detected in the cortex and pericycle of the root. The plant genes identified from mutants that are completely deficient in the RLS and show very little or no response to Nod factors, control a Nod factor signaling pathway (Catoira et al., 2000). This pathway is activated via Nod factor perception by plasma membrane-localized receptor proteins, and downstream components of signal transduction, which are largely nuclear components of the cell, are then responsible for the regulation of symbiotic gene expression (Oldroyd, 2013) (Fig. 59.1). Plant genes of the Nod factor signaling pathway are interesting genes for the question of coordination, as they control infection and nodule organogenesis. Moreover, Nod factor signaling appears to occur throughout the process of rhizobial root colonization, not just at the first stages. Studies on these genes by various approaches have provided insights into their roles at different steps of the symbiotic process and in different cell layers of the root.

The Nod factor perception gene, *MtNFP*, is genetically defined as the first gene in the Nod factor signaling pathway in *M. truncatula* (Ben Amor et al., 2003). Models predict that the MtNFP protein is a Nod factor receptor and this is supported by the LysM receptor-like kinase (LysM-RLK) structure predicted for the protein (Arrighi et al., 2006). In *L. japonicus*, the ortholog of MtNFP is called LjNFR5 (Madsen et al., 2003). Nod factor binding was recently reported for LjNFR5, as well as for another symbiotic LysM-RLK protein in *L. japonicus*, called LjNFR1 (Broghammer et al., 2012). Whether MtNFP binds Nod factors is still an open question because several Nod factor-binding sites have been characterized in *M. truncatula* that are independent of MtNFP (Hogg et al., 2006; see Chapter 51). Also, a recently reported role of MtNFP in plant immunity suggests that MtNFP could be a common component of different receptor complexes

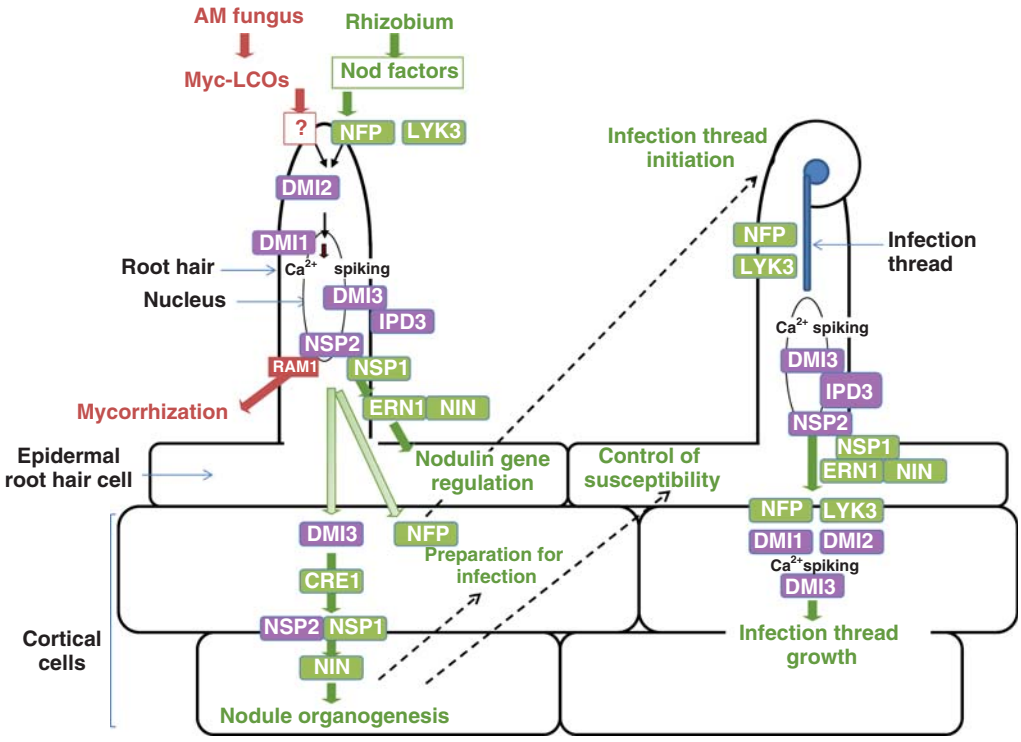

Figure 59.1 Model of early steps of symbiotic signaling in the Rhizobium-legume symbiosis, showing how key components of the plant Nod factor signaling pathway are likely to control nodule organogenesis in the root cortex and infection thread formation in epidermal root hair cells, in response to the perception of Nod factors produced by a rhizobial symbiont. Also shown are the first steps of signaling induced by arbuscular mycorrhizal signals called Myc-LCOs, which involves an as yet unknown Myc-LCO receptor (?), components of the common symbiotic signaling pathway (CSSP) (proteins in purple boxes), and the transcriptional regulator RAM1. Mycorrhizal-specific signaling is depicted in red, while nodulation-specific signaling is depicted in green. Only the *M. truncatula* names of symbiotic plant proteins are given for simplicity. For the activation of nodule organogenesis, Nod factor signaling in a root hair cell generates a secondary signaling mechanism whose interpretation in the root cortex requires DMI3, cytokinin signaling involving the cytokinin receptor CRE1, and the transcriptional regulators NSP1, NSP2 and NIN. For the infection process, the activation of the Nod factor signaling pathway in root hairs leads to the activation of NFP in underlying cortical cells. Cortical NFP, in a Nod factor and DMI3-independent manner, would then signal back to the root hair to control infection thread initiation (dashed line). Infection thread progression in the root hair involves NFP, LYK3, calcium spiking and DMI3, and, subsequently, in response to cortical calcium spiking, cortical DMI3 would be activated to control the progression of the infection thread into the cortex. Bacteria are depicted in blue inside the infection thread. Many other plant genes implicated in the rhizobial infection process are missing from this model. The coordination of epidermal and cortical responses involves as yet unknown mechanisms, but potentially there is signaling from activated cortical cells to control both the susceptibility of the epidermis for infection and the preparation for infection in outer cortical cells (dashed lines).

(Ben et al., 2013; Gough and Jacquet, 2013; Rey et al., 2013). Nonetheless, whatever the molecular function of MtNFP, this protein has a key symbiotic role and *MtNFP* is the only symbiotic gene in *M. truncatula* in which mutants are completely deficient for all symbiotic and Nod factor responses. Furthermore, in *L. japonicus* it was shown that LjNFR5 and LjNFR1 control host specificity, as their transfer into *M. truncatula* enables nodulation by the *L. japonicus* symbiont *M. loti* (Radutoiu et al., 2007).

Downstream of *MtNFP/LjNFR5* is a gene called *MtDMI2* in *M. truncatula* and *LjSYMRK* in *L. japonicus*. The *MtDMI2/LjSYMRK* gene encodes an LRR-RLK, which is a plasma-membrane localised protein, like MtNFP/LjNFR5 (Endre et al., 2002; Stracke et al., 2002). This, together with genetic models, predicts a very early role for MtDMI2/LjSYMRK in Nod factor signaling, although the mechanisms for this are unclear. The Nod factor signaling proteins MtDMI1/LjCASTOR/LjPOLLUX are localized in plant cell nuclei and are involved in the generation of a calcium signal that is induced by Nod factors and is called calcium spiking (Ane et al., 2004; Charpentier et al., 2008; Riely et al., 2007; Venkateshwaran et al., 2012; see Chapter 54). Downstream of *MtDMI1/LjCASTOR/LjPOLLUX* is a gene called *MtDMI3* in *M. truncatula* and *LjCCaMK* in *L. japonicus*. This gene encodes a calcium and calmodulin-dependent kinase that is also localized in plant cell nuclei (Levy et al., 2004; Mitra et al., 2004; Oldroyd and Downie, 2006). A clear role for MtDMI3/LjCCaMK is predicted in the deciphering of the calcium spiking signal, in which the MtIPD3/LjCYCLOPS protein, which is an

interactor of MtDMI3/LjCCaMK (Messinese et al., 2007; Yano et al., 2009), is also implicated.

MtDMI1/LjCASTOR/LjPOLLUX, MtDMI2/LjSYMRK, MtDMI3/LjCCaMK and *MtIPD3/LjCYCLOPS* all control both the RLS and the arbuscular mycorrhizal symbiosis (AMS). As such these genes are part of a common symbiotic signaling pathway (CSSP; also known as CSP or SYM) that is activated in the case of the AMS by mycorrhizal signals called Myc-LCOs, equivalent to Nod factors in the RLS (Fig. 59.1) (Maill et al., 2011; Gough and Cullimore, 2011; Oldroyd, 2013; see Chapters 42, 54, 55, 110). These dual roles of CSSP genes give them a double interest, and to some extent there are similar questions to be addressed in the AMS about signaling between cell layers of the root. *MtDMI3/LjCCaMK* is also particularly interesting as it has been questioned whether MtDMI3 could act as a switch between the CSSP and downstream pathways specific for nodulation and mycorrhization (Godfroy et al., 2006).

The first known components of these downstream pathways are transcriptional regulators. The *NSP1* gene controls a nodulation-specific signaling pathway, while *RAM1* controls a mycorrhization-specific signaling pathway (Gobbato et al., 2012; Heckmann et al., 2006; Smit et al., 2005) (Fig. 59.1). The *NSP2* gene (Kalo et al., 2005; Murakami et al., 2006) was originally thought to act in the same pathway as *NSP1*, but has recently been positioned upstream, as part of the CSSP (Maillet et al., 2011). Both NSP1 and RAM1 interact with NSP2, and they control the transcriptional regulation of nodulation and mycorrhization genes, respectively (Gobbato et al., 2012; Hirsch et al., 2009). Two nodulation-specific genes whose transcriptional regulation is controlled by the NSP1/NSP2 complex are NIN and ERN1 (Andriankaja et al., 2007; Cerri et al., 2012; Hirsch et al., 2009; Marsh et al., 2007; Middleton et al., 2007; Schauser et al., 1999; see Chapter 62) (Fig. 59.1). These are both transcription factors responsible in turn for controlling nodulation-specific signaling downstream of the CSSP (Fig. 59.1). Early "nodulin" genes are among the best characterized genes whose regulation is controlled by the Nod factor signaling pathway in epidermal root hair cells.

This chapter will concentrate on the roles that Nod factor signaling genes play in the RLS, particularly because of the question of coordinating infection with cortical cell divisions, which are absent in the AMS.

59.4 HOW THE EPIDERMAL INFECTION PROCESS IS CONTROLLED BY NOD FACTOR SIGNALING GENES

The strong phenotype of *Mtnfp* mutant plants indicates that MtNFP controls the first step of Nod factor perception, but does not exclude the fact that MtNFP could also intervene in any subsequent steps during the establishment of a symbiotic interaction. Evidence for one or more subsequent roles was provided by a study of the spatio-temporal expression pattern of *MtNFP*. As a potential Nod factor receptor, it was expected that *MtNFP* should be expressed constitutively in epidermal root cells, but interestingly this was not the only profile of expression that was found; *MtNFP* was shown to be expressed throughout the symbiotic interaction with a particularly strong expression in association with the infection process and in cortical cells (Arrighi et al., 2006). This expression pattern inspired studies aimed at deciphering what additional roles MtNFP could play, and whether MtNFP could have distinct epidermal and cortical roles. Firstly, an RNAi approach generated *M. truncatula* roots in which the level of expression of *MtNFP* was reduced. Some of these roots showed the first steps of infection in epidermal root hair cells, but these infections aborted (Arrighi et al., 2006). This showed that MtNFP controls infection as well as early Nod factor signaling, consistent with the fact that Nod factors are produced by rhizobia during infection. Recently, a novel tissue-specific expression approach has addressed the epidermal and cortical roles of MtNFP. For this, *MtNFP* was expressed in *Mtnfp* plants under the control of an epidermal or a cortical-specific promoter, and transformed plants were assessed for their abilities to establish the RLS (Rival et al., 2013, 2012). These experiments produced the intriguing result that epidermal expression of *NFP* was not sufficient to restore rhizobial infection in root hairs. This suggests that NFP fulfills a cortical function in root hair infection and, as it is not expected that Nod factors will reach cortical cells without the presence of rhizobia in infection threads, this cortical role apparently does not involve direct Nod factor perception.

Following the finding that, like *MtNFP*, the *MtDMI3* gene is expressed in both epidermal and cortical *M. truncatula* root cells, a similar tissue-specific expression approach was used with *MtDMI3* (Rival et al., 2013, 2012). In this case, epidermal expression was sufficient to restore rhizobial infection in epidermal root hairs of an *Mtdmi3* mutant, indicating a cell-autonomous role for *MtDMI3* in root hair infection. This is consistent with the induction of calcium spiking in root hair cells. The fact, that the root hair infection threads did not progress into the cortex in plants expressing *MtDMI3* only in the epidermis, is consistent with the observation that calcium spiking is also induced in cortical cells during infection of wildtype plants (Sieberer et al., 2012), and we can hypothesize that MtDMI3 has to be present in the cortex to decipher this calcium spiking. Moreover, a particular frequency of spiking is detected prior to infection of a cortical cell (Sieberer et al., 2012), indicating a role for cortical MtDMI3 in the process of preparation for infection. Other studies on MtDMI3/LjCCaMK have shown the importance of particular domains of the protein for the infection process. Thus, both the truncated

and mutated forms of the MtDMI3/LjCCaMK protein can confer on *MtDMI3/LjCCaMK* mutant plants the ability to form nodules in the absence of rhizobia (Gleason et al., 2006; Tirichine et al., 2007a), but constitutively active forms of the protein that do not carry the regulatory domains can only restore nodulation and not rhizobial infection to *MtDMI3/LjCCaMK* mutants (Takeda et al., 2012). Taken together, activation of the Nod factor signaling pathway in root hairs is necessary, but not sufficient for infection thread initiation. In addition, the underlying cortical cells are apparently somehow involved with an indispensable role of MtNFP (Fig. 59.1).

The epidermal and cortical roles of *MtDMI2/LjSYMRK* are less well characterized, but the expression profile of *MtDMI2* includes epidermal and cortical cells, as well as young nodules and the pre-infection zone of the nodule (Bersoult et al., 2005). Also, the MtDMI2 protein is detected in the plant membrane surrounding infection threads (Limpens et al., 2005). This suggests that MtDMI2 intervenes throughout the symbiotic process, notably in association with infection. The identification of an interesting *LjSYMRK* mutant allele has underlined the important role of this gene during the early steps of infection. The mutation was localized to the extracellular part of the protein, just before the LRR region in a conserved GDPC sequence (Kosuta et al., 2011). Plants carrying this mutation are defective for rhizobial infection of root hairs, but, interestingly, are still able to form nodules, and this latter ability was correlated with low calcium spiking activity (Kosuta et al., 2011). Considering that MtDMI2/LjSYMRK is implicated in generating the calcium spiking signal (Hayashi et al., 2010), and calcium spiking is associated with cortical cells during infection (Sieberer et al., 2012), LjSYMRK/MtDMI2 probably controls both root hair infection and the progression of infection threads across cortical cells. The role of MtDMI2 in nodule infection has also been studied, using an RNAi approach (Limpens et al., 2005). Here, it was shown that MtDMI2 is involved in the formation of symbiosomes, which are organelle-like elements formed by the release of rhizobia from infection threads into the host cells of the nodule. A similar block in symbiosome formation was observed in *DMI2* knock-down lines of the tropical legume *Sesbania rostrata* (Capoen et al., 2005).

Another important genetic component of the infection pathway in *M. truncatula* is the *MtLYK3* gene, which encodes a LysM-RLK very similar to LjNFR1. *Mtlyk3* mutants show normal responses to pure Nod factors, unlike *Ljnfr1* mutants that show practically the same absence of response phenotype to Nod factors as *Ljnfr5* and *Mtnfp* mutants (Radutoiu et al., 2003). This indicates that in *L. japonicus* both LjNFR5 and LjNFR1 control the Nod factor signaling pathway, while in *M. truncatula* MtLYK3 either has no role or a redundant role in Nod factor signaling (Fig. 59.1). Strong *Mtlyk3* mutants show no infection thread initiation, while a weak *Mtlyk3* allele and RNAi plants show some aborted and abnormal infection threads (Catoira et al., 2001; Limpens et al., 2003; Smit et al., 2007). This indicates that wildtype levels of MtLYK3 are needed for normal infection thread formation. Interestingly, these infection defects are more pronounced with rhizobia producing Nod factors with modifications to their structure, indicating a role for LYK3 in recognizing Nod factor structure and making LYK3 a good candidate for a Nod factor receptor controlling the infection process (Limpens et al., 2003; Smit et al., 2007). *Mtlyk3* mutants also show polarity defects in outer cortical cells that are normally associated with the preparation for infection (Catoira et al., 2001), raising the question of whether the function of MtLYK3 to prepare outer cortical cells for infection contributes to the absence of infection threads in mutants. Before rhizobial infection, the LYK3 protein is detected in mobile *puncta* on the plasma membrane of root hair cells (Haney et al., 2011). After rhizobial inoculation these *puncta* become stable, in association with a co-localization of MtLYK3 with flotillin-like 4 (FLOT4). MtLYK3 has also been shown to interact with a remorin protein, MtREM1 (Lefebvre et al., 2010), and as FLOT4 and MtREM1 both have roles in rhizobial infection and are both associated with lipid raft microdomains of membranes, it seems that the recruitment of MtLYK3 to lipid rafts could be important for rhizobial infection. How this could lead to the induction of polarity changes in underlying cortical cells remains to be elucidated.

59.5 HOW THE CORTICAL PROGRAMME OF NODULE ORGANOGENESIS IS CONTROLLED BY NOD FACTOR SIGNALING GENES

Although it has been known for a long time that a functional *MtNFP* gene is needed for nodule organogenesis (Ben Amor et al., 2003), the mechanism for this has only recently been studied. Using tissue-specific promoters, it was shown that epidermal expression of *MtNFP* was sufficient for the activation of cortical cell divisions leading to nodule primordia formation (Rival et al., 2012). This suggests that one function of epidermal NFP is a non-cell autonomous function to generate a secondary signal whose perception is NFP-independent in the root cortex for nodule organogenesis (Fig. 59.1).

Concerning MtDMI3/LjCCaMK, the demonstration that constitutively active forms of the CCaMK can induce spontaneous nodulation in the absence of rhizobia in both *M. truncatula* and *L. japonicus* (Gleason et al., 2006; Tirichine et al., 2007a), demonstrates an important role of MtDMI3/LjCCaMK in nodule organogenesis (see Chapter 54). This spontaneous nodulation is independent of upstream Nod factor signaling genes, including *MtDMI1/LjCASTOR/LjPOLLUX* and *MtDMI2/LjSYMRK*,

indicating that the main role of these components is the activation of the CCaMK (Hayashi et al., 2010; Madsen et al., 2010). This spontaneous nodulation is, however, dependent on downstream components, including NIN (Marsh et al., 2007). A key role of cytokinin in nodule organogenesis was also shown by the ability of constitutively active forms of the cytokinin receptor MtCRE1/LjLHK1 to induce spontaneous nodulation in legume plants in the absence of rhizobia (Gonzalez-Rizzo et al., 2006; Murray et al., 2007; Tirichine et al., 2007b). Both NIN and NSP2 are required for the spontaneous nodule organogenesis activated by gain-of-function mutations in MtCRE1/LjLHK1 (Madsen et al., 2010; Tirichine et al., 2007b), while MtCRE1/LjLHK1 is required for spontaneous nodulation with gain-of-function CCaMK (Hayashi et al., 2010). More recently, it was shown that the exogenous application of cytokinin can also induce nodule primordia in *L. japonicus* (Heckmann et al., 2011). Cytokinin-induced nodule primordia formation was maintained in several loss-of-function mutants impaired in epidermal responses including *LjNFR5*, *LjSYMRK* and *LjCCaMK* mutants. However, the absence of primordia in *Ljnsp1*, *Ljnsp2*, and *Ljnin* mutants confirmed the requirement for these transcriptional regulators in the cytokinin-mediated activation of the root cortex. The epidermal and cortical responses were distinguished further when it was shown that external cytokinin application induced the expression of the *NIN* gene within the root cortex, but not in the root epidermis (Heckmann et al., 2011; see also Chapter 56). This, together with other data, positions the cytokinin receptor MtCRE1/LjLHK1 after CCaMK in the signal transduction pathway, and positions the nodule organogenesis activity of the transcription regulators NSP1, NSP2 and NIN, downstream of the cytokinin signal and in cortical cells (Ariel et al., 2012; Hayashi et al., 2010; Madsen et al., 2010; Plet et al., 2011) (Fig. 59.1).

The role of the CCaMK upstream of cytokinin signaling led many models to predict that the role of MtDMI3 in activating cytokinin signaling was restricted to the epidermis. However, the tissue-specific promoter approach showed that *MtDMI3* has to be expressed both in the epidermis and in the cortex for nodule organogenesis (Rival et al., 2012). Taken together, cortical MtDMI3 intervenes in decoding a secondary signal generated by MtNFP and MtDMI3 in the epidermis (Fig. 59.1). This is followed by the activation of cytokinin signaling in the cortex and then by the intervention of the transcription regulators NSP1, NSP2 and NIN, leading to nodule organogenesis (Fig. 59.1). The role of NIN in nodule organogenesis was supported by recent data that showed that NIN over-expression induced root nodule primordium-like structures that originated from cortical cells in the absence of bacterial symbionts (Soyano et al., 2013). This work also indicates that NSP1 and NSP2 act upstream of NIN for nodule organogenesis, and identified two transcriptional targets of NIN that function to stimulate cell division for nodule organogenesis.

59.6 CONCLUSION

Recent data in model legumes have shed light on the roles played by Nod factor signaling genes in the epidermal and cortical symbiotic programmes involved in the establishment of the RLS. In several cases these roles have been pinpointed to the epidermis or to the cortex, with some genes having different roles depending on the tissue. For example, NSP1 and NSP2 control early steps of Nod factor signaling in the epidermis (leading, for example to epidermal nodulin gene induction), while in the cortex they act downstream of the cytokinin receptor for nodule organogenesis. The NIN protein also has dual roles, being essential in the epidermis for rhizobial infection, and controlling nodule organogenesis in the cortex. In addition, both cell autonomous and non-cell autonomous functions have been identified for certain plant genes. For example, nodule organogenesis in the cortex is controlled non-cell autonomously by epidermal MtNFP, while the epidermal rhizobial infection process requires expression of MtNFP both in the epidermis and in the cortex. In this way, both root tissues are implicated in epidermal and cortical symbiotic programmes.

For the infection process in epidermal root hairs, the roles of MtNFP and MtLYK3 in controlling cortical processes underline the importance of the activation of the cortex prior to the infection process. This activation involves pre-infection thread (PIT) formation characterized by polar cytoskeleton rearrangements (Timmers et al., 1999). While the cortical role of MtNFP requires expression in the cortex of the *MtNFP* gene, this question has yet to be addressed for MtLYK3. Another future challenge is to understand how cortical MtNFP controls the process of infection thread initiation, apparently without direct Nod factor perception. As an infection thread develops in an epidermal root hair cell, calcium spiking is induced in underlying cortical cells, and the frequency of the spikes increases to the same frequency as observed with pure Nod factors just before such cells become penetrated (Sieberer et al., 2012). This, together with the necessity of *MtDMI3* expression in both tissues, underlines the importance of Nod factor signaling throughout rhizobial infection in both the outer and inner cell layers of the root (Fig. 59.1). Furthermore, there are specificities in Nod factor signaling mechanisms induced early by pure Nod factors and those implicated in rhizobial infection, as illustrated recently by the study of the promoter region of an early nodulin gene, *MtENOD11*. In response to pure Nod factors the regulation of this gene is controlled by NSP1, NSP2 and ERN1 and involves a regulatory promoter element called the “NF box”, while in response to rhizobium *MtENOD11* induction is controlled by NSP1 and NSP2,

but independently of ERN1, and via a different regulatory region of the promoter region, called "INF" (Cerri et al., 2012).

Future challenges also include the identification of the signaling mechanism by which epidermal MtNFP communicates with the cortex for nodule organogenesis, and the mechanism by which this signal is intercepted in the cortex. The fact that MtDMI3 is indispensable in the cortex for the interpretation of this signal into nodule organogenesis indicates that calcium signaling will be involved. Clearly, cytokinin signaling is subsequently activated in the cortex, and the activity of the transcription regulators NSP1, NSP2 and NIN then leads to the induction of cortical cell divisions for nodule organogenesis (Fig. 59.1).

In summary, rhizobial Nod factors are first perceived by root epidermal cells, and this results in the activation of signaling mechanisms in epidermal and cortical cells, which leads to the establishment of a successful symbiotic interaction. Interestingly, there are signaling mechanisms activated in the cortex both for cortical cell division leading to nodule organogenesis and for epidermal root hair infection. In this way, both tissues take part in controlling a symbiotic process occurring in the other root tissue, and the mechanisms by which the epidermis and the cortex communicate with other for these shared roles contributes to the coordination of rhizobial infection and nodule organogenesis for a successful symbiotic interaction. Many details are still missing concerning the regulatory mechanisms that limit the area of root susceptibility to Nod factor signaling to ensure, for example, the formation of discrete nodule primordia, and the formation of infection threads uniquely above developing primordia (Fig. 59.1). However, NIN has been implicated in such spatial control and a model was suggested in which Nod factor-induced cytokinin signaling could influence epidermal susceptibility to rhizobial infection by participating in the mechanisms that regulate NIN activity (Frugier et al., 2008). More generally, cytokinin signaling could have a role in infection thread formation, and could therefore play a role in coordinating infection and nodule organogenesis (Murray, 2011; see Chapter 56). Cytokinin signaling is also implicated in the control of nodule numbers by interaction with CLE peptides (Mortier et al., 2012). The mechanisms underlying outer and inner cell layer coordination should be better understood in the future with further use of tissue-specific promoters or other tissue-specific approaches such as laser micro-dissection or fluorescence-associated cell sorting (FACS).

60.1 INTRODUCTION

Legume plants are able to form two different types of secondary organs on their roots: lateral roots (LRs) and symbiotic nitrogen-fixing root nodules. The latter depend on the presence of microsymbiont partners: bacteria called rhizobia. After exchange of specific molecular signals between the rhizobia and host legume, legume root hairs curl, trapping rhizobia in so-called shepherd's crook structures. The legume cell walls breach, initiating the development of infection threads (ITs), enabling the rhizobia to invade the plant root tissue and travel to newly divided root cortical cells. There, rhizobia become encapsulated in plant membranes into host cells, via an endocytosis-like event, forming symbiosomes that resemble acquired organelles. In indeterminate nodules, a persistent nodule meristem and characteristic nodule zones develop from the nodule primordium (Vasse et al., 1990). Both symbiotic partners undergo developmental changes that culminate in the acquisition of nitrogen-fixing ability by the rhizobia (Jones et al., 2007; Oldroyd et al., 2011; see also Chapter 59).

Similarly to nodules, LRs develop adjacent to xylem poles and are initiated as primordia, developing recognizable meristems at their distal ends (Laskowski et al., 1995; Malamy and Benfey, 1997; Malamy, 2005). Because of these shared features, it has been speculated that nodules originated evolutionarily from modified LRs (Hirsch and LaRue, 1997; Mathesius et al., 2000; Szczyglowski and Amyot, 2003), although there are significant differences in the anatomical features of the two types of organs. Despite these differences, a number of legume mutants have been identified that have defects involving both nodulation and LR development, lending support for this idea (Penmetsa et al., 2003; Gonzalez-Rizzo et al., 2006; Couzigou et al.,

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

2012). Among these are the *Medicago truncatula nip* and *latd* mutants (Veereshlingam et al., 2004; Bright et al., 2005; Teillet et al., 2008), encoding the MtNIP/LATD (NUMEROUS INFECTIONS AND POLYPHENOLICS/LATERAL ROOT-ORGAN DEFECTIVE) transporter (Yendrek et al., 2010; Bagchi et al., 2012).

Nitrate is both a nitrogen source and a signal that modulates root system development. Nitrate affects root architecture differently if it is applied locally or systemically. High nitrate concentrations supplied locally stimulate LR elongation; in contrast, high nitrate supplied systemically has an inhibitory effect on LR development which increases with nitrate concentration and is especially apparent at high (over 10 mM) nitrate concentrations (Zhang et al., 2000, 2007; Remans et al., 2006; Tsay et al., 2011). While nitrate at concentrations ≥ 1 mM suppresses both incipient nodule development and nitrogen fixation in established nodules (Harper and Gibson, 1984; Streeter, 1988; Fei and Vessey, 2008), there have been suggestions that it may have a different function at lower concentrations (Horchani et al., 2011; Meilhoc et al., 2011). One potential role is as a nitrogen source. The rapidly dividing rhizobia and plant cells in nodule (and LR) primordia constitute nitrogen sinks because of the need for protein and nucleic acid biosynthesis. A second role for the nitrate is as a precursor for nodule nitric oxide (del Giudice et al., 2011; Meilhoc et al., 2011; Cam et al., 2012; see Chapter 64). A third possible role for nitrate is as a participant in an alternative nitrate–nitric oxide respiration pathway recently proposed to be operating in the hypoxic nodule environment (Horchani et al., 2011; Meilhoc et al., 2011). Further, nitrate reductase activity has been linked to nitrogen fixation activity in functional nodules (Cheniae and Evans, 1960) and it could operate in this pathway (Horchani et al., 2011). Thus, nitrate has effects on both LRs and nodules.

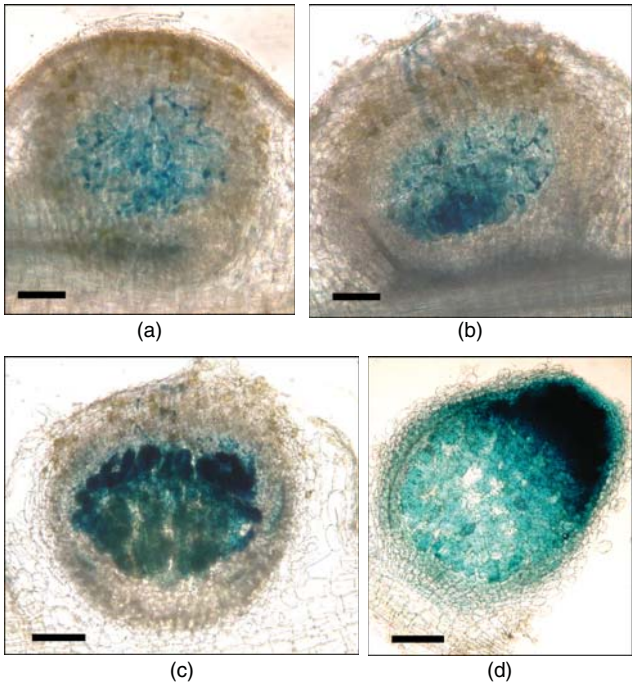

Figure 60.1 Phenotypes of *Mtnip* and *Mtlatd* nodules. *M. truncatula* plants were nodulated with *S. meliloti* containing a constitutive *lacZ* reporter gene. At 15 days post-inoculation, nodule characteristics of mutants were compared to wild-type. The localization of rhizobia was shown by X-Gal staining for the *lacZ*-containing rhizobia, resulting in a blue color. (a) *Mtnip-1*, (b) *Mtlatd*, (c) *Mtnip-3*, (d) Wild-type A17. Bar = 400 μm.

60.2 *Mtnip/latd* MUTANTS' PHENOTYPES

M. truncatula nip and *latd* mutants have defective nodules and root architecture (Haynes et al., 2004; Veereshlingam et al., 2004; Bright et al., 2005; Teillet et al., 2008). When grown without sufficient nitrogen (N), the *Mtnip-1* mutant showed N-deficiency symptoms, even in the presence of *Sinorhizobium meliloti*, *M. truncatula*'s symbiotic partner. Examination of *Mtnip-1*'s small brown bump-like nodules by conventional light-, confocal- and electron microscopy demonstrated that *Mtnip-1* mutants initiated symbiotic interactions, forming nodule primordia containing abnormally proliferative ITs that ultimately failed to deposit rhizobia within host cells (Fig. 60.1a). The ITs in the *Mtnip-1* mutant nodules were observed to be swollen compared to normal ITs in wild-type controls (Haynes et al., 2004; Veereshlingam et al., 2004). It is important to note that even the primary ITs that facilitate movement of rhizobia into the host root/developing nodule in *Mtnip-1* were observed to have abnormal morphology, indicating that the defect in *Mtnip-1* nodule ITs affects the entire rhizobial infection process (Veereshlingam et al., 2004). In the rare cases where rhizobial release occurred, neither host cells nor rhizobia appeared to develop further (Veereshlingam et al., 2004). *Mtnip-1* nodules lacked the hallmarks of differentiated tissues: no identifiable nodule meristem, invasion zone or other central nodule zones were observed (Veereshlingam et al., 2004). Histochemical staining showed that nodules accumulated polyphenolics, characteristic of a defense response. In addition, expression analyses of selected *M. truncatula* genes revealed that *Mtnip-1* nodules expressed only a subset of nodule-specific genes, indicating a block in nodule differentiation (Veereshlingam et al., 2004). A more recent study monitored the localization of MtENOD8-SP-GFP (Early NODulin 8's Signal Peptide fused to Green Fluorescent Protein) and found that it trafficks to the vacuole in root cells or to the symbiosome space in infected nodule cells. ENOD8-SP-GFP was found to localize to the vacuole in *Mtnip-1* nodule primordia cells, suggesting that *Mtnip-1* nodule cells retain root-like/nodule primordium cell characteristics (Meckfessel et al., 2012).

Mtnip-1 displays defective LRs and a semi-penetrant defect in primary root length. Complementation testing showed that *Mtnip-1* was allelic to *Mtlatd* (Veereshlingam et al., 2004), allowing a more thorough investigation of the function of this gene.

Mtlatd is the most severely affected of the mutants. Its nodules are similar to those of *Mtnip-1* (Fig. 60.1b) and were found not to express *S. meliloti bacA* and *nex38* genes, indicating that *Mtlatd* nodule primordia contain rhizobia that fail to make the developmental transition from free-living to symbiotic rhizobia. Rhizobia infecting *Mtlatd* primordia also fail to express *nifH* and thus fail to fix nitrogen (Bright et al., 2005).

Defective root architecture has been very well characterized in *Mtlatd*: LRs in *Mtlatd* are initiated, but arrest as short stumps. Primary *Mtlatd* roots appear to be normal at 3 days post-germination, but by 13 days, more than half cease growth and have deformed root tips. By 22 days post-germination, all *Mtlatd* plants were found to have profound primary root tip defects and to have stopped growth (Bright et al., 2005). *Mtlatd* root hair development was also abnormal. Microscopic examination of both primary and LRs revealed highly disorganized root tips that did not contain identifiable meristems. Thus, it was established that *MtNIP/LATD* is essential for the development and/or maintenance of all root meristems: those of the primary root, LRs and nodules (Bright et al., 2005).

Both *Mtnip-1* and *Mtlatd* were shown to have normal responses to ethylene inhibitors and precursors (Veereshlingam et al., 2004; Liang et al., 2007), suggesting that the ethylene response is normal in the mutants. In legumes and nodulating nonlegumes, abscisic acid (ABA), stimulates LR development, which is opposite to its role in root development in other plants (Liang and Harris, 2005). Interestingly, ABA was found to rescue the root architecture defects in *Mtlatd*, but not the nodulation defects (Liang et al., 2007), which has led to the hypothesis that *MtNIP/LATD* has a role in ABA signaling (Liang et al., 2007; Harris and Dickstein, 2010; Boursiac et al., 2013). In this regard, it is important to note that ABA interferes with Nod factor signaling (Ding et al., 2008; see also Chapter 56) which is essential to the earliest steps in nodulation, prior to the block to nodule development found in *Mtnip/latd* mutants.

Mtnip-3 is the weakest allele of the three existing mutants. It has shorter LRs and primary roots than wild-type, but the roots are not as defective as those of *Mtnip-1* and *Mtlatd*. *Mtnip-3* has Fix+/− nodules that were found to fix about 6% of the acetylene as wild-type in the acetylene reduction assay (Teillet et al., 2008). *Mtnip-3* nodules contain obvious meristems and invaded cells with rhizobia in symbiosomes, but also have the brown pigmentation characteristic of *Mtnip/latd* mutants (Fig. 60.1c) (Teillet et al., 2008).

Collectively, the nodule phenotypes found in the *Mtnip/latd* mutants show a correlation between the release of rhizobia into symbiosomes and the formation of a persistent nodule meristem, suggesting that these developmental hallmarks in nodulation are causally linked. The phenotypes also demonstrate that root and nodule meristems share a common genetic determinant (Veereshlingam et al., 2004; Bright et al., 2005; Teillet et al., 2008).

60.3 MtNIP/LATD PROTEIN, A MEMBER OF THE NRT1(PTR) TRANSPORTER FAMILY

MtNIP/LATD was cloned using a map-based approach and found to encode a member of the nitrate transporter 1(peptide transporter) (NRT1(PTR)) family. The protein is predicted to have eleven transmembrane domains, with a long external *N*-terminal domain and a large cytosolic loop between the fifth and sixth transmembrane domains (Fig. 60.2) (Yendrek et al., 2010). *Mtlatd*, the most severe allele, has a nonsense mutation in *MtNIP/LATD*, rendering it a null mutant, while both *Mtnip-1* and *Mtnip-3* have missense mutations. *MtNIP/LATD* was found to be widely expressed in many tissues of *M. truncatula* and to be repressed by auxin and ABA and up-regulated by cytokinin (Harris and Dickstein, 2010; Yendrek et al., 2010). Its expression was unaffected by nitrate, which is different from many other studied nitrate transporters in the NRT1(PTR) family (Tsay et al., 2011). The use of *MtNIP/LATD* promoter-*GFP* fusions established high levels of *MtNIP/LATD* expression in the nodule, primary root and LR meristems and the surrounding cells (Yendrek et al., 2010).

60.4 MtNIP/LATD BIOCHEMICAL FUNCTION(S)

The NRT1(PTR) family is large, comprising 53 members in *Arabidopsis* and at least 80 members in rice (Tsay et al.,

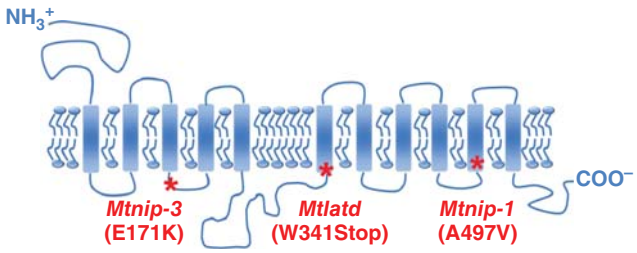

Figure 60.2 The predicted MtNIP/LATD transporter. The protein is predicted to have 11 transmembrane domains, with a long external *N*-terminal domain and a large cytosolic loop between the fifth and sixth transmembrane domains. The positions of the mutations in the *Mtnip/latd* mutants are shown.

2011). Family members that have been functionally studied mediate H^+- dependent transport of nitrate, peptides (Waterworth and Bray, 2006; Tsay et al., 2007), dicarboxylates (Jeong et al., 2004), auxin (Krouk et al., 2010), ABA (Kanno et al., 2012), and glucosinolates (Nour-Eldin et al., 2012). One NRT1(PTR) member, AtNRT1.1, has been shown to serve as a nitrate sensor (Ho et al., 2009). The predicted MtNIP/LATD protein is found in a phylogenetic clade in which the biochemically characterized members are low-affinity nitrate and glucosinolate transporters (Tsay et al., 2007; Yendrek et al., 2010; Nour-Eldin et al., 2012).

Mtnip/latd mutants were investigated for their LR responses when nitrate was provided at low (250 μM) and high (5 mM) concentrations and it was found they were more defective in their responses to low than to high nitrate (Bagchi et al., 2012). However, the mutants displayed no differences in their abilities to take up nitrate from the medium at either concentration (Bagchi et al., 2012).

The *Xenopus laevis* oocyte is a powerful system to functionally assess transporters (Sobczak et al., 2010). Expression of *MtNIP/LATD* in *X. laevis* oocytes demonstrated that it conferred on the oocytes pH-dependent high-affinity nitrate transport with a Km of 160 μM (Bagchi et al., 2012), which is below the concentration at which nitrate becomes inhibitory to nodulation. Mutant *Mtnip/latd* alleles were also tested in the oocyte system: oocytes expressing the more severe mutant *Mtnip-1* and *Mtlatd* alleles were unable to take up nitrate from the medium, but oocytes expressing the less severe *Mtnip-3* allele were not distinguishable in their nitrate transport properties from oocytes expressing the wild-type *MtNIP/LATD* gene (Bagchi et al., 2012). Taken together, these data demonstrate that MtNIP/LATD functions as a high affinity nitrate transporter and suggest that it has another function besides nitrate transport into the plant root.

Functional nitrate transport in plants can be assessed through the use of chlorate. Chlorate is an herbicide that is taken up through the major nitrate transporter, AtNRT1.1(CHL) in *Arabidopsis*, where it is reduced to toxic chlorite that kills the plant (Tsay et al., 1993). *Atchl1-5* mutants contain a deletion that spans the *AtNRT1.1(CHL)* gene and are resistant to chlorate (Munos et al., 2004). Wild-type *MtNIP/LATD*, the strong mutant allele *Mtnip-1*, and the weak allele *Mtnip-3* were each tested by constitutive expression in the *Atchl1-5* mutant to determine if each was able to restore chlorate susceptibility to the *Atchl1-5* mutant. The null mutant allele *Mtlatd*, with a stop codon in the middle of the coding region (Fig. 60.2), was not tested. Results showed that both *MtNIP/LATD* and the weak mutant allele *Mtnip-3*, restored chlorate susceptibility while the strong mutant allele *Mtnip-1* did not (Bagchi et al., 2012; Salehin et al., 2013). These data show that MtNIP/LATD transports the nitrate analog chlorate *in planta*, thus strongly suggesting that MtNIP/LATD transports nitrate *in planta* as well. Because Mtnip-3 is proficient at chlorate transport *in planta*, but the *Mtnip-3* mutant has a nodule phenotype, it also suggests that MtNIP/LATD has another function besides nitrate transport.

Another experimental approach supports the hypothesis that MtNIP/LATD may function as a nitrate transporter *in planta*: *AtNRT1.1(CHL)*, encoding a well-characterized dual-affinity nitrate transporter ((Liu et al., 1999; Liu and Tsay, 2003), was constitutively expressed in *M. truncatula Mtnip-1* mutant roots and found to partially rescue the root architecture phenotype of *Mtnip-1*. However, there was no effect on the nodulation phenotype, while in the controls that constitutively expressed *MtNIP/LATD,* full complementation was observed (Bagchi et al., 2012). These experimental results are confounded by the possibility that *AtNRT1.1(CHL)* mRNA or its product may not be stable in nodules and also by the observation that AtNRT1.1(CHL) transports auxin (Krouk et al., 2010).

Several other possible substrates for MtNIP/LATD have been experimentally tested. *X. laevis* oocytes expressing *MtNIP/LATD* were found to be unaltered in their ability to take up histidine (Bagchi et al., 2012), an amino acid transported by *Brassica napus* and rat NRT1(PTR) proteins (Yamashita et al., 1997; Zhou et al., 1998), as well as several peptide transporters (Tsay et al., 2007). This result suggests that MtNIP/LATD does not transport histidine. Attempted complementation of *Mtnip-1* root systems with *AgDCAT1* cDNA, encoding a dicarboxylate transporter (Jeong et al., 2004) and with *AtNRT2.1* cDNA, encoding a high-affinity nitrate transporter (Kotur et al., 2012; Laugier et al., 2012) did not result in any change in the *Mtnip-1* phenotype (Bagchi et al., 2012; Salehin et al., 2013). While these latter results might suggest that MtNIP/LATD transports neither dicarboxylates nor nitrate at high affinity, they are not conclusive. Indeed, AtNRT2.1 has been recently shown to require AtNAR2.1 for activity (Kotur et al., 2012) and the stability of *AgDCAT1* and its encoded protein in *M. truncatula* are unknown.

60.5 SUMMARY AND PERSPECTIVES

MtNIP/LATD is essential for nodulation and root architecture development. It regulates the development and/or maintenance of the primary root, LR and nodule meristems. It also controls the deposition of rhizobia from ITs into symbiosomes via infection droplets during nodulation and the development of nodule primordia into differentiated nodule cells; it is possible that that these latter blocks to nodule development are consequences of a primary defect in the formation of a nodule meristem. Two mutants, *Mtnip-1* and *Mtlatd*, have severe defects, with *Mtlatd* a null mutant.

The third mutant, *Mtnip-3* has less severe defects (Veereshlingam et al., 2004; Bright et al., 2005; Teillet et al., 2008). *MtNIP/LATD* was cloned and encodes a transporter in the broad-spectrum substrate NRT1(PTR) transporter family (Yendrek et al., 2010) that has a broad spectrum of substrates. It is the first member of the NRT1(PTR)family that has been identified as a high-affinity nitrate transporter and evidence points to its having a second function (Bagchi et al., 2012; Salehin et al., 2013). It has been speculated that MtNIP/LATD might transport a hormone essential for meristem and nodule development (Harris and Dickstein, 2010). Alternatively, it may serve as a nitrate or nitrogen sensor (Bagchi et al., 2012).

What role could MtNIP/LATD transport of low concentrations of nitrate serve? One possibility is that the low nitrate concentration transported may provide bioavailable nitrogen precursors for needed protein and nucleic acid biosynthesis in the dividing cells in meristems and nodules (Bagchi et al., 2012). Another possibility is that the transported nitrate might be a source of nitric oxide. Yet another is that MtNIP/LATD nitrate transport could participate in a nitrate–nitric oxide respiration pathway recently proposed to exist in nodules (Horchani et al., 2011; Meilhoc et al., 2011; Bagchi et al., 2012; see Chapter 64). Future work is aimed at identifying the second function of the MtNIP/LATD protein and understanding its role in nodule and LR development more fully.

61.1 INTRODUCTION

The unique and complex interactions between legume roots and rhizobia lead to the development of a special organ, the root or stem nodule, where rhizobia convert atmospheric dinitrogen into ammonium ion. Symbiotic nitrogen fixation allows the host plants to grow to maturity without the need of exogenous nitrogen fertilizer application. Genetic and genomic studies on nodulation in the model legumes of *Lotus japonicus* and *Medicago truncatula* have identified a set of plant genes essential for the perception and signal transduction of rhizobial Nod factors (Oldroyd et al., 2005; Stacey et al., 2006; see Chapter 59). NFR1 and NFR5 of *L. japonicus* (Madsen et al., 2003; Radutoiu et al., 2003; Radutoiu et al., 2007) and LYK3 and NFP of *M. truncatula* (Amor et al., 2003; Arrighi et al., 2006; Smit et al., 2007; see Chapter 51) are receptor-like kinases that have been shown to serve as the putative receptors for Nod factors. Recent studies have shown that several downstream components of the Nod factor signal transduction pathway also function in the signaling pathway that leads to the establishment of arbuscular mycorrhizal (AM) symbiosis (Kistner and Parniske, 2002; Banba et al., 2008). These protein components form a "common symbiosis pathway" (CSP) (also known as CSSP or SYM pathway; see Chapters 42, 55, 59, 110) that is responsible for relaying the symbiotic signals coming from either the nitrogen-fixing rhizobia or the nutrient-beneficial AM fungi. The shared CSP components include putative ion channels (DMI1/POLLUX and CASTOR) (Ane et al., 2004; Imaizumi-Anraku et al., 2005), LRR Receptor-like kinases (SYMRK/DMI2/NORK) (Endre et al., 2002; Stracke et al., 2002), nucleoporins (NUP133 and NUP85) (Kanamori et al., 2006; Saito et al., 2007), a Ca2+/calmodulin(CaM)-dependent protein kinase (CCaMK/DMI3) (Levy et al., 2004; Mitra et al., 2004; Tirichine et al., 2006), and a nuclear localized coiled-coil protein (CYCLOPS/IPD3) (Messinese et al., 2007; Yano et al., 2008; see Chapters 42, 55, 110).

Following the "CSP", two GRAS family transcriptional regulators NSP1 and NSP2 (nodulation signalling pathway 1 and 2) participate in the nitrogen fixation symbiosis pathway downstream of CCaMK (Kalo et al., 2005; Smit et al., 2005;

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

Heckmann et al., 2006; see Chapter 59). Analyses of the NSP1 and NSP2 mutants show that both of them are required for infection thread (IT) growth, Nod factors-induced gene expression, and initiation of nodule primordia, but not for root hair deformation, or calcium influx and spiking (Kalo et al., 2005; Smit et al., 2005; see Chapter 59). Interestingly, NSP2 has recently been shown to promote root colonization by mycorrhizal fungi (Maillet et al., 2011), implicating a role of NSP2 in the AM symbiosis. This suggests that NSP2 does not function exclusively in the nitrogen fixation symbiosis.

GRAS proteins are a family of key plant-specific transcription regulators. They are named after the first three members of the family: GAI (GIBBERELLIC ACID INSENSITIVE), RGA (REPRESSOR of GAI) and SCR (SCARECROW). GRAS proteins play diverse roles in root and shoot development, and in transduction of the gibberellic acid (GA) and phytochrome A signals (Bolle, 2004). The property of intercellular movement through plasmodesmata is a prominent character for GRAS domain proteins (Gallagher and Benfey, 2009). At least 33 and 60 GRAS genes have been identified in *Arabidopsis* and rice, respectively (Tian et al., 2004). Potential orthologs of NSP1 and NSP2 can be found in many nonlegume plant species, including *Arabidopsis* and rice (Kalo et al., 2005; Smit et al., 2005; Heckmann et al., 2006; Murakami et al., 2006). Rice NSP1 and NSP2 are able to fully rescue the nodule symbiosis-defective phenotypes of *L. japonicus nsp1* and *nsp2* mutants (Yokota et al., 2010), indicating that both proteins are functionally conserved in higher plants. Consistent with this, it has recently been found that NSP1 and NSP2 are indispensable for strigolactone (SL) biosynthesis in *M. truncatula* and in rice (Liu et al. 2011).

NIN (nodule inception) is another putative transcriptional regulator that is specific for the root nodule symbiosis. NIN protein shows some similarity to Notch and SREBP (sterol responsive element binding protein) transcription factors in animals. The predicted DNA-binding/dimerization domain of NIN proteins contains a consensus motif conserved in plant proteins and has been implicated in nitrogen-controlled development (Schauser et al., 1999; Marsh et al., 2007). It remains unclear what the exact function of NIN protein is and how it becomes activated. However, the *nin* mutants show unusually excessive root hair curling, abortive infection, and no cortical cell division (CCD) (Schauser et al., 1999; Marsh et al., 2007). *NIN* expression is strongly induced upon inoculation of rhizobia or application of Nod factors, and this induction requires NSP1 and NSP2 (Murakami et al. 2006; Hirsch et al., 2009). *NIN* is also up-regulated by cytokinins and may mediate the crosstalk between Nod-factor and cytokinin signals (Gonzalez-Rizzo et al., 2006; Tirichine et al., 2007; see Chapter 56).

In addition to NSP1, NSP2 and NIN, recent studies have identified more transcriptional regulators required for nodule symbiosis. The *M. truncatula bit1* (*branching infection threads 1*) alleles carry a loss-of-function mutation in the *ERN* (*ERF required for nodulation*) gene, which is identical to *Mt ERN1*, which encodes a transcription factor in the AP2/ERF (APETALA 2/ethylene response element) family that acts downstream of CCaMK-dependent Nod factor signaling (Middleton et al., 2007; see Chapter 62). A parallel study using the yeast one-hybrid screening system shows that three closely related AP2/ERF transcription factors (Mt ERN1, 2, and 3) bind to the Nod factors responsive regulatory unit (the NF box) present in the promoter of Mt *ENOD11* (Andriankaja et al., 2007). Another symbiosis mutant *astray* in *L. japonicus* contains a mutation in Lj Bzf, which is closely related to the *Arabidopsis* HY5, a transcription factor that contains a basic leucine zipper in the *C*-terminus and a RING-finger motif in the *N*-terminus (Nishimura et al., 2002). Moreover, reverse-genetic approaches have led to the functional characterization of additional transcriptional regulators, such as Ms ZPT2-1 (Frugier et al., 2000), Mt HAP2-1 (Combier et al., 2006), Lj ERF1 (Asamizu et al., 2008), and Lj SIP1 (Zhu et al., 2008).

At this stage, it is crucial to understand the transcriptional regulatory networks involved in nodule symbiosis and to identify their target promoters. A recent study shows that Mt NSP1 and Mt NSP2 form a complex that is associated with the promoters of early nodulin genes, such as *Mt ENOD11*, *Mt NIN* and *Mt ERN* (Hirsch et al., 2009). In this study, using the *C*-terminal GRAS domain of Lj NSP2 as bait in yeast two-hybrid (Y2H) screening, we identified a novel MYB family transcription factor named IPN2 (Interacting Protein of NSP2) in *L. japonicus*. The IPN2 protein shows strong transcriptional activation activity and is able to directly bind to the *Lj NIN* promoter in yeast cells and *in vitro*. We also explored the potential role of IPN2 in RN symbiosis.

61.2 METHODS

61.2.1 Y2H Library Screening

For Y2H screenings, bait constructs were made in vector pGBKT7 (Clontech, USA). A cDNA fragment encoding the NSP2 region (105–499 amino acids), which lacks the auto-activation domain (AD), was fused in-frame with the GAL4 DNA-binding domain (BD) in the pGBKT7 vector. Bait constructs were transformed into yeast strain Y187 by the lithium acetate method (Gietz et al., 1995). Screening of interacting clones was carried out via mating according to the manufacturer's instructions (Clontech, USA). A total of 10 million transformants from the cDNA library were selected for growth on the stringent SD/-Leu-Trp-His-Ade drop-out

media. Positive clones were tested for the expression of the *lac*Z reporter via β-galactosidase assays. To validate the observed interactions, prey plasmids were isolated and used for retransformation into yeast AH109. Yeast cells with preys were mated one-on-one in parallel with yeast Y187 cells expressing target baits or the negative control plasmid pGBKT7-Lam (Clontech).

61.2.2 β-Galactosidase Assay

Yeast cells grown in liquid selection media were pelleted and washed twice with Z-buffer (60 mM Na_2HPO_4, 40 mM NaH_2PO_4, 10 mM KCl, 1.0 mM $MgSO_4$, pH 7.0). The cells were resuspended in 300 µl of Z-buffer and permeabilized by three freeze-thaw cycles in liquid nitrogen and a 37 °C water bath. Cell extracts were added to 0.7 ml of Z-buffer containing 50 mM β-mercaptoethanol and 160 µl of ONPG (*O*-nitrophenyl β-D-galactopyranoside, 4 mg/ml in Z-buffer). After incubation at 30 °C for 30 min or until the yellow colour appeared, the reaction was terminated by addition of 0.4 ml of 1.0 M Na_2CO_3. The reaction mixture was centrifuged for 10 min at 13,000 rpm to remove cell debris. β-Galactosidase activity in the supernatant was measured at 420 nm and expressed in Miller units (Miller, 1972).

61.2.3 Knockdown of *IPN2* By RNAi

For RNAi-1 construction, a 201-bp fragment of the 5′-untranslated region (UTR) with a short coding region of *IPN2* was amplified by PCR with two primer pairs 5′-TCCCCC GGGTCT CTTCTT CAAAAC GCA-3′, 5′- ATCGGA TCCACC TGAGTC TCCTTG AAC-3′, and 5′-AACTGC AGTCTC TTCTTC AAAACG CA-3′, 5′-AACTGC AGACCT GAGTCT CCTTGA AC-3′. For IPN2 RNAi-2 construction, a 250-bp fragment of the 3′-UTR was amplified using 5′-AACTGC AGCCCG GGATGA CTCAAA GCCTGA AGAG-3′ and 5′- ACGCGT CGACGG ATCCAG ATTCCC AACCAA AGAC-3′. The amplification cDNA products were digested with *Sma*I-*Bam*HI and with *Pst*I-*Sal*I, and ligated into the pCAMBIA1301-35S-int-T7 vector, in which the sense and antisense *IPN2* DNA sequence were located in tandem with the Arabidopsis *actin-11* intron between them. This intron-hairpin RNA (ihpRNA) construct was placed behind the CaMV 35S promoter.

The RNAi binary vector was transferred into *Agrobacterium rhizogenes* LBA1334 by electroporation. Plants harbouring transformed hairy roots were transferred to pots filled with vermiculite and sand (1:1) with half-strength Broughton & Dilworth (B&D) medium and grown in a chamber in 16/8 h day/night cycle at 22 °C. After 5 to 7 days, plants were inoculated with *Mesorhizobium loti* MAFF303099 and allowed to continue growing in the same medium.

61.3 RESULTS

61.3.1 Identification of IPN2 as an Interacting Protein of NSP2

In *M. truncatula* and *L. japonicus*, both NSP1 and NSP2 contain the conserved *C*-terminal GRAS domain, but have a variable *N*-terminal region (Kalo et al., 2005; Smit et al., 2005; Heckmann et al., 2006; Murakami et al., 2006). In *M. truncatula*, the fusion of NSP1 and NSP2 to the Gal4 DNA BD leads to auto-activation of the Gal4 Y2H system. Auto-activation is caused by the expression of the variable *N*-terminal regions. Truncated NSP1 (NSP1 156–554) and NSP2 (NSP2 113–508) that lack the *N*-terminal region do not lead to autoactivation in the Y2H system (Hirsch et al., 2009). In an attempt to identify NSP1 and NSP2-binding proteins, we used the GRAS domains as bait to screen a *L. japonicus* root cDNA library (Zhu et al., 2008). Positive interaction clones from the primary screens were tested on stringent selective medium (SD-Trp-Leu-His-Ade). Screening with the GRAS domain of Lj NSP1 did not identify any interacting clone. Screening with the GRAS domain of Lj NSP2 resulted in isolation of two independent positive clones. Sequencing analysis of the two plasmids revealed that the two coding regions represent the same gene encoding a novel protein, designated IPN2 for Interacting Protein of NSP2.

61.3.2 IPN2, a MYB Coiled-Coil Transcription Factor of the GARP Subfamily

The full-length Lj *IPN2* cDNA (GenBank accession no. HQ343457) contains an open reading frame of 1074 nucleotides encoding a peptide of 358 amino acid residues, with a predicted isoelectric point of 8.3 and molecular mass of 40.2 kD. A BLAST search for Lj *IPN2* sequences in the NCBI (National Center for Biotechnology Information) high-throughput genomic sequence database identified a perfect match with a TAC (Transformation-competent Artificial Chromosome) clone (GenBank accession no. AP010214). Comparison between the genomic DNA and the cDNA sequence revealed that Lj *IPN2* is composed of six exons and five introns. Lj IPN2 protein contains a single MYB-like DNA-BD (1R) and a predicted coiled-coil dimerization domain (Fig. 61.1a). MYB transcription factors contain one to three copies (termed R1 to 3) of a highly characteristic DNA-BD. These are typically slightly over 50 amino acids in length. Each domain contains three helices and folds into a helix-turn-helix motif (Fig. 61.1b) with three highly conserved Trp residues regularly spaced by 18 or 19 amino acids, and the motif plays a critical role in stabilizing the DNA BD (Ogata et al., 1992). An alignment of Lj IPN2 1R region, other plant MYB-like DNA-BDs, and the R1, R2 and

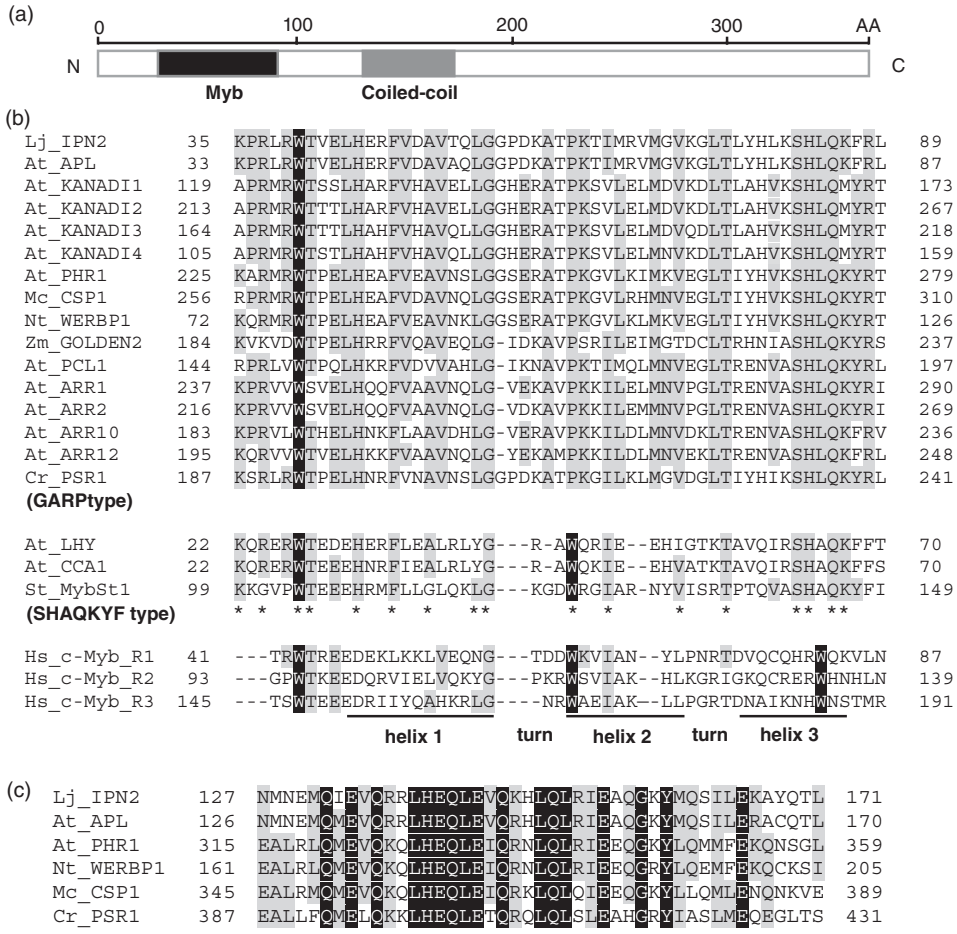

Figure 61.1 IPN2 is a novel plant Myb-related protein belonging to the GARP (GOLDEN2, ARRs, PSR1, and PHR1) subfamily. (a) Schematic illustration of IPN2 protein. Notable features include a single Myb-like DNA binding domain (1R) and a predicted coiled-coil domain. (b) Alignment of the Myb-like domain of IPN2 and the Myb-related domains with the human c-Myb repeats (Majello et al., 1986). The numbers on the left and right indicate the amino acid positions. The three regularly spaced Trp (W) residues are highlighted in reverse contrast. IPN2 has only one conserved 'W' residue and the other two 'W' residues are replaced by 'P' and 'L' in the context of 'SHLQKY/FR', respectively. Thus, IPN2 is classified into the GARP subfamily (Hosoda et al., 2002). (c) Alignment of the predicted coiled-coil conserved domain of IPN2 (amino acids 127–171) with the corresponding regions of other GARP proteins. Identical residues are highlighted in black and conserved residues are shown in grey.

R3 repeats of human c-Myb (Majello et al., 1986) showed that the IPN2 1R region contains only one conserved Trp (W) at the first helix. The other two positions expected to have 'W' residues were replaced with Pro (P) and Leu (L) in the context of 'SHLQKY/FR', respectively (Fig. 61.1b). Based on these substitutions, Lj IPN2 1R region can be classified into the GARP subfamily, which is more distantly related to the MYB superfamily (Riechmann et al., 2000).

Other members in the GARP family include maize GOLDEN2 (G2) (Hall et al., 1998), *Arabidopsis* ARRs (Imamura et al., 1999), *Chlamydomonas reinhardtii* PSR1 (Wykoff et al., 1999), and *Arabidopsis* PHR1 (Rubio et al., 2001). A GARP domain was also found in the recently identified KANADI and APL gene products, which regulates organ polarity and vascular identity in *Arabidopsis*, respectively (Kerstetter et al., 2001; Bonke et al., 2003). The GARP domains are similar to the MYB-like domain of the single repeat MYB proteins CCA1 (Wang et al., 1997), LHY (Schaffer et al., 1998), and MybSt1 (Baranowskij et al., 1994), which, however, have two conserved 'W' residues at the first and second helices and contain the consensus sequence 'SHAQKY/F' in the domain surrounding the third 'W' residue (Fig. 61.1b). Therefore, they are also known as the 'SHAQKY/F' subfamily (Hazen et al., 2005; Fukuzawa et al., 2006).

Besides the GARP domain, Lj IPN2 and some of the GARP family proteins also contain a predicted coiled-coil domain with the consensus sequence 'LHEQLE' (Fig. 61.1c).

61.3.3 Identification of Domains Required for the Interaction Between NSP2 and IPN2

Lj NSP2 contains two leucine heptad repeat domains (LHR1 and LHR2), a VHIID domain, and a Src-homology 2 (SH2)-like domain (Murakami et al., 2006). To determine which domain of NSP2 is responsible for its interaction with IPN2, we constructed the full-length and a series of truncated proteins of NSP2 fused to the Gal4 DNA BD. These constructs were tested for interaction with IPN2 fused to the Gal4 AD (Fig. 61.2a). The strength of interaction was measured using the ß-Galactosidase activity with ONPG as substrate. Most of the *N*- and *C*-terminal deletions of NSP2 failed to interact with IPN2. Only the full-length and a truncated NSP2 (105–499 aa) containing all four domains

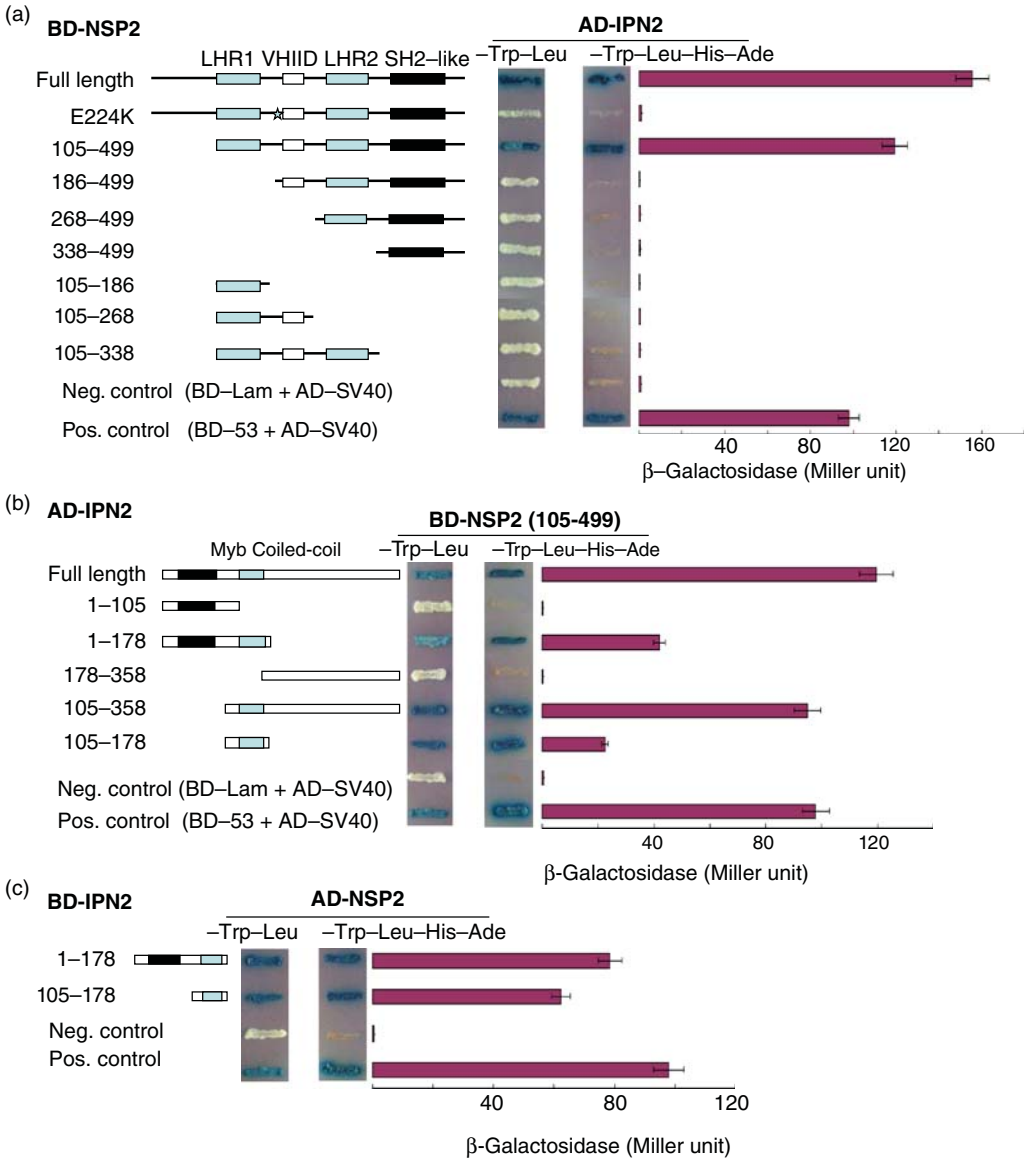

Figure 61.2 IPN2 interacts with NSP2 in yeast. (a) Dissection of the domains of NSP2 required for interaction with IPN2. The *C*-terminal GRAS domain of NSP2 (105–499 aa) was used in the initial isolation of IPN2 from the yeast two-hybrid screening. SD/-Leu-Trp medium was used to test successful mating and SD/-Leu-Trp-His-Ade medium for testing the interaction. The interaction strength was measured through the ß-Galactosidase activity using X-Gal (80 µg/ml) as indicator in plates and ONPG as substrate for quantification. One unit of ß-galactosidase was defined as the amount of enzyme that hydrolysed 1 µmol of ONPG to o-nitrophenol and D-galactose per min (Miller unit). The combination of BD-53/AD-SV40 was used as a positive control and BD-Lam/AD-SV40 as a negative control (Clontech). BD: Gal4 DNA binding domain; AD: Gal4 activation domain. (b) Dissection of the domains of IPN2 required for interaction with NSP2. The coiled-coil domain of IPN2 was necessary and sufficient for interaction with NSP2. (c) Exchanges of Gal4 BD and AD fusion domains. The BD and AD domains of NSP2 and IPN2 in (b) were swapped, and the interaction of the coiled-coil domain of IPN2 with NSP2 was confirmed.

(LHR1, VHIID, LHR2, and SH2-like) were able to interact with IPN2, suggesting that more than one domain of NSP2 is required for this interaction. In contrast, the LHR1 domain of Mt NSP2 alone has been shown to be necessary and sufficient for the interaction with Mt NSP1 (Hirsch et al., 2009). Interestingly, a site mutant (E224K) of Lj NSP2, which is equivalent to the E232K mutant of Mt NSP2, abolished the interaction with Lj IPN2. The Mt $NSP2_{E232K}$ mutant was originally identified in the *nsp2-3* mutant of *M. truncatula*, a weak *nsp2* mutant allele showing limited nodule formation in contrast to the null allele *nsp2-2* showing no nodule formation (Kalo et al., 2005). This mutation also abolishes auto-activation in the Y2H system, and can still interact with Mt NSP1 (Hirsch et al., 2009).

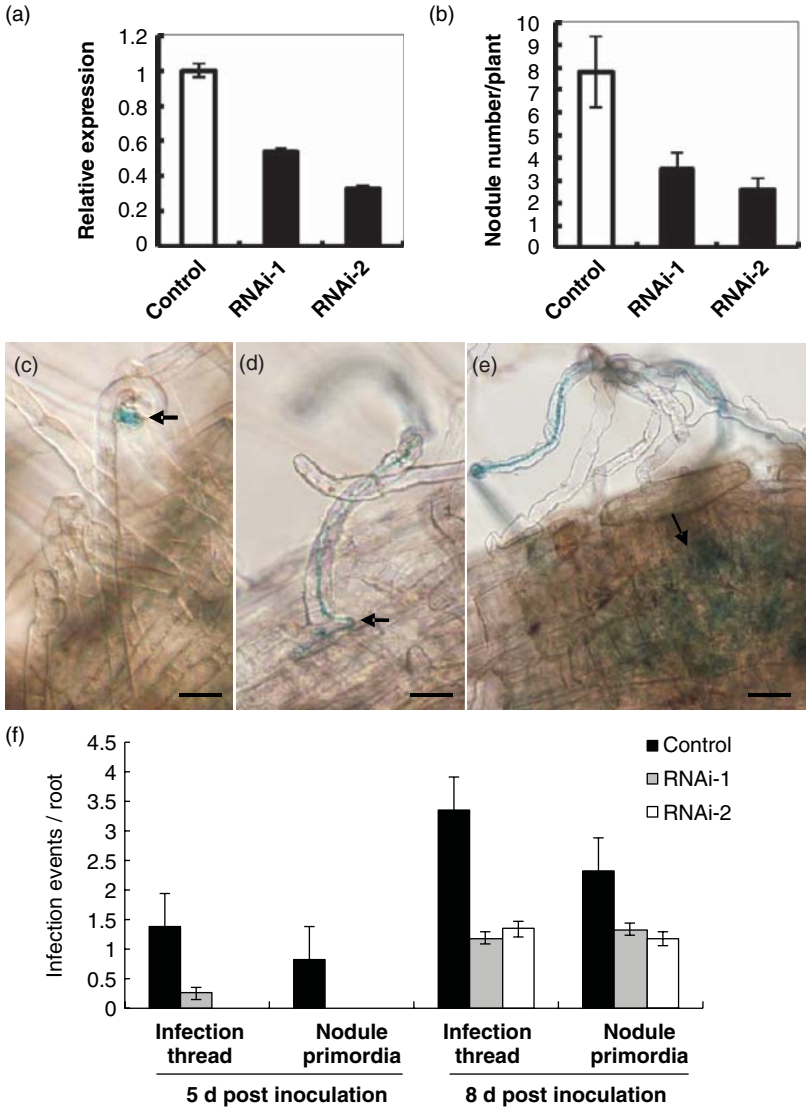

Figure 61.3 Analysis of nodulation phenotypes and rhizobial infection of *IPN2*-RNAi hairy roots. (a) Quantitative RT-PCR analysis of *IPN2* expression levels in the control hairy roots expressing the empty vector (Ct) and representatives of hairy roots expressing the *IPN2*-RNAi constructs (RNAi-1 and RNAi-2). (b) Total nodule numbers of transgenic hairy roots with the vector control and two RNAi constructs were recorded 3 weeks after inoculated with *M. loti* MAFF303099. (c–e) Infection threads (ITs) formation in *IPN2*-RNAi hairy roots. ITs were visualized after staining with X-Gal in hairy roots 8 d post inoculation (DPI) with *M. loti* expressing a *lacZ* construct. The images show the key steps of *Rhizobium* infection in hairy roots, including curled root hairs with entrapped bacterial colony (c), IT growth (d), and release of rhizobia in developing nodule cells (e). Bars = 25 μm for (c) and (d), and 50 μm for (e). (f) Frequencies of the infection events per root of the control hairy roots, *IPN2* RNAi-1 and *IPN2* RNAi-2 hairy roots at 5 DPI and 8 DPI, respectively. The data are presented as 15 individual transgenic plants each construct, and randomly scored in four roots between 4 and 6 cm per plant.

The coiled-coil conformation has been considered as a potential homodimerization or heterodimerization motif (Lupas et al., 1991; Rubio et al., 2001; Parry et al., 2008). To determine whether the coiled-coil domain of Lj IPN2 was responsible for the interaction with Lj NSP2, several deletion mutants of Lj IPN2 fused to Gal4 AD were tested for interaction with the Lj NSP2 (105–499) fused to Gal4 BD (Fig. 61.2b). We found that only the deletion mutants containing the coiled-coil domain interacted with Lj NSP2. On the other hand, the truncated Lj IPN2 (1–178) and Lj IPN2 (105–178) interacted with the full-length Lj NSP2 fused to Gal4 AD (Fig. 61.2c). These results indicate that the coiled-coil domain of Lj IPN2 is necessary and sufficient for interaction with Lj NSP2.

61.3.4 Impairment of Nodulation by *IPN2* RNAi

To elucidate the function of Lj *IPN2* in the nodulation process, we generated transgenic hairy roots expressing *IPN2* RNAi. Transgenic hairy roots expressing the empty vector served as a control. Two *IPN2*-specific RNAi constructs, with *IPN2* RNAi-1 targeting the 201-bp 5′ region and RNAi-2 targeting the 250-bp 3′ region, were expressed in transgenic hairy roots of *L. japonicus*. The levels of the *IPN2* transcripts in transgenic hairy roots were measured by quantitative RT-PCR. The data showed that the *IPN2* transcripts were reduced on average to 51% in *IPN2* RNAi-1 and 32% in RNAi-2 as compared to that in the control hairy roots (Fig. 61.3a).

The hairy roots were inoculated with *M. loti* MAFF303099 and grown for 3 weeks in a nitrogen-free environment. Nodulation phenotypes were examined. The average number of nodules formed on control hairy roots was 7.8, while that on RNAi-1 and RNAi-2 hairy roots was reduced to 3.5 and 2.7, respectively (Fig. 61.3b). This reduction in nodule number by RNAi expression was statistically significantly different from that of the control ($P < 0.01$, $n = 55$ and $P < 0.01$, $n = 61$, respectively). These results indicate that down-regulation of *IPN2* gene expression by RNAi had a negative effect on nodulation.

To determine how *IPN2* RNAi expression affected nodule formation, we analyzed the rhizobial infection process. For this, lacZ-labelled *M. loti* cells (Kang et al., 2011) were used to infect the transgenic RNAi hairy roots, and the presence of ITs were visualized under the microscope. At 5 d post inoculation (DPI), no ITs were observed in the *IPN2* RNAi-2 roots, and occasionally only a few ITs could be observed in the RNAi-1 roots while no nodule primordia could be identified. By contrast, both ITs and nodule primordia could be readily observed in the control hairy roots. The complete absence of ITs at 5 DPI in *IPN2* RNAi roots was surprising, so we recorded ITs at 8 DPI. The initiation of ITs from curled root hair tips (Fig. 61.3c) and ITs growth through well-elongated root hairs to root epidermis (Fig. 61.3d) could be observed in *IPN2* RNAi roots. Also, some ITs could reach to the nodule primordia and rhizobia could be released from ITs into the nodule cells (Fig. 61.3e). Compared to the control hairy roots, the average numbers of ITs and nodule primordia were significantly reduced in *IPN2* RNAi roots (Fig. 61.3f). Thus, both rhizobial infection and nodule organogenesis appeared to be impaired by the knockdown expression of *IPN2* in RNAi hairy roots.

61.4 DISCUSSION

Formation of a transcription factor complex is a key step in order to bind DNA and regulate gene expression. Two GRAS family transcription factors, SCARECROW (SCR) and SHORTROOT (SHR), interact with each other and control root radial patterning (Cui et al., 2007). The *Solanum tuberosum* GRAS protein RGA interacts with the PIF4 basic helix-loop-helix (bHLH) transcription factor, and functions to integrate the light and GA signals (de Lucas et al., 2008).

In *M. truncatula*, GRAS family transcription factors, Mt NSP1 and Mt NSP2 form a complex at the DNA level, and induce specific gene expression changes essential for the root nodule symbiosis (Hirsch et al., 2009; see Chapter 59). In this study, we identified a novel MYB transcription regulator, Lj IPN2, which interacts with Lj NSP2. In *M. truncatula*, the LHR1 domain of Mt NSP2 is necessary and sufficient for interaction with Mt NSP1, whereas the whole GRAS domain of Mt NSP1 (156–554 aa) is required for interaction with Mt NSP2 (Hirsch et al., 2009). In contrast, the whole GRAS domain of Lj NSP2 (105–499 aa) is required for interaction with Lj IPN2, whereas the coiled-coil domain of Lj IPN2 is necessary and sufficient for interaction with Lj NSP2 (Fig. 61.2).

Having an *N*-terminal MYB-like DNA BD, IPN2 belongs to the large MYB protein family. The MYB protein family is universal in the plant kingdom, and MYB domain proteins are classified based on the numbers of MYB-DNA BD repeats. As there is only one MYB domain, Lj IPN2 is classified as a MYB-related protein. The functions of MYB domain family of proteins vary according to the number of repeats as MYB proteins bind to DNA in different ways. MYB proteins with two MYB repeats (R2R3) represent the biggest family in plants. To date, over 100 members have been isolated in *Arabidopsis* and they play various roles in the regulation of secondary metabolism, tissue morphogenesis, phloem formation and cell cycle progression (Riechmann et al., 2000). The Myb-related transcription factors exist widely in plants. They are involved in diverse biological processes including cell proliferation, differentiation and organ development (Stracke et al., 2001; Marian et al., 2003).

Protein domain sequence analysis revealed that the Myb-like DNA BD of IPN2 is closely related to the B motif or GARP motif (Hosoda et al., 2002). The B motif was originally identified as a signature of the type-B ARRs involved in His-Asp phosphorelay systems in *Arabidopsis* (Imamura et al., 1999). The B motif is a representative of the GARP motifs commonly observed in GARP family plant transcription factors, including maize G2 and *C. reinhardtii* PSR1 (Riechmann et al., 2000). G2 controls the differentiation of a photosynthetic cell type of the maize leaves (Hall et al., 1998), whereas PSR1 is a regulator of phosphorus metabolism (Wykoff et al., 1999). *Arabidopsis* PHR1, a protein homologous with PSR1, functions in phosphate starvation signalling (Rubio et al., 2001). The recently identified KANADI gene product, which possesses a GARP motif, has been reported to regulate organ polarity in *Arabidopsis* (Kerstetter et al., 2001). In these cases, the GARP proteins appear to be involved in plant-specific processes. Although their amino acid sequences are distantly related to those of authentic mammalian Myb repeats, little is known about the structure and function of the GARP motif.

Besides the GARP motif, IPN2 also contains a predicted coiled-coil domain annotated as the LHEQLE motif. The combination of the two motifs in one protein peptide is widely found in the plant kingdom from green algae to higher plants (Fig. 61.1b, c). However, the overall structure of IPN2 appear to be unique to higher land plants, as genes coding for proteins with similar structures could not be found in the unicellular algae *C. reinhardtii*, the moss *Physcomitrella patens*, and the lycophyte *Selaginella moellendorfii*. IPN2-like proteins are clearly present in

most of the higher plant species including the dicots and monocots in the databases. Among them, *Arabidopsis* APL is the only one, whose biological function has been characterized. APL is essential for the vascular tissue identity in roots (Bonke et al., 2003). The presence of homologs in nonlegume plant species suggests that IPN2 possibly has a nonsymbiotic function. During evolution, IPN2 may have acquired an additional function in nodulation signalling in legume species.

In summary, we have described the identification of IPN2 as an interacting partner of NSP2 in *L. japonicus*. IPN2 is a MYB coiled-coil type transcription factor belonging to the GARP protein family, while NSP2 is a GRAS family transcription regulator. The two proteins may form a transcription factor complex and promote the expression of a specific set of genes essential for nodule development.

62.1 INTRODUCTION

Legumes are capable of intimately associating with rhizobial bacteria in the soil, and this unique symbiosis involves the formation of a specialized root organ, the root nodule, in which the bacteria reduce atmospheric nitrogen to a form that can be assimilated by the host plant. This beneficial interaction is initiated by the specific recognition of bacterial-produced Nod factor (NF) signals that lead to the induction of a unique nodule developmental program, involving rhizobial infection of external root epidermal/outer cortical tissues and nodule organogenesis within the root cortex (see Chapters 51, 59). The coordination of infection and organogenesis occurring in different root tissues leads to the formation of mature nodule structures, in which rhizobia are hosted intracellularly and differentiate into bacteroids which fix nitrogen for the benefit of the host plant (reviewed by Murray, 2011; Oldroyd et al., 2011; Popp and Ott, 2011; see also Chapter 59).

Transcriptomic studies conducted in a number of legume plants have revealed that thousands of genes are expressed during nodule development, including hundreds of Transcription Factor (TF)-encoding genes likely to play central roles in the regulation of this process (Udvardi et al., 2007; Høgslund et al., 2009; Moreau et al., 2011). TFs are represented by diverse gene families which are recognized by the presence of specific DNA binding (DB) domains that interact in a sequence-specific fashion with promoter regions, regulating the expression of their target genes, positively or negatively. Genome-wide analyses of sequenced genomes have revealed that TF gene families are equally distributed between legumes and nonlegume plant species, suggesting that legume-specific traits such as the ability to form nitrogen fixing nodules is not related to TF gene family specialization but rather to differences in TF gene expression patterns and functions (Benedito et al., 2008; Libault et al., 2009, 2010).

TF genes involved in the nodulation process have been identified in legume plants by different strategies, and additional detailed expression and/or functional analyses have made it possible to correlate TF function with specific stages of nodulation (Table 62.1). Firstly, direct genetic screening for nodulation-deficient mutants led to the identification of key TFs essential for both early and late stages of the nodulation process. This includes the GRAS (NSP1 and NSP2), NIN and AP2/ERF (ERN1) transcription factors characterized in *Medicago truncatula*, *Lotus japonicus* and/or *Pisum sativum*. By a complementary yeast one-hybrid screen strategy, ERN1 and two closely related AP2/ERF TFs referred to as ERN2 and ERN3, were identified as important players of early NF signaling, able to bind to the NF-responsive NF-box regulatory sequence as will be discussed later. Genetic strategies based on the identification of supernodulation mutants allowed the identification of the bZIP HY5 TF as a negative regulator of the genetic program leading to nodule development in *L. japonicus* (Table 62.1). Finally, a number of

nodule-expressed TFs belonging to different gene families were identified by transcriptomics before being further characterized throughout nodulation (Table 62.1). This review is focused on the AP2/ERF family of TFs, and in particular those related to nodule development in the model legume *M. truncatula*.

62.2 THE AP2/ERF FAMILY IN PLANTS

The AP2/ERF superfamily is one of the largest groups of TFs in plants and is defined by the presence of a conserved DB domain consisting of approximately 60 amino acid residues (for a review see Nakano et al., 2006; Yamasaki et al., 2013). This DB domain was first identified in the Arabidopsis AP2 floral homeotic gene (Jofuku et al., 1994) and in ethylene-inducible DB proteins that interact with an ethylene responsive element (Ohme-Takagi and Shinshi, 1995), giving rise to the name of the gene family. Since then, AP2/ERF or related DB domains were found in a number of plant species but also in non-plant bacterial or viral endonucleases, supporting a potential acquisition of this DB domain by plants following direct gene transfer (Magnani et al., 2004; Shigyo et al., 2006). Interestingly, AP2/ERF-like domains were also found in apicomplexan *Plasmodium* spp., that despite having an overall low homology, exhibit a domain folding similar to the one predicted for the plant AtERF1 (Allen et al., 1998; Painter et al., 2011).

Genome-wide studies have identified AP2/ERF superfamily members in a number of plant species: 157 in Arabidopsis, ∼180 in rice, 126 in *M. truncatula* and 136 in *L. japonicus* (Nakano et al., 2006; Mochida et al., 2010; Zhang et al., 2011). On the basis of amino acid conservation and the number of AP2/ERF domains, this superfamily has been further divided in three major families: the AP2 family which contains proteins with two repeated AP2/ERF DB domains, the RAV (Related to ABI3/VP1) family which

contain proteins with an AP2/ERF and a B3 DB domain and the ERF family with proteins comprising a single AP2/ERF DB domain. While the AP2 members are mainly involved in flower developmental processes, the RAV group is related to hormonal signaling, and the predominant ERF group to a variety of biological processes, and in particular plant responses to environmental conditions as discussed below.

The ERF group comprises the vast majority (>80%) of genes in the AP2/ERF superfamily (e.g., 132/157 in *Arabidopsis*, ~150/180 in rice, 106/126 in *M. truncatula* or 122/136 in *L. japonicus* (Mochida et al., 2010; Zhang et al., 2011) and is further divided into two major subfamilies, termed CBF/DREB (C-repeat binding factor/dehydration responsive element binding factor) and ERF (Fig. 62.1)

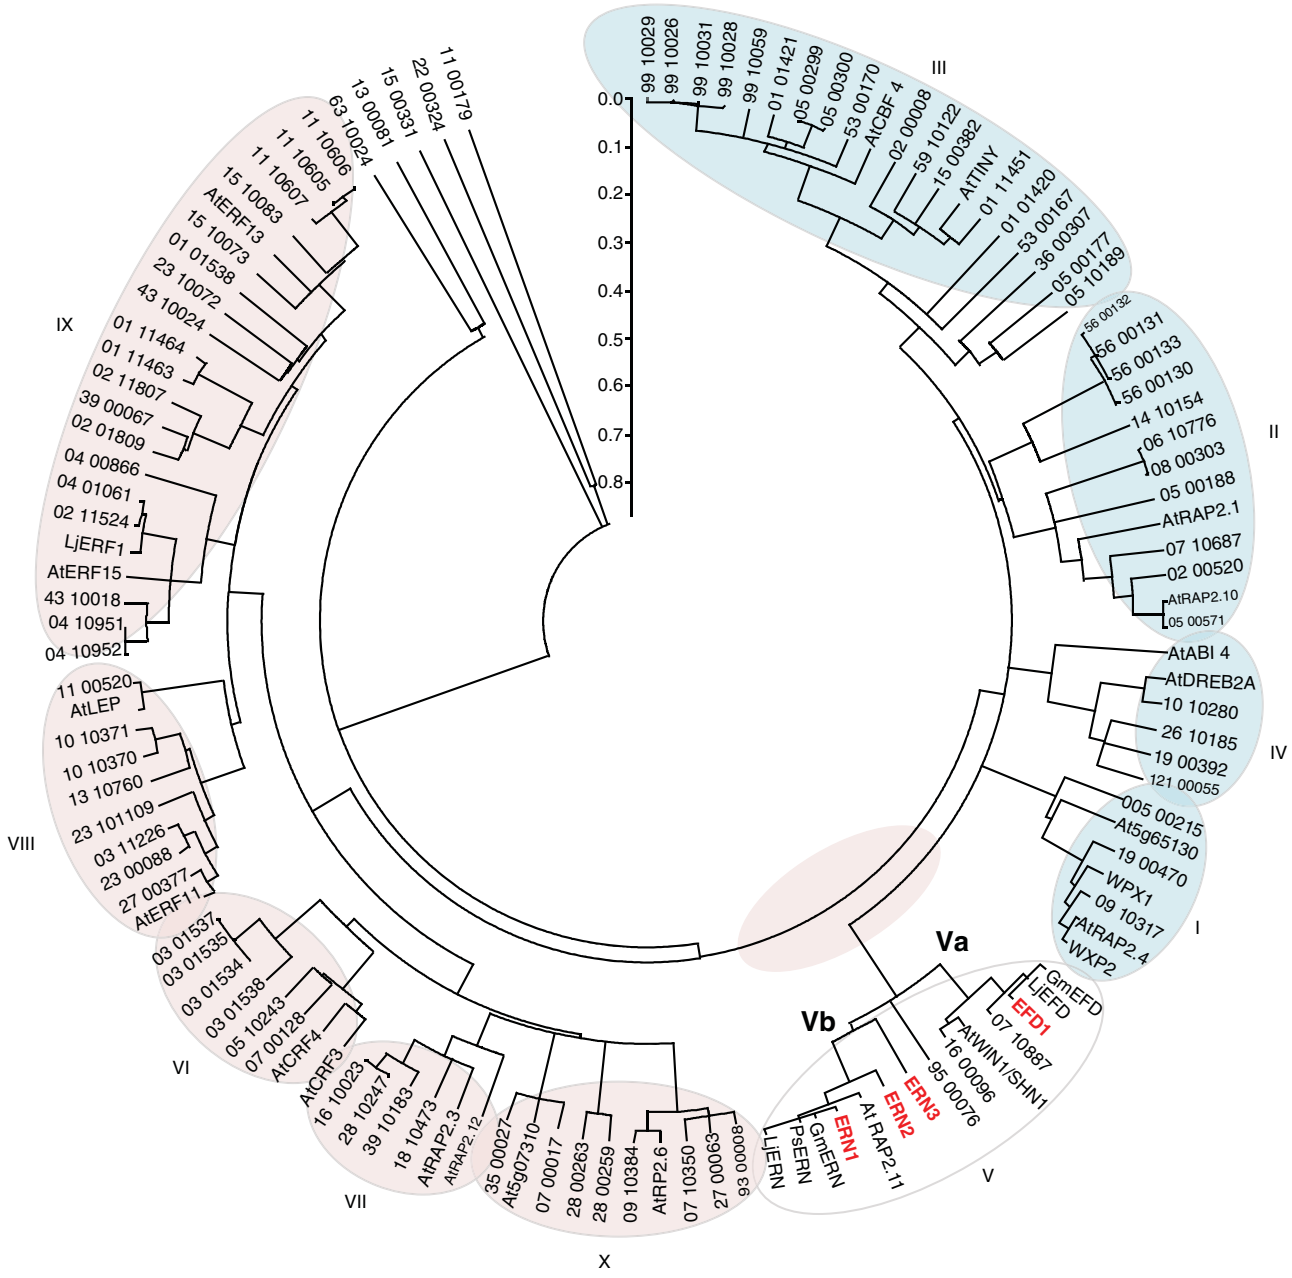

Figure 62.1 Phylogenetic analyses of nodule-expressed *M. truncatula* ERF proteins represented in Table 62.2. A tree of 95 aligned *M. truncatula* sequences was constructed using MEGA 5 (maximum likelihood method and JTT model). The 10 major ERF groups (I to IX) identified by Nakano et al. (2006) classified into respective CBF/DREB (I to IV) or ERF (V to X) families are shaded in blue or pink respectively. EFD1 and ERN TFs are indicated in red. For comparison, *A. thaliana* ERFs, *L. japonicus* ERF1, EFD- and ERN-like sequences from other legumes (Ps, *P. sativum*; Lj, *L. japonicus*; Gm, *G. max)* were included in the tree.

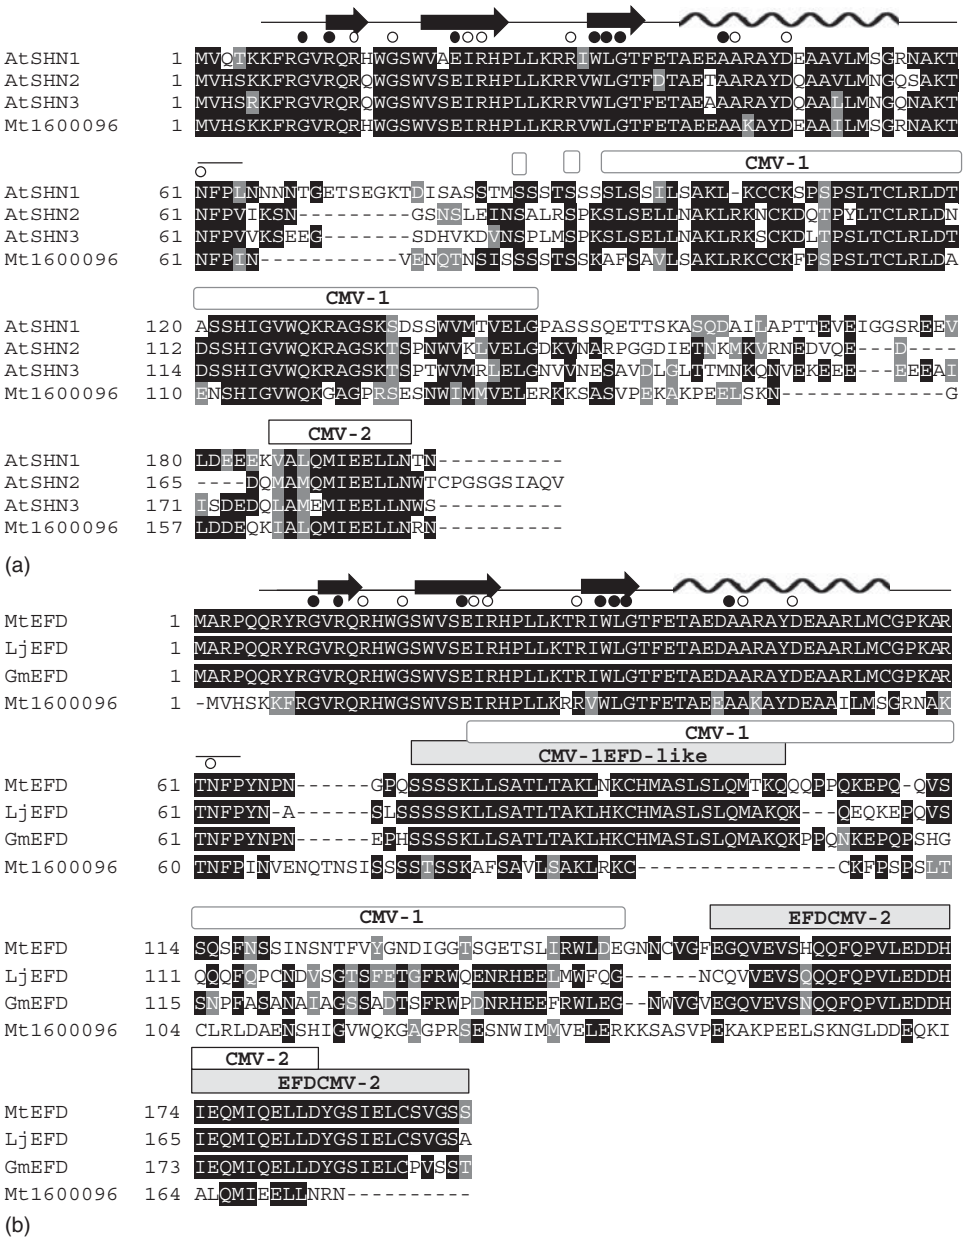

Figure 62.2 Conserved domains in Va ERF TFs in Arabidopsis and legume species. (a) Sequence alignment of the three *Arabidopsis* SHN proteins and their putative ortholog from *M. truncatula* (Fig. 62.1). All four proteins contain a conserved DB domain with 3 β-sheets (arrows) and one α-helix, and two conserved CMV-1 and CMV-2 motifs as indicated by rectangles. (b) Sequence alignment of the three *M. truncatula* group Va ERF TFs, which include the SHN homolog and EFD-like proteins. All four proteins contain a conserved DB domain with 3 β-sheets (arrows) and one α-helix. The positions of CMV-1 and CMV-2 motifs are indicated by open rectangles, while legume conserved motifs are indicated by grey rectangles. Circles indicate the positions of amino acid residues in the AP2/ERF domain being totally (solid circles) or more than 95% (open circles) conserved.

respectively. Taking into account protein conservation throughout the entire ERF protein, Nakano et al. (2006) have classified them into ten major phylogenetic groups with derived sub-groups. Since then, the phylogenetic relationships between members of the ERF group has been studied in a number of other plant species (e.g., rice, poplar or tomato; Nakano et al., 2006; Rashid et al., 2012; Zhuang et al., 2008; Pirrello et al., 2012). This group is characterized by the presence of certain amino acid residues within the AP2/ERF DB domain, either totally or more than 95% conserved as indicated in Figures 62.2 and 62.3 (Nakano et al., 2006). Nevertheless, the overall homology of the entire AP2/ERF DB domain can vary significantly between different ERF phylogenetic groups, from approximately

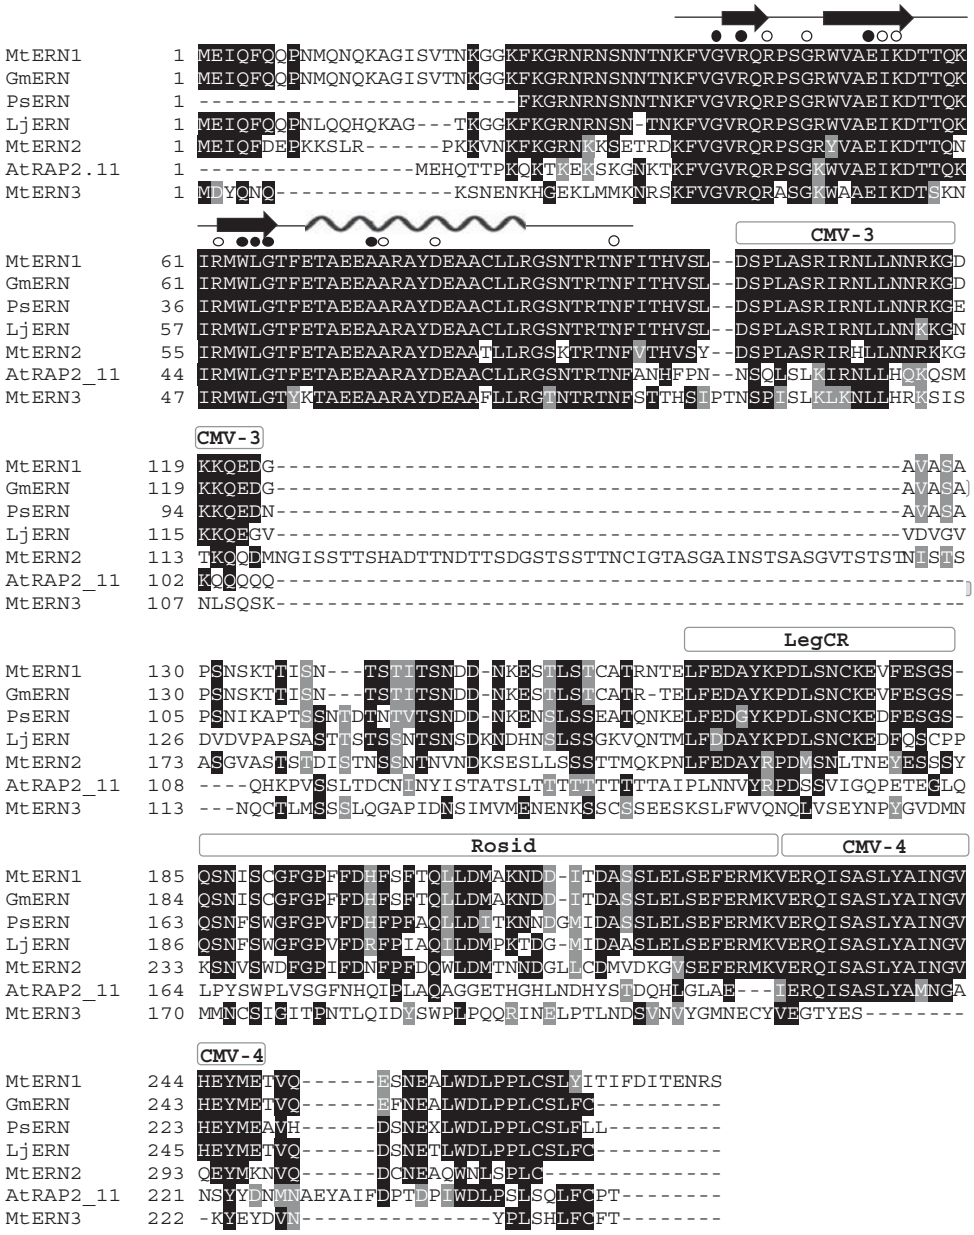

Figure 62.3 Conserved domains in ERN-related TF factors. Sequence alignment of legume (*M. truncatula, L. japonicus, G. max and P. sativum*) ERN-like proteins and the Arabidopsis RAP2.11 ortholog. All four proteins contain a conserved DB domain with 3 β-sheets (arrows) and one α-helix. CMV-3, CMV-4 and the rosid-specific regions are indicated by open rectangles. Circles indicate the positions of amino acid residues in the AP2/ERF domain being totally (solid circles) or more than 95% (open circles) conserved.

50% to 95%. This heterogeneity can be related to different DB specificities as suggested by protein-DB microarray analyses (Gong et al., 2008).

To date, the DB domain of ERF TFs has been shown to recognize GC-rich motifs found in the promoters of regulated genes, including respectively the GCC box (AGCCGCC) of defense-related genes (Ohme-Takagi and Shinshi, 1995), the DRE (dehydration response element) A/GCCGAC element of stress-related genes (reviewed by Mizoi et al., 2012) and the GCC-like motif (GCAGGC) of symbiotic responsive *ENOD* genes (Andriankaja et al., 2007). Recent studies have further suggested that promoter sequences flanking the core GCC motif may contribute to binding selectivity of tomato ERF TFs to their target sequences (Pirrello et al., 2012). Interestingly, the crystal structure of the AP2/ERF domain of AtERF1 in the presence of its GCC box target has been determined by nuclear magnetic resonance (NMR), revealing both the folding of the DB domain and the amino

acids implicated in the interaction with the DNA (Allen et al., 1998). This study revealed that the AP2/ERF DB domain is composed of three anti-parallel β-sheets followed by an α-helix, interacting directly with the GCC box almost exclusively via the β-sheets, and through arginine (R) or tryptophan (W) residues. The key amino acids involved in the direct interaction with the DNA have been defined and are mostly conserved among ERFs (e.g., R6, R8, W10, R18, R26, and W28 in Figs. 62.2 and 62.3). Outside the ERF DB domain, protein conservation is restricted to phylogenetic groups in which conserved domains or motifs are often related to functional specialization as will be discussed subsequently.

62.3 A DIVERSE NUMBER OF ERF TFs ARE EXPRESSED IN *M. truncatula* NODULES

To gain a comprehensive view of the distribution of ERF transcription factors expressed during nodulation, ERF TFs of *M. truncatula* containing a single AP2/ERF domain were identified following the analysis of the nodule transcriptome (Table 62.2). Ninety-five out of 106 ERF TFs identified were found by RNA-seq analyses to be expressed in mature (10- and 15-day-old) nodules (Roux et al., 2014). Table 62.2 shows that the level of detected RNA-seq reads varied widely between genes, from 0.18 reads per kilobase of exon per million reads (rpkm) (ERN3) to 284.2 rpkm (for a RAP2.4 homologue). To determine the evolutionary relationship between these nodule-expressed ERFs a phylogenetic tree was constructed (Fig. 62.1). *M. truncatula* ERF TFs were classified in I–X groups, as previously defined by Nakano et al. (2006) (Fig. 62.1). The relationship among the members of a given class is not only supported by the amino acid conservation of the DB domain but also by common motifs found outside the DB domain, as well as intron positions for the very few intron-containing ERFs (in particular within groups V, VII, and X). In *M. truncatula*, ERF TFs from different classes are expressed in nodules, and this includes both DREB (groups I to IV) and ERF types (V to X) (Fig. 62.1 and Table 62.2). To date, the function of only a few of these has been studied during the nodulation process, as will be described later.

62.3.1 Group I to IV DREB-Related TFs are Mostly Associated with Abiotic Stress Responses

ERF TFs belonging to the DREB-related I–IV groups are mainly associated with plant responses to abiotic stresses (cold, drought, or salinity) and are mostly described as activators of stress-related genes containing the DRE regulatory motif (reviewed by Mizoi et al., 2012), even if certain members can also act as transcription repressors (Dong and Liu, 2010; Wind et al., 2013). Other phylogenetically related DREB TFs were also shown to have specialized functions during ABA, sugar or plastid-to-nucleus signaling (ABI4, group IV, Huijser et al., 2000; reviewed by Wind et al., 2013) or to participate in both stress and differentiation processes as is the case for the Arabidopsis RAP2.4/WIND1 (group I) TFs (Iwase et al., 2011). DREB-related transcription factors were also reported to participate in abiotic plant responses in legume plants (Li et al., 2005; Zhang et al., 2007; Gruber et al., 2009). In *M. truncatula* WXP1 and WXP2 TFs, were shown to increase drought tolerance when overexpressed in plants, and this involved the increased production of cuticular waxes, known to contribute to the regulation of water uptake and ion transport between the plant and its environment. As shown in Table 62.2, WXP1 and WXP2 are also significantly expressed in mature nodules, which raise the question of whether they may participate in the production of a similar lipophilic barrier for controlled water/ion transport in nodules.

62.3.2 Group V to X ERF-Related TFs Display Variable Functions During Plant Development, Stress or Beneficial Plant Interactions

The ERF groups (V–X) have been implicated in plant signaling pathways related to diverse biological processes, from plant development to interactions with biotic and abiotic environmental factors. The largest of these, group IX, has been often related to defense signaling during biotic plant responses (reviewed by Broekaert et al., 2006). Within this group, Arabidopsis AtERF1, AtERF2, and AtERF5 act as activators of ethylene-, jasmonate- or defense-related genes through the recognition of the GCC box. Recent studies have demonstrated that a conserved 24-amino acid "EDLL" motif is critical for the activation function of a group IX ERF TF (Tiwari et al., 2012). In contrast, group VIII members, such as Arabidopsis AtERF3, AtERF4, AtERF7, AtERF10–12, act as repressors of GCC-mediated transcription, and this involves the EAR (ERF-associated amphiphilic repression) domain conserved in a number of TF repressors (reviewed by Kagale and Rozwadowski, 2011). The sequential action of activator and repressor-type ERF TFs have been implicated in the coordination of hormonal signaling pathways to finely modulate defense response during pathogen challenge (reviewed by Broekaert et al., 2006). In *L. japonicus*, a close homolog of *AtERF1* has been implicated in induced-defense responses during nodulation (Asamizu et al., 2008). This gene, named *LjERF1*, was initially identified by a cDNA microarray analysis as being early induced in roots following inoculation with the bacterial symbiont *Mesorhizobium loti*. Subsequent over-expression studies and expression inhibition by RNA

Expression levels were determined by RNA-seq analysis of 10-day-old nodules and are represented as reads per kilobase of exon per million reads (rpkm) (mean of three biological repetitions) (Roux et al., 2014). Expression values of three symbiotic genes (*Lb1* (Ott et al. 2005), *ENOD11* (Journet et al. 2001) and *NFP* (Arrighi et al. 2006)) were included as references for highly to lowly expressed genes. Gene identifiers (first column) are from a *M. truncatula* genome sequence completed by Illumina shotgun sequencing (Roux et al., 2014).

interference experiments indicated a positive role of this TF during nodule formation. However, *LjERF1* is not expressed during nodulation-related developmental processes (rhizobium infection or nodule organogenesis) but only in bacterial inoculated roots, suggesting that *LjERF1* function is probably related to the establishment of the rhizobium symbiotic interaction, potentially by the early suppression of defense genes as suggested by the authors. Nevertheless, a direct correlation between *LjERF1* overexpression and repression of defense-related genes such as PR-10 could not be demonstrated. In *M. truncatula*, two close homologues of *LjERF1* have some level of expression in mature nodules as revealed by RNA seq analysis (Fig. 62.1 and Table 62.2) but their relative importance during nodulation has not yet been investigated.

Studies on the remaining ERF groups X, VII, VI, and V are relatively recent. Groups X, VII, and V comprise atypical ERF TFs that contain single introns in their open reading frames (Nakano et al., 2006). Group X includes ABR1 and RAP2.6 TFs which have variable functions in ABA signaling, biotic or abiotic stress responses (Pandey et al., 2005; Zhu et al., 2010; Ali et al., 2013). Group VII is a relatively small ERF group and specific members have emerged as key regulators of flooding and low oxygen responses in rice and *Arabidopsis* plants (Gibbs et al., 2011; Licausi et al., 2011; reviewed by Bailey-Serres et al., 2012). These TFs are under a tightly regulated control mechanism, in which the oxygen status determines whether the protein re-localizes to the nucleus to activate hypoxia-responsive genes or whether they are post-translationally modified for protein degradation. This refined regulation control involves the recognition of an N-terminal sequence (MCGGAI/L), that is conserved among group VII members to target protein degradation under aerobic conditions. Four *M. truncatula* ERFs expressed in nodules belong to this group (Fig. 62.1 and Table 62.2), and all contain the conserved N-terminal sequence. Within the nodule where a micro-aerobic environment is necessary for nitrogenase functioning, these ERF TFs may potentially be under a similar oxygen status-dependent post-translational control.

Group VI comprises a small subset of TFs initially reported as cytokinin responsive factors (CRF) and involved in cytokinin-regulated plant developmental processes in embryos, cotyledons, and leaves (Rashotte et al., 2006; see also Chapter 56). Recently these TFs were shown to be preferentially expressed in vascular tissues, and, as supported by mutant analyses, are also implicated in leaf vascular patterning. Nevertheless, tomato CRFs seem to be regulated not only by cytokinin but also by salt and other hormones, suggesting that CRFs may function beyond CK-regulated processes (Shi et al., 2012). At the protein level, CRFs form a unique group of ERF proteins containing a clade-specific 65 amino acid-long CRF domain that is always accompanied by an AP2/ERF DB domain. Recent comparative genomic and transcriptomic analyses have redefined this group into five clades, comprising CK-regulated and non-regulated genes (Zwack et al., 2012). Proteins from different clades comprise, in addition to the conserved N-terminal CRF and AP2/ERF domains, clade-specific motifs in the C-terminal regions. Moreover, a conserved mitogen-activated protein kinase (MAPK) phosphorylation site (SP[T/S]SVL motif) is found in many CRF proteins, and this motif is common to non-CRF proteins involved in cytokinin signaling during leaf development (Rashotte and Goertzen, 2010). Six CRF-like TFs are expressed in nodules, and two of them (Mt0007_00128 and Mt0005_10243, Table 62.2) comprise this conserved motif. Some of these factors may be potentially involved in the cytokinin signaling pathway required for nodule development in legumes (Crespi and Frugier 2008; see Chapter 56).

Finally the last ERF group V, which contains the *M. truncatula* ERF factors shown to play central roles in nodulation will be described in more detail in the following section.

62.3.3 The ERF Group V Includes the Nodule-Associated *M. truncatula* EFD and ERN TFs

M. truncatula ERF factors playing crucial roles during nodulation belong to the ERF group V. This group consists of two sub-groups Va and Vb, which are quite divergent with distinct phylogenetically conserved protein domains (Nakano et al., 2006; Figs. 62.2 and 62.3). In addition to differences in protein structure, Group Va members have a characteristic intron localized at an equivalent position in all closely related members, but that is absent in Group Vb members (Nakano et al., 2006).

62.3.4 Group Va Includes the *M. truncatula* EFD TF Required for Correct Nodule Differentiation

Group Va comprises WAX INDUCER1/SHINE1 (WIN1/SHN1) and related clade members that when overexpressed in *Arabidopsis* lead to enhanced accumulation of epidermal waxes (Aharoni et al., 2004; Broun et al., 2004). Interestingly the same phenotype is observed in a gain-of function *SHN1* mutant that presents brilliant shiny leaves due to excessive wax production. WIN1/SHN1 and closely related clade members are thought to display similar functions, and this is supported by the high conservation of the DB and additional C-terminal CMV-1 and CMV-2 domains (Nakano et al., 2006, Fig. 62.2). Nevertheless, respective genes show not only overlapping but also specific expression profiles suggesting a certain degree of protein specialization (Aharoni et al., 2004). Recently, a synthetic microRNA approach used to simultaneously silence the three *SHINE* (*SHN*) clade

members of *Arabidopsis* revealed that these TFs act redundantly to regulate the surface of flower organs by controlling not only cuticular lipid metabolism but also the epidermal cell wall (Shi et al., 2011). In rice the *WIN1/SHN1* homolog *OsWR1* also acts as a positive regulator of wax synthesis and has been involved in drought tolerance (Wang et al., 2012). In barley, a *WIN1/SHN1* homolog has been identified as the gene responsible for conferring organ adhesion in covered barley, potentially by controlling lipid production (Taketa et al., 2008).

M. truncatula possesses a *WIN1/SHN1* homolog that shares highly conserved protein domains with the *Arabidopsis* orthologs, suggesting potentially related protein functions (Figs. 62.1 and 62.2). This similarity includes the N-terminal region comprising the DB domain and the CMV-1 /CMV-2 domains. *M. truncatula* also contains another group Va member referred to as EFD (ethylene response factor required for nodule differentiation) that has been associated with the development of nitrogen fixing nodules (Vernié et al., 2008). Despite relatively high conservation in both the N-terminal region and DB domain (~84%), divergences are observed in the remaining C-terminal domains. While the CMV-1 and CMV-2 domains are conserved among WIN1/SHN1 orthologs of *M. truncatula* and *Arabidopsis*, they are only partially or poorly conserved in EFD and EFD-like TFs from different legumes (Fig. 62.2). In contrast, these EFD-like TFs share highly conserved domains that are likely to be related to specific functions of EFD.

EFD was identified following transcriptomics and subtractive hybridization strategies as being up-regulated in rhizobial-induced root nodules (El Yahyaoui et al, 2004; Godiard et al, 2007). To further understand the function of *EFD* during nodulation, a deletion mutant that completely abolishes *EFD* expression was obtained following reverse screening of a fast-neutron *M. truncatula* mutant population (Rogers et al., 2009, Vernié et al., 2008). This mutant showed an abnormally high number of nodules, often accompanied by the presence of multiple infection sites developing later into multilobed nodule structures. These experiments coupled with RNA interference and overexpression approaches support a role of EFD in the regulation of nodule number. In this context, EFD has recently being implicated in the signaling pathway involved in autoregulation of nodulation (AON) in *M. truncatula*, since *EFD* expression is up-regulated in roots over-expressing a key AON CLE peptide regulator named *MtCLE12* (Saur et al., 2011).

In addition to its role in the regulation of nodule density, *EFD* is also implicated in the control of nodule differentiation since *efd* nodules present an abnormally enlarged infection nodule zone II containing numerous and defective infection threads, which is often associated with a severe alteration in their capacity to differentiate into functional nitrogen-fixing nodules. These data suggest an important role for *EFD* in symbiosome formation which requires a symbiotic signaling pathway controlled by IPD3 (Ovchinnikova et al., 2011). Consistent with the roles assigned to this factor, the expression of *EFD* is mainly observed in young nodules and in zone II of mature nodules. Finally, a transcriptomic strategy focused on mutant and over-expressing *EFD* roots led to the identification of a cytokinin A-type response regulator-encoding gene named *MtRR4* as a potential direct target of *EFD*. Further transactivation assays came to support this hypothesis, since the nuclear-localized EFD protein was able to activate the transcription of *MtRR4* when transiently expressed in *Nicotiana benthamiana* leaves. While *MtRR4*, involved in cytokinin signaling, has been related to EFD function during nodule differentiation, *MtN19* has been suggested as a potential target of EFD in the negative feedback inhibition of nodule initiation (Moreau et al., 2011).

62.3.5 Group Vb Members Display Specialized Functions in Root Tissues and Includes the *M. truncatula* ERN TFs Involved in Symbiotic Signaling and Root Infection

Group Vb is represented by one unique TF in Arabidopsis and three phylogenetically related members in *M. truncatula*. While the legume TFs are involved in root nodulation, the *Arabidopsis* member RAP2.11 has been recently implicated in root responses to low levels of phosphate (Kim et al., 2012). Indeed, *RAP2.11*, identified following an activation-tagging strategy, was shown to directly mediate the transcriptional activation of a low phosphate responsive *AtHAK5* reporter gene in *A. thaliana* roots. This activity requires a modified GCC motif (GCCGGC) found within the promoters of *AtHAK5* and other genes up-regulated in *RAP2.11*-overexpressing plants, which includes genes required for the production of reactive oxygen species (ROS), ethylene and calcium signaling.

The nodulation-associated ERN1 (ERF required for nodulation) TF was first discovered through a genetic screen, as a gene essential for nodule formation in *M. truncatula* (Middleton et al., 2007). The deletion knockout mutant of ERN1 named *bit1-1* (for branched infection threads) was strongly affected in its ability to form nodules and to initiate rhizobial infection which was primarily blocked at the root surface despite certain abnormal infections initiated in root hairs. A similar nodulation-defective phenotype was observed in other *M. truncatula* or *P. sativum ern1* mutant alleles, carrying either Tnt1-insertion or EMS point mutations (Tsyganov et al., 2002; Middleton et al., 2007; Pislariu et al., 2012). These results, together with complementation studies, confirm the importance of ERN1 for nodule formation (Middleton et al., 2007; Cerri et al., 2012; see Chapter 59). Further analyses revealed that the *ern1* knockout mutant was also affected during early

symbiotic stages, because rhizobial-secreted symbiotic NF signals were no longer able to activate the expression of the NF-responsive *ENOD11* marker gene (Middleton et al., 2007). In this NF-responsive signaling pathway, ERN1 is positioned downstream of GRAS-type TFs NSP1/NSP2 (nodulation signaling pathway), which together are able to directly regulate *ERN1* (Hirsch et al., 2009; Cerri et al., 2012).

The role of ERN1 during early NF signaling was clarified by the discovery, following a yeast one-hybrid screen, that ERN1 was able to directly bind to the *ENOD11* promoter through a ~30 bp NF-box-responsive promoter sequence, necessary and sufficient to drive NF-elicited gene expression in *M. truncatula* roots (Boisson-Dernier et al., 2005; Andriankaja et al., 2007). In addition to ERN1, the phylogenetically related ERN2 and ERN3 TFs also bind to the *ENOD11* NF-box and this requires a conserved GCC-rich motif (GCAGGC) that strikingly resembles the GCC (GCCGGC) motif recognized by the *A. thaliana* RAP2.11 ortholog (Andriankaja et al., 2007; Kim et al., 2012, L. Frances and F. de Carvalho-Niebel, unpublished data). These TFs have very similar DB domains (~90% sequence identify) and this conservation is also observed among ERN-like TFs from other leguminous (*L. japonicus*, *P. sativum*, *Phaseolus vulgaris*, *Glycine max*) or non-leguminous plant species (*Populus alba*, *Oryza sativa*) (Fig. 62.3; Middleton et al., 2007). Outside the DB domain, the *A. thaliana* RAP2.11 and the *M. truncatula* ERN1 and ERN2 TFs share the phylogenetically conserved CMV-3 and CMV-4 domains defined by Nakano et al. (2006). However, sequence conservation within these domains is particularly high among legume members suggesting that they have more closely related functions. In line with this, most legume sequences, with the exception of ERN3, comprise a rosid-specific region common to poplar but not conserved in *Arabidopsis* (Fig. 62.3; Middleton et al., 2007). In *M. truncatula,* ERN1 and 2 are functionally related and both act as transcription activators. On the other hand, the more divergent ERN3 TF is unable to activate transcription and potentially act as a transcriptional repressor (Fig. 62.3; Andriankaja et al., 2007). Recent studies have demonstrated that ERN1, presumed to be derived from ERN2, can be functionally replaced by ERN2, reinforcing the likelihood of similar biological functions for these related factors (Young et al., 2011; Cerri et al., 2012).

Genetic and expression studies suggest that ERN1 and ERN2 play partially redundant functions during early stages of signaling and rhizobial infection. Indeed, the leaky phenotype of the *ern1* deletion mutant in terms of gene expression during NF signaling and rhizobial infection could be due to the presence of ERN2 (Mitra et al., 2004; Middleton et al., 2007; Cerri et al., 2012). Functional redundancy among ERN1 and 2 is reinforced by their overlapping expression profiles during certain stages of NF signaling and rhizobial infection. However, specific differences in their spatio-temporal expression profiles and in the dynamics of protein fusion accumulation *in vivo* also suggest specialized functions for these factors. ERN1 appears to be involved in stages preceding and accompanying infection while ERN2 would be involved in certain stages of infection (Cerri et al., 2012). During these early symbiotic stages, ERN1 mRNA also seems to be under translational control by selective recruitment to polysomes following bacterial inoculation (Reynoso et al., 2012).

