Section 10 Infection and Nodule Ontogeny

Preface

Nitrogen is arguably the most important nutrient required by plants, being an essential component of all amino acids and nucleic acids. However, the availability of nitrogen is limited in many soils, and although the earth's atmosphere consists of 78.1% nitrogen gas (N_2), plants are unable to use this form of nitrogen. To compensate this, modern agriculture has been highly reliant on industrial nitrogen fertilizers to achieve maximum crop productivity (Ferguson et al. 2010).

However, a great deal of fossil fuel is required for the production and delivery of nitrogen fertilizer. Indeed, industrial nitrogen fixation alone accounts for 50% of fossil fuel used in agriculture. This can be exceedingly expensive. In recent years, the price of chemical fertilizers has increased dramatically due to rising fossil fuel costs. Moreover, carbon dioxide (CO_2), which is released during fossil fuel combustion, contributes to the greenhouse effect, as does the decomposition of nitrogen fertilizer, which releases nitrous oxide (NO_x), itself about 292 times more active as a greenhouse gas than carbon dioxide (Ferguson et al. 2010). In addition, applying chemical fertilizers is largely inefficient, as 30–50% of applied nitrogen fertilizer is lost to leaching, resulting in significant environmental problems, such as the eutrophication of waterways. Thus, there is a strong need to reduce our reliance on chemical nitrogen fertilizers and instead optimize alternative nitrogen inputs (Ferguson et al. 2010).

Biological nitrogen fixation is one alternative to nitrogen fertilizer. It is carried out by prokaryotes using an enzyme complex called nitrogenase and results in atmospheric N_2 being reduced into a form of nitrogen diazotrophic organisms, and plants are able to use (ammonia; see Introduction). It is this process and its major players, which will be discussed in this *Biological Nitrogen Fixation* book.

The research in the field of Biological Nitrogen Fixation is very active at the moment, especially in the subfield of symbiotic nitrogen fixation. Although a number of books and proceedings of the International Congresses on Nitrogen Fixation and North American Symbiotic Nitrogen Fixation Conferences have appeared during the last 10 and more years, a comprehensive book on the field from biochemistry of nitrogenase, through expression and regulation of nitrogen genes, taxonomy, evolution, and comparative genomics of nitrogen-fixing organisms; their physiology and metabolism; their life in the rhizosphere and under stress conditions, rhizobial "Omics," plant "Omics," nodulation of legumes and nonlegumes, recognition, infection and nodule ontogeny, nitrogen fixation and assimilation, field studies, inoculum preparation and application of Nod factors, endophytic nitrogen fixers, cyanobacteria, and nitrogen fixation and cereals does not presently exist, and this book aims to fill this void.

A number of authors were selected based on the programs of the 21st North American Conference on Symbiotic Nitrogen Fixation in Columbia, Missouri, USA (June 2010); the 17th International Congress on Nitrogen Fixation in Fremantle, Western Australia (December 2011); the 16th Australian Nitrogen Fixation Conference (Manly, June 2012); the programs of the "European Nitrogen Fixation Congress (ENFC)," held in Munich, Germany, from the September 2, 2012, to September 5, 2012; and the satellite meetings on "Genomics of nitrogen fixing bacteria" and the "Symposium on Biological Nitrogen Fixation with Non-legumes" (The latter three were attended by the Editor upon invitation by the Conference Organizer Dr. Anton Hartmann).

The best known and most extensively studied example of biological nitrogen fixation is the symbiotic interaction between nitrogen-fixing "rhizobia" and legume plants. Here, the rhizobia induce the formation of specialized structures ("nodules") on the roots or sometimes stems of the legume plant and fix nitrogen, which is directly assimilated by the host plant; in return, the plant provides the required energy source for the energy-intensive, nitrogen-fixation process. It is this symbiotic interaction, which will be highlighted in this book.

While this book features many chapters on the model system for indeterminate nodule formation, the *Sinorhizobium meliloti–Medicago truncatula* symbiosis, little

information is presented on the *Mesorhizobium loti–Lotus japonicus* symbiotic model system for determinate nodule formation. The reason for this is the simultaneous publication edited by Dr. S. Tabata and Dr. Jens Stougaard (Springer-Verlag) specifically focused on this topic, and the reader is referred to this book for details on this important model symbiotic system.

While legumes are important as major food and feed crops and are the second group of such crops grown worldwide, the first group (cereals such as wheat, maize, and rice) does not have this symbiotic nitrogen-fixing interaction with rhizobia. It has thus been a focus of a number of studies to transfer the ability to fix nitrogen to cereals, and different timely approaches toward this goal are also included in the book. The case of rice will be discussed in the following section.

Rice is the most important staple food for over 2 billion people in Asia and for hundreds of millions in Africa and Latin America. To feed the ever-increasing population of these regions, the world's annual rice production must increase from the present 460 million to 560 million tons by the year 2000 and to 760 million tons by 2020 (Ladha et al. 1997).

If future increase in rice production has to come from the same or even reduced land area, rice productivity must be greatly enhanced to meet these goals. Nitrogen is the nutrient that most frequently limits agricultural production of rice and other cereals. As pointed out earlier, global agriculture now relies heavily on N fertilizers derived at the expense of petroleum. Nitrogen fertilizers, therefore, are expensive inputs costing agriculture more than $45 billion (US) per year (Ladha et al. 1997).

In the tropics, lowland rice yields 2–3.5 ton per hectare, utilizing naturally available N derived from biological nitrogen fixation (BNF) by free-living and plant-associated (endophytic) nitrogen-fixing organisms and from mineralization of soil N. Achieving 50% higher rice yield needed by 2020 will require at least double the 10 million ton of N-fertilizer that is currently used each year for rice production. Manufacturing the fertilizer for today's needs requires 544×10^9 MJ of fossil fuel energy annually (Ladha et al. 1997).

Thus, alternatives to chemical fertilizer must be sought.

BNF for rice and other cereals has been the "holy grail" for decades now and has been explored in laboratories worldwide, mainly looking at free-living, associative, and endophytic nitrogen-fixing organisms. These studies have been presented and discussed at numerous International Nitrogen Fixation Congresses, Nitrogen Fixation with Non-legumes Meetings, and the IRRI funded Working Group Meetings of the Frontier Project on Nitrogen Fixation in Rice and Other Non-Legumes, the latter in the late 1990s (Ladha et al. 1997). Recently, the Bill and Melinda Gates Foundation convened a small meeting on the subject and several projects were funded, including the transfer of the nitrogen-fixation (nitrogenase) genes into cereals and the transfer of the ability to form nitrogen-fixing nodules to cereals. This has greatly stimulated research in this area.

Rice transformation is now routine and since the genome has been sequenced and extensive genetics is available, it should serve as a "model species," while for other cereals, a recently developed *Brachypodium* model system has been established.

The discovery of a "common symbiotic pathway" in arbuscular mycorrhizal, rhizobial, and actinorhizal symbioses and the identification of conserved pathway genes in legumes and monocots (including rice; Venkateshwaran et al. 2013) have made the extension of the ability to fix nitrogen in nodular associations, with cereals as a more realistic endeavor.

The direct transfer of nitrogen fixation (*nif*) genes into nonlegumes has also become more feasible especially since it has been shown that six out of the numerous *nif* genes are absolutely required for FeMo-co biosynthesis and nitrogenase activity, both *in vitro* and *in vivo*.

It is likely that the products of some genes that are required for FeMo-co biosynthesis *in vivo* could be replaced by the activities of plant counterparts.

Thus, we are entering a very promising period of research on BNF, both in more conventional systems and nonlegumes such as rice, based on rapidly advancing basic studies on the chemistry, biochemistry, genetics, physiology, regulation, taxonomy, genomics and metagenomics, and metabolism of nitrogen-fixing organisms (and their hosts). This is the topic of this book, which should be a major resource for scientists in the field, and those wanting to enter it, as well as teachers and agricultural and molecular specialists wanting to apply the technology.

Frans J. de Bruijn

Acknowledgments

I greatly acknowledge Anton Hartmann for inviting me to the European Nitrogen Fixation Congress held in Munich in September 2012 and its two satellite meetings. The programs of these meetings contributed significantly to the list of invited authors. I also thank Jean-Michele Ané for sharing a figure from one of his latest publications for my Chapter 108 of this book and Charles Rosenberg for sharing a figure from his chapter. I thank Julie Cullimore for critically reading my Chapter 108 and making helpful suggestions. I would like to thank the authors for their cooperation and excellent contributions. I would also like to thank Claude Bruand and Marcel Soon for their help with the computer work. The Laboratory for Plant microbe Interaction (*LIPM*), the Institut National de Recherche Agronomique (*INRA*), the Centre National de Recherche Scientifique (*CNRS*) and the *Labex Tulip* are gratefully acknowledged for their support of my editorial activities.

Chapter 1

Introduction

Frans J. de Bruijn
INRA-CNRS, Laboratoire des Interactions Plantes-Microorganismes (LIPM)
UMR441-2594, Castanet-Tolosan, France

Nitrogen fixation is a process by which nitrogen (N_2) in the atmosphere is converted into ammonia (NH_3) (Postgate, 1998). Atmospheric nitrogen or elemental nitrogen (N_2) is relatively inert: it does not easily react with other chemicals to form new compounds. Fixation processes free up the nitrogen atoms from their diatomic form (N_2) to be used in other ways. Nitrogen fixation, natural and synthetic, is essential for all forms of life because nitrogen is required to biosynthesize basic building blocks of plants, animals, and other life forms, for example, nucleotides for DNA and RNA and amino acids for proteins. Therefore, nitrogen fixation is essential for agriculture and for the manufacture of fertilizer (Free Wikipedia Encyclopedia, Biological Nitrogen Fixation; Postgate, 1998).

Nitrogen fixation also refers to other biological conversions of nitrogen, such as its conversion to nitrogen dioxide. Microorganisms that fix nitrogen are bacteria called diazotrophs (Postgate, 1998). Some higher plants and some animals (termites) have formed associations (symbioses) with diazotrophs.

The first nitrogen-fixing microbe to be discovered was *Clostridium pasteurianum* obtained by S. Winogradsky in 1893. The second free-living diazotroph *Azotobacter chroococcum* was first reported by the Dutch microbiologist M.W. Beijerinck in 1901. Symbiotic nitrogen fixation was discovered by the German agronomists H. Hellriegel and H. Willfarth in 1886–1888 (Postgate, 1998).

Biological nitrogen fixation (BNF) occurs when atmospheric nitrogen is converted to ammonia by an enzyme called *nitrogenase* (Postgate, 1998). The reaction for BNF is as follows:

$$N_2 + 8H^+ + 8e^- \rightarrow 2\,NH_3 + H_2$$

The process is coupled to the hydrolysis of 16 equivalents of ATP and is accompanied by the coformation of one molecule of H_2. In free-living diazotrophs, the nitrogenase-generated ammonium is assimilated into glutamate through the glutamine synthetase/glutamate synthase pathway (Postgate, 1998). Enzymes responsible for nitrogenase action are very susceptible to destruction by oxygen. Many bacteria cease production of the enzyme in the presence of oxygen. Many nitrogen-fixing organisms exist only in anaerobic conditions, respiring to draw down oxygen levels or binding the oxygen with a protein such as leghemoglobin (Free Wikipedia Encyclopedia, Biological Nitrogen Fixation; Postgate, 1998).

1.1 FREE-LIVING DIAZOTROPHS

Anaerobes: These are obligate anaerobes that cannot tolerate oxygen even if they are not fixing nitrogen. They live in habitats that are low in oxygen, such as soils and decaying vegetable matter. *Clostridium* is an example. Sulfate-reducing bacteria are important in ocean sediments (e.g., *Desulfovibrio*); some Archean methanogens fix nitrogen in mud and animal intestines, as well as in the deep ocean.

Facultative anaerobes: These species can grow either with or without oxygen, but they only fix nitrogen anaerobically. Often, they respire oxygen as rapidly as it is supplied, keeping the amount of free oxygen low. Examples include *Klebsiella pneumoniae*, *Bacillus polymyxa*, *Bacillus macerans*, and *Escherichia intermedia*.

Aerobes: These species require oxygen to grow, yet their nitrogenase is still debilitated if exposed to oxygen. *Azotobacter vinelandii* is the most studied of these organisms. It uses very high respiration rates and protective compounds

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

to prevent oxygen damage. Many other species also reduce the oxygen levels in this way, but with lower respiration rates and lower oxygen tolerance (Free Wikipedia Encyclopedia, Biological Nitrogen Fixation; Postgate, 1998).

Oxygenic photosynthetic bacteria generate oxygen as a by-product of photosynthesis, yet some are able to fix nitrogen as well. These are colonial bacteria that have specialized cells (heterocysts) that lack the oxygen-generating steps of photosynthesis. Examples are *Anabaena cylindrica* and *Nostoc commune*. Other cyanobacteria lack heterocysts and can fix nitrogen only in low light and oxygen levels (e.g., *Plectonema*), or in a diurnal rhythm.

Anoxygenic photosynthetic bacteria do not generate oxygen during photosynthesis, having only a single photosystem that cannot split water. Nitrogenase is expressed under nitrogen limitation. Usually, the expression is regulated via the negative feedback from the produced ammonium ion, but in the absence of N_2, the product is not formed and the by-product H_2 continues unabated (biohydrogen). The example species are *Rhodobacter sphaeroides*, *Rhodopseudomonas palustris*, and *Rhodobacter capsulatus* (Free Wikipedia Encyclopedia, Biological Nitrogen Fixation; Postgate, 1998).

1.2 SYMBIOTIC NITROGEN-FIXING BACTERIA

Rhizobia are Gram-negative with the ability to establish an N_2-fixing symbiosis on legume roots and on the stems of some aquatic legumes. During this interaction, bacteroids, as rhizobia are called in the symbiotic state, are contained in intracellular compartments within a specialized organ, the nodule, where they fix N_2. Similarly, *Frankia*, Gram-positive soil bacteria, induce the formation of nitrogen-fixing nodules in actinorhizal plants (Postgate, 1998).

Plants that contribute to nitrogen fixation include the legume family – Fabaceae – with taxa such as kudzu, clovers, soybeans, alfalfa, lupines, and peanuts. They contain symbiotic bacteria called *Rhizobia* within nodules in their root systems, producing nitrogen compounds that help the plant to grow and compete with other plants. When the plant dies, the fixed nitrogen is released, making it available to other plants and this helps to fertilize the soil. The great majority of legumes have this association, but a few genera (e.g., *Styphnolobium*) do not. In many traditional and organic farming practices, fields are rotated through various types of crops, which usually includes one consisting mainly or entirely of clover, alfalfa, or buckwheat (nonlegume family *Polygonaceae*), which are often referred to as "green manure" (Free Wikipedia Encyclopedia, Biological Nitrogen Fixation).

Legumes also include major food and feed crop species, such as soybean, pea, clover, chickpea, alfalfa, and mung bean. They represent the third largest group of angiosperms and are the second largest group of food and feed crops grown globally. They are cultivated on 12–15% of the available arable land and are responsible for more than 25% of the world's primary crop production with 247 million tons of grain legumes produced annually (European Association for Grain Legume Research, 2007). In addition to food and feed crops, legumes such as soybeans and *Pongamia pinnata* have gathered a great deal of attention as future sustainable biofuel sources because of their high seed oil content (Ferguson et al., 2010).

Although by far the majority of plants able to form nitrogen-fixing root nodules are in the legume family Fabaceae, there are a few exceptions: *Parasponia*, a tropical Celtidaceae, is also able to interact with rhizobia and form nitrogen-fixing nodules. Actinorhizal plants, such as alder and bayberry, can also form nitrogen-fixing nodules, thanks to a symbiotic association with *Frankia* bacteria. These plants belong to 25 genera distributed among 8 plant families. The ability to fix nitrogen is far from universally present in these families. For instance, of 122 genera in the Rosaceae, only 4 genera are capable of fixing nitrogen. All these families belong to the orders Cucurbitales, Fagales, and Rosales, which together with the Fabales form a clade of eurosids. In this clade, Fabales were the first lineage to branch off; thus, the ability to fix nitrogen may be plesiomorphic and subsequently lost in most descendants of the original nitrogen-fixing plant; however, it may be that the basic genetic and physiological requirements were present in an incipient state in the last common ancestors of all these plants, but only evolved to full function in some of them (Free Wikipedia Encyclopedia, Biological Nitrogen Fixation).

1.3 ASSOCIATIVE NITROGEN-FIXING BACTERIA

Associative nitrogen fixers form a group of mutualist systems in which there is some interdependence between the partners though both can grow satisfactorily apart (Postgate, 1998). They involve grasses (Gramineae) principally. The prospect of finding bacteria that would form associative relationships with rice, other cereals, or graminaceous crops has provoked considerable interest in those diazotrophic bacteria that inhabit the rhizosphere of such plants (Postgate, 1998). In recent years, several types have been reported, for example, species of the new genera *Herbaspirillum*, *Gluconobacter*, *Azoarcus*, and *Burkholderia*, as well as diazotrophic species of *Acetobacter* called *Acetobacter diazotrophicus* (Postgate, 1998).

1.4 OUTLINE OF THIS BOOK

In this book, the most recent findings about a variety of free-living, associative, or symbiotic diazotrophs are

covered, nitrogenase(s) and their mechanism of action and regulation are reviewed, and the use of diazotrophs in agriculture is summarized.

The flow of the chapters is as follows: This chapter is an introduction to the book by the editor, giving the background to the field, describing the flow of sections and chapters and highlighting sections, individual contributions, and some future trends. Section 1 contains a number of focus chapters (reviews) introducing the main topics of the book, including nitrogenases and how they work, evolution and taxonomy of nitrogen-fixing organisms, the evolution of *Rhizobium* nodulation, and bioengineering nitrogen acquisition in rice. Section 2 covers selected recent advances in the biochemistry of nitrogenases, including the biosynthesis of the FeMo-cofactor (FeMo-co) subunit of nitrogenase, and conserved amino acid sequence features in MoFe, VFe, and FeFe nitrogenases. Section 3 covers the regulation of nitrogen-fixation genes and nitrogenase itself. The chapters in this section will describe regulatory aspects of several different nitrogen-fixing systems, such as *A. vinelandii*, *R. capsulatus*, *Rhodospirillum rubrum*, *Pseudomonas stutzeri*, and *Rhizobium etli*. Section 4 covers taxonomic and evolutionary features of nitrogen-fixing organisms, including chapters on taxonomy as well as the origin and diversity of *Burkholderia* and other beta-rhizobia; the phylogeny of nodulation and nitrogen-fixation genes in *Bradyrhizobium*; and a global census of nitrogenases and nitrogen-fixation genes. Section 5 covers the genomics of selected nitrogen-fixing organisms and the comparative analysis of their genomes. Also included are a chapter on the transfer of the symbiotic island of *Mesorhizobium loti* and a chapter on software program for pan-genomic analysis. Section 6 covers aspects of the physiology and metabolism of nitrogen-fixing organisms and a chapter on the need for photosynthesis for efficient nitrogen fixation in a rhizobial strain, as well as chapters on cytochrome oxidases, the role of BacA in rhizobia, and the analysis of flagellins in *Rhizobium leguminosarum*. Section 7 contains a number of chapters on the rhizobial life in the rhizosphere of plants, including the effect of plant root exudates, role of quorum sensing and quenching, exopolysaccharides, flavonoids, luminochrome, and the response to various stresses. Section 8 deals with the physiology and regulation of nodulation. Chapters include the root hair as a single cell model for systems biology, two chapters on the conserved genetic program among arbuscular mycorrhizal, actinorhizal, and legume–rhizobial symbiosis, the molecular determinants of nodulation in the *Frankia*/*Discaria* symbiosis and the physiology of nitrogen assimilation in the *Datisca–Frankia* root nodule symbiosis, as well as chapters on the Nod-independent symbiosis in *Aeschynomene*, the role of phosphorus efficiency, the regulation of nodule development by auxin transport, and the *NOOT* mutant of *Medicago truncatula*. Section 9 then initiates a series of chapters on nodulation. This section covers the very early events in nodulation, including putative Nod-factor receptors and signal transduction, early signaling in *Frankia*, the role of ectopyrases and cellulose $CelC_2$ in nodulation, and calcium spiking. Section 10 addresses the infection and nodule ontogeny topics. A multitude of aspects are covered in this section, which are as follows: Ca^{2+} signaling and infection thread formation; the role of hormones in nodulation; the role of a transporter in integrating nutrient and hormone signaling with lateral root growth and nodule development; the role of genes encoding MYB coiled-coil and ERF transcription factors; the dissection of the roles in outer and inner root cell layers of plant genes that control rhizobial infection and nodule ontogeny; the multifaceted role of nitric oxide in nodulation; the role of pectate lyase in root infection; the identification of novel *M. truncatula* genes required for rhizobial invasion and bacteroid differentiation, as well as novel approaches such as RNA-seq; and cortical auxin modeling for nodulation. Section 11 covers the "next" stage in nodule biology, namely, the development of bacteroids required for nitrogen fixation and the proteomic profile of the soybean symbiosome membrane. Section 12 addresses briefly N-assimilation (ammonium transport) in nodules and nodule senescence. In Section 13, several "Omics" applications in rhizobia and *Frankia* (metagenomics, transcriptomics, proteomics, genomics) are discussed, such as the metagenomic analysis of microsymbiont selection by the legume host plant, proteomic profiling of *Rhizobium tropici*, the *Frankia alni* symbiotic transcriptome, a comprehensive survey of the Rhizobiales using high-throughput DNA sequencing and gene-targeted metagenomics of diazotrophs in coastal saline soil. Section 14 does the same with (host) plant genomics, proteomics, and transcriptomics, including chapters on the *M. truncatula* genome, retrotransposon *Tnt1* mutagenesis, leveraging large-scale approaches to dissect legume genomics and the *Rhizobium*–legume symbiosis, databases, and functional genomics of symbiotic nitrogen fixation in legumes. In Section 15, the intricacies of nodule formation and functioning are left behind, and the focus is on nitrogen-fixing cyanobacteria, with studies in the open ocean, requirement of cell wall remodeling and cell differentiation in a cyanobacterium of the order Nostocales, and nitrogen fixation in the oxygenic phototrophic prokaryotes (cyanobacteria): the fight against oxygen. Section 16 deals with diazotrophic plant growth promoting rhizobacteria (PGPR) and nonlegumes. This section begins with a historical overview of PGPR and nonlegumes. Beneficial plants associated with *Burkholderia* species, agronomic applications of *Azospirillum* inoculants, and molecular characterization of the diazotrophic bacterial community in sugarcane are discussed. Moreover, the role of auxin signaling in plant–microbe interactions is presented. Finally, a chapter on how fertilization affects the selection of PGPR by the plant is included, as well as the genetic and

functional characterization of *Paenibacillus riograndensis*, Herbaspirillum attachment to maize, and isolation of novel diazotrophs from sugarcane plants. Section 17 covers field studies, inoculum preparation, and quality and response to stress, such as dessication, evaluation of elite soybean varieties in the field, phase variation in *Azospirillum*, and the application of LCOs to legume and nonlegume seeds.

Section 18 is special and deals with the opportunities for nitrogen fixation in rice and other cereals (see Preface). This "holy grail" has been with us for a long time. The first two chapters explore the present possibilities to "engineer" rice for nitrogen fixation. In the first chapter, the history of the quest for BNF in cereals is reviewed, and associative (endophytic) diazotrophy with grasses and transfer of the legume nodulation and nitrogen-fixation traits to cereals are discussed. In the second chapter, the environmental and economic impacts of biological N_2 fixing cereal crops are discussed. In this chapter, the question is raised "how novel are nodules?" (Markmann and Parniske, 2009). Two major approaches are discussed again: Developing the root nodule symbiosis in cereals and transferring the nitrogenase genes into cereal plants, and finding a proper location for their expression in terms of low free O_2 concentration and sufficient energy supply. These two options and the associative and endophytic nitrogen fixation were already discussed in previous meetings such as those of the Working Group of the IRRI Frontier Project on assessing Opportunities for Nitrogen Fixation in Rice (Opportunities for BNF in Rice and other Non-Legumes (Ladha et al., 1997)), as well as The Quest for Nitrogen Fixation in Rice (Ladha and Reddy, 2000). However, we are in a much more informed state now. Recently, the Bill and Melinda Gates Foundation convened a small meeting on the subject and several projects were funded, including the transfer of the nitrogen-fixation (nitrogenase) genes into cereals, and the transfer of the ability to form nitrogen-fixing nodules to cereals. This has greatly stimulated research in these areas.

In the case of rice transformation, it is now routine and since the genome has been sequenced and extensive genetics is available, it should serve as a "model species," while for other cereals (grasses) a recently developed *Brachypodium* model system has been established (Bevan et al., 2010).

The discovery of a "common symbiotic pathway" in arbuscular mycorrhizal, rhizobial, and actinorhizal symbioses and the identification of conserved pathway genes (CSSP, CSP or SYM pathway) in legumes and monocots (including rice) have made the extension of the ability to fix nitrogen in nodular associations with cereals in a more realistic endeavor (Venkateshwaran et al., 2013; see Chapter 108).

The direct transfer of nitrogen-fixation (*nif*) genes into nonlegumes has also become more feasible especially since it has been shown that six out of the numerous *nif* genes are absolutely required for FeMo-co biosynthesis and nitrogenase activities, both *in vitro* and *in vivo*.

It is likely that the products of some genes that are required for FeMo-co biosynthesis *in vivo* could be replaced by the activities of plant counterparts.

Chapter 110 deals with the conservation of the symbiotic signaling pathway (SYM; see earlier) between legumes and rice and the related functional cross-complementation studies. Chapter 111 describes the ecophysiology of the natural endophytic *Rhizobium*–rice association and the translational assessment of its biofertilization performance in the Nile delta.

Section 19 contains a first chapter on nitrogen fixation and nitrogen recycling in insects. In the second chapter, a protocol for the rapid identification of nodule bacteria with MALDI-TOF mass spectrometry is presented. The last chapter of the book gives a comprehensive review on endophytes in plants.

Thus, we are entering a very promising period of research on BNF, both in more conventional systems and in nonlegumes such as rice and other cereals, based on rapidly advancing basic studies on the chemistry, biochemistry, genetics, physiology, regulation, taxonomy, genomics, and metagenomics, and the metabolism of nitrogen-fixing organisms and their hosts. These are the topics of this book, which should be a major resource for scientists in the field, and those wanting to enter it, as well as teachers and agricultural specialists wanting to apply the technology.

Chapter 2

Recent Advances in Understanding Nitrogenases and How They Work

William E. Newton
Department of Biochemistry, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

2.1 INTRODUCTION: TWO TYPES OF NITROGENASES EXIST

There are two very different types of nitrogenases (Smith et al., 2004). First, there are those that constitute the Group-1 nitrogenases. These are the three closely related, but genetically distinct, enzymes: the well-studied molybdenum-based enzyme (Mo-nitrogenase), a vanadium-based enzyme (V-nitrogenase), and an enzyme that contains neither heterometal but relies on iron alone (Fe-nitrogenase). Except for the different heterometal atom (Mo, V, or Fe) present, they are otherwise so similar that they must have arisen from a common ancestor (Fani et al., 2000; Young, 2005). In contrast, Group-2 consists of a single representative, the *Streptomyces thermoautotrophicus* nitrogenase. This enzyme is so different from the Group-1 enzymes that it may well be the result of an evolutionarily independent event (Gadkari, 2004; Ribbe et al., 1997). It is completely insensitive to the presence of O_2, CO, and H_2, all of which are potent inhibitors of nitrogen fixation with the Group-1 nitrogenases, and does not catalyze the reduction of acetylene to ethylene. Its unusual structural and mechanistic properties could hold promise of new insights into the process and possibly new ways of extending the benefits of biological nitrogen fixation in agricultural systems. However, this enzyme has not been under study recently and so there is no progress to report.

2.2 OCCURRENCE AND RELATIONSHIPS AMONG THE GROUP-1 NITROGENASES

All known nitrogen-fixing organisms have the Group-1 Mo-nitrogenase; however, the presence of either or both of the V-nitrogenase and Fe-nitrogenase appears to be completely haphazard. For example, both the free-living *Klebsiella pneumoniae* and the rhizobacteria, which form nodules on the roots of legume plants, have only Mo-nitrogenase, whereas other organisms, for example, *Azotobacter vinelandii*, have all three enzymes. Other combinations also occur, for example, *Azotobacter chroococcum* has the Mo- and V-nitrogenases, but *Rhodobacter capsulatus* has the Mo- and Fe-nitrogenases (Newton, 1993).

The expression of the various nitrogenases depends on the availability of the metal ions (either Mo or V) in the growth environment (Pau, 1994). Whenever Mo is available, only the Mo-nitrogenase (*nif*) genes are expressed and the genes, if present, for the other two nitrogenases (*vnf* and *anf*) are repressed. Similarly, when V is available and Mo is absent, only the *vnf* genes are expressed. If both Mo and V are absent, then just the *anf* genes are expressed and only Fe-nitrogenase is produced. This control by metal availability is physiologically reasonable because Mo-nitrogenase is the most efficient N_2-reduction catalyst and Fe-nitrogenase is the least efficient. However, there are only very few areas

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

on Earth where Mo is completely absent, which raises the question of whether these nitrogenases have other functions unrelated to nitrogen fixation.