In contrast to ERN2, ERN1 is expressed in nodule primordial cells in the root cortex that will further develop into nodule structures. This is in line with the *ern1* mutant phenotype that is deficient for nodule formation, and the fact that a constitutively active form of DMI3 kinase responsible for the formation of spontaneous rhizobia-free nodules, fails to form any nodules in the *ern1* mutant background (Middleton et al., 2007). Nevertheless, ERN1 does not seem to be absolutely required for initial root cortical cell divisions, but acts at a subsequent preinfection stage during nodule formation (Middleton et al., 2007; Cerri et al., 2012; see Chapter 59). Cytokinins, well known for their positive role in nodule organogenesis may be directly involved in the regulation of *ERN1* during this symbiotic stage via the potential regulation of *ERN1* by B-type cytokinin response regulators (Plet et al., 2011; Ariel et al., 2012). Finally, recent transcriptomic studies have highlighted the fact that ERN TFs may also play important roles during root endosymbiotic interactions with arbuscular mycorrhizal (AM) fungi, and in particular ERN2, which is up-regulated in AM inoculated roots (Young et al., 2011; Hogekamp et al., 2011). Future analyses of single or double ERN1/2 mutants will help to elucidate the relative importance of these two related TFs in root endosymbioses.

62.4 CONCLUDING REMARKS

The AP2/ERF superfamily constitutes one of the largest TF families, widely represented in plant species. Members of the ERF group, containing a unique AP2/ERF DB domain, are the major group within the superfamily, displaying roles in various biological processes such as the root nodule symbiosis. So far, only a limited number of ERF TFs have been shown to play essential roles during nodule formation and to date this is restricted to members of ERF group V. Despite belonging to the same phylogenetic group, ERN-type and EFD TFs display important structural differences and have quite different functions during the nodulation process. While ERN1 and 2 paralogs play critical roles during early symbiotic signaling and rhizobial infection, EFD functions at a later stage controlling nodule number and nodule differentiation (see Chapter 59). Recent RNA seq analyses have revealed that a large number of ERF TFs are expressed in mature nitrogen-fixing nodules, suggesting that ERFs from

different functional categories may be associated with nodule development. This myriad of potential candidates opens new perspectives for understanding the full contribution of AP2/ERF-mediated transcriptional reprogramming to the establishment of the root nodule symbiosis.

ACKNOWLEDGMENTS

We are grateful to Joelle Fournier and David Barker for their critical reading and useful comments on the manuscript. This work was supported by the Laboratoire d'Excellence program TULIP (grant no. ANR–10–LABX–41), by the ANR grant -08-GENO-106 "SYMbiMICS" and by the French Ministry of Education and Research (to M.R.C.).

63.1 INTRODUCTION

Legumes have the ability to develop a root endosymbiosis with soil bacteria, termed rhizobia and arbuscular mycorrhizal (AM) fungi. These capacities confer selective advantages for legumes to grow in soils of low nutrient content and render them the primary source of plant proteins for livestock feeding and human nutrition and indispensable crops in sustainable agriculture. In both nitrogen-fixing and AM associations, the microbial partners modulate the growth and development of legumes to be able to colonize the plant tissues and establish a symbiotic interaction.

The legume–rhizobial symbiotic interaction accounts for the major portion of the biologically fixed nitrogen in the ecosystem. Symbiotic nitrogen fixation takes place in root – or sometimes stem – nodules, and nodule development is initiated by the host-compatible symbiotic bacterial partner. The interaction commences following a mutual recognition process of the host plant and rhizobial signal molecules. The key signal molecule is the nodulation (Nod) factor (NF) which governs the parallel developmental processes of bacterial infection initiated in the root epidermis and nodule organogenesis activated in the root cortex (Oldroyd and Downie, 2008; see Chapters 51, 59). The attachment of rhizobia to root hairs induces the formation of a tubelike structures called infection threads (IT) which extend through the root epidermis toward the nodule primordia wherein they ramify and bacteria are released from the ITs into the cytoplasm of nodule cells (Jones et al., 2007). Bacteria are surrounded by a plant-derived membrane within the plant cells forming new subcellular compartments called symbiosomes (see also Chapters 31, 67). Bacteria in the symbiosomes divide and differentiate into their symbiotic forms (Mergaert et al., 2006), called bacteroids resulting in colonized and fully packed nodule cells with bacteroids. Similarly to rhizobia, infected nodule cells also undergo cell enlargement-coupled differentiation (Vinardell et al., 2003) to form the mature nodule. As a result of a compatible interaction between the symbiotic partners, a functional root nodule is developed wherein the plant partner supplies the bacteroids with photosynthetic products in exchange for ammonia converted from atmospheric nitrogen. *Medicago truncatula* forms cylindrical shaped indeterminate nodules characteristic for temperate legumes (Vasse et al., 1990). The mature *M. truncatula* nodules display a developmental gradient of cells, creating the zones of the typical indeterminate nodules. A group of cells forms the persistent meristematic region (zone I) at the nodule apex wherein the continuous

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

cell division produces new nodule cells. Bacteria are released from the IT into the cells of the infection zone (zone II), and the differentiation of rhizobia and plant cells is started in this region. The differentiation programs are completed in the few cell layer of the interzone (zone II–III). The major part of the mature nodule is composed of the symbiotic zone (zone III) wherein nitrogen fixation takes place. The basal part of older nodules contains a senescence region (zone IV) wherein bacteroids and nodule cells undergo degradation.

The development of the model legume systems *M. truncatula* and *Lotus japonicus* and their substantially completed genome sequences (Sato et al., 2008; Young et al., 2011) greatly advances the molecular studies of legume–microbe symbiotic interactions. Mutants impaired in certain biological processes provide a valuable tool to dissect gene function. Several mutant populations have been produced to identify symbiotic genes in model legumes applying chemical treatment (Benaben et al., 1995; Szczyglowski et al., 1998; Penmetsa and Cook, 2000; Perry et al., 2003; Le Signor et al., 2009), ionizing irradiation (Starker et al., 2006; Rogers et al., 2009) and exploiting the mobilization activity of transposons (Schauser et al., 1999; Tadege et al., 2008; Rakocevic et al., 2009; Pislariu et al., 2012; see Chapter 83). The genetic dissection of the establishment of rhizobial and AM symbiosis in both model legumes has identified many of the key components of the symbiotic signaling (Sym) pathway (also known as CSP or CSSP; recently reviewed by Kouchi et al., 2010; Madsen et al., 2010; Murray, 2011; Venkateshwaran et al., 2013; Oldroyd, 2013; see Chapters 42, 55, 59, 110). In addition, plant genes functioning in the regulation of nodule number (Nishimura et al., 2002; Krusell et al., 2002; Schnabel et al., 2005; Penmetsa et al., 2008), infection (Arrighi et al., 2008; Kiss et al., 2009; Yano et al., 2009), bacterial differentiation (Wang et al., 2010), maintenance (Kumagai et al., 2007; Bourcy et al., 2013), and transport (Krusell et al., 2005; Bagchi et al., 2012) have been also identified by analyzing mutants defective for nodulation (see also Chapter 59).

Fast neutron (FN) bombardment can provide an efficient method to generate knockout mutants in plants (Li et al., 2001; 2002; Rogers et al., 2009; Bolon et al., 2011). Compared to chemical mutagenesis which induces point mutations and to transposon or T-DNA insertion mutagenesis, FN irradiation generally induces deletions. As detected in *M. truncatula* mutant loci, the deletions can range from few base pairs (Mitra et al. 2004) to tens of kilobase pairs (Ane et al., 2004; Middleton et al., 2007). In some cases, the deletion event is coupled with point mutations, as it was found in the *ipd3-1* allele (Horvath et al., 2011), or the FN irradiation generated other rearrangements (*lin-3* allele; Kiss et al., 2009).

In this study, we report the result of a genetic screen to identify symbiotic mutants of *M. truncatula* blocked in nodule invasion, persistence of rhizobia, and nodule function. FN-bombarded and ethyl methanesulfonate (EMS)-mutagenized *M. truncatula* seed populations were screened for nodulation defects, and nonnitrogen-fixing (Fix-) mutants were selected from the candidate mutants and characterized further (Domonkos et al., 2013). In this chapter, we describe the genetic analysis of the *M. truncatula* symbiotic mutants isolated and the phenotypic characterization of the mutants defective in nodule function. Allele tests were carried out to disclose new alleles of known symbiotic genes and identify novel complementation groups. Microscopical and gene expression analyses of Fix- mutants were performed to reveal which stages of the symbiotic interaction were blocked and to analyze the potential function of the affected genes.

63.2 MATERIALS AND METHODS

63.2.1 Plant Material, Growth Conditions, and Bacterial Strains

The large-scale symbiotic screen was carried out on FN-bombarded and EMS-mutagenized seed populations of *M. truncatula* Jemalong line (FN) and genotype A17 of *M. truncatula* (EMS) as described in Domonkos et al. (2013). The seeds of the Jemalong genotype of *M. truncatula* were exposed to FN radiation as described by Rogers et al. (2009). For the symbiotic phenotype screen, nodulation tests, and expression studies, the *M. truncatula* seeds were scarified, sterilized, washed, and imbibed as described in the *M. truncatula* handbook (http://www.noble.org/MedicagoHandbook). Sterilized seeds were vernalized for 5–7 days at 4 °C and thereafter germinated on inverted agar (0.8% water agar) plates in the dark at room temperature. For the symbiotic screen, mutagenized and control wild-type seedlings were grown in 1:1 mixture of Terragreen and sand as described by Marsh et al. (2007). Four-day-old *M. truncatula* seedlings were inoculated with the robust *Sinorhizobium meliloti* strain B1 in the primary screen, and plants were evaluated for their symbiotic phenotype 5–6 weeks postinoculation. Confirmation screening experiments were carried out in the same growing substrate in walk-in growth chambers as described by Marsh et al. (2007).

For phenotypic characterization, ineffective nodulation mutants and wild-type plants were grown on either square plates containing buffered nodulation media (BNM) supplemented with 0.1 μM L-α-(2-aminoethoxyvinyl)-Gly (AVG) (Sigma-Aldrich, St. Louis) or in trays containing a 3:1 mixture of zeolite substrate (Geoproduct Kft., Mád, Hungary) and sand. Four-day-old *M. truncatula* seedlings were inoculated with *S. meliloti* strain 1021 carrying the *hemA*::*lacZ* reporter construct (pXLGD4; Boivin et al., 1990) or *S. meliloti* strain CSB357 containing the P*nifH*::*uidA* fusion (Starker et al., 2006). *S. meliloti* cultures were grown in liquid TA, and bacteria were pelleted at log phase and

resuspended in liquid BNM. A final dilution 1:50 (OD_{600} 0.03–0.1) of bacterial suspension was used for inoculation by flooding the roots on plate or adding 500 µl suspension to each plant in the tray. Plants on plates and trays were grown in growth chambers using the same light and temperature conditions as described earlier by Horvath et al. (2011).

Genetic crossings between symbiotic mutants and genotypes were carried out according to the method described by Chabaud et al. (2007). *ipd3-1/dnf5-1* double mutant plants were selected from the F2 population of the cross of *ipd3-1* and *dnf5-2* plants with PCR using gene-specific oligonucleotides able to detect the deletions in *IPD3* (Horvath et al., 2011) and *DNF5* (unpublished result) genes.

63.2.2 Microscopic Analysis

For microscopic analysis, nodules were harvested 3 weeks postinoculation with *S. meliloti* 1021 (pXLGD4) or *S. meliloti* strain CSB357 and fixed with 4% formaldehyde in 1xPBS (pH 7.4) for 30 min on ice and rinsed 3 × 15 min in 1xPBS (pH 7.4). The nodules were embedded in 5% agarose (SeaKem® LE Agarose, Lonza), and 70 µm thick longitudinally sections were prepared using a MICROM HM 650V Vibrotom. To visualize β-galactosidase activity, sections were incubated in a staining solution containing 50–50 mM potassium ferricyanide and potassium ferrocyanide and 0.08% X-gal (Fermentas, Lithuania) in 1xPBS (pH 7.4) for 30 min at room temperature. Stained nodule sections were observed under an Olympus BX41M microscope with 10x and 20x objectives, and images were captured using an Olympus Camedia E-10 digital camera. GUS staining was carried as described by Horvath et al. (2011).

To analyze the bacteroid morphology, nodule sections were stained in 1xPBS (pH 7.4) containing 5 µM SYTO13 (Invitrogen, Eugene, Oregon) for 20 min and rinsed with 1xPBS.

Confocal laser scanning microscopy was performed using an Olympus FluoView FV1000 confocal laser scanning microscope (Olympus Life Science Europa GmbH, Hamburg, Germany). Microscope configuration was as follows: objective lenses, UPLSAPO 10x (dry, NA:0.4), UPLFLN 40x (oil, NA:1.3), and UPLSAPO 60x (oil, NA:1.35); sampling speed, 4 µs/pixel; line averaging, 2x; scanning mode, sequential unidirectional; excitation, 488 nm (SYTO13); laser transmissivity, 5%; main dichroic beam splitter, DM405/488; intermediate dichroic beam splitter, SDM 490; and emission filter, 505–530 nm.

63.2.3 Gene Expression Analyses

For quantitative RT-PCR experiments, *M. truncatula* plants were grown on plates using the same conditions as described for the microscopic analysis. *Medicago* roots or nodulated roots were harvested 14 days postinoculation, and the total RNA was extracted using the TRI Reagent (Sigma, United States) following the manufacturer's protocol. The RNA samples were treated with RQ1 DNase I (Promega, United States) according to the manufacturer's instructions. RNA was cleaned up by using the RNeasy Mini Kit (QIAGEN, DE). Genomic DNA-free total RNA was quantified using a NanoDrop 1000 spectrophotometer (NanoDrop Technologies, United States) and checked for quality by gel electrophoresis.

Complementary DNA was prepared from 1 µg total RNA with the SuperScript III First-Strand Synthesis System for RT-PCR (Invitrogen, United States) using oligo-dT primers according to the manufacturer's instructions. Quantitative RT-PCR was performed using the MiniOpticon™ System (Bio-Rad, United States) employing Bio-Rad CFX Manager software 3.0. Maxima™ SYBR Green Master Mix (Thermo, United States) was used to monitor double-stranded (ds) DNA synthesis in 48-well plates. The final primer concentration of each gene-specific primer was 100 nM. The PCR conditions were as follows: a single cycle of 94°C for 10 min was followed by 45–50 cycles of 94°C for 15 s, 58–60°C for 20 s, and 72°C for 20 s. Following each PCR amplification, a melting curve was run to check genomic DNA contamination. To generate a melting profile, fluorescence of the samples was measured repeatedly as the temperature was gradually increased from 60 to 95°C over 20 min after complete denaturation. Primer–dimer formation was estimated by running a control without template DNA. Results were expressed as a threshold cycle (C_T) value, which was averaged from three replicate reactions. For normalization, the C_T value of the reference gene was subtracted from the C_T value of the gene of interest (ΔC_T). $\Delta\Delta C_T$ values were calculated by subtracting the ΔC_T of the wild-type sample from the ΔC_T value of the different mutants. Fold induction ($2^{\Delta\Delta C_T}$) of three independent experiments were averaged and plotted using SE. Primer sequences used for qPCR are published in the study of Domonkos et al. (2013). A gene with an ubiquitin domain was used as a reference gene, and its intron sequence was utilized for checking genomic DNA contamination of cDNA samples, as suggested by Kakar et al. (2008).

63.3 RESULTS

63.3.1 Developing a Symbiotic Nitrogen Fixation Mutant Screen and Identification of *M. truncatula* Mutants Defective in Nodule Function

In order to identify mutants defective in rhizobial invasion and bacteroid differentiation, we aimed to screen *M. truncatula* plants able to develop ineffective root nodules

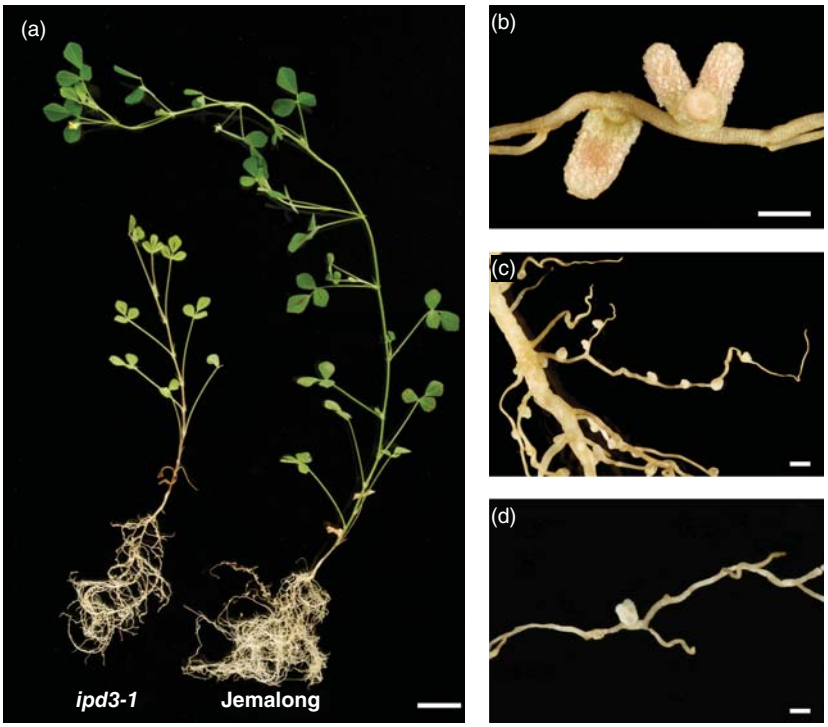

Figure 63.1 Nodulation phenotype of ineffective nodulation (*ipd3-1*) and wild-type *M. truncatula* plants 4 weeks postinoculation (wpi) with *S. meliloti* 1021. Plants were grown in zeolite/sand substrate. Ineffective mutants display retarded growth and showed the characteristic symptoms of nitrogen deficiency. Wild-type plants developed pink cylindrical nodules (b). Both spherical (c) and elongated (d) white nodules were found on ineffective *ipd3-1* mutant roots. Scale bars: 2 cm in (a), 1 mm in (b)–(d).

(nodules without the ability to fix nitrogen). A large-scale forward genetic screen was developed using FN-bombarded and EMS-mutagenized *M. truncatula* Jemalong populations (Domonkos et al., 2013). Approximately 38,000 seedlings of about 600 M2 families (Marsh et al., 2007) were grown in media of low N content and screened for symbiotic phenotype 5–6 weeks postinoculation with wild-type *S. meliloti* strain B1 (Oldroyd and Long, 2003). Plants defective in symbiotic nitrogen fixation were identified with visual screening for nitrogen deficiency symptoms (yellowish leaves, purplish stem due to anthocyanin accumulation, stunted growth) and the ability to develop nodules (Fig. 63.1). The progenies of the putative mutants were subjected to a second round of tests to confirm their symbiotic phenotype, and finally, seven ineffective nodulation (Fix-) mutants developing small white nodules on roots indicating the absence of leghemoglobin were selected for further analysis. These mutants were initially designated as 5L, 7Y, 9F, 11S, 12AA, 13U, and 14S.

63.3.2 Genetic Analysis of Ineffective Symbiotic Mutants of *M. truncatula*

The growth habit of the ineffective mutants was tested in medium supplemented with combined nitrogen to prove that the nitrogen deficiency was the result of impaired nitrogen fixation. The growth habit of the seven ineffective plants was similar to wild-type plants under nonsymbiotic conditions indicating their defects in symbiotic nitrogen fixation rather than in nitrogen uptake or metabolism. The seven Fix- mutants were backcrossed to the wild-type Jemalong and also crossed to the A20 genotype to analyze the inheritance of the Fix- phenotypes and to develop F2 mapping populations. The segregation ratios of the Fix- phenotype (Table 63.1) in the F2 progeny of these crosses indicated that all the new ineffective mutants segregated as single recessive loci. Crosses between the mutant plants and to the previously identified ineffective *dnf* mutant series of *M. truncatula* (Starker et al., 2006) were carried out to define how many independent loci were represented by the seven ineffective-nodulating mutants. The allelism test revealed two novel complementation groups. For the reasons described in the following, we called the responsible locus of one of them, *IPD3*, with the mutant allele referred to as *ipd3-1* (Horvath et al., 2011) and the other as *dnf8* (Table 63.2). The ineffective symbiotic phenotype of the F1 hybrids of 14S and *dnf5* revealed an allelic relationship, and therefore, 14S is hereafter termed *dnf5-2*.

Four additional Fix- mutants were partially analyzed. The allelism tests revealed that 5L and 11S carried mutations at the same locus, but incomplete analyses of these along with 7Y and 13U meant that we were not able to define with allelism tests alone whether these represent new genetic loci or alleles of already defined *DNF* loci. However, the allelism tests performed to date reveal no similarities with the *DNF* loci tested (Table 63.2). In order to define whether mutants 5L/11S, 7Y, and 13U represented new mutants or alleles of

Table 63.1 Segregation analysis for the ineffective symbiotic phenotype of the seven selected ineffective mutants isolated in the symbiotic mutant screen

Crosses	Number of Plants		Segregation Ratio of Wild Type and Mutant Alleles	χ^2
	Fix+	Fix−		
5L × A17	42	11	3.8:1	0.594

The plus sign indicates that progeny displayed wild-type symbiotic phenotype. The minus sign indicates that F1 hybrid plants displayed nitrogen deficiency symptoms under symbiotic conditions. Numbers in parenthesis represent the plants scored for symbiotic phenotype and the numbers of pods from which seeds originated. The allelic relationships are highlighted with gray.

known complementation groups, further allelism tests or genetic mapping of the Fix- loci are required.

63.3.3 Macroscopic Characterization Revealed That Ineffective Mutants Are Arrested in Different Stages of Symbiotic Nitrogen Fixation

In order to analyze the histology of the mutant nodules, to determine whether rhizobia were released in the mutant nodule cells and assess at which stages the nodule development was arrested in the Fix- mutants, *M. truncatula* wild-type and mutant plants were inoculated with *S. meliloti* 1021 (pXLGD4) which constitutively expresses the *LacZ* reporter gene [*hemA*::*lacZ*; Boivin et al., 1990] and with *S. meliloti* strain CSB357 containing a P*nifH*::*uidA* fusion (Starker et al., 2006).

The isolated ineffective symbiotic mutants developed exclusively white spherical or cylindrical nodules except *dnf8* on which a few pale pinkish nodules could be observed occasionally. To visualize the presence of bacteria in the nodules, we stained thin longitudinal sections of 21-day-old nodules following inoculation for β-galactosidase activity. The extent of bacterial colonization in the nodule zones was examined by light microscopy, and micrographs of sections are shown in Figure 63.2a–h. The X-gal staining showed the typical zonation (Vasse et al., 1990) of a fully developed indeterminate nitrogen-fixing nodule on wild-type *M. truncatula* Jemalong plants (Fig. 63.2a). The majority of the nodules formed on *ipd3-1* roots were spherical with abnormal nodule apices (Fig. 63.2b), but a small number of nodules developed into elongated cylindrical structures (Fig. 63.3d, e) (Horvath et al., 2011). Neither class of *ipd3-1* nodules contained cells with released bacteria, indicating an essential function of *IPD3* for bacterial release. In contrast to *ipd3-1*, the *dnf5-2* nodules contained cells harboring bacteria (Fig. 63.2c), but no characteristic zonation of the indeterminate nodules was observed in *dnf5-2* nodules.

The other Fix- mutants developed more or less elongated nodules (Fig. 63.2d–h), but the nodule zonation or occupancy by rhizobia was impaired in these mutants. The nodules of mutant 7Y showed extremely low bacterial occupancy; bacteria could be detected only in a few cells of the infection zone, and only a few IT were present in the nitrogen fixation zone (Fig. 63.2d). Moreover, an extensive brown pigmentation was observed throughout the nodule. Sporadic brown pigmentation was also present in 5L and 11S nodules (Fig. 63.2e, f) and to a lesser degree in 13U nodules (Fig. 63.2h). We believe that this brown pigmentation may be associated with the senescence of cells within the nodules of these Fix- mutants. Mutants 5L and 11S developed nodules with a narrow infection zone containing several infected cells, but the infected cells in the intermediate and nitrogen fixation zone appeared to be degraded (Fig. 63.2e, f). In *dnf8* nodules, infected cells occurred in the interzone, but no infected cells and only a few IT were found in the nitrogen fixation zone (Fig. 63.2g). Similarly, the 13U nodules showed bacteria within the cells of the infection zone but low levels of infection within the nitrogen fixation zone (Fig. 63.2h).

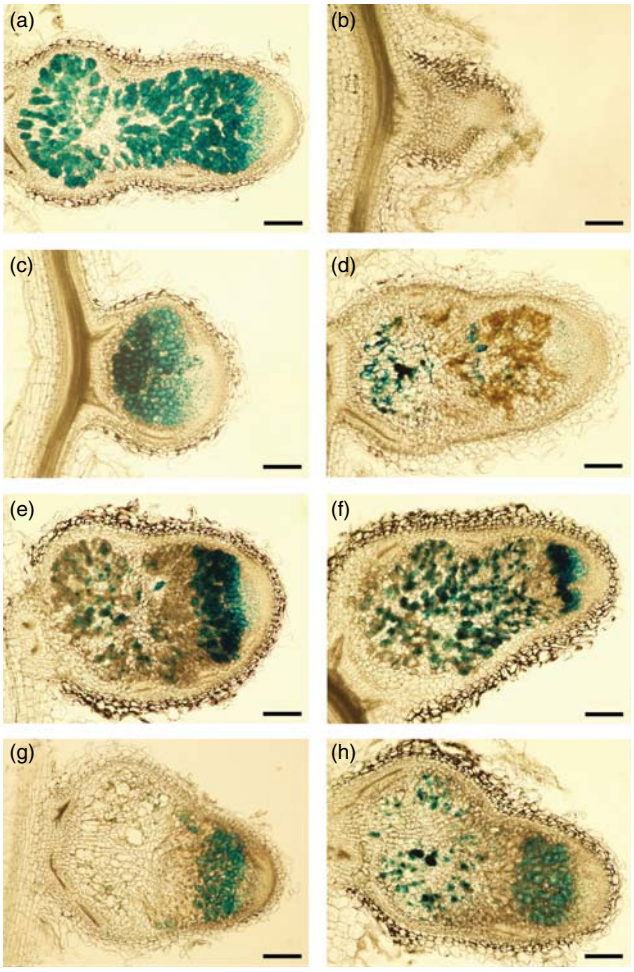

Figure 63.2 Rhizobial infection of nodules developed on roots of wild-type (a) and ineffective nodulation mutants (b–h). Nodules were harvested 3 weeks postinoculation with *S. meliloti* 1021 strain expressing the *lacZ* gene. 70 µm thick nodule sections prepared with a vibration microtome were stained with X-gal to detect β-galactosidase activity. (b–h) Nodules of *ipd3-1* (b), *dnf5-2* (c), 7Y (d), 5L (e), 11S (f), *dnf8* (g), and 13U (h) mutants show various bacterial colonization phenotypes. Bars represent 200 µm.

Analysis of double mutant phenotypes constitutes a powerful tool to analyze the functional relationship between genes involved in the same biological process. Although the nodulation phenotype of *ipd3* and *dnf5* single mutants suggested that the function of IPD3 precedes DNF5, we analyzed the nodule phenotype of *ipd3/dnf5* double mutants following inoculation with *S. meliloti* 1021 (pXLGD4).

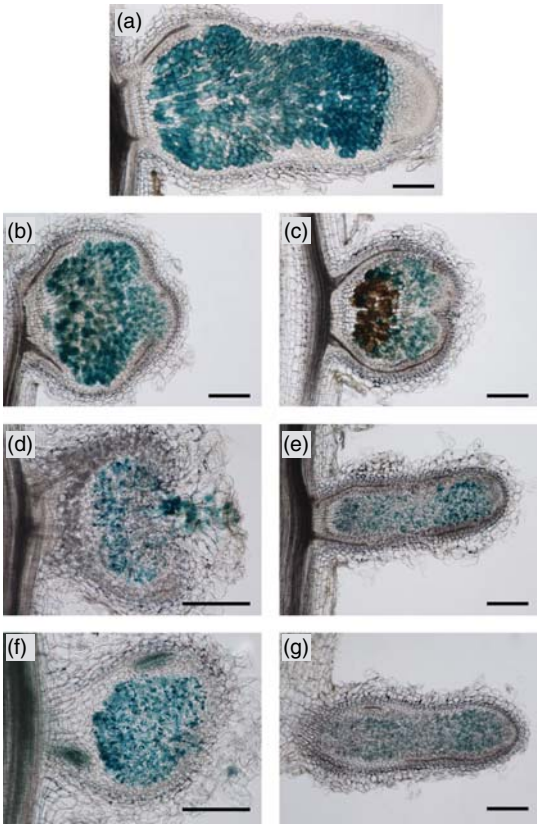

Figure 63.3 Rhizobial infection of nodules developed on roots of wild-type (a), single *dnf5-2* (b and c), and *ipd3-1* (d and e) and double *ipd3-1/dnf5-2* mutants (f and g). Nodules were harvested 3 weeks postinoculation with *S. meliloti* 1021 strain expressing the *lacZ* gene. 70 µm thick nodule sections prepared with a vibration microtome were stained with X-gal to detect β-galactosidase activity. Bars represent 200 µm.

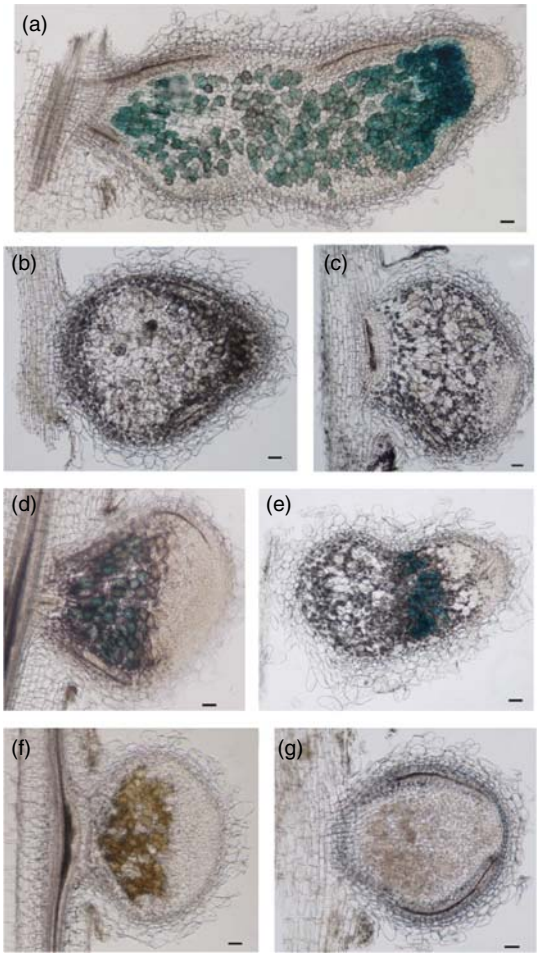

Figure 63.4 Expression of the *nifH*::*uidA* rhizobial marker gene inside mutant plant nodules. Nodules were harvested 3 weeks postinoculation with *S. meliloti strain* CSB357, and the activity of *nifH* promoter–uidA fusions was visualized with GUS staining in nodules developed on wild-type (a), 13U (b), *dnf8* (c), 5L (d), 11S (e), 7Y (f), and *dnf5-2* (g) roots. Bars represent 100 µm.

The formation of spherical and elongated nodules and the impaired bacterial colonization of the *ipd3/dnf5* double mutants were similar to the single *ipd3-1* plants, indicating that *IPD3* is epistatic to *DNF5* (Fig. 63.3).

The defects in symbiotic nitrogen fixation were also validated by analyzing the activity of the bacterial *nifH* promoter fused with the *uidA* (β-glucuronidase) gene. After 18 days inoculation with *S. meliloti* containing the P*nifH::uidA* fusion, wild-type *M. truncatula* nodules displayed high level of *nifH* expression in the different nodule zones (Fig. 63.4a). 5L and 11S nodules displayed a low level of *nifH* expression in the indeterminate zone (Fig. 63.4d, e), indicating that the arrest of the symbiotic interaction prior to invaded nodules cells is initiated in the nitrogen fixation zone. The mutants 7Y, 12AA, 13U, and 14S were all defective in inducing the *nifH* activity which correlates with the low occupancy of nodules by rhizobia in these mutants (Fig. 63.4b, c, f, g).

The effective functioning of the symbiotic nodules is accompanied by the simultaneous morphological differentiation of the nodule cells and rhizobia (Maunoury et al., 2010). To investigate the differentiation of rhizobia in the Fix- mutants, the bacterial morphology was analyzed following staining with the nucleic acid-binding dye SYTO13 and observed using confocal laser scanning microscopy (Haynes et al., 2004). Elongated bacteria could be observed in the nodule cells of wild-type plants (Fig. 63.5a). In contrast, only plant nuclei and the IT fluoresced in the *ipd3-1* elongated-type nodules (Fig. 63.5b) (Horvath et al., 2011), indicating that nodule cells were not invaded by rhizobia but were retained inside the IT. Most IT displayed an abnormal morphology; they were thick and highly crooked with enlarged, blister-like formations (Horvath et al., 2011). From these analyses, we conclude that the major function of *IPD3* is to control bacterial release from the IT. The nodules of *dnf5-2* contained nonelongated rod-shaped bacteria, indicating the failure of bacteroid differentiation

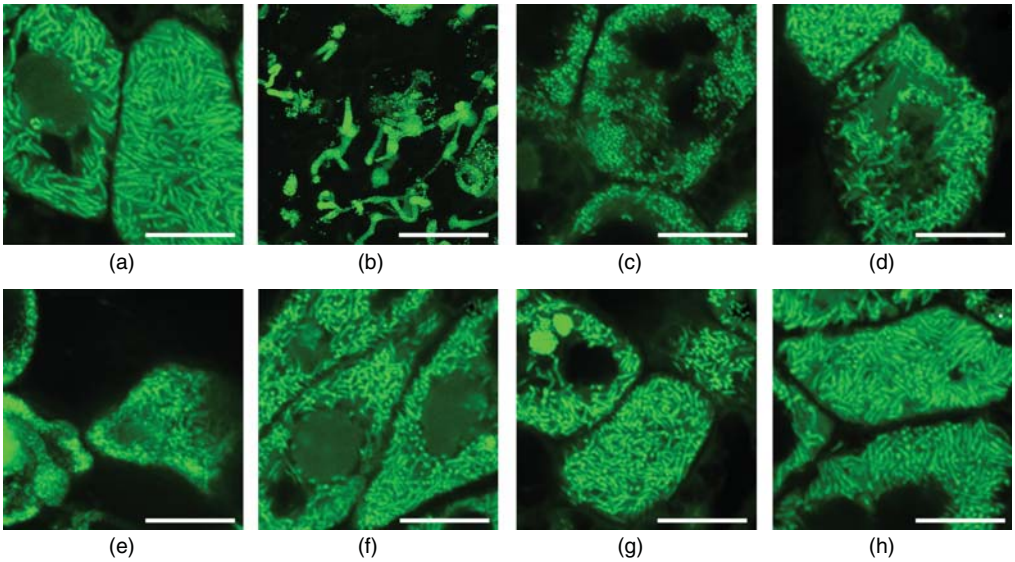

Figure 63.5 Bacterial morphology in *M. truncatula* wild-type (a) and ineffective nodulation mutant nodules (b–h). Longitudinal sections of nodules 4 wpi with *S. meliloti* were stained with SYTO13 and analyzed by confocal microscopy. The analysis revealed elongated bacteroids in the infected cells of wt nodules in the nitrogen fixation zone (a). The elongated nodules of *ipd3-1* did not contain released bacteria, but plant nuclei and infection threads with retained undifferentiated bacteria were detected (b). No bacterial elongation was observed in *dnf5-2* (c) nodule cells, indicating defect in bacterial differentiation. The bacterial development is initiated in the nodules of the other ineffective mutants (*dnf8* (d), 7Y (e), 5L (f), 11S (g), and 13U (h)). Bars represent 20 μm.

(Fig. 63.5c). The 5L and 11S nodules are dotted with a few cells containing bacteria in the nitrogen fixation zone (Fig. 63.2e, f), and these cells harbored rhizobia presenting limited bacteroid differentiation (Fig. 63.5f, g). 7Y and *dnf8* nodules did not contain infected cells in the nitrogen fixation zone (Fig. 63.2d, g), but elongated and branched bacteroids could be detected in the interzone cells (Fig. 63.5d, e). The few invaded cells of 13U nodules (Fig. 63.2h) contained elongated bacteria (Fig. 63.5h), indicating that the impaired gene is required for the persistence of rhizobia in the infected nodule cells rather than for bacterial differentiation.

63.3.4 Expression Pattern of Symbiotic Marker Genes Differentiates between Ineffective Mutants

The nodule formation and the initiation of nitrogen fixation are a result of a complex developmental program accompanied by transcriptional changes in both symbiotic partners (Maunoury et al., 2010; Moreau et al., 2011). Hybridization techniques and *in silico* analyses revealed several differentially expressed late nodulin genes (Mitra and Long, 2004; Starker et al., 2006; Maunoury et al., 2010; Moreau et al., 2011) which can be used as markers to dissect the *M. truncatula*–rhizobial symbiotic interaction. In order to differentiate between the progressions of the ineffective mutants isolated in this study at the transcription level, we selected ten symbiosis-specific genes (*MtLEC4*, *MtLb1*, *MtCAM1*, *MtN31*, *MtCP2*, *MtIPD3*, *MtNOD25*, *MtNOD26*, *MtNAP2*, and *MtNCR121*). We monitored rhizobia-induced expression of these symbiotic marker genes 14 days following bacterial inoculation (dpi) using quantitative RT-PCR (Fig. 63.6).

The nodule-specific *MtIPD3* gene, the member of the symbiosis signaling pathway, is required for rhizobial and mycorrhizal colonization (Horvath et al., 2011; Ovchinnikova et al., 2011), and following a transient decrease between 0 and 5 dpi, it is strongly expressed in wild-type nodules 15 dpi (Messinese et al., 2007). Based on the nodulation phenotype of the *ipd3* mutants (Figs. 63.1 and 63.2) (Horvath et al., 2011), we assumed that the functioning of the IPD3 protein precedes all the genes impaired in the ineffective nodulation mutants of this study. According to this, similar or moderate reduction of *IPD3* expression was detected compared to wild type in the ineffective nodulation mutants (Fig. 63.6).

Corresponding to the early arrest of the symbiotic process in *ipd3-1*, *dnf5-2*, and 7Y (Fig. 63.2), transcriptional activation of all the symbiotic marker genes was blocked or severely reduced in these mutants (Fig. 63.6). One interesting exception however was *NCR121* which was induced in *dnf5-2* to levels comparable to wild-type plants, but which was strongly reduced in *ipd3-1* and 7Y. The expression of *MtNAP2*, encoding a nodule-specific protein with unknown function, was reduced in all ineffective mutants compared

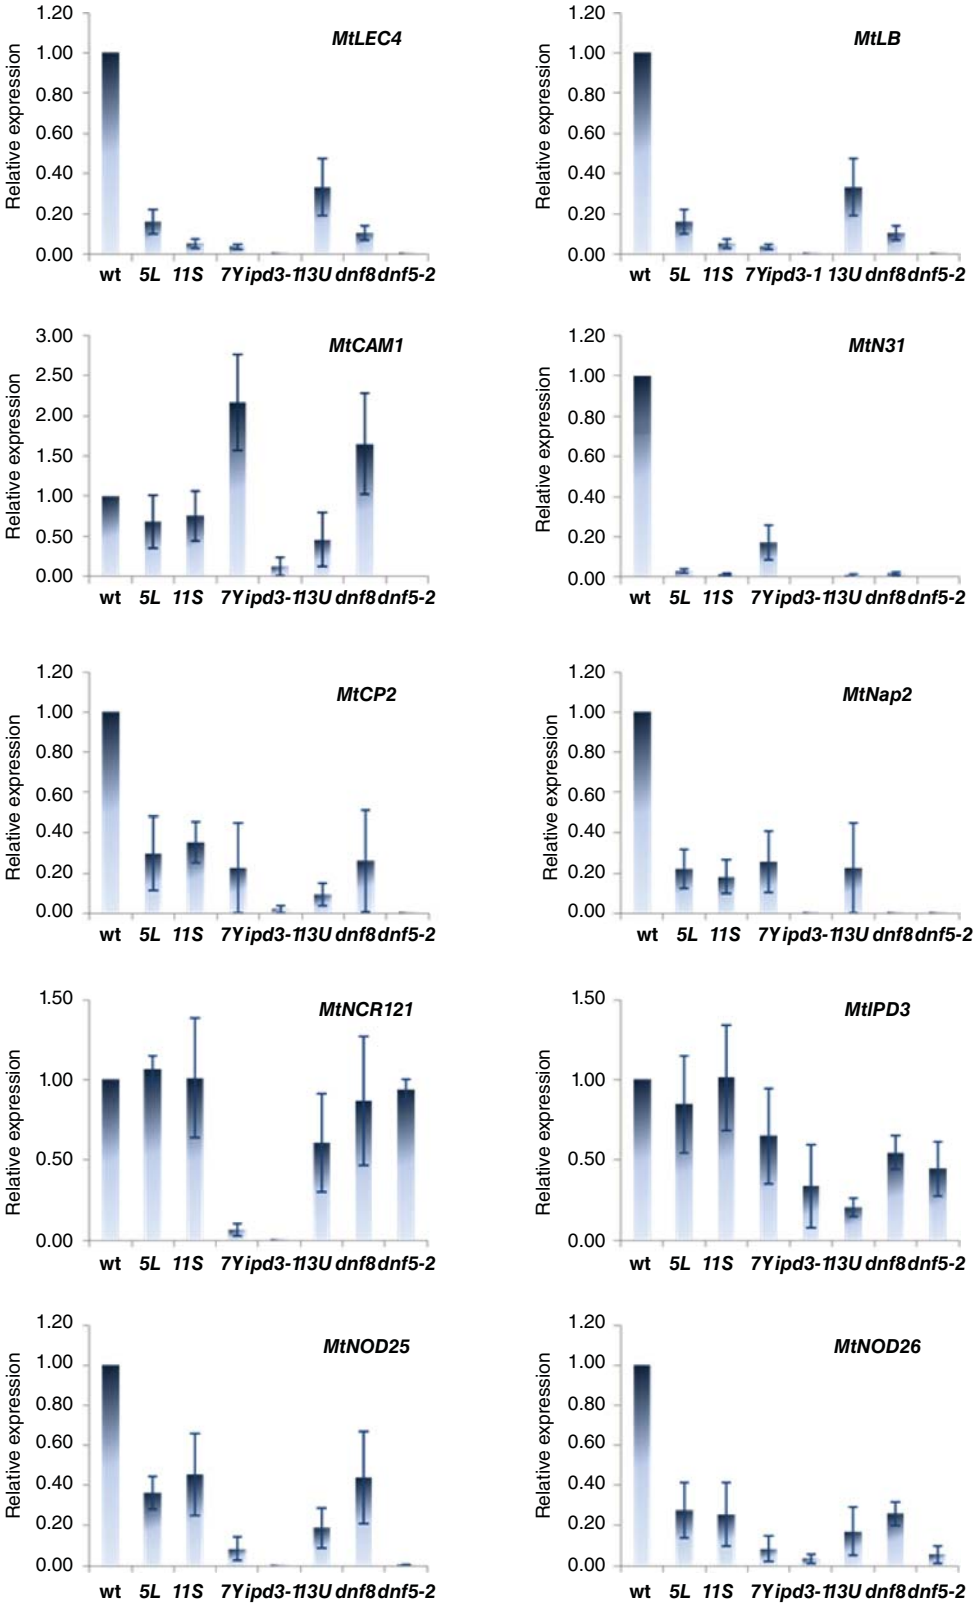

Figure 63.6 Expression analysis of selected nodule-specific genes in *M. truncatula* ineffective mutants 14 days after inoculation with *S. meliloti* 1021. The expression of genes *MtLEC4*, *MtLB*, *MtCAM1*, *MtN31*, *MtCP2*, *MtNAP2*, *MtNCR121*, *MtIPD3*, *MtNOD25*, and MtNOD26 was analyzed relative to wild type using RT-PCR. Three biological replicates for each mutant with three technical repeats were used for the analysis. Error bars represent SE.

to wild-type plants (Fig. 63.6). *MtNAP2* was expressed at lower level in nodules containing some infected cells in the nitrogen fixation zone, but the complete failure of its induction that was detected in *ipd3-1*, *dnf5-2*, and *dnf8* is related to the absence of nodule zonation or lack of bacterial occupancy in the nitrogen fixation zone (Figs. 63.3 and 63.6). The *MtLB1*, *MtNOD25*, and *MtNOD26* late nodulins were expressed at lower level in the ineffective mutants of this study than in wild type, and they were not or hardly induced in the early ineffective mutants *ipd3-1* and *dnf5-2*. One of the marker genes of early senescence in nodules, the cysteine protease gene *MtCP*, was expressed differently in the ineffective symbiotic mutants (Fig. 63.6). The *MtN31* transcript, encoding a nodule-specific Cys-rich protein (*NCR158*), could be detected at very low level in all ineffective mutants compared to wild type, indicating that its expression accompanies functioning symbiotic nodules (Fig. 63.6). The expression data of the symbiotic marker genes were consistent with the block of the symbiotic nodule development detected by microscopic analysis.

63.3.5 IPD3 Is Required for DMI3-Induced Spontaneous Nodule Formation Irrespective of the Genetic Background

The characterization of the mutant phenotypes and the analysis of gene expression indicated that *IPD3* appears to be the earliest acting gene of the genes impaired in the seven ineffective mutants. The gene was cloned by positional cloning (Horvath et al., 2011; Ovchinnikova et al., 2011), and it was demonstrated that it encodes the interacting protein of DMI3 (IPD3) (Messinese et al., 2007), the ortholog of *L. japonicus* CYCLOPS (Yano et al., 2008; see Chapter 59). Detailed phenotypic characterization and molecular studies revealed that IPD3 is required for rhizobial and mycorrhizal colonization of the host plant and is necessary for appropriate NF-induced gene expression (Horvath et al., 2011; Ovchinnikova et al., 2011). These data indicated that IPD3 is a member of the common Sym pathway. However, differences in the severity of *ipd3* mutants could be observed depending on the genetic background (Horvath et al., 2011).

It was demonstrated earlier that the autoactive form of DMI3 (DMI3 1–311*) could not induce spontaneous nodule formation, but the gain-of-function version of the cytokinin receptor MtCRE1 did trigger spontaneous nodules on *ipd3-3* roots (Ovchinnikova et al., 2011). In order to analyze whether the ability of spontaneous nodule formation depends on the genetic background, the gain-of-function version of DMI3 (DMI3 1–311*) (Gleason et al., 2006) was introduced into *ipd3-1* (*M. truncatula* Jemalong background) and *ipd3-2* (*M. truncatula* ssp. *tricycla* R108 background) roots. Spontaneous nodule formation was observed on *dmi3* roots (52 nodules/36 transformed roots) (Fig. 63.7a–c), and several

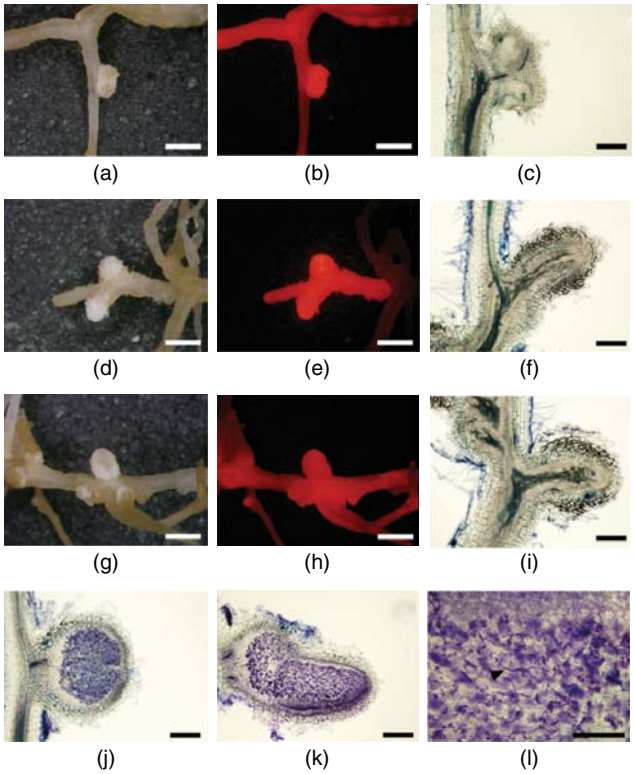

Figure 63.7 Testing the ability of spontaneous nodule formation on *dmi3* and *ipd3* mutants roots expressing the autoactive form of DMI3 (35S::DMI3 1–311*). 70 µm sections of nodule and root structures were prepared and stained with toluidine blue. Spontaneous nodule formed on *dmi3* roots (a–c), and only emerging lateral roots were detected on *ipd3-1* (d–f) and ipd3-2 (g–i) roots. The toluidine blue staining of spherical (j) and elongated (k) *ipd3-1* nodules induced by *S. meliloti* infection on native roots revealed extended invasion zones with hypertrophied infection threads with retained bacteria (l). Scale bars: 1 mm in (a), (b), (d), (e), (g), and (h); 200 µm in (c), (f), (i), (j), and (k); and 50 µm in (l).

nodule-like structures formed on *ipd3* roots (Fig. 63.7d–i). The microscopic analysis of the sections of these outgrowths showed that these structures had central vascular systems which indicated that they were emerging lateral roots and not spontaneous nodules. In addition, toluidine-blue staining did not detect bacteria entrapped in infection threads in these structures which is characteristic for nodules developed on native roots of *ipd3* (Fig. 63.7j–l). Based on these data, we could conclude that no spontaneous nodule formation was induced on *ipd3-1* (49 transformed roots) and *ipd3-2* (24 transformed roots) mutant roots, indicating no differences in the ability of spontaneous nodule formation between *ipd3* mutants in different genetic backgrounds.

63.4 DISCUSSION

Symbiotic nitrogen fixation mutants proved to be powerful and useful tools to dissect the nitrogen-fixing symbiotic

interaction and identify several essential components of the Sym signaling pathway (Venkateshwaran et al., 2013; Oldroyd, 2013; see Chapters 42, 55, 59, 110). Despite the identification of few genes required for bacterial release, persistence of bacteria, and nodule function in *M. truncatula* (Wang et al., 2010; Horvath et al., 2011; Ovchinnikova et al., 2011; Bourcy et al., 2013), relatively little is known about genes necessary for nodule invasion and maintenance of rhizobial symbiotic interaction. Early genetic screens carried out on EMS- or FN-mutagenized *M. truncatula* populations identified several ineffective nodulation mutants (Benaben et al., 1995; Starker et al., 2006; Teillet et al., 2008). Large-scale genetic screens have been initiated recently to identify mutants defective in nodule function (Pislariu et al., 2012; http://medicago-mutant.noble.org/mutant/FNB.php; see Chapter 83). These screens were carried out on FN-mutagenized *M. truncatula* Jemalong and retrotransposon-insertion *M. truncatula* ssp. *tricycla* R108 populations. In order to enlarge the collection of mutants impaired in the later stages of the *M. truncatula–S. meliloti* symbiotic interaction which fail to support efficient nitrogen fixation, a genetic screen of FN- and chemically (EMS) mutagenized *M. truncatula* Jemalong plants was carried out, as described here Domonkos et al. (2013). The seven ineffective mutants analyzed in this study represent six complementation groups. Although an incomplete allelism test has been carried out between the mutants isolated in this study and previously identified complementation groups, two novel loci (*ipd3-1* and *dnf8*), a new allele of *dnf5*, and probably three new complementation groups could be identified which indicates that the collection of ineffective *M. truncatula* mutants is far from saturation.

The characterization of the mutant phenotypes and the analysis of gene expression presented here and the study of Domonkos et al. (2013) allowed us to define the functional hierarchy of the impaired genes we identified. *IPD3* (see Chapter 59) and *DNF5* appear to the earliest acting genes, with both severe nodulation defects and greatly reduced symbiotic gene expression. However, the degree of bacterial invasion, the expression of *NCR121*, and the analysis of the epistatic relationship using double mutants showed that *DNF5* acts later in the symbiotic process than *IPD3*. The disintegration of rhizobia and the sporadic brown pigmentation in the fixation zones of mutants 5L/11S and 13U show incompatible bacterial interactions and induction of early senescence. The genes impaired in mutants 5L/11S and 13U appear to be required for the maintenance of bacterial infection, particularly in the nitrogen fixation zone of the nodule. While *DNF8* has a similar nodulation defect, the gene profiling suggests it acts at a slightly later stage than mutants 5L/11S and 13U. The presence of bacteria in the early developmental zones of *dnf8* nodules and the complete lack of rhizobia in the nitrogen fixation zone probably indicate the arrest of rhizobial differentiation in this mutant. The strong brown pigmentation in the 7Y mutant may indicate misregulation of plant defenses. If this is correct, then positioning 7Y within this sequence of loci is questionable, since the timing of the gene function may not be directly related to the stage at which the mutant aborts. However, such a statement could be true for all the genetic loci described, and a role for *IPD3* (*CYCLOPS*) during symbiotic signaling (Oldroyd, 2013; Messinese et al., 2007; Singh and Parniske, 2012) belies its apparently late mutant phenotype (Horvath et al., 2011; Ovchinnikova et al., 2011).

The characterization of the ineffective mutants may suggest the possible function of the impaired genes, but in order to assess their actual function and characterize their gene products, these genes need to be cloned. Despite the great advantages of the insertion mutants that allow the recovery of the genomic sequences adjacent to the integration sites of the transposons (Pislariu et al., 2012), the genomic resources of *M. truncatula* also render the rapid identification of deleted genes by either map-based cloning or transcript-based cloning, as successfully demonstrated in several recent papers (Horvath et al., 2011; Murray et al., 2011). The cloning and molecular characterization of genes defective in the ineffective *M. truncatula* mutants of this study will provide more details about the process of nodule invasion and differentiation and contribute to a better understanding of the molecular, developmental, and differentiation events that support a nitrogen-fixing nodule.

IPD3 is closely homologous to *L. japonicus CYCLOPS* (Yano et al. 2008), and *CYCLOPS* can complement the *ipd3-1* mutant (Horvath et al., 2011; see Chapters 54, 59). Despite their orthologous relationship, the *ipd3* and *cyclops* mutants show differences in the severity of the phenotype (Horvath et al., 2011; Yano et al., 2008). In addition, phenotypic difference in the symbiotic interaction with rhizobia and AM fungi could be also observed between *M. truncatula* plants with different genetic backgrounds. *ipd3* mutants (*ipd3-1*, *ipd3-3* = *Mtsym1-1* and *Mtsym1-8*) in the Jemalong background develop two classes of nodules; the majority of the nodules are small spherical white structures with abnormal morphology at the nodule apex (Fig. 63.2b), and a small number of nodules are less or remarkably elongated containing extended infection zone woven into the network of IT (Horvath et al., 2011; Benaben et al., 1995; Ovchinnikova et al., 2011; E. Limpens, personal communication). Bacterial release could never be detected in these nodules. Contrary, only the induction of nodule primordia could be observed on roots of *ipd3-2* plant with R108 (*M. truncatula* ssp. *tricycla* R108) background. The severity of the mycorrhizal defect also appears to be dependent on the genomic background in *ipd3* mutants. *ipd3-1* and *ipd3-3* alleles (Jemalong background) developed normal internal fungal infection structures, with apparently similar to wild-type arbuscules, but at a reduced frequency (Horvath et al., 2011; Ovchinnikova et al., 2011). In contrast, the *ipd3-2* allele

Table 63.3 The Summary of *ipd3*/*cyclops* Phenotypes in Different Legume Backgrounds

	Mutant					
	Mtipd3-1	*Mtipd3-2*	*Mtsym1-1* (TE7)	*Mtsym1-8*	*Ljcyclops*	*Pssym33*
Genetic background	Jemalong	Tnt1-insertion line in R108	Jemalong	*Tnt1*/Mere insertion line in Jemalong	Ecotype Gifu	SGE
Infection and nodulation phenotype	Two classes of nodules	Nodule Primordia	Two classes of nodules	Similar phenotype as *Mtsym* – E. Limpens, personal communication	Nodule primordia	White nodules; impaired invasion (no endocytosis) (Voroshilova et al., 2001)
AM phenotype	Arbuscule formation; reduced colonization rate	No arbuscules	Decrease colonization but abundance of arbuscules	?	No arbuscules	Decreased AM colonization but increased arbuscule abundance (Jacobi et al., 2003a, 2003b)

(R108 background) shows a complete absence of arbuscules. Interestingly, the reported phenotypes of orthologous *ipd3* alleles in other legumes also display distinct symbiotic phenotypes (Table 63.3). The symbiotic phenotype of *L. japonicus cyclops* mutants is very similar to the *M. truncatula ipd3-2* (R108) mutant, although nodule organogenesis is initiated in *Ljcyclops* but blocked in very early stage (Yano et al., 2008). The rhizobial and AM infections abort in *cyclops* prematurely: IT growth could not be observed, and intracellular AM infection is severely impaired. However, the phenotype of pea *ipd3* mutant (*Pssym33*) resembles the phenotype of *M. truncatula* Jemalong mutants (Ovchinnikova et al., 2011). White nodules are formed on *Pssym33* roots wherein the rhizobial invasion is impaired (Voroshilova et al., 2001) and decreased mycorrhizal colonization was observed with abundance of arbuscules (Jacobi et al., 2003a, 2003b). The cause of the phenotypic differences between different *ipd3*/*cyclops* mutants still remains to be disclosed. Using the autoactive form of CCaMK (DMI3), it was found that CYCLOPS is not required for nodule organogenesis beyond the primordial stage (Yano et al., 2008). However, spontaneous nodulation test revealed that IPD3 affects DMI3-induced spontaneous nodule formation. Using the autoactive form of DMI3, we could not detect difference in the ability of spontaneous nodulation in the *Mtipd3* alleles in different genetic backgrounds, indicating that *ipd3-2* is similar to *Ljcyclops* with respect to the ability to form spontaneous nodule.

64.1 INTRODUCTION

64.1.1 NO: A Key Molecule

NO is a small reactive gaseous molecule which, as a mediator of physiological processes, has a large number of beneficial effects in animals (messenger in immune response, neurotransmission, and relaxation of vascular smooth muscle) (Schmidt and Walter, 1994). The cellular environment may greatly influence the chemical form of NO and consequently its biochemical and biological effects. Not only the chemical nature but also the concentration and location of NO might influence its biological role. Thus, at high local concentration, such as on sites of its synthesis, NO can become very toxic. NO has also a vital role in the resistance of mammalian hosts to microbial infections as first established with murine macrophages colonized with *Mycobacterium bovis* (Flesch and Kaufmann, 1991). The interest for NO in the plant scientific community is more recent, but considerable progress has been made in the past decade in understanding the roles of NO in plants. The emerging picture is that NO functions as a signal involved in diverse physiological processes that include germination, root growth, lateral root development, flowering, stomatal closing, and adaptative responses to biotic and abiotic stresses (Baudouin, 2011; Besson-Bard et al., 2008; Delledonne, 2005; Gaupels et al., 2011; Mur et al., 2013). The molecular identification of NO sources and their subcellular characterization, together with specific and accurate NO detection methods, are limiting steps for understanding NO functions in plants.

Unlike in animal cells where NO is known to be mainly synthesized from arginine by NO synthase (NOS) enzymes, the origin of NO in plants is not completely understood yet.

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

It is becoming increasingly obvious that nitrate reductases (NR) play a major role in NO production, but several studies provide evidence arguing for the involvement of NOS-like enzymes and nonenzymatic reduction of nitrite in NO synthesis. Alternately, NO could also be produced from polyamines through an uncharacterized mechanism (for a review, see Moreau et al. (2011)).

64.1.2 NO: A Signal/Weapon in Plant Defense

A rapid NO burst has been shown to be induced during plant–pathogen interactions, suggesting the involvement of NO in disease resistance (Mur et al., 2006; Wendehenne et al., 2004). Indeed, NO has been implicated in defense against various pathogenic organisms (*Pseudomonas syringae*, *Botrytis cinerea*, or *Blumeria graminis*) (Delledonne et al., 1998; Mur et al., 2012; Prats et al., 2005; Bellin et al., 2013). Considering these plant responses, it is not surprising that many pathogens have evolved responses that could suppress NO-associated events. Thus, *Erwinia chrysanthemi* expresses the flavohemoglobin (fhb) HmpX which oxidizes NO to NO_3^-. Conversely, in other cases, the pathogen may actively trigger host NO production to sustain the infection process (Lamotte et al., 2004; Prats et al., 2008).

The mechanisms of NO action are being actively investigated. The first studies concerned transcriptomic assessment of NO effects, but, although the action of NO on gene expression is still being investigated, a lot of studies are now dedicated to two protein posttranslational modifications which are specific to NO action/signaling, that is, S-nitrosylation and tyrosine nitration. There have been relatively few studies on tyrosine nitration possibly because its irreversible nature made it a less attractive regulatory switch, although increasing evidence of enzymatic and nonenzymatic mechanisms of denitration is available (Abello et al., 2009). On the contrary, S-nitrosylation, consisting of the reversible covalent attachment of a NO moiety to a protein or glutathione cysteine thiol, has received much more attention. About 15 S-nitrosylated plant proteins have been well characterized, many of them being involved in plant immunity such as NPR1, the salicylic acid-binding protein (SABP3), and the transcription factor TGA1, which are key proteins in the signal transduction pathway that leads to plant resistance against pathogens, drawing a first outline of the involvement of NO in plant immune signaling (Astier et al., 2012; Astier and Lindermayr, 2012).

64.1.3 NO: A Molecule Detected at All Stages of Rhizobium–Legume Symbioses

NO has also been detected during the symbiotic interaction between legumes and rhizobia. These bacteria interact with legume roots on which they induce the formation of new organs, called nodules. The bacteria colonize the nodules wherein they differentiate into bacteroids able to reduce atmospheric nitrogen (N_2) into ammonia (NH_3) to the benefit of the host plant. In exchange, plants provide bacteria with a niche (the nodule) as well as energy in the form of carbon sources. Rhizobium–legume symbioses have been thoroughly characterized at the cytological and genetic levels, and a number of bacterial and plant genes required for bacterial infection, nodule formation, and functioning have been identified (Jones et al., 2007; Oldroyd et al., 2011; Terpolilli et al., 2012; see also Chapter 59). Nodules can be of determinate (*Lotus japonicus*, *Glycine max* (soybean)) or indeterminate (*Medicago*) type. Indeterminate nodules have a persistent meristem that yields a cylindrical shape to the nodule where four different zones can be distinguished, the zone III being the N_2 fixation zone where bacteroids convert N_2 into NH_3. In contrast, determinate nodules lack a persistent meristem and are spherical.

NO is present at various stages of rhizobium–legume symbioses (Fig. 64.1). First, using a NO-specific fluorescent probe, a transient NO production was detected on the surface of *Medicago sativa*, *L. japonicus*, and *Trifolium repens* roots 4 h after inoculation but only when the cognate bacterial symbionts were used (Nagata et al., 2008; Shimoda et al., 2005) (see Fig. 64.1a). NO was also present around 4 days postinoculation in infected *Medicago truncatula* root hairs, both in the colonized curl and along the infection thread, as well as in cells of nodule primordia, not yet infected by rhizobia (del Giudice et al., 2011) (see Fig. 64.1b, c). In addition, NO was observed (by using either a fluorescent probe or a *Sinorhizobium meliloti* NO-biosensor strain) in mature, nitrogen-fixing nodules of *M. truncatula* and *M. sativa* particularly in bacteroid-containing cells (Baudouin et al., 2006; Pii et al., 2007) (see Fig. 64.1d, e). Finally, NO was also detected directly in mature nodules of *L. japonicus* (Shimoda et al., 2009), as well as indirectly, through the detection of nitroso-leghemoglobin in nodules of soybean and pea (Kanayama et al., 1990; Meakin et al., 2007). NR has been shown to be an important source of NO in nodules (Horchani et al., 2011), but its involvement and that of other possible NO sources at the different steps of the symbiosis remain to be clarified. Interestingly, both partners (bacteria and plant) were shown to participate significantly in NO synthesis in determinate (soybean) as well as indeterminate (*Medicago*) nodules (Horchani et al., 2011; Sanchez et al., 2010).

The purposes of this review are to highlight the contrasted roles that NO might have at the different steps of symbiosis and to point out the importance not only of plant hemoglobins (Hbs) but also of bacterial NO-degrading proteins in maintaining a balanced NO level allowing the maintenance or breakdown of symbiosis.

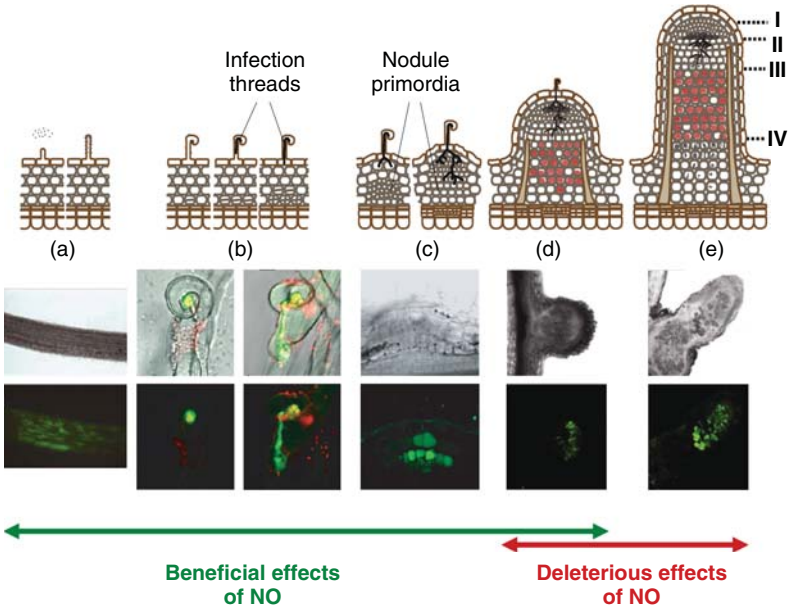

Figure 64.1 NO detection at various stages of the *Sinorhizobium–Medicago* interaction. The upper part of the figure illustrates the successive stages of the symbiotic interaction where NO was found, as shown in the lower part of the figure. I, II, III, and IV correspond to the meristematic, infection, fixation, and senescence zones of mature indeterminate-type nodules, respectively. NO was detected by microscopy using the fluorescent probe DAF-2DA on either *M. sativa* (a) or *M. truncatula* (b–e) roots or nodules, collected at 4 h (a), 3 days (b, c), 5 days (d), and 19 days postinoculation with *S. meliloti* (e). *Source*: Drawings and pictures composing this figure were reprinted with modifications from the following references, with kind permissions from the publishers and corresponding authors: Fig. 1 in (Saeki, 2011), Springer Science + Business Media; Fig. 5 in (Nagata et al., 2008), APS Press; Fig. 1 and Fig. 4 in (del Giudice et al., 2011), Wiley-Blackwell; Fig. 1 in (Baudouin et al., 2006), APS Press.

64.2 NO: POSITIVE/SIGNALING ROLES ON SYMBIOSIS ESTABLISHMENT AND NODULE FUNCTIONING

64.2.1 Infection and Nodule Development

The production of NO along the infection process points to a role of this compound in the specific recognition between the plant and the bacterial partners. In the *M. truncatula–S. meliloti* interaction, both the scavenging of NO by 2-[4-carboxyphenyl]-4,4,5,5-tetramethyl-imidazoline-1-oxyl-3-oxide (cPTIO) and the overexpression by the plant partner of *hmp*, a bacterial hemoprotein involved in NO detoxification (Poole and Hughes, 2000), lead to a delayed nodulation phenotype (del Giudice et al., 2011). This indicates that NO is required for an optimal establishment of the symbiotic interaction and nodule development. A first transcriptomic study conducted on *M. truncatula* roots treated with two NO donors, SNP and GSNO, enabled the identification of 999 putative NO-responsive genes (Ferrarini et al., 2008). Of these genes, 290 were also regulated during nodule development. More recently, a transcriptomic analysis using RNA-Seq technology was performed with *M. truncatula*-inoculated roots treated with cPTIO to identify genes potentially regulated by NO during the nodule primordium development (Boscari et al., 2013). The first result of this study shows the reversal, upon cPTIO treatment, of the downregulation of defense genes normally triggered by inoculation with rhizobia. Expression of a number of genes involved in terpene, flavonoid, and phenylpropanoid pathways and genes encoding PR proteins and cytochrome P450 is significantly affected by cPTIO. In contrast, cPTIO triggers the repression of genes potentially involved in nodule development such as those involved in regulation of transcription, protein transport, degradation, and synthesis. These findings suggest that NO could be involved in the repression of plant defense reactions, thereby favoring the establishment of the beneficial plant–microbe interaction. This action differs markedly from the signaling functions of NO in pathogenic interactions, in which NO induces hypersensitive cell death, and expression of defense-related genes (Delledonne et al., 1998).

In both transcriptomic studies (Boscari et al., 2013; Ferrarini et al., 2008), many genes involved in the developmental program of root hairs during nodulation (kinases, receptor-like kinases, transcription factors), in carbon metabolism (sucrose transport, sucrose synthase, isocitrate dehydrogenase, glyceraldehyde-3-phosphate dehydrogenase, or malate dehydrogenase), as well as in proteasome-dependent proteolysis were found to be upregulated by NO, indicating that early nodule establishment and metabolism are controlled by NO. Many genes involved in the control of cellular redox responses such as peroxidases, germin-like oxalate oxidase, glutathione S-transferase, and glutathione synthetase (GSHS) have also been identified. A previous study on the two genes involved in glutathione synthesis, γ-glutamylcysteine synthetase (γ-ECS) and GSHS, already provides evidence that glutathione synthesis is stimulated by NO in plants (Innocenti et al., 2007). These data indicate that NO-mediated redox signaling plays a key role in the establishment of a functioning nodule, as it was shown to be the case for glutathione-mediated regulation of the symbiosis (Frendo et al., 2005). It was also suggested that,

in the rhizobium–legume symbiosis, early production of NO by the plant could serve to induce the expression of bacterial genes necessary to adapt bacteria to NO encountered at later symbiotic stages (Meilhoc et al., 2011). The lower competitiveness of the *hmp*$^{++}$ strain as compared to the wild type (WT) during the *M. truncatula–S. meliloti* interaction (del Giudice et al., 2011) is an argument in favor of such a role of NO during the infection process. Regarding to the relationship between NO and oxidative stress, it was shown that during the symbiotic association between fungi and lichens, the mycobiont-driven NO has an important role in the regulation of the oxidative stress of lichens, particularly during rehydration (Catala et al., 2010). A similar role could be conceived in the rhizobium–legume symbiotic interaction where an oxidative burst occurs early after infection with symbiotic bacteria (Santos et al., 2001).

Among the NO-responsive genes in early legume–rhizobium interactions, the class 1 non-symbiotic hemoglobin (*ns-Hb1*) gene is of particular importance. A NO-scavenging activity has been associated with ns-Hb1 in NO detoxification pathways (Gupta et al., 2011). In *M. truncatula*, a decrease in the transcript level of *ns-Hb1* at four days postinoculation has been observed, suggesting that a decrease in ns-Hb1 level could allow an increase in the NO level in the root during the establishment of the symbiotic interaction (Boscari et al., unpublished). Conversely, the overexpression of *ns-Hb1* genes *LjnHb1* or *AfnHb1* in *L. japonicus* induces a decrease in NO production and results in an increased nodule number (Shimoda et al., 2009), suggesting that NO negatively affects the nodulation process. The apparent contradiction in nodulation phenotypes between *M. truncatula* (del Giudice et al., 2011; Pii et al., 2007) and *L. japonicus* (Shimoda et al., 2009) raises the question of the effect of Hmp/Hb on the NO level and suggests that a tightly regulated level of NO is necessary for successful establishment of the symbiotic relationship.

During the early steps of symbiosis establishment, NO was also detected in dividing cortical cells of the root, not yet invaded by the rhizobial cells (del Giudice et al., 2011) (see Fig. 64.1c). This NO production is similar to that detected in lateral root primordia for which NO was reported to have a role in the cell cycle regulation and in the control of primary and adventitious root organogenesis (Correa-Aragunde et al., 2004; Correa-Aragunde et al., 2006; Lanteri et al., 2006). In *M. truncatula*, NO scavenging resulting either from cPTIO treatment or from overexpression of a bacterial flavohemoglobin *hmp* gene has been found to downregulate several genes involved in nodule development, such as *MtCRE1* and *MtCCS52A* (del Giudice et al., 2011). *MtCRE1* encodes a cytokinin receptor playing a major role in the development of the symbiotic interaction between *M. truncatula* and *S. meliloti* (del Giudice et al., 2011; Gonzalez-Rizzo et al., 2006; see Chapter 56). As a consequence of NO decrease, delayed nodulation and reduced expression of genes involved in nodule development (*MtCRE1*, *MtCCS52A*) reinforce the hypothesis that NO could control the nodulation process through the regulation of cytokinin perception (del Giudice et al., 2011). NO has already been described as a component of hormone signaling in plants (Hill, 2012). Phytohormones such as auxin or abscisic acid (ABA) are known to regulate nodulation (see Chapter 56). Interestingly, the work of Pii et al. (2007) showed that auxin overexpression in *Medicago* species increased nodulation (number of nodules/plant) and NO level in these nodules (Pii et al., 2007). On the other hand, the level of ABA, which is known to be a negative regulator of legume root nodule formation, is diminished in an *enf1* mutant of *L. japonicus* where NO level is diminished accordingly, together with an increase in nitrogen fixation (Tominaga et al., 2009). The precise roles of NO in these hormonal pathways remain to be deciphered.

As a whole, NO appears to be a key regulator of symbiotic establishment, acting as a repressor of the plant defense responses when the bacteria enter into the root and an inducer of organogenesis and development processes which lead to nodule formation.

64.2.2 Mature Nodule Functioning

The role of NO in mature nodules is still an open debate. Indeed, NO has been shown to be significantly produced in the fixation zone of *M. truncatula* nodules (Baudouin et al., 2006) (see Fig. 64.1d), and the question was raised of its potential role in the N_2-fixing nodules. Based on known adaptation mechanisms of plants to hypoxia and considering that nodules are microoxic organs, a metabolic role for NO has been recently proposed in mature nodules (Horchani et al., 2011). NO production has been shown to be induced in the roots of plants submitted to hypoxia, and this production is supposed to be linked – via a cyclic respiration process – with improved capacity of the plants to cope with hypoxic stress and to maintain cell energy status (Igamberdiev and Hill, 2009). This cyclic respiration, called "nitrate–NO respiration," involves four successive steps: (i) the reduction of NO_3^- to NO_2^- by the cytosolic NR; (ii) the translocation of NO_2^- from the cytosol into the mitochondria, presumably through a nitrite transporter; (iii) the reduction of NO_2^- in NO, via the mitochondrial electron transfer chains (ETC), allowing respiration and ATP regeneration; and (iv) the passive diffusion of NO from the matrix to the cytosol, where it is oxidized by Hb into NO_3^-. Thus, under hypoxic conditions, by reducing nitrite to NO, plant mitochondria preserve the capacity to oxidize external NADH and NADPH and retain a limited power for ATP synthesis complementing glycolytic ATP production (Gupta and Igamberdiev, 2011).

Under hypoxic conditions, NO production has been shown to be increased in functional nodules of *G. max*

(Meakin et al., 2007) and *M. truncatula* (Horchani et al., 2011), suggesting that, under the microaerobic conditions prevailing in nodules, nitrate–NO respiration may be involved in energy supply for nitrogen fixation (Horchani et al., 2011). Several observations argue in favor of such a hypothesis. First, plant NR and ETC, and the bacterial denitrification pathway contribute to NO production, via NO_3^- and NO_2^- reduction, particularly under hypoxic conditions (Horchani et al., 2011; Sanchez et al., 2010). Second, leghemoglobins (Lbs) and ns-Hb1 have the capacity to efficiently react with NO to produce NO_3^- with an elevated rate constant (Herold and Puppo, 2005), and the NO generated at the ETC level may therefore be oxidized into NO_3^- by Lbs and/or nonsymbiotic hemoglobins (ns-Hbs). Third, the energy status of the nodules depends either significantly or almost entirely on NR functioning under normoxic or hypoxic conditions, respectively (Horchani et al., 2011). Thus, in symbiotic nodules, a role related to NO scavenging and metabolism may be fulfilled by Hbs and Hmp in the plant and bacterial partner, respectively. The high affinity of these Hbs for NO and their capacity to oxidize NO into NO_3^- would be favorable to keep NO concentration below toxic level for nitrogenase and to supply the nitrate–NO respiratory cycle in order to maintain a minimal energy status under hypoxia. Considered together, these data suggest that in mature nodules, NO could function as a metabolic intermediate to maintain basal energy metabolism.

NO present inside nodules could also be perceived as a signal by bacteroids. Bacteria possess transcription factors able to sense NO and respond by adjusting bacterial gene expression to this changing environment. A transcriptomic analysis performed on *S. meliloti* grown in culture treated with a NO donor identified a set of about 100 genes whose expression is induced in the presence of NO (Meilhoc et al., 2010). Most of these genes are regulated by the two-component system FixLJ already known to respond to microaerobic conditions which prevail inside mature nodules. Indeed, FixLJ was shown to be a major regulator in symbiosis since it controls the majority of the rhizobial genes expressed *in planta* in mature nodules (Bobik et al., 2006). Hence, the NO response mediated by FixLJ comprises genes involved in microaerobic respiration and NO degradation (*hmp*) and many other genes of yet unknown function. Whether NO signaling via FixLJ has a biological significance in symbiosis remains to be established.

NnrR is a well known NO-specific responsive regulator in rhizobia (Rodionov et al., 2005). It has been shown to be involved in the regulation of a set of genes including the denitrification genes (*nir*, *nor*) in *S. meliloti* as well as in *Bradyrhizobium japonicum* and *Rhizobium etli* (de Bruijn et al., 2006; Cabrera et al., 2011; Meilhoc et al., 2011). It must be underlined that *nor* genes encode a NO reductase which has a role in degrading NO. Finally, we cannot exclude that the regulator OxyR denoted as an oxidative stress sensor could be also part of the NO signaling scheme in rhizobia. Indeed, OxyR has been shown to be S-nitrosylated in *E. coli* in the presence of NO, and in that form, it is involved in the regulation of expression of genes involved in monitoring the amount of intracellular S-nitrosylation (Gusarov and Nudler, 2012; Seth et al., 2012).

Hence, NO could be a signal to build up a bacterial NO response via different regulators, and the bacterial response could be involved in the establishment or maintenance of symbiosis in a more subtle way than the sole detoxification function.

64.2.3 NO and Nodule Senescence: Deleterious Effect or Signaling Role?

The concentration of NO inside nodules has not been measured precisely but was estimated to be in the micromolar range in *Medicago* nodules (Meilhoc et al., 2010). The NO level in nodules has even been shown to be significantly increased when nitrate was applied to *Lotus*, *Medicago*, or soybean nodules (Horchani et al., 2011; Kato et al., 2010; Sanchez et al., 2010). An inhibitory effect of NO ($Ki = 56\ \mu M$) has been first demonstrated employing the *B. japonicum* nitrogenase by using purified enzyme from soybean nodules and testing the effect of various NO concentrations *in vitro* (Trinchant and Rigaud, 1982). The effect of NO on nitrogenase *in vivo* has also been studied. However, as NO sources are not completely elucidated, pharmacological (exogenous NO or nitrate treatment) or genetic approaches (bacterial or plant mutants overexpressing NO-degrading enzymes) were used to manipulate NO levels inside nodules. Addition of a NO donor to *Lotus* nodules, although probably exceeding *in vivo* NO fluctuations in terms of concentration and duration, leads to a reduction in nitrogen fixation efficiency, as measured by the acetylene reduction assay (ARA test) (Kato et al., 2010; Shimoda et al., 2009). This effect has been confirmed indirectly in another study, where overexpression of the ns-Hb1 (NO-scavenging enzyme) in *L. japonicus* leads to an increased nitrogen fixation efficiency as measured on whole plants or on detached nodules (Shimoda et al., 2009). On the other hand, *M. truncatula* inoculated with a *S. meliloti* mutant (*hmp*) affected in NO degradation displays nodules presenting a higher NO content and a lower nitrogen fixation efficiency and shoot dry weight as compared to the WT strain (Cam et al., 2012).

The transcription level of the *nifH* gene (encoding the nitrogenase reductase subunit) of *Mesorhizobium loti* bacteroids has been shown to be similar in both WT and ns-Hb1-overexpressing *L. japonicus* nodules, indicating that the enhancement of nitrogen fixation efficiency is not due to a transcriptional effect of NO depletion (Shimoda et al., 2009). NO might also modify proteins through S-nitrosylation which emerges as a key posttranslational modification in plants and a pivotal mechanism to mediate

NO bioactivity. Nitrogenase displays at least three putative S-nitrosylation sites (Xue et al., 2010), and interestingly, different nitrogenase subunits have been identified among the S-nitrosylated proteins found in *M. truncatula* mature nodules (Puppo et al., 2013). These results suggest that NO may inhibit nitrogenase activity through S-nitrosylation; nevertheless, other major enzymes could also be NO targets. Thus, ammonium generated by bacterial nitrogenase activity is released by the bacteroids in the cytosol of infected plant cells where it is assimilated through the activity of the plant glutamine synthetase (GS). It has been shown recently that the *M. truncatula* cytosolic GS1 is modulated by another NO-mediated posttranslational protein modification: tyrosine nitration (Melo et al., 2011). According to the model proposed by the authors, NO present in nodules would contribute to a decrease in ammonium level (inhibition of nitrogenase) and to a coordinated inhibition of GS. It has also been proposed that inhibition of GS could be involved indirectly in antioxidant defense (Melo et al., 2011).

Among the S-nitrosylated proteins found in *M. truncatula* nodules, many are related to carbon- and nitrogen-fixing metabolism (Puppo et al., 2013), such as several enzymes of the tricarboxylic acid (TCA) cycle (isocitrate dehydrogenase, citrate synthase, malate dehydrogenase) from either the plant or the bacterial partner. A similar observation has already been made in pathogenic bacteria, such as *M. tuberculosis* or *Salmonella enterica* (Rhee et al., 2005; Richardson et al., 2011). Finally, NO may also target and inhibit bacterial respiration (Stevanin et al., 2000). The effect(s) of NO (inhibition or activation) remains to be determined as well as the role of most of these proteins and the impact of their S-nitrosylation in symbiosis.

Recently, it has been established that an increase in NO level inside mature nodules of *M. truncatula* leads to an early nodule senescence (Cam et al., 2012). From what we described earlier, this effect could be directly linked to an inhibition of nitrogenase activity and/or GS, leading to a cessation of nitrogen fixing and a subsequent collapse of bacteroids and plant cells. Although this cannot be completely ruled out, it has been found that 250 µM of the NO donor DEA-NONOate, when added to the plant roots, induced senescence without inhibiting nitrogenase activity. It has also been shown that NO could be a senescence signal acting locally rather than systemically (Cam et al., 2012). A NO burst preceding physiological nodule senescence could not be shown at the nodule scale, but interestingly, by using a *S. meliloti* NO-biosensor strain, an increase in NO level has been detected in a few cells in the center of the nodule. A correlation has been made with previous data from Perez Guerra et al. (2010) showing that the earliest signs of nodule senescence appear in a few infected cells in the center of the fixation zone. The senescence zone then extends with a conical front toward the nodule periphery (Perez Guerra et al., 2010). Considering this pattern, it has been hypothesized that NO accumulates in only a few cells before (and probably triggering) their entrance into the senescence process (see model in Fig. 64.2).

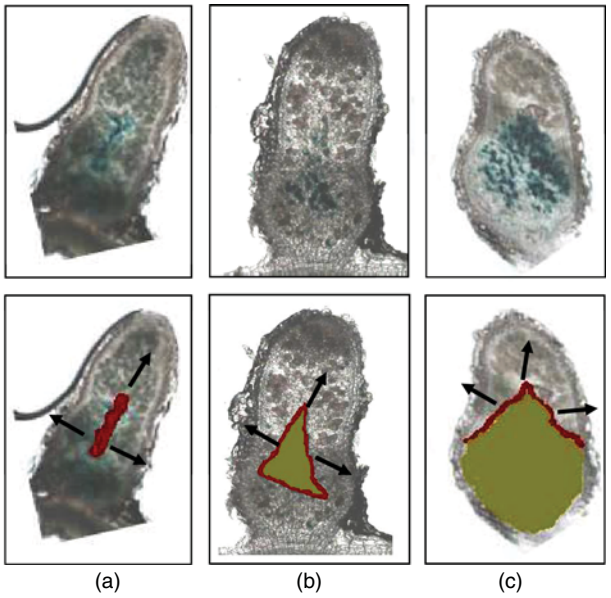

Figure 64.2 Proposed model for induction of nodule senescence by NO. Upper panels: NO detection in 3-week-old nodules using a NO-biosensor *S. meliloti* strain. This strain contains a reporter plasmid carrying a transcriptional *lacZ* fusion to the promoter of a *S. meliloti* gene specifically induced by NO. Reporter gene expression was detected using X-gal at different stages of senescence on sections of nodules containing the wild-type (a, b) or *hmp* mutant (c) strains. Lower panels: schematic representation of hypothetical NO burst starting in few cells of the center of the fixation zone (in red) and preceding the senescence zone which then extends with a conical front toward the nodule periphery (in green). Arrows indicate the direction of the senescence zone expansion. *Source*: Panels a and c were reprinted with modifications from Fig. 3 in (Cam et al., 2012), with kind permission from Wiley-Blackwell.

Lastly, overexpression of Hmp in WT nodules leads to a significant delay in nodule senescence which substantiates the hypothesis of NO being a senescence signal (Cam et al., 2012). In agreement with these data, Navascues et al. (2012) recently demonstrated that green Lb of soybean, characteristic of senescent nodules, is produced by the nitration of heme. Hence, these results provide evidence that reactive nitrogen species are produced during aging of legume nodules and further suggest that NO could also stimulate the senescence of determinate-type nodules. The way NO is involved in the senescence process remains the vast issue to be investigated. A transcriptional analysis revealed that more than 500 genes are regulated in senescent nodules of *M. truncatula* (Van de Velde et al., 2006), but it is not known yet those which are responding to NO. More recently, genetic experiments have allowed the identification of two new players in *M. truncatula* nodule senescence: a

transcription factor (MtNAC 969), which may negatively regulate nodule senescence, and a STAY-GREEN gene (MtSGR), whose expression is higher in senescent (natural or nitrate-induced) nodules as compared to young ones (de Zelicourt et al., 2012; Zhou et al., 2011). Nevertheless, the functional characterization of the genes acting in nodule senescence is very limited, and it remains to be determined whether these genes are also induced in the presence of NO.

64.3 NO LEVEL IN LEGUME NODULES: A MATTER OF BALANCE

NO can have a signaling or a toxic effect on cells depending upon its concentration. On the one hand, it can alter the expression of specific genes, therefore playing a key role in metabolism shift, defense, hormone signaling, development, and nodule senescence. On the other hand, it can inhibit enzyme activity and contribute to deleterious events and premature nodule senescence (see Figs. 64.1d, e and 64.3). In addition, NO is also present in soil, and if we suppose that the molecule is diffusing freely in plant roots, the concentration inside nodules must be rigorously controlled not only to avoid toxic effects but also to allow the signaling function(s) to occur.

In plants, Hbs are an important family of proteins known to fulfill the role of NO storage or scavenger (Gupta et al., 2011). Three major families of Hbs have been described in plants: Lbs, ns-Hbs, and truncated hemoglobins (tr-Hbs) (Gupta et al., 2011; Perazzolli et al., 2006; see Chapter 70). All plants examined so far contain one or more families of hemoglobins, which sometimes coexist, suggesting putatively different functions. Lbs are abundant (up to mM range) only in legumes and in a few other plants interacting with nitrogen-fixing bacteria (Hoy and Hargrove, 2008). Based on their affinity for oxygen and sequence homology, they belong to class 2 globins (Gupta et al., 2011). They are supposed to buffer free oxygen and have a key role in facilitating oxygen diffusion to N_2-fixing bacteria in root nodules to permit their active respiration without inhibition of nitrogenase activity. Besides this important function, deoxy-Lb has been shown to bind NO with a high affinity to form stable complexes in soybean (Herold and Puppo, 2005), and it has been proposed that Lb could act as a NO scavenger (Shimoda et al., 2009). This may also be a function of the ns-Hbs which occur in much lower concentration than Lb but are ubiquitous in the plant kingdom including symbiotic plants. Ns-Hbs are classified as belonging either to class 1 (ns-Hb1) or class 2 (ns-Hb2) based on their affinity for oxygen and sequence similarity (Hoy and Hargrove, 2008). Interestingly, ns-Hb1 could be part of a NO dioxygenase system, using traces of oxygen to convert NO to nitrate. NO has been shown to upregulate Hb expression in a number of plant species. For example, in the actinorhizal symbiosis between *Alnus firma* and *Frankia*, ns-Hb was strongly induced by the application of NO donors, and it was shown that *AfHb1*, as a NO scavenger, may support the nitrogen fixation ability of members of the genius *Frankia* (Sasakura et al., 2006). Treatment of *L. japonicus* with either *M. loti* or a purified lipopolysaccharide fraction from this bacterium or *M. sativa* with *S. meliloti* also transiently induces *ns-Hb1* expression and NO synthesis (Murakami et al., 2011; Nagata et al., 2008). On the other hand, it has been shown that nonsymbiotic rhizobia do not induce NO production and expression of *ns-Hb* genes (Nagata et al., 2008). The same group has shown that overexpression of *ns-Hb1* enhances symbiotic nitrogen fixation, suggesting that this occurs by removal of NO as an inhibitor of nitrogenase (Shimoda et al., 2009). Tr-Hbs have been shown to be induced in *Datisca glomerata* by inoculation with *Frankia* or in root nodules of *M. truncatula* elicited by *S. meliloti* (Pawlowski et al., 2007; Vieweg et al., 2005), leading the authors to propose a role for tr-Hbs in NO detoxification. Hence, plant hemoglobins are diverse, and it is emerging now that all hemoglobins may have a role to play, possibly at different stages of the symbiosis. We may have expected these molecules to be sufficient to control NO level, but recent results ruled out this hypothesis. Astonishingly, a bacterial strain of *S. meliloti* mutated in its flavohemoglobin gene (*hmp*) elicited nodules on *M. truncatula* roots which display higher levels of NO, a lower nitrogen fixation efficiency, and earlier nodule senescence than the WT (Cam et al., 2012). This strongly suggests that the expression of the bacterial hemoprotein is essential for maintaining NO levels compatible with symbiosis even though plant Hbs are proficient. Whether this bacterial hemoprotein is essential to control NO levels inside the bacteria or whether this hemoprotein is more efficient than plant Hb to degrade NO in nodules has to be investigated. A BLAST search of the *B. japonicum* genome using Hmp from *S. meliloti* revealed a gene (bll3766) which encodes a protein with only 35% identity with the one of *S. meliloti*. The search also revealed the presence of a single domain globin (sd-Hb) (blr2807) which has a high identity with sd-Hbs from *Vitreoscilla stercoraria* and *Campylobacter jejuni* implicated in NO detoxification. In *B. japonicum*, this globin was also shown to have a NO detoxification role under free-living, microaerobic conditions (Sanchez et al., 2011).

Hemoproteins are not the unique proteins involved in NO degradation in rhizobia. Indeed, in denitrifying bacteria, one candidate for NO degradation is the respiratory NO reductase (Nor) which catalyzes reduction of NO into nitrous oxide (N_2O). The best known is the cNor encoded by the *norCBQD* genes, which receive electrons from either c-type cytochrome or small blue copper proteins (azurin or pseudoazurin) (Hino et al., 2012). Under free-living denitrifying conditions, *B. japonicum* cNor is important for degradation of NO. However, inoculation of nitrate-treated soybean

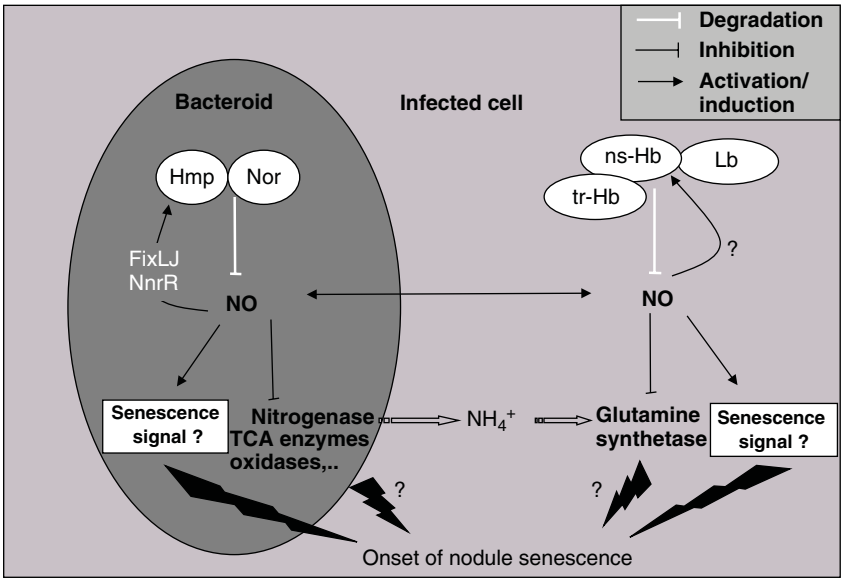

Figure 64.3 Schematic representation of known or putative molecular effects of NO leading to nodule senescence. Lb, leghemoglobin; ns-Hb, nonsymbiotic hemoglobin; tr-Hb, truncated hemoglobin; TCA, tricarboxylic acid cycle, Hmp, flavohemoglobin; Nor, NO reductase.

plants with a *norC* mutant does not affect the level of NO except in flooding stress conditions (Sanchez et al., 2010). *R. etli* lacks part of the denitrification pathway, and the presence of *norC* in this bacterium suggests a NO-degrading role for the enzyme. Indeed, Gomez-Hernandez et al. (2011) have shown that NorC is required to detoxify NO under free-living conditions; NO levels in nodules of common bean exposed to nitrate increased when elicited by a *norC* mutant as compared to the WT, indicating that Nor could also play a role in degrading NO in symbiosis. In *S. meliloti,* we have already shown that *nor* expression is induced in the presence of NO (Meilhoc et al., 2010). Preliminary results indicate that in free-living conditions, a *nor* mutant is more sensitive than a WT strain to a NO donor and triggers early senescence of *M. truncatula* nodules (Meilhoc et al., unpublished). It is interesting to note that Hmp does not compensate for the absence of Nor and vice versa, indicating that both degrading enzymes have either a specific function or a different nodule localization and both are needed to maintain an equilibrium in NO level. On the whole, both plant and bacterial proteins participate in maintaining NO balance at the different stages of symbiosis, and although the role of plant hemoglobins has been underlined for years, we should now consider bacterial NO-degrading enzymes as major components of this process (see Fig. 64.3).

64.4 CONCLUDING REMARKS AND FUTURE PROSPECTS

Even though NO has been known for decades to play major roles in mammals, it is only recently that NO was found to be also a pivotal molecule in plants. The presence of NO has been evidenced less than a decade ago in legumes–rhizobia interactions, and since then, studies on different legume models especially *Medicago*, *Lotus*, and soybean have established various roles of NO in these symbiotic interactions. How NO is generated is becoming better characterized; nevertheless, studies on the role of NO in legume nodules are still relatively limited by the lack of plant mutants with altered NO synthesis and the absence of noninvasive methods to assess *in vivo* NO status (Mur et al., 2011). Hence, experimental strategies to modulate NO levels on legume root or nodules rely on the use of NO donors or scavengers and of plant or bacterial mutants affected in NO-degrading proteins. NO donor/scavenger application may not be relevant regarding NO physiological concentration, but also their effects could be dependent upon the application method or even the type of NO donor/scavenger used (Filippou et al., 2012). Obtaining plant mutants affected in NO synthesis is a challenging perspective to avoid the use of NO donors.

The data summarized in this review indicate that NO has dual effects during symbiosis since it can have beneficial but also detrimental effects (e.g., on nitrogenase) (see Fig. 64.1). Indeed, the presence of NO is necessary for optimal infection/nodulation. Thus, NO could represent a specificity determinant for symbiont selection. Besides, it could also play a major role in repressing plant defense reactions in symbiotic conditions, thus favoring establishment of the beneficial plant–microbe interaction. In the same way, NO could also have a role to protect bacteria in the infection threads against the presence of hydrogen peroxide and/or trigger the expression of bacterial genes dedicated to adaptation to the higher NO level that bacteria could have to face at later stages of the symbiosis. In addition, we have observed that a bacterial strain which overexpresses a NO-degrading flavohemoglobin gene displays abortive infections threads (Cam et al., unpublished) which evokes

the hypothesis that NO could also be involved in infection thread development and stability. Finally, NO could also play a role in root cortical cell division and dedifferentiation and nodule formation (see Fig. 64.1c). Interestingly, a parallel can be made with the well-studied symbiosis between the squid *Euprymna scolopes* and the bacterium *Vibrio fischeri*, where NO has been shown to be a specificity determinant for successful colonization of the squid by the microsymbiont (Wang et al., 2010). Also in this interaction, NO acts as a signal molecule that prepares the symbiont to better survive oxidative and NO stresses by inducing the expression of a NO-degrading enzyme (Hmp) and a NO-resistant alternative oxidase (Davidson et al., 2004; Spiro, 2010; Wang et al., 2010; Wang and Ruby, 2010).

At later stages of the symbiosis (i.e., in mature nodules), NO has also been found to play a role in nodule energy metabolism and could act as a downregulator of N_2 fixation and carbon metabolism (by inhibiting nitrogenase and/or enzymes of the TCA cycle) to reduce energy demand in stress conditions such as a hypoxic environment. On the other hand, NO by inhibiting either nitrogenase or other essential plant metabolic enzymes (such as GS) or by inducing a yet unknown signal could promote early nodule senescence and interrupt symbiosis. Interestingly, in the coral forming symbiosis, the levels of NO found in host tissues strongly correlate with the extent of coral bleaching, leading to the hypothetical role of NO as a stress signal that mediates the breakdown of the symbiosis, in response, for example, to thermal stress (Bouchard and Yamasaki, 2008). More work remains to be done to better understand the plurality of NO effects and shed light on novel functions of this molecule at the different stages of symbiosis.

Moreover, most of the studies which have been done so far to elucidate the roles of NO at the different steps of the symbiotic interaction are mainly descriptive. The challenging issues in the coming years will be to uncover molecular targets of NO and decipher signaling pathways involving NO. Protein S-nitrosylation and tyrosine nitration are emerging as key redox-based posttranslational modifications in plants which are pivotal to convey NO bioactivity. For example, H. Carvalho's group carried out pioneering work showing that a GS of *M. truncatula* is inhibited by NO-mediated tyrosine nitration (Melo et al., 2011). In addition, a recent paper (Puppo et al., 2013) reports that *M. truncatula–S. meliloti* mature nodules contain at least 80 S-nitrosylated proteins, from either plant or bacterial origin, many of them being related to carbon and N_2-fixing metabolism. Some of these enzymes were also found to be inhibited by NO donors, that is, DEA-NONOate and S-nitrosoglutathione (GSNO) (aldolase, phosphoglycerate kinase, enolase, pyruvate kinase, phosphoenolpyruvate carboxylase, and asparagine synthetase; Brouquisse and Castella, unpublished). It may be noted that many of the proteins identified as being S-nitrosylated in the symbiotic interaction have also been reported to be S-sulfenylated in *M. truncatula* (Oger et al., 2012) or S-glutathionylated in *A. thaliana* (Dixon et al., 2005), suggesting that the same protein may be precisely and differentially regulated depending on redox state and signaling (Spadaro et al., 2010). Detailed studies of these proteins, the impact of NO on their activity, and their role in symbiosis should provide new insights in the signaling functions of NO.

Finally, as S-nitrosylated proteins are being identified as important intermediates in NO signaling, proteins involved in the regulation of these modifications will find all their importance since these modifications must be reversible to ensure transient signaling. GSNO reductase (GSNOR) and thioredoxins (Trx) are enzymes which could be involved in the reversal of S-nitrosylations (Malik et al., 2011; Sengupta and Holmgren, 2013). The *M. truncatula* genome contains a single GSNOR gene and 22 Trx genes among which two seem specific to legumes (Alkhalfioui et al., 2008). On the other hand, *S. meliloti* contains 3 GSNOR homologues, two thioredoxin genes (*trxA* and *trxC*) and one thioredoxin reductase gene (*trxB*), suggesting that both plant and bacterial systems could play a role in regulating protein S-nitrosylation. Studies on the role of these various proteins will permit to better understand how the NO signaling is transmitted and reversed.

The effect of NO should depend upon its spatiotemporal distribution/concentration in the nodule. Therefore, another challenging issue will be to assess precisely how much, where, and when NO is produced inside the nodule. Approaches based on the use of fluorescent probes have associated limits (Mur et al., 2011), and the use of NO-biosensor bacterial strains is restricted to bacteria-containing plant cells. Novel methods must be developed to accurately measure NO levels inside nodules and make it possible to better define the site(s) of NO generation. The development of experimental approaches designed to modify the NO level specifically in one of the different zones of the nodules (in the case of indeterminate nodules, see Fig. 64.1e) would create the possibility to shed light on the relevance of NO in each of these zones.

Undoubtedly, slight modifications in the NO level balance may impact the initiation or maintenance of the symbiotic interaction. Thus, lowering the NO level early in the process affects the infection and nodulation efficiency, while too much NO in mature nodules triggers their premature senescence. Therefore, the NO level should be tightly controlled at any time. Lbs as well as tr-Hbs and ns-Hbs may be committed to control NO level, but much remains to be done to clarify the role of each of these proteins at the successive steps of symbiosis. Besides, rhizobia possess NO-degrading enzymes such as flavohemoglobin and/or NO reductase, whose importance was not suspected until recently. These proteins cannot be overlooked as they emerge as essential to maintain NO level even though plant hemoglobins are

present. Other NO-degrading enzymes could be part of the bacterial NO response together with proteins important for bacterial adaptation to NO. Their role should be studied to better understand how bacteria contribute to maintain NO level and nitrogen fixation in nodules.

65.1 INTRODUCTION

Proficient symbioses between legumes and soil bacteria known as rhizobia culminate with the development of root (or stem) nodules that provide host plants with reduced forms of atmospheric nitrogen (N_2). The series of events that leads to the formation of N_2-fixing nodules can be divided into two major consecutive processes: nodulation followed by nitrogen fixation. Nodulation covers the initial steps of the symbiosis and normally leads to the formation of nodules in which compatible rhizobia form persistent intracellular colonies. Transcriptional activation of rhizobial genes required for nodulation (*nod*, *nol* and *noe*) is mediated by specific regulators of the NodD family and cognate flavonoids that are released by host roots. Ultimately, nitrogen fixation occurs once rhizobia have successfully colonized the cytoplasm of nodule cells and differentiated into bacteroids that express the nitrogenase enzyme. Metabolism of endosymbiotic bacteroids differs considerably from that of free-living rhizobia, and these cellular adaptations can be monitored at the level of the proteome (pool of proteins) and/or transcriptome (total cellular RNA species), the latter of which may change rapidly in response to environmental cues.

Transcriptome profiling has become instrumental in understanding the molecular responses of isolated cells or tissues that are experimentally challenged. Until recently, transcriptome analyses were carried out using labeled-RNA or -cDNA samples (probes) hybridized against sets of DNA targets grouped in arrays that represented either selected parts or entire genomes. Initially prepared by lysing colonies or spotting PCR-amplified products on hybridization membranes, DNA-arrays were later miniaturized, and these so-called microarrays (also known as DNA chips, or biochips) soon became the reference tools in transcriptome analysis. In these hybridization systems, signal intensities (either fluorescent, or radioactive) correlated positively with gene expression since abundance of transcript species was maintained in the pool of DNA or RNA probes. Yet, microarrays suffered from a number of limitations including unspecific hybridizations (Wu et al., 2005: Zhang et al., 2005) contributing to false-positive signals (Chen et al.,

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

2006), background noise and signal saturation that limited the dynamic range of detection (Dodd et al., 2004). With the development of massive parallel sequencing, also known as next-generation sequencing (NGS), it became possible (as well as affordable) to sequence pools of cellular RNAs and thus measure the number of copies of each RNA species. This method called RNA-Seq offers several advantages over microarrays. RNA-Seq was shown to quantify expression levels accurately, including for low abundance transcripts (Bashir et al., 2010; Mortazavi et al., 2008), and have – in principle – no upper quantification limit or saturation effect. Unlike microarrays that normally require annotated genome sequences for optimal design and construction, RNA-Seq was found appropriate for *de novo* transcriptomic or for completing transcripts inventories (Trapnell et al., 2010). Regardless of the NGS technology used (454 Sequencing, Illumina or SOLID), RNA molecules need generally to be converted into libraries of short cDNA fragments prior to sequencing. Thus, instead of few sequences of up to 1000 nucleotides long obtained with the "traditional" Sanger method, a single Illumina run may generate an output of tens of millions of sequence reads each of 50–150 bases in length. These short sequence-reads are then assembled *in silico* into longer transcripts, genes, and operons or alternatively mapped onto a genome, thus delimiting actively transcribed regions or by contrast, those that remained transcriptionally silent.

Transcriptomic studies in the field of rhizobia probably began with the analysis of the 536 kb long symbiotic plasmid (pNGR234a) of the broad host-range *Sinorhizobium fredii* strain NGR234. These analyses were carried out using DNA macroarrays of more than 400 PCR-amplified fragments and M13-phage subclones probed with radioactively labeled RNA isolated from free-living and endosymbiotic cells (Freiberg et al., 1997; Perret et al., 1999). In addition, macroarrays consisting of 921 M13 inserts of 1–1.5 kb collected to skim the genome of NGR234 (Viprey et al., 2000) were later probed in a similar manner (Perret et al., 2000b). Although relatively crude compared to today's data sets, these earlier results provided a solid basis for expression and functional studies of symbiotic open reading frames (ORFs) in NGR234 (Kobayashi et al., 2004; Perret et al., 2003; Viprey et al., 1998). In other pilot studies, the expression of up to 214 genes of *Sinorhizobium meliloti* strain 1021 was followed in as many as 10 experimental conditions using amplicons of circa 300 bp spotted by a robot onto nylon hybridization membranes (Ampe et al., 2003; Berges et al., 2003). Large DNA macroarrays consisting of circa 75,000 M13 subclones spotted on membranes were also used by Uchiumi and associates to identify a number of expression islands on the genome of *Mesorhizobium loti* strain MAFF303099 (Uchiumi et al., 2004). Microarrays of gene-specific amplicons (Becker et al., 2004) or oligonucleotide-based gene chips (Barnett et al., 2004; Domínguez-Ferreras et al., 2006) greatly facilitated the probing of entire rhizobial genomes, including for intergenic regions initially annotated as non-protein-coding. In fact, microarrays remained for many years the technology of choice for transcriptome analyses in various rhizobia, including for *Bradyrhizobium japonicum* strain USAD110 (Masloboeva et al., 2012; Pessi et al., 2007), *Rhizobium etli* strain CFN42 (Vercruysse et al., 2011), and *Rhizobium leguminosarum* biovar *viciae* strain 3841 (Karunakaran et al., 2009). In contrast, and except for a genome-wide survey of small untranslated RNAs (sRNAs) in *S. meliloti* (Schlüter et al., 2010), RNA-Seq was mainly used to analyze simultaneously the transcriptional behavior of nodule cells and bacteroids in associations between soybean and *B. japonicum* (Severin et al., 2010) or *Medicago truncatula* and *S. meliloti* (Boscari et al., 2013).

The competitive costs of NGS technologies and a recently completed genome sequence for strain NGR234 (Schmeisser et al., 2009), prompted us to use RNA-Seq to extend to the 3.9 Mb chromosome and 2.4 Mb mega-plasmid pNGR234b the initial transcriptomic studies carried out on the smaller 536 kb pNGR234a. In order to compare RNA-Seq data with results from previous analyses, total RNA was isolated from free-living cells of *S. fredii* strain NGR234 grown *in vitro* for 6 h in the absence (condition 1) or presence (condition 2) of the flavonoid daidzein, and (3) from nitrogen-fixing nodules collected on roots of the host plant *Vigna unguiculata* 38 days post-inoculation (dpi) with NGR234. Experimental conditions 1 and 2 were designed to examine the response(s) of NGR234 to the presence of a flavonoid known to induce the expression of nodulation genes, while condition 3 provided a measure of the transcriptional activity inside N_2-fixing bacteroids of NGR234. The following sections describe the experimental setups, bioinformatic and validation analyses that were carried out on the resulting RNA-Seq datasets, and some of the findings that illustrate how NGR234 responds to symbiotic cues from host plants.

65.2 METHODS

65.2.1 Growth Conditions

Cells of *S. fredii* NGR234 were grown at 27 °C in *Rhizobium* minimal medium supplemented with 12 mM succinate (RMS) and rifampicin at 50 µg/ml (Broughton et al., 1986). For flavonoid induction, cells from fresh overnight pre-cultures were diluted to an OD_{600} 0.1 prior to the addition of daidzein at a final concentration 2×10^{-7} M. As daidzein was prepared as a stock solution of 10^{-3} M diluted in ethanol, a volume of ethanol equivalent to that of diluted daidzein was added to non-induced cultures to minimize any experimental bias. Following 6 h of growth

in the presence or absence of daidzein, free-living cells (at $OD_{600} \approx 0.3$) were harvested by centrifugation at 4 °C prior to RNA isolation.

65.2.2 Plant Assays

Seeds of *V. unguiculata* (L.) Walp. were surface sterilized and germinated for 3 days in the dark at 27 °C. Seedlings were then planted in Magenta jars containing vermiculite and nitrogen-free B&D as nutrient solution (Lewin et al., 1990). Following an inoculation with 2×10^8 bacteria, plants were grown for 38 days at a day temperature of 27 °C, a night temperature of 20 °C, and a photoperiod of 12 h with maximum light intensity of 100 µE/m^2/s.

65.2.3 Isolation of Nodule Bacteria

Once collected on roots of mature plants, nitrogen-fixing nodules was rapidly processed as follows: 1 g of fresh nodules were ground in 20 ml ice-cold MES buffer (350 mM Mannitol, 25 mM 2-[N-morpholino]ethanesulfonic acid, 3 mM $MgSO_4$ $7H_2O$, pH 7) (Natera et al., 2000). To remove most plant debris, the homogenate was filtered through four layers of moist Miracloth and centrifuged at 1000 g for 3 min at 4 °C. The supernatant was transferred into a new tube and centrifuged at 8000 g for 12 min at 4 °C. The crude cell pellet containing bacteroids was resuspended in the lysis phenol-NETS buffer for RNA preparation.

65.2.4 RNA Preparation and High-Throughput Sequencing

Total RNA was extracted from 5×10^9 to 5×10^{10} cells of NGR234 using a 5 ml mixture of equal volumes of pH 4.3 phenol (Sigma-Aldrich, St-Louis, Missouri, USA) and NETS 2X buffer (NaCl 400 mM, Tris-HCl 20 mM pH 8.0, EDTA 1 mM, SDS 1% w/v) that was prewarmed in a boiling waterbath. The mixture was vortexed for 1 min, incubated for 30 s in a boiling waterbath, and then centrifuged at 16,000 g for 5 min at 4 °C. Following a second extraction with an equal volume of hot phenol at pH 4.3, the aqueous phase was then extracted with an equal volume of phenol/chloroform/isoamyl alcohol 50:49:1 (vol/vol) (Sigma-Aldrich, St-Louis, Missouri, USA), and ultimately precipitated using 1/3 vol of 8 M LiCl and 2 vol of ethanol. Following centrifugation, the enriched-RNA pellet was resuspended in 500 µl DEPC-treated and RNAse-free water, extracted twice with phenol/chloroform/isoamyl alcohol 50:49:1 (vol/vol), and precipitated using 1/10 vol Na-acetate 3 M, pH 5.2, and 2 vol ethanol. After centrifugation, the RNA pellet was washed with 70% ethanol, dried, and resuspended in 110 µl DEPC-treated and RNAse-free water. Contaminating genomic DNA was removed with two consecutive DNase I treatments using the RNeasy mini protocol (QIAGEN GmbH, Germany). Total RNA samples were examined on agarose gel for possible degradation, and their concentration and purity were determined by spectrophotometry. For depleting RNA preparations of 16S and 23S ribosomal RNA (rRNA), samples of maximum 7 µg were treated twice with the MicrobExpress™ bacterial mRNA purification kit (Ambion, Applied Biosystems, Carlsbad, California, USA). The effect of rRNA depletion on sample quality was verified using qRT-PCR. For normalization purposes, each of the RNA samples analyzed by high-throughput sequencing was a mixture of three independent RNA preparations and biological replicates. Enriched mRNA samples were given to Fasteris SA (Geneva, Switzerland) for cDNA library construction and sequencing with an Illumina HiSeq-2000 platform that ultimately yielded 50-mer paired-end sequencing reads. The major characteristics of the resulting libraries of sequence reads are listed in Table 65.1.

65.2.5 Mapping of Sequence Reads and Statistical Analysis

Reads were mapped onto the three replicons of the NGR234 genome [symbiotic plasmid pNGR234a (NC_000914.2), megaplasmid pNGR234b (NC_012586.1), and chromosome (NC_012587.1)] using BWA 0.5.8 software (Li et al., 2008) and allowing for a maximum of two mismatches in the 32 bp seed ($-l$ and $-k$ options respectively) and four mismatches on the total read sequence of 50 bases ($-n$ option). To reduce complexity, sequence reads mapping into the 5S (NGR_c26480, _c30320, c34260), 16S (NGR_c26520, _c30360, c34210), and 23S (NGR_26490, _c30330, c34240) rRNA genes were discarded from the analyzed dataset. Normalization of read counts and quantification of gene expression were performed using Seqmonk 0.22.0 (http://www.bioinformatics.babraham.ac.uk/projects/seqmonk/). To normalize datasets, each of the three libraries was scaled up to the same level, and read counts were normalized according to the length of targeted genes or transcripts. Relative expression levels were calculated from the resulting output files using scripts written in the statistical computing environment R (R Development Core Team 2013).

65.2.6 Real-Time Quantitative Reverse Transcription (qRT-PCR)

cDNA amplifications and qRT-PCR experiments were carried out as described previously (Fumeaux et al., 2011). Briefly, primers for amplicons of 100–150 bp were designed using the online Primer3 software (Rozen and Skaletsky, 2000) and are listed in Table 65.2. Reverse transcription was performed in a final volume of 20 µl with 1 µg of DNase-treated RNA, 1 µM of random hexamers, and the "iScript™ Select cDNA Synthesis Kit" (BioRad), during

Table 65.1 Major characteristics of Illumina datasets

Experimental Conditions		RMS	RMS + Daidzein	Nodules
Number of sequence reads		44,442,726	41,429,214	50,862,542
Non-NGR234 sequence reads (% of total)		2.30	1.21	88.94
Reads of 16S, 23S, and 5S rRNA (% of total)		86.42	84.20	9.99
Reads mapping elsewhere on the NGR234 genome	% of total reads	11.28	14.59	1.07
	Number of reads	5,011,460	6,045,772	543,803
	Mb equivalent	250.6	302.3	27.2
	Fold coverage	36.4	43.9	3.9

30 min at 42 °C. qRT-PCR amplifications were performed in duplicate in 20 µl of reaction mixes containing 5 µl of 10× diluted cDNA template, 10 µl of SYBR Green Supermix (Bio-Rad), and 500 nM of each primer. After an initial activation step of 3 min at 95 °C, the Biorad iCycler was programmed for 40 cycles of 30 s at 95 °C and 1 min at 60 °C, with ultimately a melting-curve analysis of PCR products to verify the specificity of amplifications. Values of relative gene expression are the means of three independent RNA preparations with one qRT-PCR for each RNA preparation, and were normalized against 16S rRNA.

65.3 RESULTS AND DISCUSSION

Major characteristics of the RNA-Seq datasets are summarized in Table 65.1. In spite of two consecutive ribosomal RNA depletion steps prior to cDNA synthesis, sequence reads corresponding to 5S, 16S, and 23S rRNA were six to nine times more abundant than non-rRNA transcripts. Mao and associates reported a similar observation when carrying out a pyrosequencing survey of the transcriptome of *S. meliloti* strain 1021 cells grown to mid-exponential phase ($O.D._{600} \cong 0.6$) (Mao et al., 2008). To reduce complexity and sizes of the datasets, sequence reads mapping into 5S (NGR_c26480, _c30320, c34260), 16S (NGR_c26520, _c30360, c34210), and 23S (NGR_26490, _c30330, c34240) rRNA genes were initially discarded. However, to preserve some information on transcription of the three rRNA operons, reads mapping into the shorter 16S–23S and 23S–5S intergenic regions, as well as upstream of the 16S and downstream of the 5S loci were not removed from datasets. As shown in Table 65.1, non-ribosomal RNA species from free-living cells of NGR234 grown in the presence or absence of daidzein (RMS and RMS + daidzein) still represented a total of 250–300 Mb of sequence data that was equivalent to a 36- to 44-fold genome coverage. In order to minimize the impact of the isolation procedure on the transcriptome of bacteroids inside 38 dpi nodules of *V. unguiculata*, the total RNA was rapidly isolated from crude cell pellets. As a consequence more than 80% of the Illumina reads collected from the nodule samples were mostly of

plant origin (data not shown) and are not discussed here. Once non-NGR234 sequence reads or those matching rRNA species were removed, the bacteroid dataset still included more than half a million reads, which together covered >27 Mb of sequence data or four times the NGR234 genome size. Although the pools of non-rRNA reads from free-living bacteria or bacteroids differed significantly in size (see Table 65.1), qRT-PCR validation experiments described further below confirmed that bacteroid data was sufficient to provide reliable expression values. For subsequent calculations of gene expression, the three libraries of sequence reads were scaled up to the same level, and read count was adjusted for gene length.

65.3.1 Core Versus Symbiotic Genomes

Once sequence reads were mapped onto each of the three replicons of the NGR234 genome, subsequent analyses were carried out using SeqMonk, a free software developed by Babraham Bioinformatics for the visualization and analysis of large mapped datasets. For each of the three experimental conditions tested, the respective contributions of the NGR234 replicons to the pool of non-rRNA transcripts were calculated. As shown in Figure 65.1, more than 85% of the sequence reads mapped onto the chromosome of 3.9 Mb when cells were actively dividing in free-living conditions. This result was consistent with the NGR234 chromosome carrying most elements of the "core genome" as was initially described for *R. leguminosarum* biovar *viciae* strain 3841 (Young et al., 2006). In contrast, the respective contributions to free-living transcripts of the symbiotic plasmid pNGR234a (1.5%) and mega-plasmid pNGR234b (10.9%) to the total number of sequence reads were minor, as befit "accessory components." Yet, the addition of daidzein to the growth medium increased significantly the contribution of pNGR234a to 3.3% of total sequence reads because of the flavonoid- and NodD1-dependent activation of symbiotic genes (Kobayashi et al., 2004; Perret et al., 1999). Contribution of pNGR234a to the pool of transcripts increased even more dramatically (up to 35%) when bacteroids fixed nitrogen inside plants, illustrating further the clear symbiotic role of the smallest of the three replicons. In contrast, the contribution of the chromosome to the bacteroid lifestyle was considerably reduced (down to 51% of total reads), while that of pNGR234b remained almost constant. Initially observed in NGR234 (Perret et al., 2000b) and *M. loti* strain MAFF303099 (Uchiumi et al., 2004), downregulation of many chromosomal and house-keeping functions inside N_2-fixing bacteroids was later proposed to result mainly from growth arrest (Capela et al., 2006; Vercruysse et al., 2011). Apparently, this phenomenon was found to be common to bacteroids of nodules of determinate (bean, cowpea and *Lotus*) or indeterminate (alfalfa, and pea) types, and also occurred in endoreduplicated cells of *S. meliloti* and *R. leguminosarum* (Capela et al., 2006; Karunakaran et al., 2009).

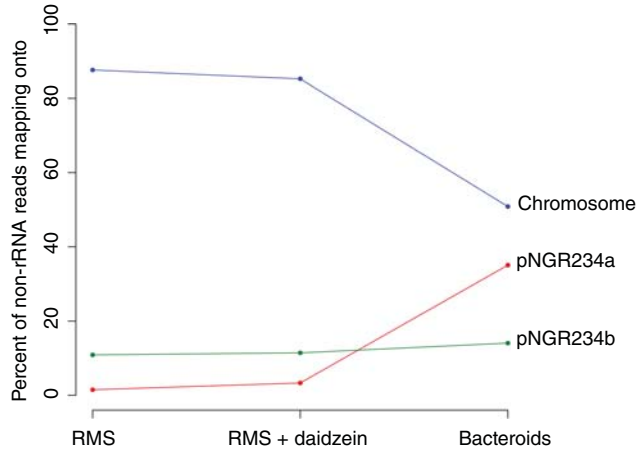

Figure 65.1 Respective contributions of the NGR234 replicons to non-rRNA transcriptome. Sequence reads from RNA-Seq datasets were mapped onto the NGR234 genome using BWA 0.5.8 software. The proportion of total reads mapping on the chromosome (blue line), symbiotic plasmid pNGR234a (red line), or mega-plasmid pNGR234b (green line) are given for each of the three experimental conditions tested: free-living growth in RMS (RMS), or RMS supplemented with 2×10^{-7} M daidzein (RMS + daidzein), or the endosymbiotic lifestyle (Bacteroids).