The relatedness of these three nitrogenases is shown by their ability to cross-complement each other (Emerich and Burris, 1978; Newton, 1993; Pau, 1994). All nitrogenases consist of two component proteins: the Fe protein and the MoFe (VFe or FeFe) protein (Smith et al., 2004). These components can be separately purified, but have no N_2-fixation activity alone (but see later). Either component protein of, say, Mo-nitrogenase from *A. vinelandii* forms an active hybrid nitrogenase when it is mixed with the complementary component protein of the V-nitrogenase from the same organism. However, not all component proteins cross-complement each other; for example, neither component protein of the *A. vinelandii* Fe-nitrogenase forms an active hybrid with the complementary protein from its Mo-nitrogenase or V-nitrogenase. Furthermore, mixtures of the Mo-nitrogenase component proteins from different organisms may not produce active hybrid nitrogenases, a notable example being the Mo-nitrogenase components from the strict anaerobe, *Clostridium pasteurianum*.

Both the origin and evolution of the nitrogen-fixation genes and proteins and the mechanisms involved in shaping the process itself continue to engender considerable debate as do the processes involved in distributing this ability among the relatively few N_2-fixing genera of bacteria and archaea. Its apparent haphazard distribution might reflect either a common ancestral property that was lost randomly during divergent evolution or a more recent example of lateral gene transfer. In fact, genome sequences appear to support the likelihood that a combination of both multiple losses and multiple transfers of the nitrogen-fixation genes has occurred. Whatever the case, the genetic relatedness of the Group-1 nitrogenases, including even the order in which the genes are found in genomes, supports a common ancient ancestry (Young, 2005).

So, which of the Group-1 nitrogenases evolved first? One view cites a pyrites-based catalyst that pre-dated enzymes and which might then have been sequestered by early protein-like materials (Wächtershäuser, 1988). This view would suggest that an Fe-based nitrogenase might be the progenitor from which the other nitrogenases developed. Consideration of the limitations that an early anoxic atmosphere would place on the chemistry and availability of Mo, V, and Fe has also led to the conclusion that the V- and Fe-nitrogenases pre-dated the Mo-nitrogenase (Anbar and Knoll, 2002; Raymond et al., 2004). Under these anoxic conditions, Mo (present as water-insoluble MoS_2) would be unavailable to support N_2 fixation, but Fe would be plentiful (Anbar, 2008). An Fe- (and/or V-) nitrogenase could then well have been the logical choice. A similar conclusion results when the occurrence of Mo/S and W/Se in hydroxylases and oxidoreductases in mesophiles, thermophiles, and hyperthermophiles is analyzed (Newton, 2000). As the hot, anoxic, early-Earth cooled, hyperthermophilic microbes would have appeared first, then thermophiles, and finally mesophiles. Only in mesophiles, after conditions have become cooler and presumably more oxygenated, thus the Mo/S-containing (rather than W/Se-containing) enzymes occur. Now, the oxygenated conditions produce the water-soluble MoO_4^{2-}, while simultaneously depleting the environment of Fe, which would be deposited as water-insoluble FeO(OH), and Mo-based enzymes, including Mo-nitrogenase, would become the norm.

A related suggestion similarly invokes a primitive nitrogenase from which the three Group-1 nitrogenases developed (Postgate and Eady, 1988). This suggestion is based on the observation that, although genetically distinct, the three sets of structural (*nifHDK*, *vnfHDGK*, and *anfHDGK*) genes were likely formed by gene iteration (Fani et al., 2000). Furthermore, the products of five *nif*-specific (*nifMBVUS*) genes are required for the biosynthesis of all three nitrogenases; the heterometal cofactors are transferable among themselves; and all have similar catalytic properties (Newton, 1993). An aboriginal enzyme is also the basis of a somewhat contrasting view of nitrogenase evolution that has its basis in phylogenetic and structural analyses (Boyd et al., 2011). Here, the suggestion is that the V- and Fe-nitrogenases are derived from, and not the ancestors of, Mo-nitrogenase, whose formation is driven by local limited supplies of Mo.

2.3 OVERVIEW OF PROPERTIES OF Mo-NITROGENASE

The Mo-nitrogenases from a variety of bacterial genera exhibit a high level of primary (amino acid) sequence identity. The sequence conservation is particularly high in the regions of the MgATP- and metallocluster-binding sites. The Fe-protein component is a homodimer (encoded by the *nifH* gene) of about 64 kDa molecular mass. A single [4Fe–4S] cluster bridges the two identical subunits, each of which has its own MgATP/MgADP-binding site. The Fe protein is a specific reductant for the MoFe protein. The MoFe protein is an $\alpha_2\beta_2$ heterotetramer (encoded by the *nifDK* genes) of about 230 kDa molecular mass. Each αβ-subunit pair contains one copy of each of two different prosthetic groups, namely, the P cluster and the iron-molybdenum cofactor (or FeMo-cofactor or the M center). The latter serves as the site of substrate binding and reduction (Scott et al., 1990). Unlike the P cluster, which is disrupted when removed from the MoFe protein, the FeMo-cofactor can be extracted essentially intact into a variety of organic solvents (Wink et al., 1989). The isolated prosthetic group is then referred to as FeMoco. Each component protein exhibits an electron paramagnetic resonance (EPR) spectrum when isolated in the presence of sodium dithionite, their so-called

"resting state." These EPR signals have been instrumental in determining the direction of electron flow between the component proteins (Orme-Johnson et al., 1972) and in monitoring many of the catalyzed reactions (see later). Three-dimensional structures of the individual component proteins from both wild-type and mutant bacterial strains and their complexes are available (see later).

The physiologically important nitrogen-fixation reaction is outlined in the following equation. Delivery of eight electrons and eight protons results in the catalyzed reduction of one N_2 to two ammonia molecules together with one H_2 molecule and consumes 16 MgATP molecules. The evolution of one H_2 for each N_2 reduced may be either a mandatory step in the mechanism (Simpson and Burris, 1984) or an as yet unexplained kinetic phenomenon.

$$N_2 + 8\,H^+ + 8\,e^- + 16\,MgATP \rightarrow 2\,NH_3 + H_2 + 16\,MgADP + 16\,P_i$$

In vivo, either ferredoxin or flavodoxin acts as the reductant of the Fe protein, whereas *in vitro*, the artificial reductant, sodium dithionite ($Na_2S_2O_4$), is most often used. The Fe protein accepts only a single electron from sodium dithionite, which is then transferred to the MoFe protein with two molecules of MgATP being hydrolyzed (Seefeldt and Dean, 1997). Other reductants, for example, Ti(III) and flavodoxin hydroquinone, used *in vitro* may transfer two electrons to the Fe protein. When both electrons are transferred in a single step to the MoFe protein, with still only two molecules of MgATP being hydrolyzed, the MgATP consumption rate is halved (Lowery et al., 2006). It remains to be seen if both one-electron and two-electron transfers occur *in vivo*. Both the rate of electron transfer (the flux) and the ratio of electrons transferred to MgATP hydrolyzed are independent of the substrate being reduced.

Wild-type Mo-nitrogenase catalyzes the reduction of many other small molecules (Fig. 2.1). All substrates have the same requirements as N_2 reduction, namely, a supply of MgATP, a low-potential reductant, and an anaerobic environment (Newton and Dilworth, 2011). The most commonly used substrate is acetylene, which is reduced by two electrons to ethylene, in a reaction that accounts for about 95% of the electron flux under a 10% C_2H_2/90% argon atmosphere with the remainder going to H_2 production. When no other substrate is present, all electron flux is used for proton reduction to H_2. In addition, H_2 is a specific inhibitor of N_2 reduction, but does not affect either the reduction of any other substrate or its own evolution. When D_2 is used as the specific N_2-reduction inhibitor, HD is formed in a reaction that has all the requirements of a nitrogenase-catalyzed reaction that is also inhibited by CO (Newton and Dilworth, 2011; Burgess and Lowe, 1996). Also shown is carbon monoxide (CO), a well-studied potent noncompetitive inhibitor of all nitrogenase-catalyzed substrate reductions except for proton reduction to H_2. Recently, CO has also been shown to be a substrate for Mo-nitrogenase (Lee et al., 2010).

2.4 OVERVIEW OF PROPERTIES OF V-NITROGENASE AND Fe-NITROGENASE

These so-called alternative nitrogenases also consist of two protein components (Eady, 1996, 2003; Smith et al., 2004). Each nitrogenase has its specific Fe-protein component. The larger component protein of the V-nitrogenase contains a VFe-cofactor, with a V atom replacing the Mo atom of the Mo-nitrogenase. Similarly, the Fe-nitrogenase has no Mo atom and instead has an FeFe-cofactor in an FeFe protein. The high level of primary sequence identity among the Mo-nitrogenases extends to the V- and Fe-nitrogenases and strongly suggests that all nitrogenases share common structural features and mechanistic similarities. One major difference is that both the VFe protein and FeFe protein have additional δ-subunits. Both were initially reported as $\alpha_2\beta_2\delta_2$ heterohexamers (Eady, 1996, 2003) but recently, using immobilized metal affinity chromatography and His-tagging, the VFe protein was purified as an $\alpha_2\beta_2\delta_4$

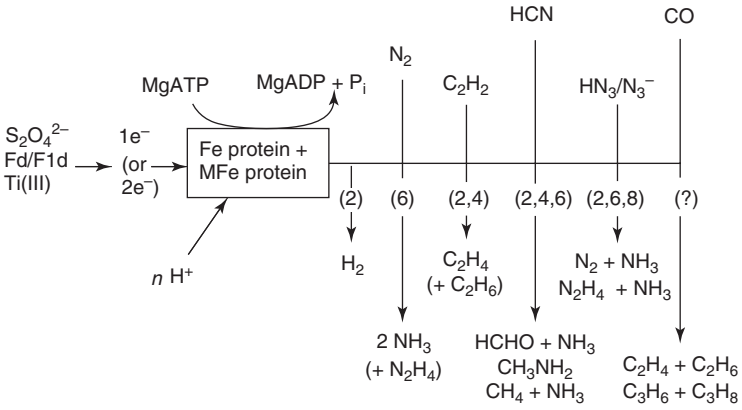

Figure 2.1 Electron donors, substrates, and products of catalysis. Not all products shown are produced by all three Group-1 nitrogenases. CO is not only a substrate but also a potent reversible inhibitor of all nitrogenase-catalyzed substrate reductions except for that of protons to H_2. Fe-p represents the Fe protein, MFe-p is the MoFe/VFe/FeFe protein; reductants are dithionite ($S_2O_4^{2-}$), titanium(III) citrate (Ti(III)), Fld (flavodoxin hydroquinone), or Fd (ferredoxin); numbers in parentheses are the number of electrons used to form the products shown.

heterooctamer (Lee et al., 2009). The δ-subunits apparently bind to the apoprotein during biosynthesis and remain bound thereafter. In contrast, the δ-subunit equivalent of the MoFe protein (encoded by the *nifY* gene) is lost in the late stages of its maturation.

EPR spectroscopy shows that both alternative nitrogenases undergo similar changes to those of the Mo-nitrogenase during turnover. Even so, the dithionite-reduced VFe protein exhibits an EPR spectrum that is considerably more complex, and still not clearly understood, than that of the MoFe protein (Lee et al., 2009), whereas the purified resting-state FeFe protein exhibits no EPR signal (Krahn et al., 2002; Schneider et al., 1997). However, under turnover conditions, the FeFe protein develops a rhombic $S = 1/2$ EPR signal indicating that it is also reduced by electron transfer from its Fe-protein partner (Schneider et al., 1997).

The catalytic properties of both the V- and Fe-nitrogenases also differ in detail from those of Mo-nitrogenase. For N_2 reduction, V- and Fe-nitrogenases use only about 50% and 30%, respectively, of the electron flux to produce NH_3 under 100% N_2 compared to about 75% for Mo-nitrogenase (Dilworth and Eady, 1991; Schneider et al., 1997). V-nitrogenase also produces a very small amount of N_2H_4, which is not observed with Mo-nitrogenase (Dilworth and Eady, 1991). V- and Fe-nitrogenases are also much less effective for C_2H_2 reduction with only about 40% and 15%, respectively, of the flux producing C_2H_4 compared with 95% for Mo-nitrogenase. Again, a small amount of additional product (C_2H_6) not seen with Mo-nitrogenase is formed under a 10% C_2H_2/90% argon atmosphere (Dilworth et al., 1988; Schneider et al., 1997). A recent significant observation is that not only is 10% carbon monoxide (CO) a noncompetitive inhibitor of the V-nitrogenase-catalyzed reduction of all substrates except that of the proton (Dilworth et al., 1988) but, above 10% CO, it inhibits catalyzed proton reduction by 35% or more (Lee et al., 2009). Some, at least, of these electrons are diverted to catalyzed CO reduction to produce a variety of C_1-to-C_4 hydrocarbons (Hu et al., 2012; Lee et al., 2010). Since this discovery, exceedingly small quantities of similar CO reduction products have been detected with wild-type Mo-nitrogenase (Hu et al., 2011) and with somewhat higher yields from a variant Mo-nitrogenase (Yang et al., 2011). The physiological significance of this discovery is yet to be determined.

2.5 STRUCTURES OF THE NITROGENASE COMPONENT PROTEINS AND THEIR COMPLEXES

X-ray-based 3D structures of the wild-type Fe protein (Georgiadis et al., 1992; Jang et al., 2000; PDB code: 1FP6), the wild-type MoFe protein (Einsle et al., 2002; Howard and Rees, 1996; Kim and Rees, 1992a, b; Mayer et al., 1999; PDB codes: 1M1N, 1QGU, 1QH1, 1QH8, 3M1N), complexes of the two proteins (Chiu et al., 2001; Schindelin et al., 1997; Schmid et al., 2002a; Tezcan et al., 2005; PDB codes: 1N2C, 1G20, 1G21, 1M1Y 2AFH, 2AFI, 2AFK), and several variant Fe proteins (Chiu et al., 2001; PDB codes: 1G20, 1G21) and MoFe proteins (Mayer et al., 2002; Sarma et al., 2010; Schmid et al., 2002b; Sørlie et al., 2001; PDB code: 1FP4, 1H1L, 1L5H, 3K1A) are all known. There are no 3D structures of either the V-nitrogenase or the Fe-nitrogenase components or complexes. However, information from both Mössbauer (Krahn et al., 2002; Ravi et al., 1994) and X-ray absorption spectroscopies (Chen et al., 1993; George et al., 1988; Krahn et al., 2002) indicates that these nitrogenases share many structural similarities with the Mo-nitrogenase components (Smith et al., 2004).

When crystallized in the presence of excess MgADP, the Fe-protein structure shows one nucleotide bound to each subunit with both oriented parallel to one another in the subunit–subunit interface cleft (Jang et al., 2000). In the 2:1 Fe protein–MoFe protein complex, the nucleotides assume the same orientation and do not interact with the MoFe protein (see Fig. 2.2). Even though nucleotide binding to the Fe protein is known to be cooperative and to modify several properties of its $[Fe_4S_4]$ cluster, including its redox potential (Burgess and Lowe, 1996; Seefeldt and Dean, 1997), it remains unclear exactly how these effects are achieved. The nucleotides do not contact the $[Fe_4S_4]$ cluster directly, but rather their binding induces a significant structural change of the protein backbone in a region called switch II; this change is likely propagated to the cluster and so alters its electronic and redox properties (Seefeldt and Dean, 1997). A similar mechanism, called switch I, might be used for communication between the nucleotide-binding sites and the part of the Fe-protein surface that interacts with the MoFe protein during complex formation. Protein–protein contact could initiate electron transfer from the Fe protein and the resulting structural change in switch I would promote MgATP hydrolysis, followed by the dissociation of the Fe protein from the MoFe protein.

Early spectroscopic and controlled-degradation studies of the MoFe protein showed that it contained two previously unrecognized prosthetic groups, each of which contains about 50% of both the Fe and S^{2-} contents. They are the P cluster and the FeMo-cofactor (or M center). The composition and distribution within the protein of these metalloclusters was only established after the structure of the MoFe protein was solved. These unique prosthetic groups are distributed in pairs, one of each type, and one pair resides within each αβ-subunit pair. The P cluster has an $[Fe_8S_7]$ composition and is located at the interface of the α- and β-subunits, with each subunit providing three ligating cysteinyl residues. The FeMo-cofactor is an $[MoFe_7S_9(C^{4-})]$ cluster with an *R*-homocitrate molecule bound to the Mo atom. It is covalently bound to the α-subunit by only two

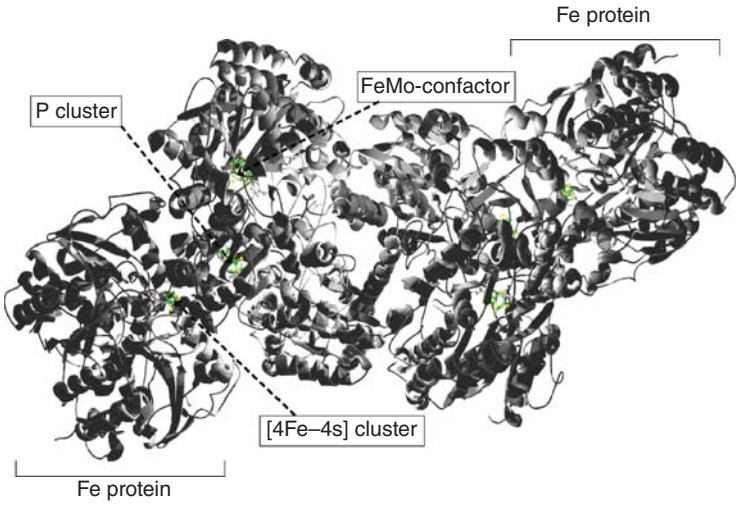

Figure 2.2 The structure of the 2:1 Fe protein–MoFe protein complex of the *Azotobacter vinelandii* nitrogenase stabilized by MgADP plus ALF_4^-. Both Fe-protein molecules bound to the centrally located MoFe protein are labeled and the three prosthetic groups are colored and labeled. Each FeMo-cofactor is situated within an α-subunit, whereas each P cluster sits at an interface of the α- and β-subunits. After docking, each Fe protein is located at an MoFe-protein α/β-subunit interface so that its [4Fe-4S] cluster is juxtaposed with a P cluster. The figure was drawn from coordinates available at PDB code: 1N2C.

amino acid residues (a cysteinyl and a histidinyl) and has no close involvement with the β-subunit (see Fig. 2.2).

A trapping technique, similar to that used for other "nucleotide switch" proteins, was successfully used with the Mo-nitrogenase components to produce the first stable complex of two Fe-protein molecules with one MoFe-protein molecule (Schindelin et al., 1997). This complex showed a significant conformational change in the Fe protein, but very little change in the MoFe protein. Each of the four Fe-protein subunits in the complex has an associated MgADP(AlF_4^-) moiety, which are again bound parallel in the subunit interface as found for the MgADP molecules bound to the Fe protein alone.

Docking of the two proteins occurs along their subunit interfaces and results in the Fe protein's [Fe_4S_4] cluster becoming buried in the protein–protein interface close to the MoFe protein's P cluster, which is then situated equidistant between the Fe protein's [Fe_4S_4] cluster and the FeMo-cofactor. This arrangement suggests a convenient electron-transfer pathway by which electrons move from the [Fe_4S_4] cluster through the P cluster to the FeMo-cofactor, where substrate reduction occurs. Another significant interaction involves the argininyl-100 residues of the Fe protein. In some bacteria, these residues are modified in a facile, reversible manner to regulate nitrogenase activity (Pope et al., 1985). The argininyl-100 residues have side chains that protrude into depressions in the surface of the MoFe protein and interact with the side chains of glutaminyl residues. Modification of these argininyl-100 residues introduces steric hindrance to the protein–protein interface, prevents complex formation, suppresses activity, and so regulates the enzyme.

Several other structures of 2:1 Fe protein–MoFe protein complexes have been solved, including one with a variant Fe protein (L127Δ-*Av*2) (Chiu et al., 2001), another from chemical cross-linking (Schmid et al., 2002a), and several with MgATP analogs (Tezcan et al., 2005). In all of these, only the Fe-protein structure is affected, the structure of the MoFe-protein component remains effectively unchanged. The last study clearly shows the importance of the nucleotide state of the Fe protein, that is, whether MgATP, MgADP, or neither is bound. The nucleotide state determines the docking geometry of the two proteins in the complex and may indicate that different circumstances induce different docking orientations or even sites. The docking option chosen, in turn, impacts the rate of electron transfer within the complex and might also direct the motion of one protein across the surface of the other.

2.6 STRUCTURES OF THE MoFe-PROTEIN PROSTHETIC GROUPS

The early reported structure of the FeMo-cofactor showed an [$MoFe_3S_3$] sub-cluster bridged by three μ_2-sulfides to an [Fe_4S_3] sub-cluster (see Fig. 2.3) (Chan et al., 1993; Kim and Rees, 1992b). As a result, only the terminal Fe atom of the latter sub-cluster had the expected tetrahedral geometry. All of the other six central Fe atoms had apparent trigonal geometry. However, a more recent, very high-resolution structure (Einsle et al., 2002) provided evidence for a single light atom, now generally considered to be carbide (C^{4-}) (Lancaster et al., 2011; Spatzel et al., 2011) within the central cavity of the FeMo-cofactor and equidistant from all six central Fe atoms (Fig. 2.3; see also Chapter 7). It is uncertain whether this light atom has a mechanistic or a structural role or both. The Mo atom has octahedral geometry provided by three sub-cluster μ_3-sulfides, the imidazole δ-N of an α-histidinyl residue, and by ligation from both the 2-hydroxyl and 2-carboxyl groups of *R*-homocitrate. The α-cysteinyl-Fe apex of the FeMo-cofactor has no associated water molecules, whereas the homocitrate-Mo apex is

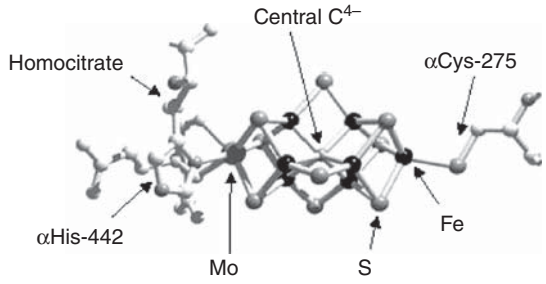

Figure 2.3 The structure of the FeMo-cofactor of *Azotobacter vinelandii* nitrogenase MoFe protein with its α-subunit-based ligating amino acid residues (αCys-275 and αHis-442) and homocitrate. The Mo, Fe, and S atoms are indicated as is the central carbide (C^{4-}). The seven darkest spheres are all Fe atoms and the eight lighter-gray spheres are all S atoms. The figure was drawn from coordinates available at PDB code: 1M1N.

surrounded by water molecules. Moreover, the homocitrate is positioned between the FeMo-cofactor and the P cluster and may be a component of an electron/proton-transfer pathway to bound substrate. There are also many important hydrogen-bonding interactions between the FeMo-cofactor and the surrounding amino acid residues (Kim and Rees, 1992a, b).

The P cluster is ligated by six cysteinyl residues, three from each subunit. The P cluster consists of an $[Fe_4S_4]$ sub-cluster that shares one of its sulfides with an $[Fe_4S_3]$ sub-cluster. This shared sulfide is in a very unusual situation as it is bound to all six of the central Fe atoms, that is, it is a μ_6-sulfide (see Fig. 2.4). The $[Fe_4S_4]$ sub-cluster is ligated by the γ-S of two α-subunit cysteinyl residues, whereas the $[Fe_4S_3]$ sub-cluster has ligation by the γ-S of two β-subunit cysteinyl residues. The two other cysteinyl residues, one from each of the α- and β-subunits, form μ_2-sulfide bridges between the sub-clusters.

When the P cluster in the protein is oxidized by redox-active dyes, it structurally rearranges to a more open structure with two of the four Fe atoms located in the $[Fe_4S_3]$ sub-cluster change ligation. They lose contact with the central μ_6-sulfide with one Fe atom becoming ligated by the γ-O of a β-serinyl residue and the other by the deprotonated backbone amide-N of the already bound and bridging α-cysteinyl residue (Fig. 2.4). Because both the serinyl – OH and the cysteinyl –NH are protonated when unbound and are deprotonated on binding, these redox-induced ligand changes raise the possibility that a two-electron oxidation of the P cluster during catalysis will also release two protons from the P cluster (Peters et al., 1997).

2.7 HOW ARE SUBSTRATES REDUCED?

Using the reductant sodium dithionite *in vitro*, the Fe protein is alternately oxidized and re-reduced as it delivers single electrons to the MoFe protein in a process that couples MgATP binding and hydrolysis to Fe protein–MoFe protein electron transfer and the association and dissociation of the two component proteins (see Fig. 2.5). The Fe protein alone is capable of binding MgATP, but both component proteins are required for MgATP hydrolysis. Neither component protein alone, with or without MgATP and/or reductant, will reduce substrate under the usual assay conditions (but see later). Use of a different reductant, for example, either Ti(III) or the *in vivo* reductant, flavodoxin hydroquinone, may impact one or more of the steps in this process (Duyvis et al., 1998; Erickson et al., 1999).

The overall reduction of N_2 to yield two molecules of NH_3 is thermodynamically favorable. So, why is MgATP required? If it is not a thermodynamic requirement, it

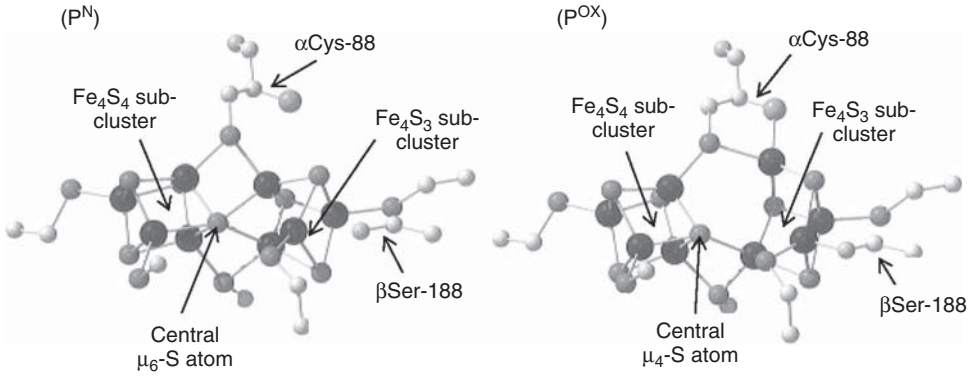

Figure 2.4 The structure of the P cluster of *Azotobacter vinelandii* nitrogenase MoFe protein in its dithionite-reduced (P^N) and oxidized (P^{OX}) states. Of its six ligating cysteinyl residues (αCys-62, αCys-88, αCys-154, βCys-70, βCys-95, βCys-153), only αCys-88 plus βSer-188 are identified because they are directly involved in the redox change. The Fe atoms are the larger darker spheres, the smaller lighter spheres are S atoms. *Source*: Modified from Peters et al., 1997 (PDB code: 3MIN and 2MIN).

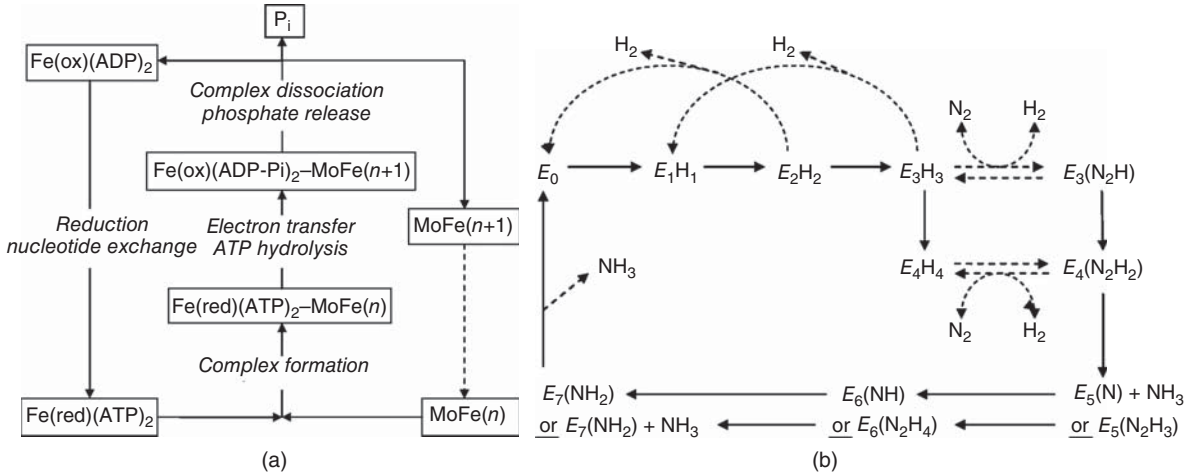

Figure 2.5 A modified Lowe–Thorneley scheme for Mo-nitrogenase catalysis. (a) The Fe-protein cycle describes the one-electron redox reactions of the Fe protein's [4Fe-4S] cluster, nucleotide exchange of the spent MgADP and phosphate (P_i) for MgATP, and complex formation with and electron transfer to the MoFe protein, when dithionite is used as reductant. Each turn of this cycle adds one electron to the MoFe protein. Fe represents the Fe protein in its oxidized (ox) or one-electron reduced (red) state; MoFe represents the MoFe protein with the number of electrons accepted shown as (n) or ($n+1$); the dashed arrow indicates that the MoFe($n+1$) protein can reenter this cycle and accept additional electrons and protons. *Source*: Modified from Lowe and Thorneley, 1984. (b) The MoFe-protein cycle for N_2 reduction. The dithionite-reduced (resting state) of the MoFe protein is designated as E_0 and, with each turn of the Fe-protein cycle, the MoFe protein goes through a succession of increasingly reduced states (E_1, E_2, … , E_7) as electrons and protons are accepted until sufficient and are accumulated for substrate reduction. An important concept of this scheme is that different substrates bind reversibly to different MoFe-protein redox states, for example, N_2 binds (as shown) at either E_3 or E_4 most likely by displacing H_2, whereas C_2H_2 binds at either E_1 or E_2. H_2 may be evolved from several redox states (as shown). The reduced-nitrogen intermediates shown are postulated and not proved (also see Fig. 2.6). Each solid arrow (⟶) represents one turn of the Fe-protein cycle, i.e., one hydrogenation (H^+/e^-) event with concomitant MgATP hydrolysis and each dashed arrow (- - -▶) represents a substrate-binding or product-release event. *Source*: Modified from Lowe and Thorneley, 1984.

must be for kinetic reasons. Most likely, MgATP binding helps drive electron transfer toward substrate reduction by increasing the difference in redox potential of the electron donor and acceptor (Lanzilotta and Seefeldt, 1997) and its subsequent hydrolysis, and complex dissociation ensures the irreversibility of the reaction. This so-called gating mechanism allows no backflow of electrons to the Fe protein and prevents energy-wasting futile cycling of electrons (Howard and Rees, 1996; Seefeldt and Dean, 1997). In this way, multiple electrons are accumulated within the MoFe protein and its bound substrate.