65.3.2 Validation of RNA-Seq Data

For each experimental condition and to normalize sample preparations, a mixture of three independent RNA preparations and biological replicates were pooled prior to the synthesis of cDNA libraries. Ultimately, to confirm that no significant bias was introduced during the construction of cDNA and sequencing libraries for RNA-Seq, the expression with more than 25 reference loci was followed by qRT-PCR. This validation step seemed particularly important for the RNA-Seq exploration of the bacteroid transcriptome, since the corresponding dataset was reduced as compared to conditions 1 and 2 (see Table 65.1). Several criteria were considered for selecting the most appropriate reference genes, mainly: (i) the functions of the encoded proteins, (ii) the relative expression levels in the three experimental conditions, and (iii) whether these loci were chromosomal or plasmid born. Although results were conclusive for all of the selected targets, Figure 65.2 shows the Log2 fold-change expression values measured for a subset of eight reference genes when cells of NGR234 were either growing in RMS (condition 1) or fixing nitrogen in association with *V. unguiculata* (condition 3). These eight selected genes code for the major 60 kDa chaperonin GroEL1 (NGR_c04080), ribosomal proteins RplL

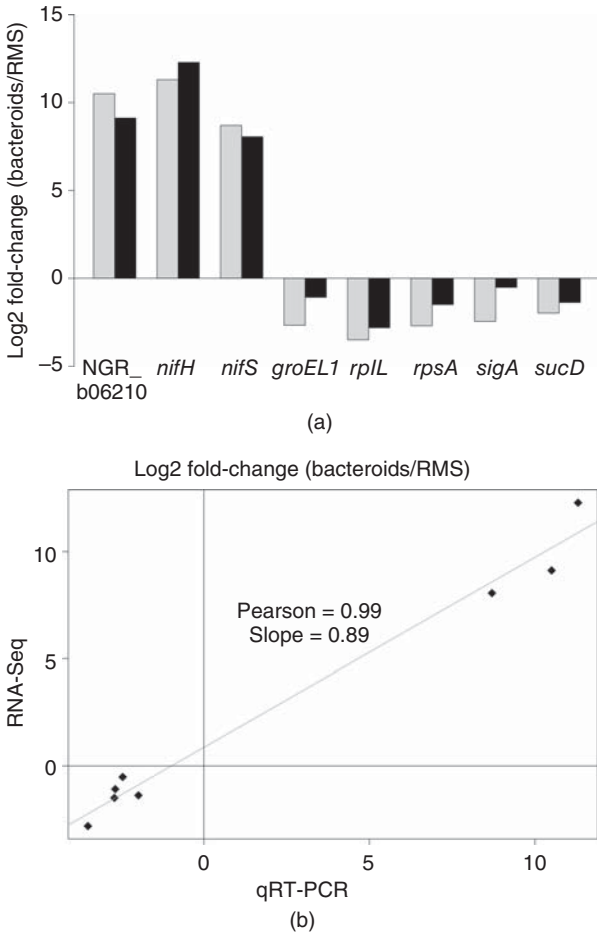

Figure 65.2 Changes in gene expression monitored with RNA-Seq and qRT-PCR. Differential expression of eight reference genes in free-living cells and bacteroids of NGR234 was compared using RNA-Seq and qRT-PCR data. Cells of NGR234 were grown in minimal medium supplemented with succinate to an $OD_{600} \cong 0.6$ (RMS) or isolated from 38 days-post-inoculation (dpi) nodules of *V. unguiculata* (Bacteroids). Changes in gene expression were calculated as the log2 fold-change using RMS as the reference condition. Expression values were the means of at least three independent qRT-PCRs, each using a different RNA preparation as template. Panel (a) shows for each of the eight reference loci the log2 fold-change in gene expression calculated using either normalized RNA-Seq datasets (black bars) or qRT-PCR results (gray bars). Panel (b) shows the result of a Pearson's R correlation test carried out on the log2 fold-change data calculated for each reference gene using either the RNA-Seq or qRT-PCR data. The resulting Pearson R value is 0.99 with a distribution of data points close to linear and a resulting slope of 0.89.

(NGR_c11820) and RpsA (NGR_c35860), sigma-70 (SigA or RpoD) factor (NGR_c22670), succinyl-CoA synthetase SucD (NGR_c31280), an oxidoreductase (NGR_b06210), as well as the nitrogenase iron protein NifH (NGR_a00890 and _a01130) and cysteine desulfurase NifS (NGR_a00930). Together, these genes belong to various functional and phenotypical classes, as well as distinct expression profiles. While expression of *nifH* and *nifS* was clearly restricted to bacteroids, transcription of many housekeeping loci during symbiotic nitrogen fixation was clearly downregulated. Although values calculated with RNA-Seq or qRT-PCR data were not necessarily identical, they were strongly correlated with a Pearson coefficient close to 1 (Fig. 65.2b). These results confirmed the quality and reliability of the RNA-Seq data collected for the three experimental conditions we chose to investigate.

65.3.3 Flavonoid-Dependent Modulation of Gene Expression

As discussed previously, and extensively reviewed elsewhere (Gibson et al., 2008; Perret et al., 2000a), flavonoids released by plant roots play an important signaling role in the molecular dialogue host plants establish with rhizobia (see Chapter 50). Flavonoid-dependent activation of rhizobial nodulation genes is mediated by transcriptional regulators of the NodD family that bind to conserved regulatory elements of 49 bp called *nod*-boxes (NB) found upstream of *nod* genes or operons. With 19 functional NB (NB1 to NB19) dispersed over pNGR234a (Freiberg et al., 1997;

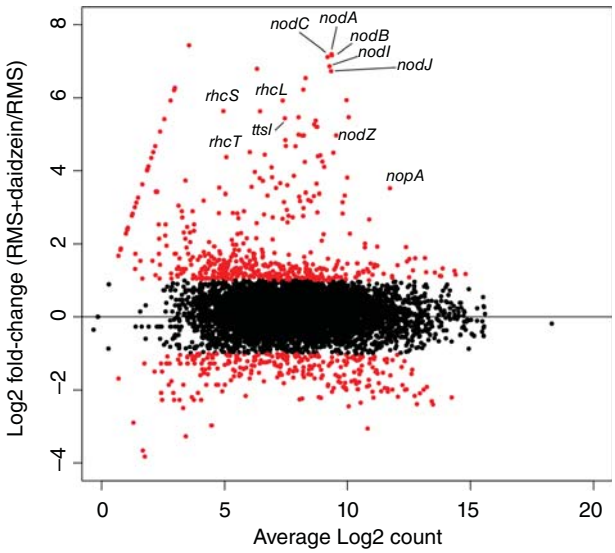

Figure 65.3 Global response of NGR234 cells to the presence of inducing-daidzein in the growth medium. For each of the annotated genes of strain NGR234, the normalized expression values measured in free-living bacteria growing in minimal medium in the absence (RMS) or presence of daidzein (RMS + daidzein) were averaged and transformed into a $\log_2$ count (average Log2 count), and plotted against $\log_2$ transformed fold-change values measured for the same experimental condition [Log2 fold-change (RMS + daidzein/RMS)]. The 754 genes displaying a |fold-change value| ≥ 2 are shown as red dots, while those whose expression varies less than the selected threshold are marked as black dots. Respective positions of a number of important nodulation (e.g., *nodABCIJZ*) and T3SS-related (*nopA*, *rhcLST*, and *ttsI*) genes are also shown.

Kobayashi et al., 2004; Perret et al., 1999), strain NGR234 has more functional NB than any other fully sequenced rhizobial strain. Detailed functional analysis showed that a NodD1-TtsI-SyrM2-NodD2 regulatory cascade controls the sequential activation of at least 75 genes in NGR234, many of which are found downstream of NB1 to NB19. Other flavonoid-responsive loci, such as those coding for a symbiotically active type three secretion system (T3SS) (Viprey et al., 1998), are regulated by TtsI-binding sequences called *tts*-boxes (TB1 to TB11) (Marie et al., 2004). In fact, the capacity of NodD1 to be activated by a broad panel of inducing flavonoids (Le Strange et al., 1990) was proposed to be one of the major keys that allowed NGR234 to initiate a symbiotic dialogue with a broad spectrum of plants (Perret et al., 2003; Perret et al., 2000a; Pueppke and Broughton, 1999). To examine how NGR234 responded to the presence of NodD1-compatible flavonoids, 2×10^{-7} M daidzein was added to the growth medium (experimental condition 2, RMS + daidzein) and cells collected for RNA-Seq analysis after 6 h incubation at 28 °C. Although activity of the NGR234 flavonoid-dependent regulatory cascade was shown to extend over 48 h, most nodulation genes were actively transcribed at 6 h post-induction (Bakkou, 2011; Kobayashi et al., 2004). Control cells were grown in the same conditions (condition 1, RMS), except for the inducing daidzein-ethanol solution that was replaced by an equivalent volume of ethanol (10^{-4} vol. of growth medium). Figure 65.3 shows how daidzein affected transcription of many of the annotated genes of NGR234, with loci having a |fold-change value| ≥ 2 highlighted in red. As expected, the *nodA*, *nodB,* and *nodC* genes for which expression was shown to be maximal after 6 h of daidzein induction, were found in the upper part of the plot. In contrast, maximal transcription of genes coding for components of the T3SS (e.g., *rhcL*, *rhcS,* and *rhcT*) as well as those coding for nodulation outer proteins (Nop) was expected to be achieved later than 6 h post flavonoid induction. Interestingly, RNA-Seq data indicated that in addition to loci directly controlled by the NodD1-dependent cascade many more genes (754 in total with a cutoff |fold-change value| ≥ 2) responded positively or negatively to the presence of inducing flavonoids in the growth medium. Although this result suggested that a purified flavonoid had a broad impact on the metabolism of NGR234, it seemed unlikely that most of these flavonoid-responding loci played a significant role in symbiosis. Nonetheless, a number of chromosomal and pNGR234b gene clusters previously unknown are currently the targets of more detailed molecular analyses.

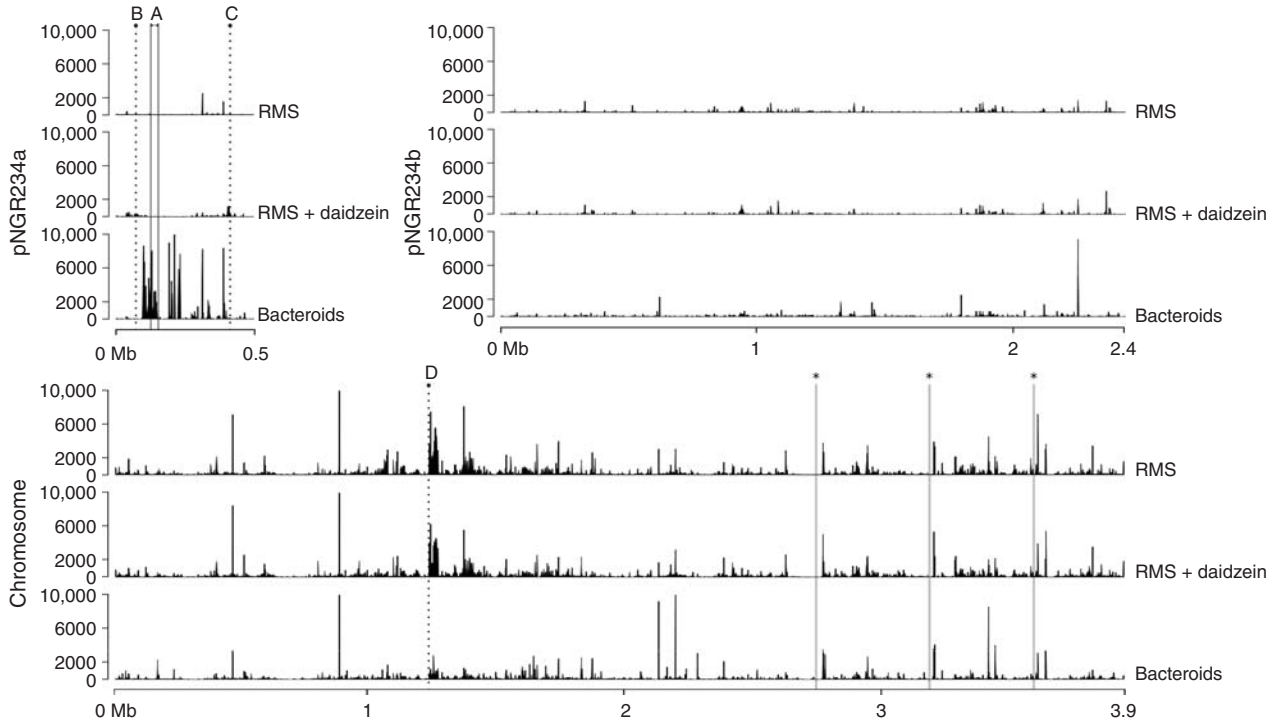

Figure 65.4 Transcription profiles of the three NGR234 replicons. To provide a measure of expression on a given section of a replicon, the number of read counts was averaged over contiguous windows of 1000 nucleotides in size and plotted on to the scale linear representations of each replicon: chromosome, symbiotic plasmid pNGR234a, or mega-plasmid pNGR234b. Read counts were normalized for the total number of sequence reads and the few values above 10,000 were not reported to ensure a better readability. Positions of the regions of particular interest (A, B, C, and D) shown at a higher resolution in Figure 65.5 are marked with dashed lines. Positions on the chromosome of the three rRNA operons are marked with asterisks.

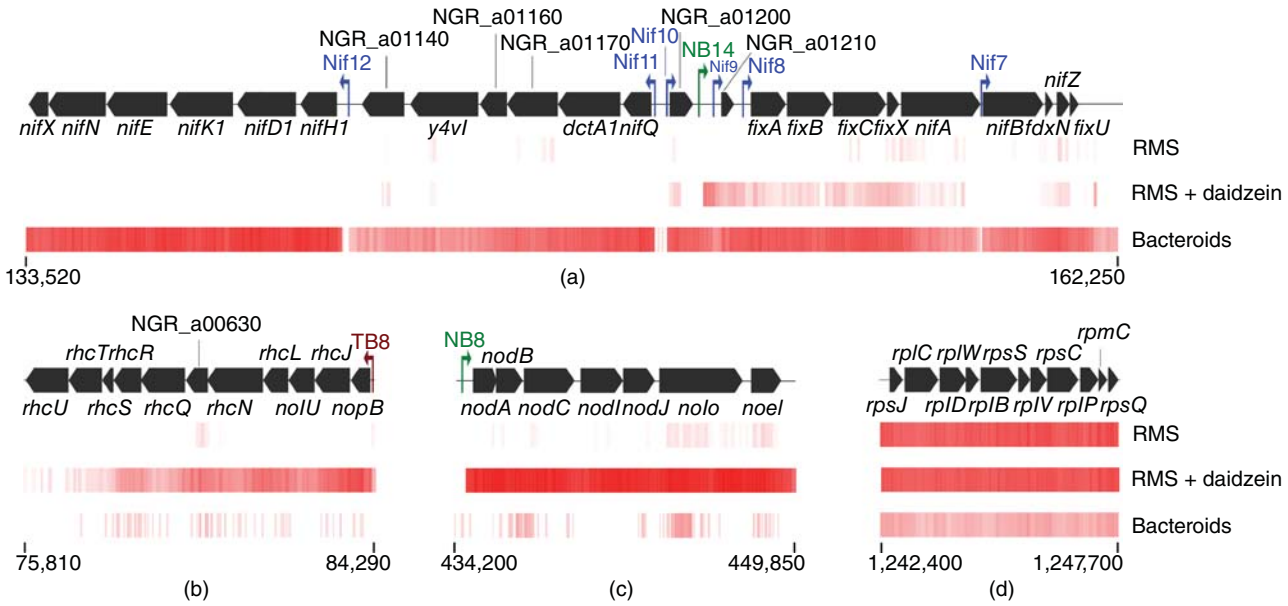

Figure 65.5 Correlated expression and genetic maps for the NGR234 genome. Three sections of pNGR234a [(a), (b) and (c)] and one of the chromosome (d) were selected to illustrate variations in gene expression in the three experimental conditions analyzed by RNA-Seq: free-living cells grown in minimal medium in the absence (RMS) or presence of daidzein (RMS + daidzein), or bacteroids found in 38 dpi nitrogen-fixing nodules of cowpea (Bacteroids). For each of the corresponding sections of the NGR234 genome, a genetic map shows the positions of annotated ORFs and known symbiotic promoters such as *nod*-boxes (NB), TtsI-binding boxes (TB), or NifA-σ^{54} promoters (Nif). These regulatory elements are numbered as in Perret et al. (2003). The intensity of gene expression was represented as a heat map using contiguous windows of 100 nucleotides, and 256 shades of red ranging from white (no expression) to dark red (averaged nucleotide coverage over 100 bases >16,865 or >41,235 for pNGR234a or the chromosome respectively). The respective positions of sections (a), (b), (c) and (d) on the symbiotic plasmid or chromosome were also highlighted in Figure 65.4.

65.3.4 Transcriptional Landscapes in NGR234

As discussed above, the replicon's contribution to the pool of cellular transcripts was considerably influenced by the environmental conditions encountered by bacteria. For example, the presence of daidzein in the growth medium that triggered the expression of nodulation genes, had little effect on the global transcriptional landscape of NGR234 (see Fig. 65.4, RMS and RMS + daidzein). In contrast, differentiation into N_2-fixing bacteroids resulted in an important shift of transcription from many chromosomal functions to regions of pNGR234a responsible for symbiotic nitrogen fixation (Fig. 65.4, RMS and Bacteroids). Interestingly, transcription profiles in free-living cells showed that strong gene expression was often restricted to narrow islands of the chromosome and did not necessarily coincide with the rRNA operons. At a higher resolution, RNA-Seq data also provided single-gene expression values. Instead of poorly informative spreadsheet tables that are difficult to read, transcription and genetic data were assembled into a single high resolution map that covered the three NGR234 replicons and for the three experimental conditions we analyzed (see Fig. 65.5). For this expression map that can be queried via a web-based platform, the normalized RNA-Seq data was converted into a series of contiguous expression windows of 100 nucleotides in size that were aligned with the annotated genome of NGR234. Transcription levels were converted into a colored heat map of 256 shades of red ranging from white (no expression) to dark red (maximal expression for a selected replicon). By scrolling over the transcription map in a particular region, the averaged expression value can be seen for each of the 100 bp-long windows. In addition, positions of known symbiotically active promoters such as the 19 NB, 11 *tts*-boxes, and 16 NifA-sigma 54 regulatory regions of pNGR234a were included. As seen in panels A, B, and C of Figure 65.5, flavonoid-dependent transcription correlated extremely well with the presence of *nod*- or *tts*-boxes, whereas bacteroid-specific transcription often coincided with NifA-σ^{54} types of promoters. In contrast, panel D illustrates the pseudo-constitutive expression of several genes coding for ribosomal proteins (*rpsJ* to *rpsQ*), all of which were downregulated once bacteroids fixed nitrogen. Values reported in Table 65.3 correspond to the normalized expression values calculated for four of the genes shown in Figure 65.5, and highlight the strict regulation of symbiotic genes such as *nodA*, *nopB,* or *nifE*, in contrast to *rplC* that was expressed in all conditions.

Table 65.3 Normalized gene-expression values for a few selected loci

Gene	Function	Normalized Expression Value in RMS	RMS + Daidzein	Bacteroids
nodA	*nod*-factor biosynthesis	9.1	1311.8	3.1
nopB	Constituant of T3SS pilus	5.6	422.4	14.9
nifE	Nitrogenase component	3.5	1.7	6365.2
rplC	50S ribosomal protein L3	2916.3	3091.2	380.1

For all of the annotated genes of NGR234, expression values for all three experimental conditions were normalized and calculated as in the Section 65.2.

65.3.5 Conclusions

In addition to single-gene expression values, RNA-Seq provides a wealth of information that cannot be easily obtained using transcriptomic tools such as conventional microarrays or DNA chips. Given that enough sequence reads are collected for transcribed regions to be extensively covered, transcription units, operon structures, transcription starts, and positions of cognate promoters can be determined. In fact, transcription units predicted for pNGR234a by earlier bioinformatic studies (Perret et al., 2003) matched well those observed in the global expression map obtained for NGR234, and for which Figure 65.5 illustrates a few telling examples. Except for its still elevated costs, which limit the number of replicates or experimental conditions one can afford to test, RNA-Seq suffers from a few drawbacks. One of these limitations is linked to the presence of numerous multicopy and nearly identical loci found in many rhizobial genomes. In fact, the NGR234 genome was shown to carry numerous repeated sequences, many of which are identical in sequence and code for transposable elements (Freiberg et al., 1997; Perret et al., 2001; Perret et al., 1997; Schmeisser et al., 2009). During the automatic mapping procedure, each sequence read that belonged to a repeat was randomly assigned to one of the multiple copies. In the case of the duplicated *nifHDK* genes that are controlled by two functional promoters of nearly identical sequences (Badenoch-Jones et al., 1989; Freiberg et al., 1997), this has no significant consequence on the true-expression value calculated for each gene copy. However, in the case of an insertion sequence such as NGRIS-13 (1573 bp long) that is found in nine identical copies on the chromosome, the random mapping of corresponding sequence reads significantly biased expression values for the gene within the IS element and for those found immediately upstream and downstream of the integration site. Most probably, transcription reported for the various NGRIS-13 copies resulted from a read-through of a single and strong promoter that was adjacent to only one of the nine transposable elements. This example shows that although RNA-Seq data provides a wealth of data, expression values must be analyzed with care and correlated with the genomic context into which transcription of a given gene or operon takes place.

ACKNOWLEDGMENTS

We are grateful to Natalia Giot for technical help, and Jurek Paszkowski for his support in initiating the RNA-Seq studies of the NGR234 genome. Financial support for this project was provided by the University of Geneva and the Swiss National Science Foundation (grant n°31003A-116591).

66.1 INTRODUCTION

The plant body plan is highly adaptive: new organs are created according to need. Legume roots form a particularly interesting example with respect to lateral organ initiation: they can form different types of organs, lateral roots, and root nodules. Although the latter are initiated in response to rhizobium-secreted signaling molecules, Nod factors, and the primordia of the two types originate in different cell layers, accumulation of the plant hormone auxin at the site of primodium initiation occurs in both (Rolfe et al., 1997; Larkin et al., 1996; Mathesius et al., 1998; Pacios-Bras et al., 2003; Takanashi et al., 2011). For a general review on the role of hormones in nodulation (see Chapter 56). Given the importance of auxin in the process (see Chapter 47), it is not surprising that the number of lateral roots can be increased by exogenous auxin application (Blakely and Evans, 1979; Woodward and Bartel, 2005). This is, however, not reported for root nodules. Auxin's textbook antagonist, cytokinin, on the other hand, can be used to induce nodule-like structures (Cooper and Long, 1994), as can auxin transport blockers (Hirsch et al., 1989). A cytokinin receptor is essential for nodulation (Gonzalez-Rizzo et al., 2006; Tirichine et al., 2007, Murray et al., 2007; Plet et al., 2011) and cytokinin response regulators are activated early in the process (Op den Camp et al., 2011). This further demonstrates the importance of this hormone in nodulation. On lateral roots, however, it has an inhibiting effect (Laplaze et al., 2007). Auxin efflux carrier PIN1, which is upregulated in lateral root formation, is readily removed from the plasma membrane of primordium cells upon cytokinin addition (Marhavy et al., 2011).

This paradox suggests that the mechanisms underlying auxin accumulation in lateral root and root nodule

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

primordia differ, for which we offer additional experimental evidence. We hypothesize that the Nod-factor-activated cytokinin signaling causes local auxin accumulation in the cortical layers that form the nodule primordium.

We start with an unbiased analysis of three conceptually different mechanisms for local auxin accumulation. From this, we continue with the best candidate and discuss the likelihood that cytokinin can trigger the proposed mechanism.

To date, the formation of **lateral roots** has been studied most extensively in the model organism *Arabidopsis thaliana*. The lateral roots of these plants originate exclusively from a few pericycle cells, the "founder cells" (Malamy and Benfey, 1997; Casimiro et al., 2003). These cells are the site of the first auxin accumulation (Hirota et al., 2007). In model legumes, which, contrary to *Arabidopsis*, all have a multilayered cortex, the lateral root primordia are also predominantly of pericycle origin (Mallory et al., 1970), and the first auxin accumulation is observed in the pericycle (Rolfe et al., 1997; Larkin et al., 1996).

The formation of **root nodules** starts with an encounter of a compatible rhizobium bacterium, which is recognized by the plant host through the species-specific Nod factors it produces (Jones et al., 2007; see Chapter 51). Two major types of legume nodules are found on the model species: determinate and indeterminate, named after the persistence of a meristem only in the latter (Hirsch, 1992). One model legume, *Lotus japonicus*, forms determinate and the other, *Medicago truncatula*, forms indeterminate nodules. Interestingly, the primordia of determinate nodules originate in the outer to middle cortical layers, whereas the indeterminate primordia originate from the inner cortical layers (Hirsch, 1992). Correspondingly, local auxin accumulation has been found at the sites of the first cortical cell divisions in *Lotus* (Pacios-Bras et al., 2003; Takanashi et al., 2011) and white clover (indeterminate) (Mathesius et al., 1998).

Lateral roots and root nodules originate in approximately the same zone of the legume root. For nodules, this is called the susceptible zone (Bhuvaneswari et al., 1981). In the youngest part of this zone the epidermal cells start developing root hairs. Cortical cells in the zone differentiated fully and in the process of nodule formation they de- and redifferentiate. Throughout this text, we sometimes refer to the legume susceptible zone using "DZ" (standing for "differentiation zone"), thereby stressing the origin of the parameters we use (see Section 66.2).

Auxin is active in minute concentrations (Ljung et al., 2001; Marchant et al., 2002; Petersson et al., 2009). The most abundant natural auxin, indol-3-acetic acid (IAA) is a weak acid with $pKa \approx 4.8$. Its protonated form, IAAH, can passively cross the cell membrane, which is, however, practically impermeable to the deprotonated form, IAA^-. Because the apoplastic is slightly acidic and the cytoplasm neutral, this difference can result in an influx of auxin against the total auxin concentration (Mitchison 1980; Steinacher et al., 2012). This influx can be enhanced by more than an order of magnitude by auxin influx carriers such as the AUX1/LAX family (Swarup et al., 2005). These are typically located homogeneously over the cell membrane, or at increased levels at the apical and basal sides of the cell (Swarup et al., 2001; 2004, Kleine-Vehn et al., 2006). Efflux occurs predominantly by efflux carriers such as the PIN proteins (Galweiler et al., 1998; Paponov et al., 2005), often concentrated on specific sides of the cells. This gives rise to directional auxin transport (Benkova et al., 2003; Blilou et al., 2005). For an excellent review on auxin biosynthesis we refer the reader to Mano and Nemoto (2012). Because no tools exist yet for monitoring the auxin concentration live in living plants, computer models have become an indispensable tool in studying the many roles of this plant hormone in plant development – see (Kramer, 2008; Grieneisen and Scheres, 2009; Garnett et al., 2010; Jonsson and Krupinski, 2010) for some reviews.

From this overview of auxin transport and metabolism we arrive at three major scenarios for increasing the auxin concentration in a cell: increasing the amount of influx carriers, decreasing the amount of efflux carriers, and local auxin production (Deinum et al., 2012). We use a computational model of a generalized legume root segment to investigate the possibilities of inducing local auxin accumulation through these mechanisms and their distinguishing properties. For this we apply these scenarios to a designated part, the "**controlled area**" of an *in silico* root segment. We find that the three scenarios all yield different spatial and spatiotemporal signatures. Of these, the signature generated by a reduction of the efflux was most compatible with the observed patterns of auxin accumulation and the morphology of the nodule primordium. Because this differs from the mechanism of lateral root primordium initiation, we expect that root nodule positioning lacks the sensitivity to root curvature found in lateral roots, which we experimentally verify. The lateral position of the cortical auxin maximum can be shifted by small changes in the distribution of cortical PIN proteins. Based on this observation we discuss the possibility that cortical PINs determine the lateral position of the first cell divisions in nodulation, which, in turn, is correlated with the type of nodules produced.

66.2 METHODS

66.2.1 Simulations of Auxin Transport and Metabolism in Root Segments

Auxin transport and metabolism are modeled with subcellular precision. Within a cell and inside the apoplast, auxin

Table 66.1 Overview of model parameters (Deinum et al., 2012)

Parameter	(Default) Value	Description
D_c	300 μm²/s	Auxin diffusion constant inside cells (Laskowski et al., 2008)
D_W	44 μm²/s	Auxin diffusion constant in apoplast (Jones et al., 2009)
$P_{out,high}$	20 μm/s	Effective efflux permeability, high value (Grieneisen et al., 2007; Laskowski et al., 2008)
$P_{out,low}$	5 μm/s	Effective efflux permeability, low value (Grieneisen et al., 2007; Laskowski et al., 2008)
$P_{out,bg}$	1 μm/s	Effective efflux permeability, background value (due to misplaced PINs) (Grieneisen et al., 2007; Laskowski et al., 2008)
P_{in}	20 μm/s	Effective influx permeability (Grieneisen et al., 2007; Laskowski et al., 2008)
C_v	Concentration	The average auxin concentration in the vascular tissue is normalized to 1 C_v (Strictly speaking, C_v is not a parameter.)
p	0; 10^{-4} C_v/μm³/s	Auxin production rate; Default: no production. Estimates for reasonable rates based on (Ljung et al., 2001), scaled relative to total concentrations (Marchant et al., 2002)
l	100 μm	Cell length
w_C	20 μm	Width of cortical cells
w_x	10 μm	Width of other cells
d_W	0.2 μm	Wall thickness (Jones et al., 2009)
d_p	2 μm	Pixel size for the cells' interior
t	0.5, 1, 2.5 s	Integration time step (dependent on interval between measurements)

See Section 66.2 and (Deinum et al., 2012) for explanation.

moves by diffusion with diffusion constants D_C and D_W, respectively. Transport over the cell membrane is modeled using directional effective permeabilities P_{in} and P_{out} for influx and efflux. This implicitly assumes non-saturating processes or carriers operating far from saturation. This results in flux over the membrane (positive means outward flux): $J_{mem} = P_{out}\ C_c - P_{in}\ C_w$. In our simulations, efflux parameter P_{out} can be set for each cell face independently, whereas influx parameter P_{in} is always the same for all four faces of the cell. Parameters and default values are summarized in Table 66.1. Further details of the simulations can be found in Deinum et al. (2012).

Because of the lack of data on PIN positioning in the relevant root of a real model legume, the PIN layout was based on an experimentally founded model developed for *Arabidopsis* (Laskowski et al., 2008), geometrically adopted to resemble model legumes *Medicago* and *Lotus* (Deinum et al., 2012).

The simulation root segments we used are much longer than the region of interest, so as to minimize effects from the boundaries. Boundary conditions and motivation are further described in (Deinum et al., 2012).

66.2.2 Changes Applied in the "Controlled Area"

A designated part of the root segment (Fig. 66.1a and b), a 0.5 mm block comprising the epidermis and the cortex on one side of the root, is designated the "controlled area." All scenarios are implemented as a change applied to these cells: (n-fold) increase in the effective influx permeability, (n-fold) INFLUX, (n-fold) decrease of the effective efflux permeability, (n-fold) EFFLUX, and local auxin production with a given rate, PRODUCTION.

66.2.3 Concentrations are Normalized with Respect to the Vascular Tissue

For easier interpretation of the results we have normalized the concentration in the root segments with the average vascular concentration in a segment without any change in the controlled area. This level is called C_v. Thus, a concentration of $2C_v$ means twice as much auxin as the average for the vascular tissue. Where applicable, auxin production occurs with rate p in normalized concentration units per second per unit volume.

66.2.4 Plant Growth and Gravitational Stimulation

7–8 *M. truncatula* A17 seedlings were grown on each $24 \times 24\ cm^2$ plate with buffered Nod medium containing amino-ethoxy-vinyl-glycine (AVG). The gravitational field of the plants was changed by turning the plates by 90° at irregular 1–3 day intervals. Upon transfer to the plates, they were inoculated with rhizobium strain *Sinorhizobium meliloti* 2011 and covered by transparent sheets to ensure continued contact with the medium. The medium, seed treatment, and germination were according to standard protocols (www.noble.org/medicagohandbook).

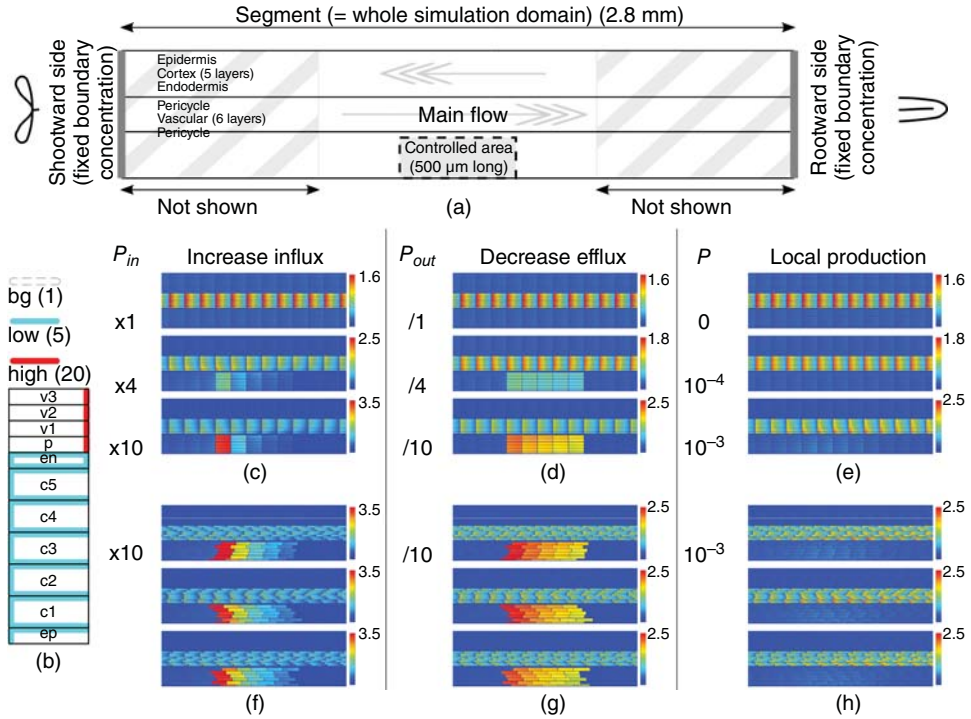

Figure 66.1 Different mechanisms for local auxin accumulation leave different signatures. General setup is a root segment representative of the susceptible zone of module legumes Lotus and Medicago (a). The distribution of PIN proteins (b) gives rise to net auxin fluxes as indicated in (a). PINs are modeled using effective efflux permeabilities P_{out} with three starting levels: "bg" (1 µm/s), "low" (5 µm/s), and "high" (20 µm/s), following (Laskowski et al., 2008). A five cells long block of cells, consisting of all five cortical layers and the epidermis is designated "*controlled area.*" Changes are applied to these cells: increase in the effective influx permeability, INFLUX (c,f), decrease in the effective efflux permeability, EFFLUX (d,g), or local auxin production, PRODUCTION (e,h), with indicated factors or rates. Note that INFLUX results in a much stronger accumulation on the right/downstream side of the controlled area, whereas EFFLUX results in more homogeneous accumulation. Randomly generated root segments (f–h) with an average cell length of 100 µm, normally distributed with $\sigma = 4$ µm, show that the observed patterns do not depend on the square layout of the default segments. Concentration ranges are adapted for maximum visibility, all ranging from 0 to the maximum (in C_v) indicated with each subfigure. Figure after Deinum et al. (2012).

66.2.5 Statistical Methods

All statistical calculations were made using self-written scripts. For comparison of fractions of lateral organs on curved vs. straight parts we calculated $p = \int_{q=0}^{1} P(f_L \leq \mathrm{q} \,\Lambda\, f_N = \mathrm{q})\mathrm{d}q$, with f_L and f_N representing the "true" fraction of lateral roots or nodules, respectively, on curved regions of the roots on a particular plate. Probability density functions for f_L and f_N were calculated based on binomial distributions: $P(f_L \leq \mathrm{q}) = \frac{1}{I_0} \int_{r=0}^{q} \binom{n}{c} r^c (1-r)^{n-c} \mathrm{d}r$, with c being the number of lateral roots on curved parts of the root out of a total of n observations, and I_0 being the total mass of the integral. With this statistic, $p = 0.5$ means that nodules and lateral roots are equally likely to appear in curved regions. As the fraction of root length that qualifies as being curved differs among plates, all comparisons were made within plates only.

66.3 RESULTS AND DISCUSSION

66.3.1 Different Mechanisms for Local Auxin Accumulation Leave Different Signatures

From the available knowledge on auxin transport and metabolism we have selected three conceptually different mechanisms that could in theory lead to local auxin accumulation: INFLUX, EFFLUX, and PRODUCTION (Deinum et al., 2012). We investigated the behavior of these mechanisms in an *in silico* root segment representative of the susceptible zone of a model legume (Fig. 66.1a and b). The PIN layout of this root segment results in a rootward auxin flux in the stele and a shootward flux in the cortex.

An increase in the effective influx permeability, INFLUX, resulted in an increase in the auxin concentration in the controlled area (Fig. 66.1c). This increase, however, was strongest on the left side of the controlled

area, which is its downstream side with respect to the cortical auxin flux. This strong focus on the downstream side occurred independent of the length of the controlled area (data not shown).

With a decrease in the effective influx permeability, EFFLUX, on the other hand, we observed a broad auxin accumulation pattern (Fig. 66.1d). Although the concentration on the shootward side of the controlled area was slightly higher than that on the rootward side, this bias was much weaker than with INFLUX.

With both INFLUX and EFFLUX, the minimal change for an increase in the maximum cortical concentration above the vascular level C_v was between 4-fold and 10-fold. Such levels were not reached with the local production scenario PRODUCTION (Fig. 66.1e). Regardless of the production rate, the concentration in the controlled area remained far below $1C_v$. This could not be attributed to a low production rate, as the highest rate we used should be considered high based on gas chromatography and mass spectroscopy measurements by Ljung et al. (2001) and Marchant et al. (2002). Moreover, the absolute increase in the vascular tissue rootward, that is, downstream, of the production site was higher than in the controlled area itself, demonstrating that the auxin was mostly transported away. This is in line with a proof-of-principle simulation (of the *Arabidopsis* root) by Grieneisen et al. in which the whole auxin maximum around the quiescent center (QC) of the root tip could be filled by a single auxin-producing cell, a distant cortical cell, that soon contained less auxin than cells near the QC and eventually contained almost the same concentration as the cortical cells surrounding it (Grieneisen et al., 2007).

These signatures did not rely on the regular alignment of the cell files and were robust against variations in cell length (Fig. 66.1f–h).

From the different signatures we can conclude that the accumulation mechanism affects the dimensions of the resulting primordium. The DR5 data of auxin accumulation in lateral root primordia by Hirota et al. (2007) actually show an auxin maximum that is more focused than the region where influx carrier AUX1 is upregulated.

The broad accumulation pattern found with the EFFLUX scenario seems most compatible with the experimental observation that nodule primordia are typically broader than lateral root primordia.

66.3.2 Lateral Roots and Nodules Respond Differently to Gravitropically Induced Curvature

On curved roots, lateral roots typically emerge on the convex side ("outside") of the curved part (Fortin et al., 1989). Moreover, lateral roots can be promoted by mechanical or gravitropical root bending (Fortin et al., 1989; Laskowski et al., 2008); the first induction method was also demonstrated in *M. truncatula* (Lillo, 2012). Computer simulations by Laskowski et al. show that the geometrical effect of the bending results in a slight increase in the local auxin accumulation, particularly in the pericycle. This can be enhanced by auxin-induced AUX1 expression, through a positive feedback between increased auxin accumulation and increased influx (Laskowski et al., 2008). If the initial auxin accumulation in root nodule primordia is indeed caused by a reduction of the efflux, we expect that they do not show the typical distribution with respect to root curvature as seen in lateral roots.

To investigate this, we subjected *M. truncatula* plants to irregular gravitropic stimuli to induce highly curved roots. Nodule and lateral root positions were scored in three categories with respect to curvature: convex, concave, and straight/unclear (Fig. 66.2). In line with observations from other species, and mechanical root bending experiments in *Medicago*, lateral roots showed a very strong preference

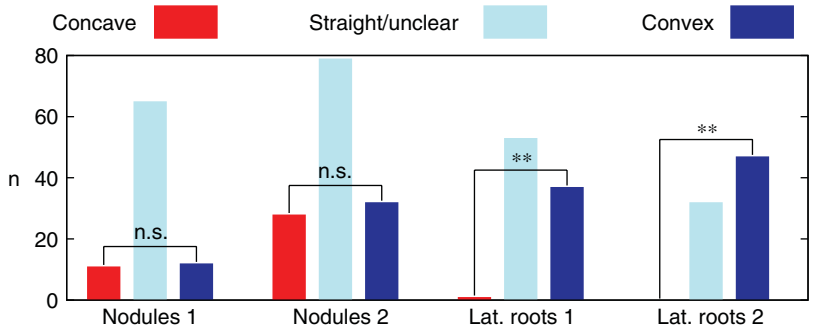

Figure 66.2 Root nodule position is insensitive to root curvature. Numbers of root nodules and lateral roots and their position with respect to root curvature: concave ("inside", red) or convex ("outside", blue) side of bend parts, or on straight parts (cyan) of the root. Root nodules showed no significant bias for either side of the root curve ($p = 1$, $p = 0.699$), whereas lateral roots showed a very strong bias toward the convex side ($p = 2.84\text{e-}10$, $p = 1.42\text{e-}14$). On both plates, lateral roots occurred relatively more often on bent regions than lateral roots (42% vs. 26%, $p = 0.014$ and 59% vs. 43%, $p = 0.011$). Roots were bent by exposing *Medicag truncatula* A17 plants on large square plates to varying gravitropic fields. Results of two representative plates with slightly different growth conditions and rotation regimes.

for the convex sides of roots ($p = 2.84\text{e-}10$, $p = 1.42\text{e-}14$, two-tailed binomial test). Root nodules, on the other hand, showed no significant bias for either the convex or the concave side of the curved parts of the root ($p = 1$, $p = 0.699$, two-tailed binomial test). Moreover, in both experiments, the percentage of lateral roots occurring in curved regions was larger than for root nodules on the same plants (42% vs. 26%, $p = 0.014$ and 59% vs. 43%, $p = 0.011$). This suggests that lateral roots are positively induced by root curvature, whereas nodules are not, or to a much lesser extent. Not only is this entirely in line with our expectation based on the different mechanisms, but it is also functionally relevant. While the average result of lateral root formation on the convex side of root curves rather than the concave side is a larger occupied soil volume, the main functional requirement for nodule primordia is that they originate close to the initial infection site and not on the other side of the vascular bundle if the root happens to be curved.

Based on our results so far we continued our investigation with a strong focus on the EFFLUX scenario.

66.3.3 Auxin Accumulation Following Efflux Reduction Starts Closest to Auxin Sources

In Figure 66.1 we investigated steady state patterns of auxin accumulation. A very relevant question is, therefore, whether the auxin accumulation occurs fast enough to be compatible with the known timing of nodulation events. In other words, a sufficient increase in auxin concentration is needed at least several hours prior to the first cortical cell divisions. This boils down to a time window of at most 20 h: at 18–24 h after inoculation, the cortical cells show cytoskeletal signs of activation for division (Timmers et al., 1999) and no cortical cell divisions are observed within 20 h after inoculation (Yang et al., 1994). As our approach involves an instantaneous change in the transport parameters and no transcription or translation of regulatory genes, the actual maximum time window is probably several hours shorter.

To check for compatibility, we followed the dynamics of auxin accumulation in the controlled area (Fig. 66.3). With our default parameters, the steady state was reached much faster than necessary (Fig. 66.3a and c). Auxin accumulation was also fast enough when we slowed down all dynamics by reducing all effective influx and efflux permeabilities by a factor 10 (Fig. 66.3b and d). Moreover, in the latter case enough time is left for processes we did not explicitly consider, such as the induction of the reduction of the efflux permeability and transcription of early nodulin genes. Such processes can happen fast, as most PIN1 disappears from the cell membrane in *Arabidopsis* lateral root primordia within 1 h upon cytokinin treatment (Marhavy et al., 2011) and early nodulin gene ENOD40 is upregulated within 3 h after spot inoculation in alfalfa (Compaan et al., 2001).

By studying the time scales of auxin accumulation under EFFLUX in different modified roots and different factors of efflux reduction, Deinum et al. found that the time scales of auxin accumulation are determined by the time scales of redistributing auxin over the whole controlled area. This, in turn, is largely set by the remaining effective efflux permeability at the shootward side of the cortical cells, that is, the side with most PINs, inside the controlled area (Deinum et al., 2012; see especially Fig. 66.3).

Interestingly, auxin accumulation after efflux reduction did not occur homogeneously throughout the controlled area. The first accumulation was seen in the innermost

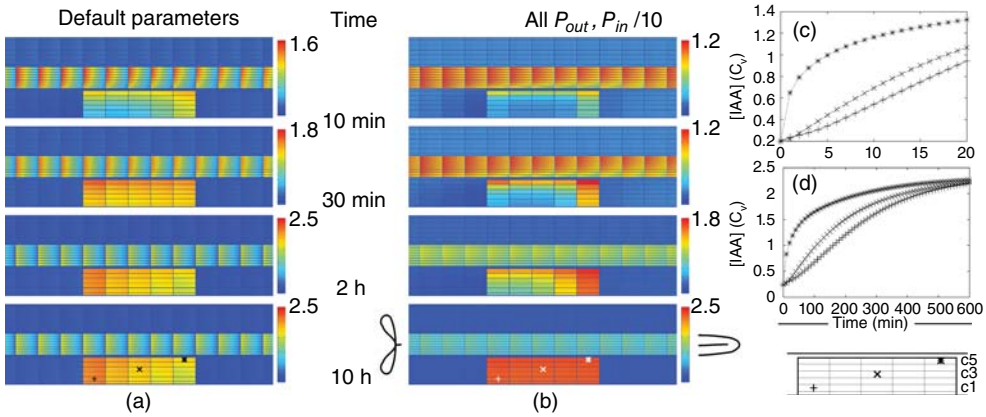

Figure 66.3 Auxin accumulation following an efflux reduction starts from the inner cortex, closest to the main auxin source. At T = 0 s, the efflux in the controlled area is reduced by a factor 10 (EFFLUX). The concentration is shown as heat maps at designated time points (a,b) and using time traces of the concentration in three designated cells in the controlled area (c,d). Both with default parameters (a,c) and with "slowed down" parameters (b,d), the auxin concentration increases first in the inner cortex and toward the left of the controlled area. These locations are closest to the vascular tissue and influx from unaffected cortex, respectively. "Slowed down": a 10-fold reduction of all influx and efflux parameters in the whole segment, prior to any change. Figure after Deinum et al. (2012).

cortical layer and also on the rootward (right) side of the controlled area (Fig. 66.3). These two locations correspond to the vicinity of auxin sources: the vascular tissue with its high auxin concentration and from the shootward flux in the cortex, respectively. The temporal difference was most pronounced with the reduced parameters (Fig. 66.3b and d; See also (Deinum et al., 2012), Fig. S2). As the auxin accumulation progressed, the transverse cortical concentration profile became flat again, just as in the root prior to induction.

66.3.4 Can Cortical PINs Make the Difference between "Indeterminate" (Inner Cortex) and "Determinate" (Middleouter Cortex) Auxin Accumulation?

A key difference between determinate and indeterminate is the radial position of the cortical cell divisions that form their primordia, and (most likely) the position of correlated auxin maximum. Determinate nodules originate from the middle to outer cortex, and indeterminate nodules from the inner cortex (Pacios-Bras et al., 2003; Takanashi et al., 2011; Mathesius et al., 1998; Libbenga and Harkes, 1973; Timmers et al., 1999). In our simulations so far, we assumed an equal amount of PIN proteins in the central and peripheral lateral membranes of the cortical cells. This resulted in an auxin maximum that was homogeneous in the radial direction (* in Fig. 66.4). We then investigated whether a central–peripheral bias in the effective efflux permeabilities could shift radial position of the EFFLUX auxin maximum and how strong such a bias would have to be.

For this we designed new reference segments with different inward and outward effective efflux permeabilities of the lateral cell membranes of all cortical cells and applied EFFLUX to all of those (Fig. 66.4). Already the smallest biases we tried, amounting to 20% more or 20% less outward than inward efflux, produced a marked radial shift of the auxin maximum in the controlled area, and even with the strongest inward bias the maximum concentration in the controlled area was well above the vascular concentration C_v.

Neither the formation of determinate nor the formation of indeterminate nodules defines a monophyletic group within the legumes (Doyle, 1994, Mergaert et al., 2003). This suggests that the transition between different nodules is relatively easy on evolutionary time scales. Moreover, grafting experiments show that the distinguishing feature must be root autonomous (Lohar and VandenBosch, 2005). Based on our results and the strict assumption that maximum auxin accumulation predicts the cell division site and through that nodule type, we tentatively hypothesize that slight changes in the lateral bias of PIN positioning could be such an "easy" change at the root of nodule type differentiation. A candidate system that could foster such changes would be the differential regulation of PINOID and/or PP2A activity, which plays an important role in the polar positioning of PIN proteins through their phosphorylation and dephosphorylation, respectively (Friml et al., 2004; Michniewicz et al., 2007). In a different context, changes in PINOID

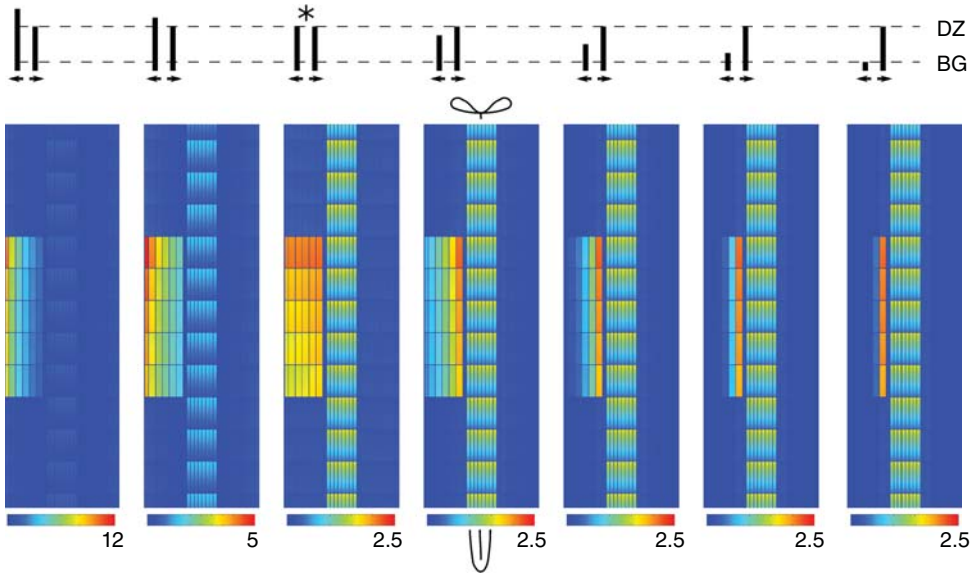

Figure 66.4 Changes in cortical PINs can shift the lateral location of the induced cortical auxin maximum. The maxima are all induced by the same decrease of efflux. The segments differ only in the effective efflux permeability of the outward faces of the cortical cell, ranging from 140% to 20% of the inward value, as indicated by the cartoon on top. The default layout, 100%, is indicated with *. In all cases, the highest concentration in the controlled area is above the vascular concentration C_v. Figure after Deinum et al. (2012).

activity affected the central–peripheral PIN distribution (Ding et al., 2011).

66.3.5 PIN Layout: Co-Determinant of the Susceptible Zone through Controlling Cortical Auxin Availability?

As the root develops, cells elongate and differentiate (Dello Ioio et al., 2008; Dolan et al., 1993) and also the distribution of PIN proteins over the different cell faces changes (Laskowski et al., 2008). In the original *Arabidopsis* model the root is divided into three major zones. Starting from the root tip, these are MZ ("meristematic zone"), EZ ("elongation zone"), and DZ (Laskowski et al., 2008). The susceptible zone for nodulation is most similar to the DZ with respect to geometry and developmental stage, as root hairs, the canonical rhizobial entry points, arise in the DZ. This made the DZ a very natural starting point for our simulation study. We wondered, however, whether other factors could also affect if and how easily lateral organs could be induced in particular root zones. We therefore investigated the effects of INFLUX and EFFLUX using the EZ PIN layout (Fig. 66.5i).

Interestingly, the same changes that produced large auxin accumulation in the default (DZ; Fig. 66.5a) segment (Fig. 66.5c and d) had apparently little effect in the EZ segment (Fig. 66.5k and l). Upon closer inspection, the radial concentration profiles in the controlled area were similar to those without any change (Fig. 66.5e–h). This shows that the propensity for auxin accumulation in the controlled area strongly depends on the cortical auxin availability, which is much larger in the DZ (Fig. 66.5b) than in the EZ (Fig. 66.5j) segment.

In the radial direction, the only difference between the EZ PIN layout – which shows markedly little auxin accumulation – and the rightmost segment of Figure 66.4 – which showed a strong auxin accumulation in the inner cortex – is in the endodermis. This suggests that a strong inward (or "L-shaped") PIN distribution in the endodermis could reinforce the distal boundary of the susceptible zone through a strong reduction in the amount of auxin available in the cortex. We like to add that the appearance and elongation of root

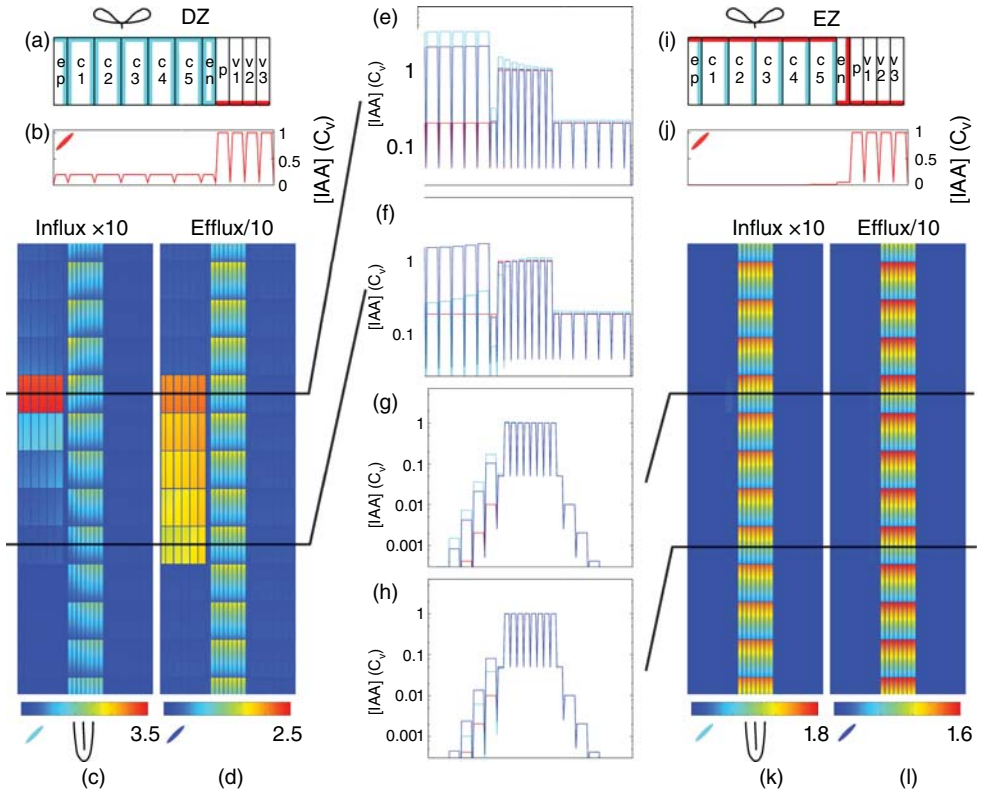

Figure 66.5 Local auxin accumulation in different zones of the root. The same changes, INFLUX and EFFLUX, are applied in different zones of the root, with strikingly different effects on auxin accumulation. The only difference between the root segments is the PIN layout (a,i), "DZ" (a–f) and "EZ" (g–l), as based on (Laskowski et al., 2008). The EZ PIN layout results in a much lower cortical auxin concentration (cf. j,b). Consequently, much less auxin accumulates in the controlled area after INFLUX (k vs. c) or EFFLUX (l vs. d) with the EZ layout. Transverse concentration profiles (e–h), plotted on a logarithmic scale for visibility, show that with both changes (INFLUX: cyan, EFFLUX: blue) the resulting profile in the controlled area resembles the original profile (red) in shape. Figure after Deinum et al. (2012).

hairs are also stimulated by auxin (Masucci and Schiefelbein, 1994; Pitts et al., 1998), so the same change of endodermal PIN positioning most likely has a double and congruent effect on specifying the susceptible zone in many legumes.

66.4 CONCLUSION AND OUTLOOK

To shed light on the earliest stages of root nodule formation and the role of auxin therein, we have investigated conceptually different mechanisms for local auxin accumulation in roots. These mechanisms all show their own characteristic signatures. Of the mechanisms investigated, a reduction of efflux was most compatible with diverse experimental observations. This is a different mechanism from the increased influx that is key to lateral root formation, predicting a different sensitivity of lateral root and root nodule formation to root curvature, which we subsequently observed in *Medicago* plants upon gravitropic stimulation. The simple approach taken here, of course, has its limitations, which marks the mechanism of their induction as an important topic for follow-up investigations. Further computational studies could also help identify downstream consequences of our tentative hypothesis on different PIN distributions in relation to nodule type that are easier to address experimentally.

67.1 INTRODUCTION

Despite constituting 78% of the atmospheric air, nitrogen is the most limiting nutrient in the soil for plant growth. This is compensated in agriculture with the extensive use of nitrogen fertilizers. Many leguminous plant species can, however, overcome this nutrient limitation by forming symbiosis with nitrogen-fixing α- and β-proteobacteria collectively known as rhizobia. Legume plants select their bacterial partners from the rhizosphere via molecular signaling. Flavonoids excreted from the host root induce in proper rhizobia the expression of nodulation genes required for the production of host-specific bacterial lipochitooligosaccharide signals called Nod factors (Schultze et al., 1994; see Chapters 50, 51). These molecules induce the formation of a specific symbiotic organ, the root nodule where bacteria in the nodule cells are converted into nitrogen-fixing bacteroids and reduce the atmospheric molecular nitrogen to ammonia. The symbiosis is mutually beneficial as the endosymbionts provide ammonia to the host for plant growth in return for photosynthetic products (carbon source and energy).

Bacterial invasion occurs generally via the root hairs: the bacteria attach to the tip of growing root hairs that curl around them and then the entrapped bacteria enter the root

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

hair cell through invagination of plasma membrane and formation of a tube-like structure, the infection thread (IT). ITs can cross cell boundaries and transport the bacteria toward the root cortex. Simultaneously with the infection cortical cells start to divide, leading to the development of the nodule primordium. When the growing ITs reach the nodule primordium, nodule differentiation begins. The bacteria are released from the ITs into the cytoplasm of nodule cells via an endocytosis-like mechanism, and as a result the rhizobia are encapsulated in a plant-derived peribacteroid membrane and exist as an organelle-like structure called symbiosome. After infection, the nodule cells start to grow mostly by repeated genome doublings via endoreduplication (ER) cycles until they are large enough to accommodate a multitude of bacteroids. Nitrogen-fixing bacteroids are differentiated rhizobia whose metabolic activity is adapted to the intracellular life style, the specific requirements for nitrogen fixation, and exchange of metabolites between the partners (White et al., 2007).

Despite the common, nitrogen-fixing function of bacteroids, the morphology, physiology, and differentiation fate of bacteroids can be strikingly diverse in the different legume nodules. Certain rhizobia can switch between the free-living and the endosymbiotic life styles while for others the symbiotic state cannot be reversed to the free-living one; thus, their fate is irreversible and terminal. In this review, the two major nodule types in relation to reversible and terminal endosymbiont differentiation are presented as well as the current knowledge on the plant effectors of terminal bacteroid differentiation.

67.2 TWO NODULE TYPES WITH COMMON FEATURES OF SYMBIOTIC HOST CELLS AND DIFFERENT FATE OF ENDOSYMBIONTS

The form and size of nodules can be quite different in the various legume hosts. Nevertheless, they can be classified either as determinate or indeterminate type (Fig. 67.1a). The nodule type depends on the host plant and frequently reflects taxonomical position (Sprent, 2007). The major difference between the determinate and indeterminate nodules is the transient or persistent nature of the nodule meristem, respectively. In addition, determinate nodules originate from division of the outer cortical cells while the indeterminate ones originate from the inner cortical cells. Determinate nodules are spherical since cell division is only maintained at the primordium stage and later, while the cell number does not increase, the nodule growth is achieved by cell growth. In the indeterminate nodules, the cell number increases as the persistent apical meristem produces permanently new nodule cells, which together with cell enlargement result in continuous nodule growth and a cylindrical nodule shape. Determinate nodules are formed on (sub-)tropical plants such as *Phaseolus*, *Glycine,* and *Vigna* species belonging to the phaseolids or on robinioids such as *Lotus* and *Sesbania* species; and dalbergioids such as *Arachis* and *Aeschynomene* species. Indeterminate nodules develop on temperate legumes, such as *Medicago truncatula, Pisum sativum, Vicia faba, Trifolium repens,* or *Galega orientalis,* which all belong to the inverted repeat-lacking clade (IRLC) but indeterminate nodules can be found in almost all major legume clades.

In the determinate nodules, the infected cells develop simultaneously and therefore the host symbiotic cells are always in the same developmental stage. The central part of mature determinate nodules is composed of a mixture of uninfected cells and large symbiotic cells packed with nitrogen-fixing bacteroids (Fig. 67.1b). The structure of indeterminate nodules is more complex (Fig. 67.1b) and an age gradient and all stages of symbiotic cell development are present in the nitrogen-fixing nodules. The central region of indeterminate nodules contains the apical meristem (zone I], the infection zone [zone II], an interzone II-III, the nitrogen fixation zone [zone III], and in old nodules a senescent zone [zone IV] (Vasse et al., 1990). Infection of plant cells with *Rhizobium* bacteria occurs in the non-dividing post-meristematic cells, which enter a multistep differentiation program along the 10–15 cell layers of zone II. It is manifested by gradual enlargement of the symbiotic nodule cells reaching an about 80-fold larger volume than the meristematic cells. It was shown in *M. sativa* and *M. truncatula* that growth of host symbiotic cells arises from repeated ER cycles: doubling the genome in each cycle along the different cell layers of zone II and resulting from diploid (2C or 4C) meristematic cells in nitrogen-fixing cells with 32C or 64C DNA content (Fig. 67.1b). Studying host symbiotic cell development resulted in the discovery of the cell cycle switch protein CCS52A, which is a key regulator of cell differentiation in plants controlling cell cycle exit, transition of mitotic cycles to ER cycles (termed also endocycles), and the execution of multiple rounds of ER cycles (Cebolla et al., 1999). ER is an essential part of host symbiotic cell development; if the 32C/64C ploidy levels are not completed, nodule development becomes aborted leading to early nodule senescence and rapid disintegration of bacteroids (Vinardell et al., 2003). Though the nodule ploidy levels show variations in the different legumes, it is generally valid that symbiotic nodule cells are large and usually polyploid, which may be necessary for hosting several tens of thousands of rhizobia in the host cytoplasm as well as for altered physiology of these cells.

The morphology of nitrogen-fixing bacteroids can be strikingly different. Three morphotypes are known: U-, S-, and E-morphotypes. The U-type corresponds to bacteroids with unaltered/undifferentiated morphology compared

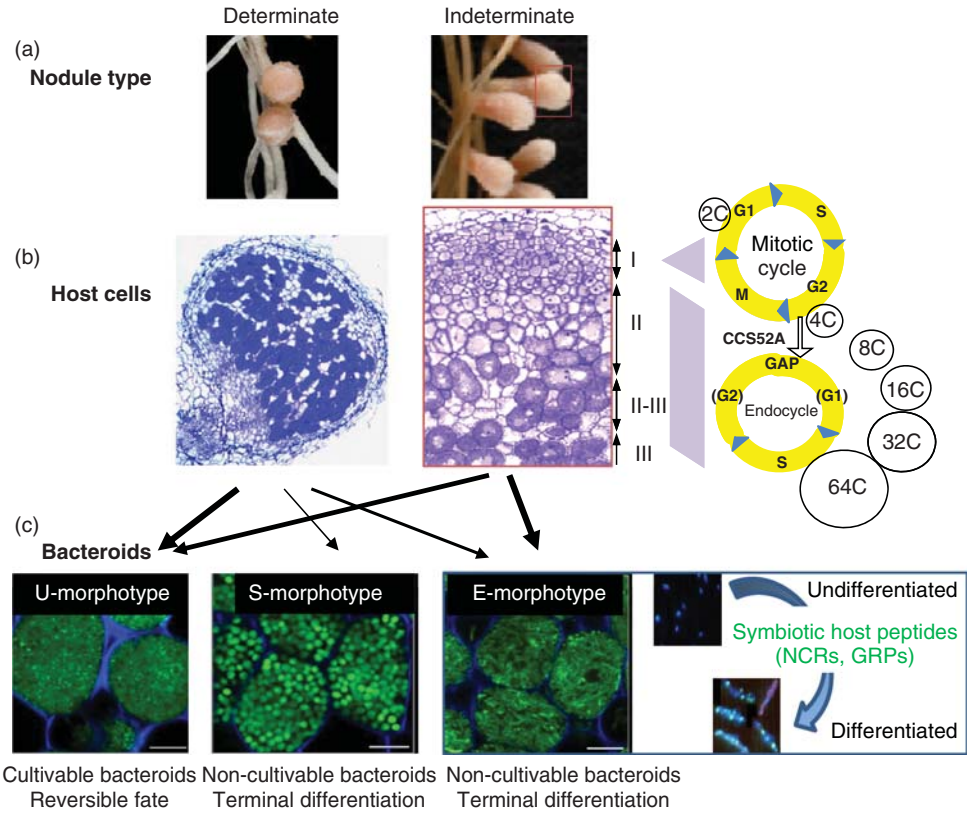

Figure 67.1 Differentiation of host symbiotic cells in legume root nodules. (a) Morphology of the two nodule types. Determinate nodules are spherical while the continuously growing indeterminate nodules are cylindrical. (b) Symbiotic cells in nitrogen-fixing root nodules are large, usually polyploid and filled with nitrogen-fixing bacteroids. The central zone of determinate nodules corresponds to the nitrogen-fixing zone [III], which contains large nitrogen-fixing plant symbiotic cells [dark blue] and smaller uninfected nodule cells. In contrast, the indeterminate nodules are composed of different nodule zones. The longitudinal nodule section shows the apical nodule region [red frame] with I: nodule meristem, II: infection zone, II-III: interzone, III: nitrogen fixation zone [only the first cell layer is visible on the section]. In zone II and interzone II-III gradual enlargement of host symbiotic cells is governed by a switch of the mitotic cycle to endoreduplication cycles, which is induced by CCS52A, resulting in the development of large polyploid host symbiotic cells. (c) Different morphology of bacteroids is host but not nodule-type dependent. U-morphotype bacteroids are similar to free-living bacteria and by maintaining their reproductive capacity they can return to the free-living life. S-morphotype bacteroids are swollen, spherical, and non-cultivable. This bacteroid morphology is rare among the tested legumes. E-morphotype bacteroids are elongated and often branched Y-shaped cells that cannot be cultivated. Thus, the S- and E-morphotype bacteroid differentiation is terminal. All three morphotypes were found in determinate nodules while indeterminate nodules were so far associated with U- and E-morphotype bacteroids. In the IRLC legumes E-morphotype bacteroid differentiation is achieved by host-specific symbiotic peptides [NCRs and possibly GRPs] that likely evolved from antimicrobial peptides of the innate immunity. Examples are *Bradyrhizobium japonicum* U-morphotype bacteroids in soybean, *Bradyrhizobium* strain ORS285 S-morphotype bacteroids in *A. indica,* and *Bradyrhizobium* strain ORS285 E-morphotype bacteroids in *A. afraspera*.

to their free-living siblings. The symbiotic life style of these bacteroids is reversible; bacteroids isolated from the nodules can be cultivated and return to the free-living state. S-morphotype corresponds to large spherical bacteroids, while the E-morphotypes correspond to large elongated and often Y-shaped bacteroids. Neither the S- nor the E-morphotypes are cultivable; thus, their differentiation fate is one way, terminal. The bacteroid morphotype is not a consequence of the nodule type. Bacteroids in the indeterminate nodules can be U- or E-morphotype or could be U-, S-, or E-morphotype in the determinate nodules (Fig. 67.1). Thus, the differentiation fate of bacteroids does not depend on the nodule type but it nevertheless depends on the host plant. For example, in *M. truncatula* nodules the bacteroids undergo always a terminal E-morphotype differentiation process while in *Lotus japonicus*, *Phaseolus vulgaris, Glycine max,* or *Sesbania rostrata*, bacteroids are of the reversible U-type. E-morphotype is common in the IRLC legumes such as *P. sativum*, *V. faba, T. repens,* or *G. orientalis* or the cultivated alfalfa *M. sativa* and any other *Medicago* species. S-type bacteroids can be found in *Arachis* species and in certain *Aeschynomene* and *Crotalaria* species. While 12,000

legume species are known to form nitrogen-fixing symbiosis, only a few of them have been studied with respect to the morphology and physiology of bacteroids. Recently, 40 legume species belonging to 6 subclasses in the *Papilionoideae* subfamily were examined and members of 5 subclasses contained terminally differentiated bacteroids (Oono et al., 2010). The terminally differentiated, non-reproductive bacteroids were proposed to be more effective in nitrogen fixation than the reversibly differentiated, reproductive ones. One possible explanation for the difference in effectiveness can be that part of the plant-provided metabolites are used in reversibly differentiated bacteroids for the production of storage compounds such as polyhydroxybutyrate (PHB), and therefore these endosymbionts require more nutrients from the plant than the terminally differentiated ones to provide the same amount of combined nitrogen. Thus, the terminal bacteroid differentiation might be a host benefit that has evolved independently with multiple origins in the *Leguminosae* family (Oono et al., 2010).

The morphological diversity of bacteroids has been known since the end of the nineteenth century but the molecular mechanisms leading to terminal bacteroid differentiation were uncovered only a few years ago in the *S. meliloti–M. truncatula* symbiosis (Mergaert et al., 2006). Nitrogen-fixing *S. meliloti* bacteroids are 5- to 10-fold longer than the free-living bacteria and are often branched, having a characteristic Y shape. The bacteroids are polyploid cells harboring multiple nucleoids. Genome amplification up to 24C DNA content is achieved by ER cycles and inhibition of cell division. All these changes result in the definitive loss of the bacteroids' reproductive capacity. In addition, the bacteroid membrane is more permeable than the bacterial membranes since propidium-iodide, a dye that cannot enter into intact cells, penetrates slowly into the isolated bacteroids. In symbiosis, the increased membrane permeability of bacteroids may be advantageous, facilitating the exchange of metabolites between the host and endosymbionts (see also below).

Terminal bacteroid differentiation is host controlled and driven by plant factors present in IRLC and missing from non-IRLC plants (Mergaert et al., 2006). It was shown that the fate of the same *Rhizobium* strains was different in the IRLC- and non-IRLC legume hosts; bacteroids in the IRLC-nodules were terminally differentiated with E-morphotype and with reversible U-morphotype in non-IRLC nodules. Similarly, *Bradyrhizobium sp. 32H1* bacteroids in peanut nodules were terminally differentiated with S-morphotype while in cowpeas it was the reversible U-morphotype (Oono and Denison, 2010). Another example is *Bradyrhizobium* strain ORS285, which forms S-morphotype bacteroids in nodules of *Aeschynomene indica* and E-morphotype bacteroids in nodules of *Aeschynomene afraspera* (Fig. 67.1) (Bonaldi et al., 2011; see Chapters 28, 45).

67.3 IDENTIFICATION OF KEY PLANT FACTORS MEDIATING TERMINAL BACTEROID DIFFERENTIATION

Discovery of plant factors responsible for the terminal bacteroid fate in the IRLC legumes was based on the presumption that the plant factors (i) are specific for the IRLC species, (ii) are produced in the infected (cells of) nodules, (iii) are targeted to the bacteroids, (iv) change the permeability of bacterial membranes, and (v) affect bacterial cell division. First, global transcript profiling of *M. truncatula* and *L. japonicus* nodules (containing terminally and non-terminally differentiated bacteroids, respectively) was used to identify IRLC-specific genes. In this way, two large gene families coding for nodule-specific cysteine-rich (NCR) and glycine-rich peptides (GRPs) were recognized in *M. truncatula* (Kevei et al., 2002; Mergaert et al., 2003). Similar sequences were found among the nodule-specific transcripts of other IRLC legumes such as *P. sativum*, *V. faba*, *G. orientalis,* and *Astragalus sinicus* (Scheres et al., 1990; Küster et al., 1995; Schröder et al., 1997; Frühling et al., 2000a; Kaijalainen et al., 2002; Chou et al., 2006), but no *NCR* and *GRP* genes could be revealed in the sequenced genomes of *L. japonicus* and *G. max* (Alunni et al., 2007).

So far, 24 members of the GRP family are known in *M. truncatula* that can be divided into six subfamilies containing 13 cationic, 8 anionic, and 3 neutral peptides (Kevei et al., 2002, Alunni et al., 2007). GRPs are composed of a relatively conserved signal peptide and a mature peptide of mostly ~100 amino acids. GRPs are expressed in the plant symbiotic cells but the different members are expressed at distinct stages of development; therefore, they are potential bacterial differentiation factors; however, their functions and their proposed roles in bacteroid differentiation remain to be discovered.

At present, about 600 members of the NCR family are known (Young et al., 2011). The *NCR* genes are scattered on the eight chromosomes of *M. truncatula* but often they are clustered. The *NCR* genes are small and usually consist of two exons: the first one codes for a relatively conserved signal peptide while the second one codes for the mature, usually 30–50 amino acid long, active peptide. The NCR peptides are highly divergent but all of them contain four or six cysteines in conserved positions (Mergaert et al., 2003). As a consequence of diverse amino acid composition, the isoelectric point [pI] of the NCR peptides is remarkably different; thus, the peptides can be anionic, neutral, or cationic.

Promoter–reporter gene fusion studies as well as microarray and *in situ* hybridization experiments (see in more detail in the next paragraph and Fig. 67.2) revealed that the *NCR* and *GRP* genes are expressed exclusively in

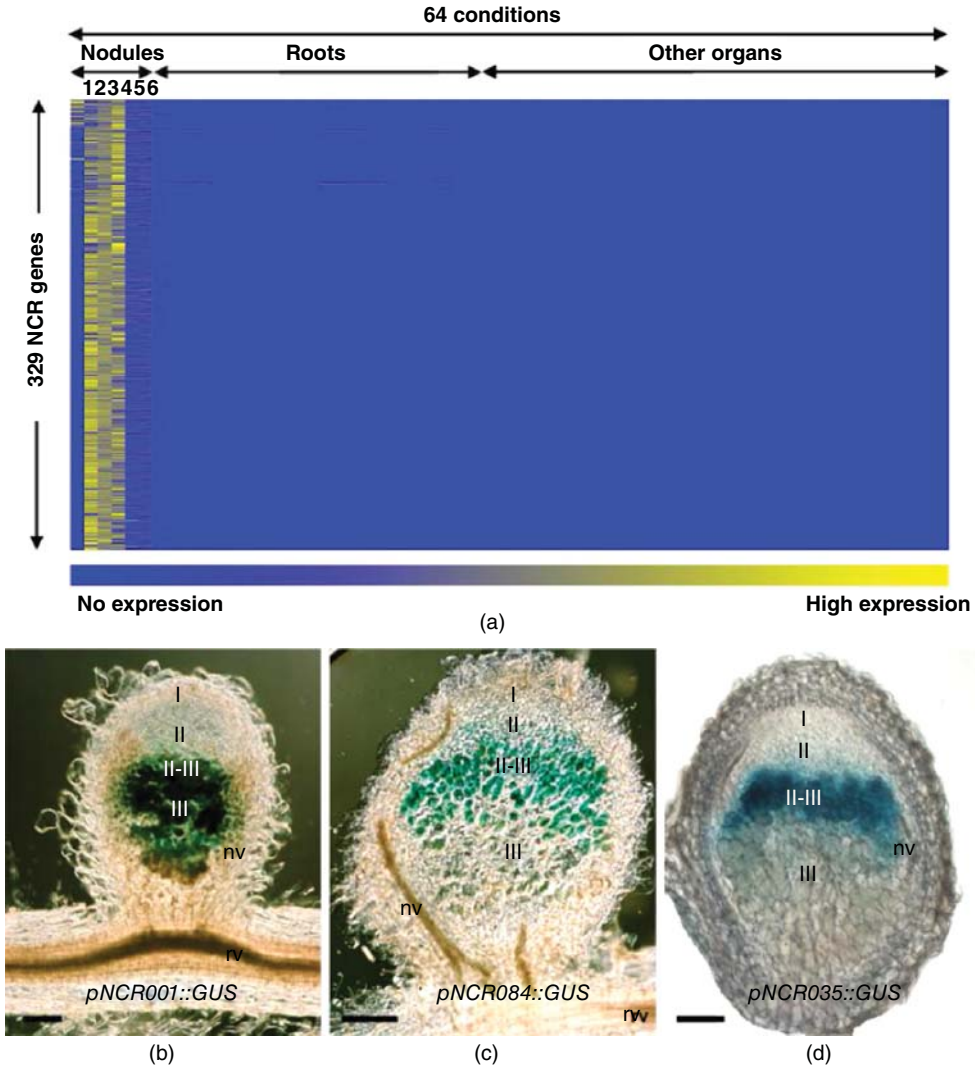

Figure 67.2 Expression pattern of NCR genes. (a) The heat map displays the expression level of 329 NCR genes over 64 different experimental conditions. The data were extracted from the MtGEA. The experiments are divided into "nodules," "roots," and "other organs." The nodules are, in the order from 1 to 6, those at 4 days post infection [dpi], at 10 dpi, 14 dpi, 28 dpi, 14 dpi plus 2 days of nitrate treatment, and whole roots carrying nodules. The roots conditions included control roots, roots infected with mycorrhiza and *Phymatotrichipsis,* and salt-stressed roots. The other organ conditions included leaves and phytohormone-treated leaves, flowers, seed pods, seeds at different stages of formation, shoots, stems, buds, and cell suspensions treated with elicitor or methyl jasmonate. (b–d) Examples of NCR promoter-GUS fusions showing expression in symbiotic nodule cells. NCR001 (b) is expressed in the nitrogen-fixing host symbiotic cells while NCR084 (c) and NCR035 (d) are expressed in young cells. Scale bars are 200 µm. nv is nodule vasculature and rv is root vasculature. The location of the nodule zones I [meristem], infection and differentiation zone [II], interzone [II-III] and nitrogen-fixation zone [III] are indicated.

the root nodules and the expression is associated with the bacterial invasion of the plant cells (Küster et al., 1995; Mergaert et al., 2003; Kevei et al., 2002; Maunoury et al., 2010; Nallu et al., 2013). The signal sequence directs the passage of proteins and peptides through the secretory pathway to their destination. The functionality of the NCR signal peptides was proven in onion epidermal cells (Mergaert et al., 2003). In nodules, the NCR035-mCherry fusion protein co-localized with bacteroids, demonstrating that the peptides are targeted to the endosymbionts (Van de Velde et al., 2010). Generally, the cationic NCRs interacted with the bacterial membranes but certain peptides such as the anionic NCR001 was found by immunogold transmission electron microscopy in the cytosol of bacteroids. Moreover, several NCRs were detected by mass spectrometry in protein extracts of bacteroids isolated from *M. truncatula* nodules (Van de Velde et al., 2010). More recently, the development of proteomics techniques has allowed the identification of ~200 NCR peptides in bacteroids (Dürgő et al., personal communication).

Targeting of the peptides to the endosymbionts depends on the presence of a functional secretory pathway in the plant. The *M. truncatula dnf1-1*(defective in nitrogen fixation) mutant is impaired in a nodule-specific subunit of the signal peptidase complex [SPC, Wang et al., 2010] and forms small white nodules that fail to fix nitrogen. SPC is present in the endoplasmic reticulum (ER) where it can remove the signal peptide from nascent secreted proteins, allowing their proper targeting via the secretory pathway to their specific destination. In the *dnf1-1* mutant, formation of ITs and release of bacteria into host cells are normal but rhizobia remain undifferentiated (Wang et al., 2010; Van de Velde et al., 2010). In the *dnf1-1* mutant, the NCR peptides remain unprocessed since the defective SPC cannot remove the signal peptide from the NCRs. These unprocessed peptides are trapped in the ER and cannot interact with the bacteroids. This has proven that (i) direct interaction of NCRs with bacteroids is essential and that (ii) NCRs (and possibly the GRPs as well) are plant factors of terminal bacteroid differentiation.

Cationic NCR peptides are able to alter the permeability of the bacterial cell membranes. When peptides were administered to cultured bacteria, the membrane impermeable dye, propidium iodide was able to penetrate the bacterial membranes. *In vitro* treatment of bacteria with peptides induced also other features of bacteroid differentiation, such as cell enlargement and an increase of the DNA content in *S. meliloti* cells (Van de Velde et al., 2010; Haag et al., 2011).

The hypothesis that NCRs can govern the terminal bacteroid differentiation was further supported by the expression of NCRs in *Lotus japonicus* nodules (naturally lacking NCRs) under the control of the *M. truncatula leghemoglobin-1 promoter (pMtLb1)*. In control transgenic nodules expressing β-glucuronidase (GUS), several small undifferentiated U-morphotype bacteroids were present within the symbiosome as in wild type *L. japonicus* nodules. In contrast, upon expression of *pMtLb1::NCR035* in transgenic nodules, the majority of symbiosomes contained a single, frequently elongated bacteroid indicating that bacteria exposed to NCR035 have lost their reproductive capacity (Van de Velde et al., 2010). These data indicate that the expression of NCR peptides could provoke features of terminal E-morphotype bacteroid differentiation in the non-IRLC legume *L. japonicus.* Thus, taken together, the *in vitro* and *in vivo* evidence demonstrates that the NCR peptides are host mediators or effectors of the initiation of differentiation of E-morphotype bacteroids.

67.4 GENE EXPRESSION ANALYSIS OF NCRs

Besides the size of the NCR family in *M. truncatula* (600 genes), another surprising feature of the family is the (nearly) exclusive expression of the genes in nodules. The expression of NCR genes has been studied – mostly in *M. truncatula* but also in some other IRLC legumes – at the level of individual genes by RT-PCR, *in situ* hybridization, immuno-localization, and promoter–marker gene fusions (Scheres et al., 1990; Kardailsky et al., 1993; Frühling et al., 2000b; Kato et al., 2002; Crockard et al., 2002; Mergaert et al., 2003; Alunni et al., 2007; Van de Velde et al., 2010; Nallu et al., 2013) or at the family level by expressed sequence tag (EST) analysis, macroarrays, dedicated microarrays, or whole-genome microarrays (Fedorova et al., 2002; Mergaert et al., 2003; Graham et al., 2004; Maunoury et al., 2010; Moreau et al., 2011; Nallu et al., 2013; Tesfaye et al., 2013). Moreover, the *Medicago truncatula* Gene Expression Atlas (MtGEA) (Benedito et al., 2008; He et al., 2009), which compiles whole genome microarray data over a large set of experiments, offers a unique resource for analyzing the expression of *NCR* genes (Fig. 67.2).

Perhaps the most surprising finding revealed by these transcription studies collectively is that the complete *NCR* gene family, with only two exceptions, is specifically expressed in nodules. For example, analysis of 120,000 ESTs in 26 different cDNA libraries that covered most plant organs as well as different growth conditions including biotic and abiotic stresses demonstrated that ESTs of the 311 analyzed NCRs were only found in nodule libraries except for NCR122 and NCR218 (Mergaert et al., 2003). In addition, this analysis revealed that the NCR transcripts constitute almost 5% of the total mRNA population in nodules. A more recent study assessing the expression of more than 500 *NCR* genes with dedicated Affymetrix chips confirmed the nodule specificity of the *NCR* gene family (Nallu et al., 2013; Tesfaye et al., 2013). Currently the richest resource for gene expression analysis in *M. truncatula* is provided by MtGEA. MtGEA is a compendium of expression profiles for the majority of *M. truncatula* genes and is generated with the whole genome Affymetrix Medicago Gene Chip. The compendium covers the plant's major organs, various kinds of abiotic and biotic stresses, and data from specific cell and tissue types (Benedito et al., 2008; He et al., 2009). The expression pattern of 329 *NCR* genes, in 64 different experimental conditions, is shown in Figure 67.2a. This analysis confirms that NCRs are not expressed in any plant organ other than nodules. Only NCR122 and NCR218 are expressed also in roots, confirming the EST analysis. Moreover, it shows that the *NCR* genes are not induced by other infections such as with the pathogenic fungus *Phymatotrichopsis omnivore* or symbiotic mycorrhiza. Likewise, phytohormones, elicitors, and abiotic stresses such as salt or nitrogen starvation do not activate the genes.

In situ detection of *NCR* expression by *in situ* hybridization, immune-localization, or promoter-GUS/GFP/mCherry analysis has demonstrated for all the tested genes that they are expressed in the host symbiotic cells but different subsets

of *NCR* [as well as *GRP*] genes are activated at different stages of differentiation of these host cells (Fig. 67.2b–d) (Scheres et al., 1990; Kardailsky et al., 1993; Frühling et al., 2000b; Kato et al., 2002; Crockard et al., 2002; Mergaert et al., 2003; Van de Velde et al., 2010; Nallu et al., 2013). Transcriptome analysis with microarrays or Affymetrix chips extended this pattern to the whole family. During development of wild type nodules, the *NCR* genes are activated in consecutive waves and their first appearance coincides with the formation of host symbiotic cells (Fig. 67.2) (Maunoury et al., 2010; Nallu et al., 2013). Moreover, the pattern of *NCR* expression in bacterial or plant symbiotic mutants, forming non-functional nodules and arrested at different stages of nodule development, is also in agreement with a specific expression in the symbiotic nodule cells. For example, in nodules of the *M. truncatula* TE7 mutant, which is affected in the *IPD3* gene (Horváth et al., 2011; Ovchinnikova et al., 2011), and in nodules of the *S. meliloti exoY* mutant no host symbiotic cells are formed and these nodules do not express any of the *NCR* genes. In the *S. meliloti bacA* mutant on the contrary, a subset of *NCR* genes is activated (see Chapter 31) while in other mutants, forming normal host symbiotic cells with differentiated bacteroids, *NCR* genes are activated to a similar extent as in the wild type (Maunoury et al., 2010; Nallu et al., 2013).

Very little is known about how the very specific regulation of the NCRs is achieved. The transcription factor EFD, belonging to the ethylene response factor family, may control, directly or indirectly, the expression of a subset of *NCR* genes since in the *efd* mutant nodules, part of the *NCR* genes are downregulated and bacteroid differentiation is partially impaired (Vernié et al., 2008). Searching in the promoters of *NCR* genes with different algorithms yielded five different conserved motifs of 41 to 50 bp that are specifically enriched in the 1000 bp promoter regions (Nallu et al., 2013). Some of these motifs show resemblance to previously described motifs that were found in soybean and *Sesbania rostrata* leghemoglobin promoters and confer symbiotic cell-specific expression (Jensen et al., 1988; Szczyglowski et al., 1994). However, the implication of these motifs in the remarkable expression pattern of the *NCR* genes needs further investigations.

67.5 POSSIBLE FUNCTIONS AND TARGETS OF NCRs

The *M. truncatula* genome has the coding potential for close to 600 NCR peptides that are highly divergent in amino acid composition and in isoelectric point (ranging from 3.2 to 11.25, with approximately equal number of anionic and cationic peptides). Generally, in nature, one or only a few proteins is/are dedicated for a given biochemical function. In large protein families, individual members can have unique specificities such as the receptor families where closely related polypeptides discriminate between different signals. Thus, it is conceivable that the NCR family is not required for a single function, but rather that it provides multiple activities during bacteroid differentiation. It can be that distinct sets of peptides act in a concerted manner at different stages. This idea is supported by the different spatial and temporal gene expression patterns of *NCR* genes (Fig. 67.2b–d): some being induced in the youngest while others in the older cells of zone II, or specifically in the interzone II-III or in zone III indicating their involvement from the earliest stage, from multiplication of the symbiosomes after their release from ITs until the later and latest developmental steps. Diversity of NCRs arises from gene duplications, the recent ones with more homologous sequences than the ancient ones. It is likely that of the 600 NCR peptides, many would have redundant functions; however, we cannot exclude the possibility that master NCRs might exist whose function is unique and cannot be substituted by any of the 600.

The major function of some nodule-specific peptides might be the inhibition of bacterial cytokinesis after symbiosome multiplication ceases, which – while DNA replication is ongoing – results in the high DNA content and cell size of rhizobia and the formation of symbiosomes containing a single bacteroid surrounded by the peribacteroid membrane. This might be achieved either by inhibiting, for example, the interaction between FtsZ monomers and thus, the assembly of the Z ring, or by affecting the structure of bacterial membranes. Other peptides might be responsible for the maintenance of the ER cycles until bacteroids reach their final size. Another group of peptides can be responsible for the membrane modifications including changes in the permeability that can be observed in the bacteroids of IRLC legume nodules. In zone III, the peptides might fight bacterial cheating by controlling the expression and/or activity of bacterial enzymes that would divert the carbon flow of plant origin from energy production for nitrogen fixation to synthesize storage products such as PHB.

The biggest challenge concerning the function of nodule-specific peptides is the identification of their molecular targets and the effectors that mediate the bacterial responses. Their obvious targets are the bacterial membranes. It is known that cationic antimicrobial peptides (AMPs) can interact with the negatively charged surface of bacteria, which leads to pore formation or loss of the membrane integrity, culminating in lysis of the bacterial cells. Cationic NCRs can also interact with bacterial membranes and increase the membrane permeability (Van de Velde et al., 2010). Nevertheless, in the nodule cells the endosymbionts remain alive and cell lysis occurs only in the senescence zone. One possibility for the physiological role

of the membrane modifications is to enhance the nutrient exchange between the bacteroids and the peribacteroid space as well as the plant cells. Another option is that cationic peptides, by forming transient pores in the membranes, help the anionic peptides to enter bacterial cells and reach their intracellular targets. Cationic and anionic peptides are produced simultaneously in the same host cell and anionic peptides may reduce and control the cell-damaging activity of cationic peptides.

In addition, a fine balance between the antibacterial activity of cationic NCRs and resistance of rhizobia against the peptides is needed for the survival and differentiation of bacteria during nodule development. The BacA protein (discussed in detail in Chapter 31 by Guefrachi et al.) might contribute to this balance. BacA is essential for terminal bacteroid differentiation because *bacA*-deficient bacteria are more sensitive than the wild-type strains toward cationic NCRs *in vitro*, and they cannot survive in the NCR-loaded environment of symbiotic nodule cells (Haag et al., 2011). To identify intracellular targets of the individual nodule-specific peptides, genomic tools such as mutant and two-hybrid libraries in symbiotic partners, comparative transcriptome studies, as well as approaches using up-to-date techniques of cell biology and biochemistry are currently deployed.

What can be the evolutionary advantage for the plants to impose terminal differentiation onto the bacterial partner with the help of NCR peptides in the IRLC legumes? Oono and Dennison (2010) showed that terminally differentiated forms of bacteria outperformed reversibly differentiated bacteroids of the same strains. Why may rhizobia maintain a symbiotic lifestyle despite plant dominance? Nitrogen-fixing, terminally differentiated bacteroids have no reproductive capacity in nodules produced by IRLC legumes, and thus cannot pass their genes to the next generation and can be considered as a dead end of the lineage. However, the rhizobial population of a nodule is composed of the descendants of the bacterium that initiated the formation of the nodule including a subpopulation of undifferentiated rhizobia similar to free-living cells (Timmers et al., 2000). Inter- and intracellular presence of these rhizobia in the most proximal part of older *Medicago* nodules containing a senescence zone is the result of a non-controlled reinvasion process of the senescing nodule tissues by rhizobia from ITs. This colonization of the senescent cells leads to the differentiation of a post-senescence zone called saprophytic zone (or zone V). Rhizobia in zone V do not reduce nitrogen, but after nodule cessation they can escape into the soil and increase the bacterial population in the rhizosphere around the nodulated legumes and ensure the passing of the founder symbiotic bacterium's genes to the next generations.

67.6 ANTIMICROBIAL PEPTIDES IN OTHER SYMBIOTIC SYSTEMS

Maintaining a large bacterial population with host tissues and cells is not unique to legume nodules. For example, the gut of animals is crowded with symbiotic or commensal bacteria. The human gut has an estimated load of 10–100 trillion bacteria (10^{13}–10^{14} or 10–100 g of bacteria or the equivalent of 2–20 l of a saturated *Escherichia coli* culture!) representing several hundreds to thousands of species (Turnbaugh et al., 2007). Nevertheless, the human gut microbiota has a very specific species composition, suggesting an active selection mechanism by the host (Ley et al., 2006). The complexity of the gut microbiota can be very different among animals, and the bacterial diversity in the studied invertebrates is several orders of magnitude lower than in the mammals. Nevertheless, also in these cases the gut bacterial population has a very characteristic composition. For example, the *Drosophila* gut is dominated by just a few dominant bacterial species (Ryu et al., 2008). Even in *Cnidaria*, the simplest animals positioned in the earliest branches of the animal tree of life, the epithelial cells actively shape their bacterial gut community to a specific population structure (Fraune and Bosch, 2007). The gut microbiota is acquired from the environment and its assembly begins at the birth of the individual. It starts with a relative low level of bacterial diversity and gradually increases its complexity and changes its composition during the growth of the host (Fraune et al., 2010; Koenig et al., 2011).

Thus, the animal host has to build up its specific gut microbiota. Moreover, the gut bacteria are numerous and they may pose a threat to their host, requiring that the microbiota is maintained in a homeostatic relationship with the epithelial cells that are in contact with it. In mammalians, the innate and adaptive immune systems are among the host factors that determine the composition of the microbiota and keep them in equilibrium (Bevins and Salzman, 2011). Among many factors, AMPs of the innate immune system, produced by the epithelial cells and in particular by the Paneth cells, located in the intestine crypts, are primordial in the determination of the makeup of commensal microbiota. In transgenic mice with either reduced or increased production of defensins by the Paneth cells, the species composition of the microbiota is drastically changed but the total bacterial load remains unchanged and increasing or reducing defensin production has an opposing outcome (Salzman et al., 2010).

Based on very similar experimental strategies – manipulating the production of AMPs by epithelial cells of the intestine – these peptides were found to be key factors that shape the structure of the gut microbial community also in *Drosophila melanogaster* and in *Hydra* belonging to the Cnidaria (Ryu et al., 2008; Fraune et al., 2010). Thus,

host–produced AMPs are conserved metazoan key actors in the interaction with epithelial microbiota.

Examples of symbiotic interactions with a unique, specific bacterial species, hosted in large amount, also exist in the animal world. Many insects require bacterial symbionts producing nutrients that are missing in their diet. Notable examples are phytophagous insects that feed on plant sap or seeds. In most cases, the insect symbionts are housed intracellularly, in symbiotic organs called bacteriomes. Bacteriomes, the insect equivalent of the legume nodule, are constituted by bacteriocytes, the bacteriome equivalent of the nodule plant symbiotic cells.

The pea aphid *Acyrthosiphon pisum* is one of the best studied insects with respect to the bacterial symbiosis. *A. pisum* is in fact a species complex consisting of multiple biotypes, each of which is adapted to specific legume plants (e.g., pea, clover or *Medicago*). The primary [obligate] symbiont of *A. pisum* is *Buchnera aphidicola,* which produces essential amino acids lacking in the plant sap diet of the aphid. In addition, *A. pisum* biotypes may or may not have secondary or facultative symbionts belonging to a variety of bacterial lineages (e.g., *Hamiltonella*, *Serratia*, *Regiella*, *Rickettsia,* and *Spiroplasma*) and having diverse effects on the host (Oliver et al., 2010). Importantly, the bacterial symbionts in aphids and most insects are vertically transmitted, from mother to offspring, although facultative symbionts may undergo some horizontal transmission [acquisition from the environment]. Thus, the acquisition of the bacteria is a fundamental difference with the legume–*Rhizobium* symbiosis where the bacteria are exclusively acquired by horizontal transmission from the soil at each plant generation.

RNA-seq transcriptome analysis of bacteriocytes and *in situ* hybridization experiments in *A. pisum* have led to the discovery of a class of genes encoding secreted cysteine-rich peptides that were called BCR peptides for "bacteriocytes-specific cysteine rich peptides," in analogy to the NCR nodule peptides (Shigenobu and Stern, 2012). The genes are specifically expressed in the bacteriocytes and not in other parts of the insect. Following their expression by *in situ* hybridization during bacteriome formation in embryos, it was found that they are induced when the early-stage bacteriome becomes first infected with *Buchnera*. Thus, drawing the analogy with the NCR peptides in nodules it is an inevitable and exciting hypothesis that the BCRs are targeted to and affect the bacterial symbionts in a similar manner as the NCRs do in symbiotic nodule cells.

In a different insect group, in the stinkbugs or *Heteroptera*, symbiotic bacteria are not located in bacteriomes as intracellular endosymbionts but in a specialized, posterior region of the midgut where numerous crypts harbor in their lumen a single and specific extracellular bacterial symbiont (Kikuchi, 2009). The stinkbug *Riptortus pedestris,* which is another legume pest, particularly for soybean, carries in its crypts a symbiont belonging to the genus *Burkholderia*, a soil bacterium that is acquired every generation from the environment during a specific developmental window coinciding with the development of the crypts in the midgut (Kikuchi et al., 2011). Transcriptome analysis of symbiotic (crypt-carrying) and non-symbiotic midgut regions from *Burkholderia*-infected and uninfected (aposymbiotic) *R. pedestris* identified among the most abundantly expressed genes in the midgut 97 different cysteine-rich secretory peptides, many of which were specifically expressed in the *Burkholderia*-containing crypts of the midgut (Futahashi et al., 2013). The authors speculated that these crypt-specific cysteine-rich peptides are secreted into the lumen of the crypts by the epithelial cells and act on the proliferation and physiology of the symbiotic *Burkholderia*, similarly to the NCRs in legume nodules and the BCRs in aphid bacteriomes (Futahashi et al., 2013).

In yet another phytophagous insect, the weevil *Sitophilus*, which is a pest of cereals, bacteriomes carry the intracellular γ-Proteobacterium "*Sitophilus* primary endosymbiont" (SPE). SPE in bacteriocytes are large polyploidy and elongated bacteria reminding of the E-morphotype bacteroids in legume nodules. Bacteriocytes of *Sitophilus zeamais* produce a peptide, called coleoptericin-A (ColA), which is targeted to the endosymbionts (Login et al., 2011). ColA is unrelated to the legume NCRs, aphid BCRs, or stinkbug crypt-specific peptides and has no cysteine residues. The pure peptide induced very strong cell elongation with high DNA copy numbers on SPE. Downregulating the expression of the *colA* gene by RNAi resulted in decreased size and DNA content of the SPE in the bacteriomes and also in the spreading of the bacteria throughout the insect tissues. Thus, the role of the ColA peptide is to control the SPE endosymbiont, very analogous to the function of the NCRs in legume nodules.

These recent studies on insect symbiotic systems and animal gut microbiota, together with our findings in the legume–Rhizobium symbiosis, indicate that the employment of antimicrobial-like peptides in the control of symbiotic bacteria is widespread in nature and may be an optimal mechanism for eukaryotic host cells to maintain a homeostatic interaction with these bacteria.

ACKNOWLEDGMENTS

We thank Hajnalka Dürgő from our institute for communicating unpublished results. Work in our laboratories has been supported by the joint grant of the French Agence Nationale de la Recherche and the Hungarian National Office for Research and Technology [ANR-NKTH: ANR-09-BLAN-0396-01 and TÉT_09-1-2010-0009] for P. Mergaert and A. Kereszt and by the Advanced Grant of the European Research Council [grant number: 269067],

the NKTH grant OMFB-00441/2007 and the OTKA105852 grant for E. Kondorosi.

68.1 SYMBIOSOME FORMATION AND DEVELOPMENT

Rhizobia enter legume roots via infection threads that are initiated when the rhizobia are entrapped by curling of the root hair (Brewin, 2004). The local cell wall is then hydrolyzed and degraded, while the plasma membrane invaginates leading to the formation of a tubular infection thread. Infection threads then grow onward into the root cortex, transporting bacteria into the nodule primordium cells that are formed from reprogrammed root cortical cells (Brewin, 2004; Rae et al., 1992). Ultimately, the bacteria are internalized into nodule primordium cells and enter the plant cell cytoplasm surrounded by a host membrane, forming an organelle-like structure called the symbiosome (Fig. 68.1).

Roth et al. (1988) proposed the term "symbiosome" as a unified terminology to describe membrane-limited compartments that form as a result of endosymbiotic interactions. They defined the symbiosome as a "membrane-bound compartment containing one or more symbionts and certain metabolic components and located in the cytoplasm of eukaryotic cells" (Roth et al., 1988). The membrane around this structure can be termed the "symbiosome membrane" (SM). We use this term here instead of the more common term of peribacteroid membrane, which ignores the general nature of such structures (Roth et al., 1988). It is important to appreciate that the SM and the bacteroid membrane (BM) are physically separated by a symbiosome space, and therefore their transport activities are distinct. Since the bacteroid is enveloped by the SM as a result of an endocytosis-like process of the plasma membrane, the SM is inverted compared to the plasma membrane, and hence metabolite movement from the infected cell cytosol to the symbiosome space (across the SM) is actually exported from the plant cell; conversely, efflux of metabolites from the symbiosome represents uptake into the plant cytoplasm (White et al., 2007). Symbiosomes undergo four developmental phases, namely initiation, proliferation, maturity, and degradation. The role and composition of the SM is considered to be different in the four phases (Brewin, 1991).

Symbiosome biogenesis begins with the formation of an infection droplet, a structure that represents an unwalled outgrowth from the infection thread. This is a region where the infection thread membrane invaginates and where rhizobia come into direct contact with the host plasma membrane without the cell wall as a barrier (Brewin, 2004; Rae et al., 1992). Bacteria are then released into the cytoplasm of cortical cells, which results in encapsulation of bacteria by the plant cell membrane (Bassett et al., 1977; Goodchild and Bergersen, 1966; Newcomb, 1976). Inside the symbiosome, bacteria differentiate into bacteroids, their symbiotic form, which enables nitrogen fixation to take place

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

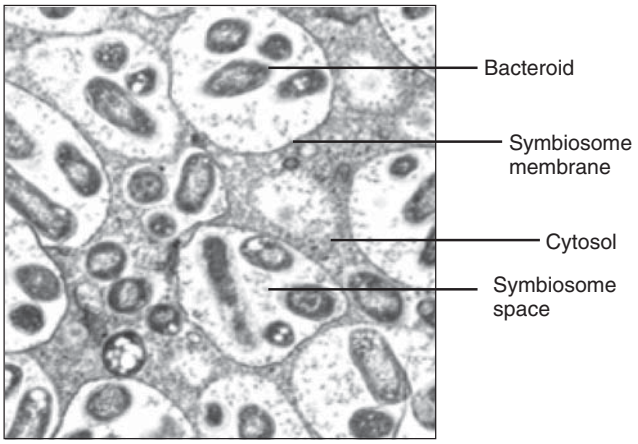

Figure 68.1 Electron micrograph of symbiosomes within infected cell of a soybean nodule.

(Vasse et al., 1990). In indeterminate nodules of temperate legumes (e.g., alfalfa, pea), symbiosomes typically house a single large bacteroid; in determinate nodules of tropical legumes (e.g., soybean), mature symbiosomes fuse to form large structures that house many bacteroids (Fedorova et al., 1999). Formation of symbiosomes involves a major reorganization of host cytoskeleton and endomembrane systems (Davidson and Newcomb, 2001). To accommodate biogenesis of symbiosomes in the infected cells, massive amounts of protein and lipid are needed. Depending on the legume species, the total surface area of SM can exceed the plasma membrane by approximately 30-fold (Verma et al., 1978). Although traditionally it is considered that the symbiosome forms through endocytosis, more recent evidence suggests that the exocytotic pathway also plays a major role.

In endocytosis, internalized cargo molecules that are taken up by the plasma membrane are transported through the endocytic pathway (Šamaj et al., 2005). The endocytotic pathway involves a multifaceted network of membrane compartments, with each compartment involved in different tasks. After internalization into the early endosome, cargo to be recycled is transported back to the plasma membrane, whereas cargo for degradation is transported to the late endosome. The late endosome will finally fuse with the vacuole in plants or lysosomes in animals for degradation (Šamaj et al., 2005).

Limpens et al. (2009) showed that in *Medicago truncatula*, symbiosomes did not acquire the (late) endosomal marker Rab5 or early endosomal/trans-Golgi network (TGN) marker, SYP4, at any stage during their development and only acquired Rab7, a late endosomal/vacuolar marker, at a later stage of development when symbiosomes had stopped dividing (the fixation zone). This marker was retained until senescence began. This suggests that the early formation of the symbiosome follows a Rab5-independent endocytic pathway, and that Rab7 might be recruited directly from the cytoplasm to regulate symbiosome formation. In *M. truncatula*, symbiosomes did not acquire vacuolar SNARE, SYP22, and VTI11 until the onset of senescence. However, the SM contains a plasma membrane t-SNARE/SYNTAXIN SYP132 throughout development (Catalano et al., 2007; Limpens et al., 2009). The delay in acquiring vacuolar SNAREs might be required for maintenance and survival of the symbiosome as an individual nitrogen-fixing organelle. The presence of SYP132 and Rab7 showed that the SM has a unique composition where proteins that move from the secretory pathway to the plasma membrane and from the endocytic pathway to the vacuole are involved (Limpens et al., 2009). The involvement of Rab1 and Rab7 GTPase in SM formation has been demonstrated in soybean (Cheon Iii et al., 1993). Nodules expressing an antisense construct for Rab1 were smaller and had fewer bacteroids per cell, and the vacuole was retained after bacteria were released into the cytoplasm. *In situ* hybridization with a soybean Rab7 probe on nodules at different development stages showed that the transcript was present in the infected zone early in the development of the nodule (7 days after infection) (Son et al., 2003). There is no clear molecular evidence for involvement of the default endocytosis pathway in the early stages of symbiosome formation.

In contrast, evidence of the involvement of an exocytotic pathway is accumulating (Ivanov et al., 2012). Exocytosis involves fusion of transport vesicles with the plasma membrane. This fusion is mediated by exocytic vesicle-associated membrane proteins (VAMPs) and in plants, which are members of the VAMP72 family. Silencing of two *VAMP72* family members in *M. truncatula* prevented symbiosome formation, supporting the role of exocytosis in their formation. GFP-VAMP72 fusions localized to dot-like structures where unwalled infection droplets are formed and symbiosomes start to develop. The unwalled infection droplets are surrounded by host membrane and cell wall is completely absent. Bacteria are subsequently pinched off when they come into close contact with the host membrane. In the VAMP72 silenced nodules, infection droplets did not form properly as they were bound within a thin layer of cell wall. The presence of the cell wall prevents close contact between bacteria and host membrane, which prevents further release of bacteria (Ivanov et al., 2012). The involvement of DNF1 (defective in nitrogen fixation), which encodes a signal peptidase complex involved in a nodule-specific secretory pathway, is further evidence that supports the formation of the symbiosome via exocytosis (Wang et al., 2010).

Bergersen and Briggs (1958) were the first to observe the SM, which consists of a membrane bilayer of 9–10 nm thick (Dart and Mercer, 1963; Mellor and Werner, 1987). The SM is derived from the plasma membrane through the infection thread membrane, as illustrated by staining by phosphotungstic acid-chromic acid (PACA) (Robertson et al., 1978a;

Roth and Stacey, 1989; Verma et al., 1978), which is usually considered a plasma membrane-specific stain. The syntaxin SYP132, as well as being present in the SM, labels the plasma membrane around the infection threads and infection droplets (Catalano et al., 2007), also linking the two membranes.

The SM proliferates and differentiates to accommodate bacteroid growth and division until the infected cells are filled with symbiosomes (Robertson and Lyttleton, 1984). Enlarged mature infected cells may house thousands of symbiosomes (Day et al., 2001). It is still unclear how the SM proliferates, but it is proposed that it may be the result of redirection of the host secretory pathway toward SM biogenesis (Leborgne-Castel et al., 2010). Proliferation of the SM is considered to occur independently of bacteroid division (Mellor and Werner, 1987). Within the developing infected cell, there is a specialized area adjacent to the nucleus that is devoid of symbiosomes where abundant membrane is observed associated with the endoplasmic reticulum (ER). This was suggested to serve as a membrane reservoir for the proliferating symbiosomes (Bulbul and Kaneko, 2009). Bundles of actin filaments that colocalized at the same site may function in delivering membranes to the developing symbiosomes (Bulbul and Kaneko, 2009) and play a role in spatial organization of the symbiosomes, maintaining effective pathways for nutrient diffusion within the symbiosomes (Whitehead et al., 1998a).

Notwithstanding the origin of the symbiosome, bacteroid division and SM proliferation result in an SM with distinct properties. Both the protein and lipid complement of the SM are unique and are supplied from a range of sources, including the ER and *de novo* membrane synthesis (Roth and Stacey, 1989). Galactolipid digalactosyldiacylglycerol (DGDG) lipids, which are usually associated with plastid membranes rather than plasma membrane, are present in the SM (Gaude et al., 2004), indicating its unique identity. The mature SM also has an exceptionally high lipid-to-protein ratio (6:1) (Robertson et al., 1978a). The phospholipid and fatty acid contents of the SM most closely resemble that of the endomembrane system (the ER and Golgi apparatus) (Bassarab et al., 1989; Mellor et al., 1985) rather than the plasma membrane. The SM also contains a high level of phosphatidylcholine, but low levels of phosphatidylethanolamine compared to the plasma membrane (Hernández and Cooke, 1996). The SM contains β-amyrin, a novel plant triterpenoid that is not accumulated in the root plasma membrane (Bassarab et al., 1989; Hernández and Cooke, 1996).

ER and Golgi apparatus are observed close to symbiosomes (Kijne and Pluvqué, 1979; Whitehead and Day, 1997), suggesting that they are involved in transport of newly synthesized proteins and lipids to the SM via vesicles from the Golgi, but there is little information available about how proteins are targeted to the SM. Targeting of two symbiosome space proteins has been investigated. For NOD25 from *M. truncatula*, a 24 amino acid signal peptide (SP) was sufficient to target green fluorescent protein (GFP) to the symbiosome space across the SM (Hohnjec et al., 2009). This suggests a posttranslational pathway for its import. The peptide was conserved in two other proteins known to be targeted to the symbiosome. Similarly, the early nodulin 8 (MtENOD8) SP could direct GFP across the SM but two other domains in the protein also had this ability, suggesting redundancy in the targeting signals (Hohnjec et al., 2009; Meckfessel et al., 2012). Further analysis of other symbiosome space and SM proteins is required to determine whether N-terminal SPs are a common feature and whether different proteins follow a common pathway to reach these destinations.

In indeterminant nodules such as *M. truncatula* and *Pisum sativum*, the meristemic activity of the apical meristem results in the formation of a gradient of developmental stages that are defined as four zones: the meristematic zone at the distal end, providing new cells to the nodules; the infection zone, where bacteria are released into the cytoplasm, forming the symbiosome; the fixation zone, where symbiosomes are completely differentiated and the *nif* genes, encoding the rhizobial nitrogenase complex, are induced (de Maagd et al., 1994); and the senescence zone at the proximal end where symbiosomes degrade (Gage, 2004). Determinate nodules such as *Glycine max* and *Lotus japonicus* lack a persistent meristem (Brewin, 1991) and have a central infected zone surrounded by nodule parenchyma. In both the fixation zone of indeterminate nodules and the infected zone of determinant nodules, large infected cells are interspersed with smaller uninfected cells. The uninfected cells are thought to accumulate reduced carbon such as sucrose and convert these to organic acids, which are then transported to the infected cells through symplastic transport (Peiter et al., 2004; White et al., 2007). In determinant nodules, they are also important in assimilation of fixed nitrogen and are the site of ureide synthesis, which in most determinant nodules is the form in which nitrogen is transported to the shoot (Smith and Atkins, 2002). Senescence of symbiosomes usually begins at week 5 after inoculation (Vasse et al., 1990). The symbiosomes are targeted and fused to the lytic vacuole for degradation.

68.2 TRANSPORT ACTIVITY OF THE SYMBIOSOME MEMBRANE

A key role of the SM is to mediate and regulate the exchange of nutrients and metabolites between the symbiotic partners in a way that optimizes nitrogen fixation (Brewin, 1996). The SM may also play a role in protecting the bacteria from plant defense mechanism (Mellor and Werner, 1987; Vance, 1983) and plants from any pathogenic behavior from the rhizobia (Brewin, 1996).

Information on the transport activity of the SM is essential to determine what regulates the amount of nitrogen fixed and how bacteroids retain a symbiotic relationship with the host plant (Rosendahl et al., 1991). Our knowledge of the transport activity of the SM mostly results from biochemical studies and transport assays using isolated symbiosomes. Transport assays using radiolabeled substrates and patch-clamp techniques have provided insights into the nature of the metabolites that cross the SM, but the molecular identities of most of the transporters involved remain largely unknown. With the availability of complete genome sequences of several legumes (http://phytozome.net/soybean: (Schmutz et al., 2010); http://www.kazusa.or.jp/lotus: (Sato et al., 2008); http://medicago.org/genome: (Young et al., 2011)), molecular characterization of these transporters is now possible.

To support nitrogen fixation, the plant must provide a carbon source to the bacteroid in exchange for fixed nitrogen. Reduced carbon for fixed nitrogen is the principal metabolite exchange between the symbiotic partners, but the bacteroid is dependent on the plant for many other (micro)nutrients that include iron, molybdenum, vanadium, nickel cobalt, sulfur, selenium, phosphate, and homocitrate (Hakoyama et al., 2009; Rosendahl et al., 1991).

68.2.1 Carbon Supply to the Bacteroid

Carbohydrate breakdown in nodules provides substrates for bacteroid metabolism and carbon skeletons for the assimilation of fixed ammonia into organic acids. The principal carbon and energy supply for nodule metabolism is derived from recently fixed plant photosynthetic carbon compounds in the form of sucrose. There is a large body of evidence that bacteroids derive their energy from oxidative respiration of organic acids, principally malate (Day, 1991 and references therein; Fig. 68.2). Bacteroids that are mutant for the dicarboxylate transporter encoded by *dctA* are unable to fix nitrogen (reviewed in Yurgel and Kahn, 2004). Isolated symbiosomes are able to take up dicarboxylic acids (but not sucrose) at rapid rates, and a transporter with specificity for univalent malate anions has been identified on the SM of soybean (Udvardi, 1988) and French bean (Herrada et al., 1989). However, the gene(s) encoding the dicarboxylate transporter remains to be identified. In nodules of actinorhizal Alder plants, a cDNA, *AgDCAT1*, was identified, and the protein it encoded was localized to the symbiotic interface (Jeong et al., 2004). AgDCAT1 is a member of the proton-dependent oligopeptide transporter (POT) family, and it was able to transport dicarboxyclic acids including malate, succinate, fumarate, and oxaloacetate when expressed in *E. coli*. Members of the same family are strongly induced during nodule development in *G. max* (Libault et al., 2010; Severin et al., 2010), *M. truncatula* (Benedito et al., 2008), and *L. japonicus* (Colebatch et al., 2004). However, members of the POT family are known to transport a range of different compounds including nitrate, peptides, auxin, and glucosinolates (Saier and Milton, 2000), so further functional characterization will be required to determine if those upregulated in nodules encode a malate transporter.

There is a range of protein families that include malate transporters in plants, and it is possible that a member of one of these could be the SM malate transporter. Members of the aluminum-activated malate transporter (ALMT) family promote organic acid efflux from the roots of nonlegumes (Sasaki et al., 2004) and regulate cytosolic malate homeostasis when localized on the vacuolar membrane (Kovermann et al., 2007). The divalent anion/Na^+ symporter (DASS) family (also called SLC13 family) mediates the transport of dicarboxylates and inorganic anions across the cellular membrane in a Na^+ -dependent manner (Hall and Pajor, 2005) and includes the *At*tDT dicarboxylate transporter from *Arabidopsis thaliana*, which is targeted to the vacuolar membrane in leaf cells (Emmerlich et al., 2003). The ATP-binding cassette (ABC) transporter AtABCB14 transports malate from the apoplast into the guard cells in *Arabidopsis* to modulate responses to CO_2 (Lee et al., 2008). As an importer of malate, the direction of AtABCB14 transport is not what would be considered for the SM malate transporter, which is expected to be related to the families that efflux malate. Although these families have members in legumes, there is little indication that any family has enhanced expression in nodules.

68.2.2 Fixed Nitrogen

Ammonia, NH_3, or ammonium ions, NH_4^+, are believed to be the most likely in the form of fixed nitrogen provided to the plant (Day et al., 2001; Udvardi and Poole, 2013). NH_3 is the product of the nitrogenase enzyme in the bacteroid and is transported out of the bacteroid into the symbiosome space, probably by simple diffusion. Enzymes involved in the ammonium assimilation pathway [glutamine synthetase (GS)/glutamine oxoglutarate amidotransferase (GOGAT)] are repressed in the bacteroid, while those in the plant are elevated, thus creating a driving force down the concentration gradient for the efflux of NH_3 out of the bacteroid (Atkins, 1991; Poole and Allaway, 2000). The symbiosome space is more acidic than the bacteroid space, and thus NH_3 that leaves the bacteroid is protonated, forming NH_4^+ ions. It was initially proposed that the transport of NH_3/NH_4^+ from the symbiosome space to the plant cytosol occurs via diffusion (Udvardi and Day, 1990). Later studies used patch-clamp techniques on isolated symbiosomes to identify a monovalent cation channel capable of NH_4^+ transport across the SM in soybean (Tyerman et al., 1995), pea (Mouritzen and Rosendahl, 1997) and *L. japonicus* (Roberts

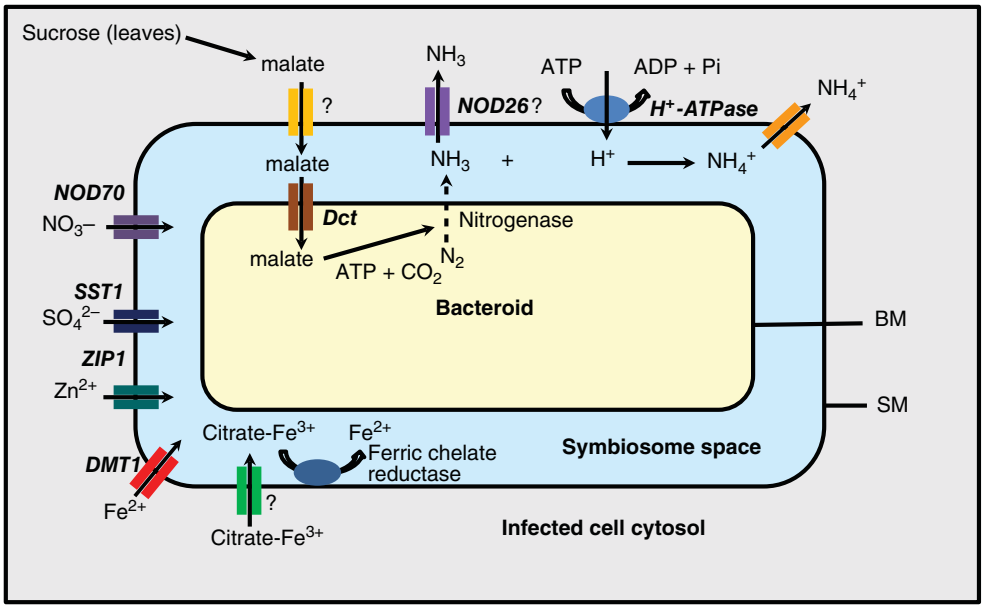

Figure 68.2 Diagrammatic representation of transport processes in the symbiosome of infected cell. Sucrose derived from photosynthesis is the major reduced carbon supply for nodule metabolism. Dicarboxylate acids (principally malate) are supplied to the bacteroids for oxidative respiration and nitrogen fixation. The gene encoding the dicarboxylate transporter on the SM has not been identified. On the BM, a dicarboxylate transport (Dct) system is responsible for importing dicarboxylates into the bacteroids. The product of nitrogenase enzyme, NH_3, is transported out of the bacteroid, probably by simple diffusion. NH_3 is either protonated into NH_4^+ and leaves the symbiosome via a monovalent cation channel or remains unprotonated and leaves the symbiosome via NH_3 channel proposed to be Nodulin 26. Fe is supplied to the symbiosome as either Fe(II) via DMT1 or Fe(III)-citrate via an uncharacterized Fe(III) transporter that will then be chelated by ferric chelate reductase, which is located on the SM side. Sulfate, SO_4^{2-}, is transported into the symbiosome via SST1 and zinc, Zn^{2+} via ZIP1. An anion transporter with a preference for nitrate, NO_3^- is encoded by NOD70.

and Tyerman, 2002; Fig. 68.2). These channels open when membrane potential is generated through acidification of the symbiosome space by a proton pumping H^+-ATPase on the SM (Blumwald, 1985) and outward rectification of the channel by the presence of Mg^{2+} on the cytosolic side of the membrane (Whitehead et al., 1998b). As a consequence, movement of NH_4^+ is unidirectional – out of the SM, and thus there is no backflow of NH_4^+ into the symbiosome. However, there is also evidence that some NH_3 may diffuse across the SM through a channel (Niemietz and Tyerman, 2000), proposed to be Nodulin 26.

68.2.3 Nodulin 26

Nodulin 26 is a major component of the SM, which makes up 10% of the total SM protein (Rivers et al., 1997) and is a member of the major intrinsic protein (MIP), membrane protein channel superfamily that includes aquaporin water transporters (see Chapter 69). Nodulin 26 may transport NH_3 from the symbiosome (Niemietz and Tyerman, 2000; Fig. 68.2), and its C-terminal domain was recently shown to interact with cytosolic GS (Masalkar et al., 2010). It is proposed that the interaction with GS creates a metabolic channel to aid assimilation of fixed nitrogen and prevent futile cycling of ammonia (Masalkar et al., 2010). It is interesting to note that other members of the superfamily, such as *Arabidopsis* tonoplast intrinsic protein (TIP) family, and mammalian AQP1 and AQP8 also transport ammonia (Jahn et al., 2004; Loqué et al., 2005; Zeuthen et al., 2009). Earlier studies on Nodulin 26 suggested that Nodulin 26 has high permeability to water and also transports glycerols and formamide (Dean et al., 1999; Guenther et al., 2003; Rivers et al., 1997), and that its permeability may be regulated by phosphorylation (Weaver and Roberts, 1992). The water transport activity of Nodulin 26 may be important for osmoregulation during the symbiosis (Dean et al., 1999; Guenther et al., 2003). Nodulin 26 reconstitution into proteoliposomes results in NH_3 transport and has approximately fourfold stronger preference for NH_3 over water (Hwang et al., 2010).

68.2.4 Energization of the Symbiosome Membrane

The SM is energized by a H^+-pumping ATPase that resembles a P-type plasma membrane ATPase (Fedorova et al., 1999; Whitehead and Day, 1997) and facilitates the exchange of malate and ammonium across the SM (Udvardi and Day, 1997; Fig. 68.2). ATPase activity was one of the first enzyme activities to be recorded on the SM (Robertson et al., 1978b; Verma et al., 1978). Biochemical studies on soybean

(Bassarab et al., 1986; Blumwald, 1985; Udvardi, 1989), lupin (Andreev et al., 1997; Domigan et al., 1988), and pea (Szafran and Haaker, 1995) suggest that ATPase activity on the SM is Mg^{2+} dependent, possesses slightly more acidic pH optimum than the plasma membrane-type ATPase, is inhibited by vanadate, and is stimulated by cations especially K^+ and NH_4^+. ATPases generate a pH gradient across the SM by pumping protons into the symbiosome space while the bacteroid respiratory electron transport chain pumps protons out of the bacteroid into the symbiosome space. Consequently, the symbiosome space is acidified. This creates SM electrochemical gradients, which drive exchange of malate and ammonium across the SM (Udvardi and Day, 1997).