This view of the catalytic process actually describes only one part of the process, the so-called Fe-protein cycle. A more detailed description has been developed that involves two interconnecting processes: the Fe-protein cycle (Fig. 2.5a) and the MoFe-protein cycle (Fig. 2.5b) (Lowe and Thorneley, 1984). Here, a mechanistic simplification, which treats each αβ-subunit pair (with its encapsulated prosthetic groups) of the MoFe protein as an independently operating catalytic entity, is employed, even though long-range interactions between the two αβ-subunit pairs have been detected (Clarke et al., 2000; Maritano et al., 2001). The MoFe-protein cycle involves the progressive reduction of the MoFe protein (plus bound substrate) by up to eight electrons for N_2 binding and reduction, which therefore requires eight turns of the Fe-protein cycle. Partially reduced-nitrogen intermediates must remain on the enzyme until the reduction cycle is finished because NH_3 is the only product of catalyzed N_2 reduction by Mo-nitrogenase. Major concerns are how and where the eight electrons necessary for the reduction of each N_2 (accompanied by one H_2) are accommodated within the MoFe protein and how the required protons are delivered. This situation has been simplified by the assertion that the metal core of the FeMo-cofactor has only two accessible redox states, the EPR-active resting state (called M^N) and the one-electron-reduced EPR-silent state (called M^R) (Doan et al., 2011). All other electrons delivered from the Fe protein must, therefore, reside on either partially reduced substrate or inhibitor.

For N_2 to be bound to the active site, either three or four electrons must have been accumulated within the MoFe protein. If only one electron can be accommodated by the FeMo-cofactor, which would then become EPR-silent, where do the other two electrons reside before N_2 binds? Most likely, they reside as either a hydride (H^-) or hydrogen atom ($H^\bullet$) that subsequently becomes either H_2 or used to partially reduce N_2 (Dance, 2005, 2006). Similarly, the four-electron-reduced MoFe protein (labeled as E_4H_4 in Fig. 2.5) would equate to an oxidized EPR-active FeMo-cofactor with two bound hydrides. In fact, this

latter conclusion has been experimentally demonstrated with both hydrides proposed as μ^2-bridges between Fe atoms (as Fe – H – Fe) on the FeMo-cofactor rather than as either Mo – H – Fe or on μ^2-/μ^3-sulfur atoms (as > S – H) (Igarashi et al., 2005; Lukoyanov et al., 2010). Furthermore, the four-electron-reduced MoFe protein has been shown to relax to its resting state in a two-step process: the first step involves evolution of H_2 and formation of the two-electron-reduced MoFe protein (E_2H_2 in Fig. 2.5), which subsequently evolves a second H_2 to form the resting state (E_0 in Fig. 2.5) (Lukoyanov et al., 2007). Other substrates and inhibitors may, of course, be bound before three electrons have been accepted (Lowe and Thorneley, 1984; Lowe et al., 1993). For example, CO binds after only two electrons have arrived at the MoFe protein. Because the resulting complexes are EPR-active, both electrons must reside either on the bound CO (possibly as –C(H) = O) or as H^- (or $H^\bullet$).

As stated earlier, substrates and inhibitors only bind to Mo-nitrogenase under turnover conditions. The first insights into where and how these small molecules bind to the MoFe protein came from studies using the potent inhibitor CO. Because it is not reduced to any significant extent while wild-type Mo-nitrogenase is catalyzing the production of H_2 from protons, its bound forms should be present in relatively high concentration. During turnover under CO, the $S = 3/2$ EPR signal arising from the resting-state FeMo-cofactor within the MoFe protein disappears and one of two $S = 1/2$ EPR signals appear. A rhombic signal appears at low CO concentrations (p(CO) < 10 kPa), whereas an axial signal results at higher CO concentration (p(CO) > 0 kPa) (Cameron and Hales, 1998; Davis et al., 1979). Under either condition, only up to 50% of the total enzyme is present as the $S = 1/2$ EPR-active entity, the remainder is in the form of undetectable (EPR-silent) enzyme-based species, some (at least) of which will have CO bound. Using isotopically labeled materials at low p(CO), only one CO was found to be bound in the rhombic-EPR species called lo-CO, most likely as a bridge between two Fe atoms of the FeMo-cofactor. At the higher p(CO), two CO molecules were bound to produce the axial-EPR species called hi-CO; both CO molecules were suggested to be terminally bound, most likely to different Fe atoms (Lee et al., 1997). Furthermore, lo-CO and hi-CO could be interconverted by either increasing or decreasing the p(CO), which suggested that the single-bridging CO present in lo-CO converts to a terminal CO in hi-CO (Cameron and Hales, 1998; Lee et al., 1997; Maskos and Hales, 2003). A third minor CO-bound species, with an $S = 5/2$ EPR signal and called hi(5)-CO, was also detected under higher p(CO) and has been suggested to have two bridging CO molecules bound (Cameron and Hales, 1998).

An alternative approach for determining the binding modes of CO to wild-type Mo-nitrogenase involves the use of photolysis and an infrared detection system (Yan et al., 2011). This system is not limited to EPR-active species, the CO-binding mode can be determined for any photoactive entity by the measurement of its vibrational frequency. In fact, high concentrations of CO-bound products that do not correlate with any of the EPR-active species have been detected and analyzed (Yan et al., 2012). This approach has clearly shown that the bound CO in lo-CO retains its bridging mode even when a second terminal CO is bound to give hi-CO. Moreover, only the terminally bound CO can be photolyzed off of the hi-CO species. These results are consistent with stopped-flow FT-infrared studies of wild-type Mo-nitrogenase turning over under CO, where only one intense CO vibration (plus two considerably weaker) from a terminally bound CO molecule was produced under high p(CO), whereas under low p(CO), an initial terminal-CO vibration rapidly decayed to give a bridging CO mode (George et al., 1997; Thorneley et al., 2000). All these studies together suggest that this bridging CO bound under low p(CO) is the primary agent of inhibition of Mo-nitrogenase-catalyzed substrate reduction.

Although CO binds to V-nitrogenase, as shown by its effective reversible inhibition of V-nitrogenase-catalyzed substrate reduction (Dilworth et al., 1988), no EPR-active species have yet been observed for V-nitrogenase turning over under a CO atmosphere (Moore et al., 1994). Any complex that is formed must await future investigation.

The same EPR-based freeze-trapping technique has shown that C_2HR (where R = –H or $–CH_2OH$) and CN^- interact with the FeMo-cofactor, mostly clearly when the variant MoFe proteins, especially those with either single or double substitutions at the α-valinyl-70 and α-histinidyl-195 residues, are used (Dos Santos et al., 2005; Igarashi and Seefeldt, 2003). In an extension of this technique to the catalyzed N_2-reduction pathway, using labeled diazene, methyldiazene, or hydrazine (Hoffman et al., 2009), it was hoped that species that reflected early-, mid-, and late-stage intermediates would be trapped, but all three substrates produced the same two FeMo-factor-bound intermediates. Both of these trapped intermediates, described as M – NH_2 (for intermediate *H*) and M – NH_3 (for intermediate *I*), have a single nitrogen atom and so are produced after N–N bond cleavage (Lukoyanov et al., 2011; 2012). Because they are the expected end-products of almost any likely N_2-reduction pathway, they have little to add in this regard. Unfortunately, the chemical nature of the trapped intermediate after turnover under N_2 is the least clearly defined (Barney et al., 2005, 2009). Of course, the enzymes in these samples are not catalytically synchronized, and so only a portion of the population is trapped with other states lying undetected. Even so, the results of these and related relaxation studies have enabled links to be forged between the kinetically derived E_nH_n Lowe–Thorneley redox states of the MoFe protein and some spectroscopically characterized catalytic

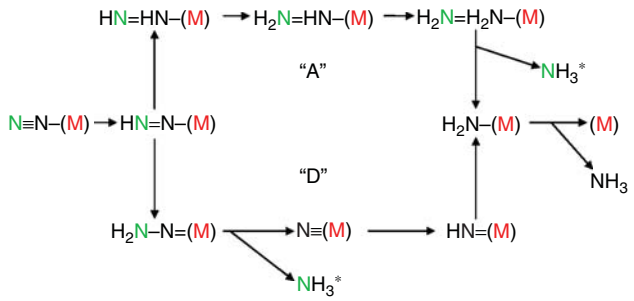

Figure 2.6 The Mo-nitrogenase N_2-reduction pathway alternatives. "A" represents the "alternating pathway," "D" the "distal pathway", (**M**) the M center (FeMo-cofactor) of the MoFe protein, **N** the distil nitrogen atom of the bound N_2 molecule, and each arrow a hydrogenation (H^+/e^-) event. A major consequence of the two different patterns of hydrogenation is that the first ammonia (**N**H_3*) is produced after only three hydrogenation events for the "D" pathway versus five for the "A" pathway. *Source*: Modified from Hoffman et al., 2009.

intermediates (Lukoyanov et al., 2007). Together with other considerations, these connections have led to the suggestion that the Mo-nitrogenase-catalyzed N_2-reduction pathway most likely occurs on Fe and via an "Alternating" hydrogenation pathway (Hoffman et al., 2009; Lukoyanov et al., 2012).

But what is an "Alternating" hydrogenation pathway? The Mo-nitrogenase-catalyzed N_2-reduction pathway can be constructed in two basic forms: both of which assume that N_2 is bound "end-on," that is, by only one (the proximal atom) of its two N atoms. One pathway, the so-called Distal pathway, has the distal (unbound) N atom being completely hydrogenated and released as NH_3 before the proximal N atom begins to be hydrogenated. The other pathway, the so-called Alternating pathway, has the two N atoms being alternately hydrogenated. These pathways are clearly delineated by the different intermediates predicted and the timing of product appearance (Fig. 2.6). Clear experimental evidence distinguishing between these two options remains elusive. Theoretical computations have been linked with both pathways; the "Distal" pathway is favored for catalysis at Mo, but the "Alternating" pathway is preferred if catalysis occurs at an Fe site.

2.8 WHERE ARE THE BINDING SITES FOR SUBSTRATES AND INHIBITORS?

It has long been assumed that binding and subsequent reduction of substrates occur at one or more metal atoms, but direct evidence has been hard to come by until recently (see earlier). Early circumstantial evidence for a role for the FeMo-cofactor in substrate binding came through variant nitrogenases (Burgess and Lowe, 1996; Scott et al., 1990; Smith et al., 2004). But where on FeMo-cofactor? The situation is complicated by a variety of observations that indicate the existence of more than one binding site for certain substrates and inhibitors. For example, two C_2H_2-binding sites have been detected by detailed kinetic analyses (Christiansen et al, 2000; Davis et al., 1979; Han and Newton, 2004; Shen et al., 1997), both of which can be occupied in the presence of CO and so are distinct from at least one of the two CO-binding sites (Shen et al., 1997). By the judicious use of combinations of substrates and inhibitors, a high-affinity ($K_m \sim 0.1\%$) C_2H_2-binding site, called site-2, has been implicated with N_2 binding and reduction and, therefore, is the physiologically relevant site (Han and Newton, 2004). Other studies with a variant enzyme indicated that the two C_2H_2-binding sites were close together and both were able to bind CO (Christiansen et al., 2000). If all this is so, then CO is likely reduced to various hydrocarbons by binding (at high p(CO)) to the physiologically relevant N_2-binding site-2, and the noncompetitive inhibitory effect of CO on substrate reduction would be the result of its binding (at low p(CO)) to the physiologically irrelevant site-1. These suggestions indicate that the responsible agent of substrate inhibition is the bridging CO bound as the lo-CO form of the enzyme. Furthermore, it suggests that the hi-CO form produced at high p(CO) reflects a catalytic intermediate in the pathway of CO reduction at site-2.

Which atoms of FeMo-cofactor bind these small molecules? Theoretical calculations are now coming to grips with the physical size, the chemical nature, the total-spin state, and the oxidation states of the constituent metal atoms of the FeMo-cofactor during catalysis (see, e.g., Harris and Szilagyi, 2011 and the references therein; see also Chapter 7). Early on, the preferred mode of N_2 binding was as a bridge between either two or four of its central Fe atoms, but these modes resulted in a small N_2-binding energy and, therefore, a weak bond. Also, immediate N_2 cleavage to metal nitrides was unfavored, which is consistent with (some) protonation of bound N_2 before bond cleavage. Now, since the discovery of the central light atom (initially assumed to be nitride, but almost certainly carbide), these various combinations of bridging Fe–N_2–Fe interactions at an Fe_4 face (Barney et al., 2006; Hoffman et al., 2009) appear to be very much less likely than binding at either a single Fe atom or an Fe_2 edge (Dance, 2006, 2011a, b). The interactions of substrates and inhibitors with the FeMo-cofactor described earlier are suggested to occur at one (the so-called Fe_6 atom; see Fig. 2.3) of the six centrally located Fe atoms with a sometime involvement of a second, the so-called Fe_2 atom (see, e.g., Dance, 2011a), although the Mo atom has had its proponents (Durrant, 2002, 2004). If all this is so, then Fe_6 of the FeMo-cofactor may be congruent with the physiologically relevant site-2 and Fe_2 with site-1.

2.9 HOW ARE ELECTRONS AND PROTONS DELIVERED?

The current dogma is that electrons are delivered by the Fe protein first to the P cluster, then through the protein matrix to the FeMo-cofactor, and finally to bound substrate. In support of this pathway, the structure of the Mo-nitrogenase complex shows the P cluster located midway between the [4Fe-4S] cluster of the Fe protein and the FeMo-cofactor. Although this arrangement could be coincidental, the redox-driven structural rearrangement of the P cluster (see earlier) supports an electron-transfer role (Peters et al., 1997). Support also comes from substituting the P-cluster-ligating β-cysteinyl-153 ligand with serinyl, which produces a variant MoFe protein that has a normal FeMo-cofactor, gives normal substrate-reduction products, and interacts usually with the Fe protein. It cannot, however, match the wild-type's maximum rate of substrate reduction. The most likely explanation is that intra-MoFe-protein electron transfer has been compromised (May et al., 1991). Furthermore, when the α-serinyl-188 residue (which binds to the P cluster when it is chemically oxidized) is substituted by cysteinyl, a new $S = 1/2$ EPR signal appears. This signal disappears when Fe protein, MgATP, and reductant are added (Chan et al., 1999). These observations indicate that the P cluster may be redox active during turnover.

In contrast, two early spectroscopic observations are inconsistent with this proposal. First, there is no change in the Mössbauer spectrum of the P clusters, which would indicate redox activity, during nitrogenase turnover (Smith et al., 1973). Second, electron transfer from the Fe protein results in the rapid loss of the FeMo-cofactor's $S = 3/2$ EPR signal, which suggests that electrons may go directly to this prosthetic group. Furthermore, a more recent freeze-trapping Mössbauer study indicates that the P clusters do not obviously change their redox state during turnover under low electron-flux conditions, even though the FeMo-cofactor accepts an electron (Fisher et al., 2007). So, under some conditions at least, electrons from the Fe protein may bypass the P cluster and go directly to the FeMo-cofactor and, if so, the P clusters might have an N_2 reduction-specific role in catalysis and, only at the highest electron-flux rates, provide the assistance necessary to commit bound N_2 to the irreversible reduction pathway (Lowe et al., 1993). However, a one-electron transfer from the Fe protein to the P cluster has been measured to be much faster than a one-electron transfer from the P cluster to the FeMo-cofactor (Danyal et al., 2011). In such circumstances, an oxidized P cluster would never be observed. But what if the P cluster undergoes a two-electron oxidation during turnover as suggested from structural studies (Peters et al., 1997)? Furthermore, is there only one or are there several electron-transfer pathways within the MoFe protein (Peters et al., 1995)? Is the P cluster involved in all of these pathways? Which substrates are serviced by which pathway?

Three likely proton-transfer routes have been identified (Durrant, 2001; Igarashi and Seefeldt, 2003). The first is a water-filled channel that stretches from the surface of the MoFe protein between the α- and β-subunits to the interstitial pool of water molecules around the homocitrate-Mo end of the FeMo-cofactor. This water-filled channel could rapidly deliver protons to bound substrate (Dance, 2005) and might also provide a pathway for substrates and products to diffuse to and from the reduction site(s). The arrival of electrons at the FeMo-cofactor increases the basicity of its sulfur atoms, which can then be protonated by water molecules in the interstitial pool. These bound protons may then be reduced to hydrogen atoms that can migrate to the Fe (or other) atoms to effect substrate reduction (Dance, 2006).

The other two potential pathways are proton-relay systems. The first involves the hydrogen bond between the imidazole of the side chain of α-histidinyl-195 and a central μ_2-sulfide (labeled S2), which bridges Fe_6 and Fe_2 of the FeMo-cofactor. This strictly conserved histidinyl residue is known to play an essential role in N_2 reduction (Dilworth et al., 1998). The same imidazole ring forms a hydrogen bond through an intervening water molecule to α-tyrosinyl-281, which is close to the protein's surface and flanked by two potential proton-capturing histidinyls, α-histidinyl-196 and α-histidinyl-383. This relay system could provide protons on demand. The second relay is more complex and involves three water molecules and three histidinyl residues, one of which (α-histidinyl-362) is on the surface and may capture protons for this relay. This path terminates in a different central bridging sulfide of FeMo-cofactor. These proton-relay systems would require a switch between alternative hydrogen-bonding networks as each proton is delivered and the system is realigned. These histidinyls are probably unable to compete with a water-filled channel to deliver multiple protons quickly enough, which suggests that the interstitial channel may be the primary route of proton delivery to substrates.

2.10 SOME CONCLUDING REMARKS

Although tremendous progress has been made, many questions remain concerning the mechanism of biological nitrogen fixation. The stringent requirements for N_2 binding and reduction appear to be satisfied by only a single site on the MoFe protein, whereas many of the alternative more easily reduced substrates and the inhibitor, carbon monoxide, have more than one binding and reduction site. Although sorting out their relevance to the overall functioning of the enzyme continues, there are several other mechanistic challenges that need answers. First, are both component proteins

and complex formation required for activity? Second, is MgATP hydrolysis absolutely required? Third, is the Fe protein the obligate electron donor?

For wild-type Mo-nitrogenase with sodium dithionite as the sole reductant *in vitro*, the answer to all three questions is "yes." However, if flavodoxin hydroquinone, which is the only physiological reductant in some organisms, is used *in vitro* (and maybe *in vivo*) to support substrate reduction, the MoFe protein/Fe protein complex does not dissociate during turnover (Duyvis et al., 1998). Some variant proteins go even further. The L127Δ Fe protein, for example, not only forms a stable complex with the wild-type MoFe protein but also completes intracomplex electron transfer without MgATP hydrolysis (Lanzilotta et al., 1996). A variant β-histidinyl-98 MoFe protein, when supplied with a low-potential Eu(II)-based reductant, catalyzes hydrazine reduction to ammonia without both the Fe protein and MgATP (Danyal et al., 2010).

An alternative approach has been to use photoreduction systems. An early success involved a light-driven process using eosin as the photo-sensitizer and NADH as the sacrificial electron donor, when Mo-nitrogenase-catalyzed photoreduction of both protons and acetylene was achieved (Druzhinin et al., 1993). A non-dissociating 1:1 MoFe protein/Fe protein complex was suggested to be the catalytic entity in a process that was more effective than with dithionite as electron donor, but still required MgATP. Photoreduction has since been taken one level further by using a surface-tethered ruthenium photo-sensitizer with dithionite as the sacrificial electron donor (Roth et al., 2010; Roth and Tezcan, 2012). In the absence of both Fe protein and MgATP, the modified MoFe-protein catalyzed proton, acetylene, and HCN photoreduction. These observations clearly indicate that neither the Fe protein nor MgATP is absolutely essential for Mo-nitrogenase-catalyzed substrate reduction. However, the challenge to develop a system that can be operated continuously or cyclically remains.

Mankind's current fixed-nitrogen requirements have outstripped the capacity of current biological nitrogen-fixing systems with the Haber–Bosch process supplying the balance. The final question is always whether biological nitrogen fixation can again become the major player in the delicate balance needed among environmental concerns and sufficient food production for the future (Dilworth et al., 2008; Leigh, 2004; Smil, 2001; Werner and Newton, 2005). In this context, we might ask why have some prokaryotes retained (or acquired) the alternative nitrogenases, especially when there are very few areas of the World where molybdenum concentrations are limiting. Do they serve some purpose other than nitrogen fixation? Will what we learn from these nitrogenases help in efforts to either enhance the nitrogen-fixation capabilities of microorganisms or endow new organisms and plants with this capability? Will they have a role in developing new commercial nitrogen-fertilizer production systems? We do not know; we will have to see what insightful creative research can produce.

Chapter 3

Evolution and Taxonomy of Nitrogen-Fixing Organisms with Emphasis on Rhizobia

Kristina Lindström, Aregu Amsalu Aserse, and Seyed Abdollah Mousavi

Department of Environmental Sciences, University of Helsinki, Helsinki, Helsinki, Finland

3.1 INTRODUCTION

Biological nitrogen fixation (BNF) is a process by which atmospheric dinitrogen gas (N_2) is reduced to ammonia under natural conditions:

$$N_2 + 8[H] \Longleftrightarrow 2\,NH_3 + H_2$$

Contrary to the industrial reduction of N_2 by the Haber–Bosch process, which requires high temperature and pressure, BNF utilizes biologically stored solar energy to force the inert N_2 molecule to combine with hydrogen (H) and produce ammonia (NH_3) at ambient temperatures. N_2 is inert in relation to most biological systems, whereas ammonia can be used by living organisms as a nitrogen source or converted into nitrate (NO_3^-) for further use in the generation of proteins, nucleic acids, and other crucial compounds of the cells. Mineral nitrogen (NH_4^+, NO_3^-) fertilization of crop plants in agriculture forms the basis for modern agriculture, often at the expense of the utilization of BNF (Stoddard et al., 2009). However, it is estimated that 1 kg of industrially reduced nitrogen requires 1.5 kg of oil, BNF is not dependent on fossil fuels but uses energy derived from the sun. In agriculture, BNF by legumes in symbiosis with nitrogen-fixing bacteria can provide all the nitrogen necessary for plant growth under optimal growth conditions (Herridge et al., 2008). The solar energy used for BNF is bound in ATP and reducing power produced in the nitrogen-fixing organisms. In the case of symbiotic BNF with plants or photosynthetic microorganisms, the solar energy is captured by the photosynthetic system and stored in carbon compounds, which are transported to the site of nitrogen fixation, in the case of legumes to the root or stem nodules, in which nitrogen-fixing bacteria reside (Udvardi and Poole, 2013). These in turn use their metabolic machinery for the production of ATP and reducing power needed for BNF. In nonsymbiotic organisms, the energy is provided by corresponding energy-yielding mechanisms. It is estimated that the reduction of 1 mole of N_2 requires 16–24 moles of ATP (Franche et al., 2009). Thus, BNF is always an investment for plants and bacteria, both during the process and, for example, while legumes construct nodules to harbor the bacteria. In a recent review, Lindström and Mousavi (2010) summarize key features of BNF and its importance for the input of N to the biosphere and also give some recent figures of amounts of N fixed in diverse systems.

3.1.1 Evolution of Nitrogenase

The nitrogenase enzyme complex is the center for the BNF process. Nitrogenase itself will be dealt with in Chapters 2 and 7 in this book. From an evolutionary point of view, the origin of nitrogenase is still obscure. In present-day nitrogen fixers, a set of genes named *nif* (e.g., *nifH*, *nifD*, and *nifK* encoding the core subunits of nitrogenase) is present in most nitrogen-fixing organisms (for a recent review, see Franche

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

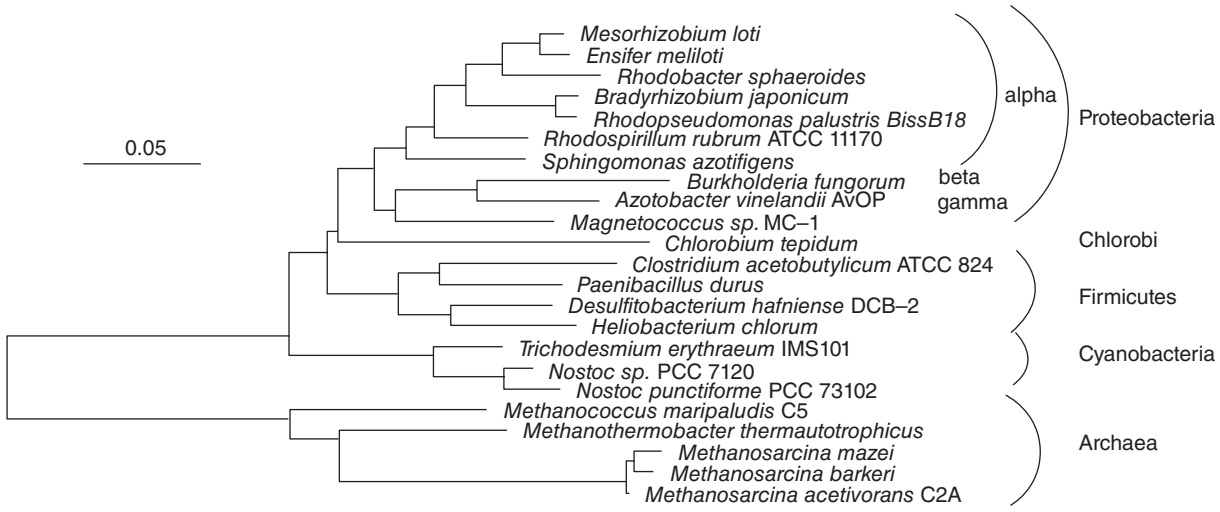

Figure 3.1 Phylogenetic 16S rRNA gene tree with prokaryotes carrying *nif* genes (by courtesy of German Jurgens). *Source*: Reprinted from Franche et al. (2009) with the kind permission of Springer-Verlag.

et al. (2009)). The genes *nifHDK* can be used as a genetic marker when studying the occurrence of nitrogen-fixing organisms in diverse taxa (Fig. 3.1).

An important component of nitrogenase enzyme complexes is the metal cofactor. The genes *nifHDK* encode a nitrogenase with an iron-molybdenum cofactor (FeMo-co). However, some nitrogen fixers use vanadium (V, genes *vnfHDK*) instead of Mo in the cofactor and some just iron (genes *anfHDK*) (Schüddekopf et al., 1993: see Chapter 2). It is a widespread perception that V- and Fe-nitrogenases are ancient forms of Mo-nitrogenase. Boyd et al. (2011) in their study of the evolution of nitrogenases came to a different conclusion. By examining multiple nitrogenase proteins phylogenetically and structurally, they proposed that Mo-nitrogenase first emerged within the hydrogenotrophic methanogenic archaea already before the "great oxidation event" (GOE), which occurred 2.45–2.22 billion years ago (Anbar et al., 2007). The alternative V- and Fe-nitrogenases then evolved in response to Mo limitation, and Mo-nitrogenase became prevalent when bioavailable Mo increased in the biosphere at the time of the GOE. According to the analyses by Fani et al. (2000), *nifDK* and *nifEN* (involved in the biosynthesis of the FeMo-cofactor) constitute a paralogous gene family that arose via gene duplications, perhaps even before the appearance of the last common ancestor (LUCA). They further propose that the *nifDKEN* genes were present before the divergence of *Bacteria* and *Archaea.*

This suggestion was supported by results compiled in a mini-review by Zehr et al. (2003), who most comprehensively describe how widespread nitrogenase (represented by *nifH*) is diverse across ecosystems and prokaryotic taxa. Hartmann and Barnum (2010) inferred phylogenies of 60 *nifK* and *nifDK* sequences across diverse prokaryotic phyla (represented by 16S rRNA gene sequence) and proposed that both horizontal and vertical gene transfers could explain the observed patterns though within phyla vertical transmission seemed to be prevalent (see also Chapters 16–19).

3.1.2 Evolution of Symbiotic Nitrogen Fixation

The evolution of symbiotic nitrogen fixation is in comparison with the evolution of *nif* genes, which is a recent phenomenon. By symbiosis we mean a situation where nitrogen-fixing bacteria enter a host plant and fix nitrogen inside the plant, most often to the benefit of both partners (Lindström and Mousavi, 2010). The symbiosis between leguminous plants and alpha- or betaproteobacterial species (rhizobia) is the best known and also agronomically most important. The symbiosis between bacteria from the genus *Frankia* with alders (*Alnus*) and other actinorhizal plants is widespread in nature (Franche et al., 2009; see Chapters 35, 42, 43, 48, 55), whereas symbioses between cyanobacteria and plants from the diverse genera *Azolla*, *Cycas*, and *Gunnera* are less known (Osborne and Bergman, 2009). Rhizobia invade their host plants via root hair or crack entry infection to enter the root nodule, which the host is constructing for the potentially beneficial microsymbionts (Sprent, 2001). Recently, similarities between arbuscular mycorrhizal and rhizobial infections have led to the proposal that nitrogen-fixing root symbioses have the same evolutionary origin as mycorrhizal ones. These aspects have recently been reviewed in terms of both signaling factors (Cough and Cullimore, 2011; see also Chapter 51) and central signaling pathways in the plant (Singh and Parniske, 2012). Figure 3.2 shows a range of evolutionary events regarding symbioses. Mycorrhizal symbioses are thought to predate the rhizobial

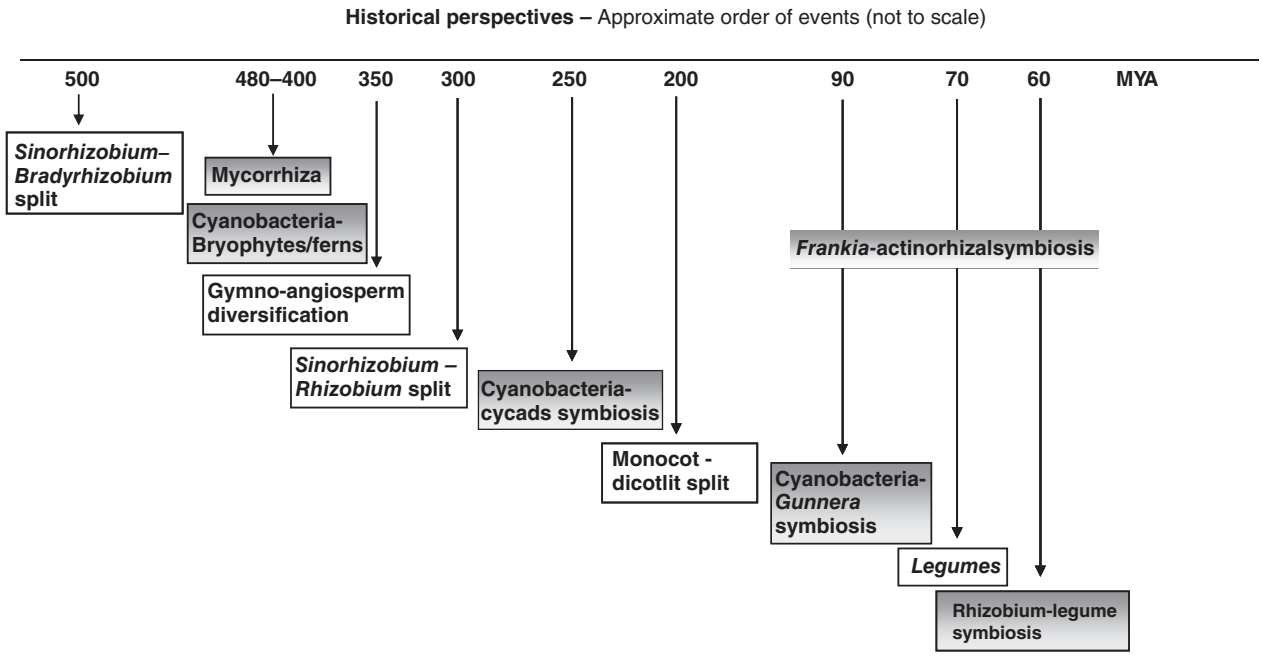

Figure 3.2 Approximate order of historical events important for the evolution of nitrogen-fixing symbioses, compiled from the sources Kistner and Parniske (2002), Lavin et al. (2005), Osborne and Bergman (2009), Sprent (2008), Turner and Young (2000), and Wang et al. (2010) and the references in them. *Source*: Reprinted from Lindström and Mousavi (2010) with the kind permission of John Wiley & Sons Ltd.

infections, which imply that the rhizobia adopted pathways in the plants already evolved in response to mycorrhizal infections.

Rhizobial symbionts are easy to cultivate in the laboratory even though most species do not fix N *ex planta* but use combined nitrogen. Thus, genes encoding both nitrogen fixation (*nif*, *fix*) and infection and nodulation (*nod*, *nol*, *noe*) have been studied since the 1980s. Forward and reverse genetic approaches have been used to assign gene functions, of which the activation of *nod* genes by plant root exudates and the expression of *nod* genes to produce lipo-chitooligosaccharide (LCO) signal molecules have been the main breakthroughs (for a recent review of the diversity of symbiotic interactions, see Masson-Boivin et al., 2010; see also Chapters 50 and 51). In legume–*Rhizobium* interactions, there is host specificity in terms of both nodulation and N fixation, the former being determined by the nature of *nod* gene inducing root exudate as well as the nature of the LCO signal molecules (Masson-Boivin et al., 2010). The specific roles of different *nod* gene products in the biosynthesis of LCOs are fairly well known, whereas the specificity of N fixation (effective vs ineffective symbiosis) is less clear cut.

The evolution of the *Rhizobium*–legume symbiosis has been proposed to be an example of co-evolution. However, there is so far no solid evidence that this is the case. True coevolution means that both partners undergo evolutionary changes to reach a common goal, the symbiosis, whereas so far only *Rhizobium* evolution under host plant constraint has been conclusively demonstrated (Suominen et al., 2001). Species producing LCO molecules with polyunsaturated fatty acid residues infect plants belonging to the same IRLC legume clade (Dresler-Nurmi et al., 2007), which is further proof for adaptation by rhizobia to legumes. Österman et al. (2011) found no evidence for adaptive evolution of symbiotic plant genes (NORK and *Nfr5*) in *Galega* species though there was diversity in the genes in the studied plant populations.

The adaptation of *Rhizobium* bacteria to their hosts is mediated by horizontal gene transfer (HGT). For a long time, it was already known that rhizobial symbiotic genes often reside on plasmids (Nuti et al., 1979, Hirsch et al., 1980). Freiberg et al. (1997) demonstrated by sequencing of a 500-kb plasmid (pNGR234a) from *Sinorhizobium* sp. strain NGR 234 that all functions needed for symbiosis as well as conjugal transfer were located on this plasmid (see also Chapter 32). Sullivan and Ronson (1998) described how a 500-bp gene region in *Mesorhizobium loti* strain ICMP3153 carrying genes encoding nodulation, nitrogen fixation, and vitamin biosynthesis was transferable to three other nonsymbiotic mesorhizobial genospecies, confirming a hypothesis arisen from field observations. This element was named the symbiotic island. It was found to integrate into mesorhizobial chromosomes by a phage-encoded integrase into a Phe-tRNA gene (see Chapter 21). Genomic (symbiotic) islands have later been found in other *Rhizobium* species, for example, *Bradyrhizobium japonicum* (Kaneko et al., 2002). Young et al. (2006) demonstrated that the genome structure of *Rhizobium leguminosarum*

strain Rlv3841 displayed both physically and functionally distinct compartments, which they named the core and the accessory genome. The accessory genes are those encoding niche adaptation, such as symbiotic host range. As they often reside on transmissible elements, they are prone to HGT. The core genes mainly undergo vertical transfer and encode housekeeping properties. The accessory genes are dispensable, whereas the core genes are indispensable for the bacteria. Harrison et al. (2010) further proposed that genetic elements that have both accessory and core properties should be named chromids. Chromids are, for example, rhizobial megaplasmids with both symbiotic and housekeeping functions (see also Chapters 25–27).

Rhizobial genomes are dynamic, which was a prerequisite for the evolution of extant symbiotic interactions. The *nif* genes at a higher taxonomic rank mainly seem to be vertically transferred within phyla, whereas rhizobial *nod* and *nif* genes show both vertical and horizontal transfer patterns (Haukka et al., 1998; Menna and Hungria, 2011; Aserse et al., 2012a).

HGT of symbiotic islands or plasmids are major genetic events that greatly change the phenotypic properties of the bacteria. Not only nodulation and nitrogen fixation but also other properties contributing to ecological niche adaptation can be genetically labile. Accessory genes and properties they encode are thus unsuitable for taxonomic classification of rhizobia, since loss of a symbiotic plasmid will, for example, greatly change the phenotype.

3.1.3 Taxonomy of Bacteria

Current taxonomic practice regarding bacteria requires that all validly described species can be distinguished from their nearest neighbors by at least one phenotypic feature (Tindall et al., 2010). The sequencing of 16S rRNA genes (but no other genes) and their phylogenetic comparison with close relatives is now obligatory for species descriptions and in most cases DNA:DNA hybridization should be used to delineate members of novel species from known ones (Roselló-Móra, 2011). The 16S rRNA gene is especially less variable in many rhizobial taxa than other housekeeping genes, and therefore its use might not properly delineate putative new species (Aserse et al., 2012a, 2012b). Unfortunately, DNA:DNA hybridization has become more like engineering than biological science, meaning that results are interpreted by rigidly applying percentage rules (70% relative homology is used as the borderline between species; (Tindall et al., 2010)) and forgetting uncertainty measures and variation between laboratories and methods.

According to a recent paper by Tamames and Roselló-Móra (2012), more and more novel species are described based on single isolates. This trend has led to a decrease in the impact factor for the *International Journal of Systematic and Evolutionary Microbiology (IJSEM)*, in which all new species should be validly described or listed. Despite the name of the journal, the description of new species is deviating from biology in a regrettable way. On the other hand, "invalidly described species" are increasing in amount, since partial 16S rRNA gene sequences are given names or called species without the corresponding culture being available, which is a prerequisite for a validly described species (Garrity and Oren, 2013).

The rules for naming prokaryotic species are published in the Bacteriological Code, published by the International Committee for the Systematics of Prokaryotes (ICSP) (Lapage et al., 1992). The rules for how to delineate species arise from the scientific community and are ultimately dependent on the *IJSEM* reviewers' opinions. To streamline procedures, the ICSP has subcommittees devoted to various taxa to assist in the taxonomic work. The ICSP Subcommittee on the Taxonomy of *Agrobacterium* and *Rhizobium* is responsible for developing guidelines for species descriptions among those genera.

Nowadays, the subcommittee has taken an interest in all taxa containing nodulating bacteria and also non-nodulating taxa related to the nodulating taxa. The subcommittee meets regularly and reports in the form of minutes from the meetings (recent minutes: Lindström and Young, 2009, 2011). The subcommittee has a website with useful information for rhizobial taxonomists and everybody interested in systematics of these interesting organisms. The website is maintained by Vinuesa (2013).

This subcommittee tries to operate on the borderline of taxonomy and biology. Thus, we consider the biology of the organisms as the baseline for taxonomy. Instead of dividing rhizobia based on single strains described by rigid but sometimes meaningless criteria, we advocate the use of multiple strains (to cover diversity) and an evolutionary or cross-disciplinary approach to speciation and taxonomy (Lindström and Gyllenberg, 2006).

The subcommittee is not consulted when new species are proposed. If this were the case, some mistakes could perhaps be avoided. Now phylogenetically close species have been given different names (e.g., *Rhizobium fabae* and *Rhizobium pisi*, some species consist of just one strain (e.g., *R. pisi*) and species are misplaced in new phylogenetic reconstructions (e.g., *Rhizobium indigoferae*) (Aserse et al., 2012b). The new species descriptions are often just snapshots of a small part of the phylogenetic tree and the diversity is hidden. We therefore decided to present phylogenetic overviews of currently described species of rhizobia and some related taxa.

3.2 MATERIALS AND METHODS

3.2.1 Analysis of 16S rRNA Genes

The sequences (>1300 bp) of 16S rRNA gene of 160 proteobacterial species were retrieved from GenBank

[http://www.ncbi.nlm.nih.gov/genbank] (Table 3.1). The sequences were aligned applying the MUSCLE software at EMBL–EBI (Edgar, 2004; Goujon et al., 2010), and the generated alignment was edited manually. The Tamura 3-parameter plus gamma distribution plus invariable site (T92 + G + I) was selected as the best-fit model of nucleotide substitution according to the Akaike Information Criterion, corrected (AICc) using the MEGA5 program (Tamura et al., 2011). The neighbor-joining (NJ) tree with 10,000 bootstrap replicates was constructed by the MEGA5 program.

3.2.2 Phylogenetic Analyses of *Bradyrhizobium* and the Related Taxa

Publicly available sequences of *recA*, *glnII*, *rpoB*, *atpD*, *dnaK*, and *gyrB* genes of all type strains of the currently described species of *Bradyrhizobium* except for *B. rifense* strain CTAW71 (which has only *recA* and *glnII* gene sequences), a type strain of *Methylobacterium nodulans*, and from the whole genome-sequenced *Bradyrhizobium* species and *Rhodopseudomonas palustris* were retrieved from the GenBank/EMBL database (http://www.ncbi.nlm.nih.gov/genbank/ and http://www.ebi.ac.uk/Tools/sss/fasta/nucleotide.html). In addition, widely common sequences, *recA* and *glnII* genes, were also collected for most root nodule forming unnamed genospecies of *Bradyrhizobium.* A list of strains and accession numbers of the sequences included in this study is shown in Table 3.2.

Sequences of each gene were aligned using ClustalW as implemented in Mega5 (Tamura et al., 2011). Phylogenetic trees were constructed from concatenated datasets of *dnaK _rpoB_gyrB_atpD_glnII5_recA* gene and *glnII_recA* gene sequences by NJ method using MEGA version 5 and with maximum-likelihood (ML) algorithms using PhyML 3.0 online programs (Dereeper et al., 2008). The NJ analyses were performed using the Kimura's 2-parameter distance correction (Kimura, 1980) model. The general time reversible with a gamma rate distribution and/or invariant site (GTR + G + I) nucleotide substitution model was used for ML tree constrictions because it was selected as the best-fit evolutionary model by jModelTest 0.1.1 program (Posada, 2008). The robustness of the ML topologies of *dnaK _rpoB_gyrB_atpD_glnII_recA* dataset was calculated with 100 bootstrap replications. Because *glnII_recA* dataset has a large number of taxa and takes a long time to compute with the bootstrap procedure, we used the faster approximate likelihood-ratio test (aLRT), which gives also branch support values very close to bootstrap values (Anisimova and Gascuel, 2006).

3.3 RESULTS

3.3.1 The *Agrobacterium–Rhizobium* Group

We constructed a 16S rRNA phylogenetic gene tree based on sequences deposited in GenBank representing mainly 160 taxonomic type strains. The strains were chosen based on the taxa listed on the taxonomy website [http://edzna.ccg.unam.mx/rhizobial-taxonomy/node/2]. On this website, pathogenic *Agrobacterium* species and nodulating alpha- and betaproteobacteria (rhizobia) as well as closely related taxa are listed. The reader is referred to this website for references for species descriptions. From this page, there are links to the website list of prokaryotic names with standing in nomenclature, which is maintained by Euzéby (2013). From this site, there are again links to the published taxonomic descriptions. The expansion of the taxonomy in this part of the phylogenetic tree has recently been very fast, and new species are described almost every month.

The genus name *Agrobacterium* traditionally meant plant pathogenic bacteria harboring Ti or Ri pathogenicity plasmids, but the genus also included nonpathogenic strains related to pathogenic strains. In a similar manner, genus *Rhizobium* stood for N-fixing species harboring symbiotic plasmids or islands. Since accessory elements (plasmids, symbiotic islands) encode niche adaptation and confer unstable properties to their host bacteria depending on the presence or absence of the elements, those should not have preference when naming species and genera. The transition from a pronounced, plant phenotype-based taxonomy to one based on the evolution of the more stable core genome has been slow.

There are two main reasons for changing genus designations. One is based on observations of evolution leading to speciation in the core genome. The other is the practical need to split genera in order to better be able to use the names when communicating and thus create new names for monophyletic clades deserving to be named (Lindström and Gyllenberg, 2006). The first well-founded new genus that arose from the *Agrobacterium–Rhizobium* group was *Bradyrhizobium* in 1982 [http://www.bacterio.cict.fr/b/bradyrhizobium.html]. The phylogeny and taxonomy of genus *Bradyrhizobium* is further elaborated on in Figures 3.4 and 3.5 and will be discussed later.

3.3.2 The *Mesorhizobium* Clade

Mesorhizobium was separated from the rest of the rhizobial genera in 1997 [http://www.bacterio.cict.fr/m/mesorhizobium.html]. It forms a well-supported clade located distantly from other rhizobial genera. However,

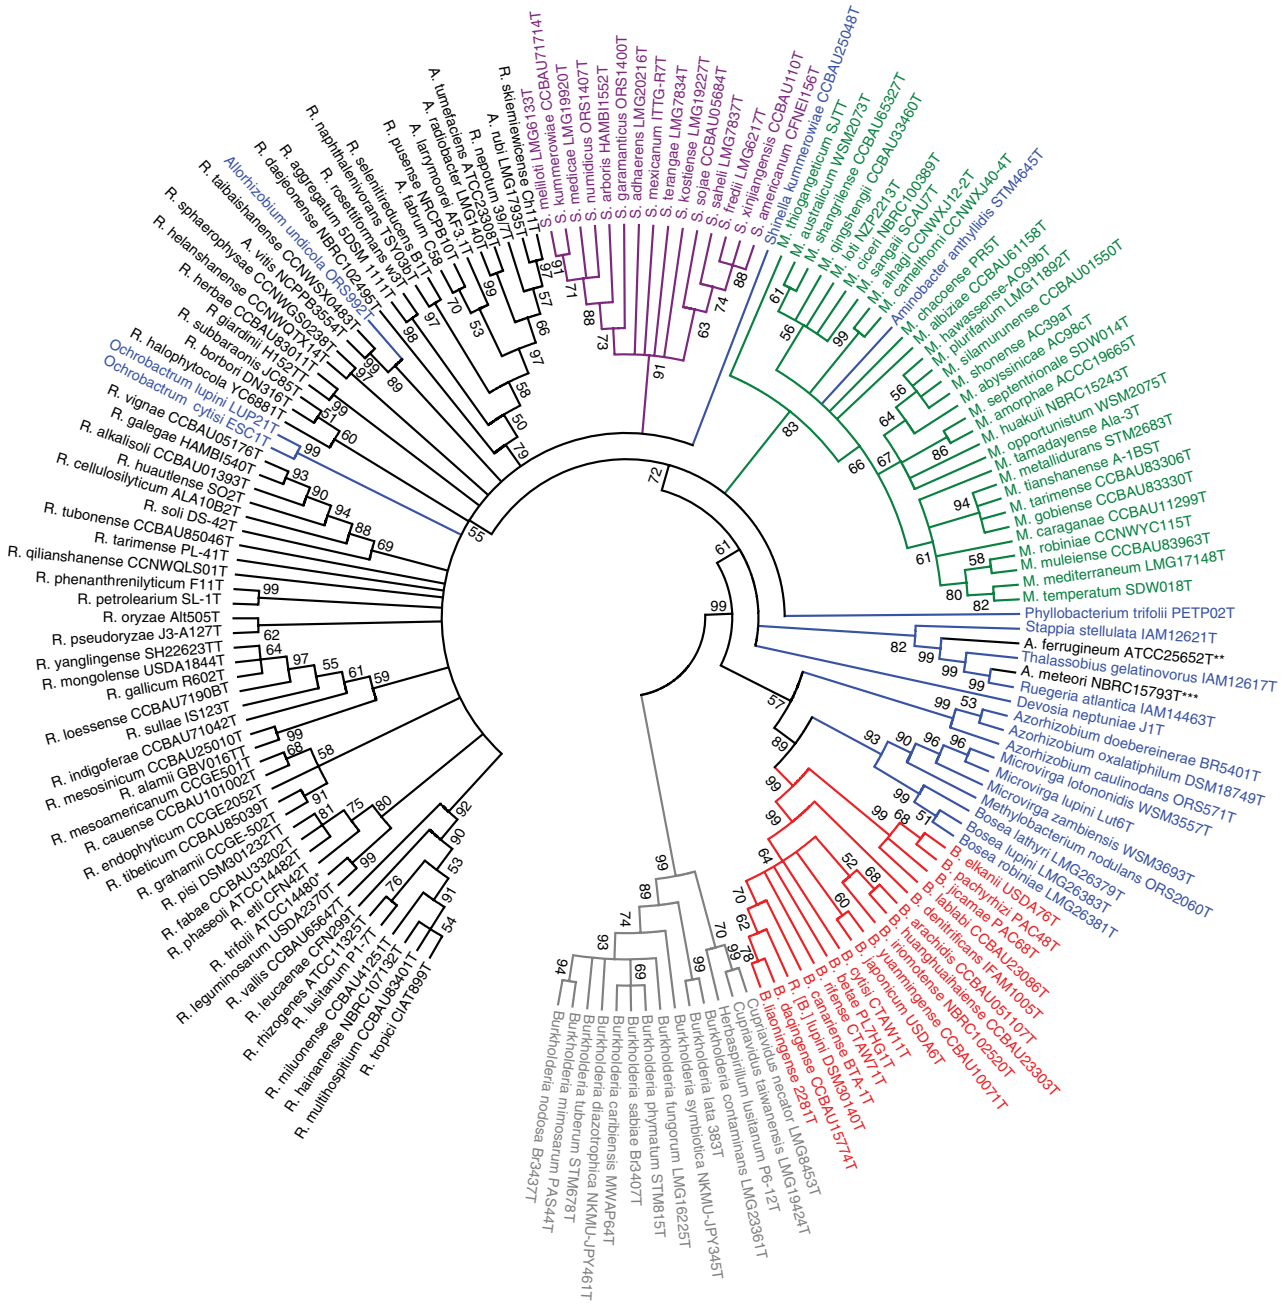

Figure 3.3 The phylogenetic tree based on 16S rRNA gene sequences, illustrating the relationships among 160 proteobacterial species. The neighbor-joining tree was constructed with 10,000 bootstrap replicates, and the cut-off is 50%. The type strains are shown by a "T" at the end of each strain code. The genus names are abbreviated as follows: *A.*, *Agrobacterium*; *B.*, *Bradyrhizobium*; *M.*, *Mesorhizobium;* *R.*, *Rhizobium*; and *S.*, *Sinorhizobium*. Other genera of *Alphaproteobacteria* are in blue, and the *Betaproteobacteria* are in gray. Alternative names: **Rhizobium leguminosarum*, ***Pseudorhodobacter ferrugineus*, ****Agrobacterium atlanticum*.

in 2012, "*Aminobacter anthyllides*" was described as a nodulating species. So far this species was not validly described [http://www.bacterio.cict.fr/nonvalid.html], but once it is validated it is possible to propose that *Mesorhizobium* and *Aminobacter* are merged and then the name *Aminobacter*, published in 1992, will be the name to use according to the Bacteriological Code [http://www.bacterio.cict.fr/a/aminobacter.html]. A valid description is one that was published in the *IJSEM*. Species descriptions published in other journals must be published in a validation list in

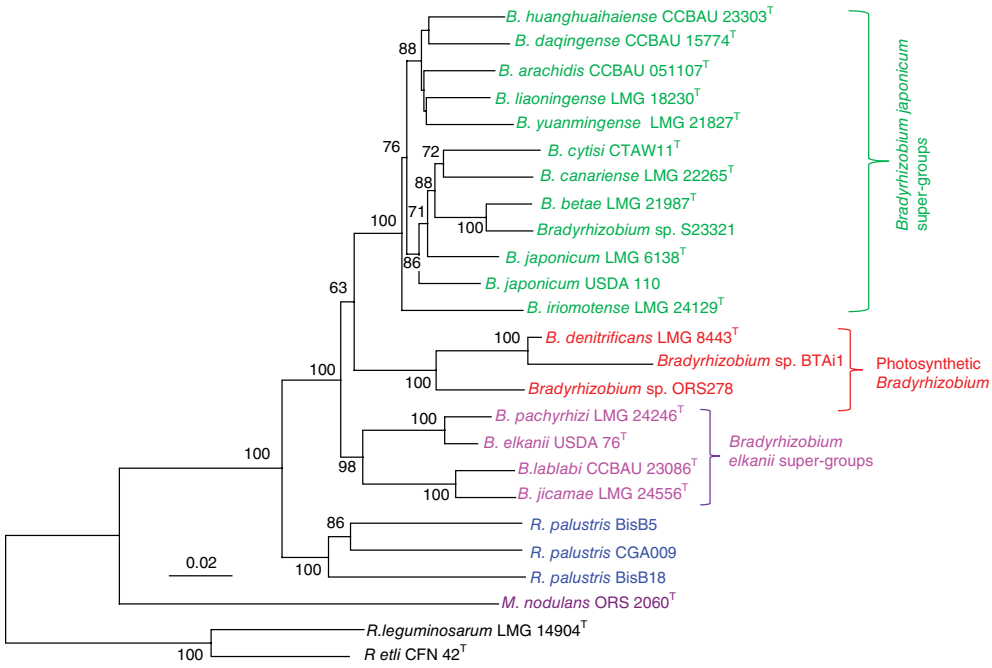

Figure 3.4 Maximum-likelihood (ML) phylogenetic tree constructed based on concatenated *dnaK_rpoB_gyrB_atpD_glnII_recA* gene sequences (total length 2773 bp including gaps), showing the relationships among root-nodulating bacterial species in the genus *Bradyrhizobium* (see also Chapter 18). The tree includes all described type strains of nitrogen-fixing bacterial species of the genus *Bradyrhizobium* except *B. rifense* strain CTAW71. In addition, the whole genome-sequenced *Bradyrhizobium* species, the type strain of *Methylobacterium nodulans*, and *Rhodopseudomonas palustris* were also included in the tree. The tree is rooted with the type strains of *Rhizobium leguminosarum* and *R. etli*, and the type strains are indicated with ^{T}. ML bootstrap support >50% indicated at each node.

IJSEM. Until validation, the name is put within quotation marks.

3.3.3 The *Sinorhizobium* Clade

The genus name *Sinorhizobium* was proposed in 1988 for a new species, *S. xingjiangense*, isolated in China [http://www.bacterio.cict.fr/s/sinorhizobium.html]. The taxonomic community was not convinced by the work. In 1994, however, the monophyletic clade carrying among other novel species of the previously described *S. xingjiangense* was proposed to form a new genus, which according to the rules of taxonomy should be *Sinorhizobium.* As the model species for molecular studies, *Rhizobium meliloti*, was a member of the newly formed clade, *Rhizobium* biologists surprisingly happily started using the new name *Sinorhizobium meliloti. Sinorhizobium* is a monophyletic clade branching out from the large *Agrobacterium–Rhizobium* group. It now carries 15 nodulating species, most of which are well studied. Using the name *Sinorhizobium* is phylogenetically sound. A problem arose when it was revealed that a species called *Ensifer adhaerens* was in fact phylogenetically *Sinorhizobium.* Why was this problematic? Since the nonsymbiotic *Ensifer* (1982) [http://www.bacterio.cict.fr/e/ensifer.html] had been published as a name before *Sinorhizobium*, all species of the genus *Sinorhizobium* had to be transferred to the genus *Ensifer*, in line with rule 38 of the Bacteriological Code. This fact causes a lot of confusion in the literature and in databases. In this chapter, we use the synonym *Sinorhizobium* for *Ensifer.*

3.3.4 Other Clades and Species in the *Agrobacterium–Rhizobium* Group

There are more clades and species to be sorted out in the *Agrobacterium–Rhizobium* group. *Agrobacterium* [http://www.bacterio.cict.fr/a/agrobacterium.html] is intermingled with *Rhizobium* [http://www.bacterio.cict.fr/r/rhizobium.html]. This led Young et al. (2001) to propose that all species in this group should be called *Rhizobium*. Contrary to Figure 3.3 and many other phylogenies, *Sinorhizobium* was placed outside the *Rhizobium clade* in their phylogenetic reconstruction. As a consequence, most authors now use the name *Rhizobium rhizogenes* instead of the former *A. rhizogenes*, which is located close to *R. tropici* in the 16S rRNA gene tree. The branches from *R. aggregatum* to *R. skierniewicense* carry species with genus name *Agrobacterium* or *Rhizobium*, reflecting the confusion caused by Young et al. (2001) by calling the whole group *Rhizobium.*

Figure 3.5 Maximum-likelihood (ML) phylogenetic tree constructed with concatenated *glnII* (516 bp)_*recA* (417 bp) gene sequences, showing the relationships among mainly root-nodulating bacterial species and genospecies of the genus *Bradyrhizobium* (see also Chapter 18). In addition, whole genome-sequenced *Bradyrhizobium* species, a type strain of *Methylobacterium nodulans,* and *Rhodopseudomonas palustris* were also included in the tree. The tree is rooted with the type strains of *Rhizobium leguminosarum* and *R. etli*, and the type strains (green) are indicated with ^{T}. ML approximate likelihood-ratio test supports >70% indicated at each node.