68.2.5 Iron

Iron supply for nitrogen fixation is important, as it is required for synthesis of various iron-containing proteins in both bacteroids and plants. In bacteroids, iron is required for nitrogenase synthesis and cytochromes that are used in the bacteroid electron transport chain, while in the plant, iron is a constituent of the heme moiety of leghemoglobin, which facilitates the diffusion of oxygen to the symbiosomes (Appleby, 1984). Iron is transported across the SM either in the form of Fe(II) by an Fe(II) transporter/channel (Moreau et al., 1998) or in the form of Fe(III)-chelate (LeVier et al., 1996; Moreau et al., 1995; Fig. 68.2). The assays used to show iron transport measured radioactive iron uptake into isolated symbiosomes. Most of the Fe(III) taken up by symbiosomes appeared to accumulate in the symbiosome space, but not in the bacteroids as these do not take up ferric iron readily (LeVier et al., 1996). Fe(III) transported across the SM to the symbiosome space may be bound by siderophore-like compounds released by bacteroids, helping to retain iron in the symbiosome space (Wittenberg et al., 1996). This has led to speculation that the symbiosome space may be the major storage of Fe in the nodule (Udvardi and Day, 1997). However, the identity of the Fe(III) transporter has not been determined.

Fe(II) uptake across the SM in soybean has been suggested to be mediated by GmDMT1 (Kaiser et al., 2003), a homolog of the natural resistance-associated macrophage protein (NRAMP)/Dmt1 family of divalent metal transporters. This family transport mainly divalent metal irons including Fe^{2+}, Mn^{2+}, and Cd^{2+} (Cellier, 2012). GmDMT1 was localized on the SM of infected cells and was able to complement a yeast strain deficient in Fe(II) transport (Kaiser et al., 2003). The proposed mechanism of iron transport via DMT1 raises an interesting problem regarding the orientation of DMT1 in yeast. Its localization in yeast was not confirmed, but was suggested to be on the plasma membrane due to its ability to take up iron from the media. Uptake of Fe(II) into the cell cytoplasm is equivalent to transport out of the SM, although clearly it can be taken up into the symbiosome. This suggests that DMT1 may catalyze bidirectional transport of iron (Kaiser et al., 2003). The importance of DMT1 for nitrogen fixation *in planta* has not been assessed. The integral membrane protein, SEN1 from *L. japonicus* that is related to the yeast CCC1 iron/manganese transporter and the *Arabidopsis* VIT1 vacuolar iron transporter, is essential for nitrogen fixation (Hakoyama et al., 2012). It is postulated that SEN1 transports iron across the SM although its localization in infected cells has not been determined experimentally. Its expression is specific to infected cells in the nodule, and symbiosome development and bacteroid differentiation are impaired in the *sen1* mutant nodules (Hakoyama et al., 2012).

68.2.6 Zinc

Transport of zinc across the SM is mediated by GmZIP1 in soybean (Moreau et al., 2002; Fig. 68.2). GmZIP1 is a member of the ZRT [zinc-regulated transporter], IRT [iron-regulated transporter]-like protein (ZIP) family, which transports a wide range of divalent cations that include Cd^{2+}, Fe^{2+}, Mn^{2+}, and Zn^{2+} (Guerinot, 2000; Lin et al., 2009; Pedas et al., 2008). An anti-GmZIP1 antibody-inhibited uptake of radiolabeled zinc into isolated symbiosomes (Moreau et al., 2002) and ZIP1 was able to complement a zinc transport deficient yeast strain. As for DMT1, the orientation of ZIP1 in yeast suggests that it may be able to mediate bidirectional transport of zinc. Although it is unclear whether GmZIP1 is vital for the symbiosis, *GmZIP1* mRNA is expressed in nodules after the onset of nitrogen fixation (in plants 18 days after inoculation with rhizobia), suggesting its importance in zinc metabolism in the nodules. Zinc plays a key role in the regulation of genes involved in phosphorus uptake in plants (Huang et al., 2000; Webb and Loneragan, 1988), and it has been postulated that zinc may play a role in regulating phosphorus levels in nodules (Moreau et al., 2002).

68.2.7 Nitrate

Nitrogen-fixing symbioses are induced in nitrate-deficient soil, and nitrate is believed to be the preferred form of nitrogen for the plant. Thus, in the presence of nitrate, nodule development is suppressed, nitrogen fixation is inhibited, and senescence is initiated (Caroll and Mathews, 1990; Drevon et al., 1988; Streeter and Wong, 1988). A putative transporter GmN70 has been cloned in soybean and localized to the SM of infected root cells using western blot and immunocytochemical analyses (Vincill et al., 2005; Fig. 68.2). GmN70 is an ortholog of the nodulin LjN70 of *L. japonicus*, a protein member of the major facilitator superfamily (MFS) that is also localized to the SM (Szczyglowski et al., 1998). GmN70 and LjN70 are proposed to be anion transporters with a preference for nitrate, which regulates ion and membrane potential homeostasis,

particularly in nitrate concentrations in the symbiosome space (Vincill et al., 2005). The high selectivity for nitrate is rather interesting as nitrate has been found to inhibit nitrogen fixation (Arrese-Igor et al., 1997). There are many proposed reasons as to why this might happen (reviewed in Luciński et al., 2002). One is because the presence of nitrate may increase oxygen diffusion resistance in the root cortex, which then caused a decline in bacteroid oxidative respiration (Minchin et al., 1986). Alternatively, increased concentrations of nitrate may lead to a reduction in membrane potential, across the SM and consequently inhibit transport of nutrient/metabolites across the SM (Udvardi, 1989).

68.2.8 Sulfate

The *Sst1* gene, which encodes a transporter thought to be specific for sulfate that is localized on the SM in *L. japonicus* (Wienkoop and Saalbach, 2003; Fig. 68.2), is essential for nitrogen fixation (Krusell et al., 2005). *Sst1* is highly induced during nodule development (Colebatch et al., 2002), and when expressed in yeast was able to complement a yeast mutant deficient in sulfate transport (Krusell et al., 2005). SST1 is proposed to transport sulfate from the plant cell cytoplasm to the symbiosome space. Sulfur is an essential component of the nitrogenase metalloenzyme, where each active nitrogenase complex consists of two NifH, a NifD and a NifK subunit, and four metal–sulfur clusters, which provide a medium for electron transfer to the N_2 (Dos Santos et al., 2004; see Chapters 2, 7). Synthesis of nitrogenase is impaired in *sst1* mutant plants. The role of SST1 and its importance to nitrogen fixation raises some questions as symbiosomes isolated from soybean do not take up sulfate (D Day unpublished observation). Some members of the symbiosome sulfate transport (SST) family are able to catalyze transport of other substances including molybdate (Tomatsu et al., 2007), which is also essential for nitrogenase and nitrogen fixation. Thus, it is possible that this transporter has a physiological role on the SM that does not include sulfate transport.

68.2.9 Amino Acids

There is evidence in pea that branched-chain amino acids, namely leucine, isoleucine, and valine (LIV), are required for effective nitrogen fixation, and that they must be provided by the plant across the SM (Prell et al., 2009). *Rhizobium leguminosarum* bv. *viciae* contains two broad specificity amino acid ABC transporters, AapJQMP and BraDEFGC (Hosie et al., 2002; Walshaw, 1996). When *aap bra* double mutants were inoculated on pea, *P. sativum*, the bacteroids appeared morphologically normal under electron micrographs, but the plants exhibited a nitrogen-starved phenotype and increased nodule number and mass (Lodwig et al., 2003). The plants only fixed nitrogen at around 30% of wild-type rates (Lodwig et al., 2003). By altering the specificity of Bra to only transport branched-chain amino acids of LIV, Prell et al. (2009) demonstrated that LIV transport is essential for effective nitrogen fixation in peas. The overexpression of glutamate dehyrogenase, *gdhA*, in bacteroids did not rescue the *aap bra* mutants, suggesting that the dependency of bacteroids on the plant for LIV is not because of the lack of ammonium incorporation into amino acids resulting from the known downregulation of glutamate synthesis. Instead, the effect is caused by transcriptional downregulation of LIV biosynthesis in bacteroids, which become dependent on amino acids supplied by plants (Prell et al., 2009). This event is called symbiotic auxotrophy. Studies with isolated soybean symbiosomes have failed to provide evidence for carrier-mediated uptake of amino acids, including branched-chain amino acids, but significant diffusion of these compounds across the SM was observed (Udvardi et al., 1990). However, since only a low rate of LIV transport is needed to overcome symbiotic auxotrophy in *R. leguminosarum* (Prell et al., 2010), diffusion across the SM may be sufficient to sustain the symbiosis.

68.2.10 Homocitrate

Homocitrate is a component of iron-molybdenum (FeMo) cofactor of nitrogenase complex (Hoover et al., 1989; see Chapter 2), and so homocitrate is essential for nitrogen fixation. Supply of homocitrate from the plant to the bacteroid may be necessary as most rhizobia, except in *Azorhizobium caulinodans* and *Bradyrhizobium* sp. lack a *NifV* gene encoding homocitrate synthase (HCS) (Hakoyama et al., 2009; Zheng et al., 1997). In *L. japonicus*, *FEN1* encodes HCS (Hakoyama et al., 2009) and *fen1* mutant nodules have very low nitrogenase activity and ineffective nodules (Imaizumi-Anraku et al., 1997). *Mesorhizobium loti* carrying *FEN1* is able to rescue the *fen1* mutant (Hakoyama et al., 2009). These results suggest that homocitrate must be transported across the SM, but to date no such transporter has been identified.

68.3 CONCLUSION AND FUTURE WORK

Given that the symbiosome is an integral part of the legume–*Rhizobium* symbiosis and the SM is a key to the interaction between the symbionts, it is surprising how little is understood about its development, protein composition, and functional role. The recent evidence for a role of exocytosis in symbiosome formation is exciting, but details are only beginning to appear and we know very little about targeting of proteins to the SM. Clearly, this is an area in need of intense study. Likewise, while early biochemical studies

provided a picture of what substances can be transported across the SM and in some instances pointed to the probable mechanisms involved, we still know very little about the molecular identity of the transport proteins involved, nor the way that the genes encoding these proteins are regulated. The recent legume genome sequencing projects and accompanying transcriptome analyses (see earlier) promise to accelerate a more detailed analysis of SM synthesis and transport properties. In particular, accurate proteomic analysis of the SM is now possible and is yielding valuable insights into novel transporters and other integral membrane proteins on this unique membrane.

Nitrogen Fixation, Assimilation, and Senescence in Nodules

Chapter 69

Nodulin Intrinsic Proteins: Facilitators of Water and Ammonia Transport across the Symbiosome Membrane

Pratyush Routray, Pintu D. Masalkar, and Daniel M. Roberts
Department of Biochemistry & Cellular and Molecular Biology and Program in Genome Science and Technology, The University of Tennessee, Knoxville, TN, USA

69.1 INTRODUCTION

During the establishment of legume–rhizobia symbioses, rhizobia infect and occupy specialized infected cells within the core of the symbiotic root nodule. Nitrogen-fixing rhizobia bacteroids reside within nitrogen-fixing organelles called symbiosomes (Roth et al., 1988; see Chapter 68). In mature nodules, the host-infected cells are occupied by thousands of symbiosomes, which constitute the major organelle within this cell type. The plant-derived membrane "symbiosome membrane" (SM) encloses the endosymbiotic rhizobia bacteroid, and possesses transport and channel activities involved in the exchange of metabolites and signaling molecules between the host and symbiont that are essential for the support of symbiotic nitrogen fixation (reviewed in Day et al., 2001; White et al., 2007; Udvardi and Poole, 2013; see Chapter 68). These include the central metabolic exchange that characterizes the symbiosis: (i) the uptake of a carbon energy source, generally in the form dicarboxylates, provided by the plant and utilized by the bacteroid to produce adenosine triphosphate (ATP) in support of nitrogen fixation; and (b) the release of the reduced product of nitrogen fixation as either ammonia (NH_3) or ammonium ion (NH_4^+) (Fig. 69.1).

Apart from this fundamental carbon/nitrogen exchange, the SM possesses multiple transport functions to facilitate the uptake of various other metal cofactors, as well as other components needed to support the symbiosis (reviewed in Udvardi and Poole, 2013; see also Chapter 68). As a result, biogenesis of the symbiosome is accompanied by the expression of a number of transporter and channel proteins, many of which are targeted to the SM. Among these are a class of plant-specific aquaporin-like channel proteins known as "nodulin 26 intrinsic proteins" (NIPs) (Wallace et al., 2006). In the present chapter, we consider the potential multifunctional roles of NIP channels in metabolic and osmoregulation in nodules, as well as the potential interplay between these proteins, ion channels, and glutamine synthetase (GS) in mediating ammonia efflux and assimilation.

69.2 THE NIP SUBFAMILY: PLANT-SPECIFIC CHANNELS OF THE AQUAPORIN SUPERFAMILY

Nodulin 26 was originally discovered as the major protein component of the soybean SM (Fortin et al., 1987) and as a target for calcium-dependent protein kinases localized on this membrane (Weaver et al., 1991). It was noted that the protein possessed homology to proteins of the aquaporin superfamily of water and solute channels, and it was among the first members of this ancient channel superfamily discovered in higher plants (Sandal and Marcker, 1988). Biochemical and proteomic studies of other legume symbiosomes indicate that nodulin 26-like proteins are major protein components (Guenther and Roberts, 2000; El Yahyaoui et al.,

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

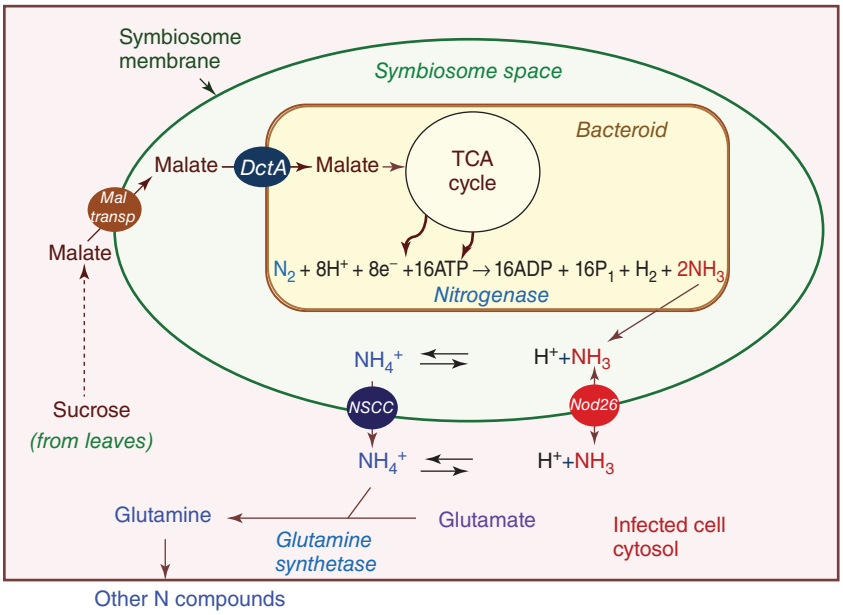

Figure 69.1 Carbon and nitrogen flux in nitrogen-fixing symbiosomes. Infected cells convert sucrose provided by the shoot to malate, which is transported to the bacteroid via SM and the bacteroid dicarboxylate transporters. Malate serves as the catabolic energy source that provides energy for nitrogenase-catalyzed fixation of N_2. Reduced ammonia is transported to the symbiosome space and is effluxed to the infected cell cytosol by one of two pathways (NSCC or nodulin 26, see text for details), where it is assimilated (see Chapter 68).

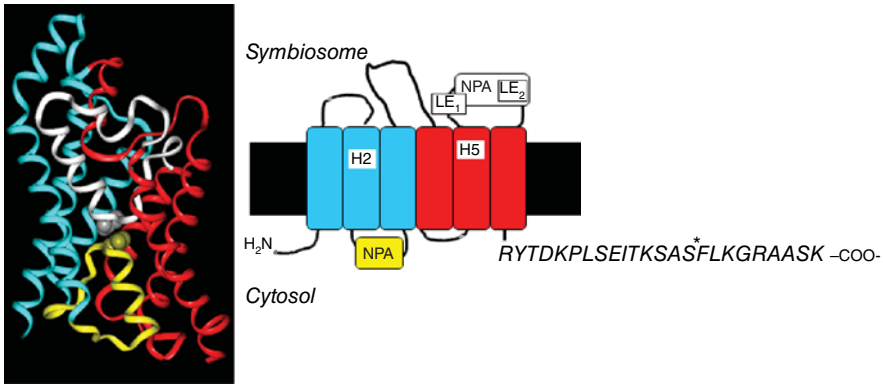

Figure 69.2 Schematic diagram of the topology of nodulin 26. (Right) The nodulin 26 topology based on structural modeling (Wallace and Roberts, 2004) is shown. The topology model shows the typical six transmembrane α-helices and twofold symmetry characteristic of the aquaporin superfamily. The two small helices that contain the conserved NPA motifs are shown in white and yellow. H2, H5, LE_1, and LE_2 indicate the four amino acids that form the selectivity filter in the channel pore. The asterisk shows the position of the CDPK phosphorylation site. (Left) A backbone ribbon structure illustrating the conserved hourglass fold of the aquaporin superfamily is shown based on the X-ray crystal structure of aquaporin 1 (Sui et al., 2001). The structure shows the disposition of the various helices and NPA motifs with the same color scheme shown in the topology model.

2004; Catalano et al., 2004), and thus are likely to play a common and integral role in transport/channel processes in the SM of most if not all legume/rhizobia symbioses.

As a member of the aquaporin superfamily, nodulin 26 possesses the conserved topology and "hourglass" fold characteristic of this protein family (Walz et al., 2009). This conserved topology consists of six transmembrane domains, five interhelical loops, and hydrophilic N-terminal and C-terminal exposed to the cytosolic side of the membrane (Fig. 69.2). Aquaporin proteins also possess two highly conserved "asparagine–proline–alanine (NPA)" motifs in loops B and E, which form small α-helices that fold back and pack with the six transmembrane α-helices to form the channel pore for substrate transport.

Unlike animal and microbial aquaporins, the evolution of higher plants was accompanied by a diversification of the number and complexity of genes encoding aquaporin proteins (Gupta and Sankararamakrishnan, 2009; Chaumont et al., 2001; Johanson et al., 2001; Sakurai et al., 2005). Based on computational modeling and structural analysis, the hourglass fold is conserved in plant MIPs, but the pore regions show unprecedented structural diversity (Wallace and Roberts, 2004; Bansal and Sankararamakrishnan, 2007; Gupta and Sankararamakrishnan, 2009) that has resulted in

the acquisition of multiple transport activities that transcend the traditional "aquaporin" paradigm (Maurel et al., 2008; Ludewig and Dynowski, 2009; Hachez and Chaumont, 2010).

NIPs are a subfamily of structurally related plant-specific channels of the aquaporin superfamily that have the conserved hourglass template, but which have three distinct "pore subgroups" (Rouge and Barre, 2008). NIPs within each pore subgroup exhibit distinct transport selectivity for various transport substrates including water, ammonia, polyols, organic acids, and metalloid compounds (e.g., boric acid and silicic acid) (Rivers et al., 1997; Dean et al., 1999; Choi and Roberts, 2007; Takano et al., 2006; Li et al., 2011; Ma et al., 2006; Niemietz and Tyerman, 2000; Hwang et al., 2010).

69.3 SYMBIOSOME MEMBRANE NODULIN 26: TRANSPORT PROPERTIES

Ever since its discovery as an aquaporin-like protein, the physiological role of nodulin 26 has been subject to debate. Functional analyses in *Xenopus* oocytes and in proteoliposomes and SM vesicles show that nodulin 26 possesses aquaporin activity (Rivers et al., 1997; Dean et al., 1999). However, these analyses show that nodulin 26 is a relatively poor water channel, with a single-channel conductance for water (P_f) that is 30-fold lower than robust water-selective aquaporins such as mammalian AQP1. However, because of its high SM concentration, nodulin 26 is responsible for the unusually high water permeability of the SM. The SM osmotic water permeability (P_f = 0.05 cm/s), is 50-fold higher than normal membrane bilayer diffusion rates (Rivers et al., 1997). Considering the fact that the symbiosome is the major organelle in the nonvacuolated infected cell, this high water permeability could serve as an osmoregulatory role in cell cytosolic volume homeostasis and osmotic adjustment, similar to the role of the central vacuole of other plant cells.

The water permeability of nodulin 26 is enhanced by phosphorylation of Ser 262 within the cytosolic C-terminal domain of the protein (Guenther et al., 2003). Phosphorylation of nodulin 26 is catalyzed by a Ca^{2+}-dependent protein kinase (CDPK) that is colocalized to the SM (Weaver et al., 1991) and is triggered by water-deficit stress. Given the sensitivity of the nodule and nitrogen fixation to osmotic stress (Del Castillo and Layzell, 1995; Marino et al., 2007; Gil-Quintana et al., 2013), another potential function could be the adaptation of infected cells and endosymbionts to osmotic challenge.

Although nodulin 26 possesses a low intrinsic aquaporin activity, it is also permeable to a number of additional uncharged solutes of potential importance to the symbiosis. For example, similar to mammalian aquaglyceroporins, nodulin 26 shows permeability to small uncharged polyols such as glycerol (Rivers et al., 1997; Dean et al., 1999). While the symbiotic significance of this activity is not clear, rhizobia can utilize glycerol as a carbon source and contain glycerol-inducible ATP-glycerokinase and glycerophosphate (Arias and Martinez-Drets, 1976).

More recently, it has also been demonstrated that nodulin 26 facilitates the transport of NH_3 (Hwang et al., 2010). Measurements of single-channel permeabilities of nodulin 26 reconstituted into proteoliposomes by using stopped-flow fluorometric techniques showed that nodulin 26 possesses a fivefold higher preference for NH_3 as a substrate compared to water (Hwang et al., 2010).

69.4 EFFLUX OF FIXED NITROGEN FROM THE SYMBIOSOME

The ammoniaporin activity of nodulin 26 is of particular interest, given the nature of the SM as a barrier for the efflux of fixed nitrogen. The process of fixed NH_3 and NH_4^+ release from the symbiosome to the plant cytosol for assimilation is complex and could occur by two distinct pathways (Fig. 69.3).

69.4.1 Pathway 1: Directional NH_4^+ Release via a Nonselective Cation Channel

Patch clamp analysis of soybean (Tyerman et al., 1995) and *Lotus japonicus* (Roberts and Tyerman, 2002) symbiosomes has revealed the presence of a voltage-activated nonselective cation channel (NSCC), which is permeated by ammonium, sodium, and potassium ions (Tyerman et al., 1995).

Although the molecular identity of this channel is unknown, it possesses the properties of inwardly rectified K_{ir} channels of mammalian systems (Hibino et al., 2010) and shows unidirectional (i.e., rectified) transport toward the cytosol due to gating by divalent cations or polyamines on the cytosolic side of the membrane (Whitehead et al., 1998, 2001; Roberts and Tyerman, 2002; Obermeyer and Tyerman, 2005). Thus, NH_4^+ in the symbiosome would be transported in a unidirectional manner toward the cytosolic compartment by the NSCC without significant backward flux.

Regulation of gating is mediated by the transmembrane voltage potential ($V_{0.5}$ = −60 to −80 mV), as well as by the symbiosome concentration of NH_4^+ ions (Whitehead et al., 1998; Roberts and Tyerman, 2002; Obermeyer and Tyerman, 2005). This channel is tightly regulated and opens only in response to a voltage gradient ($\Delta\psi$) across the membrane. The $\Delta\psi$ is established by a proton pumping SM-ATPase (Udvardi and Day, 1989), which hydrolyzes ATP and simultaneously transports a proton from the plant cytosol into the symbiosome. This establishes a "proton motive force,"

which consists of two components: an electrical component ($\Delta\psi$) and a chemical component, which is the pH gradient (ΔpH) caused by a higher H^+ inside the symbiosome.

69.4.2 Pathway 2: Facilitated Transport of NH_3 by Nodulin 26

A protein-based facilitated pathway for flux of uncharged NH_3 across the SM was originally described by Niemietz and Tyerman (2000). Based on the properties of nodulin 26 as an ammoniaporin (Hwang et al., 2010) and its high concentration on the SM, it is likely to account for this facilitated pathway observed in purified SM vesicles. This pathway shows no dependence on $\Delta\psi$ and would transport NH_3 in a bidirectional manner. Therefore, the direction of transport would depend on the concentration gradient of NH_3 across the SM.

The relative contribution of the NSCC and nodulin 26 pathways to the overall process of fixed nitrogen efflux depends on several factors: (i) the concentration gradient of NH_4^+ and NH_3 between the symbiosome space and the cytosol; (ii) The ΔpH between the symbiosome space and cytosolic compartments; and (iii) The resting voltage potential ($\Delta\psi$) of the SM. These parameters are controlled by the activity of the SM H^+-pumping ATPase. For example, highly active H^+-ATPase hyperpolarizes the SM (high $\Delta\psi$), resulting in the opening of the NSCC and acidification of the symbiosome space (elevated ΔpH). Based on mathematical modeling (unpublished), these conditions would favor efflux of fixed nitrogen through the open NSCC over the nodulin 26 pathway (Fig. 69.3a). In contrast, low ATPase activity would result in reduced SM potential (low $\Delta\psi$) and a decreased ΔpH, which would lead to the closure of the NSCC that would favor NH_3 efflux via nodulin 26 (Fig. 69.3b).

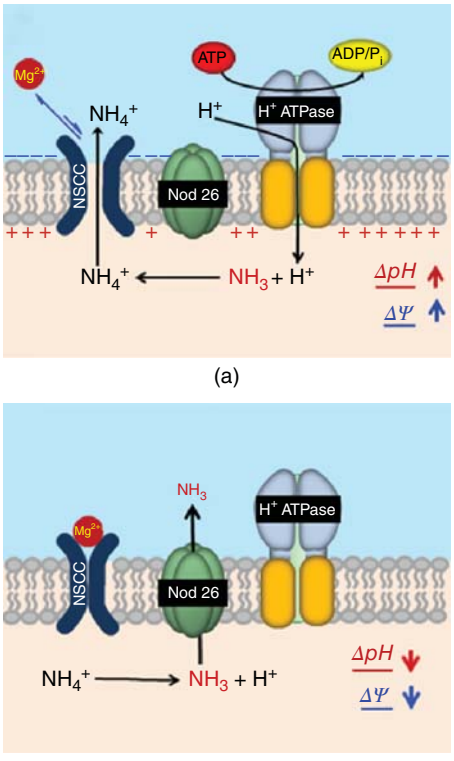

Figure 69.3 Two pathways for fixed nitrogen efflux. (a) Voltage-dependent efflux of ammonium ion through a nonselective cation channel (NSCC). This pathway is favored under high H^+-ATPase activity that leads to a proton motive force across the SM. At negative potentials, the gating particle (Mg^{2+} or polyamines) dissociates from the NSCC resulting in channel opening. The acidification of the symbiosome space also increases the $[NH_4^+]/[NH_3]$ ratio, which would also favor the NSCC pathway. (b) Facilitated diffusion and uncharged ammonia through the nodulin 26 aquaporin-like channel. This pathway would be favored under conditions of low H^+-ATPase activity, or when the SM is depolarized and the ΔpH is low. Under these conditions, the NSCC is closed and uncharged ammonia movement through nodulin 26 would be the pathway for fixed nitrogen movement.

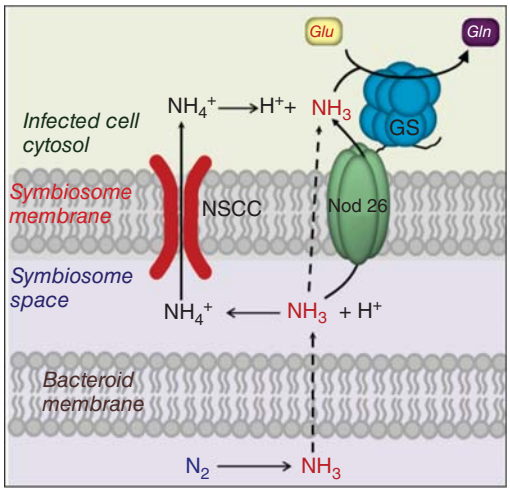
69.5 NODULIN 26, GLUTAMINE SYNTHETASES, AND AMMONIA ASSIMILATION

Upon transport to the cytosol, ammonium ion is assimilated into an organic form, principally via the action of ATP-dependent glutamine synthetase (GS) in the infected cell cytosol (Miflin and Habash, 2002). In soybean, three isoform families of cytosolic GS (designated α, β, and γ) are expressed, with the β and γ isoforms found in nitrogen-fixing nodules (Morey et al., 2002).

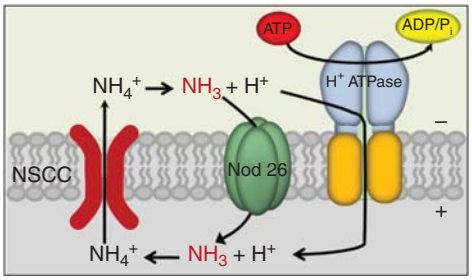
A connection between the transport activity of soybean nodulin 26 and nitrogen assimilation came from the demonstration of an interaction between the β and γ GS isoforms with nodulin 26 via its cytosolic carboxyl terminal domain (Masalkar et al., 2010). This observation is consistent with previous observations with animal aquaporins that show that the carboxyl terminal region is a common site for regulation and interaction with various cytosolic proteins (Yu et al., 2005; Moeller et al., 2010).

The potential significance of nodulin 26/GS association is summarized in Figure 69.4. Nodulin 26 interaction with GS would localize this critical assimilatory enzyme to the symbiosome surface, the site of fixed NH_3/NH_4^+ release into the infected cell cytosol. Direct interaction of GS with nodulin 26 could facilitate rapid assimilation of reduced nitrogen in the form of unprotonated NH_3 transported through the nodulin 26 channel, potentially by substrate channeling (Fig. 69.4).

Additionally, since nodulin 26 is the most abundant SM protein, interaction with GS would increase the local concentration of the enzyme at the symbiosome surface, which



(a)



(b)

Figure 69.4 Model for the nodulin 26/GS interaction and effects on nitrogen efflux and assimilation. (a) Fixed nitrogen within the symbiosome space can be transported as NH_4^+ or NH_3 by the NSCC or nodulin 26 pathways, as discussed in the text. Binding of GS to the C-terminal domain of nodulin 26 serves as a site for rapid assimilation of ammonia traversing nodulin 26. Additionally, binding of GS to the symbiosome increases its local concentration, further facilitating the assimilation of fixed nitrogen released by other pathways as well. (b) Ammonia futile cycling through the SM. H^+-ATPase mediates the movement of protons from the cytosol to the symbiosome space generating a proton gradient leading to polarization of SM and activation of the NSCC. This channel directionally transports NH_4^+ into the cytosolic compartment where alkaline conditions lead to the release of H^+, with NH_3 potentially re-entering the symbiosome space through nodulin 26. Rapid assimilation of NH_4^+ via GS would maintain cytosolic NH_4^+ levels at low concentrations, thereby preventing this potential metabolite cycling. (Adapted from Masalkar et al. (2010) with permission.)

would enhance the rate of fixed nitrogen assimilation transported by other efflux pathways such as the NSCC.

Another potentially important outcome of this interaction is that it may aid in preventing the toxic effects of cytosolic accumulation of ammonia (Fig. 69.4b). The toxicity of cytosolic ammonia in higher plant systems is potentially the result of "futile cycling" (Britto et al., 2001). For example, in the symbiosome, NSCC-mediated efflux of fixed NH_4^+ into the alkaline plant cytosol would result in deprotonation, generating NH_3 that could re-enter the acidic symbiosome space through nodulin 26. The result would be a net transport of a proton from the symbiosome to the cytosol, which would collapse the proton motive force generated by the H^+-ATPase, leading to hydrolysis of ATP and futile cycling. The maintenance of low cytosolic ammonia concentrations, which are estimated to be 50-fold lower than concentrations in N_2-fixing symbiosomes (Streeter, 1989), is critical to prevent futile cycling. The association of GS with nodulin 26 could facilitate rapid nitrogen assimilation, preventing the accumulation of free ammonia in the cytosol.

69.6 SUMMARY

The NIP channels represent a plant-specific channel family with an overall structural conservation of the aquaporin hourglass scaffold, but with pore regions that have diverged so that they have a reduced ability to transport water while acquiring the ability to transport a number of additional metabolic substrates. Nodulin 26, the archetype of the NIP family, which represents one pore subclass (NIP I subclass) (Wallace et al., 2006), is a major component of rhizobia-containing symbiosomes. The protein shows permeability for both water (aquaporin) and NH_3 (ammoniaporin), with the latter being the preferred substrate. A potential role in ammonia efflux is supported by the interaction of the nitrogen assimilatory enzyme GS with nodulin 26. While the biochemical and biophysical properties of nodulin 26 are well established, several issues regarding the biological role of this symbiosis-specific channel remain unresolved.

1. How does the interplay between the proton pump, the NSCC, and nodulin 26 mediate nitrogen efflux and assimilation. In this regard, the molecular identities of the NSCC and the H^+-ATPase, and how the later is regulated remain to be elucidated.
2. Preliminary data suggest that water and ammonia permeabilities of the SM are conversely regulated by phosphorylation (Niemietz and Tyerman, 2000). Is CDPK-catalyzed phosphorylation a mechanism to regulate osmotic versus metabolic functions of nodulin 26 in response to environmental or metabolic cues?
3. While potential roles for water and ammonia transport for nodulin 26 are demonstrated, assignments of these functions to the protein are difficult because of the multifunctional activity of NIPs (e.g., glycerol and metalloid transport). Physiological analysis of loss-of-function mutants may present an approach to elucidate which of these multiple transport activities are relevant to the symbiosis.

70.1 INTRODUCTION

Hemoglobins are widespread in all organisms, where they perform multiple and varied functions (see reviews by Vinogradov et al., 2005; Garrocho-Villegas et al., 2007; Angelo et al., 2008; Hoy and Hargrove, 2008). Flavohemoglobins of bacteria and yeast contain globin and flavin adenine dinucleotide (FAD) reductase domains and are involved in nitric oxide (NO) detoxification and protection against nitrosative stress (Angelo et al., 2008; see Chapter 64). In vertebrates, hemoglobin and myoglobin play key roles in efficient O_2 transport and storage and in NO homeostasis, whereas neuroglobin and cytoglobin might be implicated in O_2 supply and act as O_2-consuming enzymes or as O_2 sensors (Pesce et al., 2002). Plants may contain symbiotic, nonsymbiotic, and truncated hemoglobins (Garrocho-Villegas et al., 2007; Hoy and Hargrove, 2008), and the three types of globins are expressed in legume nodules (Bustos-Sanmamed et al., 2011). Symbiotic hemoglobins include leghemoglobins (Lbs) of legumes and some hemoglobins of actinorhizal plants, and their major function is to facilitate O_2 diffusion within the nodules (Wittenberg et al., 1974). Lbs are present in the cytosol of host cells at concentrations of 2–3 mM and maintain a free O_2 concentration of 20–40 nM (Becana and Klucas, 1992). This range of O_2 concentration permits an adequate supply of adenosine triphosphate (ATP) for N_2 fixation and avoids nitrogenase inactivation (Wittenberg et al., 1974). Nonsymbiotic hemoglobins are expressed at nanomolar to micromolar concentrations in most plant tissues, and are classified into two groups based on amino acid sequences, phylogeny, and O_2-binding properties. Class 1 display extremely high affinity for O_2 and participate in NO metabolism and in the maintenance of ATP production under hypoxia (Hebelstrup et al., 2007; see Chapter 64). Class 2 hemoglobins have similar O_2 affinities to Lbs and unknown function (Trevaskis et al., 1997) but, in *Arabidopsis thaliana*, the class 1 and 2 hemoglobins together are required for normal growth (Hebelstrup et al., 2006). Class 3 or truncated hemoglobins have a 2/2 α-helical sandwich secondary structure instead of the canonical 3/3 structure of other hemoglobins, and are present in bacteria, protozoa,

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

and plants (Vinogradov et al., 2005). A role for class 3 hemoglobins has not been conclusively demonstrated yet, although it has been suggested that they may be involved in NO detoxification (see Chapter 64) and, in legumes, in the suppression of the defense response during symbiosis (Wittenberg et al., 2002; Hoy and Hargrove, 2008).

In most legume nodules, Lbs exist as multiple components or isoproteins whose relative proportions vary with age and stress conditions (Fuchsman and Appleby, 1979). In soybean nodules, there are four major components (a, c_1, c_2, c_3), encoded by different genes, and four minor components (b, d_1, d_2, d_3), originated by posttranslational modification (Fuchsman and Appleby, 1979; Whittaker et al., 1979). The regulatory pathways of Lb biosynthesis have been extensively studied (e.g., O'Brian, 1996), but there is virtually no information on the *in vivo* mechanisms of Lb degradation. In animals and plants, the conversion of heme to biliverdins is catalyzed by heme oxygenase (Brown et al., 1990; Baudouin et al., 2004), but can also be carried out nonenzymatically in the presence of ascorbate and O_2 (Lehtovaara and Perttilä, 1978). In plants, biliverdin-like pigments perform important functions in photosynthesis and photomorphogenesis (Brown et al., 1990) and accumulate in senescent nodules (Virtanen and Laine, 1946; Roponen, 1970). Legume nodule senescence is a highly complex and regulated process with potential agricultural and ecological relevance as it limits the functional lifespan of nodules and N_2 fixation (Puppo et al., 2005; Becana et al., 2010).

The green proteins derived from Lb in nodules had not been characterized when we began our work (Navascués et al., 2012). Early studies by Virtanen and Laine (1946) described the presence in legume nodules of a green pigment that originated from Lb. The pigment contained a broken tetrapyrrole ring that still retained the iron. Very different green proteins were isolated from soybean nodules (Jun et al., 1994a). The modified proteins, termed Lba_m and Lbc_m, derive from Lba and Lbc and have identical apoproteins to the precursor Lbs but unknown alterations of the tetrapyrrole ring (Jun et al., 1994a,1994b). Identification of the heme modifications in Lba_m and Lbc_m is important because their proportions relative to the precursor Lbs increase during nodule senescence and because the green Lbs exhibit aberrant binding to O_2 (Wagner and Sarath, 1987). By using a combination of spectroscopic techniques and reconstitution experiments of Lb with mesoheme (heme in which the vinyl groups have been replaced by ethyl groups), we have shown that soybean Lba_m and Lbc_m have a 4-nitrovinyl in their heme groups (Fig. 70.1), and that these modified heme proteins can be generated *in vitro* by exposing Lba and Lbc to NO_2^- (Navascués et al., 2012). Here, we present a summary of the experiments carried out for the identification of nitrated Lbs and discuss relevant mechanisms for nitration of Lb hemes.

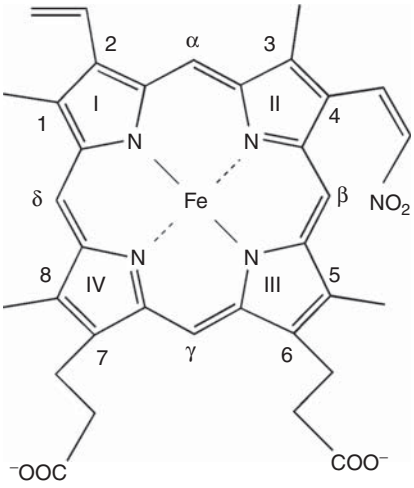

Figure 70.1 Heme structure with the position of the 4-nitrovinyl group. The figure shows an isomer with the NO_2 group in the Cβ atom and in *cis*-configuration. Fisher's numbering of protoporphyrin IX was followed (Source: from (Navascués et al., 2012) with permission).

70.2 METHODS

Soybean plants (*Glycine max* cvs Hobbit or Williams × *Bradyrhizobium japonicum* strains 61A89 or USDA110) were grown under controlled environmental conditions until the late vegetative growth stage. Nodules were harvested in liquid nitrogen and stored at −80 °C.

Soybean Lbs were purified using ammonium sulfate fractionation and chromatography on hydroxyapatite, Sephadex G-75, and DE-52 columns (Jun et al., 1994a). Proteins were subjected to in-gel digestion with trypsin, and identification of the proteins was performed by peptide mass fingerprinting with a matrix-assisted laser desorption-ionization time-of-flight (MALDI-TOF) instrument (Applied Biosystems; Foster City, USA) as described (Casanovas et al., 2009). The molecular masses of Lbs were also determined by MALDI-TOF mass spectrometry (MS).

Hemes and heme proteins were subjected to structural analyses by MS and by nuclear magnetic resonance (NMR) and resonance Raman (RR) spectroscopies as described in detail elsewhere (Navascués et al., 2012). For MS analysis of hemes, low-energy MS^n ($n = 1$–4) was carried out by nanoelectrospray ionization on an LCQ ion trap mass spectrometer (ThermoFisher, San Jose, USA). For NMR analysis of Lbs, ^1H NMR samples were prepared in D_2O containing 50 mM phosphate buffer and 2 mM cyanide to insure complete formation of the ferric Lb-cyano complexes. The entire protein sample available for each Lb was used (~1 mM of Lba and ~0.2 mM of Lbc_m). NMR spectra were collected at 30 °C with the proton chemical shifts referenced to residual water. 1D and Nuclear Overhauser Enhancement

SpectroscopY (NOESY) spectra were obtained on a Bruker DRX-500 NMR spectrometer operating at 499.38 MHz proton Larmor frequency. RR spectra were recorded using a Jobin-Yvon U1000 spectrometer, equipped with a liquid nitrogen-cooled charge-coupled device (CCD) detector (Spectrum One, Jobin-Yvon, France). Excitation at 413.1 nm (50 mW) was provided by an Innova Kr^+ laser (Coherent, Palo Alto, USA).

The Lb*a* apoprotein was obtained by the acid-butanone method (Ascoli et al., 1981). After neutralization of the aqueous phase with phosphate buffer (pH 7.0), the apoprotein was incubated overnight with a twofold excess of protoheme or mesoheme, dialyzed, and nitrated. For time-course studies of nitration, heme proteins (150–200 μM) were treated with $NaNO_2$ (200 mM) in 50 mM phosphate buffer (pH 5.5 or 7.0) for 2–48 h at room temperature. The mixtures were dialyzed, concentrated, and resuspended in water (isoelectric focusing (IEF) analysis) or in 10 mM NH_4HCO_3 (MS analysis).

70.3 RESULTS

70.3.1 Purification of Lbs and Their Modified Forms

The major Lb components and their green derivatives were purified from soybean nodules by ammonium sulfate fractionation, conventional chromatography, and IEF. All bands containing Lbs were excised from the gels, and the proteins were eluted and analyzed by MALDI-TOF/MS. The molecular masses of the apoproteins of Lb*a*, Lbc_1, Lbc_2, and Lbc_3, as well as those of their respective modified forms, were found to be 15,241, 15,256, 15,393, and 15,451 Da, respectively, which matched ±1 Da those predicted from the amino acid sequences excluding the initial Met. We also purified two fractions containing the Lb*d* and Lbd_m components. The molecular masses of the apoproteins of Lbd_1, Lbd_2, and Lbd_3 were found to be 15,299, 15,436, and 15,492 Da, which exceed by 42 ± 1 Da those of Lbc_1, Lbc_2, and Lbc_3, respectively. This mass difference is consistent with the presence of an N-terminal acetylation. Also, the apoproteins of the Lbd_m derivatives have identical molecular masses to those of the parent proteins. It can be thus concluded that all four minor Lb components of soybean arise from the major components by N-terminal acetylation, and that all the green Lb derivatives are affected in the hemes and not in the globins.

70.3.2 Structural Elucidation of Modified Hemes

Purified Lb*a*, Lb*c*, and Lbc_m from soybean nodules were used for comparative structural analyses of the protoheme and the modified heme by using UV–visible, MS, NMR, and RR spectroscopies. Ferric Lbc_m exhibits a Soret band at 389 nm with a shoulder at 436 nm and a charge-transfer absorption band at 615 nm. The pyridine hemochrome spectrum of Lbc_m was identical to that of Lba_m (Jun et al., 1994a), with prominent absorption bands at 553 nm (α band) and 522 nm (β band) and a new peak at 580 nm. Therefore, the heme of Lbc_m is not broken and retains the capacity for ligand binding, but it is chemically modified on the tetrapyrrole ring.

To identify this modification, hemes were subjected to MS^n fragmentation. Because the isolated modified hemes were relatively unstable, the whole proteins were directly subjected to MS analysis. The hemes of Lb*a*, Lb*c*, and Lb*d* had an *m/z* 616, as expected for protoheme, whereas those from Lba_m, Lbc_m, and Lbd_m had an *m/z* 661. High-resolution MS of these molecular ions proved that the difference of 45 Da was due to the insertion of an NO_2 group. The molecular ions were extensively fragmented (MS^2 to MS^4), and the elemental compositions of the most relevant fragments were elucidated by high-resolution MS. These analyses revealed that one propionic group, at least the α-carbon and carboxyl of the other propionic group, and at least three methyl groups of the tetrapyrrole were intact in the modified hemes. The fragmentation patterns of the Lba_m, Lbc_m, and Lbd_m hemes were identical, thus confirming, together with the Soret–visible spectroscopy data, that all of them contain an NO_2 group.

Further structural information on the modified hemes was obtained by ^1H NMR spectroscopy using the ferric-cyano complexes of Lb*a* (standard for comparison) and Lbc_m. The Lb*a* sample was found to have a 1D ^1H NMR spectrum with identical proton signals to that already published (Trewhella and Wright, 1980). However, the sample of Lbc_m protein was relatively small and composed of a mixture of Lbc_{1m} and Lb$c_{2m} + c_{3m}$, and hence it was not possible to assign as many of the heme resonances of these Lbc_m isoproteins. The chemical shifts of all of the heme methyl groups of the two major species of the Lbc_m sample were changed by the heme modification, in part because of a distortion of the heme seating by 7°. By contrast, no shifts were detected for the 2-vinyl group or for most of the protons of the 6- and 7-propionate groups, and it was concluded that the modification of the heme appears to be at the 4-vinyl substituent (see details in Navascués et al., 2012). However, none of the protons of the 4-vinyl group of Lbc_m could be identified, and thus we had to complement our study with RR spectroscopy and reconstitution experiments.

The RR spectra of ferric Lb*a* and Lbc_m were compared (see details in Navascués et al., 2012). The high-frequency regions of the RR spectra revealed the binding of an NO_2 group to the protoheme of Lbc_m, with a signature at 1320 cm^{-1}, specific of a nitroaromatic group. In the mid-frequency and low-frequency RR spectra, the frequencies of

modes involving the peripheral vinyl and methyl groups are significantly modified, further indicating the presence of an NO_2 group in a vinyl.

70.3.3 Reconstitution of Lbs with Mesoheme and *In Vitro* Nitration

To verify that the nitrated heme originated by a substitution of a proton by NO_2 on a vinyl group, we prepared the apoLbs, reconstituted the holoproteins with protoheme or mesoheme, and nitrated the reconstituted proteins (Fig. 70.2).

Nitration of the apoLb reconstituted with protoheme caused formation of green protein products (Fig. 70.2a) with modified visible spectra (Fig. 70.2b) and with heme groups having an *m/z* 661 (Fig. 70.2c). These Lb products showed identical fragmentation patterns to the hemes of the green Lbs from nodules. By contrast, the apoLb reconstituted with mesoheme remained unaffected after the $NaNO_2$ treatment, based on the Soret and visible spectra (Fig. 70.2b), and RR and MS analyses of the protein. The MS analysis showed a molecular ion of *m/z* 620, characteristic of the iron-mesoporphyrin lacking NO_2 (Fig. 70.2c). Taking these results together with the MS, NMR, and RR data, we conclude that the NO_2 group of the modified Lb hemes is on the 4-vinyl, and that several structural isomers are produced by nitration of the protoheme. To confirm the presence of several isomers of Lb hemes, Lb*a* purified from soybean nodules was nitrated with $NaNO_2$ at pH 7.0 or 5.5 at 25°C , and the resulting proteins were resolved on preparative IEF gels (Fig. 70.3). Nitration was faster at pH 5.5 than at pH 7.0, being completed within ~1 and ~2 days, respectively, when ~200 μM Lb and ~200 mM NO_2^- were employed. At pH 5.5, heme nitration required ~3 days to complete with ~20 mM NO_2^- and was not completed after 5 days with ~2 mM NO_2^-.

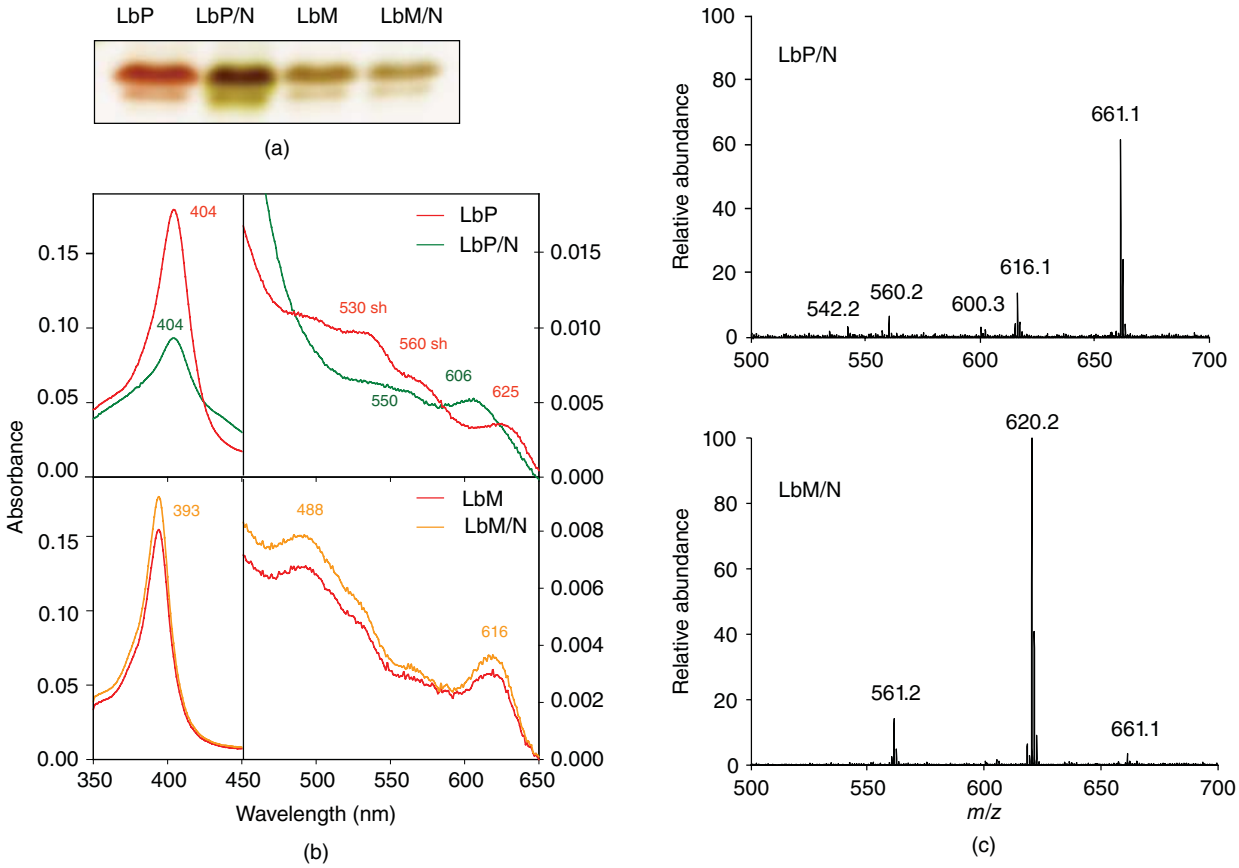

Figure 70.2 *In vitro* reconstitution and nitration of Lb. (a) ApoLb*c* was reconstituted with either protoheme (LbP) or mesoheme (LbM) and treated for 24 h at pH 6.5 with a 1000-fold excess of $NaNO_2$. The products (LbP/N and LbM/N) were loaded on an analytical IEF gel and let to proceed until separation of Lbc_1 (top band) and Lb$c_2 + c_3$ (bottom band). Green nitrated derivatives were formed from the Lb-bearing heme with vinyls (LbP/N) and not from the Lb-bearing heme with ethyl groups (LbM/N). (b) Soret and visible spectra of aliquot samples of the proteins loaded on the gel. Note that LbM and LbM/N have identical spectra, whereas LbP/N is being converted to green derivatives, with a Soret band of lower intensity and a hypsochromic shift of the 625 nm charge-transfer absorption band. (c) Mass spectra of the hemes from Lb*a* reconstituted with protoheme or mesoheme and then nitrated. Note the absence of nitration (*m/z* 620) in the mesoheme (Source: from (Navascués et al., 2012) with permission).

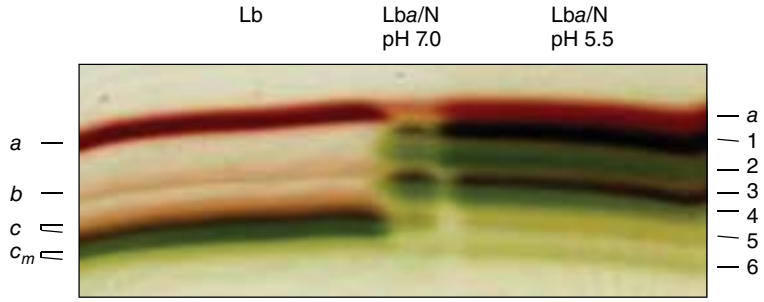

Figure 70.3 Nitration of Lb*a* and separation of the nitrated products on preparative IEF gels. *Left lane*, mixture of Lb*a*, Lb*b*, Lb*c*, and Lbc_m standards. The two Lb*c* protein bands correspond to Lbc_1 and Lb$c_2 + c_3$. *Right lane*, Lb*a* (500 µM) purified from soybean nodules was nitrated with $NaNO_2$ (500 mM) for 48 h in citrate buffer (pH 5.5), yielding six derivatives (Lb*a*N1 to Lb*a*N6). *Center lane*, a similar pattern of Lb*a*N derivatives was obtained when nitration was performed in phosphate buffer (pH 7.0) (Source: from (Navascués et al., 2012) with permission).

Typically, six Lb*a* derivatives were produced (Fig. 70.3). Lb*a*N6 was less abundant and could not be studied further. All other derivatives had pyridine hemochromes with a 580 nm band that is absent in unmodified Lbs. The ferric forms of the Lb*a* derivatives had Soret bands at 391–403 nm with shoulders at 433–436 nm, as well as a charge-transfer band at 615 nm. The Soret and RR spectra of Lb*a*N4 showed the closest match to those of Lba_m or Lbc_m, and we thus conclude that Lb*a*N4 has an identical modified heme to the modified Lbs.

All Lb*a*N derivatives had hemes with *m/z* 661 and identical MS^n fragmentation profiles. Likewise, all the apoLb*a*N derivatives were found to have a molecular mass of 15,240 Da and hence do not bear any modification in their amino acid residues. Consequently, the *in vitro* nitration of Lbs with excess NO_2^- can reproducibly generate the modified Lbs found in nodules, as well as several isomers of nitrated hemes.

70.3.4 Involvement of RNS in Heme Nitration

Both NO_2^- and NO cannot nitrate proteins directly, whereas other reactive nitrogen species (RNS) derived therefrom can do it *in vitro* and *in vivo*. These oxidant and nitrating RNS include peroxynitrite ($ONOO^-$), nitrogen dioxide (NO_2), and nitronium (NO_2^+) salts (Olah et al., 1982; Brennan et al., 2002; Nicolis et al., 2004). To investigate the nature of the RNS involved in heme nitration, *in vitro* experiments were carried out with purified soybean Lb*a*. This task is complicated because $ONOO^-$, when present as peroxynitrous acid (ONOOH), can undergo homolytic cleavage to NO_2 and hydroxyl radical ($^{\bullet}OH$), and because nitrous acid (HNO_2) can give rise to NO_2^+. Addition of 10 mM cyanide completely prevented nitration, indicating that the heme iron is participating in the reaction. To examine whether $ONOO^-$ was the nitrating agent, we used 3-morpholino-sydnonimine (SIN-1). This compound spontaneously decomposes to produce NO and superoxide anion radicals ($O_2^{-}\bullet$), which then react with each other to form $ONOO^-$. Thus, SIN-1 can mimic a slow exposure of the protein to $ONOO^-$. Incubation of Lb*a* with 0.5–1 mM SIN-1 at pH 5.5 or 7.0 for up to 4 h did not nitrate the heme, excluding any contribution of free $ONOO^-$ to nitration. Likewise, an exogenous supply of superoxide dismutase (50–100 µg) or catalase (50–100 µg) did not prevent nitration, and therefore production of $O_2^{-}\bullet$ or H_2O_2 outside the protein is not involved in the reaction. Addition of 30–100 µM H_2O_2 did not promote nitration, confirming that peroxide is apparently not required. By contrast, incubation of Lb*a* with 1 mM desferrioxamine (DFO) for 2–48 h inhibited nitration substantially (Fig. 70.4). DFO is a natural iron chelator commonly used to establish the dependence of biological reactions on free $Fe^{2+/3+}$ ions, but can also intercept free radicals (Bartesaghi et al., 2004). To gain information on the inhibitory effect of DFO and the role of metals on Lba nitration, we used ferrioxamine (FO) (1 mM), prepared by equimolar mixing of DFO and Fe^{3+} ions, and two powerful metal chelators, diethylenetriamine pentaacetic acid (1 mM), and Chelex resin (5 mg). Neither FO (Fig. 70.4) nor the other two compounds had any effect on heme nitration when added to the heme protein prior to NO_2^- and, therefore, free metal ions are involved in the reaction.

70.4 DISCUSSION

Green pigments and nitrated derivatives have been generated *in vitro* from animal and plant heme proteins. In plants, horseradish peroxidase was found to be nitrated on the vinyl groups (Wojciechowski and Ortiz de Montellano, 2007), and a green derivative of Lb was produced by the oxidative attack with H_2O_2 (Moreau et al., 1995). The latter authors proposed that the green Lb species was formed, at least in part, by heme–globin cross-linking. We failed to detect such compounds *in vivo* but instead found that the green Lbs of soybean originated by heme nitration. Spectroscopic and reconstitution analyses of the heme protein revealed that the NO_2 group is on the 4-vinyl (Fig. 70.1). The modified

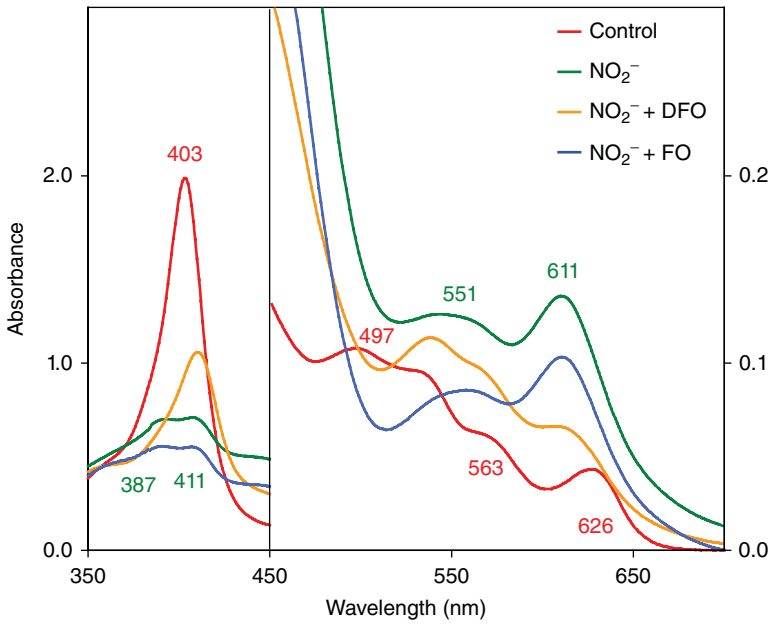

Figure 70.4 Inhibitory effect of DFO on nitration of Lb*a* after 48 h. Ferrioxamine (FO) had only a slight effect. The reaction mixtures contained 50 mM Na-phosphate buffer (pH 7.0), 150 µM Lb*a* and, where indicated, 200 mM $NaNO_2$, 1 mM DFO, or 1 mM FO. Cyanide (10 mM) formed ferric cyanocomplexes that completely suppressed nitration. By contrast, this reaction was not inhibited by addition of superoxide dismutase, catalase, diethylenetriamine pentaacetic acid, or Chelex resin. The reaction was not inhibited with 1–5 mM *p*-hydroxyphenylacetic acid, a more hydrophilic analog of Tyr, which is a good scavenger of the NO_2 radical.

Lbs were synthesized *in vitro* by exposing the proteins to excess NO_2^-. These findings are fully consistent with a study showing that nitration of the horseradish peroxidase heme occurs preferentially on the 4-vinyl rather than on the 2-vinyl (Wojciechowski and Ortiz de Montellano, 2007). Early studies had shown the presence in soybean nodules of three Lba_m derivatives with virtually identical Soret–visible spectra (Jun et al., 1994b). Here, we also found different Lba_m products from *in vitro* nitration of Lb*a* and propose that they are isomers differing in the position of the NO_2 group on the 4-vinyl, such as the α- or β-carbons and/or *cis*- or *trans*-configuration (Fig. 70.1).

To gain insights into the nature of the nitrating molecules and of the nitration mechanisms involved in the production of green Lbs, we used RNS scavengers and releasing compounds, antioxidants, and metal chelators (Figs. 70.4 and 70.5). Nitration of Lb requires binding of NO_2^- to the heme because it was inhibited by cyanide. The reaction is strongly pH dependent, which points out the implication of a nitrating agent derived from HNO_2 rather than from

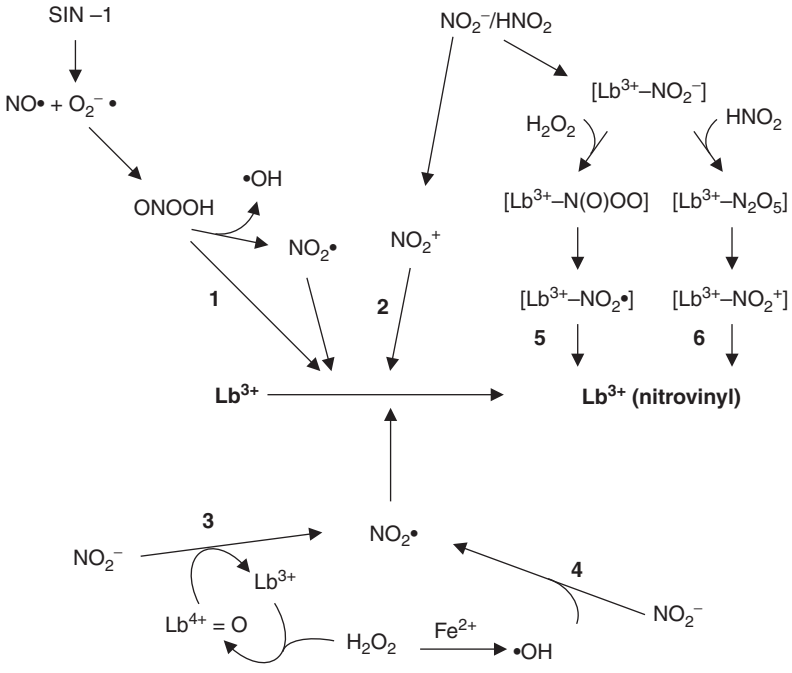

Figure 70.5 Mechanisms that may be operative in the nitration of Tyr residues and/or heme groups of Lb and other heme proteins. Experiments designed to test these pathways are described in the text. *Additional abbreviations:* Lb^{3+}, ferric Lb; Lb^{4+}=O, ferryl Lb; Lb^{3+} (nitrovinyl), ferric Lb bearing a vinyl-bound NO_2 group in the heme (Source: from (Navascués et al., 2012) with permission).

NO_2^- itself. The various mechanisms that can be potentially operative for heme or Tyr nitration in Lbs are depicted in Figure 70.5 and numbered from 1 to 6. Briefly, ***pathway 1*** requires formation of ONOOH outside the protein, but this mechanism can be excluded because SIN-1 did not nitrate the Lb heme and superoxide dismutase and catalase did not prevent nitration. ***Pathway 2*** entails an oxidative attack of Lb by NO_2^+ generated by decomposition of HNO_2 outside the protein, but this mechanism can also be excluded because addition of 1–10 mM nitronium tetrafluoroborate (NO_2BF_4) did not elicit heme nitration. ***Pathways 3*** and ***4*** involve oxidation of NO_2^- to NO_2 by ferryl Lb (formed by reaction of Lb with H_2O_2) or by $^\bullet OH$ generated *via* Fenton reactions, respectively. These mechanisms can be discarded because nitration did not need H_2O_2 and was not dependent on free metal ions. ***Pathway 4***, which is based on Fenton reactions that require free metals or free hemin, was initially proposed as an alternative to the $ONOO^-$ pathway (Thomas et al., 2002). Exogenous H_2O_2 was not required either for the nitration of horseradish peroxidase heme (Wojciechowski and Ortiz de Montellano, 2007) or for the production of NO_2-Tyr on a plant hemoglobin (Sakamoto et al., 2004). In these two cases, the nitrating agent was proposed to be NO_2 based on the peroxidase activity of the heme proteins. ***Pathways 5*** and ***6*** were recently proposed for the nitration of myoglobin (Nicolis et al., 2004; 2006) and hemoglobin (Otsuka et al., 2010) with a large excess of NO_2^-. As in our case, these two pathways require binding of NO_2^- to the heme. ***Pathway 5*** entails a subsequent reaction of the [heme–NO_2^-] complex with H_2O_2 to form a heme-bound peroxynitrite (heme–N(O)OO] species (Nicolis et al., 2004; 2006). However, ferric Lb very rapidly isomerizes $ONOO^-$ to NO_3^-, and hence ***pathway 5*** is unlikely to play a major role in Lb heme nitration (Herold and Puppo, 2005). This pathway would require formation of H_2O_2 inside the heme crevice and probably decomposition of the protonated species [heme–N(O)OOH] to NO_2. ***Pathway 6*** proposes that N_2O_5 is an intermediate (Otsuka et al., 2010). In this case, the [heme–NO_2^-] complex would react with another molecule of HNO_2 giving rise to N_2O_5, which in turn would decompose to NO_2^+ and NO_3^-. Our findings that HNO_2 is the precursor of the nitrating agent and that a [heme–NO_2^-] complex is a prerequisite for nitration are fully consistent with this hypothesis. We propose that nitration is mainly a result of an electrophilic attack on the vinyl by the NO_2^+ generated from HNO_2 inside the heme pocket according to ***pathway 6***, although we cannot discard the simultaneous formation of NO_2 by ***pathway 5*** as mentioned earlier.

The deoxyferrous and oxyferrous forms of Lb are predominant in nodules, but ferric Lb (Lee et al., 1995) and ferrous nitrosyl Lb (Lb-NO) (Mathieu et al., 1998) have been detected also in intact nodules. Ferric Lb can arise from autoxidation of oxyferrous Lb or from the reaction between NO and oxyferrous Lb, in which the heme protein would act as an NO dioxygenase producing NO_3^- (Herold and Puppo, 2005). In nodules, NO_2^- and NO are produced as a result of the nitrate reductase activities in the cytosol and bacteroids (Becana et al., 1989; Meakin et al., 2007; Horchani et al., 2011; see also Chapter 64). An NO synthase-like activity, initially reported in lupin nodules, could also be a contributing source of both RNS (Cueto et al., 1996). In soil-grown legumes, nitration reactions are likely to occur because Lb may be exposed to NO_2^- over weeks or months and because the pH decreases to 5.5 during nodule senescence (Pladys et al., 1988). The presence of a nitrovinyl in the hemes of green Lbs clearly indicates that nitrating and oxidizing RNS are produced in nodules. These reactive molecules are increasingly produced during aging or under stressful conditions. This is in agreement with the higher ratios of Lba_m to Lb*a* and of Lbc_m to Lb*c*, which were observed with advancing senescence (Wagner and Sarath, 1987). Because the green Lbs may be impaired in O_2 transport (Wagner and Sarath, 1987; Jun et al., 1994b), it will be of interest to determine whether they are generated as unavoidable by-products of Lb-mediated RNS detoxification or play physiological roles still to be discovered in legume nodules.

ACKNOWLEDGMENTS

We are very grateful to Marina Gay, Manuel Marcos, and Fei Yang for help with low-resolution MS, high-resolution MS, and NMR analyses, respectively. Thanks are also due to Hyung-Kyun Jun, Gautam Sarath, Jose F. Moran, Bob Klucas, and Fred Wagner for stimulating discussions on Lbs and hemes; Paul Ortiz de Montellano for valuable advice on Lb reconstitution; and Rafael Radi for helpful comments on protein nitration. This work was funded by MICINN-FEDER (grants AGL2008-01298 and AGL2011-24524) and Gobierno de Aragón-FSE (group A53). The LP-CSIC/UAB is a member of ProteoRed-ISCIII network.

The Role of 1-Aminocyclopropane-1-Carboxylate (ACC) Deaminase Enzyme in Leguminous Nodule Senescence

Panlada Tittabutr, Nantakorn Boonkerd, and Neung Teaumroong
School of Biotechnology, Institute of Agricultural Technology, Suranaree University of Technology, Nakhon Ratchasima, Thailand

71.1 INTRODUCTION

Leguminous plants have the ability to establish a symbiosis with a specific group of bacteria, generally called rhizobia. This interaction requires specific perception of signals between legume and *Rhizobium* to form functional organs or nodules on the host plant, in which the bacteroids fix atmospheric nitrogen and convert it to ammonium as biofertilizer for the legume plant. Thus, rhizobial inoculants can be used instead of chemical nitrogen fertilizer to reduce the cost of legume production, as well as for environment-friendly practices. The nodulation process of the legume–*Rhizobium* interaction has been fairly well elucidated. The legume–*Rhizobium* symbiosis is initiated by the release of plant flavonoids, which are a plant signal that can induce the production of Nod factor (lipochito-oligosaccharide) in specific rhizobia (Stougaard, 2000; see Chapters 50, 51). Subsequently, rhizobia enter the root hairs and penetrate the plant cortex through infection threads, while cortical plant cells are stimulated to divide and allow infection by rhizobia that develop into bacteroids surrounded by a plant-derived symbiosome membrane (Ferguson and Mathesius, 2003; see Chapter 68). To accomplish this beneficial interaction, legume plants must lower the level of plant defense mechanisms that prevent the invasion by bacteria (Colebatch et al., 2004; Shaharoona et al., 2011).

Although the overall infection process and nodule development have been studied for decades, there is little knowledge about legume nodule senescence. The senescence of nodule can be induced by developmental aging of nodules or environmental stress-induced nodule senescence. In response to nodule senescence, nitrogen fixation tends to diminish, in parallel with flowering and pod-filling stages of a plant (Bethlenfalvay and Phillips, 1977; Lahiri et al., 1993). Thus, the plant reduces the high-energy consumption by nitrogenase to provide energy for its reproductive stage. However, studies of male-sterile soybean plants that produce only 15% of the pods versus fertile controls revealed similar nitrogenase reduction rates during the pod-filling stage (Imsande and Ralston, 1982; Riggle et al., 1982). This could indicate that the supply of energy or carbon source resulting from senescence and reduced nitrogen fixation in the nodule did not contribute to pod filling. On the other hand, exogenous application of nitrogen during pod filling increases both yield and seed protein content of legumes (Merbach and Schilling, 1980). Therefore, it is possible that a delay in legume nodule senescence, extending the time of nitrogen supply to plant by nitrogen fixation, would increase the yield of legume production (Puppo et al., 2005; see Chapter 64). Thus, the process of delaying nodule senescence, caused by natural aging or by environmental stress induction, should be investigated to prolong nitrogen fixation and

biofertilizer production for legumes. In this review, the morphology, physiology, and signaling of nodule senescence, as well as the role of 1-aminocyclopropane-1-carboxylate (ACC) deaminase in the delay of nodule senescence will be summarized.

71.2 NODULE SENESCENCE

71.2.1 Morphology of Senescencent Legume Nodule

Legume nodules can be categorized into two types: determinate and indeterminate. Determinate nodules can form on soybean, mung bean, peanut, and some tropical legumes having round-shaped nodule structures because the meristematic cells, which are located in the outer cortex, are nonpersistent. The process of cell division stops during 1–2 weeks after rhizobial inoculation. Another type is indeterminate nodules, which can form with pea, alfalfa, leucaena, and many other legumes having a cylindrical-shaped nodule owing to the small meristematic cells at the tip of the nodule that are continuously dividing (Van de Velde et al., 2006). The nitrogen-fixation zone of determinate nodule occurs homogeneously in the central portion of the nodule, which is composed of the rhizobial infected cells interspersed with some uninfected cells. However, the nitrogen-fixation zone of indeterminate nodules is not homogeneously spread along the whole nodule, but instead occurs only in zone III, while zone I is the apical meristem that does not contain rhizobia, and zone II is the infection zone. Since the different types of nodules have different forms of organization, the nodule senescence pattern is also different. The senescence of determinate nodules develops radially starting from the central area and slowly spreads from the center to the periphery after a few weeks, while the senescence of indeterminate nodule occurs in zone IV that is located proximal to zone III in the mature nodule. The symbiotic relationship is lost in the senescence zone or zone IV of indeterminate nodules and then zone V develops proximal to the senescence zone. There is no presence of symbiosome features in this zone, while the rhizobia are converted to saprophytic intracellular rhizobia (Timmers et al., 2000; Puppo et al., 2005).

Senescence of legume nodules is visible by a color change in the nitrogen-fixation zone. Since the leghemoglobins decline when the nodule is entering the senescence stage, the pink color of the nitrogen fixation zone that is associated with functional leghemoglobin protein will change to a green color in indeterminate nodule due to the degradation of the heme moiety in leghemoglobin (Roponen, 1970). It is similar to determinate nodules, in which the color of symbiosome changes from a pink color to a gray color as shown in Figure 71.1a. Moreover, changes on the cellular level are also observed. It has been reported that

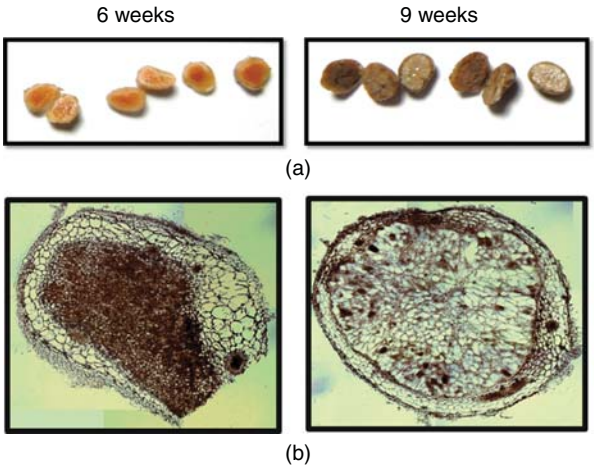

Figure 71.1 Root nodule of mung bean (*Vigna radiata* SUT1) observation at 6 and 9 weeks after inoculation. (a) Observation of symbiosome color change. (b) Observation of micromorphology under light microscope.

in senescent nodules, a wide range of proteolytic enzymes are triggered that cause a variety of nodule protein degradation processes, and the cytoplasm becomes less electron dense in the indeterminate nodule of *Medicago* (Pladys and Vance, 1993; Andreeva et al., 1998; see Fig. 71.1b). Moreover, the appearance of vesicles and some membranes occurs inside the senescence nodule, leads to disintegration of host and symbiosome membrane (Timmers et al., 2000; Van de Velde et al., 2006), and finally causes the death of bacteroid and legume nodule cells. Similar to determinate nodules, the senescence of common bean (*Phaseolus vulgaris* L.) nodules shows the collapse of the infection zone, degradation of membrane and cell walls, changes in the number and distribution of starch granules, appearance of protein granules, and disintegration of the central tissue of the nodule (Fernández-Luqueño et al., 2008). Moreover, the number of peroxisomes increases and mitochondria form elongated structures. The symbiosome membrane appears to be the target for degradation during the early senescence process. However, senescence does not occur homogeneously throughout the nodule in determinate nodules (Puppo et al., 2005). Figure 71.1 shows the determinate-type root nodule of mung bean (*Vigna radiata* SUT1) at 6 and 9 weeks after bradyrhizobial inoculation. The senescence nodule at 9 weeks shows a reduced density of symbiosomes and disintegration of the tissue inside the nodule. These nodule senescence morphologies are accompanied with a decrease in nitrogen fixation. Therefore, it is necessary to understand the signals or factors that trigger or are involved in the initiation of nodule senescence in order to extend the period of active nitrogen fixation by delayed nodule senescence and finally the improvement of yield or nitrogen content in the seed. There are two common processes of nodule

senescence, one is developmental nodule senescence and the other is stress-induced nodule senescence. However, the knowledge of nodule senescence has been mostly elucidated with indeterminate-type nodules, and data are still fragmentary at the subcellular level. In this review, we attempt to integrate these data and propose a model for the nodule senescence process.

71.2.2 Developmental Nodule Senescence

As a result of nodule development, large amounts of reactive oxygen species (ROS), such as hydrogen peroxide (H_2O_2) and superoxide radicals (O_2^-), are produced and accumulate in the nodule due to the high rate of respiration of bacteroids and mitochondria in indeterminate-type nodule (Groten et al., 2005; see Chapter 29). However, the nodule contains a strong antioxidant defense capacity, as well as a high concentration of ascorbate and reduced glutathione (Becana et al., 2000; Matamoros et al., 2003). The nodule also has high activities of antioxidant enzymes, such as superoxide dismutase, catalase, peroxidase, and enzyme for the ascorbate-glutathione cycle (ascorbate peroxidase, dehydroascorbate reductase, monodehydroascorbate reductase, and glutathione reductase) (Dalton et al., 1986; Gogorcena et al., 1995; Escuredo et al., 1996). This strong antioxidant system is very important for nodule development in order to scavenge the ROS that could reduce the efficiency of nitrogen fixation by the bacteroids. The role of antioxidants in controlling the redox state of the nodule has also been reported in determinate-type nodule. The activity of enzymes of the ascorbate-glutathione cycle and the level of glutathione are important for nitrogen fixation during soybean nodule development (Evans et al., 1999). The exogenous supply of ascorbate to soybean roots was found to increase nodule number and nitrogenase activity (Bashor and Dalton, 1999). Thus, the antioxidant system is needed to maintain the functional nitrogen-fixating nodule during nodule development.

Once aging of the nodule progresses, the nitrogen-fixation efficiency is decreased in parallel with a decrease in the levels of ascorbate and glutathione in the nodule (Groten et al., 2005). Ascorbate has an important role in the regulation of the plant mitotic cell cycle, which is related to cell growth (Potters et al., 2004). Thus, reduction of the ascorbate content may indicate the decline of nodule functioning during aging. On the other hand, glutathione may influence the redox regulation of transcription factors and the protection of DNA against oxidative damage (Matamoros et al., 2013). Thus, a reduction of ascorbate and glutathione may create oxidative stress, which is frequently associated with plant senescence and leads to cell death. Matamoros et al. (2013) also confirm the importance of ascorbate and glutathione in nodule senescence at the subcellular level. They found that the marked decline in glutathione reduced the capacity to regenerate ascorbate and also upregulated the alternative oxidase and manganese superoxide dismutase in the mitochondria of common bean nodule (*P. vulgaris* L. cv Contender) during early senescence. The early decrease in glutathione in mitochondria in mature nodules may be due to degradation by age (Clemente et al., 2012). Thus, nodule mitochondria are an early target of oxidative modifications, which produce oxidized lipids and proteins, and these molecules may act as signal molecules for the aging process (Matamoros et al., 2013). The occurrence of oxidative stress in aging nodules has been found in soybean (Evans et al., 1999), lupin (Hernandez-Jimenez et al., 2002), and bean (Loscos et al., 2008). However, the accumulation of oxidative stress due to H_2O_2 and ROS is not observed in pea nodules (Groten et al., 2005). Thus, it is possible that there may be some variations in the mechanism of nodule senescence induction in different species of legumes (Puppo et al., 2005). In addition, Matamoros et al. (2013) reported the presence of methionine sulfoxidation (MetSO) as important for regulation of glutamine synthetase (GS) in response to ROS. This posttranslational inactivation of GS may be a direct link between the decline in nitrogen-fixation efficiency and ammonia assimilation in the senescence nodule.

Not only ROS inactivates GS during nodule senescence, but also nitric oxide (NO) may play an important role in the senescence process of determinate nodules, such as soybean (Navascues et al., 2012) and *Medicago truncatula* (Cam et al., 2012; see Chapter 64). It has been reported in *M. truncatula* that NO may be produced by plant nitrate reductase and the mitochondrial electron transport chain (ETC) especially during aging of legume nodules (Horchani et al., 2011). Moreover, denitrification carried out by the bacteria is also a probable source of NO in nodules, but may vary with the bacterial species (Meakin et al., 2007; Sanchez et al., 2010; Horchani et al., 2011). The molecular target of NO in root nodules is GS (Melo et al., 2011). Thus, an increase in NO level could lead to GS inhibition and a subsequent decrease in ammonium assimilation by the plant, leading to nodule senescence. Bacterial proteins may also be targets of NO. Nitrogenase from soybean root nodules has also been shown to be inhibited by NO (Trinchant & Rigaud, 1982; Shimoda et al., 2009; Kato et al., 2010).

In view of the hormonal regulation of nodule senescence, abscisic acid (ABA) has been recognized as an important signal in several types of senescence (Hunter et al., 2004; Buchanan-Wollaston et al., 2005). A lower carbon supply from the plant together with high N-metabolite availability decreases the carbon-to-nitrogen ratio inside nodule. This sugar/N change can be sensed and transduced by an ABA-mediated signaling pathway followed by the activation of the proteolytic activities (Puppo et al., 2005). The increase in nodule ABA activates key proteinase enzymes that are intrinsic to macromolecule degradation during the senescence process. It has been found that the

most abundantly expressed genes during *M. truncatula* nodule senescence are four cysteine (Cys) proteinases (Van de Velde et al., 2006). This family of proteinases is also synthesized in legume and actinorhizal nodules, especially during senescence (Goetting-Minesky and Mullin, 1994; Asp et al., 2004). However, it was found recently that the endoproteinase activity during the senescence of common bean (*P. vulgaris* L. cv Contender) nodules is mainly due to serine proteinases, rather than cysteine proteinases (Matamoros et al., 2013). Another hormone that plays an important role as a part of a signal transduction pathway is ethylene. At early stages of *M. truncatula* nodule senescence, two genes encoding transcriptional factors belonging to the *APETALA/ETHYLENE RESPONSE FACTOR (AP2/ERF)* family were expressed (Van de Velde et al., 2006). These genes are known to be involved in development and disease resistance, as well as in stress responses (Kirch et al., 2003; Gutterson and Reuber, 2004; Yi et al., 2004). Moreover, the upregulation of ERF transcription factors and ethylene biosynthetic genes, such as *S*-adenosyl-Met (SAM) synthetase and 1-aminocyclo-propane-1-carboxylate oxidase, has also been observed in nodule senescence (Van de Velde et al., 2006). The presence of ethylene is usually associated with the induction of ROS signaling to regulate the damaging of cell (Kunkel and Brooks, 2002). There is also cross talk between sugar and N-signaling pathways with ethylene and ABA hormones during the nodule senescence process. It has been found that genes involved in ABA synthesis and signaling and also in ethylene perception are sensitive to sugar and nitrate signaling (Arenas-Huertero et al., 2000; Signora et al., 2001). The lower sugar supply from the plant may activate an increase in ethylene. Therefore, ABA and ethylene may work together in the nodule to activate the senescence process (Puppo et al., 2005). The summary of signaling and the molecules that interact during developmental nodule senescence are presented in Figure 71.2.

71.2.3 Stress-Induced Nodule Senescence

Stress-induced nodule senescence shares several characteristics with aging or developmental nodule senescence, including the decline in N_2 fixation, leghemoglobin, and antioxidant enzymes, as well as the oxidative damage of cell components (Evans et al., 1999; Matamoros et al., 1999; Hernandez-Jimenez et al., 2002; Loscos et al., 2008). However, stress induces nodule senescence development faster than developmental senescence and also presents features of oxidative stress and plant cell death (Puppo et al., 2005). Various types of stress can trigger nodule senescence, such as darkness, water deficiency, salt stress, and cadmium contamination (Gogorcena et al., 1997; Gonzalez et al., 1998; Matamoros et al., 1999; Salah et al., 2013; Balestrasse et al., 2004). As shown in Figure 71.2, stress conditions trigger ethylene production in the plant preceding the senescence in legume nodule. Ethylene is involved in seed germination, root hair development, root nodulation, flower

senescence, abscission, and fruit ripening. The production of ethylene is tightly regulated by internal signals during development and in response to environmental stresses. It has been reported that ethylene plays a role in the onset of salt-induced senescence in tomato (Ghanem et al., 2008). Ethylene acts as a signal to activate ROS, which are generated by plant cells in response to abiotic and biotic stresses (Moller et al., 2007). ROS are toxic and able to react with several molecules inside the cell resulting in senescence and cell death (Rivero et al., 2007). The redox state controls nodule metabolism. The decrease in N_2 fixation under abiotic stress is correlated with the decline in antioxidant defense and an increase in ROS levels that lead cells to an oxidative state in senescencing nodule (Gogorcena et al., 1997; Jebara et al., 2005). This correlation is established during both developmental and stress-induced nodule senescence. Another important signaling molecule NO has been observed in the developmental aging of lupin nodules (Evans et al., 1999; Hernandez-Jimenez et al., 2002) and also in stress-induced nodule senescence (Escuredo et al., 1996; Gogorcena et al., 1997; see Chapter 64). An increase in endogenous NO levels leads to a decrease in nitrogen fixation and early nodule senescence. Since NO regulates several physiological processes by affecting gene transcription (Ferrarini et al., 2008; Moreau et al., 2011), it can be hypothesized that NO regulates the expression of genes involved in the senescence program (Cam et al., 2012; see Chapter 64). These signaling molecules, such as ethylene, ROS, and NO, show a relationship between developmental and stress-induced nodule senescence processes (Fig. 71.2). Thus, a lower level of these signaling molecules may delay natural or stress-induced legume nodule senescence, and finally lead to increased nitrogen fixation as well as legume yield. The roles of bacteria-containing ACC deaminase in order to alleviate ethylene production during plant stress and delay nodule senescence are focused on in this review.

71.3 ETHYLENE STRESS AND ACC DEAMINASE ENZYME ACTIVITY IN SYMBIOSIS AND NODULE SENESCENCE

Ethylene is rapidly synthesized in response to external stresses. This kind of ethylene is called stress ethylene, which induces the expression of many stress-associated gene responses (O'Donnell et al., 2001; Saleem et al., 2007). Moreover, it has been reported that ethylene acts as a negative regulator of nodulation in legume plants (Ding and Oldroyd, 2009; Lohar et al., 2009). The exogenous application of ethylene or ethylene-releasing compounds causes abortion of infection threads and suppression of nodulation in legumes (Valverde and Wall, 2005; Tirichine et al., 2006), while application of ethylene inhibitors such as aminoethoxy vinyl glycine (AVG) or silver thiosulfate (STS) increases nodule number (Oldroyd et al., 2001; Tamimi and Timko, 2003), as well as reduces ethylene emission during growth under stress conditions, such as high concentration of nitrate, salt stress, high temperature, and water deficiency (Mann et al., 2002; Tittabutr et al., 2013). However, high concentrations of an ethylene inhibitor cause plant cell damage. Thus, an appropriate concentration of ethylene inhibitor must be used to control the level of ethylene in plant cells, which varies depending on plant species and type of stress condition. Nevertheless, it was found that not all legume species respond to ethylene. Tittabutr et al. (2013) found that mung bean (*V. radiata*) is the most responsive among tested legume species, as well as yard long bean (*V. sinensis*), common bean (*P. vulgaris* L.), and peanut (*Arachis hypogaea* L. Tainan 9). Different varieties of mung bean also respond differently to STS. These observations suggest that the level of ethylene in plant cells is a key factor that influences the nodulation process. Lower level of stress ethylene promotes nodulation as well as plant growth under stress condition.

In the ethylene synthesis pathway, ACC is a precursor. ACC is converted to ethylene by ACC oxidase in higher plant (Yang and Hoffman, 1984; Contesto et al., 2008). Therefore, production of ethylene in plants is directly related to the level of ACC inside the plant tissue. An enzyme that can degrade ACC is ACC deaminase, which is found in bacteria, fungi, and plants (Glick 2005). ACC deaminase catalyzes a cleavage of the cyclopropane ring and leads to the deamination of ACC to α-ketobutyrate and ammonia. At the protein-structure level, ACC deaminase is a multimeric enzyme with a monomeric subunit (molecular mass of approx. 35–42 kDa). It is a sulfhydryl enzyme that utilizes pyridoxal 5-phosphate as a cofactor. Several D-amino acids, such as D-serine and D-cysteine can act as substrates for ACC deaminase, but less efficiently than ACC, while L-serine and L-alanine are effective competitive inhibitors of the enzyme (Glick 2005). ACC deaminase is an intracellular enzyme, which is localized within the cytoplasm (Jacobson et al., 1994). ACC is exuded by plant tissues (Penrose et al., 2001; Penrose and Glick, 2001; Grichko and Glick, 2001) and is taken up by the ACC deaminase-containing microbes (Glick et al., 1998).

ACC deaminase has been detected in several bacteria. However, the activity and regulation of this enzyme are different. The well-known ACC deaminase-producing bacteria *Pseudomonas putida* UW4 (previously *Enterobacter cloacae* UW4) produces ACC deaminase activity equal to 20.48 μmol α-ketobutyrate/mg protein/h (Ma et al., 2003), while other bacteria usually produce low ACC deaminase activity. Some species of rhizobia also have ACC deaminase activity, but the activity level and gene regulation vary significantly in different strains (Duan et al., 2009; Nikolic et al., 2011). Transcriptional regulation of the *acdS* gene

encoding ACC deaminase has been elucidated in *E. cloacae* UW4. The DNA sequence analysis revealed the presence of an *acdR* gene located upstream of the ACC deaminase structural gene (*acdS*) in the opposite direction. The *acdR* encodes an ACC deaminase regulatory protein that has high similarity with a leucine-responsive regulatory protein (LRP). The DNA sequences between *acdS* and *acdR* genes contain several features that are involved in regulation of *acdS* transcription including half of a cAMP receptor protein (CRP)-binding site, an FNR (fumarate-nitrate reduction) regulatory protein-binding site (see Chapter 15), and LRP-binding site (Grichko and Glick, 2000). The expression of *acdR* is under the control of a stronger promoter than the one responsible for transcription of *acdS*. The LRP encoded by *acdR* is recognized as a global regulatory protein, which controls the transcription of genes through the induction of DNA bending, and it is required for *acdS* expression. Moreover, the expression of *acdS* requires ACC to induce transcription. The expression of *acdS* is increased under anaerobic condition, which coincides with the presence of FNR-like regulatory protein box (Li and Glick, 2001). On the other hand, the transcription of *acdS* in *Mesorhizobium loti* MAFF303099 and *B. japonicum* USDA110 is under the control of NifA (Uchiumi et al., 2004; Kaneko et al., 2002). Thus, the pattern of gene organization and transcriptional regulation of the *acdS* gene in different bacteria may result in different levels of ACC deaminase activity.

High ACC deaminase activity has been found to be associated with higher nodulation ability. For example, *R. leguminosarum* containing a higher ACC deaminase activity has been found to be more efficient for pea nodulation (Ma et al., 2003). Similarly, *Sinorhizobium meliloti* containing the ACC deaminase gene (*acdS*) derived from *R. leguminosarum* also showed increased ability to nodulate alfalfa (Ma et al., 2004). Uchiumi and colleagues (2004) showed that inactivation of the *acdS* gene in *M. loti* resulted in a reduced number of nodules on *Lotus japonicus*, compared to the number of nodules formed by the wild-type strain. Tittabutr et al. (2008) evaluated the effect of ACC deaminase on nodulation and growth of *Leucaena leucocephala*. The *acdS* genes were cloned from *Rhizobium* sp. TAL1145 and *Sinorhizobium* sp. BL3 in multicopy plasmids and were transferred to TAL1145. The BL3-*acdS* gene greatly enhanced ACC deaminase activity in TAL1145 compared to the native *acdS* gene. The resulting transconjugants of TAL1145 containing the native and BL3-*acdS* genes formed greater (in number) and bigger nodules and yielded higher root mass on *L. leucocephala* than TAL1145. This result suggests a role for ACC deaminase activity in legume–*Rhizobium* nodulation. Co-inoculation of legumes with rhizobia plant growth-promoting rhizobacteria (PGPR) containing ACC deaminase has also proven to promote nodulation under both normal and environmental stress conditions. Moreover, it was recently found that co-inoculation of mung bean (*V. radiata*) with *Bradyrhizobium* sp. and *Chryseobacterium* sp. ACC3 reduces ethylene production and leads to enhanced nodulation and plant growth under salt stress, water deficiency, and high-temperature stress conditions. Interestingly, the expression of *acdS* of isolate ACC3 was differentially induced when cultured in medium under different stress conditions (Tittabutr et al., 2013). The strong correlation of inducing ACC deaminase activity under stress condition and its activity to reduce the ethylene production in plant suggests that PGPR or rhizobia that produce ACC deaminase should delay senescence of nodules.

Since ethylene is one of important signals that induce both developmental and stress-induced nodule senescence, lower ethylene production in plants after inoculation with rhizobia-containing ACC deaminase may be a way to delay nodule senescence, leading to an increased yield in nodulated legumes. The role of ACC deaminase in nodule senescence has recently been supported by the results of inoculation of mung bean with the mutant of *Sinorhizobium* sp. BL3 defective in ACC deaminase activity (*acdS*$^{-}$), as compared with the transconjugant of BL3 containing *acdS* gene on a high copy number plasmid. The results showed that a defect in ACC deaminase activity affected the nodulation process, plant growth, and nodulation competition negatively, while BL3 with a high copy number of the *acdS* gene delayed nodule senescence when compared with the wild-type strain (unpublished data). As proposed in Tittabutr et al. (2008), increasing ACC deaminase activities in the nodule should decrease ethylene production. It is expected that lowering of ethylene in the root should enhance infection thread elongation and nodule formation in legumes. Enhancing ACC deaminase activities in *Rhizobium* bacteroids inside the nodules reduces ethylene biosynthesis and consequently promotes nodule development (Fig. 71.3). Although it is difficult to assess the effects of increased ACC deaminase activities on nodule senescence and maintenance using indeterminate-type nodules, the effects of increased symbiotic ACC deaminase activities are more visible in mung bean, which produces determinate-type nodules that senescence entirely after a fixed period of nitrogen fixation (unpublished data). Reducing ethylene production may help in nodule maintenance by delaying senescence. These possible benefits associated with enhanced ACC deaminase activities in the nodule should result in an increase in nitrogen fixation and better plant growth promotion.

71.4 CONCLUSION

The senescence of nodules can occur as developmental aging of nodule or environmental stress-induced nodule senescence. In response to nodule senescence, the nitrogen fixation tends to reduce in parallel with damaging of the nodule cell structure through macromolecule degradation. Ethylene plays an important signal for induction of nodule

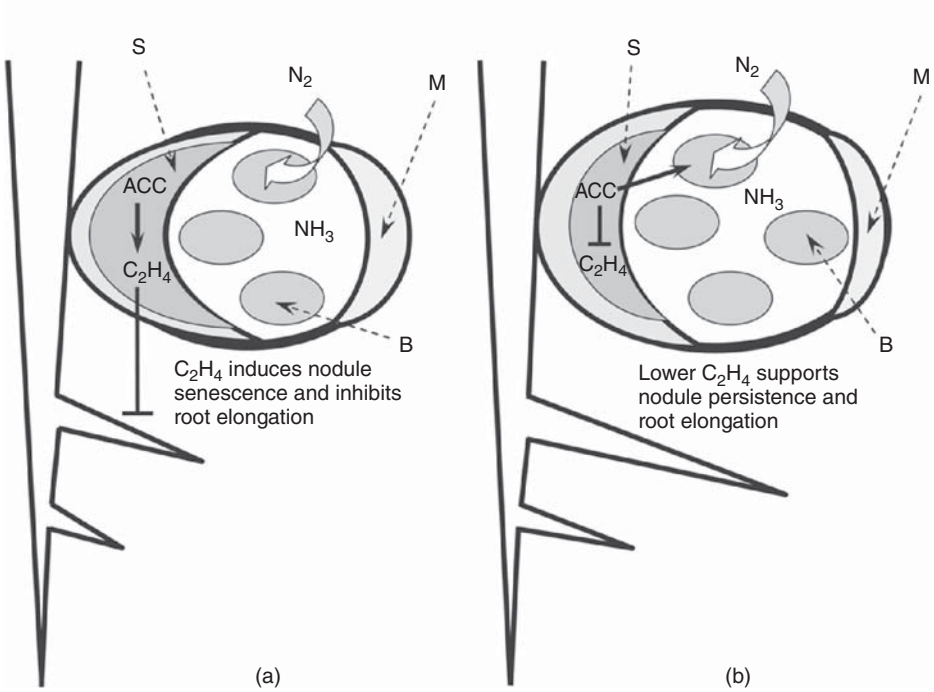

Figure 71.3 Schematic representation of leucaena nodules formed by AcdS$^-$ (a) and AcdS$^+$ (b) rhizobia, highlighting the possible effects of increased ACC deaminase activities on nodule senescence. Ethylene production in nodules formed by AcdS$^+$ rhizobia may be reduced due to ACC deaminase activities. As a result, AcdS$^+$ rhizobia may form bigger nodules with relatively smaller senescence zone and larger nitrogen-fixing bacteroid zone. The increased root size of leucaena seedlings inoculated with AcdS$^+$ rhizobia may be caused by either increased nitrogen fixation by AcdS$^+$ bacteroids or direct sequestering of ACC from the growing roots by AcdS$^+$ rhizobia on the root surface. B, bacteroid; M, meristematic zone; S, senescence zone (Tittabutr et al., 2008).

senescence in both developmental and stress-induced nodule senescence processes by triggering ROS formation and creating an oxidative state inside the cell, leading to accumulation of oxidized biomolecules that activate the aging process. Thus, it is possible to achieve delay of legume nodule senescence by using the strategy of inoculation ACC deaminase-containing rhizobia to reduce the ethylene production during plant growth under both normal and environmental stress conditions. Delayed nodule senescence should extend the time of nitrogen supply to plant by nitrogen fixation and finally increase the yield of legume production.

72.1 INTRODUCTION

The rhizobia are soil organisms that establish a highly successful diazotrophic symbiosis with legumes (see Chapter 4). This symbiosis is critical for agriculture, for the global *N* cycle in general and for modern agriculture in particular (see Chapter 5). One of the key aspects of this symbiosis is its specificity: specific rhizobia nodulate and fix nitrogen in specific legume hosts. The molecular bases for this specificity have been unraveled throughout the last 30 years (see Sections 9 and 10). However, this specificity is not absolute. Some tropical legumes are quite broad in their specificity requirements and are promiscuously nodulated by a large number of different rhizobial species and genera (e.g., *Phaseolus*, siratro, cowpea, or *Leucaena* (Bromfield and Barran, 1990; Perret et al., 2000; Martinez-Romero, 2003; Lima et al., 2009; Cardoso et al., 2012)). Conversely, some rhizobia are able to establish symbioses with very different plants. This is the case of *Sinorhizobium* sp. NGR234 (Stanley and Cervantes, 1991; Pueppke and Broughton, 1999; Perret et al., 2000; see Chapter 32), which uses multiple sets of nodulation and symbiotic genes (Freiberg et al., 1997). Other rhizobia, such as *Sinorhizobium meliloti* (Andronov et al., 1999; Ballard et al., 2005) or *Bradyrhizobium japonicum* (Oh et al., 2000; Koch et al., 2010; Lindemann et al., 2010) can nodulate different hosts depending on a specific genetic complement, often uncovered after mutant screening or isolation of specific strains that are symbiotically active with just some of the hosts.

More subtle mechanisms of adaptation to a given host may be at work in those cases when all (or most) of the isolates of a given rhizobial species can effectively establish a diazotrophic symbiosis with plants of several different genera, often from different habitats and with different lifestyles. This may be the case for *Rhizobium leguminosarum* bv. viciae. Isolates belonging to this biovar establish effective symbioses with legumes belonging to four genera: *Pisum*, *Lens*, *Lathyrus*, and *Vicia*. The last genus, in particular, includes species as diverse as vetch (*V. sativa*) and broad bean (*V. faba*). One set of nodulation and nitrogen-fixation genes, harbored on a symbiotic plasmid, allows successful establishment and development of symbiosis with the different hosts (Surin and Downie, 1989) and, in cross-inoculation experiments, when challenged with any one of the above legume hosts, any *R. leguminosarum* bv. viciae strain is able to establish an efficient symbiosis. However, it has long been hypothesized that different

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

rhizobial strains may be more adapted to a specific plant host than others, which may result in selection and enrichment of a specific strain or set of strains by the legume host from those present in a particular soil (see Chapter 19). Evidence for plant-mediated selection of specific rhizobial genotypes from soil populations has been obtained by the Laguerre (Louvrier et al., 1996; Laguerre et al., 2003; Depret et al., 2004) and Young (Palmer and Young, 2000; Mutch and Young, 2004) groups. By using molecular markers and specific polymerase chain reaction (PCR) amplification, these researchers have provided evidence that different plant hosts enrich specific genotypic marker variants of *R. leguminosarum* bv. viciae from those available in the soil.

These studies, however, were necessarily limited by the number and nature of the markers selected, and did not shed any light on the selective forces that might determine the enrichment of a specific genotype. The quick development and widespread availability of cost-effective, next-generation sequencing technologies prompted us to reappraise this problem using genomic and metagenomic approaches. In doing so, we were able to establish a set of methodologies for the genomic study of natural rhizobial populations that may find wider applicability in other systems and problems. In this chapter, we describe these methodologies using the specific problem of *R. leguminosarum* bv. viciae genotype selection by the legume host as an example.

72.2 GENOMICS OF RHIZOBIA

After the ground-breaking reports on genome sequencing of model rhizobia: *Mesorhizobium loti* (Kaneko et al., 2000), *S. meliloti* (Barnett et al., 2001; Capela et al., 2001; Galibert et al., 2001), *B. japonicum* (Kaneko et al., 2002), *Rhizobium etli* (Gonzalez et al., 2006), and *R. leguminosarum* (Young et al., 2006), a very large number of rhizobial genomes have been sequenced or are in the process of being sequenced (as many as 263 complete or ongoing genome sequence projects in GOLD, the Genomes OnLine Database – http://www.genomesonline.org, as of April 30, 2013, and over 300 if members of the related *Agrobacterium* genus are included). Although data are still quite recent, several general conclusions on the structure and organization of rhizobia emerge. In general, the rhizobia contain very large genomes, up to *circa* 9 Mb in the case of *Bradyrhizobium* sp. These are the largest proteobacterial genomes, and are among the largest prokaryotic genomes after those of other soil bacteria, such as members of the myxobacteria and actinobacteria (10–12 Mb). The symbiotic region of *B. japonicum*, however, clusters within a genomic island of just *circa* 410 kb (Gottfert et al., 2001). The genomes of other relevant genera (*Rhizobium, Sinorhizobium*) are also very large (*circa* 7 Mb). The occurrence of very large genomes in soil bacteria has been interpreted as an adaptation to this habitat, a complex, hostile, and changing environment that demands the large metabolic and behavioral plasticity that can be provided by a large gene-encoding capacity. Contrary to members of the genus *Bradyrhizobium*, both *Sinorhizobium* and *Rhizobium* present a multipartite genome, harboring several large plasmids, some of which resemble chromosomes ("chromids" (Harrison et al., 2010; see Chapter 26)). On average, 30–40% of the genome in these bacteria is present in the form of plasmids (Galardini et al., 2013; Harrison et al., 2010; Mazur et al., 2011). This characteristic, shared with the *Roseobacter* clade (Petersen et al., 2013), affords a large genomic plasticity, given that many of these plasmids incorporate conjugative systems (Crossman et al., 2008), and liberates these bacteria from the constraints of long replication times associated with a single, very large chromosome.

72.3 METAGENOMICS

Next-generation sequencing approaches can be also applied to the study of the genomic contents of specific environments without the need to isolate or cultivate the organisms therein. This has resulted in unprecedented opportunities to reveal the role and nature of the "hidden majority" in the microbial world and in the development of the discipline of metagenomics (Riesenfeld et al., 2004; National Academy of Sciences, 2007), a term first coined 15 years ago (Handelsman et al., 1998). Since then, metagenomics has revolutionized Environmental Microbiology as an emerging approach that aims to understand the genomic potential of an entire microbial community present in a complex ecosystem (National Academy of Sciences, 2007; Guazzaroni et al., 2009; Morales and Holben, 2010; Simon and Daniel, 2011; de Bruijn, 2011a,b).

Recent technical advances that resulted in cost-effective, massive sequencing technologies and the development of specific bioinformatics tools for the analysis of metagenomic data have increased the number of metagenomic sequencing projects. As of April 30, 2013, the MetaGenomics Rapid Annotation using Subsystem Technology (MG-RAST) Server (http://metagenomics.anl.gov) holds 358 public projects and over 12,000 datasets, totaling over 53 billion sequences (circa 5.5 Tb), with an average metagenome size of 2.3 Gb per dataset.

72.4 SOIL METAGENOMICS AND THE RHIZOBIA

Soil microbial communities have the highest level of prokaryotic diversity, and it is estimated that 1 g of soil can contain up to 10^9 microorganisms (Knietsch et al.,

2003; Delmont et al., 2011b). Metagenomic approaches would appear to be the ideal approximation to study such a complex system. However, even metagenomics is faced with limitations that arise precisely from this complexity. On the one hand, the sheer size of these datasets severely limits our ability to analyze them (Delmont et al., 2011b, 2012; Lombard et al., 2011; Jansson, 2012). On the other hand, soil is an environment that changes rapidly not only temporally but also spatially, even at the microlevel, and its physicochemical properties affect microbial distribution within the soil matrix, which imposes serious technical and methodological problems (Delmont et al., 2011a, 2012; Lombard et al., 2011). Despite these caveats, metagenomics constitutes a powerful approach to obtain information about the nature, composition, and function of microbial communities in soil.

The specificity of the *Rhizobium*–legume symbiosis has traditionally allowed the use of most probable number (MPN) techniques to enumerate soil rhizobia that are able to nodulate trap plants (Brockwell, 1963; Vincent, 1970). In the past years, numerous field studies that include an estimation of symbiotically proficient *Rhizobium* populations have been carried out with different trap plants. For *R. leguminosarum* bv. viciae, representative abundances are as follows (per gram of soil): Eastern France, $0.2{\cdot}10^2$–$1.2{\cdot}10^5$, with pea plants (Louvrier et al., 1996; Depret et al., 2004); Northeastern Germany, 1.4–$8{\cdot}10^4$, with *V. hirsuta* trap plants (Lakzian et al., 2002); Spain, 10^4–10^5, with *Pisum sativum* (our unpublished data); South Australia, 0–$3.2{\cdot}10^4$ (Ballard, 2004) or 0–$7.4{\cdot}10^4$ (Drew et al., 2012) both with *P. sativum* as trap plant. Louvrier and collaborators developed a semiselective medium to isolate *R. leguminosarum* directly from soils (Louvrier et al., 1995). The numbers they obtained in soils from Eastern France were circa 10^4 per gram of soil. Overall, it can be concluded that, although cultivation of the plant host results in an increase in rhizobial soil counts (albeit modest for *R. leguminosarum* (Kucey and Hynes, 1989; Hirsch, 1996)), established soil populations of *R. leguminosarum* are, at most, on the order of 10^4–10^5 per gram of soil. If typical soils are estimated to contain 10^9 bacteria per gram of soil (Knietsch et al., 2003; Delmont et al., 2011b), *R. leguminosarum* would amount to, at most, 0.01% of the total soil microbiota. In practical terms, this implies that even in one of the largest metagenomic datasets (circa 1 Tb), at most 100 Mb would be *R. leguminosarum* DNA. This, barring the crucial problem of how to specifically identify these sequences, would represent at most a 15× coverage of a single *R. leguminosarum* genome and would barely be the representative of the population diversity. Thus, the low natural abundance of rhizobia in soils precludes the use of purely metagenomic methods to study their diversity and demands an alternative approach.

72.5 THE POOL-SEQ APPROACH TO STUDY RHIZOBIAL POPULATIONS

Kofler and collaborators, working with *Drosophila melanogaster* populations, proposed for the first time the Pool-Seq term in 2011 for the next-generation sequencing and analysis of pooled DNA samples from natural populations. It constitutes a cost-effective (and hence feasible), genome-wide approach for comparison of population samples, thus allowing an easy scaling from the limitations of single markers to population genomics (Futschik and Schloetterer, 2010; Kofler et al., 2011a,b).

We reasoned that sequencing pooled DNA samples from *R. leguminosarum* bv. viciae nodule isolates obtained from different legume plant hosts used as rhizobial traps would allow an experimental test of the hypothesis that different plant hosts select specific subpopulations of rhizobia from the available population present in a given soil. We compared two nodule populations (*P. sativum* and *V. faba*) originating from the same agricultural soil. Each subpopulation contained 100 isolates that were grown independently. They were adjusted to the same optical density, strains from the same host were pooled, and genomic DNA from the pooled culture was extracted (Wilson, 2001). Genomic DNA from each pool was sequenced (Illumina Hi-Seq 2000, 180 bp PE libraries, 100 bp reads, 12 Mreads) at BGI (Hong Kong and Shenzhen, China).

In analyzing rhizobial Pool-Seq data, two specific considerations must be taken into account.

First, plant-specific subpopulations derive from the same unselected, resident soil population, whose genomic composition is, by definition, unknown, since their low numbers preclude any unselected genomic analysis. It is likely that this resident population contains both major and minor genomic types, resulting both from the soil's edapho-climatic properties and from its agricultural history. Thus, specific selection by the legume host will operate – if it does – on this original composition which, although distorted by the plant effect, will still be present in the plant-specific isolates.

Second, the large size and the multipartite composition of the *R. leguminosarum* genome (see earlier) favor both an open pan-genome and a large nonconserved (auxiliary or accessory) genome (Gonzalez et al., 2010; Lozano et al., 2010; Bailly et al., 2011). With *R. leguminosarum* bv. viciae, it has been estimated that 20–30% of the genes are strain specific (our unpublished results). This suggests that plant host selection of specific rhizobial genotypes may implicate specific genes or groups of genes (e.g., transport and metabolism of substrates). However, identification of these genes from Pool-Seq data is technically complex, since any DNA assembly will result, necessarily, in the formation of chimeras with no biological meaning.

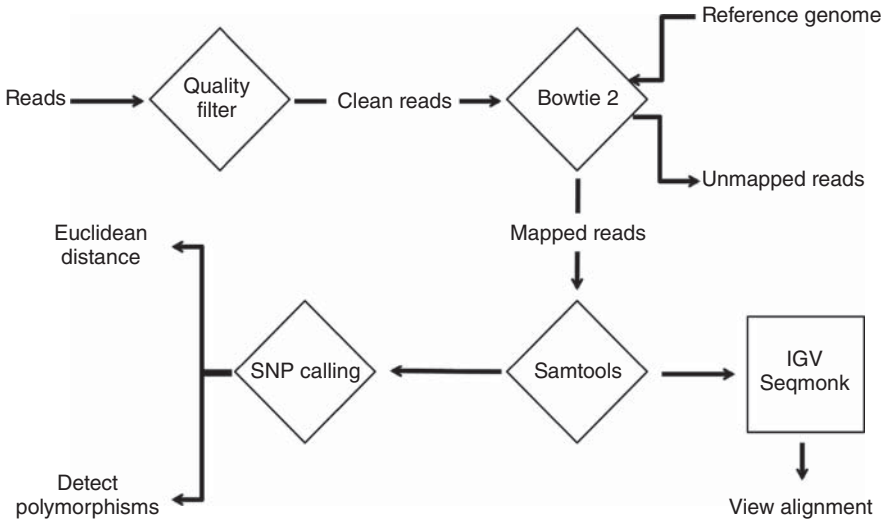

Figure 72.1 Data flow chart of the Pool-Seq DNA dataset analysis. Details are presented in the text.

With these limitations in mind, we decided to restrict the Pool-Seq comparative data analysis to conserved genes, and reads for those genes were identified following recruitment by a reference genome, which in our case was that of *R. leguminosarum* bv. viciae 3841 (Young et al., 2006). For this purpose, a data analysis pipeline was designed and implemented (Fig. 72.1). In the pipeline, after alignment of reads to the reference genome, both coverage and single nucleotide polymorphism (SNP) analysis are performed and compared between subpopulations. The rationale and operation of the pipeline are described later.

72.6 OPERATION OF THE POOL-SEQ DATA ANALYSIS PIPELINE

72.6.1 Data Cleaning

After receipt of sequence data, they must be quality-filtered. A large number of freely available tools exist, but we favor Trimmomatic (Lohse et al., 2012). It contains simple and efficient algorithms to filter by Phred-quality values.

72.6.2 Data Alignment against a Reference Genome

Many different algorithms are available to align clean reads against a reference genome, such as BLAST (Altschul et al., 1990), Maq (Li et al., 2008), Soap2 (Li et al., 2009b), and BWA (Li and Durbin, 2010). We chose Bowtie2 (Langmead and Salzberg, 2012) because of its speed and accuracy. Bowtie was designed for very fast alignment of a high number of reads against a reference genome. The last version allows the alignment in the presence of gaps, which is very useful for rhizobia because their genomes present a large number of insertion sequences (ISs) (Freiberg et al., 1997; Hernández-Lucas et al., 2006; Lozano et al., 2010). ISs are especially abundant in chromosomal islands and in plasmids, including symbiotic plasmids. Reads were aligned against strain 3841 as the *R. leguminosarum* bv. *viciae* reference genome using the "very-sensitive" option among the different default alignment methods that Bowtie2 offers. The complete alignment takes a just few hours on a standard desktop computer with 12 Gb RAM.

72.6.3 Coverage Analysis

In order to study coverage and read recruitment, Bowtie2 standard output must be first transformed with SAMtools (Li et al., 2009a) and can be visualized with any of a number of visualizers. We have used both Seqmonk (http://www.bioinformatics.babraham.ac.uk/projects/seqmonk/) and IGV (Robinson et al., 2011). Both visualizers allow an easy detection of genes or genome areas in the reference genome that are present or absent in the dataset. Seqmonk is quite useful to compare different populations, since it was primarily designed to analyze RNA-Seq data, and thus it allows statistical evaluations. IGV, on the other hand, is able to display coverage along the different replicons, as well as SNPs for each position in the reference genome. Quite usefully, it allows the definition of SNP frequency thresholds. Figure 72.2 shows graphical displays for coverage analysis of the different replicons if it is reference strain 3841.

72.6.4 SNP Calling

In order to compare SNP distribution, the SAMtools package is used. One of the scripts in the package, *mpileup*, was designed to compare different alignments carried out against the same reference genome. Its output is a tab-delimited file, where positions in the reference genome correspond to consecutive lines, and each line contains the corresponding

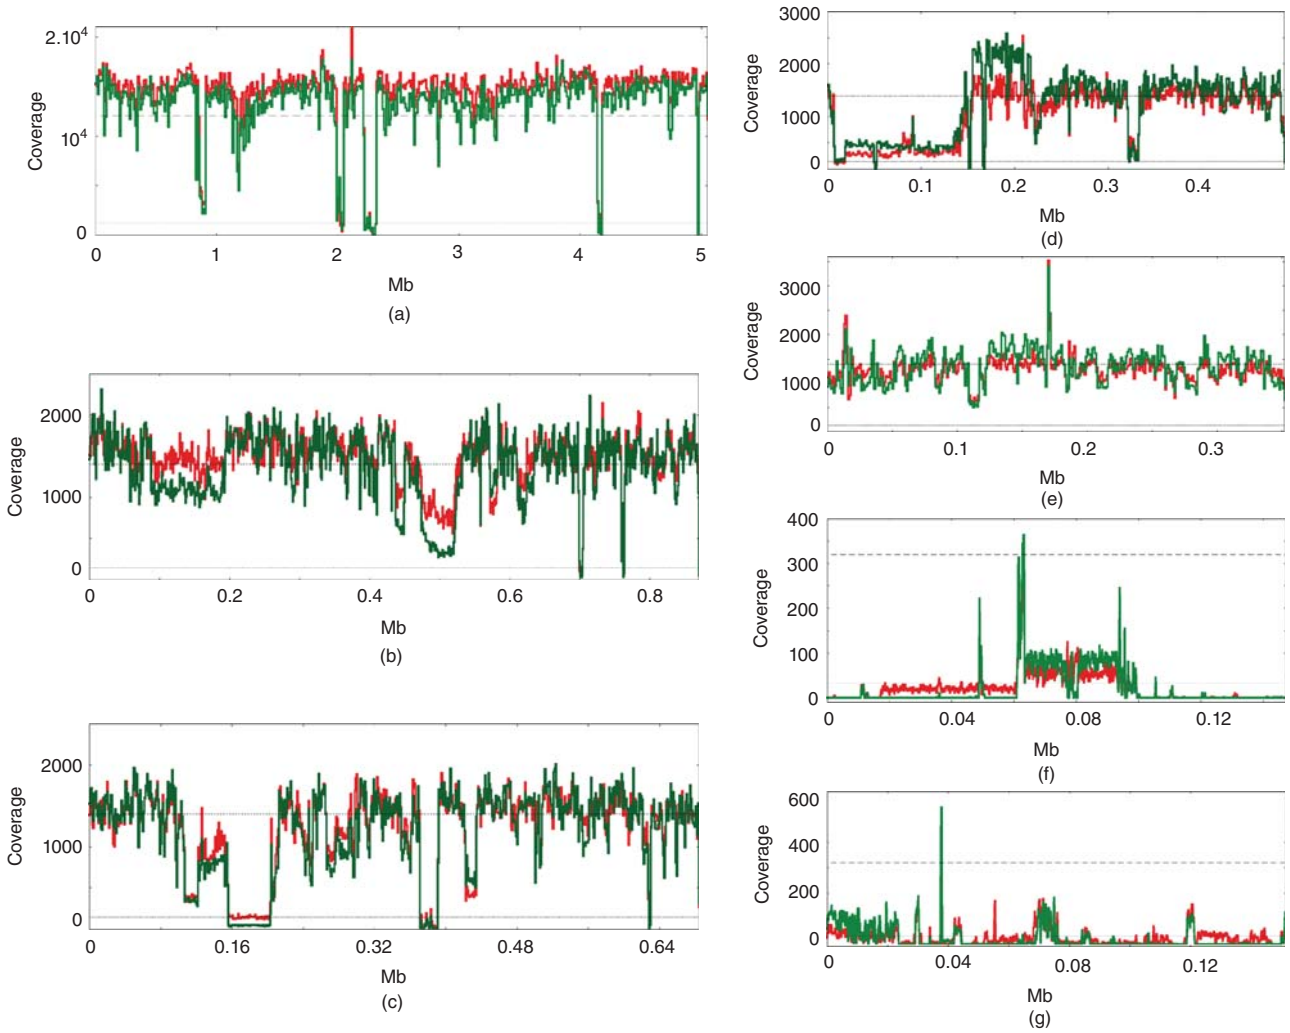

Figure 72.2 Coverage analysis of the *P. sativum* and *V. faba* Pool-Seq datasets after Bowtie2 alignment against the *R. leguminosarum* bv. viciae 3841 reference genome. (a) Chromosome; (b) plasmid pRL12; (c) plasmid pRL11; (d) plasmid pRL10 (the symbiotic plasmid); (e) plasmid pRL9; (f) plasmid pRL8; and (g) plasmid pRL7. Read coverage was plotted in red for *P. sativum* and in green for *V. faba*, along 10,000 bp (for panel a), 1000 bp (for panels b–d), and 100 bp (for panels e–f) windows.

nucleotides of the reads that are mapped in each population to that position. Several scripts are available that can read an *mpileup* file and call for variants. Most of them are designed for diploid organisms, but can also be used with haploid organisms. We chose VarScan (Koboldt et al., 2012) for SNP calling. The program reports only those positions where a variant is present and applies a Bayesian algorithm, assigning a *p*-value to all SNP calls. Figures 72.3 and 72.4 show graphical displays for SNP analysis.

72.6.5 Population Comparisons

With this approach, SNP patterns within genes or gene clusters are easily visualized for genes or gene clusters of interest. Results presented in Figures 72.3 and 72.4 show that a legume host plant-specific pattern of SNP distribution exists, at least for the randomly chosen marker gene *atpD* and gene cluster *nifHDK*, respectively, thus confirming that in the *R. leguminosarum* bv. viciae symbiotic system, the plant host selects specific genotypes from those available in the soil.

It is of course possible to extend this analysis to a large number of genes and gene clusters and to a larger number of legume hosts (such as *Lens*, *Lathyrus*, and vetches, such as *V.* sativa), and also globally to the whole conserved genome and to all the available polymorphic sites. In order to carry out this analysis, results from SNP calling are used to calculate Euclidean distances among populations (with the help of any statistical package such SPSS v.20). These Euclidean distances can also be graphically plotted in a 2D space (data not shown).

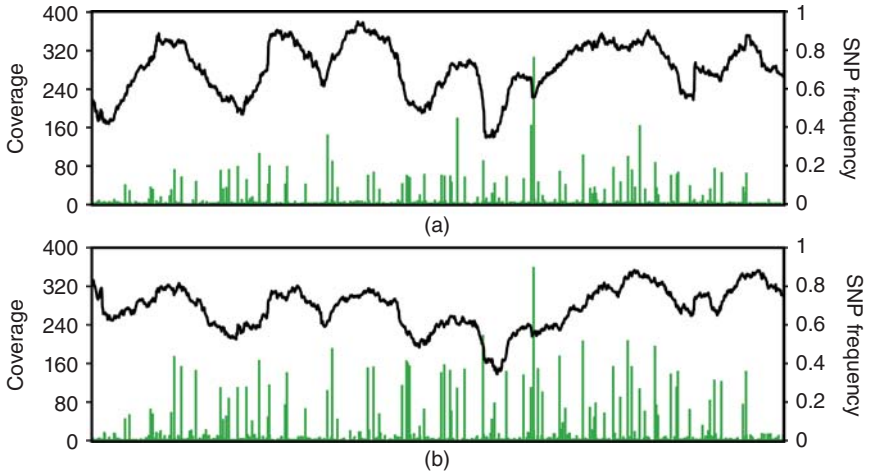

Figure 72.3 Coverage and SNP frequency analysis of Pool-Seq datasets against the *R. leguminosarum* bv. viciae 3841 *atpD* gene. (a) *P. sativum* dataset and (b) *V. faba* dataset.

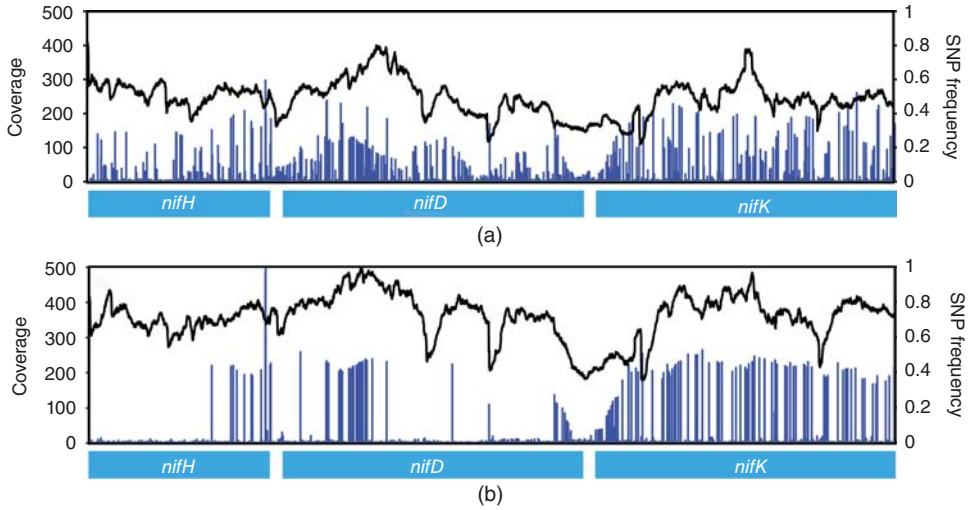

Figure 72.4 Coverage and SNP frequency analysis of Pool-Seq datasets against the *R. leguminosarum* bv. viciae 3841 *nifHDK* gene cluster. (a) *P. sativum* dataset and (b) *V. faba* dataset.

72.7 A CAUTIONARY NOTE ON METAGENOMIC ANALYSIS OF POOL-SEQ DATA

Pool-Seq datasets do not, in principle, differ much from metagenomic datasets, except for their very low complexity and very high coverage of specific DNA regions. *R. leguminosarum* datasets were uploaded to the MG-RAST server (Meyer et al., 2008) and analyzed. A phylogenetic 16S analysis was first carried out with the different databases available in MG-RAST. Since all 100 strains in the original Pool-Seq sample were isolated from symbiotically active *P. sativum* or *V. faba* nodules, the analysis was expected to identify *R. leguminosarum* exclusively. However, results from the MG-RAST pipeline suggest a population far more complex than expected (Fig. 72.5). Interpretation of these unexpected results is currently underway.

72.8 DISCUSSION: PROS AND CONS OF POOL-SEQ ANALYSIS FOR THE STUDY OF RHIZOBIAL POPULATIONS

Since rhizobial populations are a minor fraction of the soil microbiota, any attempt to approach the genomic structure of such populations will necessarily require a preliminary enrichment through the use of legume host trap plants, thus potentially introducing a host-mediated bias. Our work discussed here provides genomic evidence that such a bias does exist, and that specific hosts select specific genotypes from the available variability present in the soil. This evidence has been obtained by next-generation sequencing of DNA samples pooled from a large number (100) of root nodule isolates of *R. leguminosarum* bv. viciae from each of two different legume plant hosts, followed by coverage

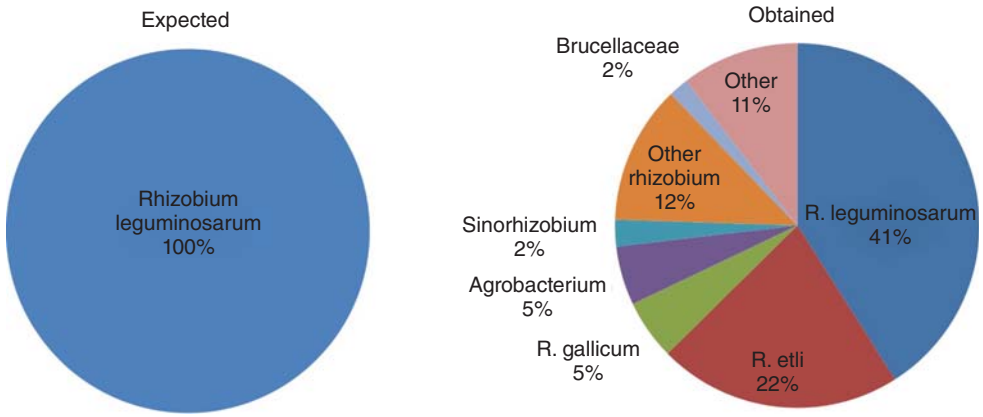

Figure 72.5 Expected and obtained 16S rDNA-based phylogenetic distribution from the MG-RAST analysis of the *P. sativum* Pool-Seq dataset.

and SNP analysis of these datasets against the genomic sequence of reference strain *R. leguminosarum* bv. viciae 3841. These analyses have been carried out with a data processing pipeline assembled from freely available tools.

Given unlimited resources for sequencing and data analysis, it is clear that individual genome sequencing of isolates followed by assembly and multiple genome comparisons represents a more powerful tool than Pool-Seq. However, such a situation is unlikely to occur, and the advantages and disadvantages of Pool-Seq must be evaluated for each project. In 2010, when this project was designed, it was not cost-effective to individually sequence and assemble 200 rhizobial strains. Even with today's higher capacity and lower costs, the pooled DNA approach would allow for a higher sequencing depth, and thus for a potentially better description of the populations. On the other hand, the Pool-Seq approach suffers from important drawbacks for this type of analysis in rhizobia. First, since the plant-specific genotype enrichment will necessarily reflect the original structure of the rhizobial population in the soil, and this can vary from soil to soil, the analysis should be repeated with different types of soil. And second, and more important, the impossibility to assemble reads without the generation of chimeras makes it very difficult to identify specific genes that are not present in the reference genome but that may be specifically enriched in plant-selected subpopulations. These genes are important because they can provide not only specific host-linked markers but also evidence for the structural or functional nature of the phenotypes selected by the plant. Two complementary approaches come to mind in order to address this limitation of Pool-Seq analysis. First, the complexity of the plant-enriched subpopulations could be reduced by any number of typing methods, for instance random amplified polymorphic DNA (RAPD) analysis (Moschetti et al., 2005), making this reduced number of isolates amenable to direct genome sequencing and assembly. Second, our Pool-Seq pipeline for coverage and SNP data analysis could be repeated with different *R. leguminosarum* reference genomes in order to incorporate coverage and SNP analyses for genes that were absent from the original reference genome. Both strategies are currently being followed in our laboratory to complement our analyses.

ACKNOWLEDGMENTS

This work was supported by the Spanish Consolider-Ingenio Program (Microgen Project, CSD2009-00006) to J.I. We thank Rosabel Prieto and Belén Brito for help with isolation of strains from root nodules and DNA preparations, and Gisèle Laguerre for soil samples. We also thank Gonzalo Martín for IT.

Chapter 73

Contribution of the RNA Chaperone Hfq to Environmental Fitness and Symbiosis in *Sinorhizobium meliloti*

José I. Jiménez-Zurdo and Omar Torres-Quesada

73.1 INTRODUCTION

The Hfq protein was discovered more than 40 years ago in *Escherichia coli* as a factor required for the replication of the RNA phage Qβ (Franze de Fernández et al., 1968). The rapidly growing genomic database reveals that nearly half of the sequenced bacterial species and a few archea encode a recognizable homolog of this protein, which is usually highly represented in the proteome repertoire. Genetic, biochemical, and structural data evidence a quaternary arrangement of Hfq into a hexameric toroid structurally related to the eukaryotic LSm family of RNA-binding proteins (Brennan and Link, 2007).

Deletion of the chromosomal *hfq* gene was early observed to impair multiple responses to stressful environmental conditions in *E. coli* (Tsui et al., 1994). Subsequently, similar reverse genetic approaches have confirmed the pleiotropy of the *hfq* mutation in a number of phylogenetically distant bacterial species representing diverse lifestyles (Sobrero and Valverde, 2012 and references therein). In animal pathogens (e.g., enterobacteria or *Brucella* species), the absence of Hfq has been shown to attenuate motility, secretion of virulence factors, host invasion, or intracellular survival of bacteria (Robertson and Roop, 1999; Sittka et al., 2007). These findings predict a universal role of Hfq in the establishment and maintenance of chronic intracellular residences within eukaryotic hosts, such as that involving root nodule colonization by nitrogen-fixing endosymbiotic bacteria.

Extensive work on model enterobacteria has revealed that loss of Hfq results in the deregulation of large arrays of genes and operons encoding widely diverse cellular functions that include transport, metabolism, and tolerance to a variety of stresses (Sittka et al., 2007, 2008). This emerging role of Hfq as a global regulator of gene expression mostly relies on its RNA-binding capacity, which renders this protein as a crucial node in bacterial RNA transactions (Vogel and Luisi, 2011). Remarkably, Hfq is the major binding protein for *trans*-acting small noncoding RNAs (sRNAs), which constitute the largest and most intensively investigated class of regulatory untranslated RNA molecules recently identified in bacteria (Storz et al., 2011). Upon binding, Hfq promotes the short, discontinuous, and imperfect antisense interaction of the *trans*-sRNAs with their mRNA targets, thereby modulating translation and/or turnover rates of the messages. The homo-hexameric Hfq

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

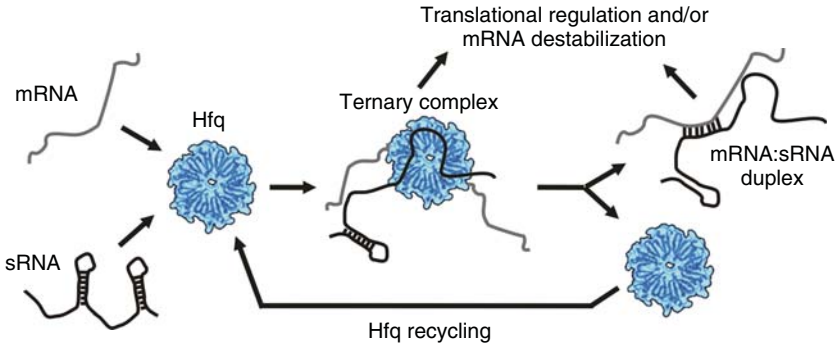

Figure 73.1 Hfq facilitates annealing between an sRNA and its cognate mRNA. The Hfq hexamer can bind different RNA molecules in either of its positively charged surfaces. RNA binding may result in secondary structure changes that promote base-pairing recognition and duplex formation due to proximity in the ternary complex. The bound sRNA may block (or even facilitate) ribosome access to the mRNA; alternatively, Hfq-recruited RNase may irreversibly downregulate mRNA expression (for further details, see Vogel and Luisi (2011)).

ring exposes two different positively charged surfaces (i.e., the proximal and distal faces), which constitute alternative binding sites that can discriminate between RNA molecules (Fig. 73.1). Studies on *Staphylococcus aureus* and *E. coli* Hfq have revealed that the proximal face has a preference for uridine-rich RNA stretches, which seem to be accommodated around the pore in a constricted conformation that is stabilized by water molecules (Schumacher et al., 2002; Sauer and Weichenrieder, 2011). As most sRNAs have typical bacterial Rho-independent terminators that usually contain a poly-U 3′-terminus, Hfq can interact with the terminators and influence sRNA stability (Vogel and Luisi, 2011). In contrast, the *E. coli* Hfq distal face presents an RNA-binding motif with preference for adenine-rich RNA segments. In this case, the RNA molecule is accommodated in a circular conformation along the distal surface. Hence, each Hfq ring is able to simultaneously bind two different RNA molecules or a single molecule bridging both faces around the oligomer rim (Fig. 73.1). If an sRNA binds on one face and a cognate target mRNA does so on the other face, this ternary complex will lead to productive RNA duplex formation (Wang et al., 2013). In addition, Hfq offers a scaffold for the interaction with several other proteins (Sobrero and Valverde, 2012). The more relevant partner of Hfq is the major bacterial ribonuclease, RNase E, which engages in the formation of an atypical degradosome (Morita et al., 2005). This silencing complex ensures the efficient modulation of the riboregulatory networks (Aiba, 2007).

Posttranscriptional regulation of gene expression mediated by *trans*-sRNAs contributes to fine-tune bacterial processes as diverse as sugar and amino acid transport and metabolism, iron and envelope homeostasis, general responses to abiotic stress, quorum sensing, or virulence (Storz et al., 2011). Even though Hfq can directly influence mRNA translation and stability, most of the Hfq-dependent genes are expected to be regulated by the concerted activity of this protein and its interacting *trans*-sRNAs.

In the order Rhizobiales, Hfq was first identified in *Azorhizobium caulinodans* as a protein factor required for the proper translation of the master regulator *nifA* (Kaminski et al., 1994); this observation lead to the designation NrfA (*nifA* regulatory factor) of the protein. The requirement of Hfq for *nifA* expression seems to be conserved in other α-proteobacteria, such as *Rhizobium leguminosarum* bv. *viciae* (Zhang and Hong, 2009) and *Rhodobacter capsulatus* (Drepper et al., 2002). Indirect evidence for Hfq-dependent regulation of genes involved in nitrogen metabolism has been revealed in *R. leguminosarum* bv. *viciae*, as spontaneous *hfq* point mutations arise as natural suppressors of a mutation in *gltB* (encoding the large glutamine oxoglutarate amidotransferase (GOGAT) subunit) that inhibits amino acid uptake through the Aap and Bra transport systems (Mulley et al., 2011).

More than one decade after the initial experiments in *A. caulinodans*, the exploration of the biological function of Hfq in rhizobia has recently been resumed in *Sinorhizobium meliloti*, upon detection of many sRNA transcripts in different strains (del Val et al., 2007; Ulvé et al., 2007; Valverde et al., 2008; Schlüter et al., 2010, 2013). Altogether, the identification of sRNAs and of an *hfq* allele in *S. meliloti* strongly suggested that Hfq-dependent riboregulation impacts physiology of this bacterium under both free-living and symbiotic conditions. In this chapter, we summarize our current knowledge on the biology of Hfq in *S. meliloti*.

73.2 THE *S. meliloti* hfq PROTEIN

In all sequenced *S. meliloti* strains, the *hfq* allele is invariably located in the chromosomal replicon, downstream of the gene encoding a putative D-alanine aminotransferase, and upstream of *hflX*, which encodes a putative guanosine triphosphatase (GTPase) of yet unknown function (Fig. 73.2a). Intriguingly, a number of genes involved in transcriptional regulation of nitrogen uptake and metabolism (i.e., *ntrBC*, *ntrYX*) are physically linked upstream of *hfq*, a feature that is also shared by other rhizobia and related α-proteobacteria. The *hfq-hflX* tandem is conserved in α-, β-, and γ-proteobacteria (Sobrero and Valverde, 2012), suggesting some degree of functional relationship. In fact,

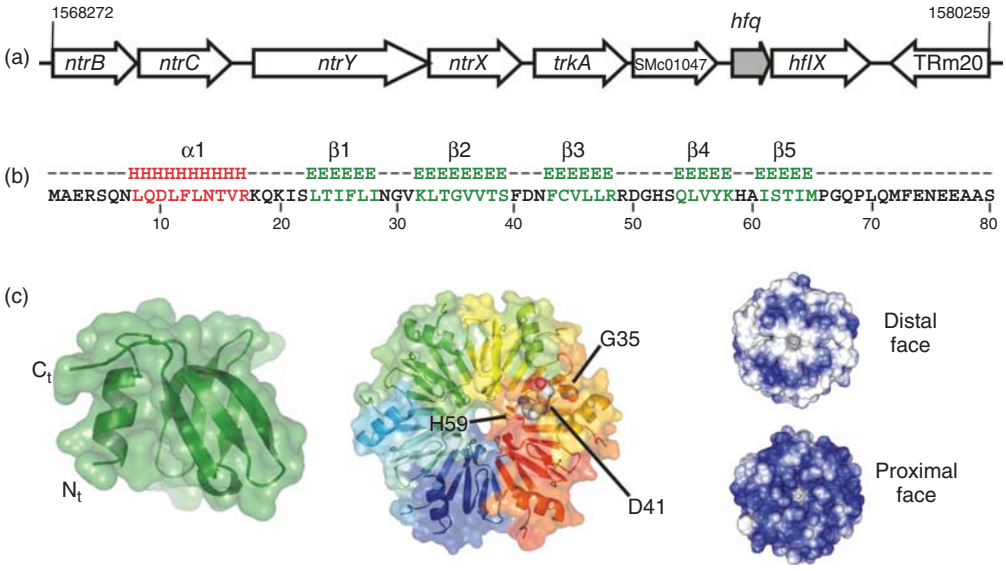

Figure 73.2 Sequence and structural properties of *S. meliloti* Hfq. (a) Genetic context of the 12-kb region encompassing *hfq* in the chromosome of *S. meliloti* strain Rm1021. (b) Amino acid sequence and predicted secondary structure elements of Hfq (predicted α-helical and β-stranded regions are indicated above the sequence). (c) Predicted ribbon model of the Hfq monomer using the *E. coli* Hfq polypeptide (PDB 1hk9) (protein data bank) as a template (left). The spatial location of critical conserved residues important for Hfq function is indicated in the hexamer model (middle). Consistent with their RNA-binding properties, the two faces of the hexameric Hfq ring have different predicted positive net charge (highlighted in blue in the right panel).

hflX is cotranscribed with *hfq* in *S. meliloti* (Sobrero and Valverde, 2011).

The *S. meliloti* Hfq monomer has 80 residues and a calculated molecular weight of 9 kDa (Fig. 73.2b). The sequence is 47% identical to that of *E. coli*, although the identity is concentrated in the first 70 residues, provided that the *E. coli* monomer is slightly larger (102 residues). The *S. meliloti* Hfq polypeptide is predicted to fold into an N-terminal α-helix followed by a tandem of five β-strands (Fig. 73.2b), a topology that has been confirmed by the crystallographic studies of *E. coli* Hfq. The significant primary and secondary structure homologies found among *S. meliloti* and *E. coli* monomers strongly suggest that *S. meliloti* Hfq oligomerizes into a 54-kDa ring-shaped hexamer with two positively charged surfaces (Fig. 73.2c). Key residues for stabilization of the *E. coli* Hfq fold are conserved in the primary sequence of *S. meliloti* Hfq (e.g., G35, D41, and H59) and are positioned in equivalent locations of the hexameric model (Fig. 73.2c), suggesting that they are relevant for the native structure of *S. meliloti* Hfq as well. In fact, an Hfq variant carrying a G35V substitution failed to complement an *hfq* deletion in strain 1021 (Barra-Bily et al., 2010a).

In *S. meliloti*, *hfq* expression is driven by a conserved and prototypical rhizobial σ^{70} promoter (Sobrero and Valverde, 2011), both in free-living and symbiotic states (Barra-Bily et al., 2010a; Sobrero and Valverde, 2011). A remarkable feature of *hfq* expression is that its translational rate remains constant along the growth curve under different nutritional conditions, which points to a tight control of Hfq protein level (Sobrero and Valverde, 2011). This is consistent with the notion derived from enterobacterial models that this RNA chaperone is a limiting factor of riboregulatory networks, with a rather stable number of molecules per cell; in this way, mRNA–sRNA regulatory outputs would be more sensitive to fluctuations in sRNA levels (Adamson and Lim, 2011; Moon and Gottesman, 2011). Interestingly, this precise control of Hfq protein levels relies on an autoregulatory loop that involves translational repression of its own mRNA. *E. coli* Hfq binds to its own mRNA leader, thus repressing *hfq* translation by competing with the translation machinery for the ribosome-binding site (RBS) (Vecerek et al., 2005). In *S. meliloti*, Hfq controls the expression of an *hfq-lacZ* translational fusion, and this process only requires the presence of the Hfq protein (Sobrero and Valverde, 2011). Whether sRNAs targeting the *hfq* mRNA leader of *E. coli* and *S. meliloti* contribute *in vivo* to *hfq* translational autoregulation is not clear. Furthermore, indirect evidence of *hfq* autoregulation has also been obtained in another α-proteobacterium, as the *R. sphaeroides hfq* mRNA was detected in the RNA pool that co-immunoprecipitated (CoIP) with Hfq (Berghoff et al., 2011). The operation of an Hfq autoregulatory loop in different bacterial lineages emphasizes the relevance of keeping Hfq protein concentration locked within a limited range.

73.3 DELETION OF *hfq* RESULTS INTO A PLEIOTROPIC FREE-LIVING AND SYMBIOTIC PHENOTYPE

Several lines of experimental evidence indicate that Hfq has a pivotal role in maintaining cellular homeostasis and fitness of *S. meliloti*. A series of contemporary studies have revealed the phenotype of *hfq* mutants derived from the closely related *S. meliloti* strains Rm1021 and Rm2011 (Barra-Bily et al., 2010a; Gao et al., 2010; Torres-Quesada et al., 2010; Sobrero and Valverde, 2011). Both strains, which arose from the same streptomycin-resistant isolate SU47, have been independently domesticated and have accumulated genotypical and phenotypical variations (Sallet et al., 2013), particularly in their response to phosphate limitation and in their interaction with the host plant (Wais et al., 2002; Krol and Becker, 2004). However, regardless of the mutated strain, the lack of *hfq* results in shared pleiotropic phenotypes, namely (a) a reduced specific growth rate, longer lag phase, and lower biomass yield in planktonic growth in complex and nutrient-rich medium; (b) the motility/chemotactic behavior on semisolid medium is severely affected; and (c) increased sensitivity to heat shock, oxidative stress, and high pH.

Probably as a consequence of these series of alterations, the *S. meliloti* wild-type strain Rm1021 strongly outcompetes its *hfq*-mutant derivative for nodule occupancy in coinoculation experiments of alfalfa plants grown hydroponically (Torres-Quesada et al., 2010). Differential traits of the *S. meliloti hfq* mutants also become evident when examining the interaction with the host plant in single inoculation experiments. Both Barra-Bily et al. (2010a) and Gao et al. (2010) describe a strong Nod^+ Fix^- phenotype for the *hfq* mutant derived from strain Rm1021, that is, bacteria are able to induce nodule formation but cannot colonize and fix nitrogen within these organs. Thus, a high proportion of the developed nodules remain white (Fix^-). Reisolation and reinoculation of rhizobia from the fewer pink and elongated nodules did not result in a higher proportion of Fix^+ nodules (Barra-Bily et al., 2010a), arguing against plant selection of *hfq* suppressing mutations. The infective defect could be a consequence of the higher sensitivity of the *hfq* mutants to the oxidative stress generated by the plant cells during root hair penetration and nodule cell invasion. This oxidative burst constitutes an important baseline defense mechanism against different invading bacteria and fungi (Santos et al., 2001). Another study reported a moderate Nod^+ Fix^- phenotype of a strain Rm1021 *hfq* mutant, although in this case the histology of the handicapped nodules suggested an impaired ability of bacteroids to survive within the nodule cells (Torres-Quesada et al., 2010). This phenotype further supports a common role of Hfq in the chronic intracellular infection of eukaryotic hosts by bacteria. Finally, an *hfq*-mutant derivative from strain Rm2011 displays a Nod + Fix + phenotype upon inoculation of lucerne seedlings, but there is a marked delay in the appearance of the first nodule with the consequent shift in the distribution of nodules toward younger portions of the root system (Sobrero and Valverde, 2011). Thus, nodule maturation is delayed and results in a retardation of nitrogen supply for plant growth. The differential symbiotic performance of the *hfq* mutants could be attributed to the host plant species (*M. sativa* (Barra-Bily et al., 2010a; Torres-Quesada et al., 2010; Sobrero and Valverde, 2011) or *M. truncatula* (Gao et al., 2010)) or to the lucerne variety (cv. Iraquois (Barra-Bily et al., 2010a), cv. Aragón (Torres-Quesada et al., 2010), or cv. Key (Sobrero and Valverde, 2011)), which may vary in the amplitude of the oxidative burst triggered by the initiation of the infection process (Santos et al., 2001). In summary, the lack of Hfq does not compromise Nod factor signaling in *S. meliloti* but impacts on intermediate and late symbiotic stages.

73.4 A LARGE REGULON EXPLAINS THE PHENOTYPIC PLEIOTROPY OF THE *S. meliloti hfq* MUTANTS

To identify the genes that are directly or indirectly regulated by Hfq, the proteome and transcriptome of *hfq* mutants from strains Rm1021 and Rm2011 grown either in rich or defined minimal media have been explored by 2D-PAGE (Barra-Bily et al., 2010b; Torres-Quesada et al., 2010), quantitative proteomics (Sobrero et al., 2012), or microarray hybridization experiments (Gao et al., 2010; Torres-Quesada et al., 2010). The compilation of the mRNAs/proteins that show differential abundance between the mutants and the parent strains in these studies reveals a large Hfq regulon consisting of 921 genes (306 upregulated, 615 downregulated in the mutants), which represents 15% of the ORFs (Open Reading Frames) annotated in the *S. meliloti* genome (Fig. 73.3). Almost half of these genes putatively encode components of either ATP-binding cassette (ABC) transport systems (24%) or metabolic proteins (22%), whereas 31% have no predictable function. The remaining deregulated genes (22%) specify diverse cellular functions that include motility, chemotaxis, regulation of transcription, or nitrogen fixation. Expression of *S. meliloti* genes related to DNA and protein synthesis is largely unaffected by the lack of Hfq, supporting a global role of this protein in the fine-tuning of the cell homeostasis rather than a housekeeping function, as anticipated by the full viability of the *hfq* mutants.

The majority of ABC transporters that are downregulated in the absence of Hfq are predicted to be involved in the uptake of carbon substrates (e.g., ribose, fructose, *myo*-inositol, or α-glucosides). Conversely, genes encoding ABC systems for the uptake of diverse nitrogen compounds

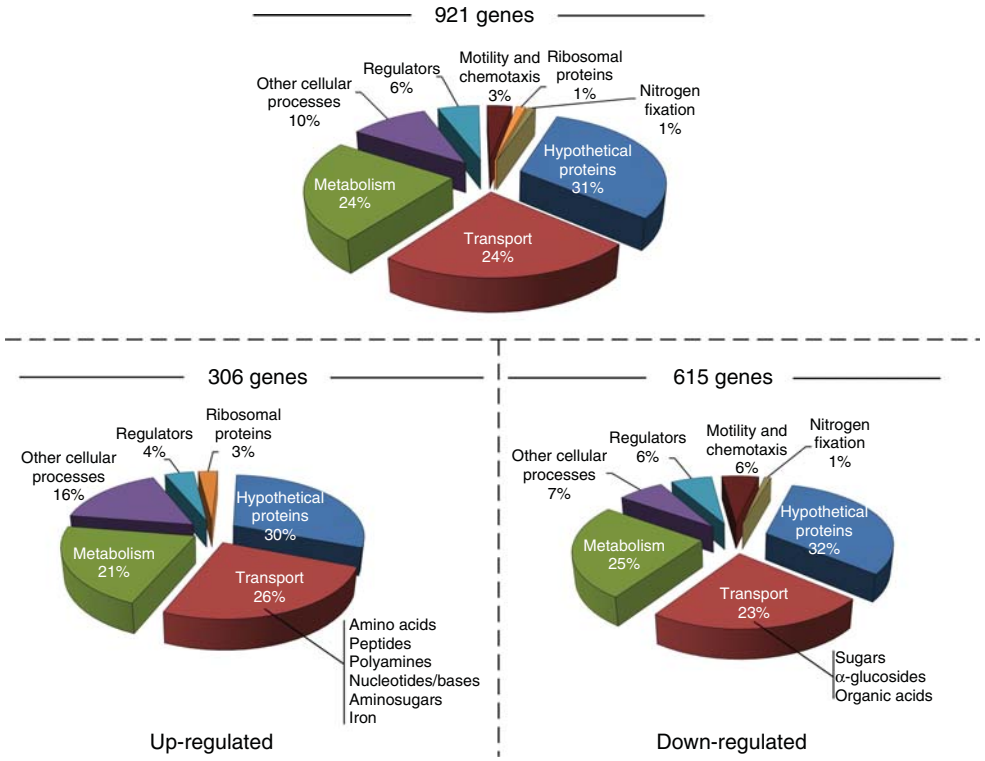

Figure 73.3 The *S. meliloti* Hfq regulon. Functional distribution of Hfq-regulated genes as inferred from transcriptome and proteome profiling of different *hfq* mutants.

(i.e., amino acids, peptides, polyamines, aminosugars, or nucleotides) are massively upregulated in the *hfq* mutants (Fig. 73.3). This observation correlates with an increased sensitivity of the mutants to bialaphos, sodium glufosinate, or 5-fluorouracil, which are cytotoxic analogs of tripeptides, L-glutamate, and uracil, respectively (Sobrero et al., 2012).

The predicted reduced efficiency of the *S. meliloti hfq* mutants in the uptake of primary carbon compounds is accompanied by a reciprocal downregulation of several genes involved in the utilization of sugars and, in turn, of those of biosynthetic pathways of macromolecule building blocks (e.g., amino acids) fueled by carbon catabolism (Torres-Quesada et al., 2010). Consistent with these changes, transcriptomic/proteomic alterations suggest a bias of metabolism to the tricarboxylic acid (TCA) cycle and gluconeogenesis as alternative energy-producing pathways in the mutants (Fig. 73.4). This metabolic shift is likely supported by the aforementioned promotion of the amino acid uptake, the upregulation of the gene encoding the enzyme phosphoenol pyruvate carboxykinase (PckA), and the increase in the nitrogen assimilatory activity in the *hfq* mutants (Barra-Bily et al., 2010b; Gao et al., 2010; Sobrero et al. 2012). However, this metabolic reprogramming seems to be not fully coordinated with transport. For example, syntheses of branched-chain amino acid (leucine, isoleucine, and valine, LIV) ABC transporters (i.e., LivHMGFK and AapJQMP) increase in the *hfq* mutants, but more than a dozen genes encoding LIV catabolic enzymes are downregulated (Gao et al., 2010). Therefore, the growth defects of the *S. meliloti hfq* mutants in unstressed cultures are likely a consequence of these series of specific alterations in the uptake of nutrients and metabolism.

The abundance of a set of proteins involved in the transport (e.g., FbpA and SMc01605) and storage (e.g., bacterioferritin or Bfr) of iron increases in *S. meliloti* Rm2011 lacking Hfq, thus contributing to elevate the intracellular iron content in the mutant (Sobrero et al., 2012). Nonphysiological high-iron concentrations could lead to oxidative stress due to Fenton chemistry in the presence of reactive oxygen species (ROS) (Cornelis et al., 2011). ROS detoxifying enzymes such as catalases (e.g., KatB or KatC) or superoxide dismutases (e.g., SodB and SodC) have been consistently found to be downregulated in the *S. meliloti hfq* mutants, thus reducing their ability to repair oxidative damage during aerobic growth and legume infection (Barra-Bily et al., 2010b; Sobrero et al., 2012). Several additional stress-related genes have been identified as misregulated in the *S. meliloti hfq* mutants in these studies, despite of being mostly conducted under nonstress conditions. Among those, *S. meliloti* Hfq has been shown to contribute to the optimal expression of *rpoE1*, *rpoE2*, *rpoE3*, and *rpoE4*, which encode extracytoplasmic sigma factors (ECFs) involved in the control of responses to a number of abiotic stresses such as oxidative stress or heat shock (Barra-Bily et al., 2010b; see Chapters 30, 40).

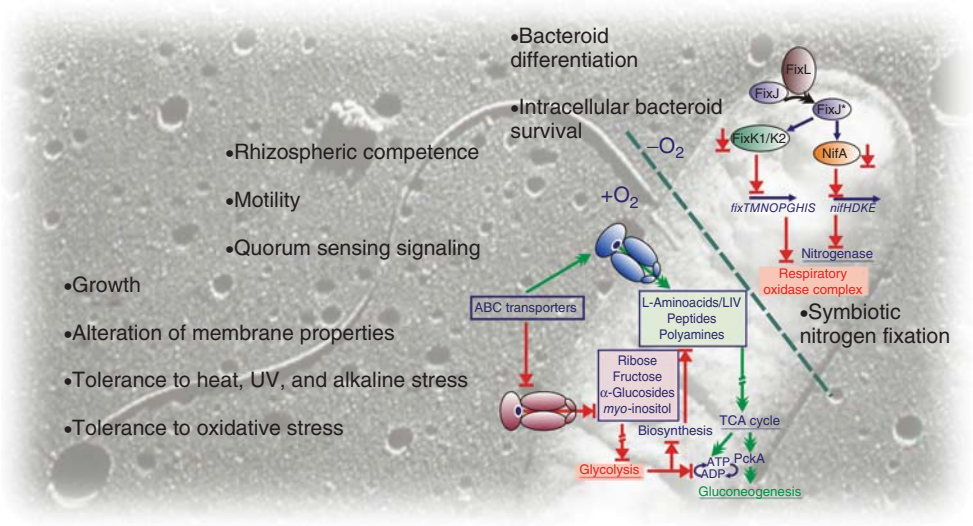

Figure 73.4 Summary of the *S. meliloti* pathways and phenotypes influenced by Hfq. Green double arrowheads and red-blocked arrows denote favored and disadvantaged pathways, respectively, in the absence of Hfq. $+O_2$, aerobic cultures; $-O_2$, microaerobic cultures. See text for details.

Expression of other genes encoding proteins contributing to heat shock recovery (e.g., the chaperones GroES1 and ClpP2) or alkaline tolerance (SupAB) has also been shown to be drastically reduced in a *S. meliloti* Rm1021 *hfq* mutant (Barra-Bily et al., 2010b; Gao et al., 2010).

Several changes in the pattern of gene expression could explain the reduced nodulation competitiveness of the *S. meliloti hfq* mutants (Torres-Quesada et al., 2010). Root exudates and decaying plant matter are likely important sources of carbon compounds such as α-glucosides (trehalose, sucrose, and maltose) or *myo*-inositol for soil-dwelling rhizobia (Fry et al., 2001). The genes encoding functions for the transport and utilization of these substrates are strongly downregulated in the mutants (Gao et al., 2010; Torres-Quesada et al., 2010). On the other hand, lack of Hfq also results in downregulation of most known flagellar and chemotaxis genes and accumulation of the *sinI* mRNA, encoding the acyl homoserine lactone (AHL) synthase, thus leading to defects in swimming/swarming motility and alteration of the quorum-sensing signal profile (Barra-Bily et al., 2010a, Gao et al., 2010; see Chapter 37). These deficiencies would compromise to a different extent that the overall responses of rhizospheric bacteria to symbiotic plant signal.

Contrasting with soil oligotrophy, legumes provide invading rhizobia with defined and abundant energy sources such as dicarboxylic acids, the catabolism of which supports the energy demands of symbiotic nitrogen fixation by the nitrogenase complex (Prell and Poole, 2006). Nonetheless, it has been also reported that transport of plant-derived LIV through the bacterial Aap and Liv(Bra) systems is required for *R. leguminosarum* bv. *viciae* bacteroid development and persistence within pea nodules (Prell et al., 2009). Such a symbiotic function of LIV uptake has not been demonstrated in *S. meliloti* (Prell et al., 2010). However, the substrate specificity of *S. meliloti* LivK and AapJ periplasmic solute-binding proteins is predicted to be broad (Prell et al., 2010; see Chapter 34). Therefore, it cannot be ruled out that the misregulation of Liv/Aap or other ABC transporters involved in the uptake of yet unidentified alternative nutrient sources for *S. meliloti* during infection and bacteroid differentiation would contribute, at least partially, to the endosymbiotic phenotype of the *hfq* mutants.

73.5 hfq CONTRIBUTES TO THE CONTROL OF SYMBIOTIC NITROGEN FIXATION

NifA/FixK-dependent transcription of the nitrogen-fixation genes (*nif/fix*) is oxygen-regulated in legume nodules and requires microoxic conditions in cultured free-living bacteria. Nonetheless, it is known that a moderate decrease in the ambient oxygen concentration in the gas phase of a culture is sufficient to trigger FixLJ-mediated activation of the FixK regulator. However, *nifA* expression demands more stringent microaerobic conditions. The transcriptomic profiling of the *S. meliloti* Rm1021 *hfq* deletion mutant revealed downregulation of mRNAs corresponding to the two copies of *fixK* and to their downstream-dependent genes, which encode the protein components of the respiratory chain associated with the nitrogenase complex (*fixN1*, *fixQ1*, *fixP1*, *fixG*, *fixQ2*, and *fixM*) (Torres-Quesada et al., 2010) (Fig. 73.4). In contrast, differential accumulation of *nifA* was not observed in either of the transcriptomic analyses. Further independent reverse transcription polymerase chain reaction (RT-PCR) experiments on RNA from cultured bacteria subjected to

microaerobiosis confirmed that full expression of the *S. meliloti fixK* and *nifA* genes requires Hfq (Barra-Bily et al., 2010a; Torres-Quesada et al., 2010). Downregulation of *nifA* and *fixK* would compromise efficiency of nitrogenase synthesis and nitrogen fixation, thus providing a further explanation to the negative effects of the lack of Hfq on late stages of the symbiotic interaction of *S. meliloti* with its legume host.

Hfq-mediated posttranscriptional regulation of *nifA* expression in *R. leguminosarum* bv. *viciae* has been shown to involve binding to and cleavage of the 5′ untranslated region (UTR) of the mRNA upon RNase E recruitment (Zhang and Hong, 2009). This Hfq-dependent RNase E cleavage enables translation of the *nifA* message, which is otherwise impaired by an inhibitory structure of the 5′-UTR that is predicted to occlude the RBS. RT-PCR data suggest that Hfq contributes to stabilize the *S. meliloti nifA* and *fixK* mRNAs. However, the mechanisms involved in the positive regulation of these *S. meliloti* genes by Hfq remain to be explored.

73.6 hfq AND RIBOREGULATION IN *S. meliloti*

S. meliloti has been shown to express a plethora of small untranslated RNA molecules, including hundreds of *trans*-acting sRNAs, whose function is mostly unknown (del Val et al., 2007; Ulvé et al., 2007; Valverde et al., 2008; Schlüter et al., 2010, 2013). The most relevant information, but also the bottleneck, to pinpoint the cellular functions of the *trans*-sRNAs is the identity of their mRNA targets. Cognate partner mRNAs of Hfq-dependent *trans*-sRNAs are usually identified among the mRNA populations differentially expressed in the *hfq* mutants.

To date only two α-proteobacterial *trans*-sRNAs homologous to each other designated AbcR1 and AbcR2 have been functionally characterized, both in the phytopathogen *Agrobacterium tumefaciens* (Wilms et al., 2011) and the mammal pathogen *B. abortus* (Caswell et al., 2012). AbcR1 negatively regulates a handful of ABC transporter mRNAs in these bacteria, including a *livK* homolog. The *S. meliloti* AbcR1 homolog (formerly Smr16 or Smr15C2) was identified in an early computational genome-wide screen to search for sRNA genes in the intergenic regions of this bacterium (del Val et al., 2007). *S. meliloti* AbcR1 is an Hfq-dependent sRNA; it coimmunoprecipitates with a chromosomally encoded epitope-tagged Hfq variant and rapidly decays in the absence of this protein (Fig. 73.5a) (Voss et al., 2009; Torres-Quesada et al., 2010; Torres-Quesada et al., 2013).

Computational predictions identified multiple mRNAs encoding the periplasmic component of ABC transport systems as putative targets of AbcR1, most of which

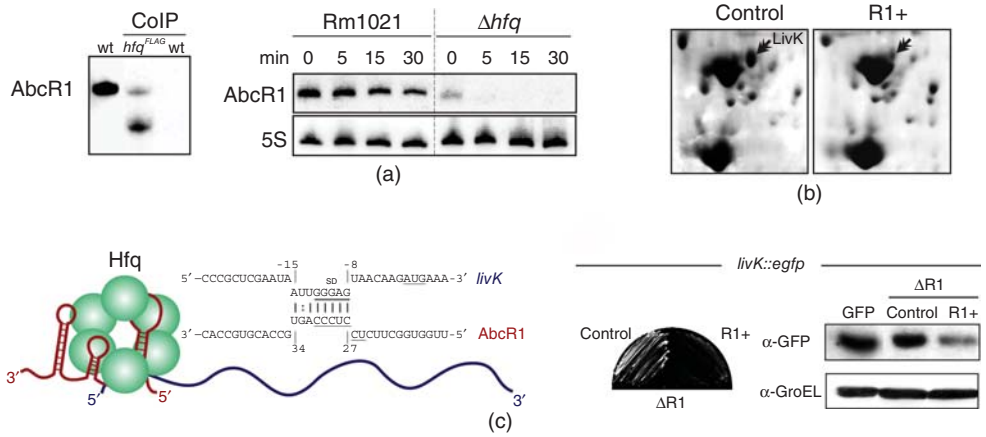

Figure 73.5 Posttranscriptional regulation of *livK* by the *S. meliloti trans*-sRNA AbcR1. (a) AbcR1 is an Hfq-dependent sRNA. Northern blot analysis of RNA species coimmunoprecipitated (CoIP-RNA) with a FLAG-tagged Hfq protein (*hfq*^{FLAG}; left panel) and of AbcR1 decay in Rm1021 and its *hfq* deletion mutant derivative (Δ*hfq*) upon transcription arrest with rifampicin (right panel). Samples were withdrawn prior to or after antibiotic addition at time-points (min) indicated on top of the panel. (b) AbcR1 downregulates LivK. 2D-PAGE analysis of the periplasmic proteome of an Rm1021 AbcR1 deletion mutant (ΔR1; control) and a derivative constitutively expressing AbcR1 from a mid-copy plasmid (R1+). Arrows indicate the LivK spot. (c) AbcR1-mediated translational control of the *livK* mRNA. Left panel: diagram of the predicted antisense interaction between AbcR1 and the Hfq-dependent *livK* mRNA. Numberings denote positions relative to the adenine-uracil-guanine (AUG) start codon of the *livK* mRNA (underlined) and the AbcR1 transcription start site. AbcR1 negatively influences translation and stability of the *livK* mRNA by masking the Shine-Dalgarno sequence (SD) in an Hfq-dependent manner. Right panel: agar plate-based colony fluorescence of the reporter Rm1021 ΔR1 strains cotransformed with a plasmid expressing a translational *livK*::*egfp* fusion and compatible plasmids either empty (control) or expressing AbcR1 (R1+). Western blot analysis of the expression of the LivK::EGFP fusion protein in the same reporter strains is shown to the right. GroEL was probed as protein-loading control.

are Hfq-dependent (Sobrero et al., 2012). Accordingly, periplasmic proteome profiling revealed dowregulation of the LIV-binding protein LivK upon constitutive overexpression of AbcR1 (Fig. 73.5b). Both the *livK* mRNA and its encoded protein have been previously shown to be upregulated in the *S. meliloti hfq* mutants. Scanning of the full-length *livK* mRNA sequence for antisense interactions with AbcR1 revealed a short 8-nt stretch of complementarity between both molecules, which involves the RBS within the target mRNA (Fig. 73.5c). Posttranscriptional AbcR1-mediated control of *livK* has been further confirmed by a double-plasmid reporter assay consisting of the constitutive coexpression of AbcR1 and a translational fusion of the 5′ region of *livK* to enhanced green fluorescent protein (EGFP) from independent compatible plasmids in an *S. meliloti* AbcR1 deletion mutant (Fig. 73.5c). Upon AbcR1 expression, fluorescence of the reporter strain is visibly reduced, which correlates with the downregulation of the LivK::EGFP fusion protein as assessed by Western-blot analysis. Altogether, these data indicate that AbcR1 and Hfq act in concert to inhibit translation of the *livK* mRNA and to accelerate its decay (Torres-Quesada et al., 2013), thus providing an example of the identification of sRNA–mRNA pairs among the cellular Hfq-dependent transcripts.

Preliminary observations indicate that only a subset of *trans*-sRNAs expressed by *S. meliloti* bind Hfq (Torres-Quesada et al., 2010). Therefore, riboregulation may also involve other protein factors in this bacterium. It has been recently reported that a mutation in an eubacterial conserved gene encoding a homolog of the *E. coli* YbeY protein mimicked several phenotypes of the *S. meliloti hfq* mutants (Pandey et al., 2011). YbeY and Hfq do not seem to interact physically in *S. meliloti*. In *E. coli*, YbeY functions as an RNase involved in maturation and quality control of ribosomal rRNA (Jacob et al., 2013). Whether YbeY influences *hfq* expression or function in *S. meliloti*, along with its functional role as an RNase, it remains to be determined.

We are just beginning to uncover the complexity of the noncoding RNome structure in rhizobia. Our current knowledge on Hfq biology provides a solid baseline for the forthcoming systems-level investigation of gene regulation by Hfq-dependent sRNAs in *S. meliloti* and the related α-proteobacteria interacting with eukaryotic hosts.

74.1 INTRODUCTION

Rhizobium tropici is a fascinating, but still little studied, rhizobial species originally isolated from root nodules on common bean (*Phaseolus vulgaris* L.) and species of *Leucaena* in South America (Martínez-Romero et al., 1991). The species is also present in soils of other continents (Africa, Central and North America, Europe, Oceania) and can establish symbiosis with several host species, including legumes indigenous to the Americas and Australia. Interest in the evolution of *R. tropici* results from its close genetic resemblance with agrobacteria, indicating the interesting possibility of discovering the linkage between symbiosis and pathogenicity (e.g., Gomes et al., 2012b). Taxonomy of the species is going through changes, with description and indication of new species, as well as the definition of a "*Rhizobium tropici* group," comprising several species that are genetically related (Ormeño-Orrillo et al., 2012; Ribeiro et al., 2012; Dall'Agnol et al., 2013). In agronomic terms, the high genetic stability of the symbiotic plasmid (pSym), the tolerance to environmental stresses and the high capacity of fixing nitrogen of some elite strains have resulted in increasing use of *R. tropici* strains in inoculants (e.g., Hungria et al., 2000, 2003). In this chapter, we discuss the biodiversity of *R. tropici* and related species and review genome-sequencing and gene-expression studies of two strains belonging to this group – *R. tropici* CIAT 899^T and of strain PRF 81, recently described as the type strain of the new species *R. freirei* – both of which have been successfully used in commercial inoculants for application to common-bean crops in the tropics.

74.2 PHYLOGENY AND TAXONOMY OF *R. tropici*

The report of *R. tropici* in 1991 (Martínez-Romero et al., 1991) represented the first description of a rhizobial species to include 16S-rRNA gene-sequence analysis. At that time, two types were recognized within the species, A and B. After two decades, accumulated data supported the description of the new species *R. leucaenae*, which included the strains

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

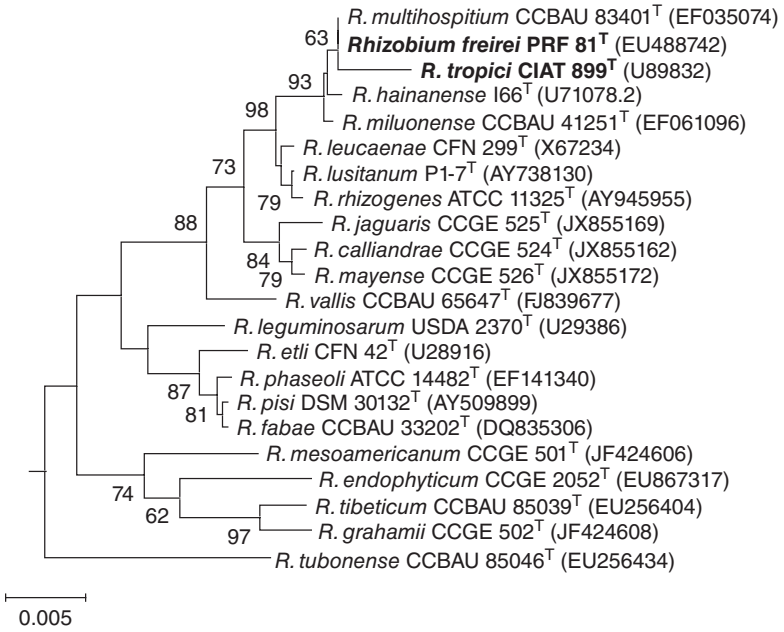

Figure 74.1 Neighbor-joining phylogeny of 16S rRNA gene sequences (1308 nt) of *Rhizobium tropici*, *R. freirei*, and other *Rhizobium* species. GenBank accession numbers are given within parentheses. Bootstrap support values based on 500 resamplings are shown at nodes only when they were ≥60%. Bar, 0.005 substitutions per nucleotide position.

previously classified as *R. tropici* type A (Ribeiro et al., 2012). In addition, evidence was generated of a new species within the strains classified as *R. tropici* (Ribeiro et al., 2009), and based on phenotypic and genomic data, the new species *R. freirei* was described for strain PRF 81^T. We must emphasize here that studies performed between 1991 and 2012 refer simply to *R. tropici*, whereas we now know that other related species are within this group; here we will refer exclusively to studies of symbionts of common bean and *Leucaena* species.

Other species are now recognized to be close relatives of *R. tropici*, including *Rhizobium lusitanum* (Valverde et al., 2006), *Rhizobium rhizogenes* (Hernández-Lucas et al., 2004; Velázquez et al., 2010), *Rhizobium multihospitium* (Han et al., 2008), and *Rhizobium miluonense* (Gu et al., 2008); the latter two, isolated in China, do not nodulate common bean. These rhizobia comprise closely related species, for which the designation "*R. tropici* group" has been proposed (Ribeiro et al., 2012).

Ribosomal sequences – with an emphasis on 16S rRNA – have become the basis of bacterial molecular phylogeny and taxonomy (Woese, 1987; Garrity and Holt, 2001). However, several species cannot be distinguished solely by analysis of their 16S rRNA, and strains within the "*R. tropici* group" fit clearly in this category (e.g., Han et al., 2008; Ribeiro et al., 2012). Strategies to improve species definition, such as the analyses of other ribosomal and housekeeping genes are discussed in more detail in Chapter 18. Here we will highlight that the use of the multilocus sequence analysis (MLSA) approach – considering other genes with evolution rates faster than that of 16S rRNA, but conserved enough to retain genetic information (e.g., Martens et al., 2007, 2008) – has been successfully used to define the taxonomy and phylogeny of strains within the "*R. tropici* group" (Ribeiro et al., 2009, 2012). Figure 74.1 shows the phylogeny based on MLSA of "*R. tropici* group" species and other rhizobial species, highlighting strains CIAT 899 and PRF 81.

Finally, we comment on the interesting resemblance of *R. tropici* with pathogenic agrobacteria (e.g., Lloret and Martinez-Romero, 2005), which has been confirmed in genomics (Ormeño-Orrillo et al., 2012) and proteomics (Gomes et al., 2012b) studies. This subject of study may help to elucidate evolutionary linkage between the processes of symbiosis and pathogenicity.

74.3 ORIGIN AND GEOGRAPHIC DISTRIBUTION OF *R. tropici*

R. tropici strain CIAT 899^T was isolated from a common-bean nodule in Colombia by an outstanding microbiologist, Dr. Peter H. Graham, when he was working at CIAT (Centro Internacional de Agricultura Tropical, International Center of Tropical Agriculture). However, the precise origin of *R. tropici* is not known, and a variety of ecosystems in Brazil have yielded the majority of the available strains, isolated both from common bean and *Leucaena* species (Martínez-Romero et al., 1991; Hungria et al., 1993, 1997, 2000, 2003; Mercante, 1993; Mercante et al., 1998; Straliotto et al., 1999; Andrade et al., 2002; Mostasso et al., 2002; Grange and Hungria, 2004; Pinto et al., 2007; Stocco et al., 2008).

It is worth mentioning that common bean is considered native to the Americas, and domestication is thought to

have taken place separately in two major centers of genetic diversification: the Mesoamerican center or northern group (from Mexico to the northern region of South America), and the Andean center or southern group (from southern Peru to the north of Argentina); a third minor domestication center may exist in Colombia (Gepts 1990; Kami et al., 1995), where CIAT 899^T was isolated. Wild common beans are not found in Brazil, but archeological evidences indicate that the legume was spread by migration and trade among Indian populations throughout history (Grange et al., 2007; Pinto et al., 2007). Therefore, the broad distribution of *R. tropici* in Brazil has at least two possible explanations: (i) as a symbiont of an indigenous legume that adapted to common bean when the legume was introduced and (ii) seeds traded from the Andean center of origin carried *R. tropici*, and its proliferation in Brazilian soils was favored by intrinsic properties of the species, such as tolerance of environmental stresses.

However, despite the strong evidence that *R. tropici* could have originated in Brazil, it is intriguing that the species has also been isolated from nodules of common bean and other legumes in Europe (e.g., in France, Geniaux et al., 1993; Amarger et al., 1994; and Spain, Herrera-Cervera et al., 1999), in Africa (e.g., in Kenya, Anyango et al., 1995; Odee et al., 2002; Tunisia, Mhamdi et al., 1999; Senegal and Gambia, Diouf et al., 2000), in Australia (e.g., Lafay and Burdon, 1998, 2001), in Central America (e.g., Mexico, Acosta-Durán and Martínez-Romero, 2002) and in North America (e.g., USA, Bernal et al., 2004). International trade in common-bean seeds carrying rhizobia (e.g., Andrade and Hungria, 2002) may have contributed to the distribution of the species, but it is noteworthy that *R. tropici* has also been reported as a symbiont of indigenous legumes far from South America (e.g., Australia, Lafay and Burdon, 1998, 2001).

In relation to other legume hosts, *R. tropici* strains have been isolated from *Gliricidia sepium* in Mexico (Acosta-Durán and Martínez-Romero, 2002) and Brazil (Menna et al., 2006; Binde et al., 2009), *Acaciella angustissima* in Mexico (Rincón-Rosales et al., 2009), *Mimosa scabrella* and *Mimosa caesalpiniifolia* in Brazil (Menna et al., 2006), *Bolusanthus* and *Aspartium* in Africa (Dagutat and Steyn, 1995), from native shrubby legumes in Australia (Lafay and Burdon, 1998) and *Lotus tenuis* in Argentina (Estrella et al., 2009). Furthermore, in studies of host range, *R. tropici* was found to nodulate *Macroptilium* sp. and several other legume hosts (Martínez-Romero et al., 1991; Hernández-Lucas et al., 1995; Hungria et al., 2000).

Altogether, these reports highlight *R. tropici* as being exceedingly promiscuous. One hypothesis to explain this broad host range is in terms of the largest number of Nod factors (or lipo-chitooligosaccharides, LCOs) described so far for a rhizobial species (Folch-Mallol et al., 1996).

74.4 INTERESTING FEATURES OF *R. tropici*

Although a variety of described and probably new rhizobial species have been isolated from common-bean nodules in Brazil, *R. tropici* (and related common bean and *Leucaena* species, *R. leucaenae* and *R. freirei*) is clearly dominant in field-grown plants, when both Andean and Mesoamerican genotypes are used as trap hosts (e.g., Hungria et al., 1997, 2000, 2003; Mostasso et al., 2002). This dominance may be attributed to intrinsic properties of the species, particularly tolerance of acidic and high temperature conditions (Martínez-Romero et al., 1991; Hungria et al., 1993, 2000, 2003; Graham et al., 1994). Strong competitiveness of *R. tropici* in acid soils has also been reported in Africa (Anyango et al., 1995).

Use of *R. tropici* related strains in inoculants for common-bean crops was suggested in light of its tolerance of environmental stresses, together with the important feature of higher stability of the pSym, in comparison to other common-bean rhizobia (Soberón-Chávez et al., 1986; Flores et al., 1988; Martínez-Romero et al., 1991; Segovia et al., 1993), probably due to the presence of a unique copy of the *nifH* gene (Martínez-Romero et al., 1991; Geniaux et al., 1993). It is essential to select genetically stable rhizobia for use in commercial inoculants, especially for countries, such as Brazil, where stressful environmental conditions frequently prevail. A selection program of *R. tropici* strains was started in Brazil in the mid-1990s, to identify strains with superior competitiveness and capacity to fix nitrogen. Since then, three strains have been recognized as very effective in fixing nitrogen with adequate industrial properties, and are now carried in thousands of doses of commercial inoculants: *R. tropici* CIAT 899^T (=SEMIA 4077), *Rhizobium freirei* PRF 81^T (=SEMIA 4080), and *R. tropici* H 12 (=SEMIA 4088); they are capable of supplying sufficient N to support grain yields of 2500 kg/ha or higher (Hungria et al., 2000, 2003). Under conditions not limiting to nitrogen fixation, for example, extremely acid soils (pH < 5.0) and severe drought, inoculated plants yield as much as plants receiving 60–100 kg of N-fertilizer/ha, and Figure 74.2 shows the results of one of these experiments. Interestingly, seed inoculation was successful even in the presence of a high indigenous population, contradicting one of the dogmas about failure of inoculation in soils with a high number of compatible rhizobia (e.g., Graham, 1981; Thies et al., 1991; Hardarson, 1993). Interestingly, in trials performed in Brazil, even in the presence of 10^3–10^6 indigenous rhizobia/g, soil nodule occupancy by elite inoculant strains was increased both by initial inoculation and by reinoculation, resulting in yield increases by 50% or higher (Hungria et al., 2000, 2003).

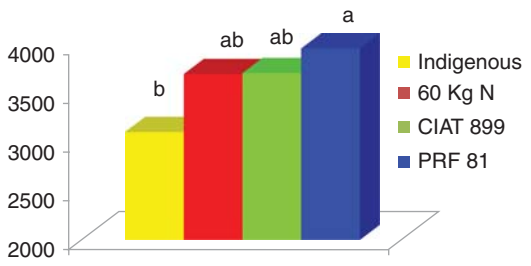

Figure 74.2 Grain yield (kg/ha) of common-bean cultivar Pérola non-inoculated, in soil with an indigenous population estimated at 10^5 cells/g soil; non-inoculated controls receiving or not N-fertilizer, split at sowing and flowering, or inoculated with *R. tropici* CIAT 899^T or *R. freirei* PRF 81^T at sowing. Experiment performed in Londrina, State of Paraná, Brazil.

74.5 GENOMICS

Recently, the genome of *R. tropici* CIAT 899^T was obtained and reported together with that of *R. freirei* PRF 81^T (Ormeño-Orrillo et al., 2012). Like other rhizobia, CIAT 899 and PRF 81 have multipartite genomes composed of several replicons. In both cases, one replicon has all of the ribosomal genes and all of the genes regarded as "essential," being thus a chromosome, whereas the remaining replicons have *repC*-type replication systems and are considered plasmids (three in CIAT 899 and four in PRF 81). These strains, and others ascribed to the "*R. tropici*" group (Acosta-Durán and Martínez-Romero, 2002; Pinto et al., 2007), possess fewer plasmids (two to four) in comparison to other rhizobia such as *R. leguminosarum*, which can have up to 11 (López-Guerrero et al., 2012).

Both strains CIAT 899 and PRF 81 possess a megaplasmid larger than 2 Mb, which can be classified as a chromid (Harrison et al., 2010) because its G + C content is similar to that of the chromosome and it harbors important genes that in other bacteria are located in the chromosome. Chromids seem to have important roles for survival in the soil and rhizosphere, as many rhizobial chromid genes are expressed in association with plants (Ramachandran et al., 2011; López-Guerrero et al., 2012). We have reported that chromids of CIAT 899 and PRF 81 contain several genes related to root and rhizosphere colonization and a large proportion of the transporter capacity of their genomes (Ormeño-Orrillo et al., 2012). Despite their importance, chromids can be cured under laboratory conditions, as has been reported for a megaplasmid-cured CIAT 899 derivative (Barreto and Baldani, 2002), probably because functions encoded in those replicons are dispensable in rich laboratory media.

CIAT 899 and PRF 81 share an almost identical pSym that has outstanding features such as possessing three *nodA* and five *nodD* genes, and also auxin- and gibberellin-biosynthesis genes (Ormeño-Orrillo et al., 2012). Reiteration of *nod* genes may explain the broad host ranges displayed by these strains. Genomic evidence indicates that this pSym is present also in *R. leucaenae* CFN 299^T (Ormeño-Orrillo et al., 2012) and in *R. tropici* WUR1 (Op den Camp et al., 2012). Other evidence, like plasmid profiles (Pinto et al., 2007) and *nod/nif* gene sequences – identical or almost identical to those of CIAT 899 – suggest that this pSym is present in several strains of the "*R. tropici*" group, including *Rhizobium* spp. (Zurdo-Piñeiro et al., 2004; Ibañez et al., 2008) and in species as *R. lusitanum* (Valverde et al., 2011) and other strains of *R. tropici* (Faghire et al., 2012). Most of these strains have been isolated from common bean and also from peanut (*Arachis hypogaea* L.) and wild legumes.

Plasmids other than the pSym have roles in nodulation and also encode important metabolic functions (for a recent review, see López-Guerrero et al., 2012). In CIAT 899, a derivative cured of its smallest plasmid (pRtrCIAT899a) induced fewer and smaller nodules in common bean than the wild type and was defective in nodulation competitiveness (Barreto et al., 2012). The defective phenotype of this cured derivative may be explained by the loss of pRtrCIAT899a *teu* genes that are important for common-bean nodulation (Rosenblueth et al., 1998). PRF 81 also has *teu* genes in one of its smaller plasmids (pPRF81b). Other genes of pRtrCIAT899a that may influence symbiosis include homologs of *yagTSR* involved in purine metabolism and a tripartite ATP-independent periplasmic (TRAP)-family dicarboxylate transporter. The two smallest plasmids of PRF 81 also carry genes that may be related to symbiosis, including an aspartate ammonia-lyase, sarcosine catabolism genes, an alpha-glucoside utilization locus in pRF81a, two TRAP transporters, a polyhydroxybutyrate metabolism gene, and an aspartate aminotransferase in pPRF81b.

The genomic analyses also emphasized the potential for stress tolerance in CIAT 899 and PRF 81. Analyses of the predicted gene functions in the genomes of both strain revealed the potential for resistance to or tolerance of unfavorable conditions such as high temperatures, low pH, high heavy-metal concentrations, as well as stressful osmotic, oxidative, and nitrosative conditions (Ormeño-Orrillo et al., 2012). As seen in Table 74.1, most of the genes that can be related to stress tolerance are located in the chromosomes of both strains; nevertheless, a large proportion of the genes is located in their megaplasmid chromids. More than 33% of all genes related to osmotolerance and oxidative stress response, and all involved in nitrosative stress, are located in the chromids. The proportion is even higher for genes related to heavy-metal tolerance, 44% and 67% in CIAT 899 and PRF 81, respectively. Chromids, having intermediate features between chromosomes and plasmids, are considered stable replicons (Harrison et al., 2010) and may be less subject to horizontal gene transfer. Finding the majority of genes related to stress response in the chromosome/chromid seems to indicate that resistance to abiotic stresses is an intrinsic

Table 74.1 Number of genes involved in stress response in each replicon of *R. tropici* CIAT 899^T and *R. freirei* PRF 81^T

	Number of Genes in Each Replicon						
	CIAT899				PRF81*

characteristic of these strains that may not be lost when a plasmid is cured. The pSym also carries stress-related genes (Table 74.1), an observation that is consistent with evidence that rhizobia are stressed at some stage(s) of formation of, and/or functioning in, root nodules.

74.6 PROTEOMICS

The term "proteome" refers to the set of proteins expressed by a cell, tissue, or organism in a specific condition; the importance of these studies relies also in their dynamics, as changes may occur with the physiologic state of cells, or in response to internal and external stimuli. Accordingly, proteomic tools were developed to study a large number of proteins, allowing a global view of protein expression (Graves and Haystead, 2002).

Most proteomics studies performed with rhizobia have employed 2D electrophoresis to separate proteins. By this approach, proteins are submitted, in the first step, to isoelectric focusing (IEF), followed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), generating bidimensional maps for the samples, where proteins are separated by their isoelectric points (pIs) and molecular weights (MWs) (Westermeier and Naven, 2004). In addition, other important information can be obtained from the gels, including expression rates and relative amounts of proteins (Cash, 1998; Pandey and Mann, 2000; Herbert et al., 2001; Jungblut, 2001).

A proteomics reference map of *R. freirei* PRF 81 grown *in vitro* revealed 150 spots, from which 115 were identified, representing 109 different proteins (Gomes et al., 2012b). Interestingly, the great majority of the proteins identified showed highest genetic similarity with *Agrobacterium* (=*Rhizobium*) species, in particular *R. radiobacter*, confirming the genomic data obtained with this strain (Ormeño-Orrillo et al., 2012).

In the reference map of PRF 81, chaperonin GroEL, elongation factor (EF) Tu, dipeptide ATP-binding cassette (ABC) transporter, and beta subunit of F0F1 adenosine triphosphate (ATP) synthase were the protein spots with highest total volumes (Gomes et al., 2012b). In the functional classification of the proteins according to clusters of orthologous groups (COGs), proteins were distributed into 17 categories (Fig. 74.3), belonging to four functional groups: metabolic function, cellular processes and signaling, information storage and processing, and poorly characterized proteins. Of the identified proteins, 51% were related with metabolic function, a key feature that could strongly contribute to the high capacity of the strain to survive in limiting environmental conditions common in the tropics.

Proteins that participate directly or indirectly in the symbiosis were also detected in the proteomic reference map of PRF 81 (Gomes et al., 2012b). Among them, glutamine synthetase I (GS I), with a role in biological nitrogen fixation confirmed in studies with auxotrophic mutants, where the mutant GS I was defective in the ability to derepress nitrogenase, being inefficient in fixing nitrogen (Kondorosi et al., 1977; Ludwig and Signer 1977).

Among the transcription factors of PRF 81, emphasis was given to the expression of LysR family transcriptional regulatory proteins (Gomes et al., 2012b). The LysR transcription regulators have a key role in signal exchanges required for plant root-hair infection, probably through the regulation of *nod*-gene expression (Doty et al., 1993; Luo et al., 2005). Several other proteins related to the exchange of molecular signals between the host legume and the symbiont were also identified in PRF 81, including the two-component regulatory system ChvI, which positively regulates the transcription of *exo* genes that encode enzymes for succinoglycan exopolysaccharide (EPS) biosynthesis in response to plant chemical signals (Cheng and Walker, 1998; Chang et al., 2002). In addition, this EPS may also

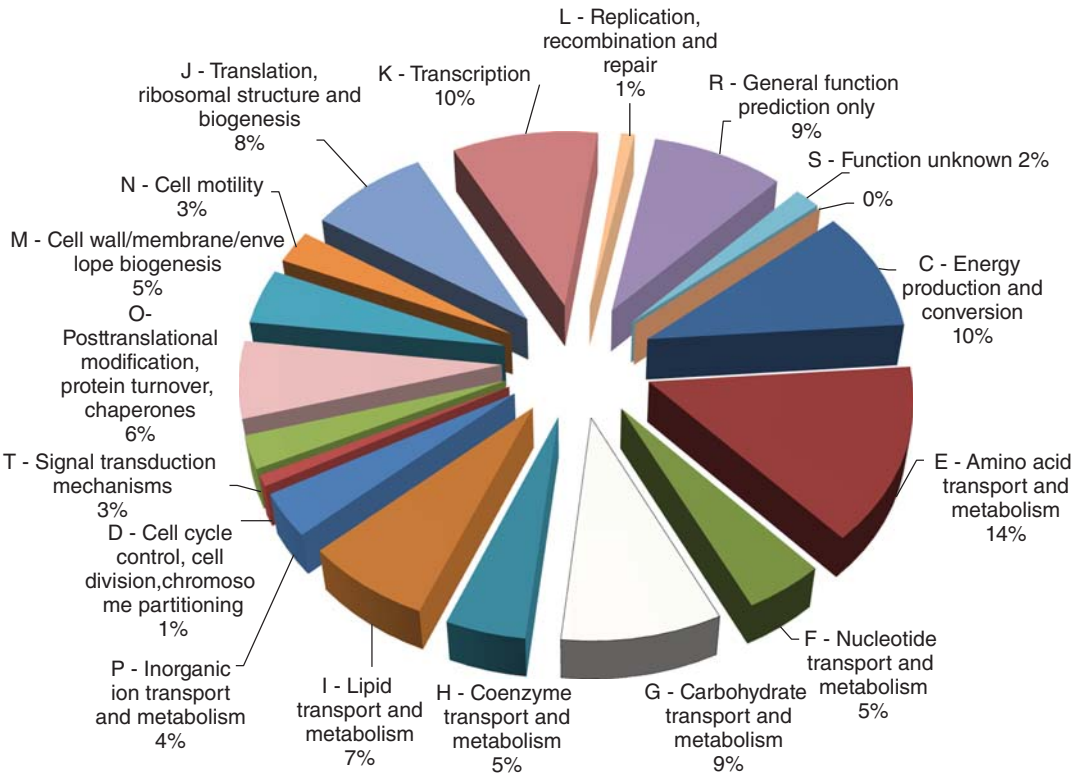

Figure 74.3 COG classes of proteins identified in the reference map of *R. freirei* PRF 81^T. From Gomes et al. (2012b).

be related to the suppression of the plant-defense response during the process of root infection (Cheng and Walker, 1998; Chen et al., 2009).

Beyond reference maps, proteomic analysis is applicable to generate a global view of responses to specific conditions; this approach, differential proteomic analysis, has been employed to elucidate peculiarities of organisms. The higher tolerance of strain PRF 81 to heat stress was investigated using this approach, and 59 proteins were found to be upregulated when exposed to high temperature (37 °C) (Gomes et al., 2012a). Heat-induced proteins identified in PRF 81 included examples that are highly conserved among bacterial species, designed for rapid adaptation to environmental and metabolic changes, including molecular chaperones such as DnaK and GroEL (Gomes et al., 2012a), which are polypeptide-binding proteins implicated in protein folding, protein targeting to membranes, renaturation, and in the control of protein–protein interactions (Wagner et al., 2009).

Still with reference to PRF 81, it is worth mentioning the upregulation of translation factors, with three EFs (EF-Tu, Ef-G, and Ef-Ts) and one initiation factor (IF-2) (Gomes et al., 2012a). In addition to their main function of ensuring gene expression accuracy by transporting the correct codons in the translation process, several authors have reported that elongation and IFs can also act as chaperones in response to heat stress (Fayet et al., 1989; Caldas et al., 1998), suggesting that they might be ancestral protein-folding factors against heat-stress damage (Caldas et al., 2000).

Interaction among groups of proteins with different functions is another important aspect that differential proteomics studies can highlight. One of the main findings from PRF 81 heat-stress proteomic data was the cross talk between heat and oxidative stresses, and several antioxidant factors were identified when PRF 81 was grown at high temperatures (Gomes et al., 2012a). Oxidative stress is characterized by high levels of reactive oxygen species (ROS) that are by-products of normal metabolic processes and may be lethal for cells. Previous studies (Kopcinska, 2009; Meilhoc et al., 2011; Peleg-Grossman et al., 2012) reported the accumulation of ROS in early stages of establishment of the *Rhizobium*/legume symbiosis, acting as specific signals (Nanda et al., 2010); however, they can also be toxic to the bacterium. To detoxify ROS, symbiotic bacteria display multiple defense mechanisms that are required for both the development and the functioning of the symbiosis (Pauly et al., 2006). Reactivation of proteins damaged by oxidative stress is one of the strategies to minimize ROS effects, a function displayed by thioredoxin (TrxA). Additionally, Fernando et al. (1992) reported an indirect action against oxidative stress performed by bacterioferritin (Bfr), which transports inorganic ions such as Fe^{2+}, resulting in the

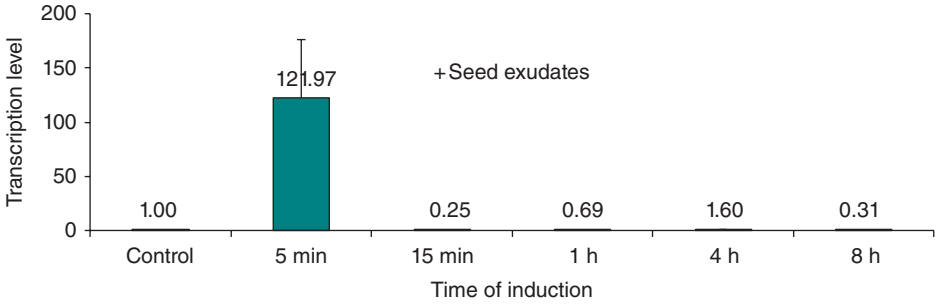

Figure 74.4 Transcription of *nodC* gene of *R. freirei* PRF 81^T grown until the exponential phase and then incubated with seed exudates for various periods of time. Data represent the means of three biological replicates, each with three replicates ± SD. Relative quantification (RQ) was estimated by the equation $1.95^{\Delta\Delta Ct}$. From Oliveira et al. (2010).

decomposition of peroxides overproduced during the oxidative stress. Other proteins, such as isocitrate dehydrogenase, play a key role in NADPH recycling under oxidative stress (Patridge and Ferry, 2006; Marino et al., 2007; Brown et al., 2010). All these antioxidant proteins were upregulated in PRF 81 at high temperatures (Gomes et al., 2012a), highlighting a finely tuned mechanism conferring stress tolerance.

Differential proteomic analysis was also applied in a study with *R. tropici* CIAT 899 to investigate the effects of acidity (Peick et al., 1999). A pH shift from 6.8 to 5.2 affected the expression of five pH-induced proteins, PipA, B, C, D, and E, and of four pH-reduced proteins, PrpA–D. PipA and B proteins were then selected for N-terminal sequencing; PipA showed high similarity with several bacterial enzymes involved in modifications in cells, mainly epimerization of glucosenucleosides (Peick et al., 1999). The highest similarity (68%) was found with PipA of *Staphylococcus aureus*, which is involved in the biosynthesis of *N*-acetylgalactosamino uronic acid, a component of staphylococcal type I capsules (Lin et al., 1994). PipA also showed similarity (66%) with a uridine diphosphate (UDP)-glucose epimerase from *Sinorhizobium meliloti*, a protein involved in EPS biosynthesis and important to biofilm formation and cell protection (Yao et al., 2004; Fujishige et al., 2006).

We conclude that, despite the few proteomic studies performed so far with *R. tropici*-group strains, important results have been obtained with both the proteomic reference map and differential proteomic experiments, helping to elucidate mechanisms related to the stress tolerance of the species.

74.7 TRANSCRIPTOMICS

Novelties have also been revealed in transcription studies. In *R. freirei* PRF 81, three genes related to nodulation and located in the pSym were investigated by reverse-transcription quantitative polymerase chain reaction (RT-qPCR): *nodC* (with a role in the biosynthesis of the basic structure of the chito-oligosaccharides, also an important determinant of LCO chain length), *nodG* (encodes a 3-oxoacyl-[acyl] carrier protein reductase involved in the biosynthesis and transfer of common fatty acids), and *glgX* (involved in the transformation of glycogen into 1,4-glycan, and located immediately upstream of *nodN* in *R. tropici*) (Oliveira et al., 2010). All three genes showed low levels of transcription when the cells were grown into the exponential phase in the presence of common-bean-seed exudates or of the root *nod*-gene inducer naringenin. However, when cells in the exponential phase of growth were incubated with seed exudates, transcription occurred after only 5 min, and *nodC*, *nodG*, and *glgX* were transcribed 122-, 15-, and 50-fold more than the control, respectively (Fig. 74.4), followed by a rapid overall decrease in gene transcription. Much lower levels of transcription were observed in the presence of naringenin, and maximum transcription in the presence of this flavonoid required 8 h of incubation for all three genes (Oliveira et al., 2010). The results could be interpreted as leading to an initial high production of Nod-factor synthesis enzymes, which, very rapidly, is reduced to much lower levels, and another hypothesis is that this mechanism prevents inhibition of nodulation by an excessively high concentration of Nod factors. The results also indicate that compounds in seed exudates – still to be determined – may be responsible for rapid induction of *nod* genes. The extremely rapid transcription described in this study (e.g., Fig. 74.4) indicates that signal exchanges between host legumes and rhizobia may occur considerably more quickly than previously thought (Oliveira et al., 2010).

Another transcription study was performed with three biosynthetic polysaccharide genes of PRF 81, *lpxA*, *lpxE* (involved in the biosynthesis and modification of the lipid-A anchor of lipopolysaccharide), and *rkpI* (involved in the synthesis of a lipid carrier required for the production of capsular polysaccharides). RT-qPCR analysis revealed, for the first time, that inducers released from common-bean seeds strongly stimulated the expression of all three genes (Oliveira et al., 2013). Again, the highest increases in the transcription rates – of about 50-fold for *lpxE* and about 30-fold for *lpxA* and *rkpI* – were observed after only 5 min of incubation. Upregulation of *lpxE*, *lpxA*, and *rkpI* genes suggests that inducer compounds in seed exudates can modulate the biosynthesis and modification of the surface

polysaccharides of PRF 81, leading to cell-wall changes that are implicated in the establishment of the symbiosis (Oliveira et al., 2013).

74.8 CONCLUDING REMARKS

In this chapter, we pooled information about biodiversity of bacteria related to the *R. tropici* species (including the recently described *R. leucaenae* and *R. freirei*). Among the main features of *R. tropici* and related species are a broad host range and high tolerance to environmental stresses. Two elite strains showing high capacity of fixing nitrogen and high competitiveness in the tropics were included in our studies, *R. tropici* CIAT 899^T and *R. freirei* PRF 81^T, both commonly applied in commercial inoculants to seeds of common bean prior to planting. High grain yields can be obtained by inoculation and reinoculation with those strains, even in soils with abundant indigenous compatible rhizobia. Interesting information about these two strains has been revealed by genome sequencing, with an emphasis on a highly conserved pSym, which may help to explain similarities in the stability of symbiotic properties. Proteomic studies have highlighted new proteins, brought interesting evolutionary information, and identified proteins related to heat and acid stresses. Transcription studies with genes related to nodulation and surface polysaccharide biosynthesis in PRF 81 indicated a remarkably rapid transcription in the presence of common-bean-seed exudates, with no parallel with any other report with rhizobia. In summary, exciting information obtained in the few studies performed so far emphasize how useful these bacteria are.

75.1 INTRODUCTION

Frankia alni and its host, *Alnus glutinosa* establish a nitrogen-fixing root symbiosis based on an exchange of signals and metabolites (see Chapters 35, 42, 43, 48, 55). Knowledge of the determinants involved has however been hampered by the lack of a genetic transformation system despite numerous attempts with protoplasts regeneration (Normand et al., 1987; Tisa and Ensign, 1987) and electroporation (Cournoyer and Normand, 1992; Myers and Tisa, 2003). The reasons for this failure are unknown but may have to do with the slow growth rate of *Frankia*, the presence of a restriction and modification system, thick wall with unusual lipids or with specific promoters. A complementation of *nodBC Rhizobium* mutants with *Frankia alni* DNA also failed (Ceremonie et al., 1998).

On the plant side, recent progress has been made. It has been shown that a kinase, SymRK homologous to the one that plays a crucial role in legumes by detecting Nod factors, is also necessary for nodulation of *Casuarina* (Gherbi et al., 2008) and *Datisca* (Markmann et al., 2008; see Chapter 55). Furthermore, an expressed sequence tag (EST) study of *Casuarina* and *Alnus* showed most of the determinants known in legumes were present in actinorhizal plants (Hocher et al., 2011). Actinorhizal host plants thus appear to have a symbiotic cascade very similar to the one existing in legumes (see Chapter 55).

The genomes of several symbiotic *Frankia* strains (see Chapter 24) were sequenced among other things to identify *nod* genes (Normand et al., 2007b); however, no canonical *nod* clusters (common *nod*ABC) could be identified (Normand et al., 2007a). It was thus decided to use a transcriptomic approach to try to identify groups of genes involved in symbiosis (Alloisio et al., 2010).

75.2 MATERIALS AND METHODS

Frankia alni ACN14a was grown at 28 °C with stirring at 200 rpm in defined BAP (Basal medium with propionate) containing 5 mM ammonium chloride (N-replete condition) and 5 mM sodium propionate as carbon source. Seeds of *Alnus glutinosa* were planted and grown for 5–10 weeks under fluorescent lighting with a 16-h light and 8-h nycthemeral regime at 21/25 °C. Seedlings were transferred to plastic pots (8 seedlings/pot) and grown for 4–9 weeks with 0.5 g of KNO_3 per liter and, then, for 1 week without KNO_3. *F. alni* ACN14a cells derived from 75 ml of log-phase culture were inoculated to a pot. Root nodules (≤3 lobes) were harvested

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

into liquid nitrogen 3–4 weeks after inoculation and stored at −80 °C. Nodules from about 24 plants per replicate were pooled for RNA extraction, and three biological replicates were treated (Alloisio et al., 2010).

RNA was purified from bacterial cells and nodules using RNeasy plant mini kit (Qiagen) and on-column DNA digestion with the RNase-free DNase set (Qiagen). In order to remove any contaminating DNA, a second DNase treatment was performed with RQ1 RNase-free DNase (Promega, Charbonnières-les-Bains, France), followed by RNA cleanup using RNeasy mini-kit. Purity, concentration, and quality of RNA samples were checked using a NanoDrop 1000 spectrophotometer (Thermo Fisher Scientific, Courtaboeuf, France) and agarose gel electrophoresis. Based on the sequence and annotation data for *F. alni* ACN14a, a whole-genome high-density microarray was designed and manufactured by Roche NimbleGen, Inc. (Madison, WI, USA). Due to high guanine-cytosine (GC) content (72.8%) of the *F. alni* genome, a 60-mer oligo length was chosen for probe design. NimbleGen design rules and analysis algorithms found probes for 6,607 genes out of 6786. There were 18 probes per gene obtained for 6340 genes and <18 probes per gene were obtained for 267 genes. Probes were duplicated on the array (Alloisio et al., 2010).

75.3 RESULTS

Overall, transcript levels were compared between young nodules (3–4 weeks old) and cultured cells grown in N-replete minimal medium, and it permitted to show that in one data set (A), 871 genes showed a differential expression in symbiosis versus *in vitro* N-replete free-living (FL) cells compared with 457 genes in the other data set (B). In the two data sets, there were 292 "common" genes, with 166 genes upregulated and 126 genes downregulated (Table 75.1). There were 183 of these genes that belonged to the core genome defined with the three first published genomes (ACN14a, CcI3, and EaN1pec). The highest upregulation was for the *nifHDK* genes that were 210–270 times upregulated in symbiosis.

75.3.1 Genes Known to be Involved in Symbiosis

There are several genes known to be involved in symbiosis comprising the *nif*, *hup*, *suf*, and *isp* + *shc* genes. The whole *nif* cluster that comprises 18 genes from FRAAL6797 (ferredoxin) to FRAAL6814 (*nifV*) was the most upregulated, while neighboring genes of unknown function were not. In the cluster, the structural genes for the nitrogenase, *nifD*, *K*, and *H*, were more upregulated than the ancillary nitrogenase genes. Another ferredoxin FRAAL3855, situated away from the *nif* cluster and postulated to provide the nitrogenase enzyme with reductants, was also highly upregulated.

Hydrogenases permit to recycle hydrogen, a byproduct of nitrogenase. Hydrogenase cluster #2 (hup2) that comprises 11 genes from FRAAL1822 (protein of unknown function or puf) to FRAAL1832 (puf) was for the most part upregulated but only at a fraction of the *nif* genes. The most upregulated *hup* gene FRAAL1830, hupS2 was 12.45-fold upregulated, less than one-tenth of the *nif* structural genes. The second hydrogenase cluster, hup1 comprising FRAAL2388–2395 was not upregulated in symbiosis.

The *suf* cluster that provides iron–sulfur cluster likely for nitrogenase and hydrogenases ranges from FRAAL4557 to FRAAl4563. The *suf* genes are upregulated at levels comparable to those of the *hup*2 genes. The most upregulated was *sufC*, upregulated 7.45-fold.

The shc1 cluster (FRAAL1428–1435) contains the major genes leading to hopanoid biosynthesis such as the *shc* gene encoding the squalene hopene cyclase and yielding the polycyclic lipids that in vesicles protect nitrogenase from oxygen. In this cluster, two genes were significantly upregulated and a squalene/phytoene dehydrogenase (FRAAL1430, fold change (fc) = 5.25). The genes in the initial part of the non-mevalonate pathway are clustered away from *shc*1 but most are nevertheless upregulated, such as *ispG* (FRAAL5772, fc = 6.65), *dxs* (FRAAL2088, fc = 5.9), or *idi* (FRAAL6504, fc = 4.20). A second *shc* gene, *shc*2, situated away from all these genes (FRAAL2491) was not upregulated.

75.3.2 Homologs of *nod* Genes

There are no significant homologs of *nodA* in *Frankia alni*, however, there are three homologs of *nodB* (FRAAL4911, FRAAL4175, FRAAL1746) and six homologs of *nodC* (FRAAL6263, FRAAL6103, FRAAL2582, FRAAL0797, FRAAL1439, FRAAL2169), the gene that codes for a glycosyl transferase that oligomerizes *N*-acetyl-glucosamine into the backbone of the Nod factor (Normand et al., 2007a) and none of these distant homologs was upregulated above the significance threshold.

75.3.3 Secondary Metabolites

Frankia genomes have been shown to contain several secondary metabolites determinants (Udwary et al., 2011). These genes are for the most part not modified upon switch to symbiosis, except for the hopanoid cluster that is upregulated, a spore pigment cluster, a Type I iterative PKS (polyketide synthase). The other genes were unmodified (Table 75.2).

75.3.4 Transporters

Exchange of nutrients between the microbe and the host plant implies in particular photosynthates that the plant feeds the microbe with and fixed nitrogen that the microbe yields

ECF, extracytoplasmic function and EF-G, elongation factor G;

"+," present and "−," absent.

*Gene number, gene name, and product description according to the Genoscope database. puf stands for protein of unknown function, cpuf for conserved puf. Core genes are highlighted in gray.

†Fold-change comparing nodules versus FL cells, average of the two data sets.

‡Clusters of orthologous genes (COGs) classification ID (Tatusov et al. 2001).

§Core genes are defined as conserved genes in the three strains (ACN, EAN, and CcI3) at a threshold level of 40% amino acid identity over 80% of the length of the smaller gene.

**Specific genes are defined as core genes not conserved in *Acidothermus cellulolyticus* (NC_008578), *Streptomyces avermitilis* (NC_003155, NC_004719), and *S. coelicolor* (NC_003888, NC_003903, NC_003904) at a threshold level of 40% amino acid identity over 80% of the length of the smaller gene.

††Synteny is defined as the presence of a group of genes in the three strains (ACN, EAN, and CcI3), having 30% amino acid identity over 80% of the length of the smaller gene, separated by no more than five intervening sequences.

‡‡Core secretome encompasses 161 conserved secreted proteins in the three strains (ACN, EAN, and CcI3) according to Mastronunzio et al. (2008).

to the plant. *Frankia* in nitrogen-fixing pure culture can assimilate NH_4^+ produced by nitrogenase mainly through GSII a glutamine synthetase encoded by the *glnII* gene, whereas in N-replete culture, NH_4^+ is mainly assimilated by GSI, encoded by the *gln*A gene (Alloisio et al., 2010; Schultz and Benson, 1990). However, in symbiosis, the *glnA* gene is strongly downregulated (FRAAL5161, fc = 0.2), whereas the *glnII* gene (FRAAL5163) was not significantly induced, suggesting that symbiotic *Frankia* produces NH_4^+ that accumulates in vesicles and is then assimilated by the host plant enzymatic machinery.

In the *F. alni* genome, there are 426 genes labeled as involved in transport, export, or efflux, 229 of which are ATP-binding cassette (ABC) transporters. However, only about a dozen (or 5% of them) were differentially expressed, suggesting that nutrients and secondary metabolites exchanged between the two partners are reduced to the minimum, to focus bacterial activity onto nitrogen fixation. Finally, a gene (FRAAL0792) encoding a putative high-affinity branched-chain amino acid ATP-binding ABC transporter was 2.35-fold upregulated, permitting to suggest amino acids are also transported.

Concerning the uptake of plant photosynthates, the *Frankia* ACN *dctA* gene (FRAAL1390) was not differentially expressed and no *dct*A homolog is present in the CcI3 genome, suggesting another transporter could be involved. There are several poorly characterized ATP-binding ABC transporters (FRAAL2212, 2213, and 1843) that were two- to threefold upregulated but only in one of the two data sets. It is also possible that the reference for the arrays, which was *F. alni* growing on propionate in BAP, uses the same transporter, and thus, that there is no upregulation. Conversely, transporter genes exhibiting remarkable expression change were those coding for a putative sugar ABC transporter (FRAAL3762 to 3765), which were highly downregulated in nodules.

75.3.5 Comparison with Rhizobia Nodule Transcriptome

Rhizobia acquired a set of genes required for symbiotic nitrogen fixation via horizontal gene transfer (Sullivan and Ronson, 1998; see Chapter 21). Some rhizobia such as *Mesorhizobium* and *Bradyrhizobium* received them in the chromosome, and this structure is referred to as a symbiosis island (Kaneko et al., 2000, 2002). In the case of *Mesorhizobium loti*, genes within the symbiosis island are collectively expressed in nodule, forming an obvious "expression island" spanning about 600 kb (Uchiumi et al., 2004). In the case of *F. alni* nodule transcriptome, however, such a large island was not found and upregulated genes are scattered over the genome (see later), suggesting different origins of the symbiotic gene set between the two bacterial lineages.

Content of regulated genes and mode of their regulation in nodule are not similar between *Frankia* and rhizobia. *F. alni* and *Sinorhizobium meliloti* (Capela et al., 2006) shared 1179 orthologs, and 345 of them showed significant expression change in either of the bacteria. But only 16 of them were similarly upregulated (11) or downregulated (5) in nodule. Dominant genes upregulated in both bacteria were *nif*-related. Most of the upregulated genes in *F. alni* were downregulated or did not show significant expression

Table 75.2 Secondary metabolite gene clusters expression level

Gene Cluster	Genes	Metabolite Type	Proposed Product	Fold Change (Extreme Values)	Gene with Significant Fold Change

changes in *S. meliloti*. Many of these genes were related to energy production (tricarboxylic acid cycle (TCA) cycle, respiration, and adenosine triphosphate (ATP) synthase) and translation (ribosomal proteins and translation factors). These results suggest that in the nodule, *Frankia* is metabolically more active than rhizobia. In contrast to rhizobia that are tamed by host plant being deprived of growth ability (Mergaert et al., 2003; see Chapter 67), *Frankia* appear to be more autonomous; for example, they have to synthesize vesicles to deal with lack of oxygen protection provided by host plants.

75.3.6 Localization on the Chromosome

Known symbiotic genes are not clustered on the genome, instead *nif* genes are close to the origin of replication, while the other clusters are scattered along the genome (Fig. 75.1).

75.4 CONCLUSION

No "smoking gun" upregulated genes could be identified that would have yielded new light on symbiosis mechanisms.

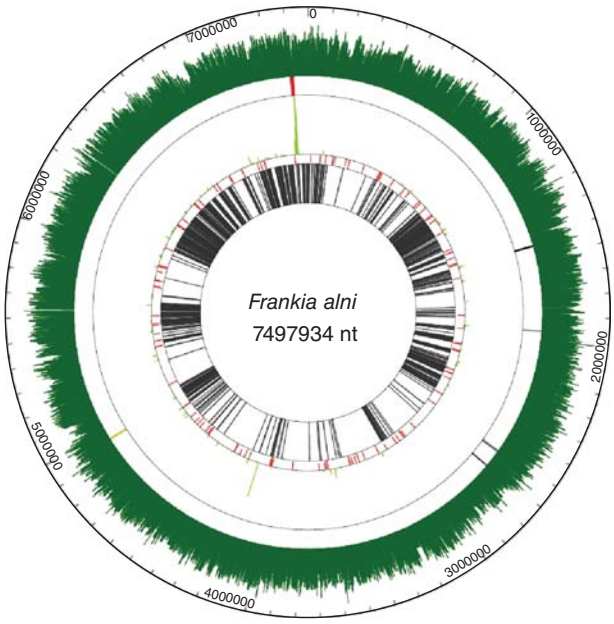

Figure 75.1 Circular representation of *Frankia alni* genome showing from the outside in (i) the GC% (in green), (ii) the symbiotic genes (*shc* genes in black, *hup* genes in gray, *suf* genes in yellow, *nif* genes in red), (iii) up-regulated genes (fc > 2, in light green), (iv) down-regulated genes (fc < 0.5, in red), and (v) conserved genome (>70% in aa).

Expected upregulated genes that were found to indicate symbiotic *Frankia* is essentially a nitrogenase machine. These upregulated clusters also indicate the DNA array approach functions but its dynamic range is probably too short, mainly because of the poor quality of high GC probes, to allow to identify symbiotic genes.

Deep sequencing of transcripts (RNA-seq) approaches should be used in the future to help identify the symbiotic determinants. The removal of ribosomal RNA is a critical step that still needs to be improved. RNA-seq can also help discern polycistronic messages, small regulatory RNAs, and tRNAs to obtain an enlarged view of the molecular regulation in symbiosis.

Chapter 76

A Comprehensive Survey of Soil Rhizobiales Diversity Using High-Throughput DNA Sequencing

Ryan T. Jones

Department of Microbiology and Immunology, Montana Institute on Ecosystems, Montana State University, Bozeman, MT, USA

76.1 INTRODUCTION

Numerous lineages from many bacterial phyla can fix nitrogen, but the majority of known rhizobia, nitrogen-fixing legume symbionts, are members of families (e.g., *Bradyrhizobia*, *Rhizobiaceae*, *Phyllobacteriaceae*) within the Rhizobiales, a diverse order within the bacterial subphylum Alphaproteobacteria.

In addition to nitrogen-fixing symbionts, the order includes lineages that are pathogenic to plants and animals and free-living lineages, some of which also fix nitrogen. A study comparing complete genomes from 30 Rhizobiales found that genomes of pathogens and symbionts contain both virulence and symbiotic genes and that horizontal gene transfer, especially of genes with activities related to host interactions and nitrogen fixation, contributes to the evolutionary plasticity of Rhizobiales (Carvalho et al., 2010).

In soil, Rhizobiales commonly fix nitrogen, and their abundance and community structure has been found to correlate positively with carbon-to-nitrogen ratio, the concentration of carbon, and the concentration of nitrogen (Shu et al., 2012; Will et al., 2010). In previously barren or disturbed soils, the abundance of Rhizobiales increases in response to new vegetation (Chen et al., 2012; Knelman et al., 2012). Agricultural practices can also affect Rhizobiales, and zero-tillage agriculture positively affects Rhizobiales abundance (Ceja-Navarro et al., 2010).

Environmental and site characteristics may affect specific lineages differently than they affect deeper taxonomic classifications. For example, abundance of the Acidobacteria phylum is negatively correlated with soil pH, but some subgroups within the phylum are positively correlated with pH (Jones et al., 2009). Similarly, environmental effects on rhizobia may differ from environmental effects on Rhizobiales as a whole. Although Rhizobiales are correlated positively with nitrogen content of the soil (Will et al., 2010), high levels of nitrogen limit diversity of *Rhizobium* populations (Caballero-Mellado and Martinez-Romero, 1999; Palmer and Young, 2000). Rhizobiales are much more abundant in the A horizon of soil (Will et al., 2010), but abundance of *Bradyrhizobium* under a leguminous tree does not differ substantially between surface and deep soils (Dupuy and Dreyfus, 1992).

A limitation of many studies on Rhizobiales diversity is the small number of soils analyzed and the focus on a specific genus or species. Until recently, surveying a large number of soils relied on fingerprinting-based approaches (e.g., denaturing gradient gel electrophoresis, terminal restriction fragment length polymorphism). While these approaches may be heuristically useful and necessary due to budgetary reasons,

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

they are not optimal because the data generated are not linked to specific taxonomic groups and no phylogenetic or taxonomic information is generated (Jones et al., 2007). Fortunately, the development of barcoded primers has unleashed the power of high-throughput DNA sequencing and made it available to studies of microbial biogeography (Hamady et al., 2008). This approach works by attaching a unique barcode of 8–12 base pairs to the primer; DNA sequences generated contain that code which allows the sequence to be assigned to the correct sample. In this way, hundreds to thousands of samples can be analyzed in a single high-throughput DNA sequencing reaction.

The barcoded high-throughput approach has been used to explore biogeographic effects on soil bacterial and fungal communities with great success. A phylum-level analysis demonstrated a strong effect of soil pH on both bacterial diversity and composition (Lauber et al., 2009). In a comparison of bacterial and fungal diversity across an experimental pH gradient, pH strongly affected bacterial diversity but pH only weakly affected fungal diversity (Rousk et al., 2010). In a study of Arctic soils, pH again had the strongest effect on bacterial community structure and Arctic soils more closely resembled soils from across the globe with similar pH than Arctic soils with different pH (Chu et al., 2010).

These studies have improved our understanding of how ecological factors affect soil bacterial community structure and diversity. However, in general, these types of studies focus on deep taxonomic levels (e.g., all bacterial diversity), and the patterns of more fine-scale bacterial groups are ignored. In this chapter, a previously published high-throughput DNA sequence data set that characterized soil bacterial diversity from a large number of samples is considered but focused on diversity and community structure of Rhizobiales. In addition, two families within the Rhizobiales, the *Bradyrhizobiaceae* and the *Rhizobiaceae*, are also considered, because these families are commonly detected in soil and many lineages within them are symbiotic nitrogen fixers.

76.2 METHODS

A previous study used barcoded high-throughput DNA sequencing to generate bacterial 16S rRNA gene DNA sequences from 88 diverse soil samples collected across the Americas (Lauber et al., 2009). This study used 156,608 DNA sequences to examine general diversity patterns of soil bacteria, generally at the level of bacterial phyla, but did not focus on more fine-scale diversity patterns. Numerous environmental variables of the collection sites and soil samples were characterized, including depth of oxygen horizon, soil moisture, pH, carbon to nitrogen ratio, percentage of silt and clay, carbon mineralization rate, total organic carbon, total organic nitrogen, soil type, soil texture, latitude, longitude, elevation, annual precipitation, and mean annual temperature (Fierer and Jackson, 2006). Here, the DNA sequences and environmental data from this project are used to explore the factors associated with abundance and diversity patterns of Rhizobiales in soil.

DNA sequences were binned into phylotypes based on 97% DNA sequence identity using the uclust algorithm implemented in QIIME v1.6 (Caporaso et al., 2010). The most abundant sequence within each phylotype was designated the representative sequence, and these sequences were classified according to the Ribosomal Database Project's (RDPs; http://rdp.cme.msu.edu) classification scheme within QIIME.

The relative abundance of Rhizobiales within individual soil bacterial communities was compared to soil and site characteristics using Spearman's rank correlations. Similarly, the proportion of Rhizobiales classified as members of the *Bradyrhizobia* and *Rhizobiaceae* families was compared to soil and site characteristics using Spearman's rank correlations.

Beta-diversity patterns were analyzed to determine the effect of environmental factors on the community structure of Rhiziobiales. A rarefied data set was constructed, in which each soil sample was represented by 50 randomly chosen Rhizobiales sequences. Phylotype presence, absence, and abundance data from this rarefied data set were processed with the Bray–Curtis algorithm in QIIME to create a pairwise distance matrix of all soil Rhizobiales communities. Pairwise distances of environmental variables were constructed using Euclidean distances. The community and environmental matrices were compared using a mantel test in QIIME to determine if environmental variables significantly governed Rhizobiales community structure.

76.3 RESULTS

76.3.1 Rhizobiales Abundance and Diversity in Soils

Of 156,608 16S rRNA gene DNA sequences generated from the 88 soils, 14,388 (9.2%) were classified as Rhizobiales according to RDP classifications. The relative abundance of Rhizobiales in individual soils ranged from 3.7% to 18.2% across all soils, and the average relative abundance of Rhizobiales in soils was 9.2%.

Twelve families within the Rhizobiales order were detected in the soils (Table 76.1). Only two of these families, *Bradyrhizobiaceae* and *Hyphomicrobiaceae*, were detected in every soil sample and their proportion relative to the total amount of Rhizobiales detected ranged from 5.2–73.7% to 1.6–56.1%, respectively. The other frequently detected families included *Beijerinckiaceae*, *Methylobacteriaceae*, *Phyllobacteriaceae*, *Rhizobiaceae*, *Rhodobiaceae*, and *Xanthobacteraceae*.

Table 76.1 Summary of abundance and distribution of rhizobiales families across the 88 soil samples

Classification	#	Range (%)	Average Relative Abundance (%)	Standard Deviation (%)
Aurantimonadaceae	4	0–2.0	0.04	0.26
Bartonellaceae	2	0–0.8	0.02	0.11
Beijerinckiaceae	49	0–15.6	1.44	2.54
Bradyrhizobiaceae	88	5.2–73.7	31.53	15.48
Brucellaceae	1	0–1.8	0.02	0.19
Hyphomicrobiaceae	88	1.6–56.1	24.93	14.76
Methylobacteriaceae	35	0–19.5	1.22	3.01
Methylocystaceae	4	0–1.4	0.04	0.20
Phyllobacteriaceae	31	0–18.6	1.29	3.07
Rhizobiaceae	56	0–11.3	1.83	2.47
Rhodobiaceae	38	0–17.9	1.56	2.95
Xanthobacteraceae	27	0–3.1	0.31	0.64
Unclassified	88	17.0–73.3	35.76	9.51

Table 76.2 Spearman rank correlations between rhizobiales abundance and environmental variables

	R	p-Value
Carbon mineralization rate	0.411	<0.001
Annual precipitation	0.291	<0.01
Total organic carbon	0.278	<0.01
Moisture deficit	−0.268	<0.05
% Silt and clay	−0.239	<0.05
Carbon-to-nitrogen ratio	0.235	<0.05

Six of the measured environmental variables significantly correlated with Rhizobiales relative abundance (Table 76.2; Fig. 76.1). Carbon mineralization rate, annual precipitation, total organic carbon, and carbon-to-nitrogen ratio correlated positively with the relative abundance of Rhizobiales, whereas moisture deficit and % silt and clay correlated negatively with relative abundance of Rhizobiales.

Lineages within the *Bradyrhizobia* were commonly detected. The proportion of Rhizobiales classified as *Bradyrhizobia* ranged from 5.2% to 73.7% across the 88 soils. On average, 31.5% of Rhizobiales were classified as *Bradyrhizobia*. Five of the measured environmental variables significantly correlated with the relative abundance (relative to all Rhizobiales) of *Bradyrhizobia* (Table 76.3). Moisture deficit and pH correlated positively with relative abundance of *Bradyrhizobia*, whereas annual precipitation, total organic carbon, and % silt and clay correlated negatively with relative abundance of *Bradyrhizobia*.

Lineages within the *Rhizobiaceae* were detected in 56 (63.6%) of the soils. The maximum relative abundance of *Rhizobiaceae* (relative to all Rhizobiales) detected was 11.3%, and on average they represented 1.8% of all Rhizobiales in soil. The relative abundance of *Rhizobiaceae* significantly correlated with three measured environmental variables (Table 76.3). Relative abundance of *Rhizobiaceae* was positively correlated with pH and moisture deficit and was negatively correlated with elevation.

76.3.2 Distribution of Rhizobiales Phylotypes Across Soils

The 156,608 16S rRNA gene DNA sequences were binned into 47,283 phylotypes based on 97% DNA sequence similarity: 2052 (4.3%) phylotypes were classified as Rhizobiales. Of the Rhizobiales phylotypes, 1262 (61.5%) were detected in a single soil and 120 (5.8%) were detected in 10 or more soils. Some phylotypes were widely dispersed across a range of soils, but most were limited to only a few soil samples (Fig. 76.2).

The abundance and distribution of particular phylotypes was highly variable. Some phylotypes were not widely dispersed but were very abundant when present, some were widespread but rarely abundant, others were rare and never abundant, and one particular phylotype was widely dispersed and abundant (Fig. 76.3).

76.3.3 Factors Driving Rhizobiales Community Structure

Comparing Bray–Curtis community distances to Euclidean distances of environmental variables shows that eight environmental variables significantly affect Rhizobiales community structure (Table 76.4). Soil and site characteristics with significant effects on community structure include pH, followed by carbon-to-nitrogen ratio, total organic carbon, mean annual precipitation, carbon mineralization, latitude, temperature, and percentage of silt and clay (Table 76.4). Soil pH had the greatest effect on community composition (Fig. 76.4).

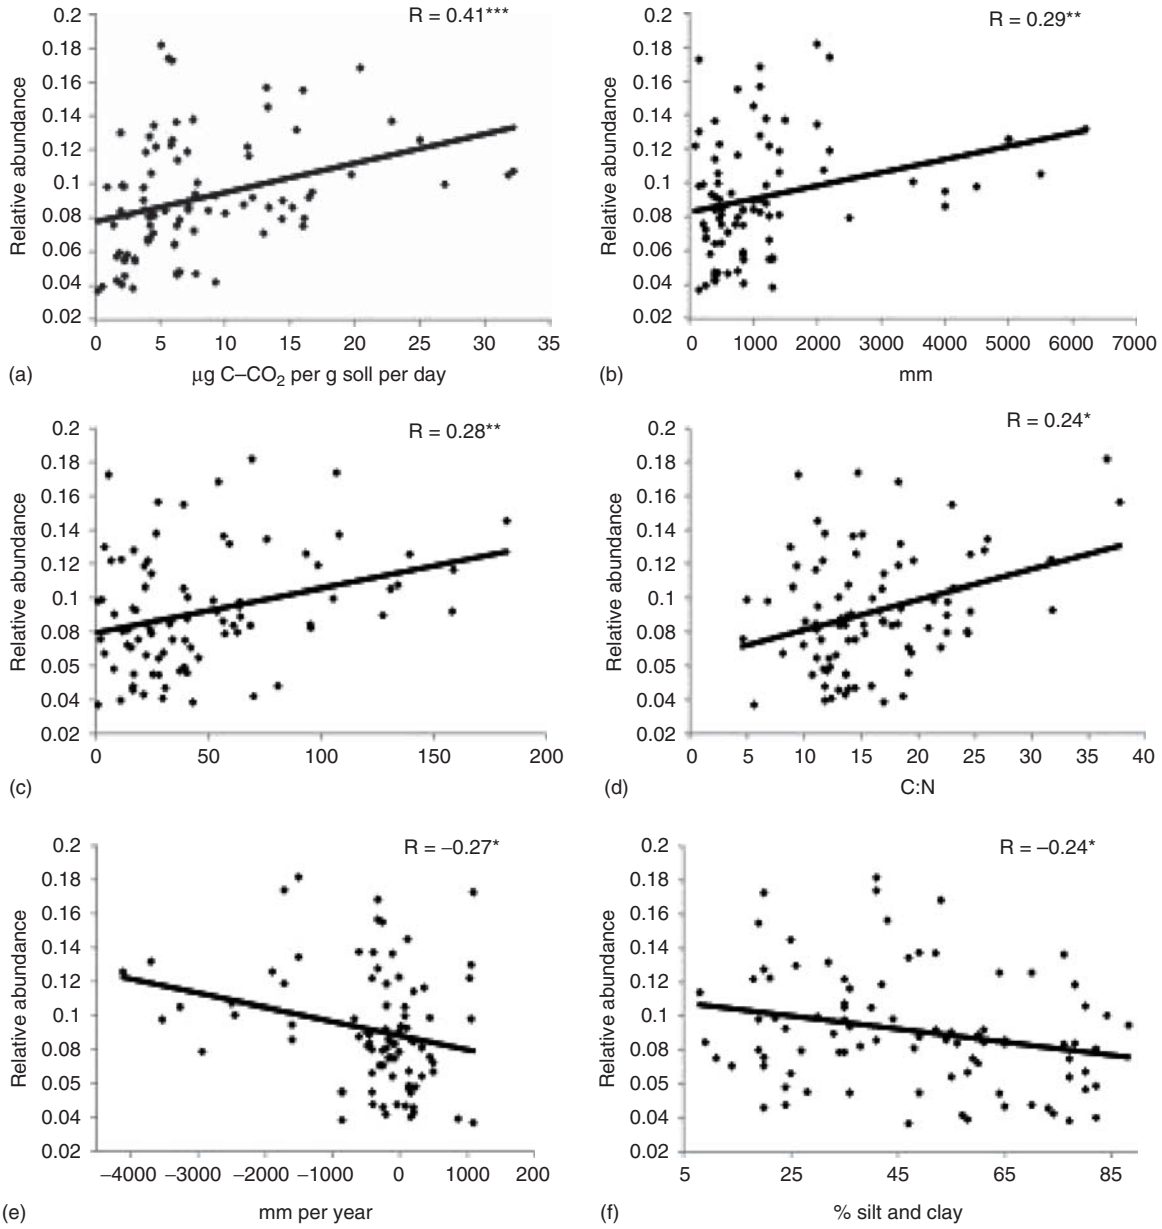

Figure 76.1 Soil and site characteristics with significant Spearman's rank correlations to relative abundance of Rhizobiales: potential carbon mineralization (a), annual precipitation (b), total organic carbon (c), carbon-to-nitrogen ratio (d), soil moisture deficit (e), and percentage of silt and clay (f). * $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$.

76.4 DISCUSSION

76.4.1 Factors Affecting Relative Abundance of Rhizobiales, *Rhizobiaceae*, and *Bradyrhiziobiaceae*

At the phylum level, soil pH strongly correlates with the relative abundance of some bacterial phyla such as, Acidobacteria, Actinobacteria, and Bacteroidetes, but not others such as Alphaproteobacteria and Beta-/Gammaproteo bacteria (Lauber et al., 2009). Since Rhizobiales is an order within the Alphaproteobacteria, it is not surprising that their abundance is not governed by soil pH. The relative abundance of soil Rhizobiales is most strongly correlated with potential carbon mineralization rates (Fig. 76.1, Table 76.2).

The relative abundances of families within the Rhizobiales do vary with pH, and the proportions of the two families that contain many nitrogen-fixing symbionts, *Bradyrhizobiaceae* and *Rhizobiaceae*, correlate positively

Table 76.3 Spearman rank correlations between bradyrhizobia and rhizobiaceae and environmental variables

	R	p-Value
Bradyrhizobia		
Annual precipitation	−0.490	<0.001
Total organic carbon	−0.453	<0.001
% Silt and clay	−0.408	<0.001
Moisture deficit	0.406	<0.001
pH	0.266	<0.05
Rhizobiaceae		
pH	0.315	<0.01
Elevation	−0.302	<0.01
Moisture deficit	0.280	<0.01

with soil pH. This finding is consistent with the well-known negative effects of soil acidity on rhizobial survival, multiplication, and nodulation (Graham, 1992).

76.4.2 Diversity Patterns of Rhizobiales

The distribution of Rhizobiales phylotypes across soils is similar to what is seen in other soil and marine systems. For example, a single acidobacterial phylotype was widely distributed across a range of soils and accounted for up to 7.4% of all detected bacteria (Jones et al., 2009). A bacterioplankton in the oceans, SAR11, is similarly widely distributed and oftentimes abundant (Morris et al., 2002]. This pattern of some lineages being both cosmopolitan and locally abundant was commonly detected in a meta-analysis of global patterns of microbial biodiversity (Nemergut et al., 2011). A Rhizobiales lineage in the 88 soils investigated here is also distributed among in a similar manner, in that it is widely distributed among soils and often abundant (Fig. 76.3). Another global pattern of microbial diversity is that the vast majority of phylotyopes are detected in a single sample (Nemergut et al., 2011). Again, soil Rhizobiales show a similar pattern with over 60% of phylotypes detected in a single soil.

76.4.3 Ecological Factors and Their Effect on Rhizobiales Community Structure

Although pH does not affect the relative abundance of Rhizobiales, it has the greatest effect on Rhizobiales community structure (Table 76.4); in other words, soil pH does not limit total abundance of Rhizobiales, but does control the presence or absence of certain Rhizobiales lineages. Using the same data set analyzed in this chapter, Lauber et al. found that pH strongly affected community structure of the full bacterial community and of the bacterial phyla Acidobacteria, Actinobacteria, Alphaproteobacteria, Beta-/Gammaproteobacteria, and Bacteroidetes (Lauber et al., 2009). Of all the other soil and site characteristics that Lauber et al. measured, only soil moisture deficit significantly correlated with bacterial community structure at the phyla level (Actinobacteria, Alphaproteobacteria, and Bacteroidetes). However, in Rhizobiales, carbon-to-nitrogen ratios, total organic carbon, mean annual precipitation, potential carbon mineralization rate, latitude, mean annual temperature, and % soil and clay also were significantly correlated with community structure (Table 76.4). These correlations were not strong (range from 0.121 to 0.243), but do indicate that at more fine-scale taxonomic resolutions,

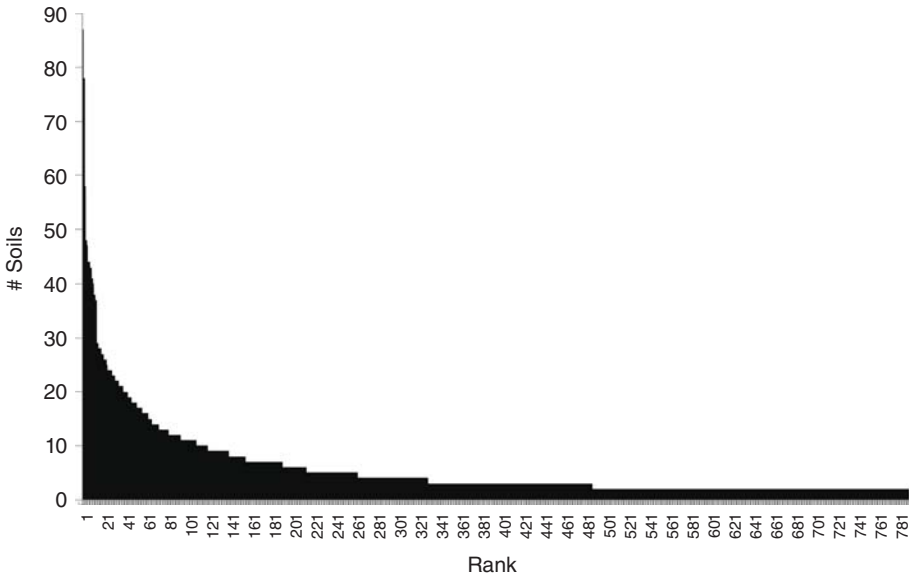

Figure 76.2 Distribution of Rhizobiales phylotypes among soil samples. One phylotype (rank 1) occurred in all 88 soils. Only 120 phylotypes occurred in 10 or more soil samples. The 1262 Rhizobiales phylotypes that occurred in only 1 soil were not included in the figure.

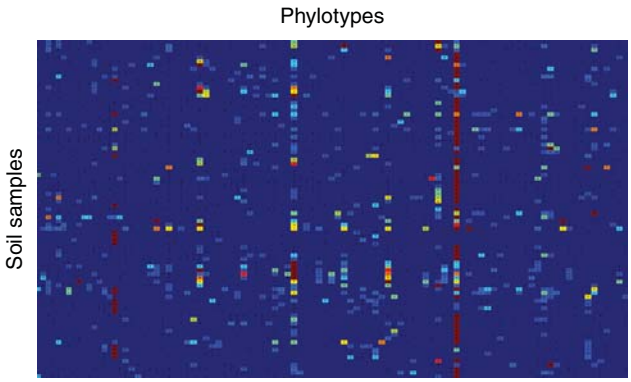

Figure 76.3 Heat map of the 100 most abundant (on average) Rhizobiales phylotypes across all 88 soils. Columns are Rhizobiales phylotypes and rows are soil samples.

Table 76.4 Mantel tests between microbial community Bray–Curtis distances and euclidean distances of environmental variables

Environmental Characteristics	Correlation	*p*-Value
pH	0.496	<0.001
Carbon-to-nitrogen ratio	0.243	<0.001
Total organic carbon	0.239	<0.001
Mean annual precipitation	0.232	<0.001
Carbon mineralization rate	0.208	<0.001
Latitude	0.193	<0.001
Temperature	0.140	<0.001
% Silt and clay	0.121	<0.001

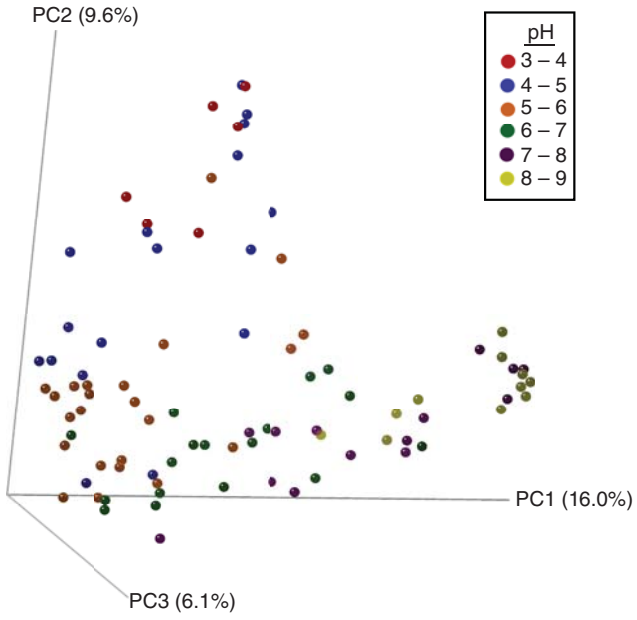

Figure 76.4 Three-dimensional principal component analysis of 88 soils based on Bray–Curtis distances. Each dot represents a Rhizobiales community and colors indicate the soil sample's pH.

these soil and site characteristics can have a greater influence on community composition.

76.5 CONCLUSION

Barcoded high-throughput DNA sequencing permits the characterization and comparison of a large number of microbial communities at a relatively inexpensive cost. This approach has been incredibly useful for determining how ecological factors govern microbial community dynamics, but they have generally focused on all bacterial diversity rather than on more fine-scale taxonomic groups. Here, it has been shown how this approach can also be useful for investigating microbial dynamics of shallower taxonomic groups, in this case the Rhizobiales.

Gene-Targeted Metagenomics of Diazotrophs in Coastal Saline Soil

Jitendra Keshri, Avinash Mishra, and Bhavanath Jha
Discipline of Marine Biotechnology and Ecology, CSIR–Central Salt and Marine Chemicals Research Institute, Bhavnagar, Gujarat, India

77.1 INTRODUCTION

Coastal land and the associated soil constitute a considerable portion of the biosphere. These lands are dynamic ecosystem, generally vulnerable to salinization, mainly due to high influx of tidal sea water. The habitat harbors taxonomically and functionally important halophiles and halotolerants as the selection pressure may favor the presence of microorganisms having physiological adaptations to survive under saline condition. The coastal habitat is unique in microbial diversity (Keshri et al., 2013b). The microbial community plays an essential role in the function and maintenance of the ecosystem through their profound effect on nutrient cycling. Nitrogen is one of the most essential nutrients for all life forms. Nitrogen fixation is a key element in the nitrogen cycling. The biogeochemistry of nitrogen on earth largely depends on the biological nitrogen fixation (Falkowski et al., 2008), contributing 61% of the total nitrogen added to the biosphere (Gruber and Galloway, 2008). Biological nitrogen fixation is mediated by free-living bacteria and symbiotic associations of phylogenetically diverse prokaryotic assemblages (proteobacteria, green sulfur bacteria, cyanobacteria, firmicutes, spirochaetes, and archaea). Nitrogen fixation is generally carried out by using the conserved enzyme complex nitrogenase reductase (Zehr et al., 2003; see Chapter 2). The detection and analysis of the marker gene(s), encoding nitrogenase reductase, provide an efficient tool to ascertain the biological nitrogen-fixation potential of an ecosystem. The Mo–Fe nitrogenase encoded by *nif* genes is the most efficient and widely distributed, while alternative nitrogenases, encoded by *vnf* and *anf* genes, are generally expressed only when molybdenum concentration is limiting (Zhao et al., 2006). The enzyme dinitrogenase reductase is encoded by the highly conserved *nifH* gene, which is being widely used to investigate diazotrophic diversity.

The culture-independent analysis of metagenomics has revolutionized the concept of microbial diversity, as the majority of microbes present in any habitat cannot be cultured. The community structure and diversity studies based only on rRNA analysis is insufficient for a complete understanding of the microbial ecology, as definitive information on biological, physiological, or ecological functions cannot be obtained (Zehr et al., 2003). Development of molecular techniques in recent years has allowed culture-independent detection of specific microbial populations, such as diazotrophs, by using the targeted analysis of the functional marker gene *nifH* (see Chapters 3, 8, 20). These methods involve polymerase chain reaction (PCR) amplification of *nifH* from metagenomic DNA, extracted from environmental samples, followed by clone library construction, denaturing gradient gel electrophoresis, restriction fragment polymorphism analysis, and/or quantitative real-time polymerase chain reaction (qRT-PCR/qPCR) to produce community profiles and phylogenetic relationship among diazotrophic microorganisms. It provides a comprehensive picture of the diazotrophic community structure and diversity compared to culture-based approaches. Molecular approaches have been used to investigate nitrogen fixation in a range of habitat by targeting nitrogenase genes to reveal a vast diversity of sequences. It leads to the enrichment of the database for nitrogenase genes (specifically the *nifH* gene; see Chapter 20), making it one of the largest nonribosomal gene data sets

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

on uncultivated microbes (Zehr et al., 2003). However, until recently, little attention has been paid to the diazotrophic community inhabiting coastal saline soil.

The approaches and advantages of gene-targeted metagenomics have been reviewed by Iwai et al. (2011). Recently, the metagenomics of coastal soils have been investigated by targeting key functional genes (Keshri et al., 2013a, Yousuf et al., 2012a,b; Yousuf et al., 2014a,b). The gene-targeted metagenomics approach to study the diazotrophic diversity based on the phylogenetic analysis of *nifH* has been recently used in several other habitats including soils of different management practices (Colloff et al., 2008), maize field soil (Hsu and Buckley, 2009), rice cultivars (Wu et al., 2009), Arctic permafrost (Yergeau et al., 2010), Antarctic desert soil (Cowan et al., 2011), pristine shallow glaciofluvial ground water systems (Shirokova and Ferris, 2013), soils of different cropping systems (Pereira et al., 2011), Antarctic dry valley soils (Niederberger et al., 2012), the cactus rhizosphere (Aguirre-Garrido et al., 2012), rice root endophytes (Sessitsch et al., 2012), bulk soils of bioenergy crop field (Mao et al., 2013), and fresh water lake (Woodhouse et al., 2013). Others are focused specifically on saline system like deep sea methane vents (Pernthaler et al., 2008), hydrocarbon-polluted mangrove sediment (Taketani et al., 2009), deep sea methane seep sediments (Dang et al., 2009), rhizosphere of salt marsh plants (Gamble et al., 2010; Davis et al., 2011), Arctic sea water and sediments (Diez et al., 2012), Pacific warm pool (Shiozaki et al., 2013), sea sediments (Dang et al., 2013), and water column of Arabian Sea (Bird and Wyman, 2013). These studies revealed a large number of unknown sequences, which belong to diverse unidentified diazotrophs.

77.2 MATERIALS AND METHODS

77.2.1 Sample Size and Metagenome Extraction

Appropriate sample collection is a primary and essential step to achieve a comprehensive coverage of the microbial diversity. The coastal saline soil is generally barren and covered with salt deposition of different texture and concentration, devoid of regular vegetation but sometimes sparsely invaded by typical salt-tolerant plants. The soil samples were collected with a sterile scoop or spade in replicates and transferred to sterile polyethylene bags and stored at −20 °C during transportation. If the samples were rhizospheric, they were obtained from plants by collecting the soil around the roots and excising the young growing roots. To compare with nonrhizospheric diazotrophs, samples were taken from soil devoid of any plants. The respective subsample replicates were homogenized and mixed thoroughly and stored at −20 °C.