The plant pathogenic *R. skierniewicense*, *A. rubi*, *A. nepotum*, *A. radiobacter*, *A. larrymoorei*, and "*A. fabrum*" strain C58 (Lassalle et al., 2011) are positioned within a larger clade in Figure 3.3 with nonpathogenic, nonsymbiotic *R. pusense*, *R. selenitireducens*, *R. naphtalenivorans*, *R. rosettiformans*, and *R. aggregatum*. We think that this clade is large and defined enough to warrant it a genus name different from *Rhizobium*, though further phylogenetic studies with more housekeeping genes are needed to verify this assumption. The symbiotic *R. daejeonense* is in the same clade though the most distant member of it.

Allorhizobium undicola and *Agrobacterium vitis* with the very close *Rhizobium taibaishanense* form another well-separated clade. *A. vitis* is pathogenic, *A. undicola* is symbiotic, and *R. taibaishanense* has no plant-related phenotype reported.

R. sphaerophysae with "*R. helanshanense*" (not validly published), *R. herbae* with *R. giardinii*, as well as *R. subbaronis* with *R. borbori* and *R. halophytocola* form small, well-separated clades in the tree (Fig. 3.3). Of those, *R. sphaerophysae*, *R. herbae*, *R. giardinii*, and *R. helanshanense* were reported as symbiotic.

Ochrobactrum cytisi isolated from *Cytisus scoparius* and *O. lupini* from *Lupinus albus* are symbiotic, but probably only minor symbionts.

Rhizobium vignae, *R. galegae*, *R. alkalisoli*, and *R. huautlense* form a clade of symbiotic bacteria with neighbors *R. cellulosilyticum* (minor symbiont) and nonsymbiotic *R. soli.*

R. tubonense and "*R. qilianshanense*" (unvalidated) were isolated from nodules and form well-separated branches in the 16S rRNA gene tree. *R. tarimense* is a recent addition to this group and presumably nonsymbiotic. The symbiotic *R. petrolearum* and nonsymbiotic "*R. phenanthrenilyticum*" (unvalidated) form another well-separated clade, as do the symbiotic *R. oryzae* and the nonsymbiotic *R. pseudoryzae.*

The symbiotic *R. gallicum*, *R. mongolense*, and *R. yanglingense* strains form a monophyletic lineage with very low genetic diversity, as pointed out by Vinuesa et al. (2005), who based on multilocus analysis suggested that they form just one species. This change of names has not formally been done, which is a pity. However, their study emphasized the need for proper phylogenetic reconstructions with several housekeeping genes to detect speciation and delineate species.

R. loessense, *R. sullae*, *R. indigoferae*, *R. mesosinicum*, and *R. alamii* are symbiotic species in the same clade. The *R. indigoferae* type strain has been distributed as two different genotypes, the second clustering with *R. leguminosarum*.

The next larger clade consists of the symbiotic *R. mesoamericanum*, *R. tibeticum*, and *R. grahamii*. "*R. cauense*" and *R. endophyticum* were isolated from plant tissue (*Kummerowia stipulacea* nodule; *Phaseolus* bean tissue, respectively). The type strain of *R. endophyticum*, isolated as a bean endophyte, became fully symbiotic when the symbiotic plasmid of *R. tropici* was introduced to it (López-López et al. 2010).

The *R. leguminosarum* "superclade," which was recognized by Aserse et al. (2012a), is also visible in the 16S tree. It consists of symbiotic, well-characterized bacteria. This clade encompasses the *R. leguminosarum* type strain, the very closely related *R. fabae* and *R. pisi*, as well as *R. phaseoli*, *R. etli*, and *R. leguminosarum* symbiovar trifolii, the former type strain of *R. trifolii*, which is not a recommended species name any longer.

Another "superclade" consists of the symbiotic *R. tropici*, *R. leucaneae*, *R. lusitanium*, *R. miluonense*, *R. hainanense*, *R. multihospitum*, and *R. vallis*, as well as the pathogenic *R. rhizogenes*.

The phylogenetic branches from *Phyllobacterium trifolii* to *Bosea lupine* represent a mix of genera and species with diverse properties. *P. trifolii* was reported as symbiotic [http://www.bacterio.cict.fr/p/phyllobacterium.html] on clover and lupine. *Devosia neptuniae* [http://www.bacterio.cict.fr/d/devosia.html] and the *Azorhizobium* [http://www.bacterio.cict.fr/a/azorhizobium.html] and *Microvirga* [http://www.bacterio.cict.fr/m/microvirga.html] species as well as *M. nodulans* [http://www.bacterio.cict.fr/m/methylobacterium.html] were reported as symbiotic and demonstrate the taxonomic diversity of symbiotic features within the alphaproteobacteria. These bacteria represent some interesting symbiotic and physiological features, as *Azorhizobium* is both stem nodulating and known to fix N *ex planta* and *Methylobacterium* consumes several one-carbon substrates. The *Bosea* [http://www.bacterio.cict.fr/b/bosea.html] species were described as endophytic but nonsymbiotic. The other species in this group were previously (and still are) erroneously described as *Agrobacterium* species and they are all aquatic bacteria.

3.3.5 The Betaproteobacteria

The betaproteobacteria in Figure 3.3 are all reported as symbiotic (see also Chapter 89). The *Burkholderia* species represent a fraction of all species in this large genus [http://www.bacterio.cict.fr/b/burkholderia.html], whereas *Cupriavidus taiwanensis* is the only symbiotic species in the genus, which otherwise displays a collection of species with diverse properties [http://www.bacterio.cict.fr/c/cupriavidus.html]. *Herbaspirillum* [http://www.bacterio.cict.fr/h/herbaspirillum.html] species are often plant associated and *H. lusitanium*, isolated from a *Phaseolus* bean nodule, is endophytic but not symbiotic.

Gyaneshwar et al. (2011) have summarized features of the symbiotic betaproteobacteria in a recent comprehensive review (see also Chapter 17). These bacteria were

so far found to infect mimosoid legumes in South America and Asia (*Mimosa* sp.), papilionoid legumes in South Africa (*Aspalathus*, *Cyclopia*), and some native papilionoid legumes in Australia. Some strains displayed promiscuity infecting, for example, *Phaseolus* bean. For scientists working with *Burkholderia*, it is important to distinguish symbiotic from pathogenic species, because a genus name that refers to pathogenic bacteria will cause problems in society.

3.3.6 The Genus *Bradyrhizobium*

Genus *Bradyrhizobium* for a long time had only two described species: *B. japonicum* and *B. elkanii*. The current list of taxa is much longer, and new species are described at an increasing pace. Some patterns are thus starting to emerge (Fig. 3.4; see also Chapter 18). As the 16S rRNA gene is not variable enough among bradyrhizobia to be useful for species delineations, other housekeeping genes should be used to produce reliable phylogenies. In Figure 3.4, a phylogenetic tree based on concatenated *dnaK_rpoB_gyrB_atpD_glnII_recA* gene sequences is shown. Three supergroups are highlighted, representing *B. japonicum* – and *B. elkanii* –related species and the group containing photosynthetic strains. Most species in the former groups are nodulating (exception *B. betae*), *Bradyrhizobium* sp. strains BTAi1 and ORS278 are photosynthetic and stem nodulating on *Aeschynomene* species, but lack the canonical *nod* genes (Giraud et al. 2007). *Bradyrhizobium denitrificans*, the former *Blastobacter denitrificans*, is also able to form root and stem nodules on some *Aeschynomene* species. The nonsymbiotic *Blastobacter oligotrophicum* is also a member of this clade (Fig. 3.5).

Figure 3.5 shows a more complex pattern. In addition to the supergroups delineated in Figure 3.4, two unnamed *Bradyrhizobium* deep lineages are pointed out. They represent isolates from the Australian continent (Stepkowski et al., 2012). Furthermore, many unnamed species, denoted as genospecies, are occupying branches in the tree. These isolates came from Australia (Aus) (Stepkowski et al., 2012), Ethiopia (ETH) (Aserse et al., 2012a), Mexico (TUXTLAS) (Ormeño-Orrillo et al., 2012), South Africa (SA) (Steenkamp et al., 2008), and the Asian continent (Vinuesa et al., 2008). The authors who discovered these have chosen not to name the species, but they represent interesting novel biodiversity.

Other authors have rushed to describe a new species. The novel "*B. arachidis*" species displays within species diversity. In Figure 3.5, it seems to represent two lineages, each one with members also from other genospecies. In the paper by Wang et al. (2013), the 16S and concatenated housekeeping gene sequences are only compared with those representing described species. This is unfortunate, since a Blast search could have retrieved also sequences representing published genospecies.

3.4 DISCUSSION

The results presented clearly demonstrate that there is a discrepancy between population genetic and phylogenetic studies, on the one hand, and taxonomy on the other. Population genetics requires several strains to be studied, and speciation can be detected in phylogenetic reconstructions only when enough strains and genes are used, whereas current taxonomic practice encourages scientists to put a minimum of effort into the selection of a representative set of strains and genes. Instead, even one single strain is enough if all tests requested by the editors of the *IJSEM* are performed to describe a new species.

Graham et al. (1991) published the paper "Proposed minimal standards for the description of new genera and species of root- and stem-nodulating bacteria," which expressed the views of the ICSP subcommittee at that time. Those guidelines are partly still valid, but many authors follow them too strictly. Phylogenies of housekeeping genes are often presented nowadays, and this is a step in the right direction. In the minimal standards, the host plants for the species that were described to that date (1991) were proposed to be used in plant tests for putative new species. Those plants are *Medicago sativa, Pisum sativum, Phaseolus vulgaris, Trifolium repens, Lotus corniculatus, Glycine max, Vigna unguiculata, Leucaena leucocephala, Macroptilium atropurpureum,* and *Galega officinalis.* Host plants known to be nodulated by the strains being tested should be included as well as the host plant from which each strain was isolated. Today, those plants are partly excessive and the selection of plants should be given proper thought.

Nowadays, the phylogeny of *nif* and *nod* genes is also often reported for new species. Since the species delineations are based on core/housekeeping gene phylogenies, but symbiotic properties of rhizobia are important for biological and practical reasons, symbiovars can be designated that refer to plant nodulation and N fixation phenotype as well as genotype. Rogel et al. (2011) listed all currently described symbiovars. Species that symbiovars have been designated for are generally well described also in terms of biological properties.

We have used the symbiotic or pathogenic to describe the phenotypes associated with the described species. If we consider several of the branches in Figure 3.3, symbiotic or pathological properties are often incompletely tested and described. Lindström et al. (2010) reviewed properties of symbiotic bacteria in the field and processes shaping their genomes. It must be borne in mind that phenotypic properties associated with many of the described species are only snapshots of dynamic genomes. The example of the

type strain of *R. endophyticum*, isolated as a bean endophyte, which became fully symbiotic when the symbiotic plasmid of *R. tropici* was introduced to it (López-López et al., 2010), demonstrated the plasticity of the genomes and the role of accessory genes in shaping them. It would be desirable that taxonomists took some more interest in these aspects, adding an evolutionary dimension to the species descriptions.

As pointed out in the introduction, symbiotic genes are inherited horizontally and vertically. Current knowledge is mainly based on properties of the alphaproteobacterial rhizobia. It is thus still a matter of speculation whether the *nif* genes of alphaproteobacteria were inherited from the betaproteobacteria, and the *nod* genes were transferred in the other direction or vice versa (Masson-Boivin et al., 2010; Gyaneshwar et al., 2011). More studies in this direction will add to the excitement of taxonomy as well.

There is certainly room for revision of genera and species described in this paper. Especially the *Agrobacterium–Rhizobium* group calls for thorough phylogenetic and population genetic studies of the clades outlined in Figure 3.3. We anticipate that *Agrobacterium* will be maintained for the clade with *Agrobacterium tumefaciens. A. vitis* on the contrary might be merged with *A. undicola* and *R. taibaishanense*. This clade displays a diversity of plant phenotypes and should be properly explored. *Rhizobium galegae* and the related taxa are in focus in our laboratory and we hope to present a taxonomic revision soon.

Nowadays full genome sequences for bacteria are easy to obtain. We propose that all type strains should have their genome sequence determined before publication. This would enable interesting comparisons between species and across taxa and would advance our understanding of the biology of these interesting plant-interacting prokaryotes.

NOTE

Two new genera, *Neorhizobium and Pararhizobium*, have been described for the family *Rhizobiaceae* since 2014 (Mousavi et al., 2014, 2015). The 16 new species combinations that were described in the family *Rhizobiaceae* in 2014 and 2015 are listed as follows: *Neorhizobium galegae, Neorhizobium huautlense, Neorhizobium alkalisoli, Agrobacterium nepotum, Agrobacterium pusense, Agrobacterium skierniewicense, Allorhizobium vitis, Allorhizobium taibaishanense, Allorhizobium paknamense, Allorhizobium oryzae, Allorhizobium pseudoryzae, Allorhizobium borbori, Pararhizobium giardinii, Pararhizobium capsulatum, Pararhizobium herbae, and Pararhizobium sphaerophysae.*

4.1 NODULE FORMATION IN A NUTSHELL

The formation of the root nodule is initiated at the epidermis of plant roots where signals of the bacteria are perceived. In response to the signal, among others, root hairs redirect their growth toward the bacterium. In this way, a curl is formed around the dividing bacteria that become entrapped in a pocket inside the curl. After completion of the curl, an infection thread is initiated starting from this pocket. This infection thread is a tubular invagination of the plasma membrane of the plant, filled with rhizobia, that grows inside the root hair toward the root cortex. While the infection thread grows inwards, cells of the cortex start to divide to form the nodule primordium from which the nodule develops (Ferguson et al., 2010; Hirsch, 1992; Luyten and Vanderleyden, 2000; see also Chapters 41, 50, 51).

4.2 SIGNALING IN SYMBIOSIS

To establish a symbiotic interaction, the two partners need to exchange signals as a biochemical handshake. For the *Rhizobium*–legume symbiosis, the signaling is mainly studied during early steps in the epidermis. The signal that sets the nodulation process in motion is the Nod factor. This is a decorated lipochito-oligosaccharide (LCO) that is perceived by two Nod factor receptors. These are the LysM receptor kinases LYK3/NFR1 and NFP/NFR5 in *Medicago truncatula* and *Lotus japonicus,* respectively (Arrighi et al., 2006; Limpens et al., 2003; Radutoiu et al., 2003; Smit et al., 2007; see also Chapter 51). The receptors activate the so-called common signaling pathway. Not only is this pathway, as its name suggests, unique to the *Rhizobium*–legume symbiosis, but it is also used in the mycorrhizal symbiosis (Catoira et al., 2000; Geurts and Bisseling, 2002; Hocher

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

et al., 2011). The common signaling pathway starts with the LRR-type receptor DMI2 (Limpens et al., 2005) and the putative cation channel DMI1 (Ane et al., 2004). Downstream of DMI1 and DMI2 act two nucleoporins: NUP133 and NUP85 (Kanamori et al., 2006; Saito et al., 2007). All these components are essential for the induction of nuclear calcium oscillations (Peiter et al., 2007; Wais et al., 2000; see also Chapters 54, 57). These oscillations are interpreted by the calcium and calmodulin-dependent kinase CCamK/DMI3 (Levy et al., 2004; Mitra et al., 2004; Oldroyd and Downie, 2004). CCamK and its interactor Cyclops/IPD3 are the last components of the common signaling pathway (Messinese et al., 2007; Ovchinnikova et al., 2011; Yano et al., 2008) and activate transcription factors that regulate a wide range of genes, which initiate the formation of a nodule and ultimately the formation of the symbiotic interface (see later).

4.3 THE INDETERMINATE NODULE

In legumes, two types of nodules can be distinguished: determinate and indeterminate nodules. Determinate nodules are formed on, for instance, the model legume *L. japonicus* and soybean. In these nodules, the meristem is transiently present and as a result the formation of infected cells, and so the symbiotic interfaces, are formed more or less simultaneously (Ferguson et al., 2010). Therefore, the subsequent developmental stages of symbiotic interface formation are rather difficult to study in determinate nodules.

Indeterminate nodules are formed among others on the model organism *M. truncatula*, pea, alfalfa, clover, and vetch. These indeterminate nodules contain a nodule meristem at their apex that continuously adds new cells to the nodule. Therefore, in these nodules, a series of subsequent developmental stages are present along their longitudinal axis. This facilitates research on the development of the symbiotic interface. The indeterminate nodule has four developmental zones: the meristem, the infection zone, the fixation zone, and the senescent zone. The meristem continuously provides the nodule with new cells. In the infection zone, the cells derived from the meristem are continuously infected by rhizobia, which are released from an infection thread that penetrates these cells. In indeterminate nodules, in general, individual bacteria are surrounded by a host-derived membrane. The bacterium with the plant-derived membrane is called symbiosome (Fig. 4.1a; see also Chapter 68). The symbiosomes continue to divide and develop into a mature state where they fix atmospheric nitrogen into ammonia in return for carbohydrates. This zone, where the rhizobia fix nitrogen and the symbiotic interface is completed, is called the fixation zone. Finally, in the senescent zone, symbiosis is terminated by the plant by fusion of symbiosomes with lytic vacuoles (D'Haeze and Holsters, 2002; Downie, 2007; Esseling et al., 2003; Ferguson et al., 2010; Hirsch, 1992; Jones et al., 2007; Murray, 2011).

4.4 SIGNALING INSIDE THE NODULE

Inside the nodules, recognition of the rhizobial Nod factor might be essential for the formation of the symbiotic interface, although this has not yet been demonstrated. In the nodules, the Nod factor receptors and other components of the signaling cascade are expressed at the apex (Limpens et al., 2005). However, attempts to visualize the Nod factor receptors in nodules failed (Haney et al., 2011; Madsen et al., 2011). Furthermore, a functional analysis of the Nod factor receptors in nodules is not available. However, some components of the Nod factor signaling cascade have been shown to control the bacterial release from infection threads and so the formation of the symbiotic interface (see also Chapter 59). Knockdown of DMI2 or IPD3 (the interactor of DMI3) blocks the formation of the symbiotic interface (Limpens et al., 2005; Ovchinnikova et al., 2011). When the *Medicago* DMI3 mutant is complemented with the DMI3 homolog from rice a nodule is formed, but release of the bacteria is blocked (Chen et al., 2007). This suggests that DMI3 is also an essential component for the release of rhizobia. How the signaling cascade is activated remains to be demonstrated, but Nod factors might play a role. The rhizobial genes essential for the production of Nod factors are active in the infection zone of root nodules (Schlaman et al., 1991; Sharma and Signer, 1990). Furthermore, rhizobia unable to produce Nod factors inside the nodules are not released (Marie et al., 1994). Whether and how Nod factors are perceived in root nodules and whether this results in the activation of the Nod factor signaling cascade remains to be demonstrated. Rhizobia are checked for their Nod factor profile/signature by the entry receptor in curled root hairs (Ardourel et al., 1994; Catoira et al., 2001; Smit et al., 2007). Nevertheless, a final Nod factor structure checkpoint would contribute to the maintenance of the symbiotic nature of the interaction.

4.5 *RHIZOBIUM* SYMBIOSIS IN *PARASPONIA*

Insight into the evolution of the legume–*Rhizobium* symbiosis can be obtained by a comparison with other (non-) legume endosymbioses. First, we make a comparison with the *Rhizobium–Parasponia* symbiosis. The symbiosis with rhizobia is almost completely restricted to legumes. The only exceptions are tropical trees belonging to the genus *Parasponia* that also can form an interaction with rhizobia. *Parasponia* is a part of the Celtidacea and so

Figure 4.1 Symbiotic interfaces are formed in several symbiotic interactions. (a) In legumes, the symbiosis with rhizobia leads to the formation of intracellular symbiosomes. (b) Formation of fixation threads in *Parasponia* in symbiosis with rhizobia. (c) Formation of arbuscules in symbiosis with arbuscular mycorrhizal fungi. (d) In pathogenic biotrophic fungi, interaction leads to the formation of haustoria.

only remotely related to legumes. Therefore, this symbiosis evolved independently. *Parasponia*, such as the legumes, forms a nodule to house the bacteria. These *Parasponia* nodules are modified lateral roots. This nodule has a central vascular bundle, no root cap, and the bacteria are hosted in the expanded cortex.

The infection thread penetrates nodule cells, but rhizobia are not released from the infection thread. Instead, fixation threads form a continuum with the infection thread. Similar to infection threads, the fixation threads are bound by a cell wall albeit it is markedly thinner than the wall of an infection thread (Fig. 4.1b; see also Chapter 57). So a clear difference between fixation threads and symbiosomes is the presence of this thin cell wall, which is absent in symbiosomes (Webster et al., 1995). The rhizobia fix nitrogen in the fixation threads and must get carbohydrates in return. This symbiotic interface of *Parasponia* is similar to the symbiotic interface formed in primitive legumes such as *Andira* spp. and many species belonging to the Fabaceae with subfamily Caesalpinioideae (Defaria et al., 1989).

Research on *Parasponia* has been recently revitalized and can now make use of the achievements obtained with model legume systems. It has not yet been studied whether the common signaling pathway is involved in *Parasponia*. However, studies on one of the Nod factor receptors provided insight into the evolution of these receptors. To prove that also in *Parasponia* the Nod factor is the signal that starts symbiosis, Op den Camp et al. (2011) knocked down the *Parasponia* homolog of the Nod factor receptor NFP. This led to a marked (90%) reduction of the nodule number. Thus, although evolved independently, the same signal molecule is recruited to induce this nonlegume nodule symbiosis. This points to an important constraint in nodule evolution. This experiment revealed an important role of Nod factor perception. In the nodules that are formed, the knockdown of NFP specifically blocked the formation of fixation threads. So it proved that Nod factors need to be perceived to form a symbiotic interface in *Parasponia*, and this strongly suggests that this is also the case in legumes which is in line with the important role of the common signaling pathway in the formation of the interface.

Parasponia acquired nodulation rather recently. This makes *Parasponia* and the closely related non-nodulating *Trema* an ideal biological system to study the evolutionary origin of nodulation as the amount of evolutionary noise is lower than in legumes.

4.6 ACTINORHIZAL N-FIXING SYMBIOSIS

Another N-fixing nodule symbiosis is the interaction of actinorhizal plants (e.g., alder, *Casuarina*, bayberry, and sweet fern) and (Gram-positive) actinobacteria of the genus *Frankia*. The root nodule that is formed is a modified lateral root such as the *Parasponia* nodules. In these nodules, the bacteria are also hosted intracellularly. The hyphae of *Frankia* enter the plant by an infection thread-like structure. Inside the nodule, these hyphae branch extensively to fill the entire nodule. As in *Parasponia*, the bacteria are not released from the thread: a vegetative hyphae surrounded by a plant membrane is formed (Fig. 4.1b). The membrane surrounding the hyphae is the symbiotic interface. From the tip of these vegetative hyphae, symbiotic vesicles are formed in which nitrogen fixation takes place (Berg et al., 1999; Pawlowski and Demchenko, 2012; Wall, 2000; see Chapters 35, 42, 43, 48, 55).

A knockdown of the SymRK homolog, a component in the common signaling pathway, blocks the formation of vegetative hyphae in *Casuarina*. Although other components of the common signaling pathway have not been tested, this suggests that the common signaling pathway (also known as CSSP or SYM) is essential for the formation of the symbiotic interface in *Casuarina* (Gherbi et al., 2008; Markmann et al., 2008; see Chapter 55). The nature of the signal molecule initiating *Frankia* symbiosis is unknown. However, the fact that the common signaling pathway seems involved suggests a shared evolutionary origin with the *Rhizobium* symbiosis.

4.7 ARBUSCULAR MYCORRHIZAL SYMBIOSIS

In comparison with the *Rhizobium*–legume and the actinorhizal symbiosis, the AM symbiosis has a much broader host range. Approximately 80% of all land plants can interact with AM fungi. The rhizobial and actinorhizal symbioses are also much younger (~60–80 million years) compared to the AM symbiosis (475 million years). The symbiosis with AM fungi provides the plant with an improved uptake of, for example, water, phosphate, and nitrogen. It is thought that this symbiosis was important for the colonization of land by plants (Hata et al., 2010). The AM symbiosis starts off with the germination of a fungal spore. Upon contact with the plant epidermis a hyphopodium is formed to allow the fungus to penetrate the root. When the fungus reaches the root cortex, it spreads longitudinally. The fungus forms a trunk that penetrates the plant cell. This trunk is still surrounded by a cell wall. From the trunk arbuscules are formed; highly branched intracellular hyphae are surrounded by a host membrane and lack a cell wall. This periarbuscular membrane is the symbiotic interface (Fig. 4.1c) (Genre et al., 2005; Hata et al., 2010; Ivanov et al., 2010). So in this way, AM fungi, rhizobia, and *Frankia* are hosted in a similar intracellular manner.

Similar to rhizobia, the mycorrhizal fungi produce signal molecules that induce symbiosis (Myc factors). One of these Myc factors has a remarkably similar structure as the rhizobial Nod factor: both are LCOs (Maillet et al., 2011; see Chapter 51). Furthermore, chitin tetramers and pentamers are produced by AM fungi. These are shorter than the chitin fragments inducing defense responses and do not trigger defense responses either (Genre et al., 2013). For defense responses, chitin octamers are needed to facilitate receptor dimerization (Liu et al., 2012). The tetramers and pentamers are not able to facilitate receptor dimerization. Interestingly, the Nod factor and LCOs have a backbone of four chitin residues. The short-chain oligomers can, like LCOs, induce nuclear calcium spiking in *Medicago* via the common signaling pathway (see Chapter 54). The receptors that recognize these AM fungal LCOs and chitin oligomers in legumes are not known. In contrast to *Parasponia* (Op den Camp et al., 2011), legume Nod factor receptors are not needed to establish a symbiosis with AM fungi (Radutoiu et al., 2003).

The legume Nod factor receptors belong to gene families where, for example, NFP is often a single copy "family" in nonlegumes. Therefore, it seems probable that at least the fungal LCOs are perceived by receptors that are closely related to Nod factor receptors. In legumes, these have probably diverged by gene duplication and neofunctionalization (Zhang et al., 2007). So most likely, both the Nod factors, its receptor and the common signaling pathway, have an evolutionary origin in the mycorrhizal symbiosis.

In both the *Rhizobium* nodule and the AM fungal symbiosis, a cell-wall-free symbiotic interface is formed. In the *Rhizobium* symbiosis this is the membrane around the symbiosome, and in the AM symbiosis the periarbuscular membrane. Ivanov et al. (2012) identified in *Medicago* a specific exocytotic pathway that is required for the formation of the symbiotic interface by studying the role of vesicle-associated membrane proteins (VAMPs). VAMPs are essential for exocytosis. VAMPs belong to the SNARE proteins. These proteins guide the fusion of vesicles with the appropriate target membrane. Only if the SNARE proteins on both target and vesicle membrane match, fusion occurs. Knockdown of two closely related VAMP72 proteins in *Medicago* inhibits the formation of a cell-wall-free interface in both the *Rhizobium* and AM symbiosis. Further, growth of the root, nodule formation, and infection thread/trunk formation are not affected. So the exocytotic pathway in which these VAMP72 SNAREs participate is essential for the formation of the symbiotic interface but not for other exocytosis-dependent processes.

So the comparison of the mechanism controlling symbiotic interface formation in AM and *Rhizobium* symbiosis strongly suggests that the signaling and cellular processes controlling symbiotic interface formation in the ancient AM symbiosis have been recruited by the *Rhizobium* nodule symbiosis. Some elements of the common signaling pathway are essential for the formation of the symbiotic interface in the *Frankia* nodule symbiosis (see Chapters 42, 43). Therefore, we hypothesize that also in this symbiosis, both signaling and cellular processes have been co-opted from the AM symbiosis.

4.8 INTERACTIONS WITH (BIOTROPHIC) PATHOGENS

In addition to endosymbiotic interactions also in interactions with biotrophic fungi, an interface needs to be created. These are formed around the intracellular feeding structures developed by the fungus to feed on the plant (Fig. 4.1d). In these biotrophic interactions, the fungal hyphae first enter the plant intercellularly. Inside the root, the hyphae branch and penetrate host cells to form haustoria. These haustoria are surrounded by an extrahaustorial membrane, a host membrane that is connected to the plasma membrane. However, a cell wall is lacking (Ivanov et al., 2010). So this interface is similar to the symbiotic interface of AM fungi, *Frankia* and *Rhizobium* in *Parasponia* and primitive legumes. This raises the question whether the biotrophic pathogenic and symbiotic interactions of fungi and plants are evolutionary related, and if so which is the oldest. Some studies showed that the common signaling pathway is not required for haustorium formation. However, this is especially involved in pathogens that interact with leaves (Mellersh and Parniske, 2006). For the

genes encoding components of the common signaling pathway, it is known that they are hardly expressed in the shoot (Benedito et al., 2008). Therefore, it is not so strange that they are not involved in the interaction with pathogens in leaves. It remains to be studied whether root biotrophs use the common signaling pathway and which exocytotic pathway is involved.

In biotrophic interactions, plants form an interface and are "forced" to support the pathogen. However, a more general response to pathogens is defense. Plants recognize the pathogens by the so-called PAMPs (pathogen-associated molecular patterns). One of the PAMPs that plants can recognize is chitin. This chitin forms the backbone of both the Nod factor and the Myc factors (LCOs and short chitin oligomers). The similarities in the structure of these signaling molecules indicate that the perception of chitin is also similar to the perception of Nod and Myc factors. Therefore, the recognition of these symbiotic signals may originate from pathogenic interactions or vice versa.