Gene-targeted metagenomics included the extraction of the soil metagenome and subsequent generation and screening of clone libraries, which were used for the exploration of complex functional groups of soil microbial communities. The validity of saline soil metagenomics was strongly dependent on an efficient extraction of high-quality microbial DNA to acquire the representative nucleic acids of the entire microbial communities, which is a technical challenge. The impediments included incomplete cell lysis, co-extraction of enzymatic inhibitors, degradation of DNA at various steps, uneven distribution of microbes within the soil matrix, and strong interaction of DNA as well as cells with the soil matrix (Grundmann, 2004; Rajendhran and Gunasekaran, 2008). Some recent reports have described a standard protocol for efficient extraction of the metagenome from coastal saline soil (Purohit and Singh, 2009; Siddhapura et al., 2010). The optimization of the total DNA extraction technique is critical and should be consistent with the sample types. The composition of habitats varies with respect to their matrix, organic/inorganic compounds, and biotic factors. The direct DNA extraction method via bead beating involves cell lysis within the sample matrix and subsequent separation of DNA from the matrix and cell debris (Ogram et al., 1987). This direct lysis method has been used recently for the construction of the *nifH* gene clone library from some of the saline soils such as the salt marsh plant rhizosphere (Gamble et al., 2010; Davis et al., 2011), mangrove sediment mesocosm (Taketani et al., 2009), sea sediment (Dang et al., 2013), and coastal saline soil (Keshri et al., 2013a,b; Yousuf et al., 2014a,b). Bead beating is one of the mechanical methods that allow good penetration of the lysis buffer by homogeneous cell disruption and sample dispersion. Therefore, it is more effective and less selective than the chemical lysis (Rajendhran and Gunasekaran, 2008). Siddhapura et al. (2010) obtained pure DNA in good quantity from saline soil of Gujarat, India, by using combinations of bead beating with lysis buffer treatment.

77.2.2 Primer Selection and PCR Amplification of the *nifH* Gene

The gene-targeted strategies for the study of diazotrophs require development of nitrogenase genes specific PCR primers. One of the widely used biomarkers is the *nifH* gene having advantages over other genes of the *nif* complex for investigating the diazotrophic assemblages. All of the dinitrogen reductase genes, namely, *nifH*, *vnfH*, and *anfH*, are highly conserved among diverse microorganisms, the phylogenetic tree based on the *nifH* gene is generally congruent with that of 16S rRNA gene (Ueda et al., 1995) and thus can be integrated with evolutionary analysis. The *nifH* gene database from environmental samples is very robust and has been comparatively well studied among

other genes of the *nif* complex (Zehr et al., 2003). The diazotrophs may belong to diverse group of proteobacteria, firmicutes, cyanobacteria, and euryarchaea (Raymond et al., 2004), exhibiting vast phylogenetic differences among nitrogen-fixers (Zehr and Mcreynolds, 1989). Therefore, designing universal *nifH* primers with a certain level of degeneracy is a prerequisite for broader analysis of diazotrophic diversity. A number of degenerate primers have been proposed by various researchers, but the degeneracy should be optimal for the coverage of maximum diversity with specificity. Degenerate primers are a mixture of primers with different binding affinities for different templates, which allow greater coverage of highly polymorphic genes (Wintzingerode et al., 1997). There are several primer sets available for the amplification of *nifH* gene commonly used for the saline habitat (**Table** 77.1). One of the most widely used primer set is PolF (5′-TGC GAY CCS AAR GCB GAC TC-3′) and PolR (5′-ATS GCC ATC ATY TCR CCG GA-3′), designed by Poly et al. (2001a) for environmental samples, and their efficiency were validated for different soil types (Poly et al., 2001b). The primer set contains sufficient degeneracy, 24 and 8 in PolF and PolR, respectively, which allows the amplification of a large number of diazotrophs from different phylogenetic groups. It selectively amplifies 360 bp of the *nifH* gene at an annealing temperature of 55 °C, which is used for meaningful derivation of phylogenetic relationship. The gene sequence database is increasing day by day; hence there is a quest for new primer data sets.

77.2.3 Molecular Analysis of the *nifH* Gene

Most of the gene-targeted studies of diazotrophs include PCR amplification of the *nifH* gene followed by clone library construction, restriction fragment length polymorphism (RFLP), denaturing gradient gel electrophoresis (DGGE), and/or qRT-PCR analysis. Recently, DGGE was used to study the rhizospheric assemblages of diazotrophs associated with salt marsh cordgrass, *Spartina alterniflora* (Gamble et al., 2010). Analysis of DGGE banding pattern of the *nifH* gene amplified with GC-clamped primer pairs (Piceno et al., 1999) revealed diazotrophic assemblages associated with the saline system. The diazotrophs consisted of both seasonally responsive and nonresponsive groups. A study of the rhizospheric community from three different salt marsh plants, using DGGE, demonstrated that diazotrophs were strongly affected by seasonal changes and most of them were novel, indicating that diazotrophy is functionally redundant and widely performed by a large number of microorganisms (Davis et al., 2011). An Arctic marine ecosystem was recently investigated using these approaches to decipher total as well as cyanobacterial diazotrophic communities in sea water, sea brine, and snow (Diez et al., 2012).

Clone libraries and qRT-PCR were used to analyze the diversity and abundance of diazotrophs, respectively, in mangrove sediment mesocosms (artificial sea water fed tidal systems) (Taketani et al., 2009). The effect of oil addition on the diazotrophic community and the abundance in pristine and polluted mangrove sediments were also investigated, and the relationship between nitrogen fixation and hydrocarbon degradation was established (Taketani et al., 2009). Similar techniques were applied to study diazotrophic diversity and abundance in the water of hypoxic basins (Hamersely et al., 2011). The archaeal diazotrophic diversity was specifically characterized in methane seep sediments using the *nifH* gene clone library and qPCR approach (Miyazaki et al., 2009). The *nifH* gene clone library revealed the occurrence of noticeably distinct cluster of nitrogen-fixers in the surface water of a tropical bay (Gonzalez et al., 2012). The oxygen-deficient waters of the Arabian Sea were examined to explore the distribution, diversity, and expression of the *nifH* gene through analysis of a clone library, generated from DNA and cDNA (Jayakumar et al., 2012). Recently, the gene-targeted clone library of pelagic diazotrophs was coupled with reverse transcriptase PCR, and specific Northern slot blot analyses were performed to quantify *nifH* mRNAs and the active heterotrophic diazotrophs in the Arabian Sea (Bird and Wyman, 2013). The diazotrophic diversity and activity in the sea water of Gulf of Aqaba has been assessed using a clone library and reverse transcriptase PCR (Foster et al., 2009).

The RFLP and clone library techniques were used to reveal the diversity of diazotrophs from the deep sea methane seep sediments, which showed high degree of novelty in the *nifH* gene sequences with almost all of the sequences belonging to uncultured or uncharacterized bacteria or archaea (Dang et al., 2009). These techniques have been also used for diversity analysis from mangrove sediments from high and mid-intertidal zones. The biogeochemical characteristics of the rhizosphere determined the structure of the diazotrophs associated with the mangrove roots (Flores-Mireles et al., 2007). Dang et al. (2013) investigated different oligotrophic sediments including estuarine, coastal, offshore, deep-sea, and methane hydrate reservoirs or their prospective areas of South China Sea targeting the *nifH* gene using qRT-PCR and clone library construction, extending the evolutionary complexity of extant of the *nifH* gene with novel and diverse sequences.

77.2.4 Data Analysis and Diversity Estimation

Gene-targeted metagenomics require the extensive analysis of the *nifH* gene sequences and for which alignment of the obtained sequences is the primary step. This can be efficiently done by online tool CLUSTALW or by using software packages like MEGA 5. The similarity matrices

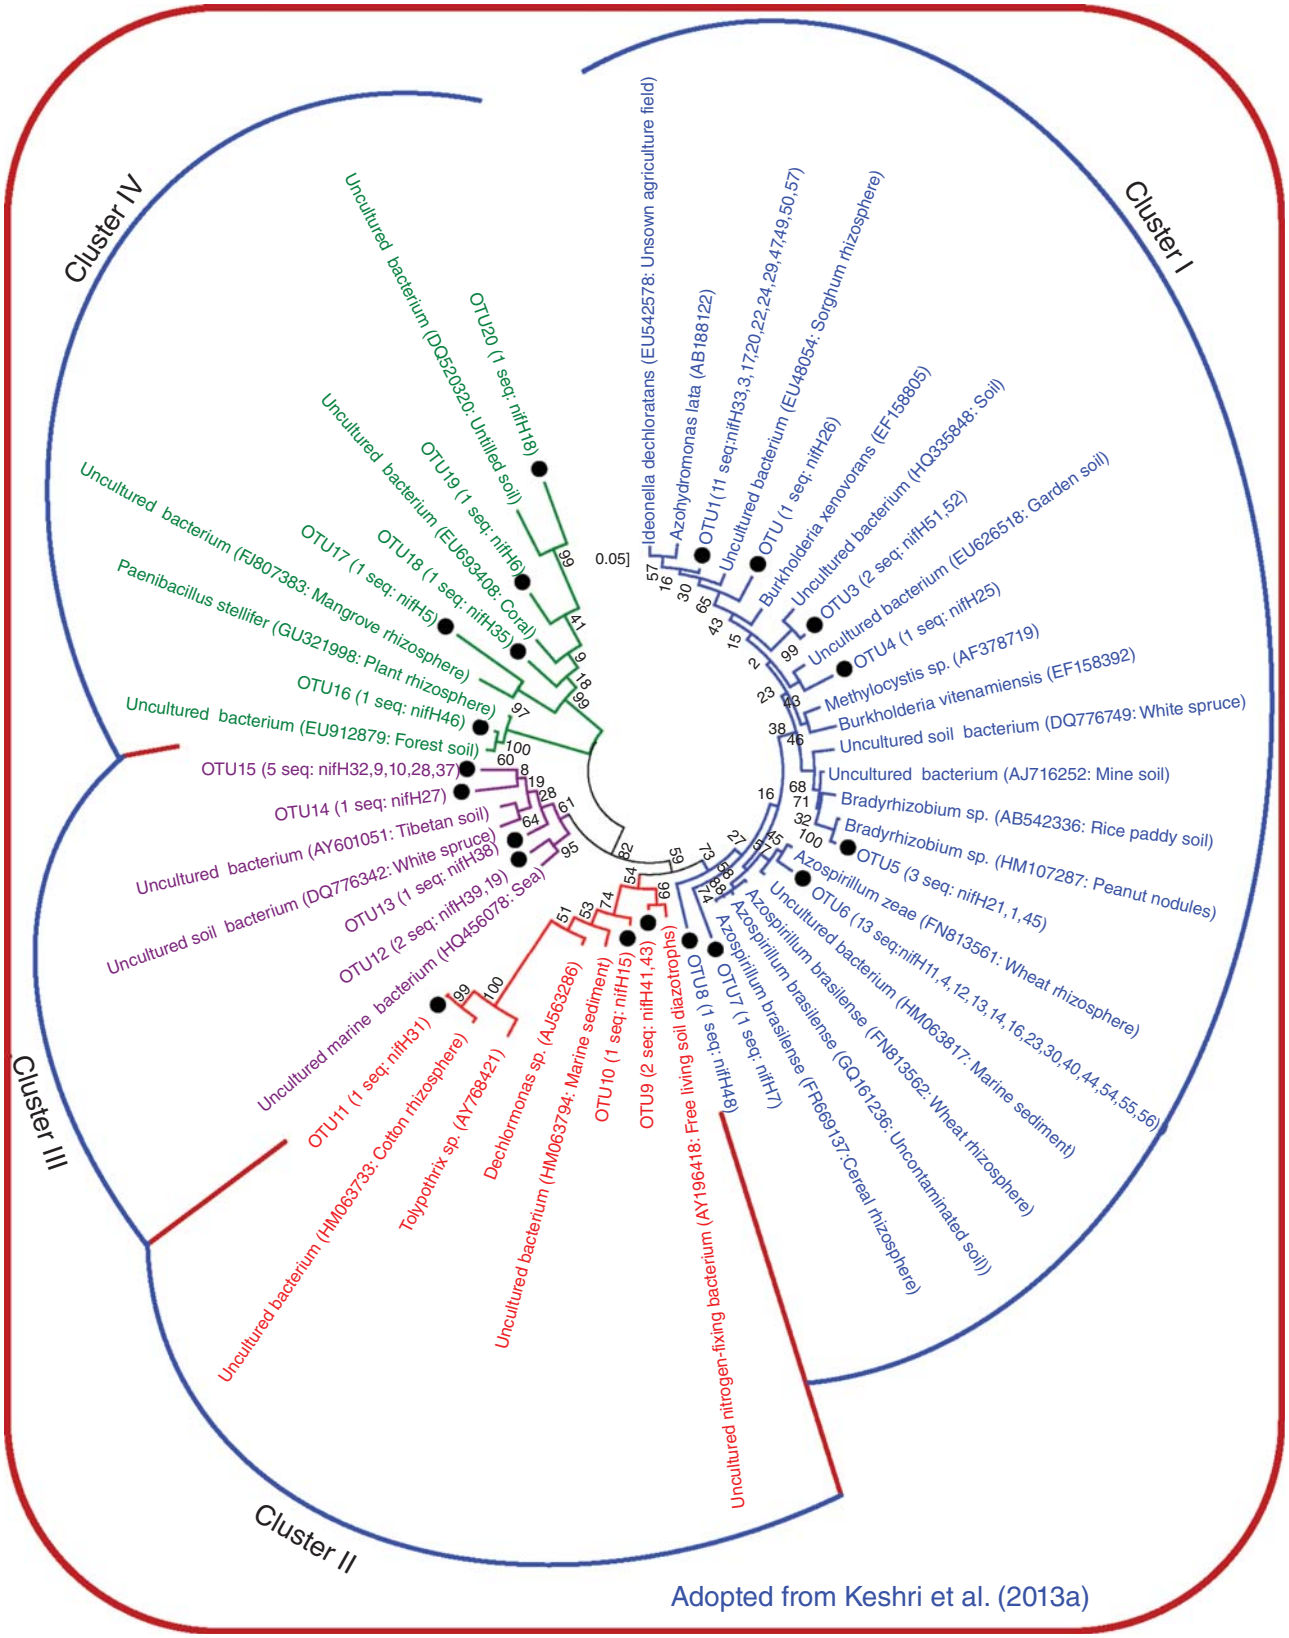

Figure 77.1 Molecular phylogeny of *nifH* using gene-targeted metagenomics of coastal saline-alkaline soil. The phylogeny was computed using the Tamura-Nei method and inferred with the maximum-likelihood method with the bootstrap test (1000 replicates), showed next to the branches. The tree was constructed with related sequences obtained from NCBI database, and in parentheses their accession numbers and source information are provided. OTUs from this study are provided after bullets (•).

generated from the aligned sequences are used to define operational taxonomic units (OTUs) using software (e.g., MOTHUR). There is no common consensus about the cutoff to define OTUs or the species for the *nifH* gene, like other functional genes. However, 90–97% sequence similarity was used to cluster the sequences into OTUs (Dang et al., 2009; Keshri et al., 2013a; Niederberger et al., 2012; Pereira et al., 2011; Taketani et al., 2009). A variety of statistical methods were used to estimate the diversity (Shannon, diversity index, Simpson index, species evenness, chao, ace) while multivariate analyses (hierarchical clustering, ordination plotting, canonical correspondence analysis, etc.) were used to reveal the pattern of diazotrophic community distribution (Aguirre-Garrido et al., 2012; Dang et al., 2009; Davis et al., 2011; Gamble et al., 2010; Niederberger et al., 2012). The community structure from the different samples is generally compared using the UNIFRAC while the genetic diversities are compared by the analysis of molecular variance.

77.3 A CASE STUDY: DIVERSITY AND ABUNDANCE OF *nifH* GENE IN COASTAL SALINE-ALKALINE SOIL

The ecological study of microbes from the coastal saline-alkaline soil is important in the context of *in situ* conservation of microbial diversity, which sustains delicate ecological processes in this type of ecosystem. We have conducted a study on the coastal soil having high salinity and alkalinity with EC 23.7 dS/m and pH 9.1 (Keshri et al., 2013a). The nitrogen-fixing community was targeted by analyzing the *nifH* gene using clone library and qPCR approaches, coupled with other functional genes involved in carbon fixation (*cbbL*), ammonia oxidation (*amoA*), and sulfur metabolism (*apsA*). The *nifH* gene was amplified using primers PolF and PolR (Poly et al., 2001a), and a clone library was constructed. The library contained 51 cloned sequences that categorized into 20 OTUs at the genetic distance of 0.1. About 25% library (13 clones) concurred with the alpha- and beta-proteobacterial species (*Bradyrhizobium* sp., *Azospirillum zeae*, *Azospirillum brasilense*, *Methylocystis* sp., *Burkholderia* sp., *Ideonella dechloratans,* and *Azohydromonas lata*). The *nifH* gene sequences representing cyanobacteria (*Tolypothrix* sp.-single clone) and Firmicutes (*Paenibacillus* stellifer-single clone) were also retrieved. These clones showed 91–97% similarity with the *nifH*-containing cultured species. However, 36 clones coincided with the environmental clones retrieved from various soil/sediment ecosystems such as rhizosphere, garden, forest, marine, the Tibetan plateau, and the Himalayas. These sequences formed four clusters in the phylogenetic tree (**Fig.** 77.1). The *A. lata*, *Bradyrhizobium* sp., and *A. zeae* were dominated in the cluster I. In this cluster, two OTUs (OTU7 and OTU8) showed a separate branching lineage without having any close affiliation and thus could be considered as novel. Cluster II and III sequences were not correlated with any known cultured organism and showed proximity with uncultured clones from the different environments. The Firmicutes, *P. stellifer* was the only cultured bacteria represented by clones from the cluster IV. While most of the sequences from the *nifH* gene clone library are not identical to those of the cultured nitrogen-fixing bacteria and the degree of divergence for most of the sequences obtained suggest the existence of novel nitrogen-fixing bacterial species in the selected soil type. The high degree of heterogeneity and low sequence similarity to the previously reported sequences suggested that the extreme physico-chemical conditions may influence the genetic structure of prevalent bacterial species and diazotrophs.

Abundance of the *nifH* gene determined by using qRT-PCR from the metagenome indicated the size of the functional guild harboring the relevant key gene for nitrogen fixation. The internal primers were designed from the conserved sequences of the clone library. 1.3×10^6 copies of the *nifH* gene per gram dry weight of soil were found, whereas the gene copies per gram dry weight of soil for the *cbbL*, *amoA,* and *apsA* genes were found to be $(1.64 \pm 0.42) \times 10^8$, $(1.19 \pm 0.21) \times 10^8$, and $(3.23 \pm 0.16) \times 10^5$, respectively. The abundance of the *nifH* gene was lower than the *amoA* gene, suggesting that oxidation of ammonia was more prevalent than nitrogen fixation. This study also suggested that the diversity and abundance of the functional genes are independent to each other and abundant gene may or may not be more diverse. The actual rate of the nitrogen fixation was not determined but the diversity and abundance of the *nifH* gene indicated the possible occurrence of the nitrogen-fixers in the hostile environment.

77.4 CONCLUSION

The study of diazotrophs based on gene-targeted metagenomics proved to be a highly efficient, accurate, rapid, and sensitive method to analyze nitrogen-fixing community present in the saline ecosystem. Our findings along with other observations demonstrated that we have still little knowledge about the microbes responsible for N_2 fixation in the coastal saline soil and the genetic diversity of N_2-fixers. The case study indicates that the saline habitats supported a unique diazotrophic community of diverse phylogenetic groups, suggesting distinctly different halotolerant nitrogenase diversity patterns in these stressful habitats. The gene-targeted metagenomic-based studies can be utilized for the isolation of novel indigenous diazotrophic species to be used as microbial inoculants for the agriculture practices in the coastal saline soils. The gene-targeted metagenomic from the coastal saline soils is indeed a valuable resource for hitherto untapped diazotrophs. Furthermore, the gene-targeted

metagenomics of diazotrophs could be explored to reveal the environmental factors controlling nitrogenase diversity.

ACKNOWLEDGMENT

CSIR, New Delhi (BSC0109-SIMPLE and BSC0117-PMSI), is thankfully acknowledged for research work conducted in the authors' laboratory.

78.1 INTRODUCTION

Due to their ability to efficiently fix atmospheric nitrogen in symbiotic association with rhizobia, legumes are of great environmental and agronomical importance, and for many years efforts have been made by the scientific community to better understand the biological process of symbiotic nitrogen fixation with the goal of eventually transferring the ability to fix nitrogen to nonlegume crops (see Chapters 5, 108, and 109). In parallel, research is carried out to enhance the attractivity of legume crops to farmers by improving yield, nutritional value, and resistance to biotic and abiotic stresses. Both approaches require the development of genetic and genomic resources for legume species. However, although early work on pea was instrumental in the development of genetics, overall legume crops are not very amenable to genetic and genomic approaches due to large genome size (pea, faba bean), polyploidy (soybean, alfalfa, clover), allogamy (alfalfa, clover), and difficult genetic transformation. Therefore, in the early 1990s, scientists selected *Medicago truncatula* as a model legume due to favorable attributes such as annual habit, short life cycle, abundant seed production, diploid and autogamous nature, small genome size (around 550 Mbp), ease of genetic transformation by *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes*, and nodulation by the well-characterized *Sinorhizobium meliloti* rhizobial bacterium (Barker et al., 1990; Cook, 1999). In addition, contrary to the model plant *Arabidopsis thaliana*, *M. truncatula* can establish symbioses with endomycorrhizal fungi that are important for plant mineral nutrition and whose establishment shares mechanisms with nitrogen-fixing symbioses. *Lotus japonicus*, another model legume, has similar features but *M. truncatula* is phylogenetically closer to temperate legume crops such as alfalfa, clover, pea, or faba bean, making it a better choice for translational genomics.

78.2 A REFERENCE ANNOTATED GENOME SEQUENCE FOR *Medicago truncatula* A17

The availability of a reference genome sequence for *M. truncatula* was central to the development of functional genomic resources in this species, the analysis of its natural diversity and evolution, as well as for comparative genomic studies in legumes. *M. truncatula* genome sequencing was thus started in 2002. At that time, *A. thaliana* was the only plant with a sequenced genome, and whole genome shotgun sequencing was not considered a realistic strategy to provide a high-quality reference genomic sequence anchored to chromosomes, for a genome of more than 500 Mbp like that of *M. truncatula*. It was thus decided to sequence *M. truncatula* by the same strategy than that previously chosen for the *A. thaliana* and rice genomes: sequencing the genome clone by clone (BAC by BAC) (bacterial artificial chromosome), each clone being anchored to chromosomes through physical and genetic mapping (Young et al., 2005). Similar strategies were adopted at the time for the genomes of plants such as *L. japonicus* (Sato et al., 2008) or tomato (Sato et al., 2012). This approach allowed sharing the work chromosome by chromosome between different groups, and an international consortium with American and European partners was established to sequence the *M. truncatula*

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

genome. In particular, due to the high costs of the Sanger sequencing technology then available, it was decided to focus the sequencing to the gene-rich part of the genome. Previous cytogenetic analysis using fluorescence *in situ* hybridization (FISH) on pachytene chromosomes indicated that in *M. truncatula* most chromosomes could be divided into euchromatic arms, rich in genes, and heterochromatic pericentromeric regions rich in repeated elements (Kulikova et al., 2001): about a hundred gene-rich BACs tested hybridized only to chromosome arms. Large-scale sequencing thus started with 500 gene-rich (expressed sequence tag (EST) containing) nonoverlapping seed BACs. These BACs were anchored to chromosomes by genetic mapping using microsatellite markers identified in their sequences (Mun et al., 2006). BAC by BAC sequencing then proceeded by a sequence tag connector approach: from a sequenced seed BAC, two BACs with minimum overlap with the seed BAC were selected on each side based on alignment of their BAC end sequences to the seed BAC sequence, then sequenced. The same process was repeated for every newly sequenced BAC, leading to large BAC contig sequences that eventually merged. Selection of BACs was also guided by a physical map constructed by restriction enzyme fingerprinting, and the progression of the assembly checked by further genetic mapping (Young et al., 2011). The final assembly was validated by optical mapping. This approach was pursued to its term in the case of chromosome 5, resulting in two sequence contigs corresponding to the two chromosome arms, covering 42 Mbp of sequence from telomeres to pericentromeric region. Due to lack of funding, BAC by BAC sequencing of the other chromosomes could not be completed. Thus, the 262 Mbp final assembly of BAC sequences included many gaps in chromosome arms and missed about one-third of *M. truncatula* genes. Further sequencing was performed using next-generation technologies, mainly Illumina. Assembly of sequences obtained from paired end libraries resulted in 100 Mbp of additional sequence contigs with N50 = 2.3 kb, allowing characterization of about 20% more genes without anchoring to chromosomes (Young et al., 2011). In the past 2 years, next-generation sequencing, using in particular paired end and mate pair Illumina technology, was used to sequence DNA libraries carrying inserts of various sizes (from a few hundred bp to more than 10 kbp). These new resources, together with data previously obtained by the consortium (BAC end sequences, genetic and optical maps, etc.) and improved bioinformatic tools, led to the development of new genome assemblies anchoring to chromosomes more than 80% of the genome and covering 95% of *M. truncatula* genes (Debellé et al., 2012; Krishnakumar et al., 2013). The sequence assembly covers most of the euchromatin (the chromosome arms), while the pericentromeric heterochromatin remains unsequenced.

Gene annotation of the genome assembly was carried out by an annotation consortium using the Eugene pipeline, which combines the use of *ab initio* predictions to that of extrinsic data (cDNA/EST, RNA-seq, homologies to gene sets from other genomes) (Town, 2006; Young et al., 2011). The number of predicted genes varied according to the level of confidence of prediction from less than 50,000 to more than 60,000 protein-coding genes. This is a high number compared to that of the related chickpea (28,000 genes), and it is similar to the number found in soybean, although this species, contrary to *M. truncatula*, is known to have undergone a recent (14 Myr ago) whole genome duplication. This high number can be explained at least, in part, by high levels of local gene duplication in *M. truncatula*, which affect many gene families and are detected across the genome (Young et al., 2011).

78.3 *M. truncatula* GENOME ORGANIZATION AND EVOLUTION

Although BAC by BAC sequencing excluded the pericentromeric regions of *M. truncatula* genome, early analysis of whole genome shotgun sequences had allowed the identification of tandem repeats with head-to-tail orientation, with unit lengths varying from 166 to 183 bp, typical of satellite repeats found in the pericentromeric regions in various plant species (Kulikova et al., 2004). Three of them, accounting for 1–4% of the genome, were characterized by FISH on pachytene chromosomes (Kulikova et al., 2004). MtR3 was found in centromeric regions (visible as primary constrictions) of all chromosomes, while MtR1 and MtR2 were located in distinct pericentromeric regions of most chromosomes. FISH also showed the presence of 5S rDNA loci on chromosomes 2, 5, and 6 and of 45S rDNA genes on chromosome 5 (Kulikova et al., 2004). The pericentromeric regions are likely to contain, in addition to tandem repeats, a large number of transposable elements, in particular retrotransposons, as is the case in many plant genomes (Du et al., 2010). Transposons have been characterized in detail in the sequenced part of the genome where they constitute about 30% of the sequence (Young et al., 2011). While DNA transposons constitute 3–4% of the sequence, long terminal repeat retrotransposons are the most abundant transposable elements (24% of the sequence) with copia and gypsy families, representing 4.1 and 5.7% of the sequenced genome, respectively (Young et al., 2011). Different families of retrotransposons, also present in other plant genomes in different proportions, have been characterized (Du et al., 2010; Wang and Liu, 2008). Along chromosomes, the density in retrotransposons varies, with possibly an increase toward the pericentromeric regions.

Self-comparison of the *M. truncatula* genome revealed conserved synteny blocks reflecting duplication events (Cannon et al., 2006). The rates of synonymous substitution per synonymous site (Ks) between paralogs in these

blocks indicated that they were the remnants of a whole genome duplication event that occurred ~58 Myr ago, early in the evolution of the Papilionoideae subfamily of legumes. Comparative genome analysis in the legume family and other higher plants also provided evidence for this duplication and clues about legume evolution (Young and Bharti, 2012; Young et al., 2011). All legumes and major groups of dicots share an ancient whole genome hexaploidy anterior to the rosid–asterid split at ~150 Myr ago. The whole genome duplication event at 58 Myr ago affected the Papilionoideae subfamily but apparently not the Mimosoideae and Caesalpinioideae subfamilies: transcriptome analysis of the mimosoid *Chamaecrista* provided no evidence of the 58 Myr whole genome duplication (Cannon et al., 2010); however, further work is required to characterize more genomes in the nonpapilionoid legumes. After the whole genome duplication, the Papilionoideae soon radiated into several clades. Among them, the millettioids (*Glycine*, *Phaseolus*, *Cajanus*) and the galegoids (*Medicago*, *Pisum*, *Lotus*, *Cicer*) separated ~54 Myr ago. *Medicago* diverged from *Lotus* ~50 Myr ago and from *Cicer* ~10–20 Myr ago. A more recent whole genome duplication occurred in soybean about 14 Myr ago (Young and Bharti, 2012; Varshney et al., 2013). Comparison of sequenced legume genomes extended previous genetic map-based comparative analyses and revealed extensive conservation of synteny, extending to whole chromosome arms (Choi et al., 2004a,b; Varshney et al., 2012, 2013; Young and Bharti, 2012). Comparison of synteny blocks conserved between different legume species allows reconstruction of an ancestral legume karyotype (Salse, 2012). There are few remnants of the 58 Myr whole genome duplication in the *M. truncatula* genome probably due to intense gene fractionation after the duplication event. However, subfunctionalization and neofunctionalization of homeologs can occur after duplication, and these processes could have played a role in the evolution of rhizobial nodulation (Young et al., 2011).

78.4 NATURAL VARIATION IN *Medicago* GENOMES

The availability of a reference sequenced genome opens the way to an in-depth analysis of natural variation within the *M. truncatula* species. The decreasing costs of sequencing make resequencing (alignment of short sequence reads on a reference genome sequence for the discovery of single-nucleotide polymorphisms (SNPs) of a large number of accessions affordable. A large number of *M. truncatula* accessions from around the Mediterranean basin have been collected (http://www1.montpellier.inra.fr/BRC-MTR/accueil.php), and the structures of these populations have been studied using a limited number of markers such as microsatellites (Ronfort et al., 2006). This allowed establishing core collections representative of the species diversity. In the *M. truncatula* hapmap program, 26 *M. truncatula* accessions from core collections were sequenced at 30× coverage, 226 accessions at 8× coverage (Branca et al., 2011; Stanton-Geddes et al., 2013). This allowed the identification of more than 6 million bi-allelic SNPs (about 10 sequence variants every 1 kb). These data were used to characterize genome-wide patterns of diversity, recombination rates, and linkage disequilibrium (Branca et al., 2011). Nucleotide diversity was found to be higher than in soybean or *Arabidopsis*. It decreased from centromeric to telomeric chromosomal regions and was negatively correlated with gene density, suggesting diversity is shaped by selection against deleterious mutations (Branca et al., 2011; Paape et al., 2013). Linkage disequilibrium was found to decay to half of the initial value within 3–4 kb, similar to what is described for *A. thaliana* but was very variable in different chromosomal regions. The population recombination rate was approximately one-third of the mutation rate, compatible with the high selfing rate of *M. truncatula* (Branca et al., 2011). Intraspecies diversity and interspecies divergence with *M. sativa* was also investigated using sequence data for >20,000 annotated genes (Paape et al., 2013): 50–75% of nonsynonymous polymorphisms were found under strong purifying selection, and only 1% of genes showed a signature of putative positive selection, among them genes involved in symbiotic and pathogenic interactions as well as epigenetic modifications. Whole genome interspecies comparison within the *Medicago* genus also helped clarify phylogenetic relationships between different *Medicago* species (Yoder et al., 2013). Finally, resequencing of *M. truncatula* lines opens the way to genome-wide association studies: statistical associations between sequence polymorphisms and phenotypic variation among natural accessions enable the identification and localization of putative causative loci. Such an analysis was conducted in *M. truncatula* to explore the genetic architecture of complex traits (flowering time, height, nodulation) and identify candidate genes underlying these traits (Stanton-Geddes et al., 2013). A number of other studies dealing with resistance to pathogens or symbiotic interactions with rhizobia or mycorrhizal fungi are in progress.

78.5 THE *M. truncatula* GENOME AND FUNCTIONAL GENOMICS

78.5.1 Transcriptomics

Many plant physiological and developmental processes are controlled at the transcription level, and the differential expression of genes in specific organs/conditions can give clues about their functions. Transcriptome analyses can be conducted in the absence of a complete reference

genomic sequence, for example, by sequencing ESTs or RNA sequencing. However, the availability of a genomic sequence, as is the case for *M. truncatula*, greatly benefits those analyses. EST data bases are often incomplete due to the low level or very specific expression of a number of genes. The gene models in the annotated *M. truncatula* genome sequence were thus used, in addition to EST sequences, to define the probes in microarrays used for transcriptome analysis, resulting in more comprehensive and specific sets of probes (Benedito et al., 2008). Over the years, more and more complete arrays have been made available, and the recent improvements in the genome sequence and its annotation should translate into still better arrays for transcriptomic analysis of protein-coding genes and open the way to tiling arrays. More recently, direct RNA sequencing approaches have been used to characterize the transcriptome of *M. truncatula*, and the bioinformatic analysis of RNA seq data generally involves mapping of the RNA sequences to the reference genomic sequence before the quantification of gene expression (Boscari et al., 2013; Young et al., 2011). It is worth noting that transcriptome data are precious to improve the quality of the genome annotation, allowing a better characterization of gene models and identification of alternative splicing sites (Town 2006; Cheung et al., 2006). A large number of transcriptomic studies have been carried out in *M. truncatula*, to identify genes differentially expressed in specific organs, in response to biotic and abiotic stresses, in the course of developmental processes (seed development, nodule development, etc.) (see Chapters 79 by Valdes-Lopez and 82 by Sinharoy et al.). It is in the field of symbiotic nitrogen fixation that these approaches have been most developed, with refinements including the use of developmental time series, of laser capture microdissection of specific nodule zones, and of various bacterial and plant mutants affected in the symbiotic process and treatments by symbiotic signal (Limpens et al., 2013; Moreau et al., 2011; Murray et al., 2011; Roux et al., 2014). These efforts have led to the identification of genes differentially expressed during the establishment of the symbiosis, among them transcription factors and other regulators that are good candidates for further functional characterization, in particular by reverse genetics approaches.

78.5.2 Proteomics

Proteomics is an important research tool to analyze biological processes. It can provide clues about protein localization, protein–protein, or protein–ligand interactions, posttranscriptional modifications, etc. Proteomic analysis generally involves high-resolution protein purification followed by proteolytic digestion and mass spectrometry (MS) and can lead to protein identification and quantification. MS data are used to search predicted proteins from DNA, RNA, or sequenced protein databases. The quality of the *M. truncatula* genome assembly and annotation is thus a crucial parameter for the success of proteomic analysis in this species. In addition MS analysis of *M. truncatula's* proteome could be used to improve the structural annotation of its genome in a proteogenomic approach (Volkening et al., 2012). Many proteomic studies of *M. truncatula* have been published, several of them dealing with the analysis of symbiotic interactions (e.g., Fliegmann et al., 2013; see Chapter 51), and also that of seed development or the proteomes of specific organs, tissues, or subcellular compartments (Lee et al., 2013). Phosphoproteome analyses were also performed to characterize components of symbiotic signaling since this process is known to involve several protein kinases (Rose et al., 2012).

78.5.3 Small RNA Analysis in *Medicago*

The availability of a reference genome for *M. truncatula* was crucial for the analysis of small noncoding RNAs in this species. Their known role in plant development and responses to biotic and abiotic stress suggested a potential role in nodulation and more generally in symbiotic interactions between legumes and rhizobia, or mycorrhizal fungi, and early on they were the focus of several analyses (e.g., Bustos-Sanmamed et al., 2013). Small noncoding RNAs, generally 20–24 nucleotides long, are generally classified into two groups, microRNAs (miRNAs) and small interfering RNAs (siRNAs), that have different biogenesis pathways and mechanisms of gene regulation (Axtell, 2013).

The *M. truncatula* genome contains six genes encoding members of the four groups of DCL (Dicer-like) proteins characterized in *Arabidopsis* and other plants that are required to cleave smRNAs precursors (including three DCL2-like proteins). Sixteen genes in the *M. truncatula* genome, in four main clades, encode AGO (Argonaute) proteins, which bind to miRNAs and participate in silencing effector complexes (RNA-induced silencing complex, RISC). Compared to *Arabidopsis* these two families have expanded, but it is not known whether this led to specialization in expression or function. More work using mutants in the different genes or coimmunoprecipitation of AGO proteins could shed light on the respective roles of DCL or AGO family members in the biosynthesis and modes of action of smRNAs (Bustos-Sanmamed et al., 2013).

miRNAs are by far the most studied smRNAs in *M. truncatula*. These smRNAs, often 21 nt long, derive from single-stranded RNA precursors that have a stem-loop secondary structure. DCL1 proteins recognize the secondary structure and generate an miRNA–miRNA* duplex. From the duplex, the miRNA binds to an AGO protein in an RISC, where the miRNA pairs to a complementary sequence in a target mRNA, leading to target cleavage or posttranscriptional repression (Axtell, 2013). The first miRNA in

M. truncatula was identified based on their sequence similarities to miRNA characterized previously in *Arabidopsis* (Boualem et al., 2008; Combier et al., 2006). More recently, the combination of high-throughput sequencing of smRNA libraries and better genomic resources allowed identification of miRNA in *M. truncatula* (Lelandais-Briere et al., 2009; Young et al., 2011). A high-quality reference sequence is required since a number of filtering steps, including mapping to the reference genome, elimination of structural RNAs and repeats, prediction of precursors based on miRNA:miRNA* pairing evaluation, and stem-loop structure are applied to smRNA sequences before the smRNAs can be considered *bona fide* miRNA candidates (Meyers et al., 2008). The miRNA targets were predicted based on the sequence similarity between miRNA and their targets, and in several cases the predictions were validated by degradome/PARE (parallel analysis of RNA ends) experiments, which identify the cleavage site in putative miRNA targets (Devers et al., 2011; Zhai et al., 2011). The current version of miRBase lists 756 mature miRNAs, a high number compared to other plants. This list is likely to evolve since all predictions were performed on incomplete versions of the reference genome, and new smRNA libraries are regularly sequenced. On the other hand, more stringent criteria for miRNA validation might remove some of them from the database. Part of the miRNA belong to families conserved between multiple plant species while some are more lineage specific (Bustos-Sanmamed et al., 2013).

Among siRNAs, tasiRNAs (trans-acting small interfering RNAs) are generated from transcripts that are first cleaved through the action of 22 nt miRNA triggers, and then transcribed into long dsRNAs that are processed by DCL4 into 21 nt tasi RNAs in 21 nt phased intervals (called phasiRNAs). More than 110 PHAS (phasiRNA-producing) loci were identified in *M. truncatula*, the majority being genes encoding defense-related NBS-LRRs (Fei et al., 2013; Zhai et al., 2011) (see below).

Finally, a major class of siRNA is heterochromatic siRNAs, mostly 23–24 long, which are associated with repressive chromatin modifications acting on the activities of transposable elements. Those have not been much studied in *M. truncatula*. Their analysis would benefit from a better characterization of heterochromatic regions of the *M. truncatula* genome and annotation of repeats.

78.5.4 Reverse and Forward Genetics

The genes identified by the above-described -omics approaches can be further tested functionally through inactivation using a reverse genetics methodology. RNA interference has been used successfully to functionally characterize several symbiotic genes, but the technology was never used on a large scale. The most efficient resource for gene inactivation was developed in recent years by European and US scientists who implemented insertion mutagenesis using the tobacco retrotransposon Tnt1. More than 20,000 insertion lines have been generated with probably overall more than 500,000 insertions in the genome (Cheng et al., 2011) (see chapters by Pislariu et al., Sinharoy et al.; see Chapters 82, 83) often resulting in knock-out mutations in genes. Mutations in genes of interest can be screened through a polymerase chain reaction (PCR) platform at the Noble Foundation or directly using Tnt1-insertions flanking sequences available in a regularly updated database. It is worth noting that most of the Tnt1 insertions have been generated in the R108 line of *M. truncatula*, which is transformed more easily than the A17 line. Although A17 and R108 are closely related, there are significant differences in their genome sequences. A *de novo* sequencing of the R108 genome with the current high-throughput technologies used to complete the A17 genome sequence would thus certainly be helpful to improve screening of the Tnt1 insertion lines. Several TILLING (targeting-induced local lesions in genomes) populations have also been developed for *M. truncatula* reverse genetics (Le Signor et al., 2009). They are very useful to obtain allelic series of point mutations in genes of interest for detailed structure function analyses, but knock-out mutants can often currently be obtained more easily with the Tnt1 insertion lines. Future developments in reverse genetics tools will certainly include the use of TALENs (transcription activator-like effector nucleases) or CRISPRs (clustered regularly interspaced short palindromic repeats) nucleases for genome modification (Gasiunas and Siksnys, 2013; Voytas, 2013).

Together with other mutated populations obtained by fast neutron, ethyl methane sulfonate (EMS), or gamma ray mutagenesis, the mutated populations used for reverse genetics have also been used for forward genetic screens, resulting in particular in the identification of numerous genes involved in symbiotic interactions with rhizobia or mycorrhizal fungi (Pislariu et al., 2012; see Chapter 63). Cloning of the mutated genes is easier in the case of Tnt1 mutants, although due to multiple insertions in a given line back-crosses with cosegregation analysis are often necessary. Moreover, the lengthy process of positional cloning in *M. truncatula* is made easier by the development of genomic resources: availability of a reference genomic sequence, resequencing of *M. truncatula* lines allowing unlimited genetic marker discovery, availability of microarrays for transcriptional cloning, and so on. The decreasing costs of sequencing open the way to direct genome sequencing of segregating populations to speed up the discovery of mutations causing a phenotype of interest.

78.6 TWO CASE STUDIES: GENE FAMILIES WITH REMARKABLE DIVERSIFICATION IN *Medicago*

Several gene families, particularly diversified in *M. truncatula*, are of interest. In particular, a group of genes encoding cystein-rich peptides (CRPs), also called defensin-like peptides, expanded in *M. truncatula* (Graham et al., 2004; Mergaert et al., 2003; see Chapter 67). These CRPs are in general short peptides with low sequence conservation. They have an *N*-terminal secretion signal in their nonmature form and are stabilized by disulfide bonds between intrapeptide cystein residues (Kondorosi et al., 2013). In plant genomes, this family seems to have expanded through ectopic and tandem duplication, followed by diversifying selection, leading to different subgroups, conserved or lineage specific. Although a minority have been functionally characterized, in plants members of this large family are known to play roles as antimicrobial agents or to be involved in various developmental processes (see Chapter 67). In the *M. truncatula* genome, about 800 CRP have been identified, most of them present in clusters containing 2–11 members often with pseudogenes, spread throughout the entire genome, compatible with their predicted mode of expansion (Young et al., 2011). Although a number of these genes are expressed in vegetative tissues or seeds (Tesfaye et al., 2013), a large majority have only been detected in nodules containing *S. meliloti* bacteroids. These were called NCRs (nodule-specific CRPs; see Chapter 67) and classified into 36 subgroups based on their sequence (Young et al., 2011). Transcriptomic analyses indicated that subsets of NCR genes have specific spatiotemporal expression profiles, some being expressed early in nodule cells just infected by rhizobia, others being more specific of cells containing fully differentiated bacteroids (Maunoury et al., 2010; Nallu et al., 2013). Conserved motifs that might correspond to *cis*-regulatory elements were identified in NCR promoter sequences, but the precise mechanisms of control of NCR gene expression remain unknown. Several pieces of evidence indicate that NCR peptides have a critical role in terminal bacteroid differentiation in *M. truncatula*: NCR peptides were found to be targeted to the plant cell secretory pathway and transported to bacteroids in symbiosomes (Van de Velde et al., 2010; see Chapter 67). A mutation in *M. truncatula* affecting NCR signal peptide cleavage and therefore NCR trafficking to bacteroids resulted in deficient bacteroid differentiation; treatment by NCR peptides of *S. meliloti* cultures induced cell elongation and an increase in DNA content similar to that seen in bacteroids; ectopic expression of NCRs in *L. japonicus*, a legume lacking NCRs, induced symptoms of terminal bacteroid differentiation (Kondorosi et al., 2013). However, targets of NCR peptides in bacteroids and their precise mode of action are unknown. In addition, it is not clear why such a large array of peptides is required for an efficient symbiosis in *M. truncatula*. Indeed no NCR encoding genes are detected in the genome sequences of several legumes that efficiently fix nitrogen in symbiotic association with rhizobia but do not form nodules with terminally differentiated bacteroids, such as *Glycine max* or *L. japonicus*. Although they have not been studied in great detail, NCR genes have been identified in legume genera related to *Medicago,* such as *Vicia*, *Pisum*, *Galega*, and *Trifolium*, which belong to the inverted-repeat lacking clade (IRLC) of legumes. Similar to *Medicago* species, these legumes form indeterminate nodules with terminally differentiated bacteroids showing amplification of bacterial genome as well as other modifications such as swelling. *Cicer* is another member of the IRLC clade forming indeterminate nodules but without swollen bacteroids (Oono et al., 2010). The recent sequencing of *C. arietinum* genome (Varshney et al., 2013) opens the way to characterization of CRPs in this species. Legume species hosting swollen bacteroids are found in other legume clades as well (Oono et al., 2010), it would be interesting to know whether NCRs play a role in these symbioses.

Another gene family that exhibits a great diversification in *M. truncatula* is that of the nucleotide-binding site leucine-rich repeats (NBS-LRRs), which confer resistance to a range of plant pests and pathogens through effector-triggered immunity. Nearly 800 NBS-LRR genes are found in the *M. truncatula* genome (Young et al., 2011), more than in the larger genomes of other legumes such as chickpea or soybean (187 and 506 NBS-LRR, respectively) and many other plants. More than 80% of these genes are found in clusters with an average of five genes/cluster distributed across chromosomes. Some very large clusters are found in regions showing a low conservation of synteny with other legume species and/or in regions with a high density of transposable elements (Young et al., 2011). Most of the NBS-LRRs belong to the TIR-NBS-LRR (toll/interleukin1 receptor) and CC-NBS-LRR (coiled-coil) groups that are found in similar proportions with a number of variants, particularly in the TIR class (Ameline-Torregrosa et al., 2008). Transcriptomic analysis following sequencing of mRNA in six different tissues showed that most of the identified NBS-LRRs genes are expressed in *M. truncatula* and allowed classification of NBS-LRR genes according to their expression pattern (Young et al., 2011). Interestingly, some of the genes were specifically induced in nodules, suggesting that members of this family could be involved in symbiotic interactions with rhizobia. Indeed in soybean, resistance genes were found to control host-specificity of the rhizobial–legume symbiosis (Yang et al., 2010). The presence of such a large number of NBS-LRR genes in *Medicago* raises one important question: how can the expression of these genes so important for biotic interactions be coordinated? It was recently found that NBS-LRR transcripts are targeted by networks of highly redundant small RNAs

(Fei et al., 2013, Zhai et al., 2011). NBS-LRRs are first targeted by 22 nt miRNAs in three unrelated families (miR2109, miR2118, miR1507) at several conserved motifs in the TIR or NBS domains. These miRNAs trigger the production of secondary siRNAs spaced in 21 nucleotide "phased" intervals, called phasiRNAs. These phasiRNAs, acting both in *cis* and *trans*, target related NBS-LRR transcripts, leading to regulation of their expression (Fei et al., 2013, Zhai et al., 2011). High levels of siRNAs matching more than 60% of NBS-LRR transcripts were detected, indicating that a majority of NBS-LRR genes can be regulated by this process. Production of secondary phasiRNAs amplifies the suppression effect of miRNAs, allowing regulation of most of the *Medicago* NBS-LRR genes. Similar processes were identified in other plant families like Solanaceae and to a lesser extent in Brassicaceae, but apparently not in Poaceae (Fei et al., 2013).

The functional relevance of the regulation of NBS-LRR gene expression by siRNAs remains to be precised. Several hypotheses have been proposed (Fei et al., 2013): suppression of NBS-LRR expression might be important for the establishment of beneficial biotic interactions, for example, with mycorrhizal fungi or rhizobia or it might play a role in plant defense against pathogens. Alternatively, such a regulation might allow steady-state regulation of NBS-LRR levels preventing accumulation of toxic level of NBS-LRR proteins, while allowing the preservation of NBS-LRR diversity necessary for response to pathogens. Further work is required to substantiate these hypotheses that are not mutually exclusive. It is also clear that the functional importance of this process varies among different plant families.

78.7 *M. truncatula* GENOME AND TRANSLATIONAL GENOMICS

One of the main incentives to develop genomic resources in *M. truncatula* was to facilitate analysis in phylogenetically related legume crops with less developed genetic and genomic resources, so-called orphan crops. Early on conservation of synteny between model and other legumes was used to facilitate positional gene cloning: once markers flanking the locus of interest were identified in the species of interest, new markers could be identified in the interval based on genomic information from the model legume, allowing fine mapping and identification of candidate genes (Endre et al., 2002; Limpens et al., 2003). On a larger scale, cross-species molecular markers were developed genome wide based on information from model legumes: PCR across introns using exon-specific primers allowed both amplification across species and discovery of polymorphisms (Choi et al., 2004a,b; Hiremath et al., 2012; Hougaard et al., 2008). The markers developed were used to construct genetic maps in different legume species, which confirmed the high overall conservation of synteny within the Papilionoideae subfamily. More recently, technical improvements and decrease in the costs of sequencing and genotyping allowed the development of genomic resources for orphan crops. In particular, transcriptome sequencing in various accessions of a given legume species led to the characterization of the gene space in these species as well as the discovery of abundant molecular markers (SNPs or SSRs (simple sequence repeats)) used to build high-density genetic maps (Bordat et al., 2011; Griffiths et al., 2013; Han et al., 2011; Hiremath et al., 2012; Sharpe et al., 2013). Comparison with genomes of model and other legume species shed light to the evolution of these genomes from a common ancestor, with a global conservation of synteny, and also many examples of rearrangements (translocations, inversions duplications, etc.). In addition, draft genome sequences of two legume crops, pigeon pea, and chickpea were published recently (Varshney et al., 2012, 2013), and that of common bean is on the way. Although these genome sequences were mostly assembled using next-generation sequencing data and genetic maps developed for these species, the *M. truncatula* genome assembly was used to tentatively orient 25% of the scaffolds of the chickpea genome (Varshney et al., 2013). Future assembly of the genome sequences of several important legume crops closely related to *M. truncatula* presents important challenges: large genome sizes due to abundant repeats (pea, lentil, faba bean), polyploidy, and heterozygosity (alfalfa, clover). These assemblies will certainly benefit from the *M. truncatula* genome assembly. Characterization of the gene space in these species through transcriptome or genome sequencing will also take advantage of the *M. truncatula* genome annotation to identify all members of various gene families, gene structure, splicing variants, and so on. In addition, comparative analysis of gene sequences in different legume genomes will identify orthologous groups as well as genes specific of some lineages or species, which might exhibit interesting functional diversification.

79.1 INTRODUCTION

Legumes are of considerable agronomic and socioeconomic importance because of their ability to provide grains for human consumption, fodder for animals, as well as their use in the manufacturing of several industrial products (Graham and Vance, 2003). A hallmark trait of legumes is their availability to develop root or stem nodules and to fix nitrogen (N_2) in symbiosis with compatible rhizobia. This symbiotic interaction is critical for legume development in nitrogen-deficient soils. This interaction also helps to reduce soil and water contamination by reducing the need for synthetic fertilizers (Graham and Vance, 2003).

Legume–rhizobia interactions result in a new organ: the root nodule or stem nodule. Inside the nodule, the rhizobia fix atmospheric N_2 and transfer it to the plant in exchange for a carbon source. The development of this symbiotic process is generally characterized by a high level of host specificity and is coordinately regulated by the mutual exchange of diffusible signal molecules (Dénarié and Debellé, 1996; Long, 2001; see Chapters 50, 51). Flavonoids and isoflavonoids present in the root exudates act as specific inducers of the nodulation genes in the compatible rhizobia (Hartwig et al., 1990; Dénarié and Debellé, 1996). These bacterial nodulation genes are responsible for the production and secretion of bacterial lipochito-oligosaccharides (LCOs) known as Nod factors (NFs; Hartwig et al., 1990). NFs are essential for rhizobial infection and nodule development. Significant metabolic changes in both symbiont and host occur during the infection process and nodule development. For example, in the earliest stages of this interaction, the invading rhizobia trigger root hair deformation, depolarization of the membrane, cytoskeleton reorientation, calcium spiking, cortical cell division, the expression of several specific genes, and posttranslational modification (i.e., phosphorylation and ubiquitination) of a variety of proteins (Ehrhard et al., 1996; Felle at al., 1998; Cardenas et al., 2000; Stacey et al., 2006; Hervé et al., 2011; Popp and Ott, 2011; see Chapter 59).

This symbiotic interaction has been extensively studied on the model legumes *Medicago truncatula* (referred to as *Medicago*) and *Lotus japonicus* (referred to as *Lotus*). Based on forward and reverse genetic analyses, several genes involved in the initial stages associated with NF perception and transduction have been identified in these two model legumes. These studies indicate that NFs are perceived with high specificity by LysM receptor-like kinases (RLKs) localized in the plasma membrane (see Chapter 51). These kinases include Nod-factor perception (NFP), which is an essential component of a signaling receptor necessary for early response to NF and rhizobial infection (Ben Amor et al., 2003; Arrighi et al., 2006). Mutants in *NFP* are affected in calcium spiking, expression of early nodulin

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

genes, and root hair deformation (Ben Amor et al., 2003). A leucine-rich repeats (LRRs)-receptor kinase, Does not Make Infections 2 (DMI2/NORK), is also localized on the plasma membrane and acts downstream of NFP (see Chapter 59). *Dmi2* mutants exhibit NF-induced root hair deformation, but are defective in NF-induced calcium spiking and rhizobial infection (Wais et al., 2000; Endre et al., 2002). Signals perceived at the plasma membrane are transduced downstream to activate signaling components residing at the nuclear level. DMI1, an ion channel, and MC8, a calcium pump, are localized on the nuclear envelope and control NF-induced calcium spiking (Ané et al., 2004; Peiter et al., 2007; Capoen et al., 2011). Calcium signatures are decoded by the calcium/calmodulin-dependent kinase (CCaMK) DMI3, which is localized inside the nucleus (Lévy et al., 2004; Messinese et al., 2007; see Chapter 54). DMI3 mutant plants are able to elicit calcium spiking and root hair deformation in response to NF, but cannot induce the expression of early nodulin genes or trigger cortical cell division (Wais et al., 2000; Lévy et al., 2004). Downstream of DMI3, two transcription regulators of the GRAS family, nodulation signaling pathway 1 and 2 (NSP1 and NSP2), control nodulin gene expression in an NF-dependent manner (Kaló et al., 2005; Smit et al., 2005; see Chapter 59). These two transcription factors (TFs) interact with each other and trigger the expression of Early Nodulin 11 (ENOD11) and Nodule Inception (NIN, Hirsch et al., 2009).

Although genetic approaches have led to the identification of different genes involved in the control of the legume–rhizobia interaction (some of them listed earlier), it is likely that additional "players" remain unidentified (see Chapter 63). For example, by using different large-scale analysis (i.e., transcriptomics, proteomics, and phosphoproteomics) in *Medicago*, *Lotus*, and *Glycine max* (soybean) treated with NF or interacting with rhizobia, several candidate genes have been identified (Serna-Sanz et al., 2011; Rose et al., 2012; Nguyen et al., 2012; see Chapter 78). Selecting the most promising candidates from the enormous amount of information generated by these "omic" approaches and then functionally characterizing them has become an imperative in this field. Here, we provide an overview of the information generated by transcriptomics and phosphoproteomics analyses of the legume–rhizobia interaction.

79.2 AVAILABILITY OF GENOME SEQUENCE: A MILESTONE FOR LARGE-SCALE ANALYSIS

New high-throughput sequencing technology and the accompanying bioinformatics tools have enabled the sequencing of several new plant genomes, including the genome of the two model legumes (*Medicago* and *Lotus*) and two of the most important legume crops (soybean and *Phaseolus vulgaris* (common bean)) (Schmutz et al., 2010; Young et al., 2011; http://www.phytozome.org/commonbean.php) (see also Chapter 78). Although the annotation and assembly of the genomes of these legumes are still in progress, about 90% of the expressed genes are represented in the current version (Schmutz et al., 2010; Young et al., 2011; http://www.phytozome.org/commonbean.php). For example, 47,845; 22,650; 73,320; and 316,338 genes have been annotated in the genomes of *Medicago*, *Lotus*, soybean, and common bean, respectively (Sato et al., 2008; Schmutz et al., 2010; Young et al., 2011). Even though these genomes are not completely assembled and annotated, the current genomic information has advanced the cloning and functional characterization of different genes and has allowed phylogenetic and syntenic analyses to be performed in these legumes (Li et al., 2011; see Chapter 78). Also, integration of the whole genome sequence with the genetic marker map that exist in some of these legumes has allowed cloning and identification of genes associated with particular quantitative trait loci (QTL, Grant et al., 2010, Joshi et al., 2012). Likewise, the genome sequence has allowed mutants to be identified and characterized more accurately. For example, after 3 years of the soybean genome sequence release, the generation of two mutant collections in soybean, one generated by fast-neutron mutagenesis and the other one by the insertion of the transposon *tnt1*, has been reported recently (Bolon, et al., 2011; Cui et al., 2013).

The availability of the genome sequences has also made it possible to accurately perform different large-scale analyses on these legumes. For example, to elucidate the molecular mechanisms that control the legume–rhizobia interaction, transcriptomic (both mRNA and smallRNA), proteomic, and phosphoproteomic analyses have been performed in *Medicago*, *Lotus*, and soybean plants treated with NF or in interaction with rhizobia (Libault et al., 2010; Boscari et al., 2012; Nguyen et al., 2012; Rose et al., 2012; see Chapter 78). These analyses have identified an enormous number of genes, proteins, and phosphorylation events that had not been identified by traditional genetic or biochemical analysis. Additionally, these -omic analyses have shown the overlap between different signaling pathways, for instance, the similarity between response to NF and the peptide flagellin (Serna-Sanz et al., 2011). These examples show how the availability of the whole genome sequence has positively impacted traditional genetic studies and also functional genomics studies in legumes.

79.3 TRANSCRIPTIONAL RESPONSES DURING THE LEGUME–RHIZOBIA INTERACTION

The initiation of the legume–rhizobia symbiosis triggers a variety of molecular and physiological changes in preparation for bacterial infection and nodule development. These changes are accompanied by different plant transcriptional events that lead to a successful interaction

(Oldroyd, 2013). Over the past two decades, different nodulin genes have been identified by forward and reverse genetic approaches (Sánchez et al., 1991; Pawlowski, 1997). One of these nodulin genes is the ENOD11, which is used as a marker gene to analyze the legume–rhizobia interactions (Journet et al., 2001). Likewise, two members of the GRAS family TF, NSP1 and NSP2, and the TF NIN are essential for both rhizobial infection and root nodule organogenesis (Kaló et al., 2005, Smit et al., 2005; Hirsch et al., 2009; see Chapter 59). In addition to the aforementioned genes, transcriptional analyses through DNA arrays or RNA sequencing (RNA-seq) approaches have demonstrated that a variety of genes show dynamic transcription during this symbiotic interaction (Libault et al., 2010; Boscari et al., 2012; Rose et al., 2012). For example, Mitra and coworkers (2004b) used a DNA microarray representing 9935 genes and identified 46 genes that were differentially regulated in *Medicago* plants exposed for 24 h to *Sinorhizobium melitoti* (*S. meliloti*; *Medicago* symbiont). Among these 46 differentially regulated genes, genes involved in ribosome biogenesis, plant-pathogen interaction, oxidative stress, and phosphorus transport were identified (Mitra et al., 2004b). Also, in this study, six Nod^- *M. truncatula* mutants (*nfp*, *dmi1*, *dmi2*, *dmi3*, *nsp1*, and *nsp2*) were used to demonstrate that these transcriptional responses are dependent on these six symbiotic genes (Mitra et al., 2004b). Likewise, these large-scale transcriptomic analyses have led to the discovery of different genes preferentially expressed in nodules or in roots following inoculation with rhizobia (Benedito et al., 2008; Libault et al., 2010; see Chapter 41).

Additionally, by combining transcriptome analysis on wild type (WT) and mutants of both symbionts (legume and rhizobia), genes involved in different stages of this symbiotic interaction have been identified (Mitra et al., 2004b). For example, in a study using a complementary DNA (cDNA) microarray representing 2366 genes, a two-stage reprogramming gene expression pattern was proposed to take place during the nodulation process in *Medicago* (Maunoury et al., 2010). However, a recent study with a 16,400 70-mer oligonucleotide microarray, in addition to the identification of 3400 differentially regulated genes, has led to the identification of four different stages of transcription reprogramming during the course of nodulation (Moreau et al., 2011). Based on this analysis, these four stages are (i) early signaling events and/or bacterial infection, (ii) plant cell differentiation dependent or (iii) independent on bacteroid differentiation, and (iv) nitrogen fixation (Moreau et al., 2011). Even within this classification, it is likely that each of these transcriptional stages could have complex subtranscriptional programming or transcriptional modules. Additionally, transcriptional studies in *Medicago*, *Lotus*, soybean, and common bean have helped to identify a variety of different transcriptional factors that play a role in each of the stages of this symbiosis (Libault et al., 2009).

It is likely that transcriptional reprogramming occurs immediately after NF perception. Since most of the transcriptional studies in the legume–rhizobia interaction (some of them mentioned earlier) have been focused on late responses, earlier transcriptional responses have not been described in detail. To address this, a recent study has reported the transcriptional changes that occur after 1 h of NF treatment in *Medicago* (Rose et al., 2012). In this study, RNA-seq (see Chapter 65) was used to analyze the transcriptional response to NF treatments in WT, *nfp*- and *dmi3 Medicago* mutant plants. One hundred and thirty-six genes were differentially regulated in response to NF treatment in the WT plants. The majority of these differentially regulated genes encoded for TFs, protein kinases, cell wall-modifying enzymes, defense-related proteins, transporters, and flavonoid biosynthesis proteins. Additionally, the ubiquitin E3 ligase PUB1, which interacts with the *Medicago* NF receptor LYK3 and negatively regulates nodulation, was upregulated after 1 h of NF treatment (Mbengue et al., 2010; Rose et al., 2012). Previously NFP was believed to be absolutely necessary for all NF-induced responses in *Medicago*. However, Rose and collaborators (2012) found that 31 genes were differentially regulated in *nfp* mutant plants after exposure to NF. This observation suggests the existence of other NFP-independent NF receptor complexes (see Chapter 51).

The molecular changes that lead to a successful legume–rhizobia interaction occur in specific root cell types. For example, the recognition of NF and the root colonization by rhizobia occurs in the root hairs (Stacey et al., 2006). The expression of genes that are essential for optimal nodule development and function is also cell type specific. Most of the transcriptional analyses on the legume–rhizobia interaction have used pooled tissue samples containing a mixture of different cell types. Because of the use of heterogeneous samples, it is likely that genes and gene-networks relevant for the symbiosis have not been identified yet. To overcome this problem, transcriptomic analyses have been performed in isolated root hairs after 24 and 48 h of rhizobia interaction in soybean plants (Libault et al., 2010; see Chapter 41). By using this single cell approach, different genes that preferentially express in the root hair with or without rhizobial interaction have been identified (Libault et al., 2010). Another approach that has been used to obtain cell type specific transcriptional data is laser capture microdissection (LCM). With this technique, the genes differentially regulated in zone II of *Medicago* nodules were identified (Damiani et al., 2012). Some of the differentially regulated genes in zone II are involved in glycolysis, mitochondrial electron transport/ATP (adenosine triphosphate) synthesis, and secondary metabolism (Damiani et al., 2012). Finally, additional efforts to integrate the transcriptional information, from either pooled tissues or single cell type studies, are necessary to better understand the transcriptional modifications that occur during this symbiosis. One of these efforts is the identification of gene regulatory modules or gene networks.

This analysis has been used to identify gene modules in soybean (Zhu et al., 2012). However, to date, there is no detailed report about the gene modules or gene networks that control the legume–rhizobia interaction.

79.4 MicroRNAs PARTICIPATE IN THE CONTROL OF THE LEGUME–RHIZOBIA INTERACTION

Like other physiological processes, the legume–rhizobia interaction is finely controlled at different levels. This interaction is controlled at the transcriptional level by different TFs, such as NIN, NSP1, NSP2, and HAP2 (Kaló et al., 2005, Smit et al., 2005; Hirsch et al., 2009). Recently, it has been demonstrated that the legume–rhizobia interaction is also regulated at the posttranscriptional level, primarily by microRNAs (miRNAs; Simon et al., 2009; see Chapter 78). miRNAs are 18–24 nucleotide, noncoding RNAs that control different developmental processes and nutrient homeostasis in both plants and animals (Mallory and Vaucheret, 2006). miRNAs play an important role in different stages of the legume–rhizobia interaction (Bazin et al., 2012). For example, miR166 and miR169 control the root and nodule development in *Medicago* (Combier et al., 2006; Boualem et al., 2008). Since the legume–rhizobia interaction is a multilayer process, it is likely that additional miRNAs are involved. To address this, different research groups have performed high-throughput sequencing analysis of small RNAs in different stages of the legume–rhizobia interaction (Subramanian et al., 2008; De Luis et al., 2012; Reynoso et al., 2013). These studies indicate that most of the miRNAs that are regulated during this symbiotic interaction belong to miRNA families conserved across different higher plant species (Subramanian et al., 2008). However, these analyses have led to the identification of novel miRNA families, some of which are present in legumes only (Subramanian et al., 2008). Some of these legume-specific miRNA families play a role in nodule development. For instance, the miRNAs such as miR482, miR1512, and miR1515 are positive regulators of nodule development in soybean (Li et al., 2010).

While some studies have investigated the significant transcriptional changes that occur during the first hour after NF perception (Rose et al., 2012), there are currently no reports about the miRNAs that are involved in the earliest stages of the legume–rhizobia interaction. However, in a recent study in rhizobia-inoculated *Lotus* roots, no significant changes in the abundance of miRNAs were found 3 h postinoculation (De Luis et al., 2012). Detection of plant-pathogen occurs in a manner similar to plant-symbiont recognition (Oldroyd, 2013). Plants can detect the presence of a pathogen through the detection of microbe-associated molecular patterns (MAMPs; e.g., flagellin and chitin) by pattern recognition receptors (PRRs), which are localized at the plant cell surface (Monaghan and Zipfel, 2012). Recently, it was demonstrated that PRR can be controlled by miRNAs (Li et al., 2012). Additionally, the abundance of different miRNAs (e.g., miR393) was significantly modified after 1 h of flag22 (a synthetic peptide of 22 amino acids from the conserved N-terminal of flagellin) treatment (Li et al., 2010). Due to the similarities between symbiont and pathogen detection, it is likely that some miRNAs play a role in the earliest stages of the legume–rhizobia interaction. Preliminary observations in the laboratory indicate that the abundance of miR2873c, miR2665, miR5207, and miR396c is significantly modified in *Medicago* roots after 1 h of NF treatment. Interestingly, putative targets of these miRNAs are E3 ligases. Two of these E3 ligases are SINA2 and SINA5, which play a role in nodule development in *Medicago* (Den Herder et al., 2008). This observation suggests that miRNAs can regulate some of the earliest responses of the legume–rhizobia interaction.

79.5 PROTEIN PHOSPHORYLATION: ANOTHER LEVEL OF REGULATION IN THE LEGUME–RHIZOBIA INTERACTION

During the legume–rhizobia interaction, a variety of proteins undergo posttranslational modifications. Some of these posttranslation modifications include ubiquitination and phosphorylation (Hervé et al., 2011; Popp and Ott, 2011). The initial steps in this symbiotic interaction involve specific receptor kinases and subsequent kinase cascades (Popp and Ott, 2011, Oldroyd, 2013). Protein phosphorylation is critical for the initiation of the legume–rhizobia interaction. The study of various plant mutants defective in nodulation led to the identification of key protein kinases essential for rhizobial infection and nodule formation. These include RLKs involved in the recognition of the NF signals, *MtNFP* (*GmNFR5* and *LtNFR5* in soybean and *Lotus*, respectively) and *MtLYK3* (*GmNFR1* and *LtNFR1*). Another important kinase is the nodulation receptor kinase (*NORK*, *MtDMI2*, and *SYMRK* in alfalfa, *Medicago*, and *Lotus*, respectively), a leucine-rich repeat receptor like kinase (LRR-RLK), first identified using a non-nodulating alfalfa mutant (Endre et al., 2002; see Chapter 59). The induction of calcium oscillations in the root hair cell is an important initial step in NF recognition and infection. These oscillations are likely detected and translated into cellular activity through the action of a CCaMK (Lévy et al., 2004; Mitra et al., 2004a; see Chapter 54). Transcriptional analysis in different stages of this symbiotic interaction indicates that the expression of different protein kinases is modified (Mitra et al., 2004b; Moreau et al., 2011; Rose et al., 2012). This observation suggests the participation of additional protein kinases as

well as the phosphorylation of additional proteins during the different stages of the legume–rhizobia interaction.

Phosphoproteome analysis allows for the survey of nearly all the phosphorylation events that occur in a particular physiological event. To identify the phosphorylation events that occur during the symbiotic interaction, phosphoproteome analyses have been conducted in *Medicago*, soybean, and *Lotus* plants (Grimsrud et al., 2010; Serna-Sanz et al., 2011; Nguyen et al., 2012; Rose et al., 2012; see Chapter 41). For example, 3457 unique phosphopeptides spanning 3404 nonredundant sites of *in vivo* phosphorylation on 829 proteins were identified in *Medicago* roots (Grimsrud et al., 2010). Interestingly, in this study, multiple sites of phosphorylation were identified on several key proteins involved in initiation of the legume–rhizobia interaction. Some of the proteins are Sickle (SKL), Interacting Protein of DMI3 (IPD3), and Nucleoporin 133 (NUP133). In an effort to characterize the phosphoproteomic changes that occur upon NF perception, a phosphoproteomic analysis was performed in *Medicago* roots treated with NF for 1 h (Rose et al., 2012). In this study, 98 differentially phosphorylated phosphoisoforms were identified. Interestingly, proteins involve in vesicle trafficking (e.g., Dynamin-related protein 2B (DRP2B)), ubiquitination (E3 ligases), translation (e.g., Eukaryotic translation initiation factor 5 (eiF5)), and proton pumping were differentially phosphorylated after 1 h of NF treatment. A similar phosphoproteomic analysis was conducted in soybean roots inoculated with rhizobia (Nguyen et al., 2012). In this study, the phosphorylation level of 240 proteins was modified after 30 and 60 min of rhizobial inoculation. These differentially phosphorylated proteins were classified into 24 functional categories. The largest functional groups were DNA–RNA related proteins (including TFs, DNA binding proteins, and chromatin-related proteins), signal transduction, protein trafficking, and cytoskeleton formation (Nguyen et al., 2012). Additionally, in both analysis in *Medicago* and soybean, a time course analysis revealed that most of the phosphorylation changes occur rapidly, that is, within 1 h after rhizobia inoculation or NF perception, whereas in later time points most the phosphorylation level decreases significantly (Nguyen et al., 2012; Rose et al., 2012). Likewise, a phosphoproteome analysis in *Lotus* roots treated with NF led to the identification of 13 differentially phosphorylated proteins (Serna-Sanz et al., 2011). Interestingly, the same 13 proteins were differentially phosphorylated upon flg22 treatment. This observation provides evidence about the overlapping in the symbiotic- and pathogenic phosphorylation pathways.

79.6 CONCLUSIONS

It is clear that large-scale analyses can provide valuable information and can help to dissect the legume–rhizobia interaction. However, how to integrate and interpret this information, it is one of the bigger challenges that researchers are facing. One possibility to deal with this is the inclusion of mutant plants and bacteria. But also, the integration of gene-network analysis, where data from any large-scale analysis (e.g., transcriptomics and phosproteomics) can be included, will help to integrate and obtain a biological sense from the large amount of data. Another challenge that we have to face is the selection of candidate genes for functional analysis. It is imperative to establish criteria that allow us select these candidate genes.

ACKNOWLEDGMENTS

This work was supported by a National Science Foundation (NSF) grant (Grant number: NSF# IOS-0701846) to MRS, by a CONACyT (CONACyT# 219759), PAPCA-UNAM (FESI-DIP-PAPCA-2014-3) and PAPIIT-UNAM (IA203815) grants to OVL. 80.1 INTRODUCTION

Legumes have been used as crops for harvesting oils, fiber, fuel, timber, medicinal, chemicals, and as horticultural varieties. As the third largest family of flowering plants, leguminous crops play important roles in raising productivity of farming in the temperate zone through building soil fertility and enhancing mulching quality. Legumes also have been well known for their ability to fix atmospheric nitrogen through symbiosis with nitrogen-fixing rhizobia, which is so highly specific that, with some exceptions, each rhizobial species interacts with only a specific group of legumes. Recently, the availability of genome sequences and expression data of multiple species such as *Medicago truncatula* (see Chapter 78), *Glycine max*, and *Lotus japonicus* opens the door to unravel the mystery of nitrogen fixing in legumes. Taking advantage of the data derived from multiple genome sequencing projects of the above-mentioned species, a large number of leguminous resources, such as legume Information (Gonzales et al., 2005), Soybase (Grant et al., 2010), MtGEA (Benedito et al., 2008), SoySeq (Severin et al., 2010), and LjGEA (Verdier et al., 2013), have been developed and comprehensive information for legume species can be queried and mined from these public data resources, which can be classified into two major types, sequence-based resources and transcriptome-based resources.

Soybase focuses on soybean breeding and research through integration information of genome sequences, gene expression, gene markers, and quantitative trait locus (QTLs). Other resources such as MtGEA, SoySeq, and LjGEA provide transcriptomics data from various stages of plant development in legume species. The development of these data resources provides a platform to understand

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

the molecular regulatory mechanisms and cellular activity for crop improvement. While these data resources focus on the information from individual genes or species, the Legume Information System (LIS), a community portal hosts a large number of legume species and gene transcripts such as expressed sequence tags (ESTs), genetic markers, and literature and external links in multiple crop and model species (Gonzales et al., 2005).

Comparative genomics and transcriptomic approaches have entailed gene discovery and gene functional characterization, for example, Libault and Joshi et al. systematically reviewed many genes that were discovered and annotated through comparative analysis of sequences and expression data (Libault et al., 2009; see Chapter 41). The effectiveness of comparative genomics and transcriptomics of model legumes, coupled with comprehensive gene annotation and gene family catalogs along with phylogenetic analysis, have also been successfully demonstrated to be able to decipher unique complex legume biological processes, such as nodulation in response to rhizobial infection. For example, MtHAP2.1, MtERN, and LjNIN genes controlling nodule development were identified through analysis of collinear relationships and expression profiles (Combier et al., 2006; Middleton et al., 2007; Schauser et al., 1999; see Chapter 59).

In this chapter, we focus on the latest development of the comparative genomics platform, LegumeIP (Li et al., 2012), which is an integrative platform built on the integration of the genome-wide sequences and expression data sets for comparative genomics and transcriptomics of model legumes to facilitate the discovery of functional associated genes, study of gene functions, and genome evolution in legumes. We demonstrate the usefulness of our LegumeIP system through mining symbiosis-related gene across three legume species and nitrogen-fixation-related genes in *M. truncatula* from gene expression profiles and coexpression networks. The LegumeIP is publicly available at http://plantgrn.noble.org/LegumeIP.

80.2 OVERVIEW OF DATA REPOSITORIES

80.2.1 Data Integration from Original Database

Facilitated by traditional BAC (bacterial artificial chromosome)-by-BAC, whole genome shotgun, and second-generation sequencing technologies, the genomes of three legume species, *M. truncatula* (http://www.medicago.org/genome; see also Chapter 78), *L. japonicus* (http://www.kazusa.or.jp/lotus), and *G. max* (soybean) (http://www.phytozome.net/soybean) have recently been sequenced (Sato et al., 2008; Schmutz et al., 2010; Young et al., 2011). These sequencing projects provide invaluable resources for legume research. LegumeIP integrates the genome sequence information of these three legume species downloaded from their websites. Genome sequences of another model species, *Arabidopsis thaliana* were also downloaded and compiled from http://www.arabidopsis.org. LegumeIP also integrates the genome sequence information of another species, *Poplar trichocarpa*, to facilitate the functional comparison of nitrogen-fixation capability. Poplar genome sequences were downloaded from ftp://ftp.jgi-psf.org/pub/JGI_data/phytozome/v9.0/Ptrichocarpa/annotation/. In total, LegumeIP integrates 222,217 protein-coding gene sequences and 221,706 amino acid sequences. Furthermore, large-scale gene expression profiling for *Medicago truncatula* (http://mtgea.noble.org/) and *Glycine max* (http://digbio.missouri.edu/soybean_atlas/) have been performed to characterize tens of thousands genes in these legume genomes (Benedito et al., 2008; Hogslund et al., 2009; Libault et al., 2010). Large-scale microarray-based and RNA-Seq based gene expression data from *M. truncatula*, *L. japonicus*, and *G. max* were downloaded from http://mtgea.noble.org/, http://cgi-www.cs.au.dk/cgi-compbio/Niels/index.cgi, and http://digbio.missouri.edu/soybean_atlas/ respectively (Benedito et al., 2008; Combier et al., 2006; He et al., 2009; Hogslund et al., 2009; Libault et al., 2010). Additional expression data set were downloaded from public data repositories, such as the Array Express (Parkinson et al., 2011) and the GEO website (Edgar et al., 2002). Up to date, we have manually curated and integrated 104 microarray data sets for *M. truncatula*, 156 microarray data sets for *L. japonicus*, and 14 microarray data sets for soybean. Figure 80.1 shows the schematic workflow of genomics and transcriptomic data integration and analysis procedures for the construction of the LegumeIP.

80.2.2 Comprehensive Gene Annotation

The gene models were annotated by referring to a series of standard databases. The protein sequences were first queried against the UniProt databases (O'Donovan et al., 2002) using BLASTP with a cutoff e-value $\leq$1e$-$04. The top five meaningful query results were listed as valid annotations. Using the same BLASTP-based annotation protocol, the protein sequences were further annotated using the Gene Ontology (GO) database (Ashburner et al., 2000), the Kyoto Encyclopedia of Genes and Genomes Pathway (KEGG) database (Kanehisa et al., 2008), Transporter Classification Database (TCDB) (Saier et al., 2006), and PLANT Transcription Factor Database (PlantTFDB) (Guo et al., 2008). The conserved domains of protein sequences were identified by the InterProScan software using its default E-value cut-off thresholds (Hunter et al., 2009).

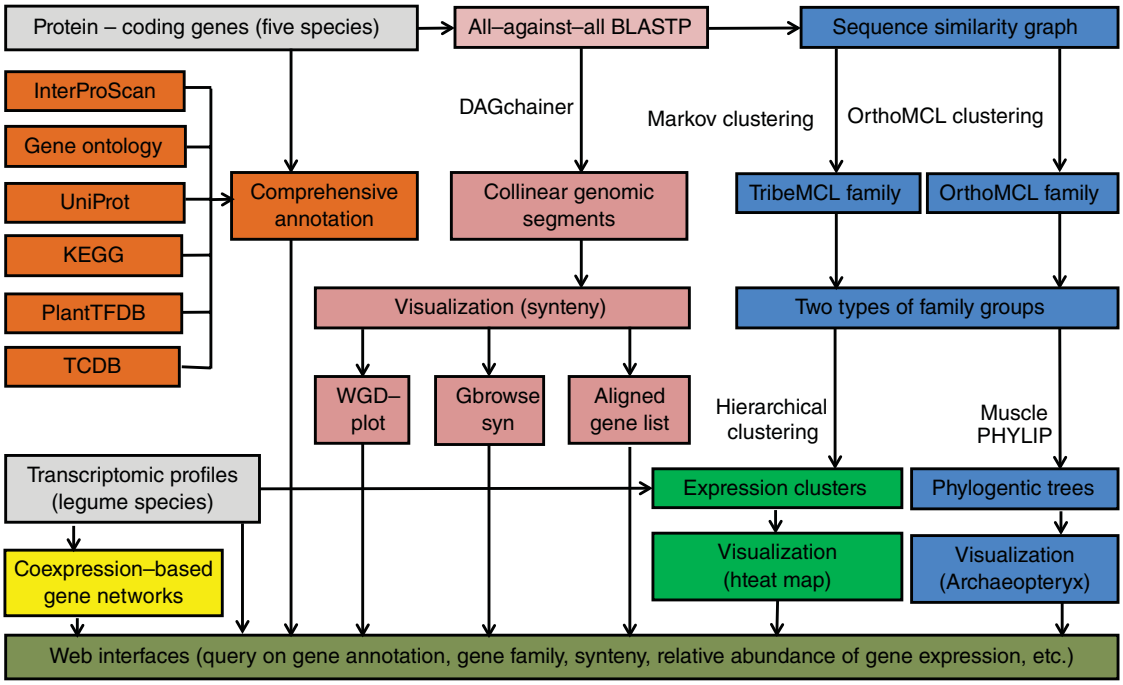

Figure 80.1 The schematic workflow on genomics and transcriptomics data integration and analysis for constructing the LegumeIP.

80.2.3 Systematic Synteny Identification

Aligning syntenic regions among legume species and non-legume species is an effective approach to identify patterns of evolution, conservation, and divergence of genome structures (see Chapter 78). The DAGchainer program (Eisen et al., 1998; Haas et al., 2004) was employed to identify syntenic regions among *M. truncatula*, *L. japonicus*, and *G. max* using *A. thaliana* as a reference outgroup. Briefly, BLASTN with e-value $\leq$ 1e−10 was applied to find intraspecies paralogous pairs and interspecies homologous pairs. DAGchainer with parameters, $Z = 12$, $D = 10$, $g = 1$, and $a = 5$, was then applied to identify orthologous pairs of interspecies collinear regions. Parameters with -s and -i in DAGchainer were used to find collinear homologous pairs in the same species. For all these identified homologous pairs in syntenic regions, we used the F3×4 model in the PAML4.0 package (Yang, 2007) to estimate the ratio of the number of nonsynonymous substitutions per nonsynonymous site (Ka) to the number of synonymous substitutions per synonymous site (Ks), that is, Ka/Ks.

80.2.4 Cross-Species Gene Family and Phylogenetic Analysis

Due to the frequent occurrence of tandem duplication or sequence diversity, orders of orthologous genes in collinear/syntenic regions may have been disrupted. To better understand gene function and genome evolution, two sizes of putative gene families were constructed in five species based on the protein-coding sequence similarity using two algorithms. First, the TribeMCL clustering algorithm (Enright et al., 2002) was employed to construct gene families of larger sizes. To circumvent the high false-positive rate generated by the nature of spurious BLAST hits within the TribeMCL algorithm, the OrthoMCL (Li et al., 2003), a low false-positive sequence clustering algorithm was adopted to construct gene families with smaller family size based on the same protein similarity graph. Briefly, first, all-by-all BLASTP was performed between coding nucleotide sequences in five species with parameter e-value $\leq$1e−10. Second, the TribeMCL with default parameter $I = 2.0$ was used to delineate corresponding gene families of larger family size based on the BLAST results. Third, the OrthoMCL was used to find more stringently defined homologous pairs, then the Markov cluster (MCL) method with default parameter $I = 2.0$ was used to construct gene families with small size but at lower false-positive prediction rate. In total, 95.70% of protein-coding genes (212,653 genes) were grouped into 12,166 gene families by the TribeMCL method, and 70.40% of all protein-coding genes were classified into 19,315 gene families by the OrthoMCL method.

To construct phylogenetic trees for gene families, multiple sequence alignment was firstly performed by the MUSCLE software (Edgar, 2004). Unrooted trees were then

created using PHYLIP software (including seqboot, proml, and consensus program) with 100 bootstrap replications.

80.2.5 Systematically Reconstruction of Genome-Wide Gene Coexpression Network and Identification of Functional Modules

Although large number of sequences could be annotated based on sequence similarity with public database such as GO, KEGG, TCDB, there still exists a large number of genes with unknown functions. Network-based gene-to-gene associated analysis provides a promising way to identify their functions. Genome-wide coexpression networks for the three legume species were therefore constructed using the DeGNServer (Li et al., 2013) and the large-scale collection of microarray data sets from public databases. These networks were further decomposed into multiple functional modules using the Markov clustering method (Enright et al., 2002). Based on the GO set enrichment analysis, the potential functions of those genes in the modules with unknown functions thus may be inferred based on other annotated genes in the same modules.

80.3 PLATFORM STRUCTURE AND WEB INTERFACE

LegumeIP was developed in Java and Groovy languages; it runs on a Linux-based RESIN J2EE web server architecture using MySQL as its database management system. The Circos software (Krzywinski et al., 2009) and Gbrowse (McKay et al., 2010) were adopted to visualize macrosynteny and microsynteny relationships, respectively. The Archaeopteryx (Han and Zmasek, 2009) was used to generate the interactive phylogenetic tree. The OpenFlashChart package (http://teethgrinder.co.uk/open-flash-chart/) was adopted to plot gene expression profiles. Gene cluster was visualized as a heatmap via HTML table coding.

80.3.1 Development of User-Friendly Web Interfaces for Data Access and Retrieval

LegumeIP provides a comprehensive set of web interfaces to search and explore genes, gene families, syntenic regions, and gene expression patterns. For example, through a simplified Keyword Gene Search interface, gene names, gene descriptions, specific biological functional categories as represented by GO terms, InterPro Domain names, KEGG compound names, a list of relevant gene IDs, gene family, and synteny regions of genes in multiple species can be searched. In the "Advanced Gene Search" page, more complex searching criteria can be created, such as combination of keywords with quantitative tissue-specific gene expression patterns. The retrieved results are usually listed in a summary page with links to batch download tools, the detailed gene page of comprehensive annotations, a plot of the transcriptomic profile if applicable, and sequence information along with "TribeGroup," "OrthoGroup," "Included gene in synteny" links to their corresponding synteny page and gene family page. The phylogenetic tree and heatmap-like table are included in the detailed gene family web page.

LegumeIP provides a simplified page to enable users to search or explore syntenic regions by either chromosomes or Contig IDs. The retrieved macrosyntenys, which include both interspecies and intraspecies syntenic regions, can be visualized as Circos maps and a summary table with links to web pages that contain more details of each gene using GBrowse syn, which is a Gbrowse-based synteny visualization tool.

LegumeIP also integrates BLAST search interfaces to allow users to search homologous genes or protein sequences based on sequence similarity.

80.4 DEMONSTRATIONS OF THE UTILITY OF LegumeIP

80.4.1 Mining SymRK Genes for Symbiosis Analysis in Legumes

Symbiosis with rhizobia in nodules is the source of nitrogen fixation of legumes. SymRK (symbiosis receptor-like kinase) genes play essential roles during establishment of endosymbioses in leguminous plants (Gherbi et al., 2008; Markmann et al., 2008). SymRK genes, which function as plant receptors in the symbiosome formation and endosymbiosis, are essential for the nod-signaling pathway in *L. japonicus.* An earlier study predicted more than seven SymRK genes in legume species (Markmann et al., 2008). Using the keyword "SymRK," we could successfully retrieve the seven genes from the LegumeIP. The results showed that these seven genes are classified in the same family, TribeMCL00867 group. Among seven genes, only four genes have corresponding probe sets presented on the Medicago GeneChip and all the four genes are highly expressed in nodules and roots. On the reconstructed phylogenetic tree, these expressed genes also located in the same clade (Fig. 80.2), which belongs to the same subgroup, OrthoMCL07722. The two gene families, TribeMCL00867 and OrthoMCL07722, have similar sequence features, and some of the member genes (Fig. 80.3) have similar gene expression patterns suggesting those genes coevolved with similar functions in legume root nodule symbiosis. Furthermore, the four genes are located in the corresponding syntenic regions (Fig. 80.4).

Figure 80.2 Phylogenetic tree of TribeMCL00867 family with the seven SyMRK genes indicated by the red box.

80.4.2 Mining Nodule-Specific Genes in *M. truncatula*

To mine nitrogen-fixation-related genes from *M. truncatula*, we used the "advance search" functions provided by our LegumeIP system to discover those genes that are highly expressed (e.g., the top 10% expressed genes) in nodules and roots, while low expressed (e.g., the lowest 30% expressed genes) in leaf and flower. Fourteen genes have been identified by LegumeIP; and nine genes are located in the third functional module/subnetwork (the list of genes in the subnetwork can be found at http://plantgrn.noble.org/LegumeIP/module.jsp?name=m2. It has been reported that in the ethylmethane sulfonate-induced snf1 mutant of *L. japonicus*, mutated *snf1* protein kinase (CCaMK, calcium-calmodulin-dependent protein kinase) is sufficient to turn fully differentiated root cortical cells into meristematic founder cells of root nodule primordia (Tirichine et al., 2006). Ca^{2+}/calmodulin genes are essential for CCaMK protein kinase to trigger *de novo* nodule formation in the absence of rhizobia or exogenous rhizobial signals (Tirichine et al., 2006; see Chapter 54). In *Medicago*, we also found a CCaMK gene (IMGA|Medtr8g043970.1), which is present in this module/subnetwork and also highly expressed in the nodule and root (Fig. 80.5), indicating the involvement of this module/subnetwork in nitrogen fixation. Furthermore, we found a nitrogen-fixation-related gene (IMGA|Medtr3g035970.2) interacting with the CCaMK gene. In addition, a nod-factor gene IMGA|Medtr8g0208401, whose orthologous gene in *Arabidopsis* is involved in the symbiotic signaling pathway (Bolle, 2004), was also present in this module. More importantly, for the nodule formation and nitrogen fixation, the gene function of *M. truncatula* CCaMK (MtCCaMK) is dependent on calmodulin-binding proteins (Routray et al., 2013). Through the autophosphorylation of S344 in the calmodulin-binding/autoinhibitory domain, the CCaMK

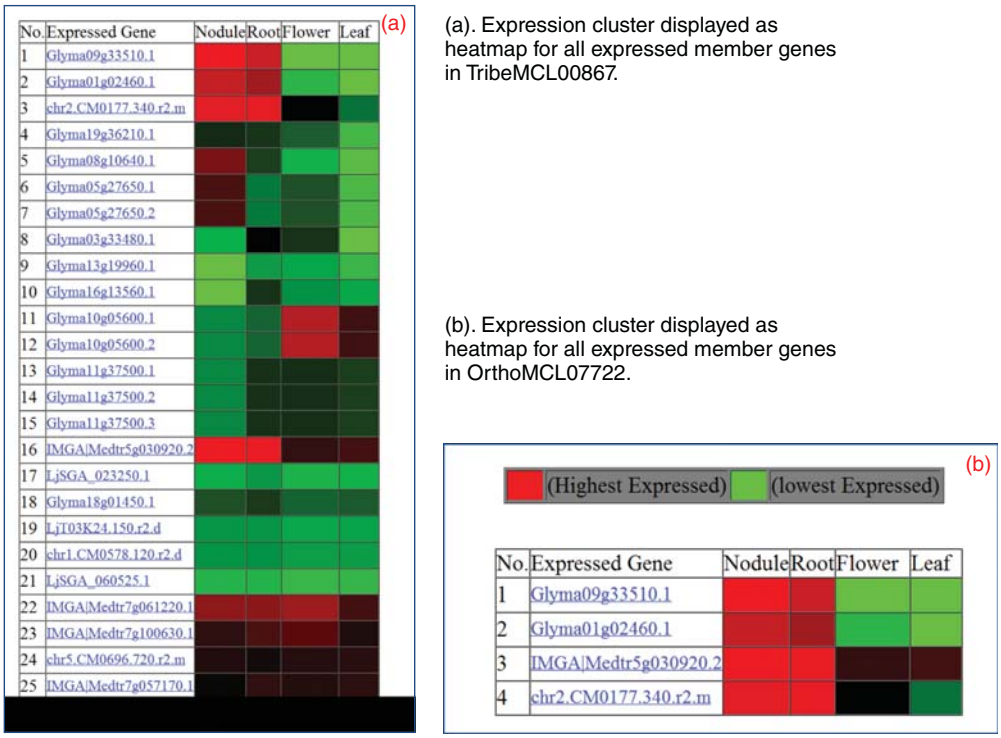

Figure 80.3 Gene expressions of two gene families, TribeMCL00867 and OrthoMCL07722, which include the SyMRK genes.

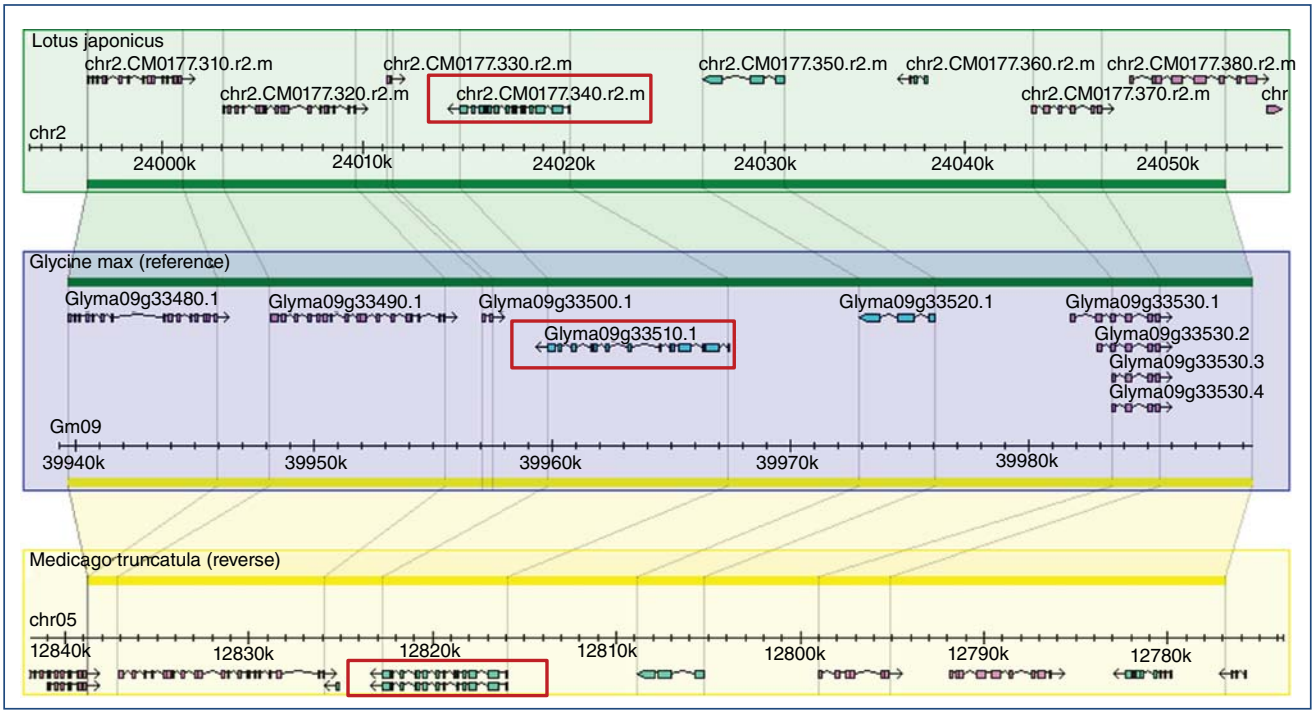

Figure 80.4 Orthologous genes of SyMRK gene family identified through collinear region analysis.

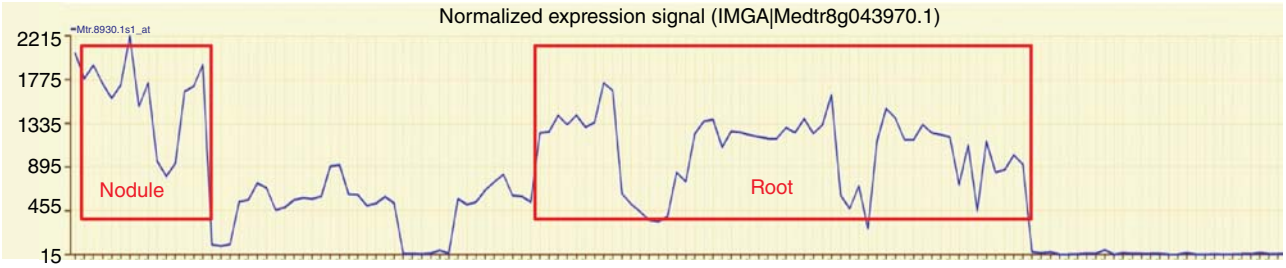

Figure 80.5 The tissue-specific expression of CCaMK gene (IMGA|Medtr8g043970.1) in *Medicago truncatula.*

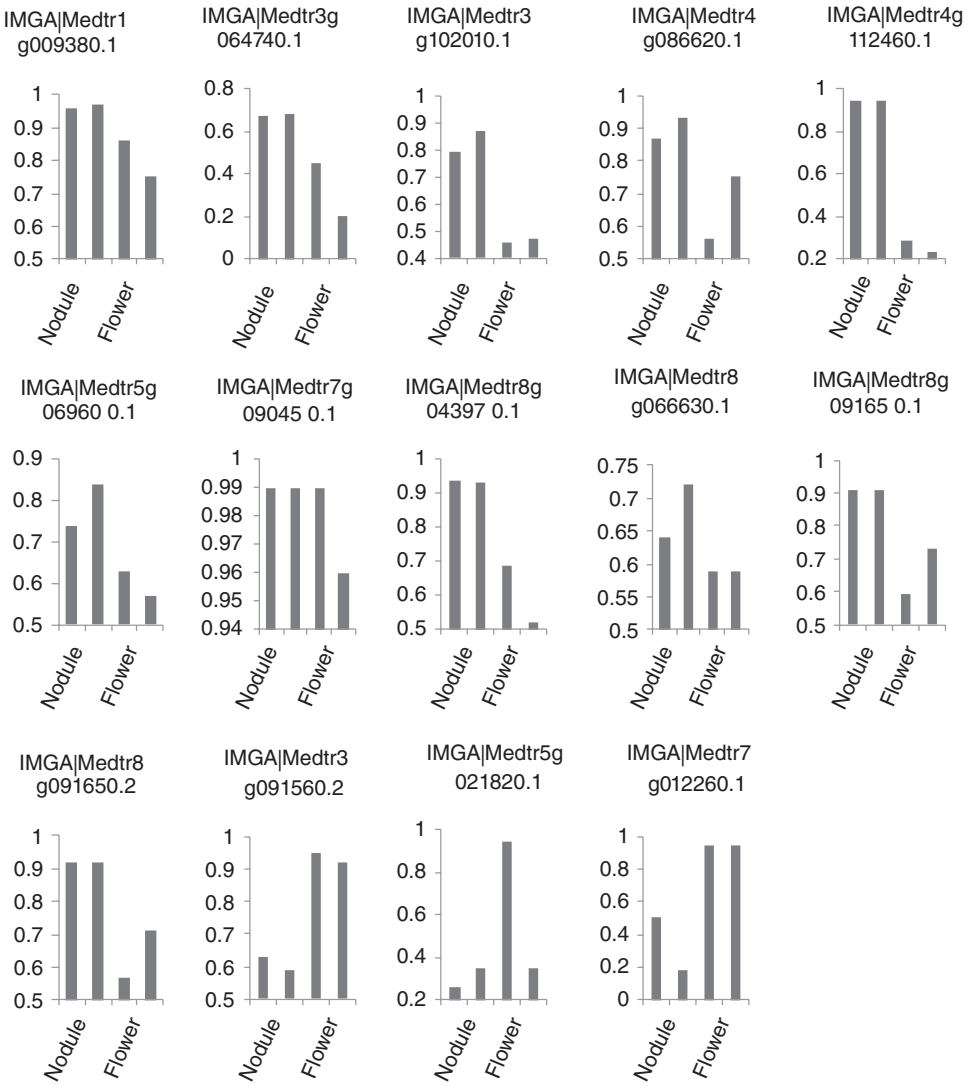

Figure 80.6 Most of the Ca^{2+}/calmodulin genes are preferably expressed in roots and nodules.

functionality was negatively affected during bacterial and fungal symbioses (Routray et al., 2013). In addition, the S337 residue is conserved across all angiosperm CCaMKs (Liao et al., 2012; Shimoda et al., 2012), and negative regulation of CCaMK protein by the S337 residue of CCaMK is essential for symbiotic infection in *L. japonicus*. In this module, more than 14 Ca^{2+}/calmodulin genes (IMGA|Medtr1g009380.1, IMGA|Medtr3g064740.1, IMGA|Medtr1g009380.1, IMGA|Medtr3g064740.1, IMGA |Medtr3g091560.2, IMGA|Medtr3g102010.1, IMGA|Medtr 4g086620.1, IMGA|Medtr4g112460.1, IMGA|Medtr5g021 820.1, IMGA|Medtr5g069600.1, IMGA|Medtr7g012260.1,

IMGA|Medtr7g090450.1, IMGA|Medtr8g043970.1, IMGA|Medtr8g066630.1, IMGA|Medtr8g091650.1, IMGA|Medtr8g091650.2) were found to be tightly connected with the gene CCaMK in the third subnetwork of *Medicago* coexpression network. In Figure 80.6, the sample genes that are highly expressed in the nodules are shown.

In the third module/subnetwork, we also found the presence of other genes that are involved in nitrogen fixation and assimilation. One of them is a nod-factor gene IMGA|Medtr8g089340.1, whose homolog in *Arabidopsis* encodes CAT8 (AT1G17120) that has been shown to participate in the symbiotic signaling pathway (Bolle, 2004). The CAT8 gene was identified as a glutamine transporter that functions at root tips with an activity independent of external pH (Su et al., 2004; Yang et al., 2010). Glutamine is one of the primary amino acids in nitrogen assimilation and often the most abundant amino acid in plant roots (Yang et al., 2010). IMGA|Medtr8g089340.1 also has the other homolog gene in *Arabidopsis* CAT1 (AT4G21120), which encodes a root-specific proton symporter to mediate high-affinity transport of basic amino acids already decades ago (Frommer et al., 1995). The other gene presented in the third module/subnetwork is IMGA|Medtr7g035060.1, whose homolog in *Arabidopsis*, NodGS (AT3G53180), belongs to TribeMCL03668 and its subgroup OrthoMCL02529. NodGS encodes a fusion gene with an N-terminal part sharing homology with nodulins. It is a nodulin/glutamine synthetase-like protein (glutamine synthetase is a key enzyme in nitrogen assimilation (Doskocilova et al., 2011)). In nitrogen/glutamate metabolism, the NodGS gene was found to affect the pool of endogenous glutamate/glutamine and also root morphogenesis in consequence (Doskocilova et al., 2011). All above-mentioned evidence suggests that the third module/subnetwork has cohesive functions related to nitrogen fixation through integrating the components of CCaMK, as well as signaling components.

Taken together, LegumeIP system comprises comprehensive sequence and information-enriched expression data and enables users to discover biological knowledge, such as genes/functional modules/subnetworks that are closely associated with nitrogen fixation.

80.5 CONCLUSIONS AND FUTURE PERSPECTIVES

LegumeIP hosts comprehensive genomics data related to nitrogen fixation from multiple species and the analytic tools that can be used to not only extract but also analyze information from these data, such as to retrieve comprehensive BLAST-/InterProScan-/GO-/KEGG-based gene annotations, calculate the relative abundance of gene expression, and perform gene family and macrosynteny analysis. The data and analysis tools are thoughtfully arranged and presented. Users are able to quickly search for the genes of their interests through friendly designed web interfaces. Meanwhile, the transcriptomics profiling, synteny, and phylogenetic analysis are powerful tools for gene function identification and annotation. For example, identification of genes involved the nodule formation process, one of essential biochemical reactions for the proper functioning of the biosphere. Furthermore, synteny and phylogenetic analyses provide information for scientists to better understand evolution of terrestrial plants, especially legumes. These functionalities and capabilities manifest the great potential of LegumeIP in studying fundamental questions of common interest in biology.

Aiming at a long-term empowering of the comparative genomics and transcriptomics of model legumes, we are committed to continuous improvement of the LegumeIP. In the near future, we will populate more sequences, microarray gene expression data, RNA-seq data from currently included and additional model and crop legume species into the LegumeIP database. Furthermore, we plan to integrate large-scale single-nucleotide polymorphism (SNPs) and genome-wide association studies (GWAS) data from various sources, for example, the *Medicago* Hapmap project (http://www.medicagohapmap.org/), which will deliver large-scale genomic information associated with 384 inbred lines spanning the range of *Medicago* diversity. These resources will further expand our knowledge related to SNPs, GWAS, and gene evolution, and better cover those unannotated genes without corresponding hits in the reference database, or without corresponding expression data due to lacking of present probe sets on the arrays.

81.1 INTRODUCTION

The availability of genome sequences of soybean (*Glycine max*) (http://www.phytozome.net/soybean), *Lotus japonicus* (http://www.kazusa.or.jp/lotus), and *Medicago truncatula* (http://www.medicago.org/genome; http://www.phytozome.net/medicago; see Chapter 78) has opened an opportunity for comparative genomic studies of transcriptional regulatory networks, which are controlled by sequence-specific DNA-binding transcription factors (TFs), in these legume species (Sato et al., 2008; Schmutz et al., 2010; Young et al., 2011). Among these three leguminous plants, soybean has been known as a very important crop worldwide, providing an abundant source of oil and protein for human consumption and animal feed (Manavalan et al., 2009; Tran and Mochida, 2010a; Thao and Tran, 2012; Ha et al., 2013). In addition, one of the prominent features of the legumes is their ability to fix atmospheric nitrogen through the symbiotic interaction with rhizobia, which allows them to grow under limited nitrogen sources (Sulieman and Tran, 2013; Sulieman et al., 2013a, b; see Chapter 99).

TFs that bind to DNA and either activate or repress gene transcription control diverse biological processes, such as development, growth, cell division, and responses, to environmental stimuli (Riechmann et al., 2000; Guilfoyle and Hagen, 2007; Tran et al., 2007; Tran and Mochida, 2010a;

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

Jogaiah et al., 2013). Typically, the TFs contain a distinct type of DNA-binding domain (DBD) and a transcriptional regulation region (TRR). However, in some cases, TFs may also contain other domains, such as protein–protein interaction domains or transmembrane motifs that play important roles in the regulation of the TF actions (Guilfoyle and Hagen, 2007; Seo et al., 2008; Tran et al., 2009; Le et al., 2011; Puranik et al., 2012). The specific interactions between TFs and their specific binding sites, the so-called *cis*-regulatory sequences that are contained in the promoter regions of genes, affect spatial and temporal gene expression, thereby playing a central role in the regulation of various biological processes. The TFs and their *cis*-acting motifs together function as molecular switches for gene expression as well as terminal points of signal transduction in the regulatory networks.

With approximately 4–7% of the total genes in a plant encoding TFs (Udvardi et al., 2007; Perez-Rodriguez et al., 2010; Mochida et al., 2011; Zhang et al., 2011; Mochida et al., 2013), which in turn control the expression of the whole genome, it would be ideal to perform functional studies of the TFs at the genome-wide level to gain a whole picture about their regulatory functions (Riechmann et al., 2000; Tran and Mochida, 2010b, 2010c). The completion of genome-sequencing projects of many plants, such as *Arabidopsis thaliana* (Arabidopsis Genome Initiative, 2000), rice (Sakai et al., 2013), poplar (Tuskan et al., 2006), maize (Schnable et al., 2009), sorghum (Paterson et al., 2009), and legume species (Sato et al., 2008; Schmutz et al., 2010; Young et al., 2011), and the development of high-throughput -omics techniques (Ma et al., 2012; Jogaiah et al., 2013; Komatsu et al., 2013) have enabled scientists worldwide to identify TF repertoires in various plant species to provide a basic foundation for comparative and functional studies at a genome-wide level (Mochida et al., 2009, 2010, 2011, 2013; Yilmaz et al., 2009; Perez-Rodriguez et al., 2010; Zhang et al., 2011). In this chapter, we briefly summarize the databases describing TF repertoires from three model legumes: *L. japonicus*, *M. truncatula*, and soybean. These are either species-specific databases that house TF repertoire of a single-legume species or integrative databases that contain TF repertoires of many plant species including the leguminous species.

81.2 SPECIES-SPECIFIC DATABASES FOR LEGUME TFs

Recently, the genome sequences of soybean, *L. japonicus* and *M. truncatula*, have been made available to public (Sato et al., 2008; Schmutz et al., 2010; Young et al., 2011; see Chapter 78). Taking advantage of this, different research groups have initially compiled the TF repertoires from these species for large-scale functional studies of their TFs. Among the TF repertoires of these three leguminous plants, only the TF set of soybean was reported in soybean-specific databases in addition to integrative databases. These specific databases were made available to soybean scientists at concurrent time in 2009 by two independent research groups from Japan (SoybeanTFDB) (Mochida et al., 2009) and the United States (SoyDB) (Wang et al., 2010).

The SoybeanTFDB database (http://soybeantfdb.psc.riken.jp) hosted by the RIKEN Plant Science Center (currently known as RIKEN Center for Sustainable Resource Science) of Japan used the earliest annotation version of the soybean genome sequence (Glyma1.0 model) provided by Phytozome for the identification of the TF set of soybean. This database provides access to 4342 genetic loci encoding 5035 TF models that are classified into 61 families based on their DBDs (Mochida et al., 2009; Tran and Mochida, 2010b). This soybean TF set was compiled by using 51 HMMs (hidden Markov models) of Pfam and those of 11 HMMs, which were originally created using HMMbuild of the HMMER package (http://hmmer.janelia.org/), to search against the proteome data set of Glyma v1.0. The search results for each TF family were then analyzed to retrieve discovered regions as conserved DBDs and relevant annotation information. SoybeanTFDB basically allows researchers to browse predictions for all the predicted 5035 TF models and to receive classifications for their respective submitted nucleotide and protein sequences. Significant information such as functional motifs, domain alignments, promoter regions, genomic organization, and putative regulatory functions based on annotations of gene ontology (GO) inferred by comparative analysis with *Arabidopsis* is available for each soybean TF. Multiple alignments of amino acid sequences within TF families are also available for downloading and can be used for the construction of phylogenetic trees. In addition, clustering results showing amino acid similarity with different levels of amino acid identity (30%, 60%, and 90%), search functions for functional motif information of InterProScan, *cis*-motifs in promoter regions of TFs and GO annotations are also provided in the database. Furthermore, cross-references and links to other databases, such as *Arabidopsis* TAIR8, TIGR rice, UniProt, SoyBase, soybean FL-cDNA, as well as other TF databases, either species-specific, such as AtTFDB (Davuluri et al., 2003), DATF (Guo et al., 2005), RARTF (Iida et al., 2005), DRTF, or integrative TF databases, such as Grassius (Yilmaz et al., 2009), PlnTFDB (Perez-Rodriguez et al., 2010), are also supplied. This feature provides a unique option for comparative studies of TF repertoires among various plant species. Hyperlinks linking the soybean TF-encoding genes to the available FL-cDNA clones (Umezawa et al., 2008), Unigenes, and Affymetrix Gene ID (Grant et al., 2010; Le et al., 2012) are also provided in detailed page of each TF to ease functional genomics research. Additionally, it is worthy to mention an interesting feature of SoybeanTFDB, which

provided information on known *cis*-elements predicted in the promoter region of each soybean TF. This feature enables those who have interest to easily carry out functionality predictions for any TF of interest based on the search results of *cis*-motifs and GO annotations. Soybean TFDB was perhaps the first TF database that provides such helpful information.

The SoyDB database (http://casp.rnet.missouri.edu/soydb/) built by Wang et al. (2010) identified more TFs −5671 genes encoding putative TFs in soybean, than did the SoybeanTFDB, although the two databases used the same annotated Glyma v1.0 version. These TFs were classified into 64 families based on the HMMs used in the study. The main components provided by SoyDB are as follows: protein sequences, predicted tertiary structures, DNA-binding sites, domain predictions, homologous proteins from the protein data bank, protein family classifications, multiple sequence alignments, consensus DNA binding motifs, and web logo of each family. Users can use five search keys "Text search," "PSI-BLAST search," "Browse database," "Family prediction by HMM," and "FTP" to access the provided information. Compared with the SoybeanTFDB, SoyDB did not provide the information for putative *cis*-motifs located in promoter region of each TF-encoding gene. However, it has an interesting feature that provided prediction of tertiary structure for those TFs, which have homologous template proteins in the Protein Data Bank (http://www.rcsb.org/pdb/home/home.do) (Berman et al., 2000), using the MULTICOM (Cheng, 2008).

81.3 INTEGRATIVE DATABASES FOR LEGUME TFs

There are several integrative databases housing TF repertoires of legume plants (Charoensawan et al., 2010; Ma et al., 2012). In this chapter, we focus on two major plant integrative databases, namely LegumeTFDB and PlantTFDB, which house TF sets of legume species.

The LegumeTFDB (http://legumetfdb.psc.riken.jp) was built by our group to provide a platform for comparative genomics of the TFs within legumes and beyond (Mochida et al., 2010). To continue the success with SoybeanTFDB, upon the availability of the genomic sequences of *L. japonicus* and *M. truncatula*, we computationally analyzed the annotated proteome data sets of *L. japonicus* and *M. truncatula* to identify their TF repertoires using the same approach that was used to compile the TF repertoire of soybean. All the relevant information that was provided for the soybean TFs were also supplied for the TFs from *L. japonicus* and *M. truncatula* on LegumeTFDB. Users familiar with SoybeanTFDB's interface can easily use LegumeTFDB to access the information provided for the TF(s) or TF families of their interest as these two databases have a similar design. For soybean researchers, an updated feature for soybean TFs was also provided in LegumeTFDB in comparison with SoybeanTFDB. The expression data for a total of 2411 soybean TF models (highlighted by red-colored letters in the search results of TF search page of each soybean TF family), including expression patterns for 32 different organs and tissues and those in response to several biotic stresses, such as treatments with *Phytophthora sojae* or *Phakopsora pachyrhizi*, housed on Genevestigator (https://www.genevestigator.com/gv/index.jsp) (Hruz et al., 2008), are accessible on LegumeTFDB through hyperlinks. All the search functions available on SoybeanTFDB are also found on LegumeTFDB as tools for comparative genomic analyses of TFs within these three important legume species or among the legumes and nonlegume model plants, such as *Arabidopsis*, poplar and rice. The expression data together with information of *cis*-motif analyses, GO annotations, and sequence similarities inferred from comparative analyses of the legumes can facilitate the systematic functional predictions of identified TFs (Tran and Mochida, 2010c).

The current PlantTFDB v2.0 (http://planttfdb.cbi.edu.cn) houses TF repertoires of 49 plant species, out of which 29 species have completed genomes (Zhang et al., 2011). In addition to the three well-known legumes – soybean, *L. japonicus*, and *M. truncatula* – PlantTFDB v2.0 also contains TF sets of *Arachis hypogaea* although its full genomic sequence has not been yet available. PlantTFDB classified the identified TFs into 58 TF families. Apart from the general information, including GO, domain feature, ortholog groups, expression patterns, and cross-references to various databases and literature citations, this database provided a unique feature that shows the multiple sequence alignments and phylogenetic trees for each TF family.

81.4 CONCLUSIONS

With their user-friendly interface, the databases described here meet the broad demands of researchers who are performing research on legume TFs with the goal of gaining greater understanding of their regulatory roles in different signaling pathways that control different biological processes, including plant development, differentiation, and environmental responses. Extensive research on the TFs has provided fruitful results, leading to a better understanding of the functions of the TFs, their regulatory networks, as well as the development of various crop varieties with improved performance under adverse growing conditions. With the future improvement in the annotation of the legume genomes analyzed by these databases and the availability of updated HMM libraries or refinements of existing ones, information provided by these databases needs to be occasionally fine-tuned and updated to improve the TF prediction accuracy, which in turn provides a great assistance to researches who focus on research of legume TFs.

ACKNOWLEDGMENTS

This work was supported by a grant (No. AP24-1-0076) from the RIKEN Strategic Research Program for R&D to Tran's lab, a Grant (project code 03/2012/HĐ-ĐTĐL) from Ministry of Science and Technology, Vietnam, to the Research Group of N.V. Dong. C.V. Ha is supported by a Ph.D. fellowship from "International Program Associate" of RIKEN, Japan. S. Sulieman is indebted to the Japan Society for the Promotion of Science (JSPS) for a postdoctoral fellowship.

82.1 INTRODUCTION

Legumes, the third largest angiosperm family, have been utilized as important pulse crops for several millennia (Doyle and Luckow, 2003). In symbiosis with soil bacteria called rhizobia, leguminous plants significantly contribute to the global nitrogen cycle. Every year, approximately 40 million tons of nitrogen enter agricultural ecosystems through symbiotic nitrogen fixation (SNF) (Peoples et al., 2009). These features make SNF central to sustainable agriculture.

Symbiotic association between fungi from the phylum *Glomeromycota* and the majority of terrestrial plant species (70–90%) is known as arbuscular mycorrhizal (AM) symbiosis (Parniske, 2000). AM symbiosis emerged 400–460 million years ago (Mya). The origin of SNF, on the other hand, is dated back to around 60 Mya (Sprent, 2008). Forward genetic studies using model legumes (*Medicago truncatula* and *Lotus japonicus*) have shown that SNF evolved in part by recruiting and modifying the genetic pathways established in the ancient AM symbiosis (Oldroyd, 2013; Popp and Ott, 2011 called CSSP, CSP or SYM; see Chapters 54, 55, 108, 110). In contrast to AM symbiosis, SNF involves the formation of a new organ called the "nodule" and a new organelle-like structure the "symbiosome" in which rhizobia are entirely enclosed by a host cell membrane. During AM symbiosis, neither a new organ is formed nor is there complete endocytosis of the symbiont. Nevertheless, in both cases the host needs to generate a membrane interface equipped for nutrient exchange (Parniske, 2000; Sprent and James, 2007; see Chapter 68). Transcriptomic studies indicate that thousands of genes are expressed during SNF. For AM symbiosis, however, this number is in the hundreds (Gaude et al., 2012; Gomez et al., 2009).

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

This difference supports the notion that SNF, though originating from AM symbiosis, has evolved as a much more elaborate, if not sophisticated, system.

In this chapter, we focus on two functional groups of genes, namely (i) transcription factors (TFs) and transcriptional regulators (TRs) as major determinants of genetic reprogramming during nodule development; and (ii) transporters that may be involved in exchange of nutrients between plant and rhizobia.

82.2 CURRENT KNOWLEDGE ON THE TRANSCRIPTIONAL CONTROL OF SNF IN LEGUMES

Classically, TFs are proteins that bind to specific DNA sequences and control the transcription from DNA to mRNA. A TR, on the other hand, does not necessarily have a DNA-binding domain (DBD); it influences transcriptions by altering transcription rates. A TR could be a transcription coregulator, a histone-modifying enzyme or even a DNA methyltransferase. Several TFs and TRs have been directly implicated in SNF, based on studies mainly using *M. truncatula* and *L. japonicus* as model systems (Table 82.1; see also Chapter 81). At least nine TFs and TRs have been genetically connected with nodulation. Although a few more TFs have been described, their mode of action remains elusive (Table 82.1). Briefly, four TFs are required at the early stage of bacterial recognition. Among them are two GRAS domain-containing TFs: *nodulation signaling pathway 1* (*NSP1*) and *NSP2* (Kalo et al., 2005; Smit et al., 2005). Mutations in these plant genes result in an inability to support infection thread (IT) formation (Catoira et al., 2000). It has been shown that NSP1 has a DBD, but NSP2 does not. NSP1 and NSP2 form a heterodimer that binds to the promoters of nodulation-specific genes, such as the TFs *nodule inception* (*NIN*) and *ethylene response factor required for nodulation 1* (*ERN1*) (Hirsch et al., 2009; see Chapter 59).

ERN1 is crucial at the early stage of Nod-factor signaling. This TF belongs to the AP2-EREBP family. Mutation in *ERN1* blocks the initiation and development of ITs. The *MtERN1* mutant *bit1-1* forms small bumps 2 months after inoculation with *Sinorhizobium meliloti* (Middleton et al., 2007). Further studies indicated that *ERN1* has a paralog in *Medicago*, called *ERN2* (Andriankaja et al., 2007; Young et al., 2011). *ERN1* is predominantly expressed during SNF,

Table 82.1 List of transcription factors and regulators required for SNF

Gene Name	TF Type	Mutagenesis and (Phenotype)	Reference*
MtNSP1/LjNSP1	GRAS	EMS/*Tnt1*; EMS (Nod-)	(Heckmann et al., 2006; Smit et al., 2005)
MtNSP2/LjNSP2	GRAS	EMS/*Tnt1*; EMS (Nod-)	(Heckmann et al., 2006; Kalo et al., 2005)
MtNIN/LjNIN	NIN-like	FNB/*Tnt1*; T-DNA) (Nod-)	(Marsh et al., 2007; Schauser et al., 1999)
MtERN1	AP2-ERFBP	FNB; EMS; *Tnt1* (Nod-)	(Middleton et al., 2007)
MtERN2	AP2-ERFBP		(Andriankaja et al., 2007; Cerri et al., 2012)
MtERN3	AP2-EREBP		(Andriankaja et al., 2007)

MtEFD	AP2-EREBP	RNAi, FNB (Fix-)	(Vernie et al., 2008)
MtHAP2-1/LjNF-YA1	NF-YA	RNAi/RNAi (Nod+/− Fix-)	(Combier et al., 2006; Soyano et al., 2013)
LjNF-YB1	NF-YB		(Soyano et al., 2013)
PvNF-YC	NF-Y-TF	RNAi (Fix-)	(Zanetti et al., 2010)
LjSIP1	ARID	RNAi (Fix-)	(Wang et al., 2013)
MtRR1	Cytokinin response regulator	RNAi (no phenotype)	(Ariel et al., 2012)
MtRR9/MtRR11	Cytokinin response regulator	RNAi (reduction in nodule primordium)	(Op den Camp et al., 2011)
MtRR4	Cytokinin response regulator		(Ariel et al., 2012)
MtbHLH476	bHLH	RNAi and *Tnt1* (reduction in nodule number)	(Ariel et al., 2012)
MtbHLH1	bHLH	CRES-T	(Godiard et al., 2011)
MsZPT2-1	C_2H_2	Antisense RNA (Fix-)	(Frugier et al., 2000)
MtNAC969	NAC	RNAi (premature senescence)	(de Zelicourt et al., 2012)
GmCND	MYB	RNAi (reduction in nodule number by 40%)	(Libault et al., 2009)
LjBzf	Leucine zipper RING-finger	EMS (enhanced and early nodulation)	(Nishimura et al., 2002)
MsNMHC5	MADS Box		(Heard et al., 1997)
MsNGL9	MADS Box		(Zucchero et al., 2001)
MtWOX5	HOMEOBOX	Ectopic expression (no phenotype)	(Osipova et al., 2012)
MtNOOT	BTB/POZ	*Tnt1* (emergence of roots from nodule apex)	(Couzigou et al., 2012)

Notes: Mt, *Medicago truncatula*; Lj, *Lotus japonicus*; Pv, *Phaseolus vulgaris*; Ms, *Medicago sativa*; Gm, *Glycine max*. Genes underlined are also involved in AM symbiosis.

*Only the most relevant references are mentioned.

whereas *ERN2* is expressed mostly during AM colonization. *ERN2* can functionally replace *ERN1* when expressed under the control of the *ERN1* promoter (Cerri et al., 2012). Another AP2-EREBP family member, the *ethylene-response factor required for nodule differentiation* (*EFD*), has been directly implicated in nodulation. Mutation in *EFD* causes a Fix- phenotype. EFD directly activates cytokinin signaling, which governs nodule differentiation (Vernie et al., 2008).

NIN is a plant-specific TF. It contains an RWP-RK domain conserved from algae to higher plants. Mutations in NIN block bacteria at ITs (Marsh et al., 2007; Schauser et al., 1999). Upon binding to DNA, NIN controls the expression of pectate lyase, which is crucial for IT formation (Xie et al., 2012). Several NIN targets have been identified by chromatin immunoprecipitation, gel mobility shift assay (GMSA), and inducible activation of NIN expression in transgenic plants. Among these targets are two NF-Y family members: LjNF-YA1 (*MtHAP2.1*) and LjNF-YB1. *NIN* overexpression induces nodule primordium-like structures, indicating that NIN and its direct targets (LjNF-YA1 and LjNF-YB1) control cortical cell division (Soyano et al., 2013; see Chapter 59).

Reverse genetic studies have connected an NF-Y family of TFs (MtHAP2-1/NF-YA1) with SNF (Combier et al., 2006). NF-Y TFs are heterotrimeric transcription factors usually composed of NF-YA (HAP2/CBF-B), NF-YB (HAP3/CBF-A), and NF-YC (HAP5/CBF-C) subunits (Laloum et al., 2013). RNAi knockdown (KD) of *MtHAP2-1* in *Medicago* indicates that this TF controls the development of the nodule meristematic zone. Bimolecular fluorescence complementation analyses in *Nicotiana benthamiana* leaves show that LjNF-YA1 and LjNF-YB1 interact with each other. Furthermore, in *Phaseolus vulgaris*, SNF is impaired by RNAi KD of NF-YC1 (Zanetti et al., 2010). Altogether, these results indicate that a heterotrimeric NF-Y complex is required for nodule development.

Two *MtbHLH* TFs have also been implicated in nodule development. Repression of *MtbHLH1* activity through chimeric repressor silencing technology (CRES-T) associated this gene with vascular patterning and nutrient exchange during SNF (Godiard et al., 2011). Another bHLH-TF (bHLH476) has been identified as a direct target of cytokinin signaling. A *Tnt1* retrotransposon insertion in this gene leads to a reduction in nodule number (Ariel et al., 2012).

Nodular Root (*NOOT*) is a homeotic gene coding for a BTB/POZ-ankyrin repeat protein that is necessary for the maintenance of nodule identity. Mutation in *MtNOOT* converts nodules to roots at various time points during nodule growth and development (Couzigou et al., 2012) (see Chapter 49).

Although nine TFs have already been shown to be essential for SNF, this number is probably the "tip of the iceberg" and certainly cannot account for the known complexity of transcriptional regulation associated with nodule development. We took a systematic reverse genetic approach to identify novel TFs and TRs required during SNF (see later).

82.3 FUNCTIONAL STUDIES ON MEMBRANE TRANSPORTERS INVOLVED IN SNF

Transporters facilitate nutrient exchange between closely interacting organisms and are essential for the establishment and maintenance of endosymbioses. A comprehensive summary of transport and metabolic processes relevant to the legume–rhizobia association was presented in a recent review (Udvardi and Poole, 2013; see also Chapter 68). To date, 22 transporter genes from nitrogen-fixing nodules have been cloned and functionally characterized (Table 82.2). The majority of these genes were discovered in legume species including *M. truncatula*, *L. japonicus*, *Glycine max*, *P. vulgaris*, *Vicia faba*, and *Lupinus angustifolius*. AgDCAT1 is the only SNF-related transporter cloned from a nonlegume species, *Alnus glutinosa* (Jeong et al., 2004). The existence of 11 more transport proteins active in nodules has been deduced using biochemical methods. In the case of the symbiosome membrane (SM), transport activities mediated by unknown transporters have been documented for H^+, malate, succinate, other carboxylates, glucose, and five forms of chelated Fe^{3+}, NH_4^+, Ca^{2+}, and K^+ (Andreev et al., 1999, 2005; Herrada et al., 1989; Kaiser, 1998; LeVier et al., 1996; Robertson et al., 1978; Udvardi et al., 1991; see Chapter 68). Furthermore, protoplasts derived from uninfected nodule cells have been shown to import sucrose, glucose, and amino acids, such as leucine (Peiter and Schubert, 2003; Peiter et al., 2004). In total, over 46 diverse substrates have been tested for transmembrane movement in nitrogen-fixing nodules. Direct or indirect evidence for subcellular localization is available for eight nodule transporters. Among them, GmNod26 (see Chapter 69), N70-homologs from soybean and *Lotus*, GmDMT1, GmZIP1, and AgDCAT1 are localized in the SM (Jeong et al., 2004; Kaiser et al., 2003; Masalkar et al., 2010; Moreau et al., 1998; Vincill et al., 2005), whereas LjAMT2;1, GmUPS1-1, GmUPS1-2, and GmPT5 probably reside in the PM of uninfected cells, including cells of the vascular tissue (Collier and Tegeder, 2012; Qin et al., 2012; Simon-Rosin et al., 2003). Mutant analyses of symbiotic transporters with potential roles in SNF in legumes have been described for only eight transporters. The first such transporter, LjSST1, was identified through both insertional (T-DNA) and chemical mutagenesis (EMS), whereas mutants for LjSEN1 and MtLATD/NIP (see Chapter 60) were isolated from EMS populations (Bagchi et al., 2012; Hakoyama et al., 2012; Krusell et al., 2005). More recently, LjPT3, GmPT5, GmUPS1-1, GmUPS1-2, and LjMATE1 have been studied by RNAi (Collier and Tegeder, 2012; Maeda et al., 2006; Qin et al., 2012; Takanashi et al., 2013).

Table 82.2 List of characterized transport systems associated with SNF

TCDB, Transporter Classification Database (http://www.tcdb.org); SM, symbiosome membrane; PM, plasma membrane; TP, tonoplast.
*The transport systems are listed in the order of their first biochemical characterization or gene cloning; the most relevant study is referenced in each case.

In this chapter, we report on symbiotic transporters identified on the basis of two transcriptomic resources (MtGEA and nodule zone profiling) and targeted by *Tnt1* insertional mutagenesis.

82.4 ESSENTIAL RESOURCES FOR FUNCTIONAL ANALYSIS OF SYMBIOTIC GENES IN *Medicago*

Model legume species are essential genetic systems for the discovery and characterization of genes central to SNF. In order to enhance the value of *Medicago* as a legume model, several genetic tools have been developed (see Chapter 78). Among them, the *Medicago* gene expression atlas (MtGEA) contains the most comprehensive transcriptomic data for all major organs of this species including a nodule developmental time series (Benedito et al., 2008). More than 26,000 genes are expressed during SNF, and 30.2% of them are differentially expressed more than twofold compared with roots. The version 2 of MtGEA contained 64 experiments and data from 156 Affymetrix chips. The database was recently updated to version 3 and now consists of 256 experiments and 670 chips. Importantly, this new MtGEA version includes transcriptomic data from several nodulation-related

TF mutants such as *efd*, *hap2.1*, and *noot* (Niebel et al., and Ratet et al., unpublished data). Furthermore, a large tobacco retrotransposon (*Tnt1*)-insertion mutant population of *Medicago* has been developed at the Samuel Roberts Noble Foundation, USA (Tadege et al., 2008). A detailed review of this valuable resource is presented in Chapter 83.

82.5 STRATEGIES OF CANDIDATE GENE SELECTION FOR REVERSE GENETIC STUDIES

We took several alternative approaches to identify genes for reverse genetic studies. Preliminary lists of nodule specific TFs and TRs are already present in MtGEA, they have been refined by annotation based on the current genome release (IMGAG 3.5v4). We started with annotation (Young et al., 2011) and re-annotation of TFs and TRs in the *Medicago* genome. Comprehensive annotation and transcriptional analysis of *Medicago* transporters based on MtGEA uncovered 50 nodule-specific and 196 nodule-enhanced transporters with transcript levels greater than fivefold compared to roots (Benedito et al., 2010). This annotation work presents an excellent source of candidate transporter genes for reverse genetic studies. We generated a new spatially resolved transcriptomic data set for *Medicago* nodule development (Pislariu et al., unpublished data). This useful data set aids in "smart" selection of candidate TF and transporter genes for functional characterization.

82.6 RE-ANNOTATION OF NODULE-INDUCED TF AND TRs

TFs are major determinants of any developmental program. According to MtGEA, 532 putative TF genes are differentially expressed (more than twofold) during SNF. It is conceivable that the de-differentiation of root cortical cells during early stages of SNF depends on epigenetic changes in chromatin structure. Accordingly, chromatin-remodeling enzymes and other chromatin modifiers might play key roles as TRs in differentiation and development of the nodule. We have re-evaluated the annotation of the 532 nodule-specific TFs using the IMGAG 3.5v4 gene models and online annotation tool PlantTFcat (plant transcription factor and transcriptional regulator categorization and analysis tool). We identified 417 TFs and TRs that were induced more than twofold during SNF. Of these, 358 are TFs and 59 are homeotic genes and chromatin regulators (TRs) (Fig. 82.1). Only 18 of the 417 genes have been directly implicated in SNF by genetic studies so far (Table 82.1). Given a very low proportion of characterized genes in this category, it is clear that a large number of nodule-induced TFs are potentially important for SNF, and thus deserve functional analysis. Among the 358 TFs induced during SNF, the most represented TFs belong to the C_2H_2 family (13%), followed by AP2-EREBP (13%), MYB (10%), WD-40 (9%), NAM (8%), C_3H, bZIP, bHLH (5% each), NF-Y, WRKY (4%

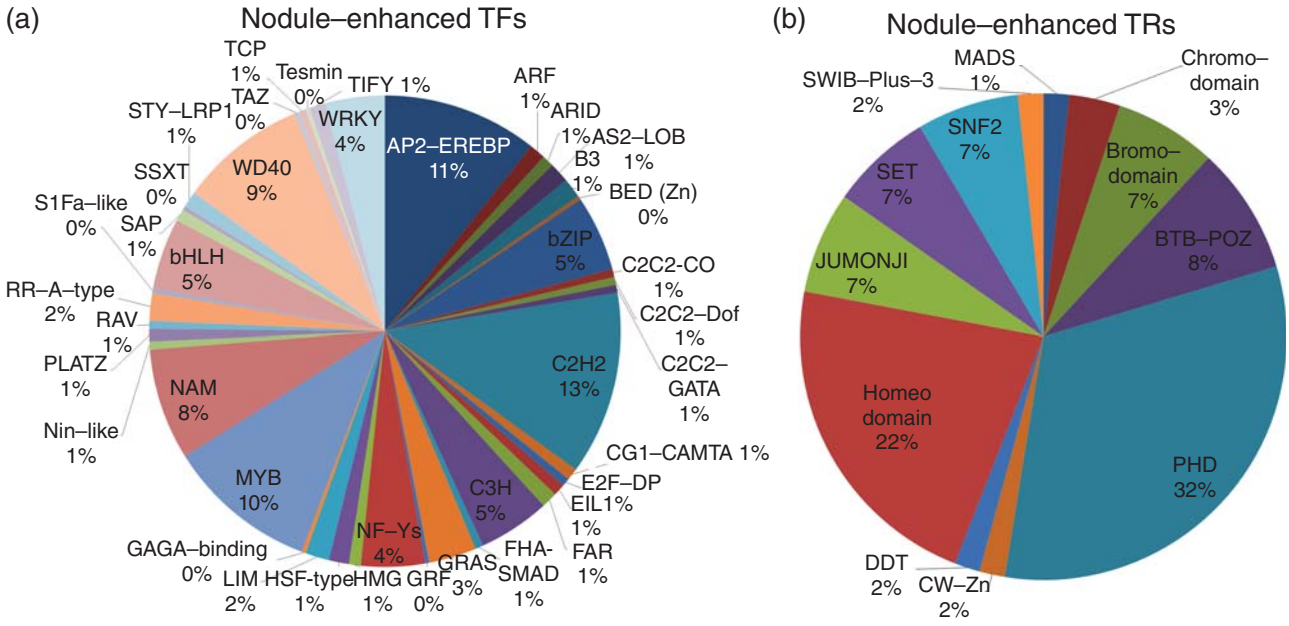

Figure 82.1 Re-annotation of *Medicago* nodule-enhanced transcription factors and regulators. Categorization of nodule-enhanced (≥twofold change of gene expression in nodules compared to roots) TFs and TRs in families is presented. Pie charts show the percentages relative to the total number of genes for TFs (a) and TRs (b) indicated by the number in the middle of each chart.

each), GRAS (3%), while the remaining 24% cover other TF families (Fig. 82.1a).

Among TRs and chromatin remodelers, most genes belong to the homeotic gene family represented by three subgroups as in Figure 82.1b: PHD, homeo domain, and BTB-POZ. In classical understanding, "homeotic gene" is a collective term for genes that control the pattern of body formation during early phases of organ development (Mukherjee et al., 2009). The most represented group of homeotic genes (32%) is the plant homeodomain (PHD)-containing family (Fig. 82.1b). PHD proteins usually reside in the nucleus and are involved in chromatin-mediated gene regulation. Most probably, they act by binding to trimethylated lysine residues of H3 histones (Sanchez and Zhou, 2011). The next major homeobox gene group (24%) is the homeobox domain family (Fig. 82.1b), which essentially encompasses a helix-turn-helix (HTH)-type DNA-binding structure that has been directly implicated in DNA binding, though the specificity of a single homeodomain protein is usually not enough to recognize only its preferred target genes, rather it requires additional protein–protein interactions for binding to promoter (Mukherjee et al., 2009). The third group of homeotic genes, the BTB-POZ domain-containing family (Fig. 82.1b), is also well represented (8%). The BTB-POZ domain is a protein–protein interaction module. It regulates gene expression through the local control of chromatin conformation. Other histone-binding protein families are the bromodomain-containing family (8%), Jumonji family (7%), chromodomain family (4%), DDT (2%), and CW-Zn (2%) (Fig. 82.1b).

82.7 NODULE DEVELOPMENTAL SPATIOTEMPORAL GENE EXPRESSION PATTERN

Indeterminate nodules acquire cylindrical shape because of a meristem that remains active in the mature organ. A morphophysiological gradient can be observed in mature, nitrogen-fixing indeterminate nodules. *Medicago* forms indeterminate nodules that contain a persistent apical meristem (zone I), a bacterial invasion zone (zone II), a maturation interzones II–III, a nitrogen-fixing zone (zone III), and a senescence zone (zone IV) that is proximal to the root and only observed in older nodules (Vasse et al., 1990). Gaining insight into the spatial distribution of gene expression adds value to existing *Medicago* transcriptomic resources. To achieve this, we manually dissected nodules into five zones based on nodule morphology and the gradient of leghemoglobin color intensity. The Medicago Affymetrix Gene Chip was used to generate a global, nodule-specific, and spatially resolved transcriptome (Pislariu et al., unpublished data). The analysis of nodule zone-specific expression of TF and TR genes was conducted as described (Benedito et al., 2008). An overview of the zone-specific expression of TF and TR genes is shown in Figure 82.2a. The gradient of expression points toward the existence of functional groups and their potential linkage to zone-specific developmental and/or metabolic pathways. Before proceeding to selection of candidate genes, we verified that the spatial expression profiles of previously characterized nodulation genes matched expectation (data not shown). Nine TFs have been functionally characterized and shown to be critical for SNF. Among these, NSP1, NSP2, HAP2.1, EFD, ERN1, and ERN2 are induced very early during nodulation and have been shown to be critical for nodule initiation (see Chapter 59). Both MtGEA and our spatial data correlate well with published reports on these genes (Fig. 82.2b, c).

Although NIN is required for nodule initiation, its expression is not confined to the invasion zone; it is highly expressed throughout the nodule. Promoter-GUS analysis of NOOT and MtbHLH1 suggested transcript accumulation predominantly in the nodule vasculature (Couzigou et al., 2012; Godiard et al., 2011; see Chapter 49). Our results show a rather uniform expression of both genes along all zones, matching the distribution of vascular tissue in nodules.

82.8 SELECTION OF TRANSCRIPTION FACTORS AND TRANSPORTERS FOR REVERSE GENETIC SCREENING

MtGEA contains gene expression data from different time points of nodule development, beginning at 3 days postinoculation. Based on the temporal (Benedito et al., 2008) and spatial (Pislariu et al., unpublished data) expression patterns, we chose several TFs, TRs, and transporter genes for functional analysis. As a primary criterion, we chose genes that are expressed exclusively during nodule development, but we also did not eliminate those genes that have additional expression during AM formation. Furthermore, we paid attention to the genes specifically induced in the invasion and interzone, because the molecular events occurring in these two zones are crucial to nodule development in Medicago. A gradient of bacterial development from essentially "free-living" to the mature nitrogen-fixing form is seen within the invasion and interzones. Moreover, a few genes that satisfy the above criteria are also expressed during AM formation. These were given the highest priority. We isolated *Tnt1* mutants for 21 TFs and TRs (Sinharoy et al., unpublished data) (see also Chapter 83) and 20 transporter genes (Kryvoruchko et al., unpublished data). Lists of the genes that were chosen for reverse genetics, with preliminary phenotypes, are presented in Table 82.3 (TFs and TRs) and Table 82.4 (transporters). Reverse screening for the *Tnt1* mutants was performed as previously described (Cheng et al., 2011).

Figure 82.2 Nodule zone-specific expression of transcription factor and regulator genes. (a) Hierarchical clustering of 417 nodule-enhanced transcription factors during nodule development. Clustering was performed using Pearson correlation. (b) Nodule zone-specific expression of nine TFs that have been functionally characterized and implicated in nodule development. For each probe set, relative expression was converted to the log2 value of the ratio representing the zone-specific expression over the average expression along all five zones. Data analysis was conducted on zone-specific transcriptomes generated in three biological replicates. (c) Induction in gene expression for nine TFs according to MtGEA temporal data at three time points with respect to 0 dpi. MER, meristem; INV, invasion zone; INT, interzones II and III; FIX, nitrogen-fixation zone; SEN, senescence zone.

82.9 ZINC-FINGER PROTEINS IN NODULE DEVELOPMENT

Zinc-finger proteins (ZFP) comprise the largest TF family in animals. They code for almost half of all annotated TFs in the human genome (Zhang et al., 2012). The classical Cys_2-His_2 (C_2H_2) zinc-finger domain was first identified in the *Xenopus* transcription factor IIIA (Hanas et al., 1983). Plant TFIIIA proteins usually contain one to four zinc fingers (Kubo et al., 1998). The phylogeny of nodule-enhanced proteins from this family is shown in Figure 82.3a. The most striking difference between plant and animal ZFPs is the presence of a highly conserved unique amino acid sequence (QALGGH) in the C_2H_2 DBD of the plant proteins (Takatsuji, 1999). Among the 19 nodule-enhanced C_2H_2-ZFPs, eight contain this consensus sequence. Half of these have two C_2H_2-DBDs while the other half have only one C_2H_2-DBD. The mouse Zif268 TF crystal structure suggests that the α-helix of zinc-finger domain interacts with the major groove of DNA. The zinc finger interacts

with three successive DNA bases. This is controlled via hydrogen-bond interactions with amino acid residues in positions −1, 3, and 6 on the α-helix (Pavletich and Pabo, 1991). These three positions are usually hypervariable among different ZFPs, which confers variable specificities to the target. In the case of QALGGH-type ZFPs, two of the three hypervariable positions are present inside the QALGGH motif (underlined).

Among the QALGGH-type TFs, MsZPT2-1 (Krüppel-like Cys_2/His_2 ZFP) from alfalfa has been implicated in SNF (Frugier et al., 2000). Antisense *Mszpt2-1* plants were affected in the formation of SNF nodules. In these plants, initial root infection proceeded normally, whereas formation of the nitrogen-fixing zone was severely affected. Via a BLASTp search of the *Medicago* genome, we identified the *M. truncatula* ortholog of *MsZPT2-1* Contig_55524_1.1, whose protein is 92.8% identical to MsZPT2-1 (Fig. 82.3a, c). We also found three other nodule-induced TFs very closely related to MsZPT2-1, namely Medtr1g018420.1, Medtr2g096540.1, and Medtr7g100100.1. They belong to the same clade in the phylogenetic tree (Fig. 82.3a). Amino acid alignment indicates that these four proteins have two QALGGH-type zinc-finger domains (Fig. 82.3c). The three DNA interaction residues are identical to Medtr1g018420.1 and MtZPT2-1 (i.e., contig_55524_1.1). Other domains such as the NLS and the protein–protein interaction motif are highly conserved between Medtr1g018420.1 and MtZPT2-1 (Fig. 82.3c). The expression patterns of Medtr1g018420.1,

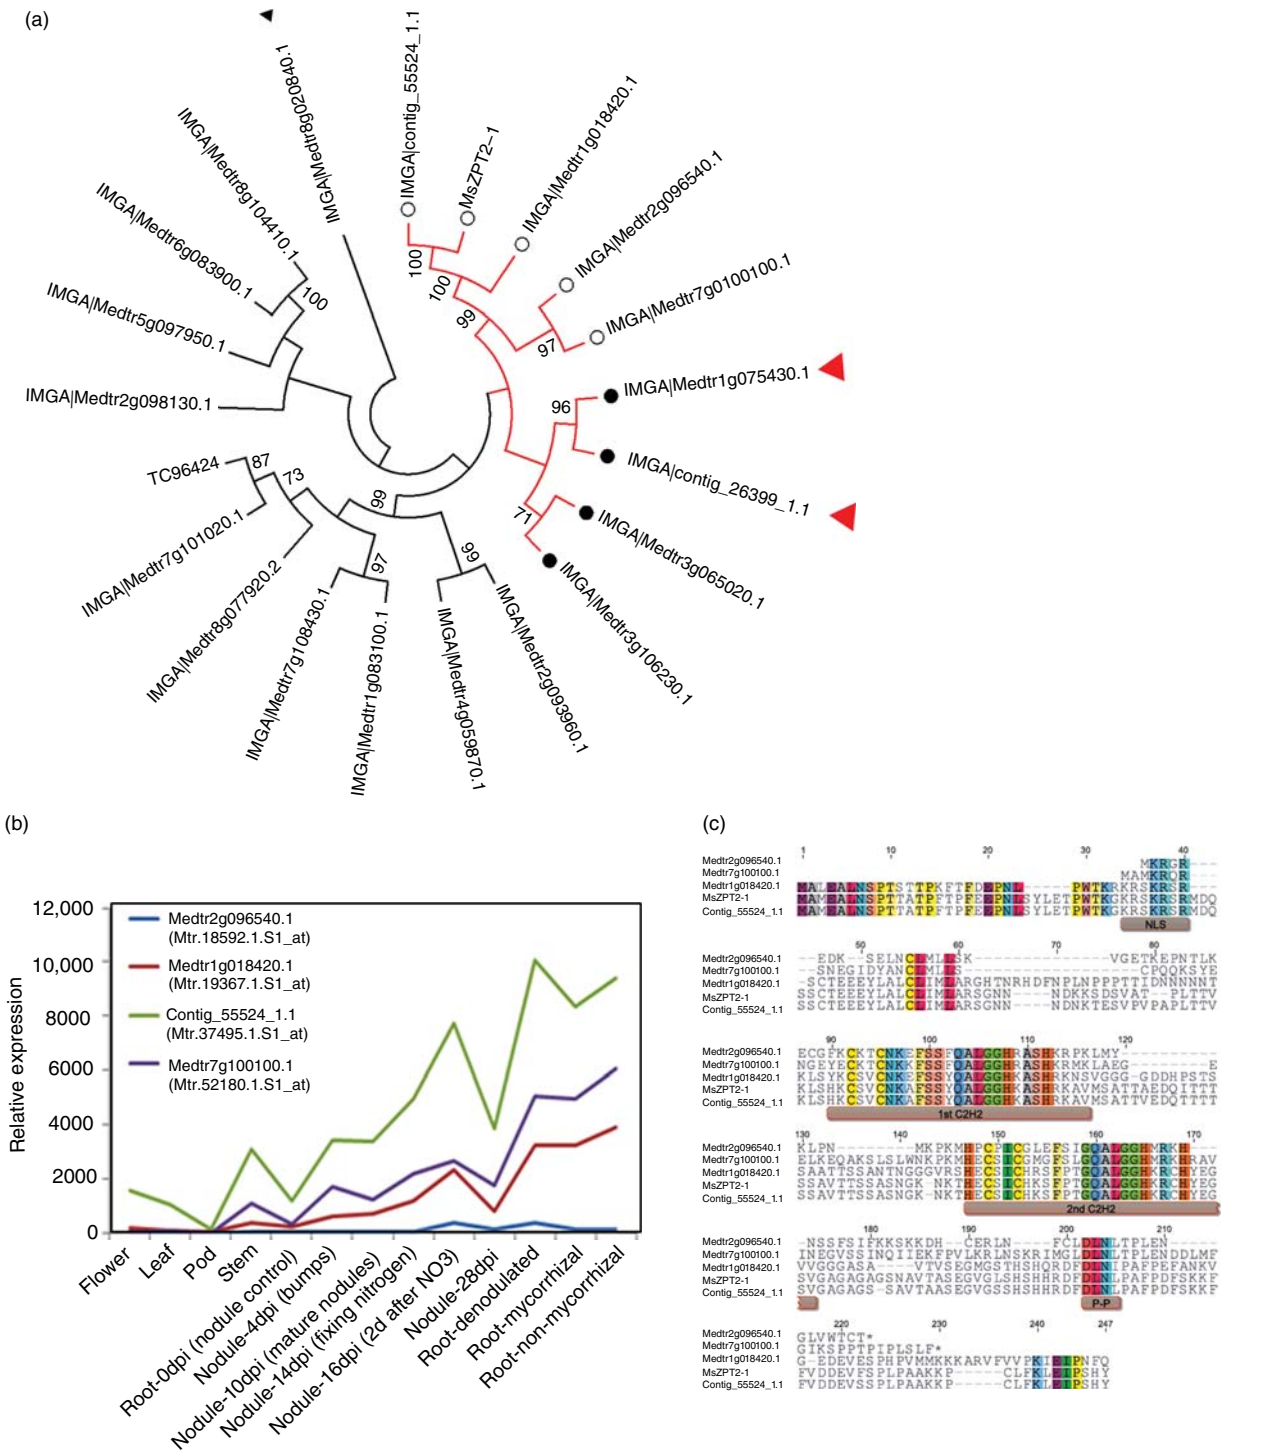

Figure 82.3 Nodule-induced C_2H_2 transcription factors. (a) Phylogenetic tree of nodule-enhanced C_2H_2 TFs from *Medicago truncatula*. Protein sequences from *Medicago* IMGAG 3.5v4 were used for the phylogenetic analysis. Medtr8g020840.1 (NSP1) served as a reference to root the tree, which was generated with MEGAv.5.1 (Tamura et al., 2011). TFs with QALGGH motif in the DNA-binding domain are highlighted with red in the tree. Zinc-finger proteins with two (unfilled circle) or one (filled circle) zinc fingers are marked. Proteins with EAR-type repressor motif are indicated by red arrowheads, and the outgroup is indicated by black arrowhead. The *Medicago sativa* ZPT2-1 protein (Frugier et al., 2000) was included in the analysis. (b) Expression profiles of two C_2H_2 zinc-finger domain-containing proteins according to MtGEA. (c) Alignment of two C_2H_2 zinc-finger domain-containing proteins. Protein alignment was carried out using MUSCLE (Multiple Sequence Comparison by Log Expectation) in the Geneious software suite (Biomatters). Two zinc fingers, NLS and protein–protein interaction domain (P–P) are highlighted.

Medtr7g100100.1, and contig_55524_1.1 are quite similar (Fig. 82.3b), indicating that they may play redundant roles during SNF. The antisense construct reported in the *MsZPT2-1* paper was generated against a 598-bp region between nucleotides 15–612 (Frugier et al., 2000). The nucleotide sequence of this region is 62.5% identical between *MtZPT2-1* (contig_55524_1.1) and *Medtr1g018420.1* (data not shown). Thus, the *Mszpt2-1* antisense construct might have targeted two or more homologs in alfalfa. Now, with the availability of the *Tnt1* mutant collection, it will be interesting to approach functional studies of MtZPT2-1 and Medtr1g018420.1 separately and in combination.

The second group of nodule-enhanced QALGGH-motif C_2H_2 TFs encompasses four single-finger classical ZFPs (Fig. 82.3a). Among these, two show nodule-specific expression. They have an *N*-terminal DBD and a *C*-terminal hexapeptide (DLELRL) called the EAR motif. This motif has been shown to confer transcriptional repression upon DNA-binding proteins (Hiratsu et al., 2003; Ikeda and Ohme-Takagi, 2009). Several proteins from this family have been functionally characterized and shown to play important roles in plant development (Kagale et al., 2010), but none of the EAR domain-containing proteins has been implicated in SNF until now. Of the two EAR domain-containing C_2H_2 TFs, contig_26399_1.1 is expressed 170-fold higher during SNF than in noninoculated roots, according to MtGEA. Apart from contig_26399_1.1, Medtr1g075430.1 belongs to the same EAR domain-containing C_2H_2 TF clade in the phylogenetic analysis (Fig. 82.3a). However, their sequences are quite distinct, which suggests that they may play different regulatory roles. We have shown that contig_26399_1.1 (*MtRSD*) plays a major role in the regulation of symbiosome development (Sinharoy et al., 2013, Table 82.3).

82.10 SNF-ASSOCIATED TRANSPORTERS TARGETED BY *Tnt1* INSERTIONAL MUTAGENESIS

We have selected 20 candidate transporters and isolated 52 *Tnt1* mutant lines, 41 of which carry transposons in exons of the target genes (see Table 82.4 for examples). Nearly all of the selected transporters are strictly nodule specific. Among these are mutants in two *Medicago* homologs of *GmNod26*. We also have *Tnt1* mutants for a *Medicago* homolog of *LjSST1*, a sulfate transporter required for effective SNF in indeterminate nodules. Preliminary analysis of the mutant phenotype (Fix+) suggests that in *Medicago*, the function of this transporter is probably redundant with that of another similar transporter(s). Three nodule-specific candidates for malate transport have also been tagged in the *Tnt1* population: two from the POT family and one from TDT family. Preliminary characterization of their phenotypes suggests that at least one of them, *MtPOT1*, is indispensable for SNF. Mutants in two nodule-specific SWEET transporter genes, *MtSWEET11* and *MtSWEET15*, are among the most interesting targets in our collection. SWEET transporters have recently been shown to be upregulated by bacterial and fungal pathogens and are thought to provide them with monosaccharides or disaccharides (Chen et al., 2010). These two genes are not expressed in AM, whereas a member of the SWEET family with expression in nodules and in AM roots has been identified recently (Harrison et al., personal communication). Given the existence of at least four nodule-enhanced SWEET transporters with predicted partially overlapping substrate specificities, the greatest challenge for elucidating their roles in SNF and AM is posed by possible functional redundancies, which may call for generation of double, triple, or even higher order mutants.

In our labs, we aim to characterize transporters and other gene products potentially involved in nodule iron metabolism. We have isolated *Tnt1* mutants for homologs of *LjMATE1* and *LjSEN1*. The *Medicago MATE* is not orthologous to *LjMATE1*, but it is also required for SNF. We have identified mutants for other iron-related nodule-specific genes, including a putative Fe^{3+}/Fe^{2+}-reductase, an Nramp transporter, a YSL transporter, and a ZIP transporter. Characterization of these mutants will help us understand iron homeostasis and metabolism, as well as roles of these transporters in SNF.

To date, no report has been published on putative Cu^+ transporters in nodules. We have obtained a *Tnt1* mutant for a nodule-specific channel from the CTR family, which is a candidate for Cu^+ transport. In addition, we have isolated *Tnt1* insertion alleles of a putative Zn^{2+} transporter gene from the CDF family. The synchrotron-based X-ray fluorescence technique provides subcellular resolution of metal partitioning and has been applied to nodulation studies only recently (Rodriguez-Haas et al., 2013). We are using this approach to visualize metals in mutants that are relevant to metal homeostasis in nodules.

82.11 CONSIDERATIONS ASSOCIATED WITH THE USE OF THE *Tnt1*-INSERTION MUTANT POPULATION

Because of superior *in vitro* regeneration and nodulation properties of *M. truncatula* ecotype R108 (Blondon et al., 1994; Hoffmann et al., 1997), it was chosen as the basis for the *Tnt1* mutant resource (Tadege et al., 2008; see Chapter 83). The genome sequencing and annotation efforts, however, have been conducted mostly on the related ecotype A17 (Young et al., 2011). Genetic divergence between these ecotypes presents a challenge for designing primers to be used in PCR-screening for *Tnt1* insertions in specific

genes. In many instances, the gene model is not identical between the two ecotypes. Thus, for each gene of interest, it is very important to determine the R108 gene model. A *Tnt1* insertion expected to inactivate a gene according to an A17-based gene model sometimes may cause no mutant phenotype. This can happen because the insertion is actually located outside of essential elements of the gene according to an R108-based model. Recently, as a part of the *Medicago* Hapmap project, the R108 genome has been sequenced (Stanton-Geddes et al., 2013), which should make reverse genetics using this genotype easier.

Although the *Tnt1*-insertion mutant population is a fairly new genetic resource, several genes have already been characterized using this population (see Chapter 83). Cloning of *MtNOOT* and *DNF2* are examples of how forward genetic screening of this population can lead to the discovery of new genes (Bourcy et al., 2013; Couzigou et al., 2012; see Chapter 49). Reverse genetics using this resource yielded the *MtRemorin* mutant and helped in the validation of map-based cloning of *MtIPD3* and *MtVPY* (Horvath et al., 2011; Lefebvre et al., 2010; Murray et al., 2011). Furthermore, 39 *Tnt1*-insertion alleles of known symbiotic genes have been identified in the *Tnt1*-insertion mutant population, demonstrating its power as a resource for gene discovery (Pislariu et al., 2012; see Chapter 83).

In a forward genetic screen, a *Tnt1* mutant with aborted IT phenotype was isolated and named *knocks but can't enter* (*KCE*). This phenotype was then linked with a mutation in *MtLIN* (Kiss et al., 2009). Interestingly, the mutation was not caused by a *Tnt1* insertion. A G-to-A transition at position 1740 in *MtLIN* introduced a premature stop codon (Guan et al., 2013). In line with the higher susceptibility of the R108 ecotype to stresses and colonization by rhizobia, both *ipd3* and *lin* mutants displayed a stronger phenotype in the R108 background compared to Jemalong ecotype A17. The point mutation that affected *MtLIN* in the *Tnt1* mutant illustrates possible consequences of the somatic embryogenesis-mediated regeneration process used as trigger for *Tnt1* remobilization, namely somaclonal variation. Although this phenomenon may impede attempts to clone genes causing mutant phenotypes in some forward genetics experiments, it will have little effect on reverse genetics experiments, especially if segregation analysis or genetic complementation confirms the link between genes and phenotypes.

The most probable effect of a *Tnt1* insertion is the inactivation of a gene (see Chapter 83). Five kinds of *Tnt1* mutants can be isolated from the population: (i) *Tnt1* insertion in an exon. This usually results in a complete loss of function or knockout (KO) phenotype. (ii) *Tnt1* insertion in the 3′ UTR. Such insertions can cause either complete KO (null mutant) or a KD phenotype, since it can destabilize the mRNA and reduce the expression of the gene. However, since the protein-coding region remains intact, it is possible that a smaller amount of the protein is produced, which might be sufficient to fulfill the necessary function. Disruption of the poly(A) tail resulting from *Tnt1* positioned in the 3′ UTR can have more profound effect on the transcript's fate. It is known from animal studies that interaction between poly(A)-binding protein and eukaryotic translation initiation factor 4G generates a circular structure important for recruiting the 43S ribosome assembly, which stimulates the 60S ribosomal subunit to join the 48S pre-initiation complex (Kahvejian et al., 2005; Searfoss et al., 2001). (iii) *Tnt1* insertion in the 5′ UTR. Such a *Tnt1* location can be associated with a wide range of phenotypes: from a very strong KO to no mutant phenotype. Several cases are known in which the 5′ UTR controls translation in a eukaryotic cell (Bugaut and Balasubramanian, 2012). Again, these examples involve mRNA destabilization and compromised translation. On the other hand, sometimes the 5′ UTR is not so crucial and/or alternative splicing can generate a functional mRNA, removing the insertion altogether and producing an unaltered phenotype. (iv) *Tnt1* inserted in a promoter region near the 5′ UTR. If the insertion is inside the TATA box, the most probable phenotype is a KO. However, if the promoter is disrupted outside of a major TF-binding site, a KD mutant phenotype could result. (v) *Tnt1* inside an intron. It may not cause a mutant phenotype, if the insertion is removed with the intron during transcript splicing, unless the 5-kb insertion interferes with transcription elongation. If the insertion coincides with an intron–exon junction, it is likely to cause a KO phenotype. Although these situations are theoretical scenarios, experimental evidence accumulated over the past few years of exploring the *Tnt1* population suggests examples for nearly all categories.

82.12 CONCLUSION

The *Medicago Tnt1* mutant population and the MtGEA are valuable resources for reverse genetic studies of the legume *M. truncatula*. Some 21,700 independent *Tnt1* insertion lines have been generated with probably over 500,000 insertions in the genome. This is predicted to cover ~90% of *Medicago* genes with an insertion. We took a systematic approach to isolate *Tnt1* mutants of nodule-enhanced TFs and transporters. The mutants recovered are a great platform for comprehensive functional studies on the corresponding genes and will significantly advance our knowledge about SNF.

83.1 INTRODUCTION

The legume family (*Fabaceae*) of >18,000 species is the third largest among angiosperms and is second to cereals (*Poaceae*) as source of human food and animal forage and feed. Most legumes establish symbiotic associations with nitrogen-fixing bacteria (rhizobia), and by so doing, they contribute up to 40 million tons per year of "fixed" nitrogen to the soils they grow in (Peoples et al., 2009). This environmentally friendly interaction begins with a remote chemical signaling between compatible symbionts and culminates with the development of a new organ, the root nodule, where rhizobia reside and fix N_2 (Timmers et al., 1999). In response to flavonoid signals exuded by the legume roots, compatible rhizobia synthesize lipochito-oligosaccharide (LCO) signals known as nodulation (Nod) factors (NF) (D'Haeze and Holsters, 2002). Their perception by the *NOD FACTOR RECEPTOR 1*/*LYS-M DOMAIN-CONTAINING RECEPTOR-LIKE KINASE 3* (*NFR1*/*LYK3*) and *NFR5*/*NOD FACTOR PERCEPTION* (*NFP*) (see Chapter 51) triggers the infection signaling pathway that paves the way for rhizobial invasion and nitrogen fixation (Radutoiu et al., 2003; Limpens et al., 2003; Smit et al., 2007). Colonization starts with the attachment of rhizobia to root hair tips, followed by root hair deformation and curling, resulting in the entrapment of rhizobia in the so-called shepherd's crock (Fig. 83.1a). Local cell wall loosening, plasma membrane invagination, and the deposition of new cell wall material results in the development of a tube-like infection thread (IT), which serves as the path for rhizobia through several layers of plant cells toward the dividing inner cortical cells of the nodule primordium (NP) (Fig. 83.1b–d). Rhizobia are subsequently released from ITs into NP cells via an endocytosis-like process, encapsulated in a plant-derived membrane to become

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

a new "organelle," the symbiosome (Brewin, 2004; Udvardi and Day, 1997). While nodule primordia continue to divide and grow into functional nodules, rhizobia differentiate, induce nitrogenase genes, and start fixing N_2. Reduced nitrogen from bacteroids and reduced carbon and other nutrients from the plant cytoplasm are transported across the symbiosome membrane for mutual benefit (Udvardi and Poole, 2013; see Chapter 68). In legumes of the robinoid subclade such as *Lotus*, bacteroids reach their mature state without changes in shape or size (Mergaert et al., 2006). In contrast, in legumes of the Inverted Repeat-Lacking Clade (IRLC) that include *Medicago*, *Cicer*, and *Pisum*, rhizobia undergo multiple rounds of endoreduplication en route to becoming the large, elongated, functional bacteroids (Van de Velde et al., 2010) (Fig. 83.1h). Host cells also undergo developmental reprogramming with different temporal layout among legumes, depending on the type of nodules they form: determinate or indeterminate. Legumes of the genera *Glycine*, *Phaseolus*, *Lotus*, and *Vigna* develop determinate, spherical nodules, whose meristem is lost shortly after their initiation, and their growth is solely a result of cell expansion. Members of the genera *Medicago*, *Trifolium*, *Pisum*, and *Vicia* form indeterminate, elongated nodules, which maintain an active apical meristem, display developmental and functional zonation, and continue to harbor functional bacteroids throughout their growth (Maunoury et al., 2007) (Fig. 83.1f).

Similar to 80% of vascular plants, legumes also establish symbiotic associations with arbuscular mycorrhizal (AM) fungi, which, in exchange for reduced carbon from the host, deliver phosphate, sulfur, nitrogen, and micronutrients into the host root cells (Harrison, 2012). Much like the nodulation symbiosis, mycorrhization starts with a signal exchange between the two partners: plant-released strigolactones and fungal mycorrhization (Myc) factors, triggering a symbiotic signaling cascade starting with Myc perception by *NFP* (Maillet et al., 2011). This process culminates with the intracellular development of highly branched fungal structures, arbuscules. Similar to nodulation, the nutrient exchange occurs at the interface between symbionts, the periarbuscular membrane (PAM) (Javot et al., 2007).

To gain insight into the genetic and molecular mechanisms governing the two symbioses, various bacterial, fungal, and plant model species have been used over the past few decades. Some agriculturally important legumes have complex polyploid or allopolyploid, and large genomes, and genetics can be difficult because some are out-crossing. The two selected model legumes are *Medicago truncatula* and *Lotus japonicus* (Handberg and Stougaard, 1992; Cook, 1999). They have relatively small genomes (~550 and ~470 Mbp, respectively), they are diploids, are in-breeding, and can be transformed by *Agrobacterium tumefaciens* and *Agrobacterium rhizogenes* (Chabaud et al., 2003). Several genetic resources have been developed for these two model legumes, including massive genome-wide expression repositories and mutant collections, which are instrumental for the fast pace discovery and functional characterization of key symbiotic genes. In this chapter, we present a summary of the *Medicago* and *Lotus* symbiotic genes and the mutagenesis methods used to characterize them functionally. In this context, we focus on the tobacco retrotransposon *Tnt1*-insertion *M. truncatula* mutant collection developed at the Samuel Roberts Noble Foundation (d'Erfurth et al., 2003; Tadege et al., 2008). With more than 21,000 independent insertion lines, this is the largest DNA-insertion mutant collection in legumes. From 9300 lines, we isolated 179 mutants displaying a range of defects in nodule development and function (Pislariu et al., 2012).

83.2 GENOMIC, TRANSCRIPTOMIC, AND MUTANT RESOURCES FOR THE FUNCTIONAL DISSECTION OF LEGUME SYMBIOSES

Legume interactions with both rhizobia and AM fungi involve extensive and coordinated transcriptional reprogramming in the symbiotic partners (Becker et al., 2004; Benedito et al., 2008; Verdier et al., 2013). Transcriptomic resources have been instrumental for the identification of key symbiotic genes (Table 83.1) and continue to lay the foundation for reverse genetics in legumes.

Both the *Medicago* and *Lotus* genomes have largely been sequenced, although the former is more complete (Young et al., 2011; Sato et al., 2008; see Chapter 78). Also, Illumina-Solexa technology is currently being used to resequence 384 *M. truncatula* ecotypes with at least 5× coverage and a subset of 30 lines with deep coverage (20× or more) to reveal single nucleotide polymorphisms (SNPs), insertions/deletions (INDELs), and copy number variants (CNVs) as part of the haplotype map (HAPMAP) project (Paape et al., 2012; Young and Bharti, 2012; see also Chapter 78). Linking common patterns of genetic variation with accession-specific phenotypes will enable genome-wide association mapping of agriculturally important traits such as seed nutrient composition, increased biomass production, and more efficient SNF and AM, which may be translated to crop legumes, to improve food production for example. Even though soybean is not a model legume, its genome has also been sequenced to completion (Schmutz et al., 2010), and transcriptomic resources are now available (Libault et al., 2010; Severin et al., 2010; see Chapter 41).

The development of mutant populations for forward genetics has been a priority for legume researchers over the past 10–15 years, and several mutant populations are now available for the functional characterization of plant genes involved in SNF, AM, and other processes. Chemical mutagenesis using ethyl methanesulfonate (EMS)

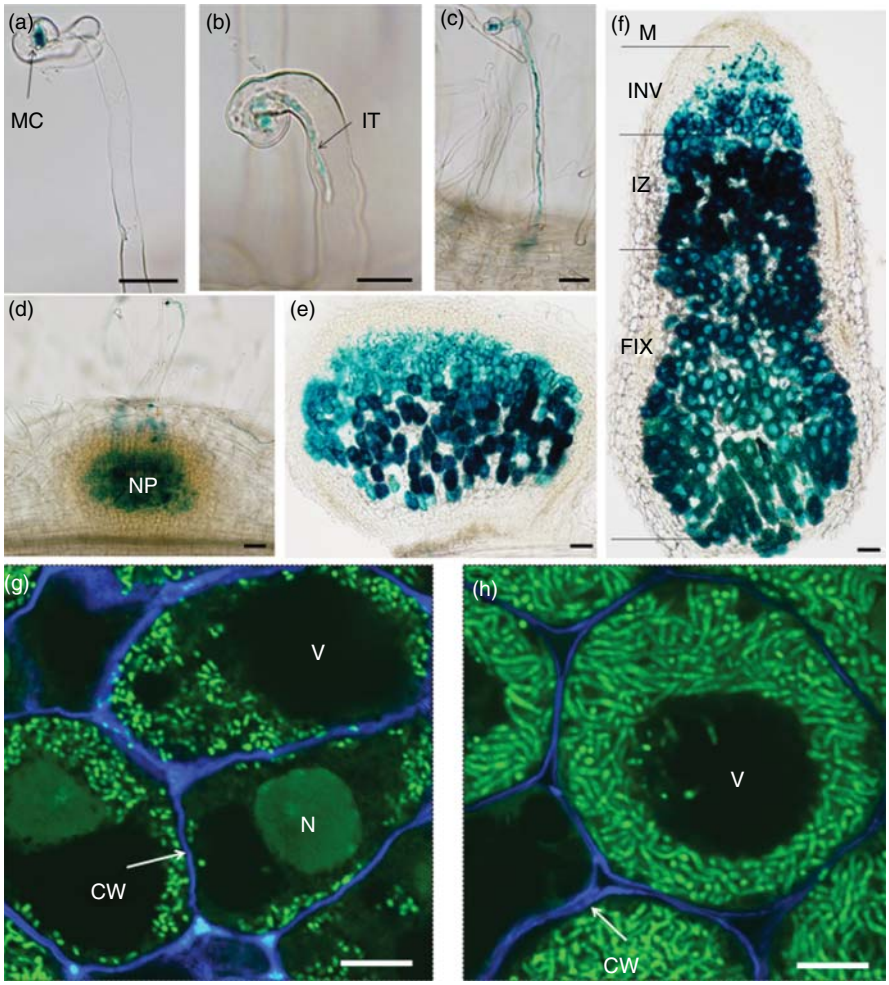

Figure 83.1 Nodule development in *Medicago truncatula*. *Sinorhizobium meliloti* carrying the *hemA*::*LacZ* reporter was used to infect *Medicago* roots. Samples harvested at 2 days postinoculation (DPI) (a, b, c), 4 DPI (d), 8 DPI (e), and 15 DPI (f) were stained with X-Gal to produce blue-stained rhizobia. Infection starts with root hair curling, entrapment of rhizobia, and development of a microcolony (MC) inside the curl (a). Along the root hair, an infection thread (IT) develops (b, c) and from this, rhizobia are released in the dividing cells of the nodule primordium (NP) (d). By 8 DPI, most cells of the emerging nodule are filled with rhizobia (e). The nodule continues to elongate and by 15 DPI, the nodule zonation including meristem (M), invasion zone (INV), interzone (IZ), and the nitrogen fixation zone (FIX) is visible. The same nodule sections were counterstained with the fluorescent DNA dye Syto13 and with calcofluor-white that stains cellulose and chitin in the cell walls. Rhizobia are shown as green fluorescence, and cell walls stained by calcofluor are seen in blue. Once inside host cells, rhizobia undergo differentiation from free-living-like small bacteria as seen in the invasion zone (g) to elongated, rod-shaped bacteroids, as seen in the nitrogen-fixation zone (h). Abbreviations: V, vacuole; N, nucleus; CW, cell wall. Scale bars: 100 µm (a, c, d, e, and f); 50 µm (b) and 10 µm (g, h).

induces random point mutations and has been used successfully in *Medicago* (Benaben et al., 1995; Penmetsa and Cook, 2000; see Chapter 63). Molecular and genetic characterization of EMS mutants defective in nodule initiation and development, nodule number, and/or AM symbiosis led to the map-based cloning of 13 key symbiotic genes in *Medicago*: Nod factor receptor *LYK3*; the Nod-factor and Myc receptor *NFP*; the common SNF and AM symbiotic pathway genes *DOESN'T MAKE INFECTIONS 1*, *2*, *3* (*DMI1*, *DMI2*, *DMI3*); *INTERACTING PROTEIN OF DMI3* (*IPD3*); *NODULATION SIGNALING PATHWAY 2* (*NSP2*); SNF-specific transcription factors *ERF REQUIRED FOR NODULATION 1* (*ERN1*) and *NODULATION SIGNALING PATHWAY 1* (*NSP1*); genes involved in infection, *NUMEROUS INFECTIONS AND POLYPHENOLICS/LATERAL ROOT ORGAN DEFECTIVE* (*NIP/LATD*), *RHIZOBIUM-DIRECTED POLAR GROWTH* (*RPG*); and *SICKLE* (*SKL*) and *SUPER NUMERIC NODULES* (*SUNN*) that control the extent of nodulation (Table 83.1). EMS mutagenesis has also been applied successfully to *Glycine* (Carroll et al., 1985) and *Lotus* (Szczyglowski et al., 1998). Symbiotic genes *NFR1*; *NFR5*; ion channels *CASTOR* and *POLLUX*; the *SYMBIOSIS-RELATED KINASE* (*SYMRK*); the *Ca2+/CALMODULIN-DEPENDENT KINASE CCaMK*; *CYCLOPS*; *LjNSP1*; and *LjNSP2* were positionally cloned using *Lotus* EMS populations (Table 83.1). Molecular cloning of soybean symbiotic genes has been less successful due to the higher complexity of its larger, paleotetraploid genome, and is most commonly approached by taking advantage of the syntenic relationship with *Lotus* (Indrasumunar et al., 2010).

Ionizing radiation in the form of gamma rays and fast neutrons induces deletions and other chromosomal rearrangements, and often generates complete loss-of-function or knockout (KO) mutants. The first *Medicago* symbiotic mutants were isolated from a gamma-ray mutagenized population (Sagan et al., 1995). Among these were deletion alleles of *DMI2*, *DMI3*, and *SUNN* (Table 83.1). Large, fast-neutron bombardment (FNB) mutant collections have been generated at The Samuel Roberts Noble Foundation in the United States and at the John Innes Center in the United Kingdom

Tnt1-insertion lines with flanking sequence tags (FSTs) identified by sequencing DNA pools representing the entire *Tnt1*-insertion population and unconfirmed at the level of individual plant are shown in bold font. Shaded in gray are genes with no mutants described at this time. Due to space limitation, a selection of references is shown.

(Wang et al., 2006). From these collections, transcript-based cloning was used to identify deletions affecting the following symbiotic genes: *ERN1*; *DMI1*; *DMI3*; *NSP2*; *NODULE INCEPTION* (*NIN*); *DEFECTIVE IN NITROGEN FIXATION* (*DNF1*); *ETHYLENE-RESPONSIVE FACTOR REQUIRED FOR NODULE DIFFERENTIATION* (*EFD1*); *REQUIRED FOR INFECTION THREAD* (*RIT1*); *VAPYRIN* (*VPY*); and *SENSITIVITY TO ABA* (*STA1*) symbiotic genes (Table 83.1). Despite some success, transcript-based cloning is not trivial. The recently developed *M. truncatula* genome-wide tiling microarray by NimbleGen may speed up gene discovery in deletion mutant populations in the future, although no novel symbiotic gene has been cloned so far using this approach.

When expressed sequence tag (EST) libraries became available (Gyorgyey et al., 2000), RNA-induced gene silencing or RNA-interference (RNAi) was developed to characterize functionally genes of interest in a reverse genetics approach (Limpens et al., 2003). Even though it is not a high-throughput method, it requires plant transformation and tissue culture, and transcript reduction is highly variable (phenotypes ranging from wild-type-like to KO), RNAi has been used to characterize at least 20 symbiotic genes for which no mutants were available (Table 83.1). Among these are the *Ca^{2+}-DEPENDENT PROTEIN KINASE 1* (*CDPK1*); *FLOTILLINS FLOT2* and *FLOT4*; *CYTOKININ RECEPTOR CRE1*; *EARLY NODULIN ENOD40*; *3-HYDROXY-3-METHYLGLUTARYL COENZYME A REDUCTASE 1* (*HMGR1*); *MATRIX METALLOPROTEINASE-LIKE 1* (*MtMMPL1*); *LIPID TRANSFER PROTEIN* (*LTP*, *MtN5*); and *PIN-FORMED AUXIN EFFLUX CARRIERS PIN2*, *PIN3*, *PIN4*. Another reverse genetics approach that has emerged recently is TILLING (targeting-induced local lesions in genomes), which allows PCR-based identification of allelic series using EMS-mutagenized collections (Le Signor et al., 2009; Perry et al., 2003). In combination with next-generation sequencing (NGS), TILLING has the potential for high-throughput assays by multiplexing gene targets and genomes. Recently, two nuclease-based approaches to introduce genomic modification have been tested: zinc finger nucleases (ZFNs) (Curtin et al., 2011) and transcription activator-like effector nucleases (TALENs) (Kay and Bonas, 2009). It is plausible that such methods will revolutionize engineering of crop genomes, mainly because of their remarkable specificity and because most modifications are not likely to be regulated as transgenic, thus facilitating widespread improvement of crop quality. For the time being, however, discovering biological functions for many open-reading frames (ORFs) of unknown function revealed by genome-sequencing projects, using mutant collections, remains a powerful and straightforward approach. The development of DNA-insertion mutagenesis as a tool for linking visible mutant phenotypes with new gene functions is beginning to increase the pace of gene discovery in model legumes.

T-DNA, transposons, and retrotransposons are excellent tools for disrupting genes to generate loss-of-function mutants. The mutated genes can quickly be identified by PCR, using the inserted DNA sequence as a "tag." T-DNA tagging has been very successfully applied in *Arabidopsis thaliana* because of the small plant size, ease of *Agrobacterium*-mediated transformation, and possibility to regenerate enormous number of plants in a short period of time (Clough and Bent, 1998). However, this method had limited success in legumes because they are larger, are not as easy to transform, and the time frame between transformation and seed harvest is between 7 and 12 months. DNA transposons translocate to new positions within genomes via a "cut-and-paste" mechanism, and because of their tendency to reinsert in the proximity of their original location, multiple rounds of transformation are required for good coverage and eventual saturation mutagenesis (Scholte et al., 2002). Transposons that have been tested in legumes are the maize (*Zea mays*) *Ac*/*Dc* system in *Lotus* (Thykjaer et al., 1995) and soybean (Mathieu et al., 2009), the *En*/*Spm* and *Tag1* systems in *Medicago* (d'Erfurth et al., 2006), and the rice miniature inverted repeat transposable element *MITE mPing* element in soybean (Hancock et al., 2009). However, they also tend to transpose into A/T-rich regions, often in intergenic spaces, and can be excised, resulting in the loss of tag from mutated genes, but leaving behind INDEL footprints, which makes them less suitable for genome-wide mutagenesis. These elements also show rapid inactivation when introduced into heterologous genomes, probably as a result of silencing, making them not usable for large-scale mutagenesis. On the other hand, the mPing element continues to transpose during normal plant growth, thus causing more mutations that may complicate genotyping and phenotyping of progeny.

Retrotransposons are mobile elements that transpose via a "copy-and-paste" mechanism through an intermediate mRNA, which is transcribed to cDNA and integrated at random in the genome, albeit preferentially in gene-rich regions within the genome (Amar et al., 1999). Transposition occurs during tissue culture, and, unlike DNA transposable elements, it causes stable mutations that are passed onto progeny during seed-to-seed propagation (d'Erfurth et al., 2003). Several retrotransposons have already been characterized in legumes and proved to be useful insertion mutagens in both autologous and heterologous systems. They include the LOtus REtrotransposon 1 (*LORE1a*), an exon-targeting endogenous member of the "*Gypsy*" superfamily, which has been shown to transpose in male germline (Madsen et al., 2005); the MEdicago RetroElement 1–1 (*MERE1-1*) in *Medicago*, which was identified as an insertion in the *NSP2* symbiotic gene (Rakocevic et al., 2009); and the *Cicer arietinum* retro-element 1 (*CARE1*), a *TY3-Gypsy*-like long terminal repeat LTR retroelement in chickpea (Rajput and Upadhyaya, 2010). LTR retrotransposons from tobacco (*Tnt1* and *Tto1*) and rice (*Tos17*) have been used to generate insertional mutants in *Arabidopsis* (Okamoto and Hirochika, 2000) and in *Medicago* (d'Erfurth et al., 2003; Tadege et al., 2008). A concerted effort by European and US researchers to implement *Tnt1*-insertion mutagenesis in

Medicago resulted in the largest collection of DNA-insertion mutants of all legumes (d'Erfurth et al., 2003; Tadege et al., 2008).

83.3 ISOLATION OF *TNT1*-INSERTION MUTANTS WITH DEFECTS IN NODULE DEVELOPMENT AND SYMBIOTIC NITROGEN FIXATION

Approximately 21,000 independent insertion lines have been generated at The Samuel Roberts Noble Foundation by somatic embryogenesis using leaf explants from a starter line, Tnk88-7-7 containing approximately five *Tnt1* copies that were transferred to wild-type R108 by *A. tumefaciens*-mediated transformation (Fig. 83.2). Approximately 10,500 lines have been preliminarily screened so far for visible phenotypes during community screening workshops, and 11,544 photographs are currently available at the mutant database (http://medicago-mutant.noble.org/mutant/). Approximately 30% of all screened lines displayed developmental, morphological, and symbiotic phenotypes, as reported earlier (Tadege et al., 2008). *Tnt1* was also deployed into the Jemalong 2HA ecotype as part of the European Union-Grain Legumes Integrated Project (EU-GLIP) (Iantcheva et al., 2009). Currently this European collection consists of approximately 5000 insertion lines from which nearly 2000 flanking sequence tags (FSTs) have been recovered.

Since 2006, the Noble Foundation has been hosting annual community screening workshops where researchers have the opportunity to identify, first-hand, *Tnt1*-insertion mutants with phenotypes of interest to them. In most years, the *Tnt1*-insertion populations were coinoculated with wild-type rhizobia and AM fungi to identify nodulation and

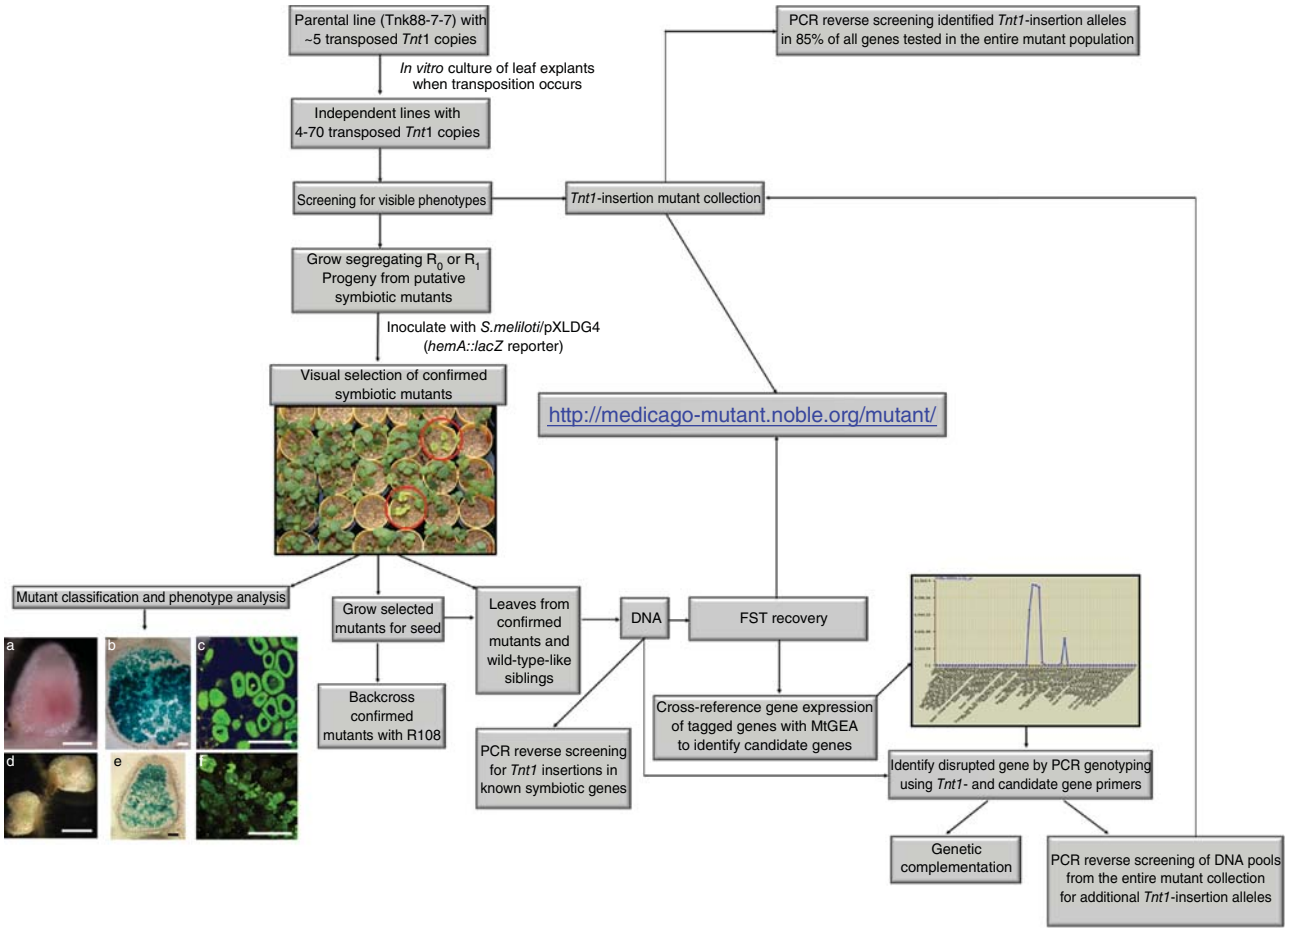

Figure 83.2 Flowchart detailing the establishment of the tobacco retrotransposon *Tnt1*-insertion mutant population in *Medicago truncatula* and steps taken to identify disrupted genes by forward and reverse genetics. Nodule phenotypes are shown for wild type (a, b, and c) and NF0440 (d, e, and f). Images represent whole mounts (a and d), 50-µm-section stained with X-Gal (b and e), and Syto-13-stained sections imaged by confocal microscopy (c and f). Scale bars: 2 mm (a); 1 mm (d); 100 µm (b, c, e, and f).

mycorrhization mutants. Approximately 1500 lines were screened every year, and a wide array of phenotypes has been reported (Tadege et al., 2008). From 317 lines with putative SNF phenotypes, which were identified after screening 9300 lines, 230 were rescreened in the presence of *Sinorhizobium meliloti* Sm2011, and symbiotic phenotypes were confirmed in 156 lines. *Rhizobium*-inoculated plants were analyzed at 15 and 21 days postinoculation (DPI), when wild-type R108 displayed healthy shoots with dark green leaves and large, functional, pink nodules. Generally, plants impaired in nodule development or defective in nitrogen fixation display stunted growth and are easily distinguished due to their nitrogen-deficiency phenotypes (increased anthocyanin accumulation in the shoot and leaf chlorosis/yellowing) (Fig. 83.2). From 156 lines, 179 SNF mutants were isolated; in some instances, multiple symbiotic mutants were found in a single line, presumably due to tagging of multiple symbiotic genes. The phenotypes were classified into six categories and included 72 Nod− (roots devoid of nodules); 51 Nod+Fix− (nodules develop but generally fail to accumulate leghemoglobin and rhizobia they harbor do not fix nitrogen); 17 Nod+Fix+/− (nodules are pale pink and rhizobia fix nitrogen less efficiently); 27 Nod+/−Fix− (small, ineffective bumps), 1 dNod+/−Fix+ (nodules develop later than in wild type but eventually develop into nitrogen-fixing organs), and 11 Nod++Fix+/− (larger number but less effective nodules than wild type) (Fig. 83.3). Symbiotic phenotypes were analyzed in detail, by a combination of stereo, bright field, and confocal microscopy. *S. meliloti* Sm2011 carrying the *hemA*::*LacZ* reporter was used for inoculation; histochemical staining with X-Gal (5-bromo-4-chloro-3-indolyl-b-D-galactopyranoside), enabled rhizobia to be seen via blue precipitate (Figs. 83.1 and 83.2). Nod- and Nod+Fix− mutants were described in detail and unusual, potentially new phenotypes were highlighted (Pislariu et al., 2012). Among the latter are mutants isolated from lines NF0438, NF0359, NF5794, NF5654, NF0063, NF2496, NF4608, NF4928, NF1320, NF0440, and NF0134.

To assess the degree of rhizobial differentiation into bacteroids in Nod+Fix− mutants, the same nodule sections were counterstained with the fluorescent DNA dye Syto13, shown as green fluorescence (Figs. 83.1, 83.2, and 83.4). In wild-type nodules, functional bacteroids appear as elongated, rod-shaped organelles (symbiosomes), packing the cytoplasm of infected cells (Figs. 83.1h and 83.4a). Incomplete bacteroid differentiation, as suggested by the shorter rod-like appearance, was observed in numerous Fix- nodules such as those isolated from NF0134, NF2496, and NF4608 (Fig. 83.4c, g, h) and in many Fix+/− nodules, for example, in NF0306 and NF1858 (Fig. 83.4e, f). In some mutants, bacteroids undergo early degradation (NF1858, NF2496, and NF4608). An example of rhizobia that do not differentiate and remain small, similar to the free-living form, is the mutant identified in line NF0235 (Fig. 83.4d). In some mutants, the nodules appear almost empty, with sparse ITs from which rhizobia are released, but remain undifferentiated. Such an example is the mutant isolated from line NF0063 (Fig. 83.4b).

Symbiotic phenotype	Number of symbiotic mutants	Representative phenotype
Nod–	72	Nod+ Fix–	51

Figure 83.3 Classification of the symbiotic *Tnt1*-insertion mutants generated in the *Medicago* R108 ecotype. Representative phenotypes for each category are depicted. Images were acquired using an Olympus SZX12 stereomicroscope equipped with a Nikon DXM1200C digital camera. Scale bars: 1 mm.

Overall, this collection consists of mutants displaying a wide array of symbiotic phenotypes, some similar to those of known symbiotic mutants, other displaying unique features.

83.3.1 *Tnt1*-Insertion Alleles of Known Symbiotic Genes

In order to establish the *Medicago Tnt1*-insertion mutant collection as a primary resource for forward and reverse genetics among legumes, efficient sequencing of the genomic regions adjacent to the sites of *Tnt1* integration is imperative. Thermal asymmetric interlaced-PCR (TAIL-PCR) (Cheng et al., 2011), touchdown-PCR, and inverse-PCR (Ratet et al., 2010) have been used to recover

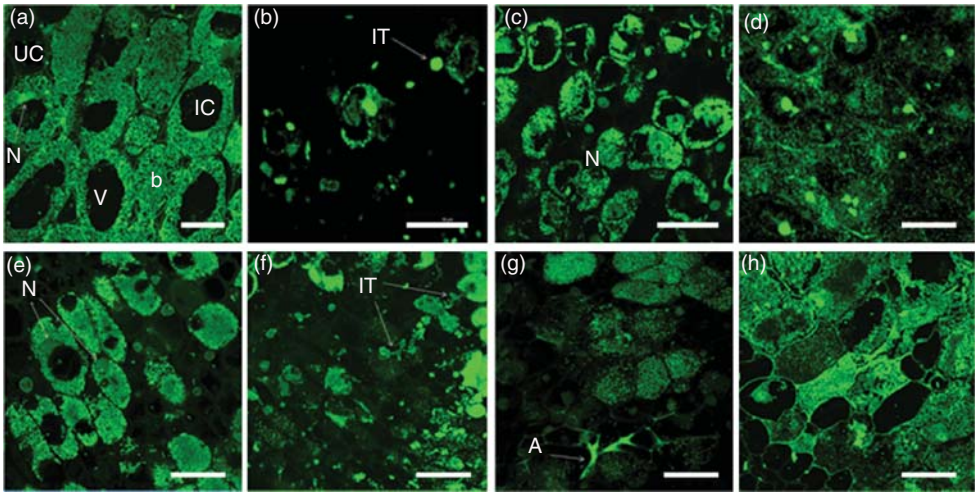

Figure 83.4 Symbiotic phenotypes of *Tnt1*-insertion mutants. Nodule sections of 50 µm thick were stained with the green fluorescent DNA dye Syto13 and imaged using confocal microscopy. In R108 wild-type nodules (a) rhizobia fill up the host cell cytoplasm and they differentiate into rod-shaped, elongated, nitrogen-fixing bacteroids (b). Panels (b–h) depict representative images of symbiotic phenotypes in NF0063, NF0134, NF0235, NF0306, NF1858, NF2496, and NF4608. Abbreviations: V, vacuole; IT, infection threads; A, autofluorescence; N, nuclei; UC, uninfected cell; IC, infected cell. Scale bars = 50 µm.

these so-called FSTs. To date, 44,238 FSTs have been sequenced and added to the searchable mutant database (http://medicago-mutant.noble.org/mutant/). Between 4 and 70 FSTs have been retrieved from each line sequenced, leading to an estimate of more than 525,000 insertions in the entire mutant population.

To assess the extent of mutagenesis in the *Tnt1*-insertion population, screening for insertions in known genes that cause either Nod− or Nod++ phenotype when mutated was carried out on mutants with confirmed Nod− and Nod++ phenotypes. FST sequencing and PCR reverse screening using combinations of gene-specific and *Tnt1*-specific primers followed by sequencing were used to identify mutants with insertions in the following genes: *NFP*, *DMI1*, *DMI2*, *DMI3*, *ERN1*, *NSP1*, *NSP2*, *NIN*, *LYK3*, *NUCLEOPORINS* (*NUP85* and *NUP133*), *SKL*, and *SUNN*. In the case of *NFP*, *LYK3*, *NUP85*, and *NUP133*, no insertion alleles were identified. However, between 1 and 13, alleles were identified in the other 9 genes tested: 3 for *DMI1*, 2 for *DMI2*, 4 for *DMI3*, 1 for *ERN1*, 3 for *NSP1*, 5 for *NSP2*, 13 for *NIN*, 1 for *SKL*, and 7 for *SUNN* (Pislariu et al., 2012). A total of 31 *Tnt1* insertions in known nodulation genes were found in Nod− mutants, which means that novel nodulation genes may be tagged in the remaining 41 Nod− mutants. Alternatively, it is possible that during tissue culture, which is used to trigger *Tnt1* retrotransposition, other endogenous DNA transposons may have been activated (Rakocevic et al., 2009), or single base pair changes may have been induced (Guan et al., 2013). Consequently, the mutant collection may contain some non-*Tnt1*-insertion alleles of known symbiotic genes. A protocol for recovering MERE1 FSTs has been developed and may help identify such non-*Tnt1*-insertion alleles. Nevertheless, several Nod− phenotypes appear to be unlike any of the known Nod− mutants, so it is expected that novel nodulation genes will be identified among the remaining 41 Nod− mutants.

In line with the previously reported preference of *Tnt1* to insert in gene-rich regions, and especially in exons, 80% of insertions identified in the nine genes tested were exonic, 10% were intronic, and 10% were either in the 5′ or the 3′ untranslated regions (UTRs). Because of this feature, many *Tnt1* insertions cause KO mutations. From a total of 39 insertion alleles, 4 were retrieved by FST sequencing only, 25 were identified by PCR reverse screening, and 10 by using both methods. Despite the fact that this was a small-scale experiment and was conducted mainly to demonstrate the reliability of the mutant collection, it is clear that most insertion alleles were identified by PCR reverse screening, highlighting the moderate performance of TAIL-PCR-based FST identification. Currently, we are developing cost-effective high-throughput means to recover FSTs by Illumina sequencing of DNA pools. We have tested 10×10 (for 100 lines) and 20×20 (for 400 lines) 2D pooling methods with pool-specific 7-base bar-codes in the primers for the second-round TAIL-PCR. In two pilot runs, we have achieved satisfactory results. The resulting sequences are regularly added to the mutant database.

Screening for AM phenotypes in 39 Nod− mutants showed that 25 of these could not establish AM symbiosis (Myc−), 5 mutants had less severe defects (Myc+/−), and 9 mutants were not defective (Myc+). Among these were 10 mutants in which *Tnt1* disrupted common symbiotic genes *DMI1*, *DMI2*, *DMI3*, and *NSP2*, and displayed the expected Myc− phenotypes. Some of the *nin* insertion

alleles had Myc− phenotypes, which is not consistent with the *nin* mutant phenotype that is limited to nodulation, and may therefore be due to additional insertions in unknown mycorrhization genes. The combined nodulation and mycorrhization screens revealed that mutants isolated from lines NF0455, NF0549, NF0577, NF0662, NF2853, and NF3057 may contain insertions in novel common symbiotic genes, while mutants isolated from NF0342, NF0438, NF1241, and NF3037 may contain insertions in novel, specialized nodulation genes.

83.3.2 *Tnt1*-Insertion Mutant Collection as Resource for Functional Genomics in *Medicago*

Apart from the 71 Nod− mutants, the *Tnt1*-insertion symbiotic mutant collection consists of nearly 100 mutants with various defects in nodule growth and/or SNF (Fig. 83.3). These mutants were not subjected to systematic screening for insertions in known symbiotic genes, since this was beyond the scope of the original work, which was mainly to demonstrate proof of concept (Pislariu et al., 2012). Identification of disrupted genes in these, and all other mutants, relies now on the development of high-throughput sequencing strategies to efficiently recover as many FSTs as possible. Identification of candidate genes is being done by cross-referencing genes with *Tnt1* insertions with their expression profiles in the *Medicago* Gene Atlas (MtGEA) (http://mtgea.noble.org/v3/) and the generation of segregating populations to confirm cosegregation of insertions with the observed phenotypes (Fig. 83.2). If a gene for an interesting mutant is discovered, a PCR-based reverse screening is then conducted in the entire mutant population to identify additional *Tnt1*-insertion alleles. Ultimately, the positive gene identification is confirmed by the similar phenotype observed in all insertion alleles and/or by complementation. By using this strategy, we identified several novel symbiotic genes that are currently being characterized functionally (Pislariu et al., unpublished results; Sinharoy et al., unpublished results). So far, 90 FSTs in nodule-expressed genes and 11 nodule-specific FSTs have been retrieved from *Tnt1*-insertion symbiotic mutants, including Medtr6g006140.1 (putative glucose transporter); Medtr8g088740.4 (Ser/Thr protein kinase); Medtr7g013170.1 (Beta-glucan-binding protein); Medtr1g104780.1 (Hexose transporter); Medtr4g085800.1 (phosphoinositide-specific phospholipase C-like protein); Medtr6g052300.1 (cystathionine β-synthase domain-containing protein) (Sinharoy et al., unpublished results); Medtr8g018570.1 (nodule- and Myc-specific lipoxygenase); and Medtr7g009730.1 (nodule- and Myc-specific WRKY transcription factor 73) (Sinharoy et al., unpublished results). From the seven *defective in nitrogen fixation* (*dnf1-7*) mutants (Mitra and Long, 2004; Starker et al., 2006; Pislariu and Dickstein, 2007), two genes have been clones so far: *DNF1* (Wang et al., 2010) and *DNF2* (Bourcy et al., 2013). Cloning of *DNF2* was facilitated by the *Tnt1*-insertion mutant collection. Among the 51 Nod+Fix− mutants were NF0217 and NF2496, which displayed similar phenotypes, with small, white, or brownish nodules, and stunted plant growth. *Tnt1* flanking sequences corresponding to the Medtr4g085800 gene that encodes a phosphatidylinositol-specific phospholipase C X domain (PI-PLCXD)-like protein were recovered from both lines. Subsequently, it was demonstrated that these mutants (designated *dnf2-2* and *dnf2-3*, respectively), together with an additional *MERE1*-insertion mutant (*dnf2-4*), belong to the same complementation group with the Jemalong *dnf2-1* mutant. It is conceivable that more of the potentially new *Tnt1*-insertion mutants may be alleles of EMS or deletion mutants with similar phenotypes. Nearly 44,000 FSTs have so far been recovered from the entire *Tnt1*-insertion mutant population, and the goal is to have ~200,000 FSTs deposited in the mutant database by the end of 2014.

The *Medicago Tnt1*-insertion population is also a valuable resource for reverse genetics. An efficient PCR reverse-screening platform has been developed at the Noble Foundation and *Tnt1* insertions have been identified in 715 genes, representing 85% of all genes tested (Fig. 83.2) (Cheng et al., 2011). An average of 1.7 insertion alleles for each gene has been achieved. Several transcription factors and transporters, for which multiple alleles have been isolated, are currently being characterized (Sinharoy et al., unpublished results; Kryvoruchko et al., unpublished results). Furthermore, the identity of several genes cloned from EMS and FNB mutant collections (generated in the A17 background) was confirmed by isolating additional R108 alleles in the *Tnt1*-insertion mutant population (Murray et al., 2011; Horvath et al., 2011). Approximately 25 genes that, according to transcriptomic data, were predicted to play roles in symbiosis have been characterized in more or less detail in the absence of mutants (Table 83.1). Although biochemical and pharmacological experiments can provide clues about the molecular function of a protein, the exact role in symbiosis is hard to predict when corresponding mutants are not available. For example, it has been shown that root hair curling and IT formation are inhibited by the phosphatidylinositol-specific phospholipase C inhibitor U-73122 (Peleg-Grossman et al., 2007). This result, however, seems to be inconsistent with the symbiotic phenotype observed in the *dnf2* phospholipase C mutants, which develop smaller but more numerous nodules than the wild type (Bourcy et al., 2013). It is, therefore, important to isolate mutants in order to accurately assess the biological function of a gene. Some of the genes in Table 83.1 have already been targeted for PCR reverse screening to identify *Tnt1*-insertion alleles and, ultimately, gene function.

83.4 DISCUSSION

Tnt1-insertion mutagenesis has been established as an excellent tool for large-scale, saturation mutagenesis in *Medicago*. From 230 lines with putative symbiotic phenotypes, we isolated 179 mutants impaired at various stages of symbiosis. From 83 Nod− and Nod++ mutants, we found 39 insertion alleles in 9 known symbiotic genes. Several Nod−, Nod+/−Fix−, Nod+Fix−, and Nod+Fix+/− mutants have symbiotic phenotypes unlike others described in the literature, and may, therefore, be impaired in novel symbiotic genes.

The available genome sequence and transcriptomic resources for functional genomics have placed *Medicago* at the forefront of genetic studies aimed at a better understanding of SNF and AM (see Chapter 78). From transcriptomic studies, it is clear that several thousand genes are involved in these symbioses, although few of them have been characterized at the molecular level. Although members of the common symbiotic pathways and a few nodulation- and mycorrhization-specific genes have been described in recent years, there are many gaps in our knowledge of the molecular and biochemical events required to establish these mutualistic symbioses. A lot of work has been focused so far on the early steps required for the establishment of symbioses, which is indeed critical. However, molecular mechanisms occurring downstream of the rhizobium-specific (*ERN1*, *NIN*) and mycorrhizal-specific (*RAM2*) (Wang et al., 2012) genes are poorly understood at this time. It is also important to learn more about the genetic control of nodule senescence, which could have implications in the extended persistence of efficient, nitrogen-fixing nodules.

For many years RNAi has been used to infer biological function, although gene knock-down rather than knock-out is a more common occurrence, which complicates data interpretation. Nevertheless, nearly 40 *Medicago* symbiotic genes have been characterized using this method (Table 83.1). One advantage of *Tnt1*-insertion mutagenesis is that it causes mostly KO mutations, especially when insertions are exonic, toward the 5′-end of the gene or in the proximal region of the promoter.

The *Medicago* tobacco retrotransposon *Tnt1*-insertion mutant collection has also been instrumental in the cloning and characterization of *Medicago* genes not involved in symbiosis (Tadege et al., 2011; Laurie et al., 2011; Chen et al., 2010; Pang et al., 2009; Wang et al., 2008; Zhao et al., 2010; Zhou et al., 2011). As previously described, *Tnt1* transposition in *Medicago* offers advantages that have not been surpassed by other mutagenesis methods in the past 6 years (d'Erfurth et al., 2003; Tadege et al., 2005). They include transposition to unlinked sites, multiple insertions per line that should allow near-complete genome coverage; insertion primarily within coding sequences; generation of mostly KO mutations; stability during seed-to-seed propagation (copy-and-paste transposition); and simplification of gene cloning by the ease of FST recovery. There are some drawbacks, such as the tissue culture step that is required for the *Tnt1* activation, with the potential of triggering endogenous mobile elements, and somaclonal variation (Larkin and Scowcroft, 1981). Also, having multiple insertions in other genes can complicate genetic analysis and necessitates the use of at least two alleles and/or backcrosses for cosegregation analysis. This contrasts with the *Arabidopsis* T-DNA lines, which average 1.5 insertions per line. However, *Medicago* is larger and slower to set seed than *Arabidopsis*, and has a much larger genome, so generation of a saturation population using T-DNA would be prohibitively expensive, while using *Tnt1* has allowed this goal to be achieved using a much smaller population size and in shorter time.

The robustness of *Tnt1*-insertion mutagenesis has been confirmed by the large number of publications reporting gene cloning and functional characterization using this resource, and by the attempt to extend the same technology to soybean (Cui et al., 2013). The *Medicago Tnt1*-insertion population is an excellent tool for gene discovery and molecular characterization using both forward and reverse genetic approaches. Improving FST recovery will certainly speed up the identification of novel key symbiotic genes. Furthermore, conducting large-scale PCR reverse screenings for *Tnt1* insertion alleles of genes of interest will help clarify the biological functions of partially characterized genes for which no mutants were available previously.

ACKNOWLEDGMENTS

This work was funded by the National Science Foundation grants DBI-0703285 and IOS-1127155. Confocal imaging was possible as a result of the NSF equipment grant DBI-0400580. Dr. Igor Kryvoruchko is acknowledged for critical reading of the manuscript.

Marine Nitrogen Fixation: Organisms, Significance, Enigmas, and Future Directions

Jonathan P. Zehr and Deniz Bombar
Department of Ocean Sciences, University of California, Santa Cruz, CA, USA

84.1 INTRODUCTION

The biological productivity of the oceans is constrained by the cycling and biological availability of nutrients, of which nitrogen (N) is critical (Gruber and Galloway, 2008; Canfield et al., 2010). N is primarily recycled in the open ocean through remineralization of organic matter. A primary new N input comes from upwelling of deep water containing nitrate formed from remineralization and oxidation of the organic matter, which sinks through the water column. However, other important inputs of N are atmospheric deposition of fixed N compounds, terrestrial runoff, and biological N_2 fixation (Seitzinger and Kroeze, 1998; Jickells, 2006; Duce et al., 2008; Gruber, 2008). Some marine biological N_2 fixation occurs in relatively small, localized habitats such as seagrass beds and sediment microbial mats, where N input is important ecologically for that specific habitat or ecosystem (Capone, 1983, 1988; Bebout et al., 1994). However, biological N_2 fixation also occurs in the vast expanses of the open ocean and is globally the largest marine input, and it balances N losses from the mixed layer to the deep sea and sediments, as well as losses to the atmospheric N_2 pool via denitrification and anaerobic ammonia oxidation.

In the past two decades, continued new discoveries have been made about the organisms involved, how N_2 fixation is distributed in the oceans, and the factors that control N_2 fixation in the sea (Ward et al., 2007).

84.2 N_2 FIXATION, MARINE HABITATS, AND CYANOBACTERIA

Biological N_2 fixation is catalyzed by diverse bacteria and Archaea, but not by Eukaryotes, although some bacteria and Archaea fix N_2 in symbiosis with eukaryotes (see below). In the marine environment, there are many habitats that contain diverse N_2-fixing microorganisms (diazotrophs) (Fig. 84.1) from all of these groups (Table 84.1). Open ocean N_2-fixing habitats range in temperature and pressure and include warm tropical and subtropical surface waters, and also cold polar and cold mesopelagic- and deep ocean waters. Benthic habitats include sediments, coral reefs, and benthic microbial mats (Zehr and Paerl, 2008). Marine habitats also include special environments such as hydrothermal vents, characterized by high temperatures and are rich sources of electron donors.

The N_2-fixing microbial taxa generally differ among these marine habitats (Table 84.1) and include Archaea and diverse (photo)heterotrophic and chemolithotrophic bacteria and photoautotrophic cyanobacteria. For example, archaeal nitrogenase (*nifH*) genes have been found in deep water and near hydrothermal vents (Mehta et al., 2003; Mehta and Baross, 2006; Dekas et al., 2009). Many heterotrophic bacterial *nifH* genes are typically found in sediments (Capone, 1983; Dang et al., 2009), salt marshes (Moisander et al., 2005), and microbial mats (Olson et al., 1999;

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

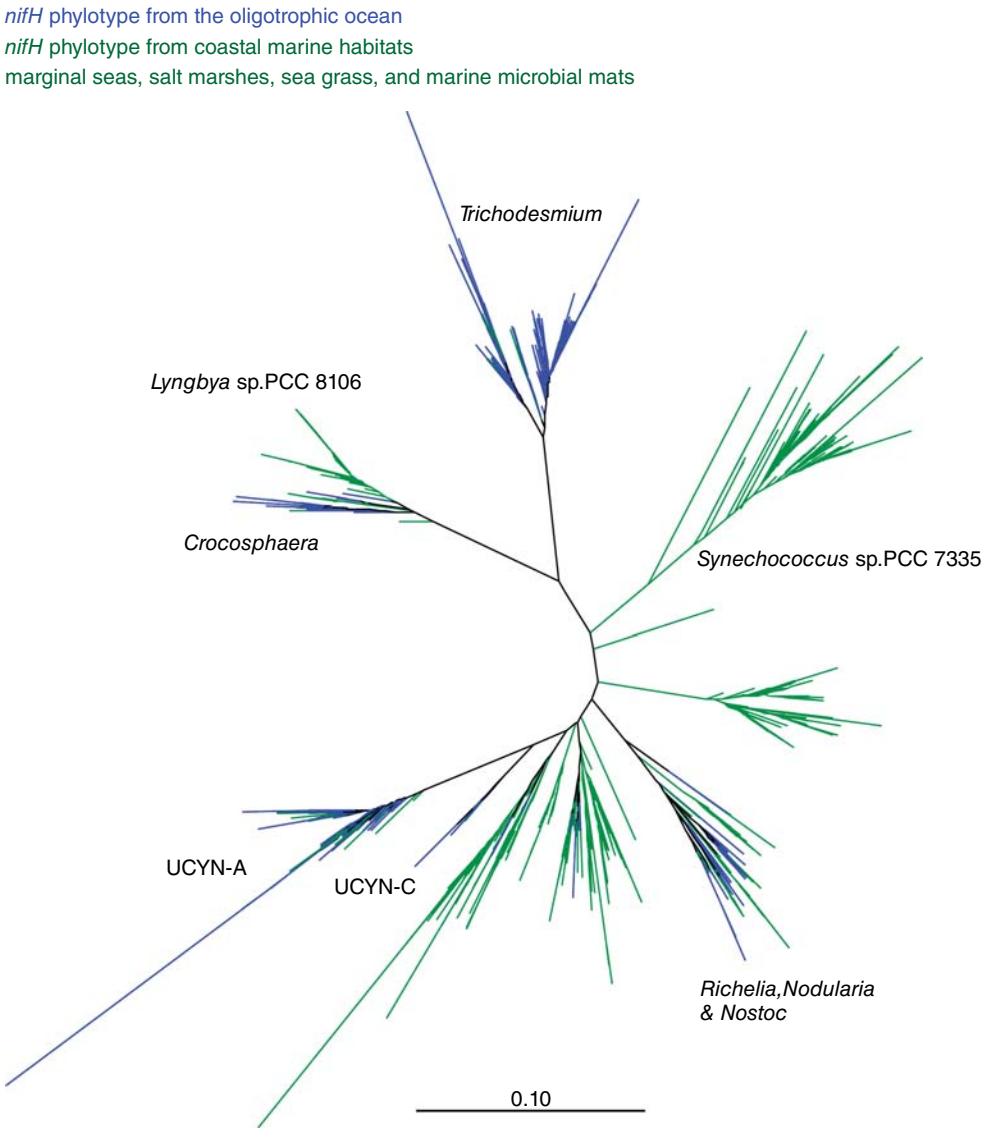

Figure 84.1 Phylogenetic distribution of cyanobacterial (*nifH* cluster 1B) *nifH* genes in the marine environment.

Moisander et al., 2006; Severin and Stal, 2010) (Table 84.1). Thus, marine diazotrophs can thrive across large ranges in temperature, salinity, and oxygen, and these variables themselves do not constrain N_2 fixation in the marine environment.

Cyanobacteria are obvious and important components of many of these marine habitats, such as in microbial mats (Zehr and Paerl, 2008; Paerl, 2012). Cyanobacteria of a variety of morphologies and phylogenies are involved in N_2 fixation in microbial mats, ranging from filamentous heterocyst-forming and nonheterocyst-forming species to unicellular N_2-fixing species (Zehr and Paerl, 2008; see Chapters 85, 86). Strikingly, the N_2-fixing cyanobacteria in the ocean water column are represented by only a handful of lineages, in contrast to the rich diversity of microbial mats (Zehr and Paerl, 2008) (Fig. 84.1).

Heterotrophic bacteria in the ocean water column have largely been ignored until recent reports of heterotrophic bacterial *nifH* gene expression (Zehr et al., 2001; Bird et al., 2005; Church et al., 2005b; Bird and Wyman, 2012) and high *nifH* sequence diversity (Riemann et al., 2010; Farnelid et al., 2011) in the open ocean (Fig. 84.2). This review focuses primarily on what is known about N_2-fixing cyanobacteria in the open ocean, but will also touch upon aspects of the potential for heterotrophic or (photo)heterotrophic N_2 fixation.

84.3 WHY IS N_2 FIXATION IN THE OPEN OCEAN INTERESTING?

On land and in the sea, the availability of nutrients constrains the productivity of the biosphere (Vitousek and Howarth, 1991). In the oceans, the primary nutrients and trace elements that limit growth and productivity are N, phosphorus (P), and iron (Fe). The water-column microbes of the vast open sea dominate the C and N fluxes of the ocean (Longhurst, 1991; Raven and Falkowski, 1999; Zehr and Kudela, 2011). Primary productivity in the surface waters of the oceans is roughly equivalent to that on land (Field et al., 1998), and is mainly carried out by the unicellular cyanobacteria *Synechococcus* and *Prochlorococcus* (Johnson and Sieburth, 1979; Waterbury et al., 1979; Chisholm et al., 1988). Similarly, N_2 fixation in the water column of the ocean dominates global ocean N_2 fixation (Fowler et al., 2013; Voss et al., 2013), and is roughly equivalent to the magnitude of anthropogenic N_2 fixation in agriculture and industry (Fowler et al., 2013). In the oceans, marine biological N_2 fixation, along with upward fluxes of deep water NO_3^- to the surface ocean, fuels primary productivity and quantitatively balances the losses by sinking of organic material, which sequesters CO_2 from the atmosphere to deep waters (Karl et al., 1997; Sohm et al., 2011).

Although N limits the productivity and the ability of the oceans to sequester CO_2, equally, or ultimately more important, is the availability of other nutrients that control the growth of photosynthetic- and N_2-fixing microorganisms (Mills and Arrigo, 2010; Sohm et al., 2011). Phosphorus (P), which does not have a significant reservoir as a gas in the atmosphere, is largely sequestered in rocks and sediments (Delaney, 1998), and can be an important limiting factor for diazotrophs and primary producers in the sea (Wu et al., 2000; Karl et al., 2001; Sanudo-Wilhelmy et al., 2001; Mills et al., 2004; Hynes et al., 2009; Kitajima et al., 2009). The trace element Fe, important for many enzymes (including but not limited to nitrogenase), is often in limiting supply because it is insoluble in oxidized seawater and also plays a critical role in the environmental control of photosynthetic CO_2 fixation and N_2 fixation (Webb et al., 2001; Wu et al., 2001, 2003; Boyd et al., 2007; Moore et al., 2009; Chappell et al., 2012; Shi et al., 2012). In the open ocean, the factors that control the availability of these nutrients and trace elements include large-scale processes, such as global and local water mass circulation (Palter et al., 2011), and atmospheric wind transport and deposition of dust (Baker et al., 2003; Bonnet and Guieu, 2004; Mills et al., 2004; Duggen et al., 2010). Due to the vast expanse of the oceans (Fig. 84.3) and the difficulties of sampling the ocean over the necessary large scales, gaining global-level estimates of N_2 fixation and the organisms responsible is extremely challenging (Church et al., 2009; Voss et al., 2013; see Chapter 87).

84.4 N_2 FIXATION IN THE SEA

For many years, rates of N_2 fixation in the open sea were assumed to be negligible, or at least biogeochemically unimportant (Mague et al., 1974; Carpenter and McCarthy, 1975; Eppley and Peterson, 1979). This assumption changed when it was demonstrated that *Trichodesmium*, a filamentous cyanobacterium that is easily observed because of its tendency to form aggregates large enough to see with the unaided eye, could fix N_2 (Dugdale et al., 1961). In the ensuing years, pioneering N_2 fixation work showed that *Trichodesmium* was widely distributed and that N_2 fixation occurred in many places in the surface ocean, but was highly variable temporally and spatially (Dugdale et al., 1964; Carpenter, 1973, 1983; Mague et al., 1974; 1977; Carpenter and Culliney, 1975; Carpenter and Price, 1977; Saino and Hattori, 1978; Capone et al., 1997).

Interest and research focus on N_2 fixation intensified in the late 1990s because biogeochemical calculations predicted that there must be much greater rates of oceanic N_2 fixation than previously estimated (e.g., from *Trichodesmium* rates and abundances) (see Chapter 87). This interest in oceanic N_2 fixation led to new discoveries about the organisms and processes responsible for controlling open ocean N_2 fixation (Ward et al., 2007; Zehr, 2011)

84.5 WHAT ARE THE N_2 FIXATION RATES OF THE OCEANS?

Determining reliable rates of N_2 fixation, a seemingly simple experimental measurement, is in reality a very challenging endeavor. Since sampling for N_2 fixation rates even within a single ocean basin is time- and money-intensive, some of the best large-scale estimates are not based on direct experimental rate measurements, but rather on mathematical models (Monteiro et al., 2010, 2011) or biogeochemical estimates (Gruber, 2005; Deutsch et al., 2007). There is no accurate way to assess N_2 fixation in the ocean by remote sensing, as has been used for primary productivity (Behrenfeld and Falkowski, 1997), except maybe in very special situations, such as surface blooms of *Trichodesmium*, which can cover hundreds of miles and are visible on satellite images (Capone et al., 1997; Subramaniam et al., 1999; Westberry and Siegel, 2006). However, satellite remote sensing does not detect subsurface biomass, and biomass cannot be easily translated to N_2 fixation rates. Biogeochemical models based on regenerated nutrient stoichiometry (N and P) can be used to predict basin-scale rates and regional patterns of N_2 fixation (and denitrification). It was these types of estimates that led to the conclusion that oceanic N_2 fixation rates were higher than previously assumed (Michaels et al., 1996; Gruber and Sarmiento, 1997; Lee et al., 2002; Codispoti, 2007). These models are based on a variety of assumptions (stoichiometry

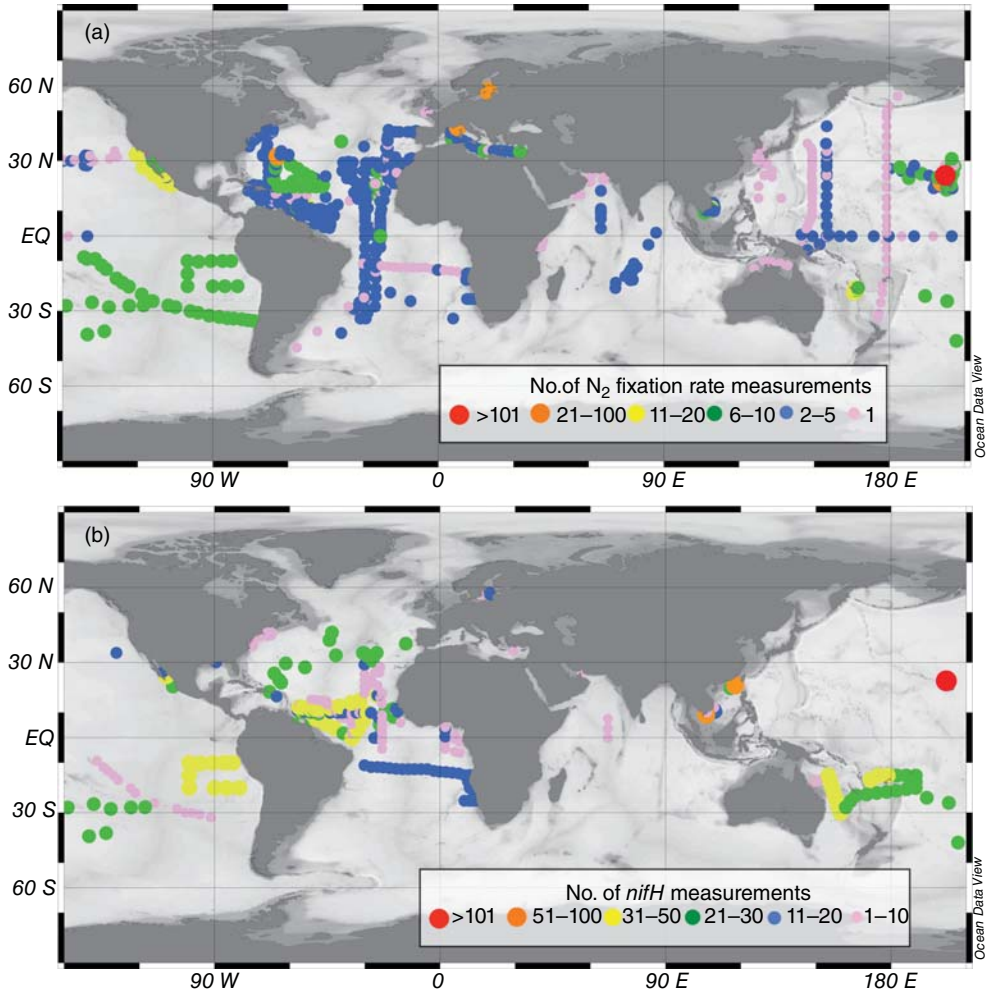

Figure 84.3 Global map of N_2 fixation rate measurements and quantitative *nifH* assays (modified after Luo et al., 2012).

of nutrients in microorganisms, rates of sedimentation, water mass flow rates, scales of integration), and thus the calculated magnitude of global N_2 fixation (in the range of $100–200 \times 10^{12}$ g N/year) strongly varies between different studies (Gruber and Sarmiento, 1997; Hansell et al., 2004; Koeve and Kahler, 2010), and the first higher estimates of N_2 fixation rates more closely balanced known oceanic denitrification rates (Hansell et al., 2004; Gruber, 2005; Codispoti, 2007).

It would seem that the most direct way to determine N_2 fixation rates is to measure rates using conventional stable isotope ($^{15}N_2$) or acetylene reduction methods. This is not as simple as it may seem to the nonoceanographer because of the large horizontal and vertical scales of variability, and because of the dilute nature of the oligotrophic (low N) environment. For many years, oceanic N_2 fixation rates were estimated by incubating hand-picked macroscopic colonies of *Trichodesmium*, but the discovery of microscopic unicellular N_2 fixers (see later) led to the need for bulk seawater measurements. However, since N_2-fixing microorganisms are not very abundant relative to dominant species, measuring rates of $^{15}N_2$ incorporation (or acetylene reduction) in bulk seawater are difficult due to the limits of detection. Recently, there have also been suggestions of experimental artifacts using the traditional $^{15}N_2$ gas bubble addition assay in seawater (Mohr et al., 2010), which may differentially bias rate measurements from different types of microorganisms (Grosskopf et al., 2012). In addition, considering the size and variability of the ocean ecosystem, it appears impossible to use shipboard sampling (which is constrained in space and time) to carry out representative incubations that cover the range of seasonality, and small- and large-scale patchiness of microorganisms and nutrients over the vast ocean basins. Depending on the spatial resolution achieved during different research cruises, estimates regarding the magnitude of N_2 fixation in a particular area can vary considerably (Shiozaki et al., 2009, 2010; see Chapter 87).

Another approach to estimate oceanic N_2 fixation rates is to identify the responsible organisms, to determine their distributions and activity, and to reveal the factors that control their distributions and activity. This information is then used to model rates (Goebel et al., 2007, 2010) or the global patterns of N_2 fixation (Monteiro et al., 2010). This approach requires obtaining data on the abundance of the organisms, their specific N_2 fixation rates in seawater (or good estimates of cell-specific rates of N_2 fixation, (Goebel et al., 2010)) and on the nutrients that control the distribution and activities of these organisms in order to develop models related to the fluxes of these nutrients (P and Fe). It is not easy to identify N_2-fixing microbes in a drop of seawater, let alone to measure their specific rates of N_2 fixation. *Trichodesmium* is easily observed and concentrated by net tows. Thus, even though typical high concentrations of *Trichodesmium* are only a few cells per milliliter of seawater, enough *Trichodesmium* can be collected from long net-tows to obtain a reliable rate, which can be extrapolated over large volumes of seawater. This is generally true of the diatom symbionts as well. However, the unicellular cyanobacteria, including the UCYN-A symbiont, are extremely difficult to detect, and it is difficult to measure rates from a few cells per milliliter of small organisms that cannot be visualized or easily concentrated to make similar rate measurements. Also, some of these organisms can only be quantified by molecular techniques, which means that the organisms are not detected until long after sampling. Rates determined in bulk water when multiple species are present make it difficult to deconvolute individual species rates (Goebel et al., 2010). The use of stable isotopes and nanoscale secondary ion mass spectrometry (nanoSIMS) has made it feasible to determine N_2 fixation rates on individual cells (Finzi-Hart et al., 2009; Foster et al., 2011, 2013), but the variability among cells and incubation conditions challenge scaling up to large areas. Attempts to model the relative contributions of different N_2 fixers rely on limited available microscopic counts and the abundance data from quantitative PCR (Luo et al., 2012) (Fig. 84.2). Thus, models need to extrapolate in space and time from a relatively small data set, considering the size of the oceans, and they need to consider the seasonality of plankton communities.

The ability to estimate or model integrated N_2 fixation from measured rates and/or organismal abundances is constrained by the frequency and spatial coverage of sampling by ships or with remote instruments (Fig. 84.3). Recent development of a N_2 fixation database provides the first comprehensive amalgam of such information from diverse sources (Luo et al., 2012) and also highlights the problem of uneven spatial coverage of N_2 fixation studies (Fig. 84.2) and diverse sampling procedures (Zehr and Kudela, 2011) associated with different surveys. The expense and logistics of oceanographic cruises often led to research being carried out in areas where N_2 fixation was known to occur, such as the Atlantic Ocean and Caribbean Sea or the North Pacific (Fig. 84.3). In recent years, a number of longer survey transects have been sampled, although methods and measurements differ among studies, making it difficult to define the regions, temporal dynamics, and rates of N_2 fixation in the global ocean (Zehr and Kudela, 2011). However, such surveys have led to hypotheses regarding the general patterns of N_2 fixation in the oceans (Sohm et al., 2011).

Models and extrapolations are also sensitive to the unknown physiological status at the time of sampling and the general controlling factors in the ocean. The now known symbiotic relationship of UCYN-A represents a further complication, since it is unknown how cell-specific rates of UCYN-A vary (Goebel et al., 2010) and how they are regulated within the symbiosis with a photoautotrophic eukaryote. Thus, the question of whether *Trichodesmium* dominates oceanic N_2 fixation rates is not resolved and will not be easily resolved. However, the much greater geographic distribution of UCYN-A compared to *Trichodesmium* suggests that the integrated global rates will be greatly affected by UCYN-A. Recently, instrumentation has been developed that can perform quantitative PCR *in situ*, and deployment of that enables unmanned detection of N_2-fixing microorganisms (Robidart et al., 2014). Ultimately, this type of instrumentation may help to obtain higher resolution data on the abundances of different diazotrophs than has been acquired by oceanographic expeditions (Fig. 84.3).

84.6 OCEANIC N_2-FIXING MICROORGANISMS AND CHANGES IN PARADIGMS

Studies of N_2-fixing microorganisms in the oceans based on molecular biology and genomics have led to the revision of a number of dogmas about marine N_2 fixation. Following are several examples of previous dogmas, and how recent findings have led to important changes in what we know about N_2 fixation.

1. *Trichodesmium*, a filamentous, nonheterocyst-forming cyanobacterium, was believed to be the only important N_2 fixer in the oceans (Capone et al., 1997; LaRoche and Breitbarth, 2005). This assumption led to a variety of conclusions and development of mathematical models (Coles et al., 2004; Hood et al., 2004) that predicted where and when N_2 fixation occurs.

   It is now known that *Trichodesmium* is not the only important N_2-fixing cyanobacterium in the sea. Early microscopic studies showed that there were other cyanobacteria, especially the heterocyst-forming symbionts of diatoms, present in ocean waters (Carpenter and Capone, 1983; Villareal and Carpenter, 1989). More recently, applications of molecular biology and genomic approaches uncovered unexpected new microorganisms

involved in oceanic N_2 fixation. Although it may be that *Trichodesmium* still dominates oceanic N_2 fixation, it is necessary but difficult to assess the relative contributions of the less easily observed and uncultured unicellular cyanobacteria (Zehr et al., 2000; Capone, 2001).

2. Oceanic N_2 fixation is constrained to warm surface waters. This dogma arose primarily because of the belief that *Trichodesmium* is the primary N_2 fixer, and it is largely only found in warm tropical or subtropical waters.
   The discovery that other N_2-fixing cyanobacteria have different temperature optima (Needoba et al., 2007; Langlois et al., 2008; Moisander et al., 2010) and are more widely distributed geographically, including at high latitudes (Rees et al., 2009; Blais et al., 2012; Diez et al., 2012) and in coastal waters (Mulholland et al., 2012), has challenged this dogma. The integrated rates over the greater latitudinal range may change global estimates of oceanic N_2 fixation.
3. N_2 fixation does not occur in waters with fixed inorganic N. N_2-fixing microorganisms are believed to be only competitive when fixed inorganic N is not available, based on a relatively small number of studies of ecological competition between N_2-fixing and non-N_2-fixing microorganisms. Also, since N_2 fixation is an energetically expensive process, it is assumed to be highly regulated by the cell (in response to oxygen and fixed N availability) and not expressed when fixed inorganic N is present (Mulholland and Capone, 2000; Holl and Montoya, 2005; Knapp, 2012). There have been many studies of model microorganisms that demonstrate the regulation of N_2 fixation genes and N_2 fixation activity in response to the presence of fixed inorganic N. These assumptions led to the focus of sampling and research on N_2 fixation in oligotrophic waters with extremely low fixed-N concentrations (Capone et al., 1997) and to the conclusion that N_2 fixation does not occur in coastal or upwelling waters, or in sediments, where fixed inorganic N concentrations are relatively high.
   The finding of N_2 fixation in nutrient-enriched upwelling regions appears to contradict these assumptions. Also, the studies on which this dogma is founded involve experiments with relatively high concentrations of fixed N (e.g., millimolar ammonium or nitrate), and other studies have shown that some N_2-fixing cyanobacteria will fix N_2 in the presence of fixed N (Ohki et al., 1991; Mulholland et al., 1999, 2001; Holl and Montoya, 2005; Knapp, 2012). Furthermore, N_2 fixation has been demonstrated to be important in upwelling areas or near riverine inputs where fixed N is present, albeit at low concentrations (Voss et al., 2006; Foster et al., 2007; Subramaniam et al., 2008; Bombar et al., 2011). N_2 fixation is only slightly more energetically expensive than using NO_3^- (Karl et al., 2002), making the argument that N_2 fixers are not competitive when fixed inorganic N is present more complicated. Finally, N_2 fixation has been detected in sediments (Slater and Capone, 1984; Burns et al., 2002; Fulweiler et al., 2007), even in the presence of high concentrations of ammonium, suggesting that N_2 fixation proceeds even when fixed N is present in high concentrations and may be regulated or employed for a metabolic reason other than obtaining N. *Rhodobacter* in culture was shown to regulate nitrogenase expression as a function of redox conditions (Tichi and Tabita, 2000), for example. There is no direct evidence, however, that nitrogenase in the environment is expressed for any other reason than obtaining N.
4. N_2 fixation is a strictly anaerobic process. The fact that the enzyme is sensitive to inactivation by oxygen, and that model microorganisms have physiological or cellular adaptations for fixing N_2 in photosynthetic organisms or aerobic environments (Stal and Krumbein, 1985; Milligan et al., 2007; Staal et al., 2007), has led to assumptions about how and where N_2 fixation can occur and the kinds of organisms that could be capable of N_2 fixation (see Chapter 86). This assumption was one of the reasons that it was not believed that *Trichodesmium* was a N_2-fixing cyanobacterium in early studies, because it did not make heterocysts to allow simultaneous N_2 fixation and photosynthesis. Ultimately, it was clearly demonstrated that *Trichodesmium* does fix N_2, and only in the light (Dugdale et al., 1961). Many studies have attempted to determine how *Trichodesmium* can evolve O_2 while simultaneously fixing N_2 (Paerl and Bebout, 1988; Carpenter et al., 1990; Kana, 1993; Berman-Frank et al., 2003; Küpper et al., 2004), but it is a difficult problem because of its filamentous growth morphology, is somewhat controversial, and is not completely resolved (see Bergman (1999) and Thompson and Zehr (2013)).
   This assumption also questioned the significance of recently discovered unicellular cyanobacteria "UCYN-A," which appeared to fix N_2 during the light and express *nifH* genes during the light (Church et al., 2005b). Ultimately, it was found that this organism is not photosynthetic and neither evolves O_2 nor fixes CO_2 (Zehr et al., 2008; Tripp et al., 2010). However, it still lives on or in a photosynthetic unicellular alga, which is evolving O_2. In photosynthetic unicellular diazotrophs like *Cyanothece*, respiration plays an important role in quenching away oxygen to enable the cells to carry out N_2 fixation (Bandyopadhyay et al., 2013).
   More recently, it has been suggested that heterotrophic bacteria are more abundant than cyanobacteria (based on representation in amplified gene sequence libraries, such as pyrosequencing) and may also be important in

oceanic N_2 fixation (Riemann et al., 2010; Farnelid et al., 2011). It is unclear how these heterotrophic bacteria would avoid inhibition by O_2 at saturating concentrations in surface waters, but it might be plausible that they have protective mechanisms such as the high respiration rates and other mechanisms, for example, found in terrestrial *Azotobacter* (Dalton and Postgate, 1969; Oelze, 2000). It is also unclear how they would support the energetic needs of a high respiration rate, let alone the costs of N_2 fixation, using the low concentrations of dissolved organic matter in the surface ocean.

84.6.1 New Discoveries about Oceanic N_2-Fixing Cyanobacteria

N_2-fixing microorganisms, traditionally observed by microscopy, became the target for molecular biology in the late 1980s (Zehr and McReynolds, 1989; Zehr et al., 1995). Sequencing of amplified *nifH* genes was first used to confirm that *Trichodesmium* fixed N_2, and that measured N_2 fixation rates were not due to the associated heterotrophic microorganisms (Zehr and McReynolds, 1989). The molecular approach proved to be a powerful technique for characterizing diversity (Zehr et al., 1995) but, more importantly, for identifying novel microorganisms in the open ocean (Zehr et al., 1998, 2001). These approaches yielded new information on the previously known N_2-fixing cyanobacteria *Trichodesmium* and the diatom symbionts (*Richelia*), and also identified new and novel important unicellular N_2-fixing species.

84.6.2 Trichodesmium

Trichodesmium is enigmatic in that it does not form heterocysts and yet fixes N_2 only in the light (Capone et al., 1997). This enigma has been long-studied, starting with demonstrating that the aggregates fixed N_2 (Dugdale et al., 1961), that it has cyanobacterial *nifH* genes (Zehr and McReynolds, 1989), and that the nitrogenase protein is found in *Trichodesmium* cells (reviewed in Bergman et al. (2013)). Physiological and immunological evidence suggests that there is spatial variability in cell nitrogenase distribution and possibly activity, and that there are short temporal variations in photosystem II activity that could help to reduce the damaging effects of O_2 generated in photosynthesis (Bergman, 1999; Berman-Frank et al., 2001; Küpper et al., 2004). However, it still has been impossible to assay nitrogenase activity and photosynthetic activity in the same cells at the same time, and thus there is still some uncertainty in how N_2 fixation works in *Trichodesmium*. Part of the explanation might be a temporal segregation of CO_2 fixation (maximal in the morning) and N_2 fixation (peaking in the afternoon) (Finzi-Hart et al., 2009). This topic has been reviewed elsewhere (Stal and Zehr, 2008; Bergman et al., 2013; Thompson and Zehr, 2013).

84.6.3 Diatom Symbionts

Among the various examples of marine symbioses that involve diazotrophs (Fiore et al., 2010), the cyanobacterial symbionts of diatoms are an important open-ocean example. Molecular approaches showed that these symbionts, previously observed by microscopy, were composed of several distinct lineages that may be host-specific (Janson et al., 1999; Foster and Zehr 2006; Hilton et al., 2013). These cyanobacteria range in how they are physically associated with their hosts from epibiotic on the spines of *Chaetoceros* diatoms (*Calothrix*) to inside the frustule of *Hemiaulus* and *Rhizosolenia* (*Richelia*). Recently genomic sequencing of isolated filaments of *Calothrix* cultures (Foster et al., 2010) and *Richelia* isolated from *Hemiaulus hauckii* and *Hemiaulus membranaceus* showed that the genomes are substantially different, with the genomes of the endosymbiotic forms highly streamlined (Hilton et al., 2013) (Table 84.2). The genome of *Richelia* associated with *H. hauckii* is only

Table 84.2 Genome Comparison Between the Cyanobacterial Diatom Symbionts, *Calothrix* and *Richelia* (taken from Hilton et al., 2013)

	Richelia (Hh)	*Calothrix* SC01
Genome size, Mb	3.2	6.0
Transporters	55	144
GOGAT	X	✓
GS-inactivating factor	X	X
Glutaminase	X	✓
NH_4^+ transporter	X	✓
NO_3^- transporter	X	✓
Urea transporter	X	X
NO_3^- reductase	X	✓
NO_2^- reductase	X	✓
Urease	X	X
Nif insertion element	*nifH* (9.1 kb)	*nifH* & *nifK*

Calothrix is an epibiont on the diatom *Chaetoceros*, and *Richelia* is an endosymbiont in diatom *Hemiaulus* spp.

3.2 Mb, whereas that of *Calothrix* is 6.0 Mb. More interestingly, the *H. hauckii* endosymbiont is lacking many core N metabolism genes, including ammonium transporters and glutamine oxoglutarate aminotransferase (GOGAT). Clearly, genome streamlining appears to be correlated with the extent of the symbiotic association.

84.6.4 Unicellular Cyanobacteria (UCYN-A, B, and C)

NifH gene sequences that were phylogenetically closely related to unicellular strains were the first clues that *Trichodesmium* was not the only N_2-fixing cyanobacterium in the open ocean. Some *nifH* gene sequences amplified from oceanic water samples were phylogenetically related to the *Cyanothece* clade. There have been three groups of sequences found, called Groups A, B, and C (now called UCYN-A, B, and C (unicellular cyanobacteria)) (Langlois et al., 2005; Foster et al., 2007). Group B sequences were virtually identical to the sequences from *Crocosphaera watsonii*, which had been cultivated from the Atlantic (Zehr et al., 2001, 2007), but had not previously been recognized as being a widely distributed important ocean N_2-fixing cyanobacteria. *Crocosphaera*-like cyanobacteria had been observed by microscopy or flow cytometry a few times (Campbell et al., 1983; Neveux et al., 1999), but molecular approaches first documented how widely spread and common they are (Mazard et al., 2004; Church et al., 2005b; Hewson et al., 2009; Webb et al., 2009). A representative of UCYN-C (Foster et al., 2007), which appears to be not as common as UCYN-A or -B, has recently been cultivated from the oligotrophic western Pacific Ocean (Taniuchi et al., 2012).

UCYN-A was known only from its *nifH* gene for many years, as it could not be cultivated or identified microscopically. By coupling flow cytometry with high-throughput sequencing, the genome sequence was obtained (Zehr et al., 2008) and was closed (Tripp et al., 2010). The surprising finding was that although evolutionarily closely related to the *Cyanothece* clade, the genome was only 1.44 Mb and lacked many metabolic pathways, including those usually assumed to define cyanobacteria, like the oxygen-evolving photosystem II and Rubisco. This clearly suggested that the "cyanobacterium" was a symbiont. By coupling flow cytometric sorting (Zehr et al., 2008) with *in situ* hybridization to identify UCYN-A (Krupke et al., 2013), and nanoSIMS to visualize $^{15}N_2$ and $^{13}CO_3$ fixation, a symbiotic eukaryotic

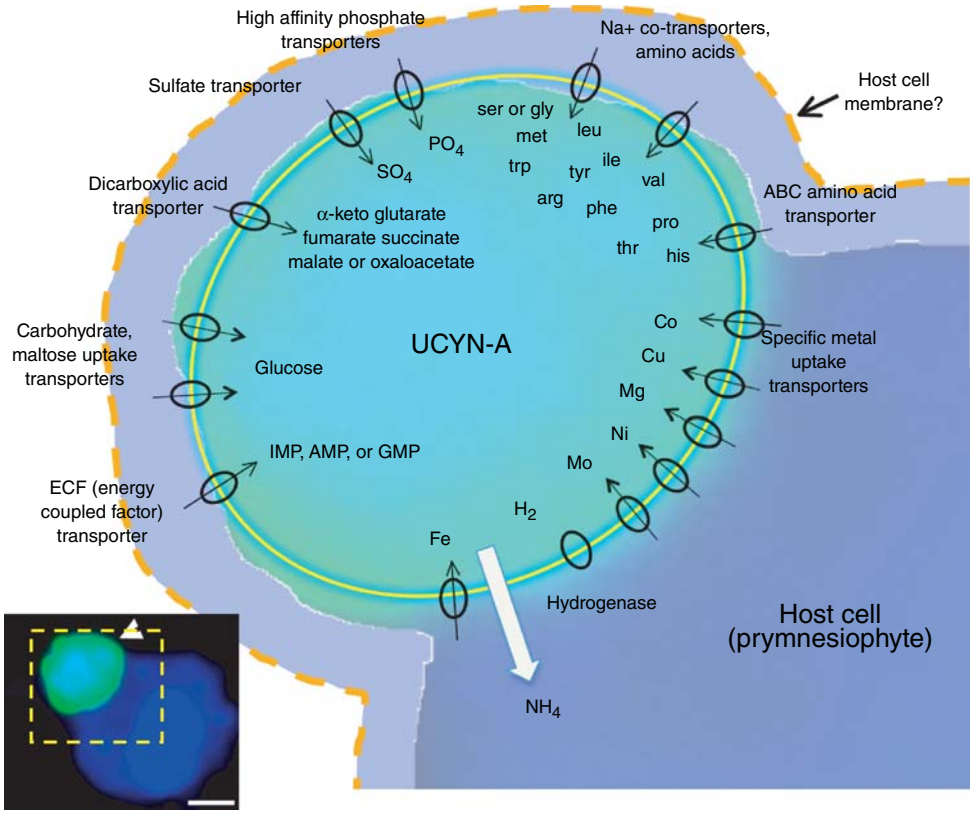

Figure 84.4 Proposed basic metabolism of the unicellular symbiotic cyanobacterium *Candidatus* Atelocyanobacterium thalassa (UCYN-A). The scale bar represents 1 μm.

prymnesiophyte partner was identified (Thompson et al., 2012). The host, or partner, was the first known example of a symbiosis with a haptophyte unicellular algae. UCYN-A cannot fix CO_2 and lacks the ability to synthesize several amino acids and purines (Tripp et al., 2010). The genome sequence of UCYN-A provides clues as to how metabolites such as sugars, dicarboxylic acids, amino acids, and other nutrients are exchanged between the host and symbiont (Fig. 84.4). Sugars are presumably degraded via glycolysis to pyruvate, and further to acetyl CoA and CO_2, thereby providing energy. The lack of ability for biosynthesis of basic cellular building blocks and energy substrates, and overall the extensive degree of genome streamlining, suggest that this symbiosis is obligate. However, it remains unclear whether UCYN-A is an endosymbiont, and how cells are vertically transmitted by the dividing host cells. It is known that the association is relatively fragile (Thompson et al., 2012), and UCYN-A has at times presumably been observed as free cells (Krupke et al., 2013). Thus, there are important details about this symbiosis yet to be revealed. Furthermore, there may be more symbioses yet to be discovered. UCYN-A was only discovered because of the focus of research to elucidate the organism associated with the UCYN-A *nifH* gene sequence. Other cyanobacteria have been observed in association with eukaryotic algae, including diatoms and dinoflagellates (Carpenter and Foster, 2002; Janson, 2003; Foster and O'Mullan, 2008). Also, there are possibly other types of interactions involving diazotrophy, such as for the marine diazotroph cyanobacteria *Leptolyngbya nodulosa*, which only express functional nitrogenase when growing together with heterotrophic bacteria (Li et al., 2010).