In rice, chitin oligomers are recognized by two receptors: CEBIP and CERK1. CEBIP has several extracellular LysM domains, but lacks an active kinase. CERK1 is an LysM receptor-like kinase. This is very similar to the Nod-factor receptors (Fig. 4.2) (Gough and Cullimore, 2011; Nakagawa et al., 2011; see Chapter 51). When the extracellular part of the Nod factor receptor is combined with the intracellular part of CERK1, this chimeric receptor is able to function as a Nod-factor receptor. This shows that the intracellular part of the receptor hardly changed.

Furthermore, it is shown that in *Lotus*, that Nod factor not only induces symbiosis but also activates defense-related genes (Nakagawa et al., 2011). When the receptors are expressed in *Nicotianum* leaves, they cause cell death in the absence of Nod factors (Madsen et al., 2011; Pietraszewska-Bogiel et al., 2013). These studies underline the close relationship of these pathogenic and symbiotic receptors.

In *Parasponia*, it is shown that the kinase death NFP receptor is required for Nod factor as well as for mycorrhizal responses. However, whether a second LysM domain receptor-like kinase is involved in the AM symbiosis is not known. Information about the LysM domain receptors involved in the AM symbiosis will be important to resolve the evolutionary relationship of these symbiotic and pathogenic receptors.

4.9 THE EVOLUTION OF THE *RHIZOBIUM* NODULE SYMBIOSIS

Studies that are described before strongly indicate that the *Rhizobium* nodule symbiosis evolved from the more ancient AM symbiosis. In both cases, a symbiotic interface forms the heart of the symbiosis as it allows an intracellular hosting of the microsymbiont and a well-controlled exchange of nutrients. The cellular mechanism by which the interface is formed involves the same exocytotic pathway (Ivanov et al., 2012). Also the signaling mechanism by which responses are induced in these two endosymbioses is, in part, still identical (the common symbiotic pathway). Some elements, for example, the LCO (Nod factor) receptors, have probably diverged due to gene duplication and neofunctionalization. This hypothesis is especially based on studies in *Parasponia*, which revealed that the same receptor is essential in both interactions and identification of the structure of LCOs made by AM fungi. The latter revealed that AM LCOs have a very similar structure as basal Nod factors (see Chapter 51). However, as rhizobia can produce decorated LCOs that play an important role in host specificity, co-evolution of receptors and Nod factor structure should have taken place.

The *Rhizobium–Parasponia* symbiosis evolved independently from the legume–*Rhizobium* symbiosis. The fact that both are based on Nod factor induced signaling points to an important evolutionary constraint, namely that the AM mechanisms form the foundation for the evolution of the *Rhizobium* symbiosis. Phylogenetic data suggest that in the Fabaceae, the symbiosis has evolved up to six times. It will be interesting to determine whether in all cases the AM machinery was the evolutionary driving force (Doyle, 2011; Geurts et al., 2012; Streng et al., 2011). Further support for the importance of the AM symbiosis for the

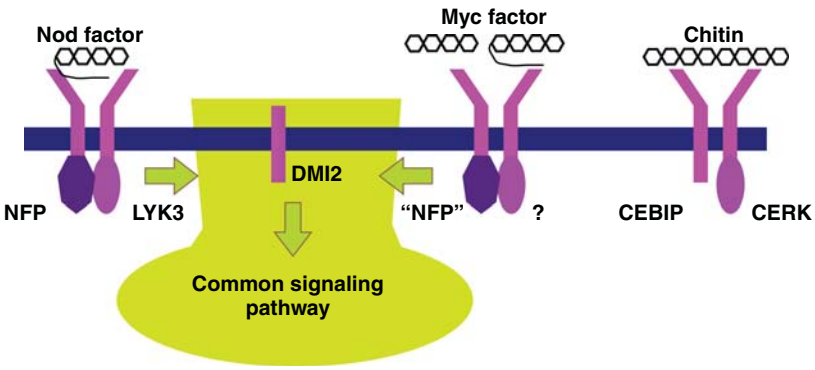

Figure 4.2 Perception of symbiotic and pathogenic signals is similar. Two LysM-type receptors perceive the signal of which one has no (active) kinase. The signal is a chitin-derived molecule. For the perception of the Myc factor in legumes NFP is not needed, but in the nonlegume *Parasponia* it is essential. Likely, in legumes another receptor performs this function.

evolution of N-fixing nodule symbiosis comes from the actinorhizal–*Frankia* symbiosis. This interaction has been shown to depend on the homolog of SymRK from the common signaling pathway (see Chapters 42, 43). Therefore, we also propose that this endosymbiosis evolved from the AM symbiosis.

The AM symbiosis is maintained in the vast majority of land plants. Therefore, the observation that this symbiosis forms the evolutionary blueprint for the N-fixing endosymbioses shows that these novel symbioses evolved by co-opting rather common mechanisms. These N-fixing nodule symbioses further evolved by recruiting other common processes. Examples are the cell cycle machinery that is modified to support infection thread growth (Yang et al., 1994) and recruitment of the transcriptional regulators of strigolactone biosynthesis as the key regulator of nodule symbiosis (Liu et al., 2011).

The co-option of common processes during nodule evolution seems to contrast with earlier studies on molecular mechanisms, controlling root nodule formation. Before the development of model legume systems that allowed the cloning of mutated genes, studies were especially focused on genes that were particularly expressed in root nodules (nodulins) (Bisseling et al., 1983; Legocki and Verma, 1980). These studies were, in part, driven by the idea that the evolution of nodule symbiosis had created novel genes. However, further studies on nodulin genes revealed that they are often expressed in other organs, albeit at a low level. Furthermore, several nodulins are the result of gene duplication by which nodule-specific variants could evolve. Examples are Flotillins (Haney and Long, 2010) and Remorins (Lefebvre et al., 2010; Toth et al., 2012). The importance of gene duplication in the refinement of the nodule symbiosis is also shown by the analysis of the *Medicago* genome (Young et al., 2011). This revealed that a whole genome duplication contributed most likely to the evolution of nodulation. Of the whole genome duplication, a certain percentage of the genes is maintained. From these maintained genes, only a subset is expressed during nodulation. The notion that nodulins are late additions in nodule evolution is supported by the fact that many of these genes are specific to the *Rhizobium*–legume symbiosis and not shared with the AM symbiosis (Deguchi et al., 2007; Manthey et al., 2004).

Although there are many similarities between the *Rhizobium* and AM symbiosis, there must be some striking differences, otherwise all plants would be able to establish a *Rhizobium* symbiosis. A major difference between the two symbioses is the fact that rhizobia never establish a symbiotic interface in existing/normal root cells, where AM fungi always do. AM fungi form arbuscules in root cortical cells, whereas rhizobia always form an interface in newly formed cells, mostly in root nodules. Even a basal legume such as *Gleditsia triacanthos* that does not form root nodules induce cell divisions in the root cortex to create an environment in which the bacteria can be hosted intracellularly (Fehér and Bokor, 1926). We hypothesize that in normal root cells the turgor pressure is too high to allow the release of symbiosomes from an infection thread. In contrast, a fungus can create force to enter a plant cell against the turgor of the host cell allowing intracellular growth (Howard et al., 1991). Therefore, we hypothesize that a major step in the evolution of the *Rhizobium* symbiosis is the formation of a cell type, probably with a temporal reduced turgor pressure, that allows the formation of a symbiotic interface by bacteria.

Chapter 5

Bioengineering Nitrogen Acquisition in Rice: Promises for Global Food Security

Herbert J. Kronzucker and Devrim Coskun

Department of Biological Sciences and Canadian Centre for World Hunger Research (CCWHR), University of Toronto, Toronto, ON, Canada

5.1 INTRODUCTION

Nitrogen (N) is the most often limiting of the nutrients that terrestrial plants need to acquire from the soil (Reich et al., 2006; Tilman et al., 1996; Vitousek and Howarth, 1991; Vitousek et al., 2010). On account of this, N additions in the form of fertilizers, largely derived from the Haber–Bosch process, to agricultural fields have produced among the largest successes in boosting crop growth and yield in the past 100 years (Tonitto et al., 2006). Currently, some 80–170 Tg of N are applied to crops annually (Cassman et al., 2002; Smil, 1999), representing a more than 8.6-fold increase in the past 40 years alone (Mulvaney et al., 2009). In the world's number one crop species, rice, N applications are particularly dramatic, and most modern varieties require very high input rates, as high as 7×10^6 tons of elemental N per year (Cassman et al., 1993, 1998; Dobermann and Cassman, 2002; Khush, 1995; Kropff et al., 1993; Matson et al., 1997; Sheehy et al., 1998). To further aggravate the problem, fertilizer-use efficiency for N is low in practical settings, and in most cropping systems some 45–55% of applied N is lost back to the environment through denitrification, volatilization, leaching, and erosion (Galloway and Cowling, 2002; Smil, 1999; Tonitto et al., 2006). In rice, the typical recovery rate for N applied through fertilizers in aboveground biomass is even lower and typically does not exceed a third (Cassman et al., 1993, 1998, 2002; Hakeem et al., 2011; Kirk and Kronzucker, 2005; Kronzucker et al., 2000; Li et al., 2012b; Vlek and Byrnes, 1986). As a result, the need for improving N-use efficiency in rice is a major priority, and has, in recent years, increasingly guided molecular biology approaches that are hoped to lead to new, bioengineered, rice lines with optimized N acquisition traits in the near future. Some of these approaches, early successes, associated challenges, and hopeful developments are reviewed here.

5.2 PRIMARY NITROGEN UPTAKE AND NITROGEN-USE EFFICIENCY: GENE CANDIDATES AND CAVEATS

The main form of N available in most rice soils, in particular the irrigated paddy soils in which the bulk of the world's rice is grown, is that of ammonium-N (NH_4^+) (Arth et al., 1998; Kirk and Kronzucker, 2005; Shen, 1969; Shrawat et al., 2008; Tabuchi et al., 2007; Wang et al., 1993a, b). Meanwhile, the NH_4^+-use efficiency of rice in field settings is exceptionally low (Cassman et al., 2002; Li et al. 2012c; Rehman et al., 2013). Biotechnologists have, thus, shown great interest in the primary process of NH_4^+ uptake by the rice plant (Britto and Kronzucker, 2004). At the physiological level, NH_4^+ uptake in rice is well characterized (Bonner, 1946; Fried et al., 1965; Kronzucker et al., 1998, 1999, 2000; Shen, 1969; Wang et al., 1993a, b, 1994), and the main molecular players have been identified. Of the transport systems situated in root plasma

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

membranes responsible for catalyzing NH_4^+ uptake, the best characterized are the members of the AMT family of transporters. Indeed, a member of the AMT family was the first high-affinity NH_4^+ transporter identified in higher plants, and AMT transporters are now well studied at the molecular level in *Arabidopsis thaliana* (Gazzarrini et al., 1999; Loqué and von Wiren, 2004; Ninnemann et al., 1994; Sohlenkamp et al., 2000, 2002), tomato (Lauter et al., 1996; von Wiren et al., 2000), *Lotus japonicus* (D'Apuzzo et al., 2004; Salvemini et al., 2001; Simon-Rosin et al., 2003), *Brassica napus* (Pearson et al., 2002), and rice. Localization of the transporter proteins in plasma membranes is now solidly established (Ludewig et al. 2002, 2003; Loqué et al. 2006; Simon-Rosin et al. 2003; Sohlenkamp et al. 2002; Yuan et al. 2007a). In the *Arabidopsis* model system, mutant analysis has allowed the conclusion that three members of the AMT1 subgroup of the transporter family, specifically AtAMT1;1, AtAMT1;3, and AMT1;5, account for as much as 80% of total root uptake in that species (Loqué et al., 2006; Yuan et al., 2007a, b). Recent studies have shown that a minimum of 12 members of the gene family are present in rice, and that these differ greatly in tissue distribution and expression response to NH_4^+ withdrawal and resupply (Gaur et al. 2012; Li and Shi, 2006; Li et al., 2009a, 2012b; Kumar et al., 2003, 2006; Sonoda et al., 2003a, b; Suenaga et al., 2003; Yao et al., 2008). At this juncture, it is critical to emphasize that most NH_4^+ transporters, and the transport functions catalyzed by them, are subject to potent feedback cycles, that is, display upregulation in response to NH_4^+ withdrawal and downregulation in response to NH_4^+ resupply, processes that are affected both by NH_4^+ itself and by amino compounds, such as glutamine, that are synthesized in NH_4^+ metabolism (Kronzucker et al., 1996, 1998; Rawat et al., 1999; Sonoda et al., 2003a, b; Wang et al., 1993a, b). This reality is summarized in Figure 5.1. The inset in Figure 5.1 illustrates the rapidity of these up- and downregulation responses; peaks in transport function are achieved within 48 h in rice (Li et al., 2012b) or even faster (Kronzucker et al., 1998; Wang et al., 1993a), and responses in transcript abundance for some members of the *AMT* family are already detectable within 30 min (Sonoda et al., 2003b; Tabuchi et al., 2007).

It is an often neglected reality that these plasticities in expression and function in response to nutritional "filling state" must, by their very nature, present a formidable obstacle to improving NUE from the perspective of simple overexpression of transporters, as such overexpression is bound to result in even more rapid downregulation of transport at both transcriptional and post-transcriptional levels than would occur under "natural" conditions (see Britto and Kronzucker, 2004, 2005, for an extensive discussion of this constraint). Even more importantly, toxicity can, in fact, result from simple overexpression, which has been observed for *OsAMT1;1* (Hoque et al., 2006). Such toxic responses likely occur because of unrestrained NH_4^+ uptake and tissue

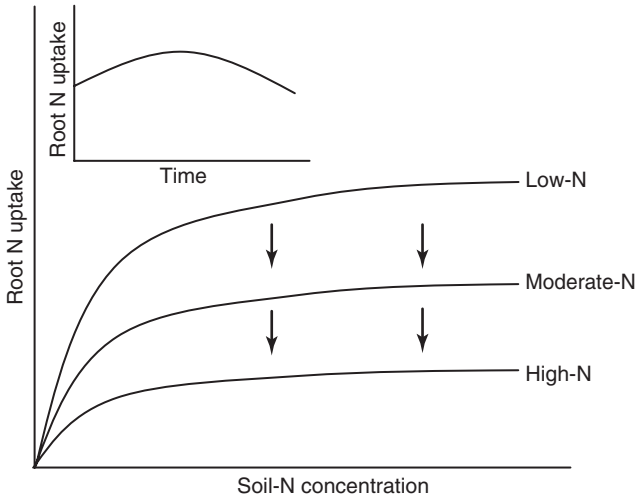

Figure 5.1 Feedback regulation of NH_4^+ influx in rice, as influenced by the level of N supply during growth (main panel; based on Wang et al., 1993b), and in response to N withdrawal for an extended period (here: 96 h) followed by NH_4^+ resupply (inset; based on Li et al., 2012b). Arrows indicate downregulation of fluxes with increasing steady-state N status. Data based on labeling experiments with the radiotracer ^{13}N (main panel) and the stable tracer ^{15}N (inset).

accumulation of the ion (Balkos et al., 2010; Britto et al., 2001; Britto and Kronzucker, 2002; Chen et al., 2013; Li et al., 2012a). Of the large number of rice AMT transporters, only three *OsAMT1* members, and *OsAMT2;1*, have thus far been examined in heterologous yeast expression systems, clearly exhibiting NH_4^+-transport activity (Sonoda et al., 2003a, b; Suenaga et al., 2003), while *in planta* analyses have remained scarce (Kumar et al., 2003, 2006; Li et al., 2012b). However, a recent detailed analysis of expression responses of *OsAMTs* (Li et al., 2012b), in conjunction with earlier studies (Sonoda et al., 2003a, b), has shed light on the variable responses of the key members in the rice system. In Table 5.1, we summarize the chief tissue/organ localization (root vs shoot) of these members of the transporter family, and their responses to NH_4^+ withdrawal and resupply. It emerges from this analysis that the main players for NH_4^+ uptake by the rice root system are *OsAMT1;1*, *OsAMT1;2*, and *OsAMT1;3*, of which the first is also expressed in shoots (and is both constitutive and inducible; Tabuchi et al., 2007), but the latter two are predominantly present in the roots, whereas other members are characterized by predominant shoot expression (Li et al., 2012b). Of these, *OsAMT1;1* and *OsAMT1;3* show clear inducibility, that is upregulation of transport in response to N withdrawal (Table 5.1), in keeping with classic expectation (Fig. 5.1). Data on *OsAMT1;3* are conflicting at present, both in the sense that downregulation has been recorded in response to N withdrawal (Li et al., 2012b) and resupply (Sonoda et al., 2003b), and in that

Table 5.1 The main NH_4^+ transporters in rice, their expression in root versus shoot, and the response to N withdrawal and resupply (based on Li et al., 2012b)

Ammonium Transporter	Root Expression	Shoot Expression	Response to NH_4^+ Withdrawal	Response to NH_4^+ Resupply
OsAMT 1;1	✓	✓	↑	--- (↑)
OsAMT 1;2	✓	Minor	↑	↓
OsAMT 1;3	✓	Minor	↓	↑
OsAMT 2;1	✓	✓	↑	--- (↑)
OsAMT 2;2	Minor	✓	↑	↑
OsAMT 2;3	✓	✓	↓	↓
OsAMT 3;1	Minor	✓	↑	↑
OsAMT 3;2	Minor	✓	↑	↑
OsAMT 3;3	Minor	✓	↑	↓

Check marks indicate the predominant sites of expression, and Minor marks a minor presence. Up and down arrows indicate whether a gene is up- or downregulated under either NH_4^+ withdrawal or resupply, respectively (strong arrows indicate strong changes, small arrows small changes; dashed lines indicate little to no change). Bold indicates genes that show the highest promise for enhancing NUE in roots (for important caveats, however, see text).

resupply has also been shown to increase expression in some cases (Li et al., 2012b).

Importantly, expression levels differ at different stages of development of the rice plant, and, for instance, *OsAMT1;2* and *OsAMT3;1*, are upregulated significantly in the critical tillering stages in roots and shoots, respectively, while playing relatively minor roles in earlier vegetative stages (Li et al., 2012b). One may deduce from this survey that a most promising route for the biotechnologist would be to target the expression of *OsAMT1;1* and *OsAMT1;2* to higher levels than in the native state, if the goal is to increase agronomic NUE from the perspective of primary N uptake by rice roots, with special emphasis on *OsAMT1;2* given its importance in the stages of tillering. However, we underscore and extend our caveat expressed previously (see also earlier) pertaining to such attempts, on account of the native dynamics of downregulation (following the principle: "what goes up must come down"), summarized conceptually in Figure 5.1, and the possibility of excess tissue NH_4^+ buildup, which is known to carry toxic consequences (Barker 1999; Li et al., 2012a; You and Barker 2004), even in rice (Balkos et al., 2010). Altogether these realities create a forbidding scenario in the pursuit of this goal and explain the limited success to date (Hoque et al., 2006).

Some reports are also available in the literature that suggest that NH_4^+ may be taken up by some plants and, under some circumstances, by other transporters, such as nonselective cation channels (Demidchik et al., 2002; White, 1999), potassium channels (Bertl et al., 1997; ten Hoopen et al., 2010; see also Kronzucker and Britto, 2011), or aquaporins (Jahn et al., 2004). Although most do not consider these pathways to be significant under normal agronomic conditions (Balkos et al., 2010), they may yet offer potential as alternative targets for improving NUE but might also pose problems when attempting to increase NUE by targeting of AMT transporters, as such parallel pathways, where present, may compensate in unpredictable ways.

We should also add a comment on nitrate-N: it is important to keep in mind that, while the bulk of N present in the most intensely cultivated rice soils is in the NH_4^+ form, there is some presence, and production, of NO_3^-, in particular in the rhizospheric microenvironment that experiences oxygen extrusion into the rooting medium via aerenchyma tissue in the rice plant (Kirk and Kronzucker, 2005; Li et al., 2008). This production of NO_3^- can be facilitated by periodic wetting–drying regimes in rice paddies, a process that fosters nitrification in the soil (Kirk and Kronzucker, 2005; Kronzucker et al., 2000), and indeed, under some conditions, as much as 40% of the total N in the rice plant may derive from the NO_3^- source (Kirk and Kronzucker, 2005). Furthermore, the co-presence of NO_3^- along with NH_4^+ has been shown to produce significant synergistic growth responses in rice, as it does in many other species (Kronzucker et al., 1999). Thus, an examination of NO_3^- transporters in addition to those that mediate NH_4^+ uptake may prove useful in the future. Recent studies have examined the expression responses of the chief members responsible for NO_3^- uptake in rice from agronomically relevant concentrations (Araki and Hasegawa, 2006; Tang et al., 2012; Yan et al., 2011), members of the *OsNRT2* group of genes (Plett et al., 2010), and using knockdown approaches for transporters involved in the long-distance nitrate transport from root to shoot, Tang et al. (2012) showed that, in the NO_3^- case, there may yet exist possibilities of uncoupling from negative-feedback loops of the type displayed in Figure 5.1 for NH_4^+ uptake. This, in turn, holds promise for increasing NUE that deserves further exploration. Also interesting in this regard is the observation

that negative feedback in rice appears to proceed differently than in the model system *Arabidopsis* (Tang et al., 2012), underscoring the importance of studying the rice system directly, rather than relying on models that derive only from the study of the *Arabidopsis* system.

5.3 THE CARBON–NITROGEN INTERFACE AND N-TRANSFER: REMOVING ENZYMATIC BOTTLENECKS

Once N is taken up by the plant, it must be assimilated to drive growth, and it is at this juncture of carbon and nitrogen metabolism where promise for improvement of NUE in the rice plant might be especially high (Britto and Kronzucker, 2004; McAllister et al., 2012; Shrawat et al., 2008; Tabuchi et al., 2007). For the NO_3^- source of N, attempts on increasing NUE by virtue of reengineering the entry step of NO_3^- into metabolism, that of nitrate reductase (NR), have been largely disappointing (Crawford, 1995; Britto and Kronzucker, 2004), and, although patent applications based on NR genes from algae supporting the approach have been filed (Loussaert et al., 2010; Liu et al., 2011; see also McAllister et al., 2012), the promise of this target point is not generally considered high (see Britto and Kronzucker, 2004, 2005, for more discussion). For the entry step of NH_4^+ into metabolism, however, that is, the incorporation of N into carbon skeletons via glutamine synthetase (GS), more potential is typically assumed. As the importance of NO_3^- for rice, while not negligible (see earlier), is clearly secondary to that of NH_4^+, this potential is of particular interest in this discussion. Early successes based on manipulation of GS include biomass stimulation in *Lotus corniculatus* (Vincent et al., 1997) and the stimulation of height growth in trees, which was recorded to reach 76% in initial stages of growth, although this gain declined to only ~21% in later stages (Gallardo et al., 1999). Biomass increases, based on both overexpression of the genes coding for the various forms of the GS1 isoform (rice has three *GS1* gene family members alone; Tabuchi et al., 2007) and those for GS2 (this isoform is localized predominantly in chloroplasts, where it is linked to the photorespiratory N cycle; Husted et al., 2002), have been reported in *L. japonicus* (Hirel et al., 1997) and tobacco (Fuentes et al., 2001; Migge et al., 2000; Oliveira et al., 2002). Results on rice have been more difficult to evaluate, even though some positive results have been obtained, albeit not in relation to growth and yield under "normal" conditions without superimposition of stress (Britto and Kronzucker, 2004; Hanzawa et al., 2002; Hoshida et al., 2000; Tabuchi et al., 2007). One of these reports has shown enhanced stress tolerance by virtue of GS2 overexpression, however, in particular in the context of salt stress (Hoshida et al., 2000), which may be attributed to enhanced substrate flow through photorespiration (Kozaki and Takeba, 1996). A more recent appraisal of successes in improving NUE in rice via GS manipulation has been more critical, however (Brauer et al., 2011). Similarly, a positive report on account of overexpression of another key enzyme of primary N assimilation, glutamate dehydrogenase (NADH-GOGAT) in tobacco (Ameziane et al., 2000) has, unfortunately, not as yet been corroborated in large-scale studies or in cereals, even though the enzyme's role in primary N metabolism and remobilization, and its tissue distribution, are well established in rice (Tabuchi et al., 2007).

One particularly exciting development in modifying internal N metabolism has been the targeting (using tissue-specific expression, an approach of increasing promise in genetic engineering; see Møller et al., 2009) of a gene coding for an aminotransferase enzyme, alanine aminotransferase (*AlaAT*; Good et al., 2007; McAllister et al., 2012, 2013; Shrawat et al., 2008). It has been argued that the gene and its product may also serve as a useful marker for NUE in general (Cañas et al., 2010). Most importantly, the role of *AlaAT* expression has been examined in rice. Table 5.2 summarizes the increases in root, shoot and total biomass, N content, and seed yield obtained in overexpressor lines of *Japonica* rice (Shrawat et al., 2008). The gains reported are impressive and are easily in line with the best results achieved via GS manipulation in the most optimistic settings (see earlier and Britto and Kronzucker, 2004). In general, the potential for alterations in internal N cycling, in particular in relation to N remobilization from previously synthesized organic N compounds in aboveground tissue, including during the important process of tiller formation and grain filling, appears significant (El-kereamy et al., 2012; Fei et al.,

Table 5.2 Increases in biomass, total N, and seed yield in roots, shoots, and whole plants, on a dry-weight basis of overexpressor lines for the gene-encoding alanine aminotransferase (*AlaAT*) in 45-day-old *Japonica* rice (cv Nipponbare; after Shrawat et al., 2008)

	Root Tissue	Shoot Tissue	Total Plant at Maturity
Total biomass, %	+9–51	+26–47	+30–34
Total N, %	+14–54	+40–65	**+36–61**
Seed yield, %	N/A	N/A	**+31–54**

2003; Good et al., 2004; Seger et al., 2009), and may present a promising alternative to modifications of primary-uptake mechanisms.

One area that is peripherally related to N acquisition and metabolism where success has been achieved, and more may be expected in the future, is in the targeting of an enzyme that plays an especially important role in C_4 species, phosphoenolpyruvate carboxylase, PEPC (Britto and Kronzucker, 2004). PEPC is a key enzyme in C_4 plants, where it is responsible for primary C fixation, and has been engineered into an overexpressed state into rice, using a *PEPC* gene from corn, with yield data indicating a 10–30% increase (Jiao et al., 2002). This success was even more impressive when a second enzyme, PPDK, was co-expressed with PEPC – additional 5–10% increases were seen in this approach. This work is interesting in that it indicates that the feasibility of achieving a partial C_4 habit in a major C_3 crop (Britto and Kronzucker, 2004), and engineering the superior carbon- and water-use efficiencies characteristic of C_4 species into rice is a major goal in modern rice research (Sage and Zhu, 2011). We have previously argued that optimizing the PEPC apparatus in rice may also be critical because of improved (anapleurotic) carbon supply for N metabolism, and we have also shown that such a feat may be accomplished by nutritional poising of nutrient media, in particular through the optimization of supply ratios of K^+ to NH_4^+ (Balkos et al., 2010; see also Roosta and Schjoerring, 2008).

5.4 NITROGEN FIXATION: THE HOLY GRAIL

One of the most elusive, and yet also most promising, targets pursued by plant biologists with respect to increasing NUE in rice has been achieving biological nitrogen fixation (BNF) within the rice plant, much like members of the Leguminosae family (Beatty and Good, 2011; Britto and Kronzucker, 2004; Ladha and Reddy, 2003; Shantharam and Mattoo, 1997). Such an achievement could relieve the enormous economic and environmental burden presented by fertilizer application, which costs upward of $100 billion per year and causes alarming environmental N pollution (Beatty and Good, 2011; Britto and Kronzucker, 2002; Galloway et al., 2008; Vitousek et al., 2009). Although this continues to be a difficult long-term prospect, especially considering the complex molecularly machinery involved (Charpentier and Oldroyd, 2010), its success in crops like rice is not considered insurmountable (Britto and Kronzucker, 2004; Beatty and Good, 2011). As discussions of details of N fixation fill the pages of this book, we will limit ourselves to the broader strokes pertaining to the rice system in particular.

One intensely pursued strategy has involved developing root nodule symbioses with diazotrophic bacteria (N-fixing bacteria containing the nitrogenase enzyme system) similar to those found in legumes (de Bruijn et al., 1995; Khush and Bennett, 1992; Ladha and Reddy, 1995; Oldroyd et al., 2009). The key to achieving such a goal involves engineering bacteria to first recognize and infect the host cells of the rice root system, followed by engineering of nodule organogenesis in the rice plant itself, so as to encapsulate bacteria in a low-oxygen environment. The latter is critical to support the bacteria's oxygen-sensitive nitrogenase enzyme complex (Gallon, 1981; see Chapter 108). In legumes, a complex signaling crosstalk between rhizobia and the plant initiates nodulation, whereby the secretion of phenolic compounds (particularly flavonoids) from the plant triggers bacteria to secrete nodulation (Nod) factors that promote nodule formation in the plant (Denarie and Cullimore, 1993; see Chapter 51). Interestingly, rice appears capable of perceiving Nod factors, and several homologs to legume "early nodulin" genes (ENODs) have been found in rice (Reddy et al., 1999, 2000). A possible explanation to this may be found in the similarities, both at the genetic (Hirsch and Kapulnik, 1998; Venkateshwaran et al., 2013; see also Chapter 108 by de Bruijn in this book) and functional (Maillet et al., 2011) levels, between plant symbioses with diazotrophs and those with arbuscular mycorrhizal (AM) endosymbiotic fungi, the latter of which are found in 70–90% of terrestrial plants, including rice (Khan and Belik, 1995). Thus, exploiting the endogenous AM (Myc-based) signaling pathway in rice to engineer diazotroph symbioses appears to be the most promising avenue. Further engineering progress is likely to involve bacterial entry and nodule organogenesis – two processes for which our understanding is still poor, although is quickly advancing (Charpentier and Oldroyd, 2010). Initial indications are that similar mechanisms exist between AM-fungal and rhizobial invasions of plant roots, which bode well for establishing BNF in rice (Madsen et al., 2010; see Chapter 108). Moreover, closely related research into the development of symbiotic nitrogen fixation in maize, based on "common pathway genes" among legumes and monocots, has recently received considerable financial support from the Bill and Melinda Gates Foundation (www.foundationcenter.org/gfp/foodsecurity; see also Chapter 109 by Beatty et al. in this book). While no true nodule formation has been demonstrated in rice thus far, early indications are that nodule formation in legumes uses plant hormones that are in fact ubiquitous throughout the plant kingdom rather than being unique to legumes (Madsen et al., 2010). Also, earlier studies have demonstrated morphological responses to rhizobial inoculation in rice, such as short and thick roots (Reddy et al., 1997) and root hair deformation, an early response involved in bacterial infection (Reddy et al., 2000). However, a key understanding that is currently lacking is what produces the specificity of responses in legumes to changes in auxin and cytokinin levels that initiate nodulation-specific developmental processes.

Indeed, it has long been known that rice already takes advantage of BNF under natural conditions, where N-fixing endophytic rhizobia form nodule-independent associations with rice (Ladha and Reddy, 2003; Stoltzfus et al., 1997; Yanni et al., 2001; see Chapter 88). Although the addition of some of these bacteria to fertilizer mixtures has yielded positive results in rice (e.g., ~30% increase in yield and agronomic NUE; Yanni et al., 2001; see Chapter 111), it remains contentious whether yield increases are actually due to BNF. One field study indeed attributed yield increases with biofertilizers not to BNF, but to changes in root morphology, stimulated by rhizobial production of the plant growth hormones IAA and GA7, which appeared to improve soil extraction of nutrients including N (Yanni et al., 2001). Although new rice endophytes that fix nitrogen at higher rates are currently being screened (Yanni and Dazzo, 2010), it would appear that such a strategy is limited in terms of the amount of fixed nitrogen that can be achieved.

Perhaps the most challenging strategy for BNF in rice is to directly introduce the nitrogenase enzyme system into a plant organelle so that the plant can fix its own nitrogen (Merrick and Dixon, 1984; see Chapter 108). Such a task may require incorporating the 16 nitrogen fixation (*nif*) genes essential to nitrogenase activity into the rice genome (Ladha and Reddy, 2003). The products of at least six genes, *NifB*, *NifEN*, *NifH*, and *NifDK*, have been shown to be absolutely required for FeMo-co biosynthesis and nitrogenase activity both *in vivo* and *in vitro*, while products of some genes that are required for FeMo-co biosynthesis could be replaced by the activities of plant counterparts (Jimenez-Vicente et al., Chapter 7; de Bruijn, Chapter 108, this book). It has been proposed that the ideal locations for introducing these genes are mitochondria and chloroplasts, rather than cell nuclei, as plastidic genetics are most similar to those of N-fixing bacteria (Whitfeld and Bottomley, 1983), and these organelles can provide high concentrations of ATP and reducing power required for nitrogenase activity (Merrick and Dixon, 1984). A potential problem with this approach, however, lies in the oxygen sensitivity of nitrogenase (see earlier), as virtually all plant cells process or generate oxygen, particularly chloroplasts. This could theoretically be overcome by regulating *nif* expression in chloroplasts diurnally, such that nitrogen fixation only occurs at night. Also, oxygen-sensitive enzymes within this organelle are not without precedent (Muraki et al., 2010). Conversely, the issue of oxygen sensitivity could be circumvented by limiting *nif* expression to root plastids in rice, where photosynthetically produced oxygen is absent. Mitochondria also have efficient oxygen-consuming respiratory enzymes and functioning oxygen-sensitive enzymes (Lill and Mühlenhoff, 2008); thus, they are also suitable candidates. Yet another potential solution involves the expression of the oxygen-tolerant nitrogenase found in the bacterium *Streptomyces thermoautotrophicus* (Ribbe et al., 1997). While such strategies are, in principle, achievable, they will likely require many more years of intensive research and development.

5.5 CONCLUDING REMARKS

We show here that many attempts to improve NUE in rice have been contemplated and attempted, but a large number of these have been disappointing (Good et al., 2004), although new funding from the Bill and Melinda Gates Foundation has newly stimulated this research (see earlier). It now emerges that, in addition to focusing on the primary intake step of N in the quest to improve NUE in rice, targeting downstream steps in metabolism may hold considerable promise. This is illustrated in successes such as those associated with the overexpression of the gene coding for alanine aminotransferase (Shrawat et al., 2008). We believe successes in this area may be related to the potential for relief from negative feedback of N transport (Fig. 5.1) that is exerted both by the externally provided N sources (NH_4^+ and NO_3^-) themselves and by endogenous N compounds formed in the N-metabolic machinery. Any approach, therefore, that may facilitate at least partial uncoupling from the potent downregulatory effects of many of these compounds by changing the internal chemical N signature may "bring out" the potential for uptake that is already in place without the need for insertion of foreign transporter genes. In the case of K^+ uptake, we have recently shown how pronounced the inherent plasticity of transport may be, based on the already present set of transporter genes, and how simple alterations of the nutrient environment may unlock this potential, resulting in substantial benefits to tissue nutrient accrual and growth (Coskun et al., 2013; Coskun and Kronzucker, 2013). Similarly, recent studies in the "nutritional poising" of NH_4^+ uptake and metabolism by potassium (Balkos et al., 2010; Roosta and Schjoerring, 2008) and the well-established growth and yield synergism on mixed N sources (Kirk and Kronzucker, 2005; Kronzucker et al., 1999) illustrate that a similar potential exists in the rice plant with respect to N acquisition, that is, successes in improving NUE in the field may not only come about through biotechnological manipulations of the genome, but may also include nutritional modifications of the rooting environment, which may be achieved through agricultural management practices such as imposition of wetting/drying regimes in paddy fields or precision farming (Cassman, 1999; Balasubramanian et al., 2004). In addition, the area of achieving N-fixation symbiosis in the rice plant remains a "holy grail" for plant biologists, and research in this area is benefitting from an upswing in activities, in part, driven by new funding (see earlier; see Chapters 108, 109). The improvement of NUE in rice, by any number of means, remains a very high priority, given the enormous challenge

of assuring global food security under currently flattening per capita yield increases, and the premier position rice holds, and will continue to hold, as a staple food for nearly half the human race.

6.1 INTRODUCTION

Iron–sulfur (Fe–S) proteins are ubiquitous and evolutionary ancient prosthetic groups that are essential in maintaining basic processes of life such as photosynthesis, respiration, central metabolism, cofactor biosynthesis, ribosome biogenesis, gene regulation, RNA modification, replication, nitrogen fixation (see Chapter 2), and DNA repair (Balk and Pilon, 2011; Kesawat et al., 2012). A few billion years ago, the earth's atmosphere was plummeting into an anaerobic environment in which the earliest forms of life evolved. The abundance of iron and sulfur on earth, and possibly the structural versatility and chemical reactivity of Fe–S clusters, allowed them to gain diverse functions that are required for the fundamental processes of life. Many of the biochemical pathways that developed in this early phase of life became and remain essential to all kingdoms of life (Huber et al., 2003). Therefore, it would come as no surprise that proteins containing Fe–S clusters exist in all living organisms and play an essential role in diverse biological processes at the cellular level. Fe–S cluster formation attracted the attention of chemists and biochemists around the world in the late 1960s, when electron paramagnetic resonance spectroscopy, chemical analyses, and biophysical technique provided plenty of evidence for the presence of these versatile inorganic cofactors in a number of proteins. The spinach ferredoxin was one of the first Fe–S proteins identified and described (Hall et al., 1966; Palmer and Sands, 1966).

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

It was thought for a long time that the assembly of Fe–S proteins occurred spontaneously, since the process was easily replicated chemically *in vitro* and led to the view that these cofactors can assemble spontaneously in proteins. However, genetic, biochemical, molecular, and cell biology studies in the late 1990s provided ample evidence that demonstrated that the assembly of Fe–S clusters *in vivo* is a catalyzed process rather than a spontaneous one and that it requires a plethora of genes assisting in the maturation of Fe–S clusters and their insertion into the apoproteins. Therefore, the formation of intracellular Fe–S clusters does not occur spontaneously, but requires a complex biosynthetic machinery. This was the starting point for the rapid discovery of numerous biogenesis components that participate in Fe–S cluster biosynthesis in both prokaryotes and eukaryotes (Johnson et al., 2005). Despite the relative simplicity of Fe–S clusters in terms of structure and composition, their synthesis, assembly, and transfer to apoproteins is a highly complex and coordinated process in living cells.

Over the past decade, the mechanisms of maturation of Fe–S cofactor and insertion into apoprotein *in vivo* have become an area of intense investigation. Numerous Fe–S cluster synthesis components have been discovered that assist Fe–S protein maturation according to distinct biosynthetic principles in several model organisms (Table 6.1), including *Saccharomyces cerevisiae*, *Escherichia coli*, *Azotobacter vinelandii*, *Erwinia chrysanthemi*, *Arabidopsis thaliana* as well as *Salmonella enterica*, and humans (Balk and Lobréaux, 2005; Kessler and Papenbrock, 2005; Ayala-Castro et al., 2008; Xu and Moller, 2008; Lill and Muhlenhoff, 2005; Rouault and Tong, 2008). The genes that participate in Fe–S cluster synthesis appear to be conserved in bacteria, fungi, animals, and plants (Table 6.2). With the availability of the whole-genome sequencing database, it was revealed that the Fe–S biogenesis machinery is widespread and highly conserved from prokaryotes and eukaryotes (Balk and Lobréaux, 2005; Lill and Muhlenhoff, 2005).

The presence of proteins in various species exhibiting similarity to the known ISC and CIA components of the yeast *S. cerevisiae* was evaluated by BLAST searches (Fig. 6.2). High sequence identity or similarity is indicated by ++ and +, limited sequence similarity is depicted by ?, and no evident similarity by −. Searches were performed for *Neurospora crassa*, *Homo sapiens*, *Drosophila melanogaster*, *Oryza sativa*, *A. thaliana*, the microsporidium *Encephalitozoon cuniculi*, the apicomplexa *Cryptosporidium parvum*, and the diplomonad *Giardia intestinalis*.

Three distinct Fe–S protein biogenesis systems have been identified in prokaryotes so far: the NIF system present in nitrogen-fixing bacteria (*A. vinelandii*) is specialized in the assembly of the complex Fe–S protein nitrogenase, which is responsible for the conversion of N_2 to NH_3 in nitrogen-fixing bacteria (see Chapters 2 and 7); the ISC system is responsible for the generation of the majority of cellular Fe–S proteins and thus, might perform a general housekeeping biosynthetic function particularly under normal and low oxygen concentrations. Finally, the SUF (sulfur-mobilization) machinery was discovered as an independent assemblage that might be used preferentially under oxidative stress and iron-limiting conditions (Jacobson et al., 1989; Zheng et al., 1998; Patzer and Hantke, 1999). On the other hand, three different types of Fe–S cluster biosynthesis machineries (Fig. 6.1) have been discovered in eukaryotes. The ISC assembly machinery is required for the biogenesis of all cellular Fe–S proteins (Strain et al., 1998; Kispal et al., 1999; Schilke et al., 1999; Lill and Kispal 2000). The ISC export assembly and cytosolic iron–sulfur protein assembly (CIA) machinery is required for the formation of cytosolic and nuclear Fe–S proteins (Roy et al., 2003). Here, we briefly summarize the basic principle, steps, and all the major components and mechanisms of Fe–S protein biogenesis in prokaryotes and eukaryotes.

6.2 SOURCE OF IRON AND SULFUR

Ferredoxin and frataxin (an iron-binding protein Yfh1 in yeast and CyaY in bacteria) are believed to function as potential iron donors because they interact with the sulfur donor IscS and the scaffold protein IscU. However, detailed experimental evidence to establish the roles of these genes remains to be determined. The source of sulfur in Fe–S clusters is l-cysteine, and the action of cysteine desulfurases (Nfs1–Isd11 in yeast and NifS, IscS, or SufS in bacteria) converts the l-cysteine to l-alanine, resulting in the release of the sulfur atom. As an intermediate, a persulphide is formed on a conserved cysteine residue of the enzyme. This persulphide might be transferred to conserved cysteine residues or directly to scaffold proteins. This provides an excellent mechanism for making sulfur atoms available without releasing them in solution (Mihara and Esaki, 2002).

6.3 STRUCTURES AND PROPERTIES OF Fe–S CLUSTERS

As the name itself indicates, Fe–S clusters are composed of ferrous or ferric iron and inorganic sulfide and, in rare cases, other heavy metals such as molybdenum, vanadium, nickel, or other cofactors (Rees, 2002; see Chapter 2). Fe–S clusters were discovered in the early 1960s by purifying enzymes with characteristic electron paramagnetic resonance signals, for instance, plant and bacterial ferredoxins and the respiratory complexes I–III of bacteria and mitochondria

Table 6.1 Core Fe–S cluster synthesis components in bacteria, yeast, mammalians, rice, and arabidopsis, their function, and subcellular localization

Fe–S Biogenesis Components in Yeast	Full Name	Alternatives Name	Homologs				Function	Sub-cellular Localization
			Bacteria	Mammalian	Arabidopsis Locus	Rice Locus		
ISC assembly machinery

(Malkin and Rabinowitz, 1966). To date, numerous Fe–S clusters have been identified and described in virtually all organisms (Table 6.1). The most common and chemically simple forms of Fe–S clusters are the rhombic [2Fe–2S] and the cubane [4Fe–4S] types, which contain iron and sulphide. A vast majority of Fe–S clusters are usually integrated through coordination of the iron ions by cysteine or histidine residues; however, sometimes cysteine or histidine residues are replaced with aspartate, arginine, serine, peptidyl-N and non-protein ligands homocitrate, CO, and CN, particularly in more complex Fe–S clusters (Meyer, 2008). The simplest form of an Fe–S center is the rhombic [2Fe–2S] cluster, for example, Rieske Fe–S protein, ferredoxins, ferrochelatase, and biotin synthase. The [4Fe–4S] clusters can be viewed as a duplication of [2Fe–2S] clusters. This type of cluster is present in many proteins, for instance, sulfite reductase, ferredoxins, aconitase and aconitase-like proteins, and DNA glycosylase. Some proteins such as subunits of complexes I and II of the respiratory chain contain [3Fe–4S] clusters in which one corner of the cube is vacant. There are numerous proteins that contain more than one Fe–S cluster. The most extreme form is complex I (NADH-ubiquinone oxidoreductase) of the respiratory chain, which contains eight (eukaryotes) to nine (bacteria) Fe–S clusters (Hinchliffe and Sazanov, 2005). More complex structures with two or more of these simple Fe–S clusters substitute iron ions with heavy metals such as molybdenum, vanadium, nickel. Most well-known examples of such complex metalloclusters are the P-cluster of nitrogenase, H-cluster of bacteria, the FeMo cofactor, the nickel-containing cluster of bacteria, NiFe hydrogenases, xanthine dehydrogenase, plant aldehyde oxidase, plant nitrate reductase, and algal iron-only hydrogenases (Meyer, 2007).

There is no single common consensus motif binding for Fe–S clusters. However, some consensus motifs have been reported; especially, the conserved positioning of cysteine residues in the protein, for example, the CX4CX2CX ≈ 30C motif in plant and mammalian [2Fe–2S] ferredoxins and [4Fe–4S] clusters, is often coordinated by the consensus motif CX2CX2CX20–40C, which was originally defined in [4Fe–4S] ferredoxins, but seems to be present in many other members of the [4Fe–4S] cluster type. Frequently, a proline residue is located next to one of the cysteine residues. The lack of consensus motif makes it difficult to predict and discover the new Fe–S proteins based on their sequence information encoded in genomes. The various biophysical techniques available to study the structure and properties of Fe–S clusters are ENDOR, NMR, Mössbauer, EXAFS, and resonance Raman spectroscopies. These techniques provide valuable information mainly about the oxidation state, the type, and electronic and magnetic properties of the Fe–S clusters (Moulis et al., 1996). Many Fe–S proteins

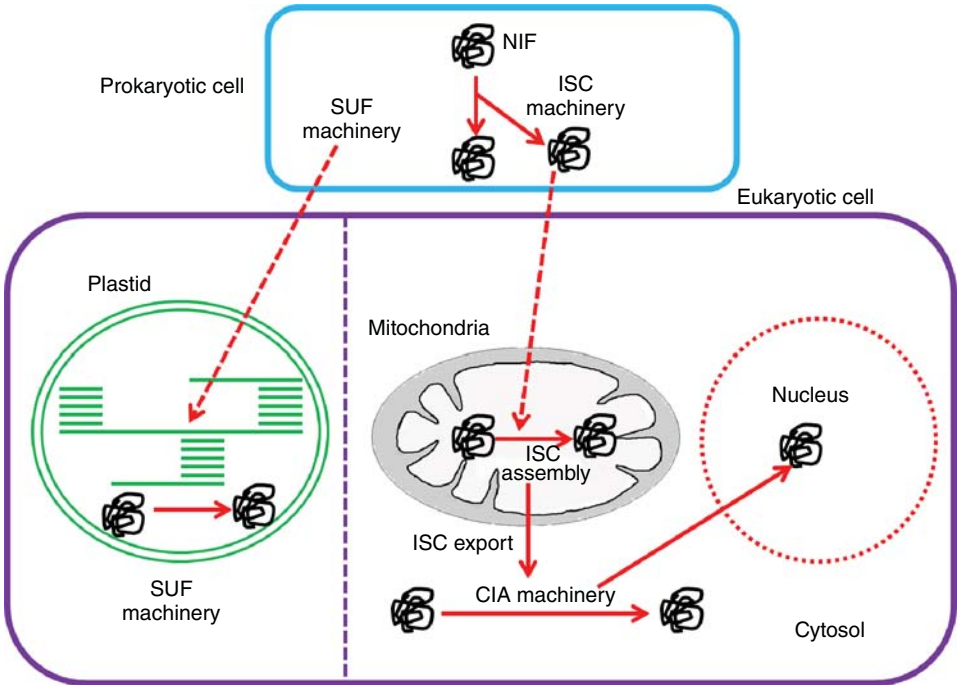

Figure 6.1 Three distinct types of machineries support the cellular Fe–S protein biogensis in prokaryotes and eukaryotes and their putative evolutionary origin. In prokaryotes: the NIF system present in nitrogen-fixing bacteria (*Azotobacter vinelandii*) is specialized in the assembly of the complex Fe–S protein nitrogenase, which is responsible for the conversion of N_2 to NH_3 in nitrogen-fixing bacteria (see Chapters 2 and 7). The ISC system is responsible for the generation of the majority of cellular Fe–S proteins particularly under normal and low oxygen concentrations. The SUF system is used preferentially under oxidative stress and iron limiting conditions. In eukaryotes, Fe–S protein exists in mitochondria, cytosol and the nucleus. The mitochondrial ISC assembly machinery is required for generation of all cellular Fe–S proteins. The ISC export apparatus and the CIA machinery are particularly required for the maturation of cytosolic and nuclear Fe–S proteins. The mitochondrial ISC assembly machinery is required for every generation of virtually all cellular Fe–S proteins. The mitochondrial ISC and SUF machineries were inherited by the eukaryotic cell from the bacterial endosymbiont that gave rise to modern mitochondria and plastids. These three different types of machineries are highly conserved from prokaryotes to eukaryotes.

are quite sensitive and are destroyed under oxidative conditions or exposure to air, NO, or H_2O_2. Most of the Fe–S proteins possess versatile electrochemical properties with reduction potentials ranging from +300 to –500 mV (Meyer, 2008).

6.4 FORMATION OF Fe–S CLUSTERS

The initial identification of proteins involved in Fe–S cluster assembly came from genetic and biochemical analysis of proteins specifically required for biological nitrogen fixation in *A. vinelandii* (Jacobson et al., 1989; see Chapter 2). Fe–S clusters can be assembled in apoproteins *in vitro* in the presence of sulfur, ferrous or ferric, and a thiol compound, for example, dithiothreitol. However, *in vivo* conditions are more complicated and require numerous key components. In addition, free sulfide and ferric iron are extremely toxic for cells; thus, they require the so-called Fe–S biogenesis machinery. Fe–S biogenesis is well documented in the model organisms *E. coli* and *S. cerevisiae*. The basic principles and key molecular players needed for Fe–S cluster formation are conserved almost in all kingdoms of life. In brief, a cysteine desulfurase produces sulfur from L-cysteine and iron and meets at the scaffold protein, which provides a molecular platform to form an Fe–S cluster, and finally this cluster is transferred to the target apoprotein.

6.5 DIVERSE FUNCTIONS OF Fe–S PROTEINS

Since the discovery of ferredoxins in the early 1960s, numerous proteins have been identified that contain Fe–S clusters known as Fe–S proteins. To date, more than 120 distinctive types of enzymes and proteins contain Fe–S clusters and have been proliferating greatly (Beinert et al., 1997). A summary of the types of biological Fe–S clusters, their functions, and localization are presented in Table 6.3. Since Fe–S clusters form the most ancient and functionally versatile prosthetic

Table 6.3 Known Fe–S proteins present in prokaryotes and eukaryotes (bacteria, yeast, plants, and animals), their cluster types, localization, and functions

Fe–S Proteins	Cluster Types	Localization	Functions
Aconitase	[4Fe–4S]	Mitochondria matrix	Citric acid cycle
Homoaconitase	[4Fe–4S]	Mitochondria matrix	Biosynthesis of lysine
Dihydroxy acid dehydratase	[4Fe–4S]	Mitochondria matrix	Biosynthesis of branched chain amino acids
Lipoate synthase	[2Fe–2S]? [4Fe–4S]	Mitochondria matrix	Biosynthesis of lipoic acid
Biotin synthase	[2Fe–2S]? [4Fe–4S]	Mitochondria matrix	Biosynthesis of biotin
Ferredoxin	[2Fe–2S]	Mitochondria matrix	Maturation of Fe–S proteins, biosynthesis of heme A, steroid biosynthesis in mammals (adrenodoxin)
Ferredoxin-like	[2Fe–2S]	Mitochondria matrix	Electron transport
Ferrochelatase	[2Fe–2S]	Mitochondria inner membrane	Heme biosynthesis (no cluster in yeast)
Complex I	8–9 cluster of [2Fe–2S], [3Fe–4S], [4Fe–4S]	Mitochondria inner membrane	Electron transport chain (NADH ubiquinone oxidoreductase)
Complex II	[2Fe–2S], [3Fe–4S], [4Fe–4S]	Mitochondria inner membrane	Electron transport chain (Succinate dehydrogenase)
Complex III	[2Fe–2S]	Mitochondria inner membrane	Electron transport chain (Ubiquinone cytochrome c oxidoreductase)
Cytokine-induced apoptosis inhibitor 1 (Dre2)	[2Fe–2S], [4Fe–4S]	Cytosol, Mitochondria inner membrane	?
DNA glycosylase	[4Fe–4S]	Nucleus	DNA glycosylase
Iron–sulfur cluster scaffold homolog (Isu1)	[2Fe–2S]	Mitochondria matrix, cytosol	Scaffold
Elp3	[4Fe–4S]	Nucleus	Histone acetyltransferase subunit of the elongation complex, cluster binds S-adenosyl-methionine
Isopropylmalate isomerase	[4Fe–4S]	Cytosol	Biosynthesis of leucine
Iron-regulatory protein 1	[4Fe–4S]	Cytosol	Post-transcriptional control of iron uptake, storage and use in mammals (Cytosolic aconitase')
Nucleotide-binding protein 1 (Nbp35)	[4Fe–4S]	Cytosol	Scaffold
Nucleotide-binding protein 2 (Cfd1)	[4Fe–4S]	Cytosol	Scaffold
Sulfite reductase	[4Fe–4S]	Cytosol	Biosynthesis of methionine, contains siroheme
Scaffold protein (Nfu1)	[4Fe–4S]	Mitochondria matrix, cytosol	Alternative scaffolding protein
Glutamate dehydrogenase	[4Fe–4S]	Cytosol	Biosynthesis of glutamate
Glutaredoxin 5		Mitochondria matrix	Cluster transfer
ABC protein Rli1 (Rli1)	[4Fe–4S] ?	Cytosol and nucleus	Biogenesis of ribosomes, rRNA processing, translation initiation
P-loop NTPase Nbp35	[4Fe–4S] ?	Cytosol and nucleus	Maturation of cytosolic and nuclear Fe–S proteins
Iron only Hydrogenase-like Nar1	[4Fe–4S]	Cytosol and nucleus	Maturation of cytosolic and nuclear Fe–S proteins
Iron-sulfur protein required for NADH-dehydrogenase (NUBPL)	[4Fe–4S]	Mitochondria matrix	Maturation of respiratory complex 1
MOCS1A	[3Fe–4S], [4Fe–4S]	Mitochondria matrix	Biosynthesis of Moco (molybdenum co-factor)
Dihydro-pyrimidine dehydrogenase	[4Fe–4S]	Cytosol	Degradation of pyrimidine nucleotides
CMP-N-acetyl-neuraminic acid	[2Fe–2S]	Cytosol	Biosynthesis of N-glycolyl neuraminic acid,
Xanthine dehydrogenase	[2Fe–2S]	Cytosol	Degradation of xanthine to urate, contains FAD and molybdopterin
Glutaredoxin 2	[2Fe–2S]	Mitochondria	Glutathione-dependent oxidoreductase

group, this allows them to participate in many vital processes of life (Fig. 6.2 a, b).

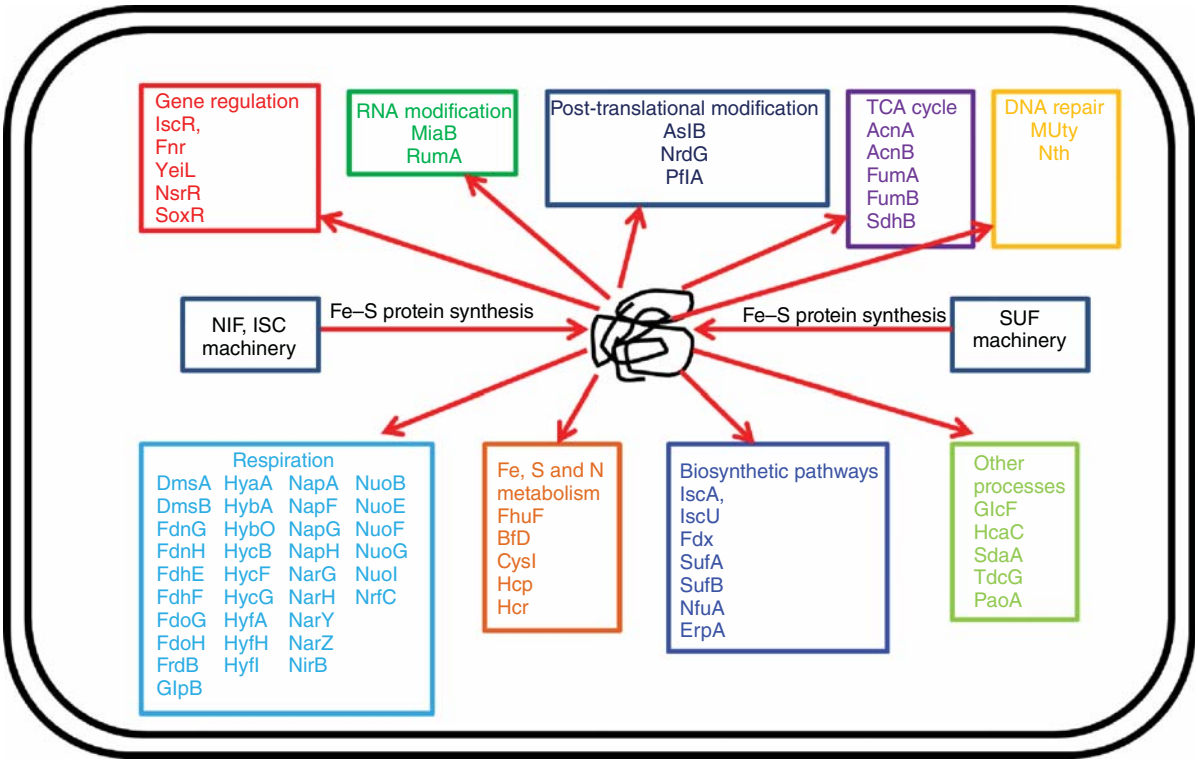
The main function of Fe–S proteins is electron transfer through the oxidation states of iron. Fe–S clusters have a wide range of redox potentials ranging from −500 to +300 mV (Meyer, 2008). Hence, Fe–S clusters can serve as excellent donors and acceptors of electrons in diverse biological processes: for instance, mitochondrial respiratory complexes I–III, *S*-adenosyl methionine enzymes, hydrogenases, ferredoxins, biotin synthase, photosystem I, and lipoate synthase. Therefore, the above example demonstrates that Fe–S proteins play an important role in electron transfer in the respiratory complexes of mitochondria and in the photosynthetic apparatus of chloroplasts (Booker et al., 2007). Fe–S clusters also play an essential role in sensing environmental or intracellular conditions to regulate gene expression such as the bacterial transcription factors FNR, IscR, and SoxR, which sense oxygen, Fe–S clusters, and superoxide or NO, respectively (Rouault, 2006; Wallander et al., 2006; Imlay, 2008; Volz, 2008). A well-studied example is cytosolic iron-regulatory protein 1 (IRP1), which regulates gene expression at the post-transcriptional level in mammals. The binding of IRP1 to 5′ end of IREs (iron responsive elements) causes inhibition of the ribosome scanning to the start AUG codon, resulting in a block in translation. However, the binding of IRP1 at 3′ end IREs protects mRNAs from nucleolytic degradation and leads to increased translation (Walden et al., 2006]. In addition, numerous catalytic functions have been known for bacterial and eukaryotic Fe–S enzymes involved in metabolism as well as for those playing a structural role (Meyer, 2008). Hence, Fe–S clusters also serve as the active sites of catalytic enzymes. For instance, the recently discovered Fe–S clusters in adenosine triphosphate (ATP)-dependent DNA helicases are involved in nucleotide excision repair (FANCJ, XPD, Rad3, and RTEL1) and telomere maintenance (Rudolf et al., 2006). Fe–S prosthetic groups are cofactors for sulfite and nitrite reductases, which are involved in sulfur and nitrogen assimilation, respectively, in the chloroplasts.