84.7 OTHER KNOWLEDGE GAPS

84.7.1 Different Ecosystem Roles of Cyanobacterial Diazotrophs

It is likely that the major oceanic diazotroph species have been identified (although the potential of heterotrophs remains unresolved), but we are just beginning to understand the complex ecological roles of each type in an ecosystem context. From a biogeochemical perspective, the obvious role of these diazotrophs is to provide new N to the ocean, but the different types of diazotrophs have different effects and fates. Depending on their lifestyle, some diazotrophs also photosynthesize (such as *Trichodesmium*, *Crocosphaera*) or provide N to photosynthesizing symbiotic hosts (DDAs, UCYN-A), or in the case of heterotrophic diazotrophs, are involved in the breakdown of biomass and CO_2 release. There are ecologically very important differences among different diazotrophs due to the fate of the fixed N (and C). For example, it is assumed that a large share of N fixed by *Trichodesmium* is released as NH_4^+ or DON, and is thus channeled through the dissolved pool/the microbial loop in the mixed layer (Glibert and Bronk, 1994; Mulholland et al., 2004, 2006). In contrast, DDAs have been typically classified as being fast-sinking and thus important in sequestering N and C in the deep ocean (Scharek et al., 1999a, b; Subramaniam et al., 2008; Karl et al., 2012). The unicellular diazotrophs (UCYN-A, *Crocosphaera*) have usually been assumed to mainly channel through the microbial loop, since they are small and thus subject to grazing (Mulholland, 2007). However, with the discovery that UCYN-A is a symbiont of a larger, possibly calcifying eukaryotic alga, the situation appears more complex and the fate of N from organisms such as UCYN-A is unknown. Similarly, *Crocosphaera* strains are different, some of which produce large amounts of exopolysaccharides (Bench et al., 2011; Sohm et al., 2011), which should promote the aggregation and sinking from the surface layer.

Apart from the scarce knowledge about the relative contributions of different species types to N_2 fixation, and in addition to the already-mentioned difficulties in quantifying oceanic N_2 fixation on different temporal and spatial scales, there is very little knowledge about how these diazotroph inputs are coupled with C cycling. Among the photosynthetic diazotrophs, *Trichodesmium* has been studied the most (Mulholland et al., 2006; Mulholland, 2007), and direct CO_2 fixation measurements vary dramatically, with no consistent stoichiometric relationship to the amount of fixed N; this makes it difficult to infer, for example, C fluxes from N_2 fixation measurements, or vice versa, using Redfield stoichiometry (Mulholland, 2007). There is no straightforward way to resolve this except to study the physiologies of each individual diazotroph species and relate this knowledge to biogeochemical forcing. In order to study the elemental stoichiometry in novel UCYN-A symbiotic associations, additional studies are required to understand the ecology of the host species and the physiological regulation of N_2 fixation between the symbiotic partners under different settings. The factors regulating N_2 fixation in free-living and symbiotic diazotrophs, trophic interactions, and the community ecology, in general, will all influence the fate of fixed N and C as well, including the fractions of total diazotroph N inputs that directly fuel either autotrophic or heterotrophic growth.

84.7.2 Coupling of N_2 Fixation to Other Oceanic N Cycle Processes

The complexity of the oceanic N cycle is exemplified by how much we still do not know about the ecology of N_2-fixing microorganisms, despite the immense progress seen in recent years. Consequently, even further away is a good understanding of how different processes in the N cycle are connected and how different nutrient cycles (P, Fe) are interlinked, both at the microscale and at the

scale of ocean basins. One topic of great interest has been to better constrain the main input and loss terms, that is, the interplay between oceanic N_2 fixation and the return flux of N_2 to the atmosphere via denitrification and anammox. Biogeochemical model studies suggested that N_2 fixation and denitrification/anammox should be spatially coupled in the ocean, with active N_2 fixation occurring in relatively cold, partially denitrified, phosphate-rich waters overlying oxygen minimum zones (OMZs), including the Eastern Tropical South Pacific (ETSP) (Deutsch et al., 2007). However, various field campaigns in the ETSP have found very low rates of N_2 fixation, presumably carried out mainly by heterotroph diazotrophs typically occurring at very low abundances (Moutin et al., 2008; Fernandez et al., 2011; Halm et al., 2012). These findings are not in accordance with what the model studies have suggested, and it remains unknown whether heterotroph diazotrophs, or cyanobacteria, episodically occur with higher abundances and fix more N_2, and what energy source heterotrophs use.

84.7.3 Heterotrophic N_2-Fixing Bacteria

Apart from the difficulties in studying heterotroph diazotrophs *in situ* (low abundances, hard to distinguish from contaminants), it is known that they are present in the ocean, and that they express *nifH* (Bostrom et al., 2007; Farnelid et al., 2013). Heterotroph diazotrophs have also been previously cultivated from oceanic surface waters (Maruyama et al., 1970; Werner et al., 1974; Guerinot and Colwell, 1985). However, little is known about the physiology and *in situ* N_2 fixation rates of any specific heterotrophic bacteria. It is difficult to determine the role of heterotrophic bacteria partially because they have usually been studied in the same habitats where cyanobacteria occur (euphotic zone, oxygenated surface waters); environments which appear rather unfavorable for a heterotroph N_2 fixer that presumably needs low O_2 conditions and an adequate supply of carbon for energy. In the upper water column of the oligotrophic oceans, such habitats exist within suboxic microzones of particles, or within zooplankton guts (Braun et al., 1999) or associated with other plankton (Farnelid et al., 2010), but whenever single *nifH* phylotypes are quantified they usually are found in very low abundances relative to cyanobacterial diazotrophs, with few exceptions (Church et al., 2005a). It could be possible that individual phylotypes are very rare but that the sum of many single phylotypes is a quantitatively significant community. The possibility that heterotroph diazotrophs could be symbionts has also been suggested in a number of cases, based on microscopic observations (Farnelid et al., 2010) or on detection of the organism or their *nifH* genes in larger size fractions (Guerinot and Colwell, 1985; Bombar et al., 2013), but a conclusive identification of a symbiosis is lacking. A symbiotic lifestyle would be a possibility for heterotroph diazotrophs to obtain a carbon source for energy from a photosynthetic host, but would also present an O_2 problem.

There are a number of recent reports of heterotroph diazotrophs in OMZs, for example, off Peru, in the Arabian Sea, in the Southern California Bight (Fernandez et al., 2011; Hamersley et al., 2011; Jayakumar et al., 2012), and in the aphotic, anoxic chemocline of the Baltic Sea, where presumably anaerobic heterotroph diazotrophs can reach quite high abundances (up to 10^7 *nifH* gene copies per liter (Farnelid et al., 2013)). It remains to be shown whether these organisms play a significant role in N_2 fixation in these environments, which obviously have more favorable conditions for such diazotrophs and do not contain cyanobacteria. So far, rates measured are relatively low, such as in the Baltic Sea deep waters (Farnelid et al., 2013). Cultivated isolates have been obtained from the Baltic Sea as well (Bostrom et al., 2007; Farnelid et al., 2014), and thus in the near future, genome analyses and physiological experiments might help to better determine their ecological niche.

84.8 CONCLUDING REMARKS

Studies of well-known diazotrophs such as *Trichodesmium*, the recent discoveries of new diazotroph groups, improvements in mathematical modeling and sampling techniques, and increased sampling coverage of the ocean have all improved our understanding of the global significance of oceanic N_2 fixation. While oceanic N_2 fixation undoubtedly plays a key role in global N cycling, challenges remain in answering even basic questions about the organisms and their distributions, the factors that control their abundances and activity, community interactions, and the fate of different diazotrophs in the ocean food webs. The answers to these questions are particularly challenging, since long-term global environmental change, such as ocean acidification, may have many unknown effects on oceanic microbial communities. Comprehensive studies are necessary that combine genomic information, novel sampling techniques, and biogeochemical rate measurements to address questions regarding not only nutrient acquisition but also symbiont–host interactions, grazing, and other ecosystem properties. The continued development and application of new tools and approaches facilitates testing of established paradigms, such as the dominance of oceanic N_2 fixation by *Trichodesmium*, or regulation by abiotic factors such as temperature, oxygen, fixed inorganic N or Fe availability. Methodologies that allow for high resolution- and autonomous detection of key species might help to tackle some of the greatest challenges in achieving adequate sampling coverage, that is, the vastness of the ecosystem at study and the large spatiotemporal variability of the microorganisms inhabiting it. With these new analytical

and instrumentation capabilities, there are likely to be yet more discoveries and surprises that will result to yet more modifications of the paradigms of oceanic N_2 fixation.

Chapter 85

Requirement of Cell Wall Remodeling for Cell–Cell Communication and Cell Differentiation in Filamentous Cyanobacteria of the Order *Nostocales*

Iris Maldener and Karl Forchhammer

Lehrstuhl für Mikrobiologie/Organismische Interaktionen am Interfakultären Institut für Mikrobiologie und Infektionsmedizin der Eberhard-Karls-Universität, Tübingen, Germany

85.1 INTRODUCTION

Cyanobacteria of the order *Nostocales* and *Stigonematales* are the prokaryotes with probably the most highly evolved multicellular properties, which include functionally differentiated cells in a multicellular network (Maldener et al., 2014) (see Fig. 85.1). According to the classification by Rippka et al. (1979) they are classified in Section IV and V. Recent phylogenetic studies based on whole genome sequences show that these two orders form in fact one monophyletic branch (Subclade B1) within the tree of cyanobacteria (Shih et al., 2013). The defining property of this subclade is the formation of multicellular filaments comprising nitrogen-fixing heterocysts (Fig. 85.1). The two orders differ in one morphological feature: formation of true branching is a specificity of the *Stigonematales* (section V), whereas the filaments of *Nostocales* are non-branched (section IV). Only species of the *Nostocales* have so far been used for molecular studies of multicellular development due to the availability of genetic tools (Cohen et al., 1994; Thiel and Wolk, 1987). In particular, the strain *Anabaena* (*Nostoc*) sp. PCC 7120, also known as *Nostoc* sp. PCC 7120, has been widely used to study heterocyst development (Kumar et al., 2010). The strain *Nostoc punctiforme* ATCC 29133 (in the following *N. punctiforme*) has attracted attention due to its complex life style, comprising the ability of symbiotic interactions with various plants and complex differentiation properties (Meeks et al., 2002), and genetic tools for this strain have been developed. For these practical reasons, the following studies on the role of cell-wall modification in multicellular development in the cyanobacteria have been mostly performed with the strains *N. punctiforme* and *Anabaena* sp. PCC 7120.

85.2 REQUIREMENT FOR CELL WALL MODIFICATION DURING HETEROCYST DIFFERENTIATION AND DIAZOTROPHIC GROWTH

Nostoc sp. forms filaments of hundreds of metabolically interacting cells, surrounded by a continuous Gram-negative outer membrane (OM) (Flores and Herrero, 2010; Flores et al., 2006; Lehner et al., 2011; Schneider et al., 2007; Wilk et al., 2011). Under nitrogen-limiting conditions, about 5–10 % of the cells differentiate in a semi-regular pattern into heterocysts, which are specialized cells that provide the micro-oxic compartment necessary for nitrogen fixation. A remodeling of the cell wall seems to be a requisite for the formation of the special envelope of heterocysts. This

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

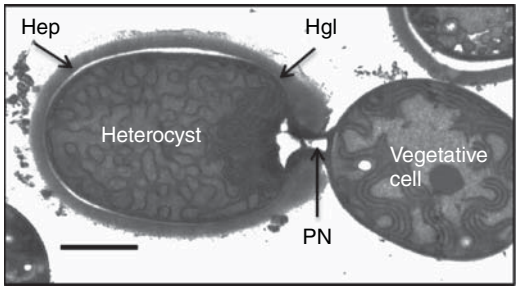

Figure 85.1 Electron micrographs of ultrathin sections of chemically fixed filaments of *Anabaena* sp. PCC 7120 showing the morphological changes in heterocysts: narrow polar neck (PN), envelope of 2 layers: Hgl = glycolipids, Hep = polysacharides. Scale bar = 1 μm.

envelope consists of an outer polysaccharide layer (Hep in Fig. 85.1) and an inner glycolipid layer (Hgl in Fig. 85.1), the barrier for the entrance of oxygen from outside (Wolk et al., 1994). It has been speculated that the transfer of the envelope building blocks from the cytoplasm to the surface requires remodeling of the Gram-negative cell wall, which consists of the peptidoglycan (PG) layer and an outer membrane (Huang et al., 2005; Léganes et al., 2005). Specific transport complexes, such as the DevBCA transporter for the heterocyst glycolipids (Staron et al., 2011), contain periplasmic-spanning channel proteins, which transverse the PG layer and connect to the TolC porine.

Furthermore, the differentiation of heterocysts involves extensive alterations in the shape of the developing cells, in particular in the so-called neck-region connecting to the vegetative cells (PN in Fig. 85.1). Since the shape of the PG sacculus determines the morphology of the cells, it is a necessary consequence that the PG sacculus has to be modified during heterocyst development. It is therefore not surprising that several genes encoding cell-wall processing enzymes are needed for heterocyst development. In *Anabaena* sp. PCC 7120, the following such genes have been identified to be required for heterocyst differentiation: *pbp*2, *pbp*3, *pbp*6, and *hcwA* (Huang et al., 2005; Lázaro et al., 2001; Léganes et al., 2005; Zhu et al., 2001). A mutant in the *conR* gene of *Anabaena* sp. PCC 7120, bearing a LytR-CpsA-Psr domain related to septum formation and cell wall maintenance, cannot grow on N_2 although nitrogenase activity develops. In this mutant the septum between the cells seems to be defective. The protein could be involved in the regulation of septal muramidases (Fan et al., 2005; Mella-Herrera et al., 2011). The functional characterization of other cell wall proteins of *Anabaena* sp. PCC 7120 revealed that they are involved in heterocyst differentiation and function (Nicolaisen et al., 2009). Several PG-binding and cell wall-related proteins were identified, which are highly upregulated under the control of the heterocyst regulator HetR in *Anabaena* sp. PCC 7120 (Mitschke et al., 2011).

Once a functional heterocyst is formed, the products of nitrogen fixation have to be delivered to the neighboring vegetative cells, and conversely, the heterocysts derive carbohydrates from their neighbors (Wolk et al., 1994). The route of the molecules through the individual cell envelopes, which results in highly efficient metabolite and signal exchange between the diverse cells along the filament, has not yet been clarified (Flores and Herrero, 2010; Kumar et al., 2010). In addition to these problems, formation of other types of differentiated cells in *Nostoc* strains, such as the motile hormogonia and the spore-like akinetes, involves structural changes in the cell envelope. A key issue in these processes is the understanding of the role of the PG cell wall. Unfortunately, the structure, biogenesis, and metabolism of PG in cyanobacteria in general, and of the *Nostocales* in particular, have been poorly investigated. For example, until recently it has not been studied how in the multicellular cyanobacteria the cell wall is organized in particular in the region of the septum between neighboring cells. Recently, we set out to address this question and the current review summarizes the essence of these studies.

85.3 THE PG LAYER OF FILAMENTOUS CYANOBACTERIA

The PG of Gram-negative bacteria is a large heteropolymer that consists of linear glycan strands of alternating β-1-4 linked *N*-acetylmuramic acid and *N*-acetylglucosamine, which are connected by peptide bridges of four amino acids. Although the precise architecture of the arrangement of the strands toward each other is still debated (Turner et al., 2013; Vollmer and Seligman, 2010), it is clear that this macromolecule entirely surrounds the cells and determines the cell shape and the stability against turgor pressure of the cells (Margolin, 2009; Vollmer and Bertsche, 2008). In typical Gram-negative bacteria the PG is located between the cytoplasmic membrane (CM) and the OM and has an average thickness of 2,5 nm. Interestingly, cyanobacteria, which belong to the Gram-negative bacteria, have a much thicker murein, ranging from 10 to 700 nm, depending on the strain (Schleifer and Kandler, 1972). Diverse PG synthases and PG hydrolases are involved in PG turnover during cell growth and cell division (Vollmer et al., 2008). At the site of cell division, constriction of the cell goes along with the synthesis of septal PG and the simultaneous formation of two new cytoplasmic membranes.

A first step in cell division in unicellular cyanobacteria as well as in other Gram-negative bacteria is the organization of the divisome machinery at the prospective division site of the cell by the FtsZ ring (Adams and Errington 2009; de Boer, 2010; Mazouni et al., 2004; Miyagishima et al., 2005; Sakr et al., 2006), followed by a constriction of the new septum toward the middle of the cell.

This constriction results in a diminishing annulus in the center of the new septum and finally the CM meeting in the center and separating. Simultaneously, the PG layer is formed by *de novo* synthesis of PG, resulting in one PG layer shared between the originating daughter cells. In *E. coli*, cell division is achieved by splitting of the newly synthesized septal PG from the outside to the center of the septum. Concomitantly with this, newly made OM invaginates into the septum where it is attached to the cleaved PG layers, and finally closes the annulus in the center of the septum (de Boer, 2010). In the process of cleavaging the septal PG, three paralogs of the autolytic enzyme LytC-type N-acetylmuramyl-L-alanine amidase (Pfam: amidase_3) play a prominent role: AmiA, AmiB, and AmiC (Uehara and Bernhardt, 2011; Uehara et al., 2010; Vollmer et al., 2008). Mutants lacking all three amidases fail to split the septal PG and grow in long chains (Heidrich et al., 2002). Interestingly, filamentous cyanobacteria of the order *Nostoc* possess several genes encoding homolog hydrolases, although they apparently do not separate daughter cells following cell division. The function of these amidases is therefore enigmatic, in particular, since it is unknown whether the PG in the septum is split in two layers or remains as a single layer that mechanically connects the neighboring cells. As detailed below, this issue has recently been debated.

The last step of cell division, invagination and fusion of the OM, does not occur during cell division within the filaments of *Nostocales*. Instead, the OM encompasses all cells of the filament without entering the septum, forming a continuous encasement (Flores et al., 2006). Thus, the individual cells possess their own CM, but it is not clear whether cleaving of the PG layer by hydrolytic enzymes and partition between the two cells occurs. In some electron micrographs of chemically fixed filaments, one dark line in the middle of the septum between the CMs of the adjacent cells appears to represent one common PG layer (Flores et al., 2006; Lehner et al., 2013). In contrast, a recent study using the polysaccharide stain ruthenium red revealed two electron dense lines adjacent to the outer face of each CM, and this has been interpreted as representing two separated PG layers (Wilk et al., 2011). To solve the problem, we isolated the pure PG sacculi from filaments of *Anabaena* sp. PCC 7120 and *N. punctiforme* ATCC 29133, respectively, devoid of any proteins and investigated their structure in the light microscope and by TEM. If the septal PG was split, each cell should be surrounded by its own sacculus. Upon sacculus preparation, the filaments should disintegrate into sacculi of individual cells. However, this was not the case. Instead, the sacculi retained the filamentous structure (Fig. 85.2) and the PG was connected at the septum. The filamentous sacculi were not broken at the cross walls but at the thinner lateral sidewalls. A similar result has already been suggested by light micrographs of isolated sacculi of *Anabaena cylindrica* (Dunn and Wolk, 1970).

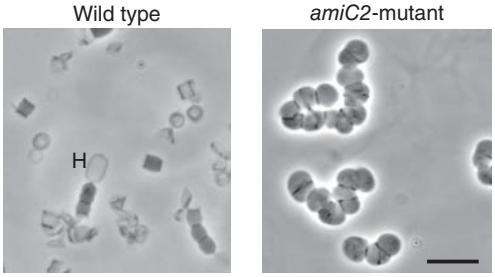

Figure 85.2 Light micrographs of purified sacculi of *N. punctiforme* wild type and the *amiC2* mutant strain: The peptidoglycan represents the shape of the filaments. The peptidoglycan is continuous and not distributed between adjacent cells. Fragmentation of the PG took place during preparation, mostly in the lateral walls. The cell wall of the mutant strain appears more rigid and stable compared to the wild type strain. H = heterocyst. Scale Bar = 10 µm. *Source*: Micrographs by Josef Lehner.

In our TEM analysis, when sacculi were applied in total on coated copper grids, the septa were clearly visible as circular discs defined by a dark ring, which was very stable during sample preparation (see Fig. 85.3). In contrast, the lateral walls were more lightly stained and more labile, resulting again in disruption of the filaments at these sites (Lehner et al., 2013) (Figs. 85.2 and 85.3).

Since "unicellular" sacculi were rarely detected, the PG is not split in the septum as in cell division of unicellular bacteria. In unicellular bacteria, PG splitting is coordinated with OM invagination, suggesting that these processes are interconnected. However, as stated above, the OM does not invade the septum in the *Nostocales*, which is in agreement with the maintenance of a single layered septal PG. Further insights into the cell wall structure of *Nostocales* was obtained by staining the sacculi and the living filaments of *N. punctiforme* with fluorescent vancomycin, which specifically attaches to the non-cross-linked peptides of PG. Using this dye, one common PG layer in the septum could also be visualized. As shown in Figure 85.4, strong staining of the septal PG ring occurred. The non-cross-linked peptide residues that are stained by fluorescent vancomycin are present in those parts of the cell wall where PG synthesis takes place: this is the septal cross wall during cell division. In summary, we propose that the PG sacculus is a macromolecule that surrounds and connects all cells of the filaments with a single layered septal PG that forms a rigid discoidal structure.

85.4 THE NANOPORE ARRAY OF SEPTAL MUREIN

In addition to identifying the overall structure of the PG sacculus of the *Nostocales* filaments, we could identify in those electron micrographs of isolated sacculi an array of

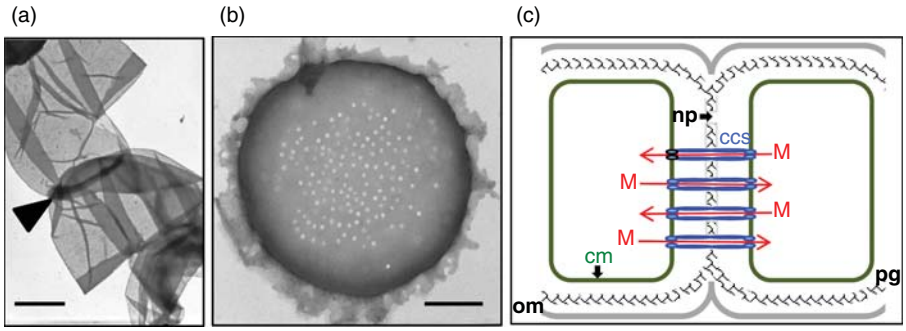

Figure 85.3 The nanopore array of the septal peptidoglycan: electron micrographs of purified sacculi of *N. punctiforme*. A septum is indicated by an arrow head in (a). (b) Isolated septal PG showing the nanopore array. (c) Model of a cross section through the septum between two cells of a filament. np, nano pore; ccs, cell communication structure; M, metabolite; cm, cytoplasmic membrane; pg, peptidoglycan layer; om, outer membrane. Red arrows show transfer of molecules through ccs, anchored in the cm and traversing as protein complexes in the septum through the nanopores with large extracellular domains. Scale bar = 1 µm in (a) and = 300 nm in (b). *Source*: Electron micrographs by Josef Lehner.

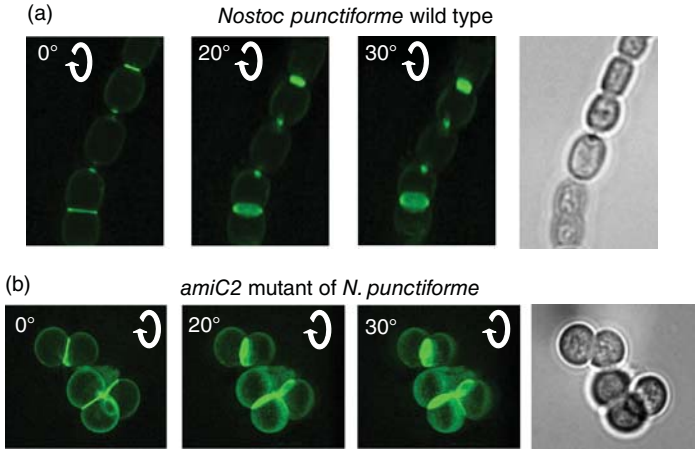

Figure 85.4 *In vivo* fluorescence staining of filaments of *N. punctiforme* wild type strain (a) and the *amiC2* mutant strain (b). Vancomycin, VanFL, strongly labeled the disk-shaped septa in both strains, indicating deposition of new cell wall material and unlinked residues preferentially at the septa. The fluorescence images were created by a deconvolution technique. 0°, 20° and 30° show rotation angles of the image. Bar = 10 µm. *Source*: Micrographs by Josef Lehner.

nanopores in the center of the septal disc (see Fig. 85.3). In addition, in the lateral walls small pores were visible; however, in contrast to the septal array, they were much smaller and irregularly spaced. Similar pores are present in the PG of other bacteria (Turner et al., 2013). The nanopore array, instead, is comprised of roughly 140 nanopores, each 20 nm wide. In some of the pores, dark material was visible, which could be the remnants of non-hydrolyzed PG or proteins, which had escaped chymotrypsin digestion during sacculi preparation (Lehner et al., 2013).

The physiological significance of this nanopore array was revealed by the analysis of mutants in cell-wall hydrolases. We had created mutants of *Anabaena* sp. PCC 7120 and *N. punctiforme* by site-directed mutagenesis of open reading frames *alr0092* (*amiC*1_{Ana}) and NpF1846 (*amiC2*), respectively (Berendt et al., 2012; Lehner et al., 2011). Because of their sequence homology to the cell division protein *N*-acetylmuramyl-L-alanine amidase of *E. coli* (Pfam: amidase_3), these genes were named AmiC. The *Nostoc* AmiC2 mutant strain showed a severe morphological phenotype already under standard growth conditions: Cells were irregularly shaped and the plane of cell division was displaced. Instead of linear filaments, this mutant grows in clumps with clover-leaf-like cell clusters (Fig. 85.4). Furthermore, this mutant is unable to differentiate special cell types (heterocysts, akinetes, and hormogonia) (Lehner et al., 2011). The *Anabaena* AmiC1 mutant strain grew normally as long filaments on a source of combined nitrogen, but was also unable to differentiate heterocysts and hence to grow on N_2 as the sole nitrogen source (Berendt et al., 2012). Since several amidase genes are present in the genomes of these strains, we cannot exclude redundancy with respect to filament morphology in the case of the *Anabaena* mutant. Interestingly, both mutant strains were not able to transport the fluorescent dye calcein in FRAP (fluorescence recovery after photobleaching) studies, indicating lack of cell–cell communication (Mullineaux et al., 2008). Sacculi were prepared from these mutants and analyzed similarly to those of the wild type (see above). Importantly, no nanopores were visible in the septal discs of both mutants (Lehner

et al., 2012, 2013). This indicates that cell wall amidases $AmiC1_{Ana}$ and AmiC2 are involved in the hydrolysis of the PG at specific sites where the nanopores are formed. In other words, they drill holes in the septum, resulting in functional filaments capable of exchanging molecules between cells.

The pores themselves cannot be sufficient to mediate cellular communication, since the CM is closed on both sides of the septum and does not penetrate the septum, as shown clearly in electron micrographs. Instead, the nanopore array in the septal PG could be the framework for cell–cell joining or communication structures, which were suggested in previous studies. Previous ultrastructural analysis of filamentous cyanobacteria revealed connecting structures, which were termed "microplasmodesmata" (Giddings and Staehelin, 1978, 1981; Lang and Fay, 1971; Wildon and Mercer, 1963). The numbers and average diameter of the pores/microplasmodesmata in the studies by Giddings and Staehelin were in the range of our estimations with *N. punctiforme* and *Anabaena* sp. PCC 7120. The nanopore array, as visualized now by the sacculus preparation (Fig. 85.3), provides the first complete view on the arrangement of the connecting structures on the entire septum. Concerning the nomenclature of these structures, we prefer the more general term cell–cell joining structures, since the molecular architecture and composition is not known yet. The term "microplasmodesmata" would imply that the joining structures are direct plasma bridges, delimited by CM, which is, however, not the case (see above).

Candidate channel proteins that are embedded in the nanopores and could form a cell-joining complex are the Fra proteins, which were characterized in *Anabaena* sp. PCC 7120. FraG (also known as SepJ), FraC, and FraD have been localized to the septum of *Anabaena* sp. PCC 7120; mutants of their genes could not grow diazotrophically and their filaments fragmented (Nayar et al., 2007; Flores et al., 2007; Merino-Puerto et al., 2010, 2011; Mariscal et al., 2011). Importantly, these mutants were impaired in molecule exchange between the cells, implying that all three proteins together or separately could form a cell–cell joining complex.

In conclusion, it appears that the cell-wall amidases play a key role in the evolution of multicellular cyanobacteria. These enzymes, which normally are responsible for daughter cell separation, have altered their function: instead of splitting the daughter cells, they perform a fine-tuned remodeling of the septal PG by drilling holes the for insertion of a cell-joining machinery (see model in Fig. 85.3). This structure can be regarded as a prokaryotic organelle for direct cell–cell communication and metabolite exchange. Future studies will focus on the analysis of the septal PG and the mode of function of the amidases in the formation of the nanopore array in *Nostocales*, in context with the Fra-proteins and other factors that conduct the precise and located amidase activity.

Chapter 86

Nitrogen Fixation in the Oxygenic Phototrophic Prokaryotes (Cyanobacteria): The Fight Against Oxygen

Enrique Flores, Antonio López-Lozano, and Antonia Herrero
Instituto de Bioquímica Vegetal y Fotosíntesis, CSIC and Universidad de Sevilla, Seville, Spain

86.1 CYANOBACTERIA AND NITROGEN FIXATION

Cyanobacteria represent a phylogenetically coherent group of organisms that are characterized by their ability to perform oxygenic photosynthesis (Giovannoni et al., 1988). Predecessors of extant cyanobacteria evolved oxygenic photosynthesis more than 2.4 billion years ago (Knoll, 2008), and therefore the history of cyanobacteria parallels in a substantial part the history of life on Earth. In oxygenic photosynthesis, two photosystems, PSI and PSII, work in series to transfer electrons from water to the universal metabolic electron donors, ferredoxin and NADPH (DeRuyter and Fromme, 2008). Splitting of water in a specialized complex (the Oxygen Evolving Complex) that is adjacent to PSII releases oxygen as a byproduct. In all cyanobacteria studied to date but the special *Gloeobacter violaceus*, the photosynthetic reactions occur in intracellular membranes termed thylakoids. This implies that in an oxic environment, the cytoplasm of cyanobacteria not only contains oxygen that may diffuse from the atmosphere into the cell but additionally contains oxygen produced inside the cell. This poses a tremendous burden to those cyanobacteria that perform nitrogen fixation, which is carried out by the extremely oxygen-sensitive enzyme nitrogenase (Gallon, 1981; Fay, 1992; see Chapter 1).

In spite of the unifying character of oxygenic photosynthesis, disparate morphologies are displayed among cyanobacteria, which can be found in an organization ranging from single cells to complex filaments made of long chains of interconnected cells. In a classic taxonomy of cyanobacteria based on the study of pure microbial cultures, Rippka et al. (1979) classified these organisms into five groups termed Sections. Sections I and II comprise unicellular cyanobacteria, in which those belonging to Section I reproduce by binary fission or by budding and those of Section II by multiple fission or by both multiple and binary fission. Sections III, IV, and V include filamentous cyanobacteria, that is, cyanobacteria that make trichomes (chains of cells) that grow by intercalary cell division and reproduce by random trichome breakage or, in some cases, by formation of hormogonia or germination of akinetes. While the filaments of Section III cyanobacteria are composed only of vegetative cells, the trichomes of Section IV and V cyanobacteria contain heterocysts specifically when the organisms grow lacking any source of combined nitrogen, and some strains also form hormogonia or/and produce akinetes (Rippka et al., 1979). While in Sections III and IV cell division occurs only in one plane (perpendicular to the filament axis), in Section V cyanobacteria cell division can take place in more than one plane producing truly branched filaments. Nonetheless, Sections IV and V together comprise a monophyletic group

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

of organisms implying that heterocysts, whose presence is a defining taxonomic character, arose only once in evolution (Giovannoni et al., 1988). It is now well established that heterocysts are sites of nitrogen fixation (Herrero et al., 2013). The capability to fix atmospheric nitrogen is however widespread among cyanobacteria, being exhibited by organisms in the five taxonomic Sections (Rippka et al., 1979). Thus, non-heterocyst-forming as well as heterocyst-forming cyanobacteria, and among the former, unicellular as well as filamentous strains, express nitrogenase activity (Rippka and Waterbury, 1977). Although cyanobacteria diverged relatively early in evolution (Schirrmeister et al., 2011), the widespread presence of nitrogenase-encoding genes in cyanobacteria comes as no surprise given the very early origin of this enzyme in evolution (Fani et al., 2000).

86.2 PHYLOGENETIC ANALYSIS

Our knowledge of cyanobacteria as a group has significantly improved after the sequencing of numerous cyanobacterial genomes, as is the case for living beings in general. As of this writing, about 150 cyanobacterial genome sequences have been completed (see Dagan et al., 2013; Shih et al., 2013). A phylogenetic tree based on 31 concatenated proteins common to all analyzed cyanobacteria unravels seven major clades (clades A to G) in the phylogeny (Shih et al., 2013; see schematic in Fig. 86.1). Of note is the confirmation that heterocyst formers constitute a monophyletic group (clade B1), and that this group is phylogenetically related to groups (B2, B3, A) in which filamentous cyanobacteria are present, consistent with the notion (obvious in any case) that heterocyst formers evolved from a filamentous cyanobacterium (Swingley et al., 2008). In contrast, Sections I and III are widely polyphyletic, and their characteristic genera, such as Section I *Synechococcus* (defined on morphological grounds), are found scattered in the tree. Indeed, filamentous cyanobacteria are found in most clades (in all but clades E and G), consistent with the idea that the ability to form filaments evolved early in cyanobacterial history, although it was lost and regained several times (Schirrmeister et al., 2011). Also of note is that within clade C, no filamentous cyanobacterium is found in subclade C1, which is constituted by the abundant marine unicellular cyanobacteria of the genera *Synechococcus* and *Prochlorococcus*. Finally, most Section II cyanobacteria cluster together in subclade B2, but one sequenced strain is found in subclade B1.

The distribution of the genes encoding nitrogenase and accessory proteins can be traced in the sequenced genomes (Dagan et al., 2013; Shih et al., 2013). Figure 86.1 shows that cyanobacteria bearing the nitrogenase genes are scattered throughout the phylogenetic tree, although they are not present in clades E and F or in subclades C1 and C2. Very frequent occurrence of nitrogenase genes can be

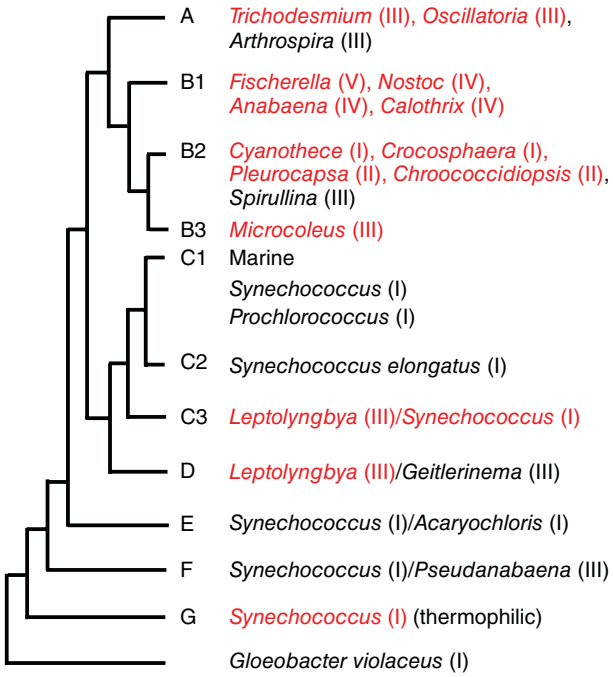

Figure 86.1 Schematic of the phylogenetic tree of cyanobacteria (based on the phylogenetic analysis published by Shih et al., 2013). The tree recognizes seven major clades, with clades B and C further divided in subclades. *Gloeobacter violaceus*, which lacks intracellular thylakoids, is apart from all other known cyanobacteria. Some characteristic genera are indicated for each clade or subclade, and the taxonomic Section of Rippka et al. (1979) to which they belong is indicated in roman numerals (I to V). Nitrogen fixing organisms (demonstrated or predicted from the presence of the *nif* genes in their genomes) are indicated in red. Phylogenetic distances are not depicted.

noticed in the upper part of the tree, which includes clades A and B that contain strains belonging to the five taxonomic Sections. The phylogeny of nitrogenase does not match, however, that of the organisms, likely reflecting that events of horizontal gene transfer have been relatively common in the evolution of cyanobacteria contributing to the current distribution of the capability to fix nitrogen among these organisms (Swingley et al., 2008). The *nif* genes encoding nitrogenase and genes encoding some nitrogen fixation auxiliary proteins are generally found clustered together in the genomes of nitrogen-fixing cyanobacteria (see examples in Fig. 86.2a, b). In some heterocyst-forming cyanobacteria, *nifD* and *fdxN* are interrupted by DNA elements that are removed during heterocyst differentiation (Golden et al., 1991; Carrasco et al., 1994) resulting in *nif* gene clusters that are similar to those of other cyanobacteria (Fig. 86.2c). In these clusters, the presence of the nitrogenase structural genes *nifHDK*, the nitrogenase Fe-Mo cofactor biosynthesis genes *nifEN*, *nifX*, and *nifBSU* (Rubio and Ludden, 2008; see Chapter 7), as well as ferredoxin-encoding genes, is

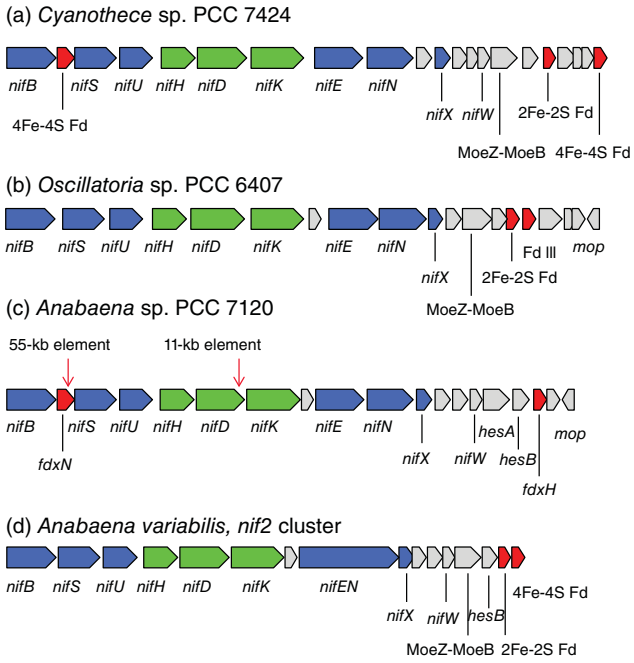

Figure 86.2 Nitrogen fixation gene clusters of cyanobacteria. (a) *nif* gene cluster from *Cyanothece* sp. strain PCC 7424 (redrawn from the genomic sequence; http://img.jgi.doe.gov/). In addition to some identified *nif* genes, there are genes encoding ferredoxins (Fd), a molybdenum cofactor-related protein of the MoeZ-MoeB type and hypothetical proteins. (b) *nif* gene cluster from *Oscillatoria* sp. strain PCC 6407 (redrawn from the genomic sequence; http://img.jgi.doe.gov/). *mop* encodes a molybdopterin-binding protein. (c) *nif* gene cluster from *Anabaena* sp. strain PCC 7120 (drawn from information in the literature; see Böhme, 1998). *hesA* encodes a molybdopterin biosynthesis protein (similar to MoeZ-MoeB proteins) and *hesB* encodes a protein related to iron–sulfur cluster biogenesis. The *nifVZT* genes are in a different chromosome location (see Böhme, 1998). (d) *nif2* gene cluster from *Anabaena variabilis* ATCC 29143 (redrawn from the genomic sequence; http://img.jgi.doe.gov/). This organism also contains a gene cluster (*nif1*) similar to that of *Anabaena* PCC 7120, but lacking the *fdxN* 55-kb intervening element, and *vnf* genes (see the text). Color code: green, nitrogenase structural genes; blue, biosynthesis of the Fe–Mo cofactor genes; red, ferredoxin genes.

evident (Fig. 86.2). Clustering of related genes can facilitate coordinated regulation of gene expression, but it could also reflect that those genes were jointly received as a package (or gene-cassette) from a heterologous biological source.

86.3 STRATEGIES OF NITROGEN FIXATION

In the initial characterization of cyanobacteria, the heterocyst-forming strains proved to be aerobic nitrogen fixers, since they were able to grow readily in the absence of combined nitrogen (Rippka et al., 1979). A few unicellular strains of *Gloeocapsa* (now known as *Gloeothece* sp.) were also observed to grow fixing N_2 aerobically (Rippka et al., 1979). Nonetheless, the question arose whether, as is the case for many free-living nitrogen-fixing bacteria, other strains could fix nitrogen under anoxic conditions. *Plectonema boryanum*, a Section III cyanobacterium, was found to fix nitrogen and grow using N_2 as the nitrogen source when incubated in a gas phase without added oxygen, indicating that there are anaerobic fixers, or perhaps organisms capable of nitrogen fixation under micro-oxic conditions, among cyanobacteria (Stewart and Lex, 1970). Rippka and Waterbury (1977) developed a test in which the cells, after being forced to accumulate glycogen, were subjected to strict anaerobic conditions (including inhibition of PSII by DCMU) and checked for the ability to reduce acetylene to ethylene as an indication of nitrogenase activity. The expression of nitrogenase under such anaerobic conditions was found widespread among the cyanobacteria (Rippka and Waterbury, 1977), consistent with the presence of nitrogen fixation genes widespread in the phylogenetic tree of cyanobacteria as discussed above. However, an important question is whether these cyanobacteria that can fix N_2 under artificial anoxic conditions do so in natural habitats, such as anoxic sites that may exist within some microbial mats, or are somehow able to fix N_2 aerobically. Some cyanobacteria that may fix N_2 anaerobically are those of the genus *Oscillatoria* that bear nitrogen fixation genes and can perform anoxygenic photosynthesis, which is based on inhibition of PSII by H_2S, which provides electrons to PSI (Padan, 1979).

86.3.1 Temporal Separation

Determination of nitrogenase activity (acetylene reduction) and photosynthetic oxygen evolution in batch cultures of *Gloeothece* sp. or *P. boryanum* (under micro-oxic conditions for the latter) showed that nitrogenase and photosynthesis were highest at different times in the cultures (Gallon et al., 1974; Misra and Tuli, 2000), indicating that a temporal separation of both processes could be a mechanism to make them compatible. Introduction of diel light–dark periods in these studies further clarified this mechanism, since nitrogenase activity was found mainly in darkness whereas photosynthesis was, of course, restricted to the light periods (Gallon, 1981). This temporal separation of nitrogenase activity and oxygenic photosynthesis in non-heterocyst-forming cyanobacteria has been amply documented thereafter in both unicellular and filamentous cyanobacteria (see, e.g., Stal and Krumbein, 1985; Mitsui et al., 1986; Colón-López et al., 1997; Compaoré and Stal, 2010; Mohr et al., 2013).

Because nitrogen fixation requires a reductant and energy in the form of ATP, the question arises of how nitrogenase is metabolically supported. In *Cyanothece*, nitrogenase activity requires respiration rather than photosynthesis, which is manifest in a strict dependence on O_2

levels that have to be high enough to support respiration but not as high as to inhibit nitrogenase (Maryan et al., 1986). Indeed, nitrogenase activity and respiration coincide in the dark period of light–dark cycles (Colón-López et al., 1997). Respiration has the additional role of decreasing the intracellular concentration of O_2, which is reduced by terminal respiratory oxidases including cytochrome *c* oxidases, in order to diminish damage to nitrogenase (Toepel et al., 2008). Respiration in turn depends on carbohydrate accumulated in the form of glycogen during the period of photosynthetic activity (Mitsui et al., 1986; Schneegurt et al., 1994). *Cyanothece* sp. strain ATCC 51142 is an aerobic N_2-fixing unicellular cyanobacterium in which detailed gene expression, transcriptomic and proteomic studies have been performed (Colón-López et al., 1997; Toepel et al., 2008; Aryal et al., 2011). It is of interest for our discussion that these studies have shown that photosynthesis, ATP synthase, CO_2 fixation, and glycogen biosynthesis genes are expressed in the light period of light–dark cycles. In contrast, glycogen degradation, respiration, and *nif* genes are expressed entering the dark period (in the case of the respiration genes) or within the dark period. Soon after nitrogenase peaks in this period, a nitrogen reserve material, cyanophycin (multi-L-arginyl-poly-L-aspartic acid), accumulates, which is subsequently utilized during the light period (Li et al., 2001).

Studies on thermophilic, aerobic N_2-fixing unicellular *Synechococcus* spp. in a natural site (a microbial mat) have shown a rise in *nif* transcripts in the evening, with a subsequent decline during the night (Steunou et al., 2008). Interestingly, however, the level of the NifH polypeptide remained stable during the night and only declined when the mat became oxic in the morning. Thus, it is well established that under natural diel cycles, many nitrogen-fixing, non-heterocyst-forming cyanobacteria separate nitrogen fixation and photosynthesis in time. Conditions can be established, nonetheless, for example by manipulating oxygen levels, under which some of these cyanobacteria can fix nitrogen under illumination (see, e.g., Ortega-Calvo and Stal, 1991; Compaoré and Stal, 2010), and variations in the rhythms of respiration and nitrogen fixation have been noted between related cyanobacterial strains (Bandyopadhyay et al., 2013).

In diel light–dark cycle studies with aerobic N_2-fixing unicellular cyanobacteria such as *Cyanothece* sp. strains PCC 8801 (formerly known as *Synechococcus* sp. strain RF-1) and ATCC 51142, it became clear that when the incubation is changed to continuous light, rhythmicity in the expression of *nif* genes and some other genes is maintained to some extent (see, e.g., Mitsui et al., 1986; Colón-López et al., 1997; Huang et al., 1999). These observations imply a circadian regulation of the expression of genes relevant for diazotrophy in these aerobic N_2-fixing cyanobacteria, and as many as 10% of the genes in the genome of a cyanobacterium such as *Cyanothece* sp. strain ATCC 51142 exhibit a circadian behavior (Toepel et al., 2008). Thus, the oscillation required to keep nitrogenase activity restricted to periods in which photosynthesis is not operative appears to be connected to the circadian clock. It is of note that circadian control has been investigated in depth in a unicellular cyanobacterium, *Synechococcus elongatus* (Dong et al., 2010).

86.3.2 Spatial Separation

Different physiological behaviors are found concerning the expression of nitrogenase activity among non-heterocyst-forming filamentous (Section III) cyanobacteria (Fay, 1992; Bergman et al., 1997). Nonetheless, some strains belonging to this group show the diel variation described above for unicellular aerobic N_2 fixers confining nitrogenase activity to the dark period (see, e.g., Stal and Krumbein, 1985). A strikingly different organism is, however, *Trichodesmium* sp., a globally important oceanic N_2 fixer (Bergman et al., 2013; see Chapter 84). Direct comparison shows that, in contrast to *Cyanothece* nitrogenase activity that peaks in the dark, *Trichodesmium* nitrogenase activity peaks during the light period of a light–dark cycle (see Fig. 2 in Bergman et al., 1997). *Trichodesmium* does not produce heterocysts, making its capability to fix N_2 in the light puzzling. Confining nitrogenase expression to some central zones in the filament, in which photosynthesis and CO_2 fixation appear to be downregulated, seems to be the solution (for a recent review, see Bergman et al., 2013). These zones consist of rows of 10 to 20 cells, termed "diazocytes," which have a lighter pigmentation than other cells in the filament and in which a nitrogenase protein such as NifH and a respiratory protein such as cytochrome *c* oxidase can be immunolocalized at increased levels (Bergman et al., 1993). The frequency of diazocytes changes in diel cycles (Sandh et al., 2009). Whether diazocytes are genuine differentiated cells or are cells transitionally devoted to nitrogen fixation is under debate (Bergman et al., 2013; Stal and Zehr, 2008). In addition to this spatial separation, *Trichodesmium* also appears to segregate CO_2 fixation and N_2 fixation during the day, with transient accumulation of fixed nitrogen in cyanophycin (Finzi-Hart et al., 2009).

As is the case with *Trichodesmium*, in studies involving diel light–dark cycles heterocyst-forming cyanobacteria normally fix N_2 in the light (Gallon, 1981). Heterocyst formers represent the paradigm of spatial separation of photosynthesis and N_2 fixation (Flores and Herrero, 2010), which is discussed below. Heterocyst differentiation and the capability to fix N_2 in any type of non-heterocyst-forming cyanobacterium develop only when the organism faces conditions of nitrogen deficiency, lacking any source of combined nitrogen. Thus, two main mechanisms appear to regulate nitrogenase gene expression in cyanobacteria: the circadian control referred

to earlier and nitrogen control. The latter has been mainly investigated in relation to heterocyst differentiation. On the other hand, the detailed studies on control of *nif* gene expression by oxygen that have been done in other nitrogen-fixing organisms have not been done in cyanobacteria.

86.4 NITROGEN FIXATION IN HETEROCYST-FORMING CYANOBACTERIA

A remarkable solution to carrying out the incompatible processes of oxygenic photosynthesis and nitrogen fixation at the same time is the confinement of each activity in a different cell type, as found in the filamentous, heterocyst-forming cyanobacteria. The heterocysts have been shown to contain most, if not all, of the nitrogenase enzyme of a diazotrophic filament and to be the sites of expression of *nifHDK* (reviewed in Herrero et al., 2013; see Fig. 86.3). Under conditions of combined nitrogen scarcity, some cells located at defined positions in the filament differentiate into heterocysts through a complex process that results in cessation of photosynthetic water splitting and expression of the machinery for N_2 fixation. In contrast, in the diazotrophic filament, the vegetative cells keep the capability to perform oxygenic photosynthesis. Therefore, in these cyanobacteria diazotrophic growth depends on the activity of two interdependent cell types: the vegetative cells that perform oxygenic photosynthesis and fix the bulk of CO_2 and the heterocysts that fix N_2. Thus, heterocyst-forming cyanobacteria represent a case of truly pluricellular bacteria with different cell types that are specialized in specific nutritional tasks and contribute to the performance of the filament as the organismic unit (Flores and Herrero, 2010).

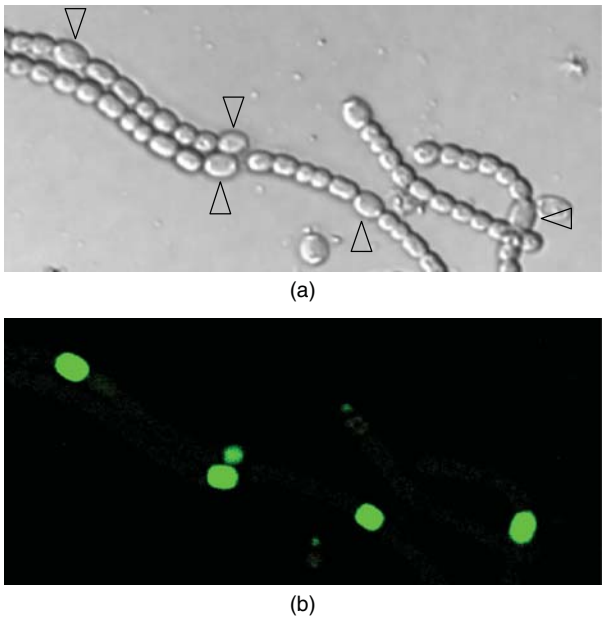

Figure 86.3 Localized expression of a *nif* structural gene in the heterocysts. Bright field (a) and GFP fluorescence (b) micrographs of a filament suspension of a derivative of *Anabaena* sp. strain PCC 7120 bearing in the chromosome the *gfp-mut2* gene fused to the 5′ region of *nifH* (strain CSAM138). The suspension was incubated in $BG11_0$ medium (without combined nitrogen) for 13 h and the GFP fluorescence was visualized by standard methods (see, e.g., Olmedo-Verd et al., 2006). Note that GFP fluorescence originates from heterocysts, which are marked by arrowheads in the upper panel. Strain CSAM138 constructed and micrographs taken by Alicia M. Muro-Pastor in the authors' laboratory.

86.4.1 Intercellular Communication in the Diazotrophic Filament

In relation to the cell specialization established in the diazotrophic filament, growth depends on molecular exchanges between the different cell types. The vegetative cells transfer to the heterocysts fixed carbon in the form of some metabolites, of which sucrose (López-Igual et al., 2010; Vargas et al., 2011) and alanine (Pernil et al., 2010) are likely vehicles that serve as reductant and energy sources, whereas glutamate serves as a skeleton for the incorporation of the ammonium resulting from N_2 fixation (Thomas et al., 1977). In turn, the heterocysts donate to the vegetative cells fixed nitrogen, with some amino acids such as glutamine and cyanophycin-related metabolites (aspartate, arginine, and the aspartyl-arginine dipeptide) being likely nitrogen vehicles (Herrero et al., 2013; Burnat et al., 2014). In addition, signaling molecules, such as a PatS morphogen that is involved in determining the pattern of heterocyst distribution along the filament, are also intercellularly transferred (Yoon and Golden, 1998; Corrales-Guerrero et al., 2013).

The precise mechanism(s) of intercellular molecular exchange are unknown, but recent work has identified possible paths of transfer. The cyanobacteria are diderm bacteria bearing an outer membrane outside of the cytoplasmic membrane and the peptidoglycan layer (Flores and Herrero, 2010). In the heterocyst formers, the outer membrane is continuous along the filament defining a continuous periplasmic space that might represent a communication conduit between the cells in the filament (Mariscal et al., 2007). On the other hand, some channels permitting direct communication between cells that can be probed with fluorescent tracers appear to exist (Mullineaux et al., 2008). In the model heterocyst-forming cyanobacterium *Anabaena* sp. strain PCC 7120 (hereafter *Anabaena* PCC 7120), proteins located at the intercellular septa in the filaments have been identified that appear to be part of those channels. These are SepJ (Mariscal et al., 2011) and FraCD (Merino-Puerto et al., 2011), which would constitute two different types of channels. Which molecules are intercellularly transferred

through the periplasmic space (if any) or through each of these proteinaceous channels remains to be established.

86.4.2 The Heterocyst

The differentiation of the cyanobacterial heterocyst is a complex process producing cells with multiple morphological and biochemical differences compared to the vegetative cells. These differences are aimed at increasing the efficiency of the process of N_2 fixation and its protection against external O_2. The heterocyst bears special layers in the cell envelope that are outside of the outer membrane and represent a barrier for the penetration of gases, notably O_2, into the cytoplasm: a layer of specific glycolipids and, external to it, a layer of specific polysaccharides (Walsby, 2007; Flores and Herrero 2010). Indeed, many mutant strains have been isolated, which, as the result of impairment in the synthesis or deposition of any of these layers, lose the ability to fix N_2 under aerobic conditions, although they can fix under anoxic conditions (Herrero et al., 2013). Heterocysts are connected with the neighboring vegetative cells by narrowed septa exhibiting a differentiated structure that allows intercellular molecular exchanges while keeping a minimum surface of cell-to-cell contact, which would hamper oxygen permeation into the heterocyst (Walsby, 2007).

Regarding metabolism, associated to conspicuous reorganization of the internal thylakoid membranes, the heterocysts lack activity of oxygenic photosynthesis although they exhibit photosynthetic activity based on PSI. They also lack ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco), and thus photosynthetic CO_2 fixation, which enables directing the available ATP and reductant to the reduction of N_2. On the other hand, heterocysts have increased levels of sugar catabolic enzymes including a specific invertase, InvB (López-Igual et al., 2010; Vargas et al., 2011), enzymes of the oxidative pentose phosphate pathway such as glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase, and specific terminal respiratory oxidases such as Cox2 and Cox3 (reviewed in Herrero et al., 2013). The increased respiratory activity of the heterocysts is related to the metabolism of sugars such as sucrose received from the vegetative cells, and serves to scavenge traces of O_2 that could have penetrated into the cells. The heterocysts also have a specific membrane-bound (NiFe)-uptake hydrogenase that recycles H_2 produced in the nitrogenase reaction and contributes, through respiration, to O_2 scavenging (Bothe et al., 2010). Additional mechanisms to protect nitrogenase from oxygen or oxygen-reactive species appear to exist. Flavodiiron proteins induced specifically in the heterocyst have recently been described that may protect N_2-fixing enzymes by reducing molecular oxygen directly to water (Ermakova et al., 2013). A rubrerythrin (RbrA) that participates in the reduction of H_2O_2 with NADPH in a reaction that depends on ferredoxin:$NADP^+$ oxidoreductase is expressed in the heterocysts of *Anabaena* PCC 7120, where it has been suggested to protect nitrogenase (Zhao et al., 2007).

In the heterocysts, a number of pathways contribute to the ATP pool used mainly to drive N_2 fixation and the incorporation of the resulting NH_4^+ into C skeletons. ATP can be produced photosynthetically by cyclic photophosphorylation through PSI or by oxidative phosphorylation using H_2, with the concourse of the uptake hydrogenase, or reduced pyridine nucleotides resulting from carbohydrate catabolism. Indeed, a *Nostoc* sp. ATCC 29133 mutant of the *zwf* gene encoding glucose-6-phosphate dehydrogenase fails to grow diazotrophically, stressing the importance of this route (Summers et al., 1995). Electrons from H_2 and reduced pyridine nucleotides can be also used to reduce, either via PSI or through ferredoxin:$NADP^+$ oxidoreductase, a ferredoxin that donates electrons directly to nitrogenase. The *fdxH* gene encodes a heterocyst-specific [2Fe–2S] ferredoxin, which is a principal electron donor to nitrogenase in these cells (Böhme and Haselkorn, 1988; Masepohl et al., 1997). The ammonium resulting from N_2 reduction is incorporated by glutamine synthetase, of which heterocysts bear high activity, into glutamate received from vegetative cells (reviewed in Herrero et al., 2013). In addition to transferring nitrogen to vegetative cells, heterocysts conspicuously accumulate the nitrogen reservoir cyanophycin, which is visible as granules located at the heterocyst poles where it could serve the role of a nitrogen buffer (Sherman et al., 2000).

86.4.3 Nitrogen Fixation Genes in Heterocyst-Forming Cyanobacteria

All heterocyst-forming cyanobacteria studied to date bear nitrogen fixation gene clusters encoding a Mo-dependent nitrogenase system similar to that of other well-studied diazotrophic bacteria (Fig. 86.2c), which is expressed specifically in the heterocysts (see Böhme, 1998). The genes for this conventional Mo-nitrogenase were first identified by heterologous hybridization (see, e.g., Haselkorn et al., 1983) and later by genome sequencing. Nitrogen fixation has been most extensively studied in two strains, the essentially photoautotroph *Anabaena* PCC 7120 and the facultative heterotroph *Anabaena variabilis* ATCC 29413. In *Anabaena* PCC 7120, a recent transcriptomic study has shown that expression of genes in the nitrogenase gene cluster takes place at high levels after 21 h of incubation of the filaments in the absence of combined nitrogen (Flaherty et al., 2011). In *Anabaena* PCC 7120, it had been described previously that, after excision of the 55-kb DNA element from inside *fdxN*, *nifB*, *fdxN*, *nifS*, and *nifU* could be cotranscribed in the absence of combined nitrogen from a transcription start point (TSP) located 189 nucleotides upstream from the *nifB* start (Mulligan and Haselkorn, 1989). After excision of the

11-kb DNA element from inside *nifD*, the *nifH*, *nifD*, *and nifK* genes were also described to be cotranscribed from a TSP located 128 upstream from *nifH* (Golden et al., 1991). Indeed, transcripts that include the messages of *nifH*, *nifHD*, *and nifHDK* are readily detected (e.g., Valladares et al., 2007). Recently, in studies performed in *A. variabilis* the detected transcripts including the messages of *nifHDK* alone have been described to result from processing of larger transcripts that originate from promoters located inside *nifU* and, principally, upstream of *nifB* (Ungerer et al., 2010; Pratte and Thiel, 2014). These results cast doubt on the actual location of the promoter(s) for *nifHDK* expression also in *Anabaena* PCC 7120.

Besides the heterocyst-specific Mo-nitrogenase that is similar to that of *Anabaena* PCC 7120 (Nif1), *A. variabilis* bears another gene cluster (*nif2*; Fig. 86.2d) encoding a second Mo-enzyme system that is expressed in all cells of the filament but only under anoxic conditions (Schrautemeier et al., 1995; Thiel et al., 1995). The molecular mechanism for the possible oxygen control of the expression of the *nif2* gene cluster is unknown. Expression of Nif2 nitrogenase under anoxic conditions appears not to prevent heterocyst differentiation or expression of the Nif1 system, so that both can be simultaneously expressed under those conditions. The Nif2 nitrogenase system is the product of a gene cluster that has an organization similar to that of the *nif1* cluster (Thiel et al., 1997). In addition, *A. variabilis* bears genes similar, although with some differences in their organization, to the *vnfDGK* genes of *Azotobacter vinelandii* encoding a V-dependent nitrogenase (Vnf) (Kentemich et al., 1988; Thiel, 1993). In *A. variabilis*, the genes *vnfG* and *vnfD* are fused into a single gene designated *vnfDG*, and *vnfH* is located in a different genomic region. The *vnfDGK* genes, on the one hand, and the *vnfEN* genes, on the other hand, are expressed in the absence of ammonium and Mo, with or without vanadium, the former ones producing transcripts that would correspond to *vnfDG* and *vnfDGK* (Thiel, 1993, 1996; Pratte et al., 2013). The *vnfEN* genes of *A. variabilis* show higher similarity to the *vnfDK* genes of the same organism than to the *vnfEN* genes of *A. vinelandii*, thus pointing to an origin of the *Anabaena* genes by genomic duplication rather than by lateral transfer together with *vnfDK* (Thiel, 1996). The *nifB* gene in the *nif1* gene cluster, which is expressed irrespective of the presence of Mo and V in the external medium, is required for the activity not only of the Nif1 enzyme, but also of the Vnf nitrogenase (Lyons and Thiel, 1995).

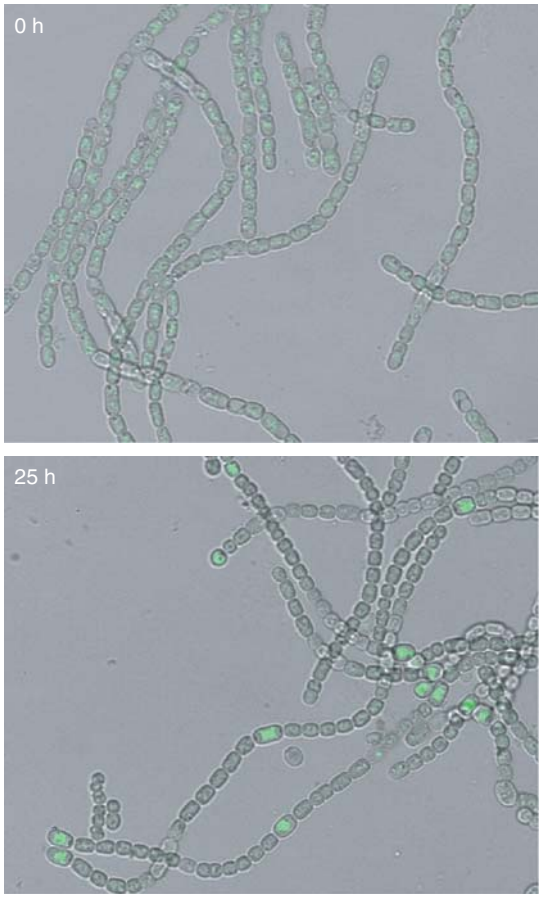

Figure 86.4 Localization of NtcA in filaments of *Anabaena* sp. strain PCC 7120. The *gfp-mut2* gene (stop codon removed) was linked to the 5′ end of *ntcA* (start codon removed) by a sequence encoding a four-Gly linker, producing a gene that encodes a fusion GFP-NtcA protein. *Anabaena* strain CSAL23, in which the *gfp-mut2-ntcA* fusion gene replaces *ntcA*, was grown in $BG11_0$ medium supplemented with ammonium as a nitrogen source (0 h) and subsequently incubated for 25 h in $BG11_0$ medium lacking any source of combined nitrogen. A merge of bright field and GFP fluorescence images is shown. Note that GFP-NtcA can be detected at low levels in all the cells of the ammonium-grown filaments and, upon incubation without combined nitrogen, at increased levels specifically in heterocysts.

86.4.4 Regulation of Gene Expression During Heterocyst Differentiation

The conspicuous structural and metabolic differences between the two cell types of the diazotrophic filament of heterocyst-forming cyanobacteria are the result of a distinct program of gene expression displayed during the developmental process that includes the differentiation of the heterocysts. This program involves the activation or repression of hundreds of genes specifically in the differentiating cells and at specific times throughout the differentiation process (Herrero et al., 2013). The serial gene expression activation is orchestrated by two principal transcriptional regulators, the global regulator NtcA, which is a member of the CRP/FNR family of transcription factors (Herrero et al., 2004; Zhao et al., 2010), and the differentiation-specific factor HetR, which does not exhibit similarity to any other known protein (Buikema and Haselkorn, 1991; Kim et al.,

2011). The differentiation process responds to the external cue of combined nitrogen scarcity and is initiated when NtcA perceives a condition of high carbon-to-nitrogen balance, signaled by high levels of 2-oxoglutarate, which is a positive effector of the regulator (Valladares et al., 2008; Zhao et al., 2010). Mutual activation of the expression of the *hetR* and *ntcA* genes by NtcA and HetR (Muro-Pastor et al., 2002), potentiated by autoregulation (Black et al., 1993; Buikema and Haselkorn, 2001; Olmedo-Verd et al., 2006), leads to increased levels of NtcA and HetR in the differentiating cells. At least the NtcA levels appear to remain high in the mature heterocysts (Fig. 86.4). Accumulation of NtcA and HetR allows for direct induction of some genes during the early and medium stages of differentiation (see, e.g., Camargo et al., 2012; reviewed in Herrero et al., 2013), including genes for other regulators that co-operate with NtcA in the induction of late genes, among them the *nif* genes.

Expression of the genes encoding the N_2 fixation system is integrated in the heterocyst differentiation program, thus responding to the external cue of nitrogen availability. Indeed, *nif* gene expression seems not to be regulated by the intracellular O_2 levels (Elhai and Wolk, 1990), consistent with the fact that *nifHDK* expression is unaltered in mutants of *Anabaena* PCC 7120 lacking one or both of the heterocyst-specific terminal respiratory oxidases, Cox2 and Cox3 (Valladares et al., 2007). Transcription of *nifHDK* requires NtcA (Frías et al., 1994), which can bind *in vitro*, although with low affinity, to sequences in the intergenic region between *nifU* and *nifH* (Valladares et al., 1999). However, if this region were not to include a promoter for *nifHDK* expression, as reported for *A. variabilis* (Ungerer et al., 2010), the role of NtcA binding at this location would be unresolved. The *pipX* gene encodes a small protein only found in cyanobacteria that interacts with NtcA (Llácer et al., 2010). In *Anabaena* PCC 7120 *pipX* is expressed specifically in the cells differentiating into heterocysts at medium-to-late stages of the process, and PipX is required for normal diazotrophic growth (Valladares et al., 2011). In a mutant strain lacking PipX, expression of *nifHDK*, as well as of some other late heterocyst-differentiation genes tested, is severely impaired and retarded with regard to the wild-type strain (Valladares et al., 2011). Thus, PipX is a co-activator of NtcA to promote gene induction during the last steps of differentiation, consistent with a direct positive role of NtcA in *nifHDK* expression. Delayed transcription of *nifHDK* and *fdxH* are also observed in a mutant of the group 2 sigma factor SigE, implicating this sigma factor, which is upregulated late in differentiating heterocysts, in *nifHDK* induction (Mella-Herrera et al., 2011). Unraveling the precise mechanism for activation of the *nif* genes in the heterocyst, including the action of NtcA, PipX, and SigE, will be of much interest in the study of diazotrophy in these unique organisms.

86.5 CONCLUDING REMARKS

The literature summarized in this review indicates that the capability to fix N_2 is widespread in cyanobacteria. Because oxygenic phototrophy is the dominant metabolic mode of these organisms, strategies to make compatible N_2 fixation and oxygenic photosynthesis have been selected in evolution. Temporal separation of the two processes, with an evident circadian regulation that adapts metabolic processes to the appropriate periods of our planet's diel cycle, is widely used. In filamentous cyanobacteria, spatial separation restricting N_2 fixation to some cells in the filament is also found. This strategy permits N_2 fixation when the cyanobacteria are metabolically most active, in the light. In the case of heterocyst-forming cyanobacteria, the strategy of spatial separation has led to the development of one of the simplest multicellular systems known in the living world. Much has been learnt in recent years on these N_2-fixing systems, but some key aspects remain to be explored. These include molecular details of regulation of *nif* gene expression linked to the circadian clock and, in the case of heterocyst formers, to developmental control. In heterocyst formers, structural and functional details of the operation of intercellular molecular exchange in the diazotrophic filament are also major research issues for future research.

87.1 INTRODUCTION

Biological N_2-fixation is the largest source of fixed-nitrogen input into the ocean and controls marine primary productivity on geological timescales (Falkowski, 1997; Duce et al., 2008). Yet, estimates indicate a greater total oceanic N-loss than N-gain when extrapolated from discrete measurements (Codispoti, 2007; Deutsch et al., 2007). This discrepancy could be ascribed to either an overestimation of N-loss, which even with the most conservative calculations has been considered to be unlikely; or to an underestimation of the N-gain term (see Chapter 84). One general difficulty with calculating the N-gain term is that global estimates are mainly based on N_2-fixation by photoautotrophic diazotrophs in surface waters (~100–200 Tg N/a), consequently underestimating the global N-gain by not considering a large part of the diazotrophic habitat. These measurements of N_2 fixation cannot balance the nitrogen N-loss (~400 Tg N/a) (Karl et al., 2002; Codispoti, 2007) resulting from microbial processes such as anammox (anaerobic oxidation of ammonium with nitrite to N_2 (Dalsgaard et al., 2003; Kuypers et al., 2003)) as well as denitrification (the 4-step reduction of nitrate to N_2 (Falkowski 1997; Codispoti 2007)).

Over the past years, molecular techniques have led to the discovery of a variety of previously unrecognized diazotrophs in oceanic niches previously not regarded important for N_2-fixation (Hamersley et al., 2011). Those diazotrophs have been demonstrated to express their nitrogenase (*nif*) genes and fix N_2, and might therefore significantly contribute to oceanic N_2-fixation (Löscher et al., 2014; see Chapter 84); however, they have previously not been considered for the oceanic N-budget. The discovery of N_2-fixation in mesopelagic waters in the Pacific (Fernandez et al., 2011; Farnelid et al., 2011; Turk et al., 2011) and the possibility of significant involvement of heterotrophic bacteria in global marine N_2-fixation reinforce the idea that a large term of global marine N input by N_2-fixation is clearly underestimated, mainly by not considering niches other than the oligotrophic ocean surface (e.g., OMZs).

In addition, an experimental bias regarding N_2-fixation rate measurements has been identified (Mohr et al., 2010). Those measurements account for ~90% of the geochemically derived estimates (Falkowski, 1997); thus, obtaining correct rates is highly important when estimating the N input. Classically, direct measurements of N_2-fixation rates are obtained either using the $^{15}N_2$-tracer addition method

Biological Nitrogen Fixation, Volume 2, First Edition. Edited by Frans J. de Bruijn.

(Montoya et al., 1996) or the acetylene reduction assay (ARA) (Capone, 1993).

Comparing N_2-fixation rates using those two methods already showed a potential discrepancy (Mulholland, 2007), which we now know is most likely due to the incomplete dissolution of the $^{15}N_2$ gas bubble, which is directly injected into a seawater sample (Montoya et al., 1996). In order to improve the quality of the direct N_2-fixation rate measurements, a novel method was established involving addition of $^{15}N_2$-enriched seawater, which assured a well-defined and constant $^{15}N_2$ enrichment of the dissolved N_2 gas at the beginning of the incubations. This method has subsequently been tested and validated in the environment (Großkopf et al., 2012).

87.2 COMPARING N_2-FIXATION RATES CALCULATED USING THE TWO METHODS

In order to test the impact of this method in the environment, the magnitude of the underestimation of N_2-fixation rates was investigated in an open-ocean setting. During two research cruises to the Atlantic Ocean (AO) between 25°N and 45°S, investigators compared the established $^{15}N_2$ tracer method for measuring N_2 fixation (bubble-addition method (Montoya et al., 1996)) with the recently developed method (Mohr et al., 2010) in which the $^{15}N_2$ tracer is added as a dissolved gas (the dissolution method). At each station, parallel incubations were conducted with the dissolution and the

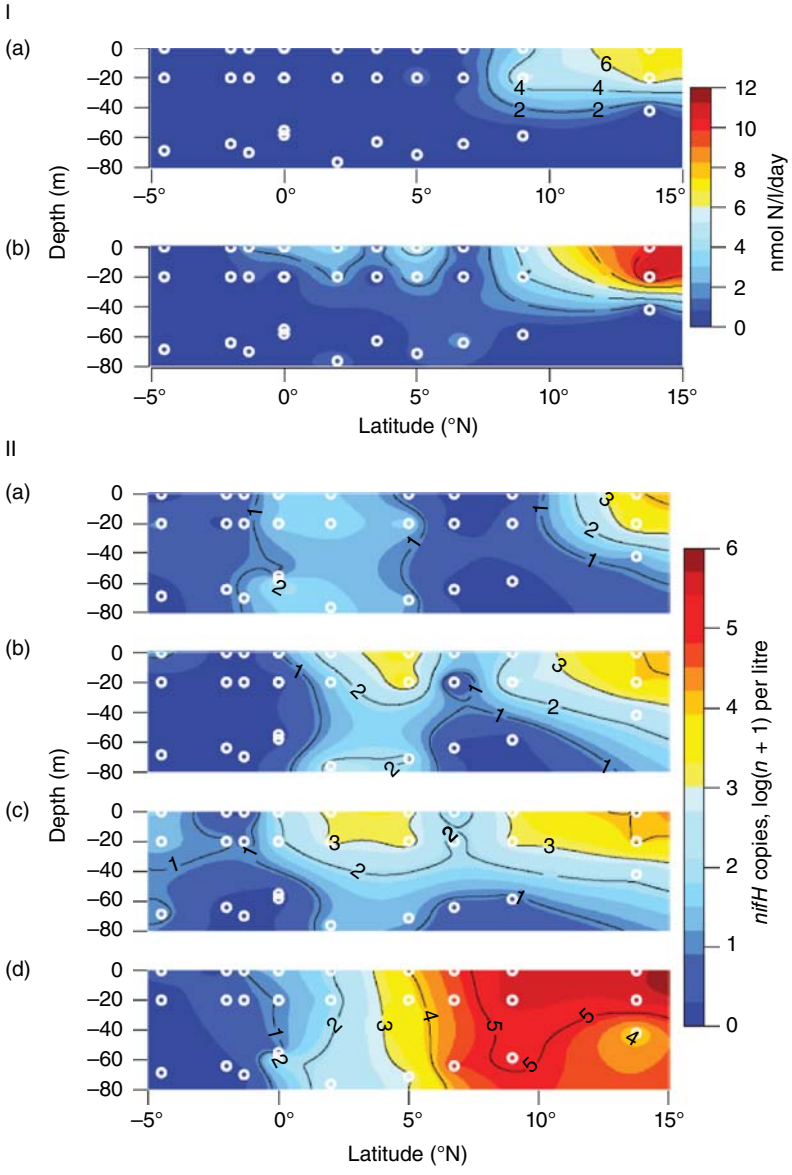

Figure 87.1 I Mixed-layer inventory of N_2-fixation rates in the tropical and equatorial Atlantic Ocean. a, N_2-fixation rates measured with the bubble-addition method. b, N_2-fixation rates measured with the dissolution method. II Relative abundance of various phylotypes of diazotrophic bacteria from the same stations as the N_2-fixation rate measurements, estimated with TaqMan *nifH* gene assays. a, Unicellular cyanobacteria (Group A, Group B and Group C cyanobacteria). b, Diatom-associated heterocystous cyanobacteria. c, Diazotrophic γ-proteobacteria. d, *Trichodesmium*. There was no DNA sampling at the 3.5°N station. Note that the *nifH* gene copies (n) per liter of diatom-associated heterocystous cyanobacteria (such as *Richelia*) detect all cells of the symbionts, not just the heterocysts in which N_2-fixation is actively taking place. This figure was originally published in Großkopf et al. (2012).

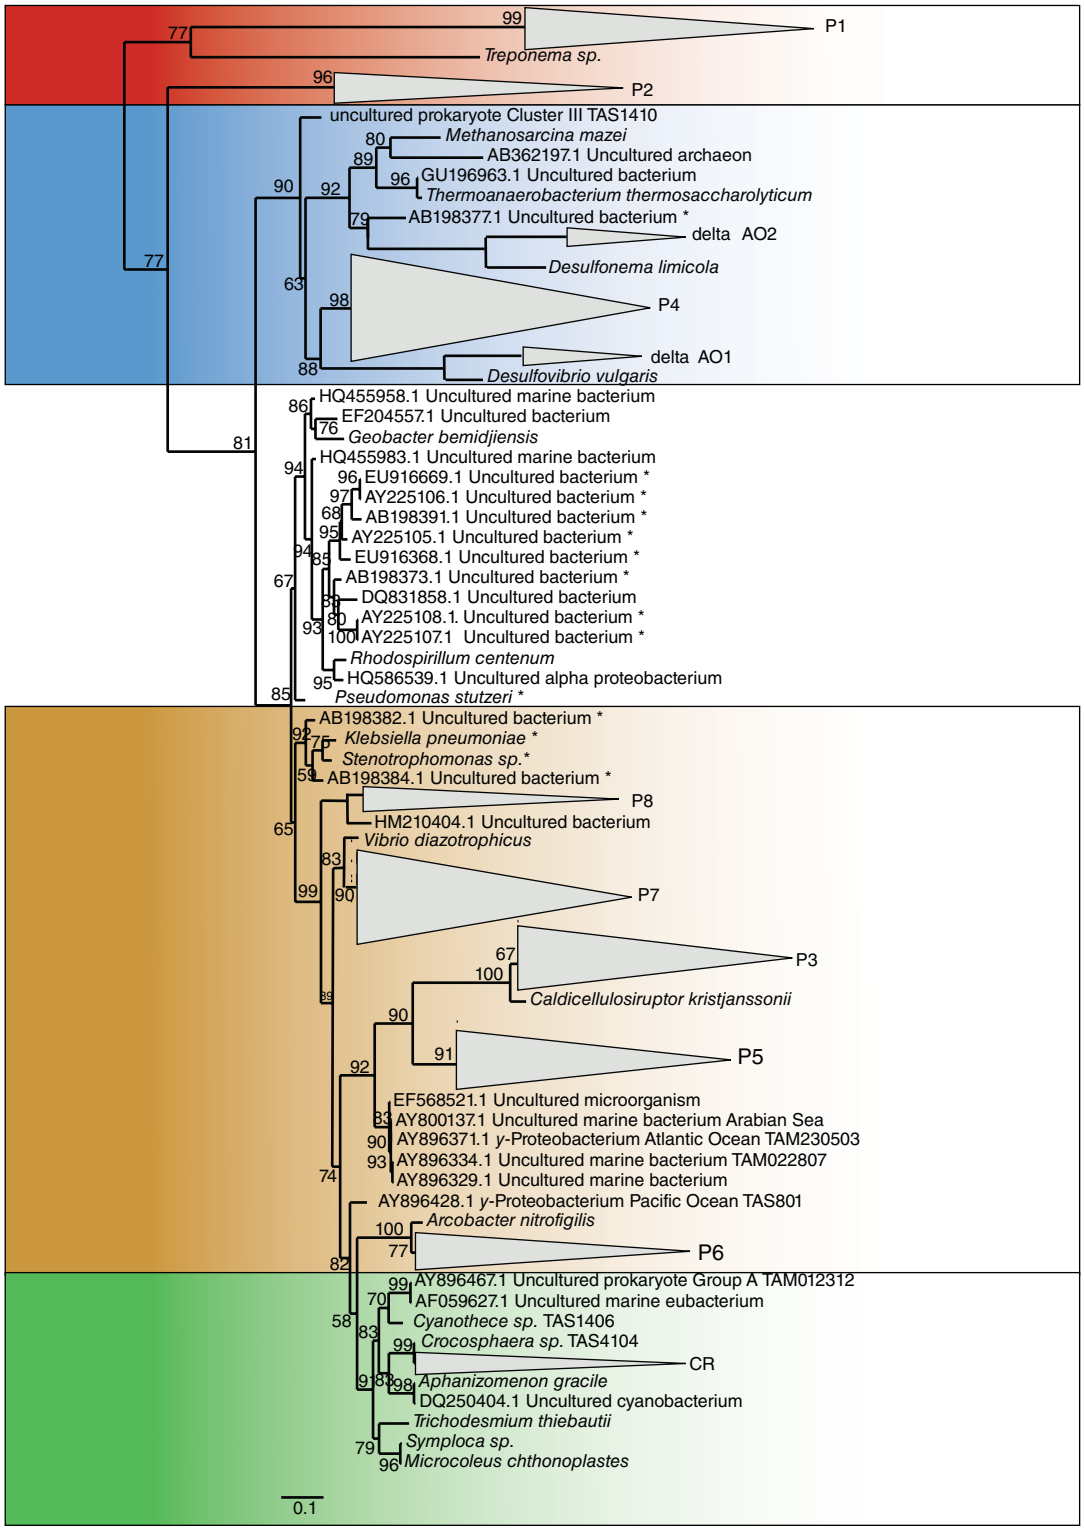

Figure 87.2 Phylogenetic tree based on the analysis of ~600 *nifH* gene and transcript sequences retrieved in Löscher et al. (2014). The newly identified clusters are indicated with grey triangles. Cyanobacterial sequences are highlighted in green, proteobacterial sequences are highlighted in brown, Cluster III sequences as defined by Zehr et al. (2000) are shown in blue, and two novel deep branching clusters are highlighted red. Bootstrapped values (%) above 50, out of 100, are shown on branches. The scale bar represents 10% estimated sequence divergence. Sequences marked with an asterisk indicate likely contaminated PCR products previously reported by Turk et al. (2011); the novel clusters are mostly distant from those sequences.

bubble-addition methods, using dual labeling with $^{13}CO_3$ (to check for differences in biological activity) and $^{15}N_2$ gas in the same incubation bottles to measure dissolved inorganic carbon (DIC) assimilation and N_2-fixation simultaneously with both methods. There was a large difference and poor overall correlation between the N_2-fixation rates calculated using the two methods.

Average depth-integrated rates of N_2-fixation over the whole AO (25°N to 45°S) differed by a factor of 1.7 for the dissolution and bubble-addition methods, respectively, with a geographical pattern emerging among the differences in the rates measured with the two methods (Großkopf et al., 2012).

Moreover, a region previously not considered important for N_2-fixation (Moore et al., 2009) was found in the equatorial AO (4.5°N to 5°S). Here, depth-integrated N_2-fixation rates were on average 570 % higher with the dissolution method than with the bubble-addition method (Fig. 87.1).

87.3 PRESENCE, DISTRIBUTION, AND EXPRESSION OF THE KEY FUNCTIONAL GENE FOR NITROGENASE REDUCTASE (*nifH*) IN NOVEL HABITATS

Comparing the detected N_2-fixation with the distribution of the nitrogenase reductase (*nifH*) gene (see Chapters 3, 8, 20, 77), highest N_2-fixation rates were found inside a *Trichodesmium* bloom measured with the dissolution and bubble-addition methods, respectively. Throughout the tropical North Atlantic (5–15°N), *Trichodesmium* was dominant, and the underestimation of N_2-fixation rates by the bubble-addition method was less severe but still significant. However, the largest underestimation (570%) with the bubble-addition method was detected in the equatorial Atlantic (4.5°N to 5°S), an area dominated by diazotrophs other than *Trichodesmium*. This indicates that the magnitude of underestimation in N_2-fixation rates measured with the bubble-addition method relative to the dissolution method correlated with the composition of the diazotrophic community. A growing knowledge of the phylogenetic diversity of diazotrophs adds up to those results (Turk et al., 2011; Farnelid et al., 2011; Fernandez et al., 2011; Löscher et al., 2014).

Our phylogenetic studies on *nifH* presence and distribution in the eastern tropical North Atlantic revealed the presence of several *nifH* clusters, e.g. filamentous and unicellular cyanobacteria, as well as γ-proteobacteria belonging to the AO cluster (Langlois et al., 2005; Zehr et al., 2003). Moreover, two novel clusters could be identified (delta AO1, delta AO2; (Löscher, Joshi, et al., unpublished)) (Fig. 87.2), both closely related to heterotrophic organisms belonging to the δ proteobacteria. Although both novel clusters were present in low abundances compared to previously described diazotrophs, their potential to fix N_2 awaits closer investigations.

In the OMZ off Peru, seven novel potentially heterotrophic *nifH* clusters (P1–P7) were identified, which have not been described before. Clusters P1 and P2 (Fig. 87.2) are deep branching compared to all previously described clusters. In addition to those newly identified clusters, sequences of two already known clusters (P8 and *Crocosphaera*, (Zehr et al., 2003)) were detected. Cluster-specific TaqMan probes were designed according to the present sequences and gene abundances were determined along vertical and horizontal gradients using quantitative (q)PCR. Clusters P1 and P4 showed significant abundances up to 10^6 copies per liter.

Moreover, the different clusters were distributed along certain patterns, e.g. the P1 cluster appears to be associated with deeper waters (100–300 m), whereas the P2 and P3 clusters show higher abundances in surface waters. Contrary to the general belief that diazotrophs thrive mainly in N-depleted waters, the P1, P4, and P8 clusters were present at high nitrate concentrations (up to ∼40 μmM); *Crocosphaera*, commonly regarded as one of the most important diazotroph in the ocean (Church et al., 2005; Zehr, 2011), was only present in the more oligotrophic parts of the OMZ off Peru. Active nitrogen fixation and the presence of *nifH* genes measured along 10°S point toward a key role of the newly identified clusters for nitrogen fixation in this area.

On the 10°S transect, a broad peak of nitrogen fixation extending into the oxygen minimum zone could be observed. The N_2-fixation activity could be stimulated by the addition of glucose and further by the addition of oxygenated water and glucose. This suggests that heterotrophic diazotrophs thrive within the upper portion of the oxygen minimum zone that seems to be limited by the availability of reduced carbon compounds. Further south of 10°S the N_2-fixation rates increased and showed higher activity at the surface than at depth, which is consistent with the very low N:P ratios in that area. The highest rates of 24.8 +/− 8.4 nmol/day/l were measured at the sulphidic station on the Peruvian shelf at 13.75°S in surface waters. The whole station's water column nitrogen fixation exceeded 1 mmol N/day/m^2, comparable to rates reported from major *Trichodesmium* blooms.

87.4 DISCUSSION AND CONCLUSION

Using published measurements of N_2-fixation rates obtained with the bubble-addition method, a global total of 103 ± 8 Tg N/a (Großkopf et al., 2012) has been calculated. In contrast, our average N_2-fixation rates measured with the dissolution method rises, in case it applies equally to all ocean basins, to 177 ± 8 Tg/N/a (Großkopf et al., 2012).

This difference can first be ascribed to the gap between the novel and the classical methods; however, the presence of

a large number of *nifH* phylotypes other than *Trichodesmium* in the Atlantic and Pacific oceans represents an additional factor leading to the underestimation of N_2-fixation in the ocean.

We identified two major reasons for the underestimation of marine N_2-fixation: (i) a methodological bias, which could be solved by the development and application of a novel method; and (ii) the detection of novel diazotrophic clusters of potentially heterotrophic diazotrophs in the Atlantic and Pacific OMZs. The activity of diazotrophs below the euphotic zone has currently not been considered in estimates of global N_2-fixation rates – neither from biogeochemical models, nor from geochemical tracer studies or direct measurements – and, combined with the underestimation from the classical method, might have been underestimated significantly.

Together, our results demonstrate that the marine N budget might be balanced when calculated using more realistic rate measurements and considering the full habitat of diazotrophs, which exceeds the oligotrophic ocean surface by far.

ACKNOWLEDGMENTS

We thank the authorities from Peru, Cape Verde and Mauritania for the permission to work in their territorial waters. We acknowledge the support of the captain and crew of the R/V Meteor, as well as the chief scientists Martin Frank, Lothar Stramma and Peter Brandt. Moreover, we thank I. Grefe for sampling during M77/4; we further thank K. Stange, F. Malien, V. Leon and P. Fritsche for oxygen and nutrient measurements and G. Klockgether for assisting with the mass spectrometry. Financial support for this study was provided by the DFG, Sonderforschungsbereich 754 (www.sfb754.de).

Diazotrophic Plant Growth Promoting Rhizobacteria and Nonlegumes

Chapter 88

One Hundred Years Discovery of Nitrogen-Fixing Rhizobacteria

Claudine Elmerich*
Institut Pasteur, Département de Microbiologie, BMGE, Paris, Cedex, France

88.1 DISCOVERY OF SYMBIOTIC AND NON-SYMBIOTIC NITROGEN FIXATION

What is the source of plant nitrogen? This topic was reviewed by Prof. P. W. Wilson in 1957, to commemorate the centennial of the Rothamsted experiments on nitrogen fixation, and by Prof. P.S. Nutman (FRS) in the "Centenary lecture," which he contributed at a meeting of the Royal Society (London) (Fig. 88.1a) in 1987, to commemorate the discovery of nitrogen fixation by nodulated legumes by the German scientists Hellriegel and Wilfarth (Wilson, 1957; Nutman, 1987). Both authors acknowledged the work of the two Germans, but they also recalled former contributions by the French scientists Boussingault, Ville, and Jodin, and the English scientists Lawes, Gilbert, and Plugh (from Rothamsted) who tried to demonstrate that plants could use nitrogen gas from the atmosphere, an hypothesis strongly refuted by their contemporaries, in particular, by the great plant nutritionist Liebig who was totally against this possibility. Beijerinck isolated a microorganism from nodules in 1988, named *Bacillus radicicola* (*Rhizobium leguminosarum*), responsible for the nitrogen fixation process in symbiosis with the host plant, but unable to fix nitrogen in the free-living state (Fisher and Newton, 2004; Elmerich, 2007).

Another author is Pierre Eugène Marcellin Berthelot (Fig. 88.1b) who discovered nitrogen fixation in clay soils (Doremus, 1907), although Winogradsky (1949) criticized his data. Berthelot (1827–1907) was a professor of organic chemistry at the Collège de France, in Paris. He was extremely popular and famous in his time as a scientist and a politician. He became Perpetual Secretary of the Academy of Sciences (succeeding Louis Pasteur in 1889), as well as a senator and minister (Langlois-Berthelot, 2000). He was the first scientist to perform synthesis of organic compounds such as acetylene and benzene. In 1883 he founded a laboratory in Meudon, near Paris, which included glasshouses and field plots. It was there that he first discovered chemical nitrogen fixation by lightning, incubating samples on top of a 28 m high tower constructed for that purpose. He performed an incredible number of experiments using soils with and without plants (common vetch, wheat, etc.). By comparing the nitrogen gain of sterilized and non-sterilized soil (without plants) he concluded that microscopic living organisms in the soil were responsible for the fixation of atmospheric nitrogen (Berthelot, 1885). Berthelot (1893), in conjunction with his colleague Guignard, tried to isolate the responsible microbe(s) from the soil, from which they reported the isolation of several unidentified bacterial isolates that "potentially" could be involved in the nitrogen fixation process.

It was Serge Winogradsky (Fig. 88.1c) who, in St-Petersburg, isolated the first bacterial strain capable of nitrogen fixation in the free-living state. Serge Winogradsky (1856–1953) was born in Kiev. He studied both music and plant physiology, and finally turned his interest to bacteriology. He had a very productive scientific career,

*Retired member.

studying bacteria of the sulfur cycle, iron cycle, nitrification, cellulose degradation, and nitrogen fixation, and established the principle of lithotrophy. At the age of 66, in 1922, he accepted the invitation of Emile Roux, to become a staff member of the Institut Pasteur and founded a laboratory, outside of Paris, at the Brie-Comte-Robert where he continued to work, with the help of his daughter Hélène (Courrier, 1957; Dworkin, 2012). In the last years of his life Winogradsky prepared a volume containing commented copies of his main publications as well as his memories and views on soil microbiology and ecology (Winogradsky, 1949).

Winogradsky (1893, 1894) reported the isolation of a nitrogen-fixing culture and showed that it contained an anaerobic spore-forming bacterium. In a paper published in the Archives of St-Petersburg Imperial Institute in 1895, Winogradsky obtained a pure culture resembling *Clostridium,* a genus described by Prazmowski in 1880. It differed from *C. butyricum* by its fermentation products and he

proposed the name *Clostridium pastorianum* (now *pasteurianum*) (see Winogradsky, 1949). Further characterization of the bacterium was published in 1902 (Winogradsky, 1902). A dozen of other *Clostridium* species were confirmed to fix nitrogen in 1949 (Rosenblum and Wilson, 1949).

In 1901, Beijerinck isolated *Azotobacter.* The nonsymbiotic nitrogen fixation era was born.

88.2 *Azotobacter* AND OTHER RELATED NITROGEN-FIXING BACTERIA

Considering the existing knowledge and techniques, progress in the isolation and proper identification of new species of nitrogen-fixing bacteria, as well as the demonstration of their nitrogen fixating ability, remained tedious until the early 1970s (Balandreau, 1983) (Table 88.1). New isolates of free-living, gram-negative, aerobic nitrogen-fixing rods were often considered to be part of the azotobacters and initially named as an *Azotobacter* species (Table 88.1). Thus, the family *Azotobacteraceae* now comprising *Azotobacter* and *Azomonas* genera (De Smedt et al., 1980; Tchan and New, 1984) was reported to also include *Beijerinckia* (Jensen, 1954) and *Derxia,* and even *Azospirillum* (see Elmerich, 1984a).

Martinus Willem Beijerinck (1851–1931) was born in Amsterdam. He was a pioneer in plant virology with his work on tobacco mosaic virus. He isolated a number of bacterial and yeast species working at the Netherlands Yeast and Alcohol Manufactory in Delft. He became a professor at the Delft Polytechnic School in 1895, and remained so until his retirement in 1921 (Chung and Ferris, 1996). In 1901, he isolated two strains of free-living nitrogen-fixing bacteria from soil and water, which he called *Azotobacter chroococcum* and *Azotobacter agilis* (Table 88.1) (see Soriano, 1939). *A. chroococcum* strains produced a brownish pigment and formed cysts. *A. agilis,* producing a greenish pigment with no cysts, was for some time believed to be uniquely found in the Delft canal (Soriano, 1939). Two other *Azotobacter* species, designated *vinelandii* and *beijerinckii*, were obtained by Lipman, during the period 1903–1904 in the United States (Soriano, 1939; Jensen, 1954; see Chapters 7, 9). Beijerinck isolated another strain, in 1922, named *Azotobacter spirillum*, classified later as *Azospirillum lipoferum* (see *Azospirillum* section). *Azotobacter indica*

1958	*Beijerinckia fluminensis*	*B. doebereinerae* (2009)	Döbereiner & Ruschel (1958); Oggerin et al., (2009)
1960	*Derxia*	—	Jensen et al., (1960)
1965	*Klebsiella*	—	Mahl et al., (1965)
1966	*Azotobacter paspalum*	—	Döbereiner (1966)

*It was not proved for sure that blue green algae could fix nitrogen before 1928 due to the difficulty in obtaining pure culture.

†Nitrogen fixation in *R. rubrum* was not known before 1949; it was demonstrated by using $^{15}N_2$.

was isolated in 1939 (Starkey and De, 1939) and classified later as *Beijerinckia indica* (Derx, 1950) (Table 88.1).

In the Brie-Comte-Robert laboratory, Winogradsky developed several methods for studying the dynamics of *Azotobacter* populations in the natural environment and he is considered to be the first microbial ecologist (Courrier, 1957; Dworkin, 2012). He developed the use of silica gel plates that were devoid of combined nitrogen or sifted soil, and to which mannitol or other carbon sources were added. Applying a range of different physiological conditions resulted in changes in the concentrations of samples of *Azotobacter.* In particular, the addition of a carbon source led to a great increase of *Azotobacter* colonies. He proposed that the number of *Azotobacter* colonies present in soil were correlated to the nitrogen-fixation potential of the soil (Winogradsky, 1926; 1932; 1949).

Winogradsky (1938) re-examined the classification of azotobacters. The initial *A. agilis* strain of Beijerinck was lost. He succeeded in isolating strains corresponding to *A. agilis* from water in France. Subsequently, by comparing a number of *Azotobacter* strains from different collections to the water isolate, he concluded that *A. agilis* corresponded to a different genus that he called *Azomonas.*

Jacques Pochon (1907–1978), a medical doctor working at the Pasteur Institute laboratories in Garches, near Paris, was interested in pursuing studies in soil microbiology, in particular nitrogen fixation and cellulose decomposition. He recruited Tchan Yao-Tseng (Fig. 88.1d) in 1945. Tchan (1918–2013) came to France in 1937 to study agriculture. Maurice Javillier (1875–1955) was his professor. He obtained a Doctorate Thesis at the Sorbonne, in Paris, in microbial ecology. Familiar with the work and the techniques of Winogradsky he was eager to work with him, but Winogradsky, who was already advanced in age, did not welcome students and suggested to Tchan to cooperate with his daughter Hélène (1890–1957) at the Institut Pasteur campus in Paris. Tchan chose to integrate into the laboratory of Jacques Pochon, first in Garches, and then in Paris (Tchan, personal communication) resulting in a fruitful 4 years of collaboration. Pochon and Tchan each contributed to the teaching of the "*Grand Cours de Microbiologie*" (Fig. 88.1e); they published a number of papers on *Azotobacter* and related topics in the *Annales de l'Institut Pasteur,* as well as the *Manual of Soil Microbiology* (Pochon and Tchan, 1948).

Subsequently, Tchan accepted a position as Senior Microbiologist of the Linnaean Society of New South Wales in 1950 and migrated to Australia. He later established the Chair of the Department of Microbiology at the University of Sydney for the students of Science and Agriculture. He continued his work, in Australia on the taxonomy, physiology, and biochemistry of *Azotobacter*, *Azomonas*, *Beijerinckia*, and also on cyanobacteria (e.g., Tchan, 1952, 1953; New and Tchan, 1982; Tchan and New, 1984, Tchan et al., 1980, 1983). Tchan collaborated with the famous Danish microbiologist Hans Laurits Jensen (Tchan et al., 1962). HL Jensen (1898–1977) described *Derxia*, another acid-tolerant strain (Jensen et al., 1960), named in honor of the Dutch microbiologist HG Derx (1894–1953).

Emeritus Professor Tchan continued to work on *Azospirillum* and I was fortunate to work with him for a short time in Sydney (Zeman et al., 1992). To quote in his communication to me: "*I started my research in the Pasteur Institute and finished it with the collaboration of a fellow Pasteurian.*"

By 1952, Pochon created a theoretical and practical "Soil microbiology course" in the Pasteur Institute, which attracted students from France and from many other parts of the world. Johanna Döbereiner (Fig. 88.1f) followed that course in 1956. She discovered two other species of azotobacter-related bacteria: *Beijerinckia fluminensis* (Döbereiner and Ruschel, 1958) and *Azotobacter paspali* (Döbereiner, 1966) (Table 88.1).

88.3 CONTRIBUTION OF *Azotobacter* TO SOIL FERTILITY

For many years *C. pasteurianum* and *Azotobacter* were considered as the main non-symbiotic nitrogen-fixing bacteria in soil (Winogradsky, 1949; Jensen, 1954; Chang and Knowles, 1965). Indeed, proliferation of bacteria in the root zone of plants was noted very early; this is the rhizosphere effect described by Hiltner in 1904 (Starkey, 1958; Hartmann et al., 2008). Most of the bacteria isolated from plants were considered as saprophytes. *Azotobacter*, which was not found in higher concentration in the root zone than in the soil, was not considered a rhizospheric bacterium (Starkey, 1958; Döbereiner, 1974).

Bacterization experiments (1927–1960) were initiated in the Soviet Union because Russian soils contained large numbers of *Azotobacter*. By 1958, about 10 million ha were treated with the fertilizer azotobacterin, a preparation of *A. Chroococcum,* and with phosphobacterin, containing *Bacillus megaterium* (Macura, 1966; Brown, 1974). The *Bacillus* was used for organic phosphate mineralization. Results of bacterization generated controversy. Up to 10% yield increase with cereals was reported and even up to 50% with some vegetables (Brown, 1974; Mishustin, 1970). Mischustin (1970) in an analytical report noted that 10% increase might be considered "*within the limit of field experiment error.*"

Research programs were conducted in other parts of the world – California, Australia, and England (in particular in Rothamsted) – to understand how these bacterial fertilizers could replace mineral fertilizers (Brown, 1974). Delwiche and Wijler (1956) performed experiments using $^{15}N_2$. In particular, they confirmed nitrogen fixation by soil, with dramatic increase when a substrate such as glucose was added to the soil. However, they found little increase when

the soil was amended with straw or when it was inoculated with *Azotobacter* (in contrast to Chang and Knowles (1965) who reported increases after *Azotobacter* inoculation).

Many studies dealt with occurrence of *Azotobacter* in soil and its survival after inoculation. It appeared that *Azotobacter* concentration in soil was rather low (some soils which were too acidic did not contain any), that no effective colonization of the rhizoplane was found, and that the survival of the bacteria after inoculation was poor (Döbereiner, 1974). Meiklejohn (1965) concluded from the experiments she performed on Broadbalk field (Rothamsted) that "*Perhaps,* Azotobacter *indicates conditions for fixation but the fixation is mainly by other species*" and she suggested that *C. pasteurianum* instead could be effective. Chang and Knowles (1965), in Canada, reached a similar conclusion. These authors identified *C. pasteurianum* from most of the studied soil samples whereas *Azotobacter* was rarely present. By using $^{15}N_2$ they detected nitrogen fixation in anaerobic conditions with an increase in anaerobes and aerobes populations. They concluded that, in addition to *C. pasteurianum*, nitrogen fixers other than *Azotobacter* were present in Canadian soil.

Many authors noted that the inoculation of *Azotobacter* resulted in the modification of plant morphology (Brown, 1974). For example, Patel (1969) showed spectacular increases in plant growth after the inoculation of wheat seedlings; Dénarié and Blachère (1966) noted growth stimulation on several plants (potato, tomato, ray-grass), but positive effects were also found with *Arthrobacter* and *Xanthomonas*; Rovira (1963) equally reported stimulation of plant growth by *Azotobacter* and also by *Clostridrium*. Bacterization using non-nitrogen-fixing strains (*Bacillus*, *Pseudomonas*) also resulted in plant growth promotion (PGP) (Brown, 1974). Production of vitamins, amino acids, phytohormones, and antifungal metabolites by soil- and plant-associated microorganisms was established (Vancura, 1961; Rivière, 1963; Macura, 1966; Brown, 1974, Rovira, 1991). It was concluded that production of bacterial metabolites resulted in promoting plant growth or protection of the plant from diseases. Therefore, the PGP effect resulting from *Azotobacter* bacterization was not linked to nitrogen fixation.

An exception is the case of the specific association between *Azotobacter paspali* and the grass *Paspalum notatum* cv. Batatais (Döbereiner et al., 1972). Effective nitrogen fixation by this association was demonstrated by the ^{15}N isotope dilution method (Boddey et al., 1983).

88.4 *Azotobacteraceae* AND THE CLASSIFICATION IN *Proteobacteria*

Azotobacter distribution was found to be limited to neutral soils. The acid-tolerant *A. indica* species with a smaller cell size was isolated from tropical soil and reclassified as *Beijerinckia indica* by Derx (1950). It was emphasized that *Beijerinckia,* which predominates in tropical soil, could be of agricultural importance (Becking, 1961; Döbereiner, 1961; Dommergues, 1963; Dommergues and Mutaftschiev, 1965; Döbereiner, 1974). In particular, Döbereiner (1961) reported the presence of *Beijerinckia* in the rhizosphere of sugarcane. Both of the *Azotobacter* and *Beijerinckia* genera differed in major properties; for example, *Azotobacter* could form cysts in old cultures and fix nitrogen with vanadium instead of molybdenum, while *Beijerinckia* could not (Becking, 1962). However, based on phenotypic features the differentiation between *Azotobacter, Beijerinckia* and *Derxia* remained difficult.

Jozef de Ley (1924–1997) played a pioneering role in the classification of nitrogen-fixing bacteria. He founded the "Laboratory for Microbiology" of the Ghent University, Belgium, and with his team contributed to the taxonomy and phylogeny of many bacterial groups. Development of molecular techniques based on DNA base composition and DNA–DNA hybridization enabled the confirmation that *Azotobacter*, *Azomonas, Beijerinckia,* and *Derxia* belonged to different genera (De Ley and Park, 1966; de Ley, 1968). With his team he then performed an extensive analysis of hybridization of DNA with ribosomal RNA. This technique enabled to group gram-negative bacteria within four "rRNA superfamilies" and showed that *Beijerinckia*, *Azotobacter,* and *Derxia* belonged to different RNA superfamilies (De Smedt et al., 1980; de Vos et al., 1985). Tchan et al. (1980, 1983) used immunoelectrophoresis to better differentiate *Azotobacter* and *Azomonas* genera.

The classification of rRNA superfamilies was replaced by that proposed by Carl Woese (1922–2012) and collaborators who first used RNA oligonucleotide catalogs, and then the sequencing of 16S rDNA, classifying gram-negative bacteria (purple bacteria) into alpha, beta, gamma, and delta subgroups (Woese, 1987). The term *Proteobacteria*, currently used, was proposed in 1988 (Stackebrandt et al., 1988). Thus, *Azotobacter* is a member of the gamma subgroup of *Proteobacteria* close to *Pseudomonas, Beijerinckia* is an alpha *Proteobacteria* close to *Rhizobiales,* and *Derxia* belongs to the beta subgroup.

88.5 *Azospirillum* HISTORY

Johanna Döbereiner and her team discovered bacteria of the genus *Azospirillum* in Brazil in the early 1970s (Döbereiner and Pedrosa, 1987; Baldani and Baldani, 2005). Johanna Döbereiner (1924–2000) was born in Czechoslovakia and studied agronomy at the University of Munich. She emigrated to Brazil in 1951, where she established a soil microbiology laboratory in Seropédica, 42 km from Rio de Janeiro (Figures 88.1f and 88.2a). Her discovery of several new genera of root-associated diazotrophs that benefit the growth of non-leguminous plants stimulated research of

Figure 88.2 Pictures from Brazil and Asia. (a) Johanna Döbereiner in her laboratory in 1987; (b, c) Vera and Jose Ivo Baldani, in 1995; (d) Fabio Pedrosa (right) and his group, in Curitiba, in 1987; (e) Christina Neves and Robert Boddey, in 1995; (f) Ben Bolhool (1940–1991), Chong Biao You and Kauser Malik, at a meeting in Philippines (IRRI) in 1985; (g) Mercedes Umali-Garcia in 1982; (h) CB You and Lin Min, in Beijing, in 1994; (i) Iowa Watanabe at IRRI, in 1985; (j) JK Ladha, in 1985; (k) Kiwamu Minamisawa, in Kyoto in 2012.

non-symbiotic nitrogen fixation all over the world (reviewed by Baldani and Baldani, 2005). Avílio Franco and Robert Boddey organized an international symposium in Angra dos Reis (Rio de Janeiro, Brazil) in 1995, to commemorate Johanna's 71st birthday (Fig. 88.2e). Many of her friends and former collaborators attended the meeting. The proceedings were published as a special issue of *Soil Biology and Biochemistry* (Vol. 29, No 5/6, 1997). Fraser Bergersen (Fig. 88.1g) (1929–2011), Yvon Dommergues (Fig. 88.1i) (1922–2009), and Christina Kennedy (Fig. 88.1j) (1945–2008) contributed to the meeting.

The first record of nitrogen fixation by a spirillum-like bacterium, named *Azotobacter spirillum*, then *Spirillum lipoferum,* was in the period 1922–1925 (Becking, 1963), although the strain could not fix nitrogen in pure culture (Döbereiner, 1988). Jan-Hendrix Becking (1924–2009), a Dutch microbiologist, isolated a strain in Africa that he probably considered identical to Beijerinck's *S. lipoferum* strain (Becking, 1963). He showed nitrogen fixation in pure culture, using $^{15}N_2$, but could not conclude on the taxonomic status of the strain (Becking, 1963).

The strains isolated in Brazil were first named *Spirillum lipoferum* Beijerinck. An ecological survey showed that *S. lipoferum* was present in different parts of Brazil, United States, and Africa, and it was isolated from soil, roots of forage grass (*Digitaria, Panicum, Pennisetum*), and cereal

crops (maize, sorghum, wheat) (Döbereiner et al., 1976). An association was also found with rice in Asia (Watanabe and Roger, 1984).

Based on the nutritional properties of the different isolates, DNA base composition and DNA–DNA hybridization experiments with other bacterial genera, Tarrand et al. (1978) proposed to create a new genus *Azospirillum*, with two species *A. lipoferum* and *A. brasilense*. De Smedt et al. (1980) found that *Azospirillum* was in the same rRNA superfamily as *Beijerinckia*, which is in agreement with its further classification in the alpha subgroup of *Proteobacteria*. Seven species were recognized in 2007: *A. brasilense, A. lipoferum, A. amazonense, A. irakense, A. halopraeferens, A. Largimobile,* and *A. doebereinerae* (Schmid and Hartmann, 2007), but a number of new species have been described in recent years (see Wisniewski-Dyé et al., 2011) (Table 88.2).

Soon after the report of "Spirillum" bacteria promoting growth of Gramineae by J. Döbereiner at the First International Symposium on Nitrogen Fixation, at Pullman, Washington, in (1974), many laboratories in North and South America, Europe, Africa, and Asia started to implement research on this bacterium (see reviews by: Patriquin et al., 1983; Elmerich, 1984a,1984b; Okon, 1985, 1994; Danneberg et al., 1986; Döbereiner and Pedrosa, 1987; Elmerich et al., 1987; Michiels et al., 1989; Bashan and Levanony, 1990; Okon and Labandera-Gonzales, 1994; Costacurta and Vanderleyden, 1995; Steenhoudt and Vanderleyden, 2000; Elmerich and Newton, 2007; Franche et al., 2009; see also Chapter 90).

Azospirillum (as well as many other root-associated diazotrophs) have been isolated after surface sterilization of the plant root. The "intimate" association of *Azospirillum* with the host plant was first referred as "associative symbiosis" because invasion of root cortical cells was noted (Döbereiner and Day, 1976). However, it was argued that the colonization was essentially limited to the surface, but that bacteria could proliferate in damaged tissues and be protected from the sterilizing agent (Umali-Garcia et al., 1980; Hallmann et al., 1997). Use of confocal laser scanning microscopy (Rothballer et al., 2003) helped solve the controversy by noting differences in the localization depending of *Azospirillum* strains. The *A. brasilense* Sp7 bacterial cells were localized preferentially on the root surface, while *A. brasilense* Sp245 was on the surface but also in the intercellular spaces of the root epidermis, and could then be considered as an "endophyte."

Robert Burris (1916–2010) (Fig. 88.1k) had already a brilliant career in the field of the biochemistry of nitrogenase, when he started to work with *Azospirillum*. He also became involved in the study of *Gluconacetobacter* in collaboration with Christina Kennedy (Sevilla et al., 2001). Yaacov Okon (Fig. 88.1l) and Anton Hartmann (Fig. 88.1m) joined Burris' Lab as post-doctorants and contributed to the physiology and biochemistry of the bacterium (Okon et al., 1976, 1977; Ludden et al., 1978; Hartmann et al., 1986, 1987).

In Germany, Walter Klingmüller (Fig. 88.3a), professor of genetics at the University of Bayreuth, organized four *Azospirillum* workshops to discuss the progress of genetics, physiology, and ecology in the field. Proceedings' books were published after each meeting (Klingmüller, 1982, 1983, 1985, 1988). Most of the European laboratories involved in *Azospirillum* research attended these meetings (Fig. 88.3b–e) and, with time, the audience became international and the workshops also included reports on other rhizobacteria. Becking attended the first and third workshops and Johanna Döbereiner attended the second one.

Istvan Fendrik and Maddalena Del Gallo organized the workshop in Hannover, Germany, in 1991 (Fig. 88.3b and e), and the proceedings were published as a special issue of *Symbiosis* (vol. 13, 1992). At this workshop, Johanna Döbereiner reported data on new root-associated diazotrophs, *Herbaspirilum* (isolated in 1986; see Chapter 93) and *Acetobacter diazotrophicus* (*Gluconacetobacter*, isolated in 1988), which could also colonize aerial parts of the host plant (xylem vessels), without disease symptoms and launched the concept of endophytic nitrogen fixers (Döbereiner, 1992) (Table 88.2; see also Section 16 and Chapter 108).

88.6 ABOUT PROGRESS IN ISOLATION, IDENTIFICATION, AND QUANTIFICATION

Johanna Döbereiner (1988) stressed the importance of the use of appropriate selective media. In particular, the success in the isolation of microaerobic nitrogen fixers depended on the use of nitrogen-free semisolid media, which led to the formation of a gradient of decreasing oxygen concentration below the surface. It enabled growth of nitrogen-fixing bacteria, forming a pellicle, at the oxygen concentration compatible with their physiological requirements for synthesis and functioning of the nitrogenase. In their historical review paper, Baldani and Baldani, 2005 (Fig. 88.2b and c) discussed the impact of the method. They recalled that it was Fábio Pedrosa, when working in Seropédica before he founded his group in Curitiba (Fig. 88.2d), who improved in 1975 the recipe of the semi-solid medium, named Nfb; "*N stands for new and Fb for Fábio Pedrosa.*"

Another major issue was to establish that the bacterial isolates could fix nitrogen in the free-living state and to quantify nitrogen fixation in association with the host plant. It may be worth recalling that the Kjeldhal method is dated 1883, and the use of $^{15}N_2$ was adapted to measure N_2-fixation in 1941 (Burris and Miller, 1941). The first crude extract for nitrogenase activity was obtained in 1960 (Carnahan et al., 1960) and the discovery that acetylene was a nitrogenase substrate was dated in 1966 (Dilworth, 1966).

Figure 88.3 *Azospirillum* workshops. (a) Walter Klingmüller and his family, in Bayreuth, Germany, in 1987; (b) delegates at the *Azospirillum* V workshop, in 1991: Paul Kaiser (1932–2010), Wolfgang Zimmer (1958–2002), René Bally and Yao-Yun Liang; (c) Jos Vanderleyden (in 1995); (d) Barbara Reinhold (in 2012); (e) Group picture at the *Azospirillum* V workshop; second row left: Istvan Fendrik and Maddalena del Gallo.

The difficulties and limitations of different techniques to quantify nitrogen fixation with non-legumes are discussed in many review papers (e.g., Hardy et al., 1973; Van Berkum and Bohlool, 1980; Rennie and Rennie, 1983), and Fraser Bergersen (1980) edited a volume of techniques (Fig. 88.1h) that was so useful that it was translated into Chinese.

The acetylene reduction assay (ARA) became a method of choice to assay nitrogen fixation although it should be correlated to quantitative nitrogen fixation with caution (Bergersen, 1970). In particular, ARA performed on excised roots or on plant soil cores was a source of some controversy (Van Berkum and Bohlool, 1980). Many groups implemented research to validate the assay, such as the conversion factor between ARA and nitrogen fixation (theoretically of three) or estimation of diurnal, seasonal, and varietal variations (e.g., Bergersen, 1970; Rinaudo and Dommergues, 1971; Balandreau et al., 1974; Lee and Watanabe, 1977; Hirota et al., 1978; Sano et al., 1981).

Around 1990, rapid development of molecular tools for bacterial identification and phylogenetic studies boosted the research on the ecology of nitrogen fixation. The DNA amplification technique by polymerase chain reaction (PCR), design of oligonucleotides probes specific for ribosomal RNA, or nitrogen fixation genes as well as primers

for DNA fingerprinting enabled not only identification of new bacterial species but also analysis of microbial population (culturable or non-culturable) associated to the plant (Stoltzfus et al., 1997; Schmid and Hartmann, 2007).

88.7 DIVERSITY OF NITROGEN-FIXING ROOT-ASSOCIATED BACTERIA: ROOT COLONIZERS AND ENDOPHYTES

Less than a dozen of "free-living" nitrogen-fixing genera of bacteria were identified by the end of the 1960s, including *Klebsiella*, *Bacillus polymyxa,* and *Rhodospirillum rubrum* (Table 88.1). Nitrogen fixation was also established for a number of blue-green algae (cyanobacteria, which were not considered eubacteria in 1967; see Chapters 84, 86) (Stewart, 1967). Jacques Balandreau (Fig. 88.1n) in his review paper in 1983 cites a few other genera (e.g., *Arthrobacter*, *Achromobacter, Mycobacterium*, and photosynthetic bacteria) not discussed here. The review article of Peter Young (1992) contains a comprehensive list of nitrogen-fixing species that are classified according to the nomenclature proposed by Woese, which is extremely useful to consult.

Research on the bacteria present in the rhizosphere led to the discovery of a number of new species of nitrogen-fixing root-associated bacteria (Table 88.2). Their distribution and frequency differed greatly with the geographical regions and the plant material (Balandreau, 1983; Bally et al., 1983; Rennie, 1980, 1981; Döbereiner and Pedrosa, 1987; Döbereiner, 1992; Elmerich et al., 1992; Baldani and Baldani, 2005; Schmid and Hartmann, 2007; Pedraza, 2008).

In early reports, in addition to *Azotobacter* and *Beijerinckia* and *Azospirillum* (discussed above), *Bacillaceae* (classified later in a new genus *Paenibacillus*) (Seldin et al., 1984; Achouak et al., 1999), *Enterobacteriaceae* (*Klebsiella, Enterobacter*, *Erwinia, Pantoae*) (Ladha et al., 1983; Kleeberger et al., 1983; Gavini et al., 1989), *Campylobacter* (McClung and Patriquin, 1980), and *Pseudomonas*-like bacteria were frequently identified (Table 88.2).

Microbiology of rice was of particular interest for researchers in Asia (Fig. 88.2f–k). Beside cyanobacteria, a number of aerobic and anaerobic heterotophs were found (Watanabe and Roger, 1984; You et al., 1992; Ladha et al., 1997; Malik et al., 1997; Elbeltagy et al., 2001; see Chapter 108).

The existence of nitrogen-fixing *Pseudomonas sensu stricto* was refuted for a long time since a number of early reports corresponded in fact to bacterial species reclassified later as members of the alpha and beta subgroups of *Proteobacteria* (Young, 1992; Chan et al., 1994; Vermeiren et al., 1999; Yan et al., 2008, 2013). Krotzky and Werner (1987) were the first to isolate a nitrogen-fixing *Pseudomonas stutzeri* (see Chapter 10); several other *Pseudomonas* nitrogen-fixing strains, from different geographical origins, have been reported, including *P. stutzeri* A1501 (for a review see, Yan et al., 2013).

P. stutzeri strains (first described as *Alcaligenes faecalis*) isolated from rice root in China, by Chong-Biao You and his team, have been particularly well studied. CB You (1932–1994) (Fig. 88.2h) was a biochemist from the Institute for Application of Atomic Energy of the Chinese Academy of Agricultural Sciences in Beijing. He obtained a PhD in Moscow in 1961 and later worked in California on *Azotobacter* nitrogenase with Barbara Burgess and William Newton. With his team in China he studied many aspects of the ecology, genetics, and biochemistry of bacteria associated to rice (for a review see: You et al., 1992). A variety of nitrogen-fixing strains were found (including *Klebsiella*), but *A. faecalis* (*P. stutzeri*) was predominant (You and Qu, 1982; You et al., 1992). Lin Min (Fig. 88.2h) who continues active research on the molecular biology of *P. stutzeri* is now directing the Chinese group in Beijing (see Chapter 10).

Following J. Döbereiner's publication in 1992, particular interest was focused on the bacterial endophytes. Many new species were isolated from sugarcane, rice, and other plants including coffee, pineapple, and banana (Table 88.2). *Herbaspirillum* and *Gluconacetobacter* biology was particularly well studied and both species were reported to contribute significantly in fixing nitrogen to sugarcane (James, 2000; Baldani and Baldani, 2005; Elmerich and Newton, 2007; Rothballer et al., 2007; Pedroza, 2008).

Azoarcus and several related genera, *Azovibrio*, *Azospira,* and *Azoxenus*, were among the new nitrogen-fixing species isolated in Pakistan from a salt-tolerant plant, Kallar grass, or from fungal resting stages (sclerotia) (Reinhold et al., 1986; Malik et al., 1991; Reinhold-Hurek and Hurek, 1998, 2000; Hurek et al., 2002) (Table 88.2). The best studied strain *Azoarcus* sp. BH72 could invade rice and its complete genome sequence was determined (Krause et al., 2006; see also Chapter 108). Chelius and Triplett (2000), in the United States, reported on a *Klebsiella pneumoniae* strain 342, an endophyte of maize. New species were also reported among *Proteobacteria* of the beta subgroup, for example, *Burkholderia* isolated from rice in Vietnam or from coffee plant in Mexico (Trân Van et al., 1994; Estrada de los Santos et al., 2001; Baldani and Baldani, 2005; Schmid and Hartmann, 2007). *Herbaspirillum* and *Azospirillum* were also isolated as rice endophytes in Japan (Elbeltagy et al., 2001; Xie and Yokota, 2005; Kaneko et al., 2010).

88.8 CONCLUDING REMARKS

For many years, research was focused on symbiotic nitrogen fixation systems because they are the most efficient in deriving nitrogen from the atmosphere. In contrast, the importance of non-symbiotic nitrogen fixation by soil

bacteria or root-associated bacteria was long considered as negligible. *Azospirillum* inoculation resulted in modification of the root morphology and increase in crop yield was consistently noted (Okon and Labandera-Gonzales, 1994; see Chapter 90). The cause of the PGP effect led to controversy. Similarly to what happened in the case of *Azotobacter* bacterization it was concluded that plant growth stimulation resulted essentially from phytohormone production rather than from nitrogen fixation (Okon and Labandera-Gonzales, 1994; Costacurta and Vanderleyden, 1995; Elmerich and Newton, 2007; see Chapter 91). Endophytes offered new perspectives since some of them benefited plant growth through nitrogen fixation (Sevilla et al., 2001; Hurek et al., 2002; Rothballer et al., 2007; Elmerich and Newton, 2007). The research on root-associated and endophytic nitrogen-fixers has never been so active and several chapters of this book cover updated information on various aspects of research on these systems (see Chapters 90, 92, 93, 94, 108, 111).

ACKNOWLEDGMENTS

The author is indebted to Prof. YT Tchan for sharing his memories and Anita Zeman for her help and reading of the typescript. I wish also to thank Yves Dessaux, Denis Faure, Claudine Franche, Eva Kondorosi, Philippe de Lajudie, Sandra Legout, Lin Min, Kiwamu Minamisawa, and Barbara Reinhold for their answers to some of my questions and Anton Hartmann and Frans de Bruijn for their invitation to talk and write on this topic.