6.6 Fe–S CLUSTER BIOSYNTHESIS IN PROKARYOTES

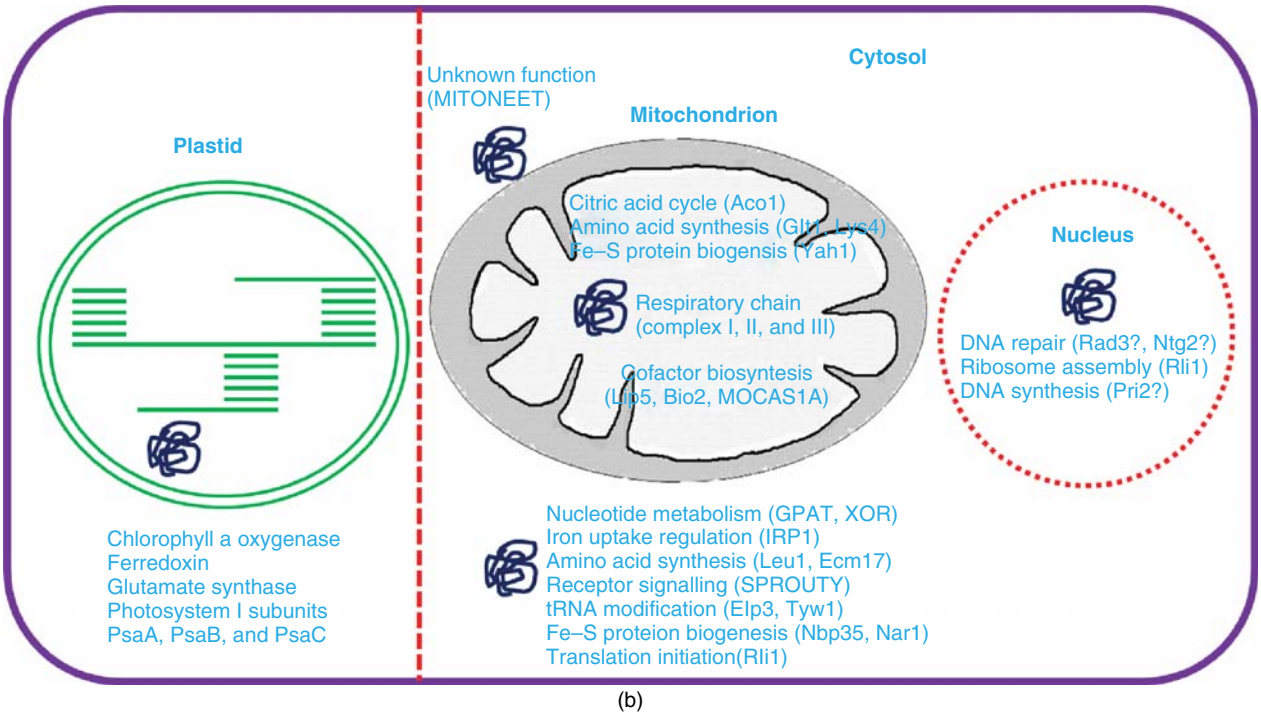
A search for nitrogenase maturation factors in *A. vinelandii* led to the discovery of the *nif* operon, *isc* operon, and subsequently *suf* operon. The biosynthesis of Fe–S clusters has been well documented in *E. coli* and *A. vinelandii*. However, the molecular mechanisms involved differ from organism to organism. Components of all of these systems are usually encoded by operons and exist almost in all microorganisms, supporting the idea that these systems are ubiquitous. Bacterial genome analyses revealed that the number and type of these operons varies from one microorganism to another. For instance, *E. coli* encodes the *isc* and *suf* operons, *A. vinelandii* contains the *nif* and *isc* operons, and *E. chrysanthemi* has the *nif*, *isc*, and *suf* operons. The components encoded for Fe–S cluster biogenesis by these operons also vary among microorganisms. One would expect that the increase in the availability of genome sequence data would provide more information about the Nif, Isc, and Suf systems. Indeed, bacterial genome analyses have identified new Fe–S cluster synthesis components. Interestingly, most of these genes have been implicated in the transfer of Fe–S clusters to the recipient target apoprotein. Here, we describe the general principle of Fe–S protein maturation in ISC and SUF systems. The assembly pathways of nitrogenases used by the NIF system are not addressed here (see Chapter 2).

6.7 ISC ASSEMBLY MACHINERY

In *E. coli*, the *isc* genes form an operon that encodes a regulator (IscR), a cysteine desulfurase (IscS), a scaffold (Iscu), an A-type protein (IscA), a Dnaj-like co-chaperone (HscA, HscB), and a ferredoxin (Fdx). General principles of Fe–S cluster biogenesis require that the Fe–S cluster assembles on a scaffold protein, which receives sulfur from a cysteine desulfurase and iron from an as-yet-unidentified source. Then, the preformed Fe–S cluster is transferred to a carrier protein, which delivers it to the final apotarget. Fe–S protein synthesis can be separated into two main steps. In the first reaction, the Fe–S cluster is initially assembled on the scaffold proteins IscU, which contain three conserved Fe–S cluster-coordinating cysteine residues (Kato et al., 2002). The assembly of the Fe–S cluster on IscU strictly depends on the function of IscS (cysteine desulfurase), which is a sulfur donor (Zheng et al., 1993). To date, the crystal structures of several desulfurases are known and illustrate a dimeric two-domain protein, one domain harboring the pyridoxal-phosphate-binding site and another a small domain containing the active-site cysteine that transiently carries the sulfur released from free cysteine as a persulphide. After the binding of iron to IscU, the Fe–S cluster forms but the molecular mechanism underlying this formation still remains to be clarified. The iron-binding protein frataxin (CyaY) is believed to function as a potential an iron donor by undergoing an iron-stimulated interaction with IsuU–IscS; however, its role is still uncertain and under debate (Gerber et al., 2003; Bencze et al., 2006; Layer et al., 2006; Wang and Craig, 2008). Fe–S cluster assembly on IsuU further depends on electron transfer from the [2Fe–2S] ferredoxin (Fdx), which receives its electrons from the mitochondrial ferredoxin reductase Arh1 and NADH. It is likely that the electron flow is needed for the reduction of the sulphan sulfur present in cysteine to the sulphide present in Fe–S clusters, but this remains to be established experimentally. An additional electron requirement was suggested for the fusion of



(a)



(b)

Figure 6.2 Functions and localization of Fe–S proteins in prokaryote (a) and eukaryotes (b). In eukaryotes, Fe–S proteins are located in mitochondria, cytosol, nucleus and plastids. They are involved in the basic cellular processes including gene regulation, DNA repair, Fe–S protein biogenesis, electron transfer, biosynthetic pathways and Fe, S and N metabolism. The functions of three Fe–S proteins located at the nucleus are not known (?). The names usually represent the abbreviations from the yeast *S. cerevisiae* and *E. coli.*

two [2Fe–2S] clusters to a [4Fe–4S] cluster by reductive coupling (Chandramouli et al., 2007; Unciuleac et al., 2007).

The second main step of biogenesis formally comprises the release of the Fe–S cluster from IscU, cluster transfer to recipient apoproteins, and its assembly into the apoprotein. However, these three partial reactions have not been separated experimentally so far. The overall process is specifically assisted by a dedicated chaperone HscA and HscB in an ATP-dependent manner. HscA recognizes and binds to a specific conserved motif of IscU (Leu-Pro-Pro-Val-Lys) and its interaction with the scaffold protein is regulated by the co-chaperone HscB. This complex formation and the involvement of HscB are thought to induce a structural change in IscU, thereby labilizing Fe–S cluster binding. Hence, it assists the cluster in dislocating and transferring to apoproteins (Cupp-Vickery et al., 2004; Dutkiewicz et al., 2004; Andrew et al., 2006; Chandramouli and Johnson, 2006; Bonomi, et al., 2008). As all available evidence suggests, assembly and release steps depend on the diverse conformational states of the scaffold, chaperone, and target apoproteins. Many of the Fe–S carrier proteins act as a step between cluster assembly on the scaffold and transfer to the target, but these carrier proteins remain to be defined. Fe–S cluster transfer from Isu1 to apoproteins is performed by the mitochondrial monothiol glutaredoxin Grx5; yet, its precise function remains to be elucidated. Fe–S cluster transfer to target recipient apoproteins varies, depending on the receiver apoprotein and the diverse environmental conditions that regulate the process by cellular demand. The above-mentioned ISC proteins are required for generation of all mitochondrial Fe–S proteins, but some biogenesis components play a more specific role. The interacting mitochondrial proteins Isa1, Isa2, and Iba57 (Table 6.1) are specifically involved in the maturation of a subset of Fe–S proteins that are members of the aconitase superfamily (Gelling et al., 2008; Muhlenhoff et al., 2011).

6.8 THE SUF MACHINERY IN BACTERIA AND PLASTIDS

It has been recently shown that *suf* systems are also involved in Fe–S cluster biosynthesis in bacteria, photosynthetic eukaryotes, and in the plastid of plants. Components of the SUF machinery are found in a variety of bacteria, including Archaea and photosynthetic bacteria. The *suf* genes are organized in an operon and consist of *sufA*, *sufB*, *sufC*, *sufD*, *sufS*, and *sufE* genes and particularly operate under specific conditions such as iron limitation and oxidative stress (Patzer and Hantke, 1999; Takahashi and Tokumoto, 2002; Ayala-Castro et al., 2008). SufA plays the role of a scaffold protein in the SUF system, which provides a platform to bring elemental sulfur and iron together into transient assembled clusters. SufB contains several conserved cysteine residues that can assemble an Fe–S cluster. Genetic, biochemical, and molecular biology studies in *E. coli* and *E. chrysanthemi* demonstrated that *sufC* plays an essential role in the formation of Fe–S clusters. Inactivation of SufC in *E. coli* and *E. chrysanthemi* results in a wide range of phenotypic changes that are related to iron homeostasis and oxidative stress. SufC is an ATPase located in the cytosol that is stimulated 100-fold by complex formation with SufB–SufD. Hence, SufC may assist the Fe–S cluster in detaching from SufB and subsequently transferring to apoproteins. In the SUF system, the cysteine desulfurase activity is served by the SufS/SufE complex, in which SufS acts similarly to bacterial IscS or NifS and mitochondrial Nfs1–Isd11. SufE stimulates SufS activity more than tenfold and allows the cysteine-bound persulphide intermediate on SufS to be transferred to a conserved cysteine residue on SufE from where it is passed on to scaffold proteins (Liu et al., 2005; Fontecave and Ollagnier-de-Choudens, 2008; Riboldi et al., 2009). The complex displays a drastically enhanced cysteine desulfurase activity as compared with SufS alone. Some of the *suf* genes also have been identified in archaebacterial genomes but, so far, nothing is known about Fe–S protein biosynthesis in Archaea.

6.9 Fe–S PROTEIN ASSEMBLY IN EUKARYOTES

In this section, we briefly summarize our current knowledge of the components of the various assembly systems and describe their respective mechanistic functions and functional interaction. Maturation of the nitrogenase complex in *A. vinelandii* led to the discovery of the *nif* operon. This discovery attracts the attention of several research groups working with Fe–S proteins and also influenced the first attempts to identify Fe–S cluster maturation in eukaryotes. The yeast *S. cerevisiae* has served as an excellent model organism with which to establish the preliminary details of the complex Fe–S biosynthesis machinery in eukaryotes. Genome analysis revealed that mitochondria contain a machinery that shares similarity with the bacterial ISC system. The striking similarities between the bacterial and mitochondrial ISC components and assembly mechanisms justify the conclusion that mitochondria inherited them from the bacterial endosymbiont that gave rise to modern mitochondria (Johnson et al., 2005; van der Giezen and Tovar, 2005). Over the last dozen years, several researchers have shown that not only the ISC assembly components but also the basic mechanisms of Fe–S cluster synthesis and transfer to target apoproteins are highly conserved from prokaryotes to eukaryotes.

6.10 MITOCHONDRIAL ISC ASSEMBLY MACHINERY

In eukaryotes, Fe–S proteins exist in mitochondria, the cytosol, plastids, and the nucleus. Mitochondria play a crucial role in the maturation of Fe–S clusters not only inside but also outside the organelle (Kispal et al., 1999; Lange et al., 2000). The mitochondrial ISC assembly machinery is required for the generation of all cellular Fe–S proteins. The biosynthesis of mitochondrial Fe–S proteins is accomplished by the ISC assembly machinery in three major steps. To date, more than 15 yeast proteins are known to assist this complex biosynthetic process. In the first step, the Fe–S cluster is initially synthesized de novo on a scaffold protein termed Isu1 and Isu2, which contains three cysteine residues that are crucial for de novo Fe–S cluster assembly. Isu1 is one of the best evolutionary conserved proteins and exists in almost all bacteria and virtually all eukaryotes (Yuvaniyama et al., 2000; Muhlenhoff et al., 2003; Raulfs et al., 2008). The first step critically depends on the function of the cysteine desulfurase complex Nfs1–Isd11 as a sulfur donor releasing sulfur from cysteine via persulfide intermediates (−SSH). The persulfide group is subsequently transferred from Nfs1 to Isu1, which is highly dependent on Isd11. The amino acid sequence of Isd11 is only moderately conserved but the protein is found basically in all organisms. Even though organisms lack the classical mitochondria (mitosomes and hydrosomes) they contain a homolog of Isd11, suggesting the fundamental role of Isd11 in Fe–S protein biogenesis (Adam et al., 2006; Wiedemann et al., 2006). The iron-binding protein frataxin (Yfh1) is believed to function as an iron donor by undergoing an iron-dependent interaction with Isu1 and may serve as a potential iron donor or an allosteric regulator of this step. Although the source of sulfur for Fe–S cluster formation has already been discovered, the source of iron is still under debate. However, mutations in the acidic ridge of Yfh1 impair both iron binding and the interaction with Isu1, indicating the functional significance of this region (Wang and Craig, 2008). Iron can be imported into the mitochondrial matrix only in its reduced form (Fe2+). This step uses the proton motive force as a driving source for membrane transport, which is assisted by the integral inner membrane proteins Mrs3 and Mrs4 (Zhang et al., 2005).

The second main step of biogenesis formally comprises the release of the Fe–S cluster from Isu1 and its transfer to recipient apoproteins by coordination with specific amino acid residues. The overall process is specifically assisted by a dedicated chaperone system comprising the Hsp70 ATPase Ssq1, the DnaJ-like co-chaperone Jac1, and the nucleotide exchange factor Mge1. Ssq1 binds to a small highly conserved motif (LPPVK) of Isu1. This complex formation stimulates the ATP-dependent hydrolysis of Ssq1 and dislocates the Fe–S cluster from Isu1. Jac1 is a co-chaperone and stimulates the ATPase function of Ssq1, thus assisting its transfer to apoproteins (Hoff et al., 2002; Dutkiewicz et al., 2004). The nucleotide exchange factor Mge1 serves to exchange the binding ADP for ATP to start a new cycle. The Fe–S cluster is released from Isu1 by the binding of an ATP-dependent Hsp70 chaperone Ssq1, its co-chaperone Jac1, and the nucleotide exchange factor Mge1 (Schilke et al., 2006). The Fe–S cluster may transiently be taken over by a monothiol glutaredoxin Grx5 toward apoproteins with the help of transient binding of the Fe–S cluster in a glutathione-containing complex (GSH) and finally its assembly into apoproteins by coordination with specific amino acid ligands. The above-mentioned proteins are required for the generation of all mitochondrial Fe–S proteins, for cytosolic and nuclear Fe–S protein biogenesis, and for transcriptional iron regulation. Thus, these proteins are called the "core ISC" assembly proteins. However, some proteins play a more essential and specific role. In the last step, some specialized proteins such as Isa1, Isa2, and Iba57 are specifically required for the maturation of the aconitase family members, for instance, aconitase-type (Aco1, Lys4) and SAM-dependent (Bio2, Lip5) Fe–S enzymes (Gelling et al., 2008; Muhlenhoff et al., 2011). The first two steps are required for maturation of all mitochondrial Fe–S proteins. Depletion of "core ISC" assembly proteins, for instance, Nfs1–Isd11, ferredoxin, or the chaperones leads to a severe impairment of Fe–S cluster insertion into cytosolic and nuclear target apoproteins such as Rli1, Leu1, Ntg2, or Rad3 (Kispal et al., 1999; Lange et al., 2001; Rudolf et al., 2006; Netz et al., 2012).

6.11 MITOCHONDRIAL ISC EXPORT SYSTEM

The mitochondria localized ISC assembly machinery is suggested to produce a still unknown component that is exported from the mitochondrial matrix to the cytosol, where it is required for efficient maturation of extramitochondrial Fe–S proteins. This suggests that the mitochondrial export system supports the synthesis of the Fe–S cluster in the cytosol and nucleus. The unknown component is predicted to be a sulfur-containing preassembled Fe–S cluster. The export reaction is accomplished by the ABC transporter Atm1 of the mitochondrial inner membrane. Another component required for the export reaction is the sulfhydryl oxidase Erv1, located in the intermembrane space. This enzyme has also been shown to catalyze the formation of disulphide bridges in the intermembrane space during Mia40-dependent protein import into the intermembrane space. The enzyme may deliver the electrons derived from the sulfhydryl oxidation process to either molecular oxygen or cytochrome *c*. Thus, Erv1 seems to perform multiple functions. A third component of the ISC export machinery is the tripeptide

glutathione. Apparently, depletion of GSH in yeast results in the downregulation of Atm1 or Erv1-led defective CIA Fe–S cluster synthesis, resulting in increased iron uptake in the cell and mitochondria. However, the maturation of mitochondrial Fe–S proteins is normal. Therefore, it seems that Atm1 plays a critical role in CIA Fe–S protein maturation and also in cellular iron regulation. Atm1, Erv1, and GSH have been described as the ISC export machinery (Kispal et al., 1999; Lange et al., 2001; Sipos et al., 2002).

6.12 CIA ASSEMBLY APPARATUS

The CIA machinery consists of seven known components. The CIA components do not share any sequence similarity with the ISC components, and their defect does not show any noticeable effects on the biosynthesis of mitochondrial Fe–S proteins. However, the basic mechanisms of Fe–S protein maturation and transfer to recipient apoproteins in model organisms have demonstrated that the entire process follows similar biosynthetic rules and is highly conserved in almost all eukaryotes. The first-known example of an essential CIA Fe–S protein is the ABC protein Rli1, which is involved in ribosome assembly and export from the nucleus (Kispal et al., 2005). Experimentally, CIA assembly can be split into two major steps. In the first step, the Fe–S cluster is assembled on the hetero-tetramer P-loop NTPases Cfd1 and Nbp35 serving as a scaffold. These two proteins are present in almost all eukaryotes and they contain three conserved cysteine residues. Two of these residues were shown to be essential for the function of Cfd1. Nbp35 possesses an additional Fe–S cluster at its N terminus with four essential cysteine residues that bind an ISC (Hausmann et al., 2005). This segment is essential for its function, yet its precise role remains elusive. An electron transfer chain consisting of NADPH, the diflavin reductase Tah18, and the Fe–S protein Dre2 is required for stable insertion of the Fe–S proteins into Nbp35 (Netz et al., 2010). However, the mechanism and precise molecular function of the electron transfer chain remain to be elucidated. The core mitochondrial ISC and export ISC machinery components are required for this step but the molecular details of this dependence still remain to be dissected in more detail. In a second step, the Fe–S cluster is transferred from the Cfd1–Nbp35 scaffold to target apoproteins, a reaction requiring the CIA proteins Nar1, Cia1, and possibly Cia2. Holo-Nar1 and the WD40 repeat protein Cia1 facilitate the dissociation of newly assembled Fe–S clusters from Cfd1-Nbp35 and their incorporation into cytosolic and nuclear apoproteins (Roy et al. 2003). Assembly of Fe–S proteins in the eukaryotic cytosol and nuclei requires the assistance of both the mitochondrial ISC assembly and a mitochondrial ISC export machinery. The molecular mechanisms of CIA protein functions are still poorly understood but are conserved in all eukaryotes. Recently, two other essential (nuclear) Fe–S proteins were identified, one (Rad3) with a function in nucleotide excision repair and the other (Pri2) with a function in RNA primer synthesis for DNA replication (Rudolf et al., 2006; Klinge et al., 2007). It seems that maturation of mitochondrial Fe–S proteins have been maintained during the evolution with an essential function in gene expression. This intimate connection between the endosymbiontic host and the bacterial ancestor of mitochondria may have been decisive in the maintenance of these organelles in eukaryotes. The crucial role of mitochondria in Fe–S protein synthesis has raised several questions about those organisms that lack classical mitochondria such as how and where these proteins are assembled in such organisms. These include diplomonads (*G. intestinalis*), microsporidia (*E. cuniculi*), Trichomonads (*Trichomonas vaginalis*), Apicomplexa (*C. parvum*), and *Entamoeba* (van der Giezen and Tovar, 2005; Embley and Martin, 2006). Cell-biological studies over the past years have identified small organelles in these amitochondriate species that are derived from the ancestral mitochondrion. It is now accepted that mitosomes descended from classical mitochondria by reductive evolution. Therefore, it is tempting to speculate that these organelles might accommodate ISC-like proteins. Genome analysis of amitochondriate species revealed the presence of homologs of the ISC, ISC export assembly, and CIA machineries. In support of these findings, the *G. intestinalis* proteins Nfs1 and Isu1 are located in mitosomes, which suggests that the other ISC proteins might be co-localized. Recently, hydrogenosomes of *T. vaginalis* have been shown to contain the ISC proteins Nfs1 and Isu1 (Tovar et al., 2003; Goldberg et al., 2008). These proteins are capable of assembling an Fe–S protein in vitro. These initial data suggest that both mitosomes and hydrosomes might be the place of Fe–S protein biogenesis.

6.13 CONCLUSION

Tremendous progress has been made in our understanding of the Fe–S protein cluster synthesis over the past years. The abundance of ISC, ISC export, SUF, and CIA assembly components has been identified and characterized in prokaryotes and eukaryotes. However, we still lack fundamental understanding of the function of many associated components at the biochemical and molecular levels. It would be intriguing to elucidate the mechanisms of Fe–S cluster transfer from the scaffold proteins to recipient apoproteins. The dissection must be into the partial steps and describe the precise function of the assisting component during each step. Solving of the three-dimensional structures of the distinct Fe–S cluster assembly components, specifically the holo forms of Fe–S scaffolds, will support the unraveling of the molecular mechanisms of *de novo* Fe–S cluster biogenesis.

In addition, the specificity and diverse needs of the various scaffold proteins by ISC and CIA biosynthetic machineries must be decoded to understand their precise individual roles. This will require combined studies and *in vitro* and *in vivo* investigations of the participating functional components, and therefore, will lead to a better understanding of the physiological significance of the suggested molecular mechanisms defined with purified components. Furthermore, it is important to reveal the conversion of [2Fe–2S] clusters to [4Fe–4S] clusters and illustrate the function of participating components. Another exciting area of future research will be the identification and biochemical and molecular characterization of the unknown component exported by Atm1 from mitochondria to cytosol. Moreover, the source of iron and sulfur in Fe–S protein assembly in the CIA and SUF system remains to be addressed. Additionally, we need to understand the link between Fe–S cluster maturation and iron homeostasis inside the cell. Finally, the fundamental process of life associated with Fe–S cluster synthesis would allow us to understand the physiological consequences of Fe–S protein defects and will lead to the development of therapeutic strategies in the treatment of Fe–S diseases. Recently, the global proteomics and genetic approaches in *E. coli* have identified the new candidate genes involved in Fe–S cluster metabolism, for example FdhD, which interacts with IscS and is involved in the maturation of Fe–S clusters containing formate dehydrogenase complex. In addition, the *ygfZ* and *folB* encoded for folate and mutation in *ygfZ* and *folB* have similar phenotypes of *isc* mutations. Detailed studies might lead to the finding of an unexpected link between folate and Fe–S cluster biosynthesis. Therefore, it is tempting to speculate on the greater diversity of the Fe–S biogenesis than expected, and new components of this complex machinery remain to be identified.

ACKNOWLEDGMENTS

We thank Marina May Carstens for her constructive comments, editing and helpful suggestions throughout the manuscript.

I deeply thank to my parents, Bajrang Singh Kesawat and Uchhab Kanwar Kesawat and my wife Namrata Singh for their love support, and help in formatting this book chapter.

7.1 INTRODUCTION: DINITROGENASE AND APO-DINITROGENASE

Two major strategies for metal cofactor biosynthesis can be found in nature. In some cases the cofactor is assembled while directly attached to its target. The [4Fe–4S] cluster of the scaffold protein SufU and the nitrogenase [8Fe–7S] P-cluster are examples of *in situ* cofactor assembly (Malkin and Rabinowitz, 1966; Johnson et al., 2005; Rubio and Ludden, 2005; Fontecave and Ollagnier-de-Choudens, 2008; Albrecht et al., 2010; see Chapter 6). In the case of more complex metal cofactors, the *ex situ* approach is normally used. The iron–molybdenum cofactor (FeMo-co) of nitrogenase, the molybdenum cofactor (Mo-co) of nitrate reductase, and the H-cluster of [FeFe]-hydrogenase are examples of cofactors where *ex situ* assembly occurs (Rubio and Ludden, 2008; Shepard et al., 2011; Mendel, 2013; see Chapter 2). FeMo-co synthesis is completed outside the target enzyme in a biosynthetic pathway completely independent of the production of the structural polypeptides. Thus, FeMo-co needs to be inserted into the apo-enzyme in order to render the mature, active nitrogenase enzyme.

NifDK (also referred to as dinitrogenase or MoFe protein or nitrogenase component I) is a 230-kDa $\alpha_2\beta_2$ tetramer of the *nifD* and *nifK* gene products. The α and β subunits arrange as a pair of αβ dimers that are related by a twofold rotation axis. Despite low similarity between primary structures, both α and β subunits display a similar tertiary structure consisting of three domains each. NifDK contains two unique metal clusters per αβ-dimer: the P-cluster and FeMo-co (Chan et al., 1993; see Chapter 2).

The P-cluster is a [8Fe–7S] cluster in which two [4Fe–4S] cubanes share a sulfide atom in between. The P-clusters are located at the interface between the α and β subunits at around 12 Å below the protein surface (see Chapter 2). In the dithionite-reduced state, amino acid residues α-Cys^{88} and β-Cys^{95} provide the thiol groups bridging the two cubanes, whereas residues α-Cys^{62}, α-Cys^{154}, β-Cys^{70}, and β-Cys^{153} coordinate the remaining Fe sites in the P-cluster (unless otherwise noted, amino acid residue numbering corresponds to the *Azotobacter vinelandii* NifDK sequence). NifU and NifS are needed for the initial formation of two pairs of [4Fe–4S] clusters that serve as precursors to the P-clusters. In addition, the concerted action of both NifZ and NifH is required for the biosynthesis of the complete set of P-clusters. A NifDK protein with

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

only one P-cluster, or with two [4Fe–4S] clusters (but no P-cluster), is obtained from deletion mutants lacking NifZ or NifH, respectively (Hu and Ribbe, 2011).

FeMo-co is a [Mo–7Fe–9S] cluster with a single carbide atom residing in the cavity formed by the six central Fe atoms (Schmid et al., 2002; Spatzal et al., 2011). One Fe and one Mo atoms cap both ends of the cofactor. The Mo atom is coordinated by the C-2 carbonyl and hydroxyl groups of the organic acid *R*-homocitrate (Fig. 7.1; see Chapter 2).

FeMo-co is buried within the α-subunit of each NifDK pair, 10 Å below the protein surface and 14 Å away from the P-cluster. Hydrophilic residues form the majority of the protein environment around FeMo-co, although a number of hydrophobic residues are required as well for cofactor positioning. Unlike the P-cluster, FeMo-co is ligated by only two NifD amino acid residues: α-His^{442} (which binds to the Mo atom) and α-Cys^{275} (which binds to the Fe atom located at the opposite end of the cluster) (Chan et al., 1993). Several other residues surrounding the cofactor binding site are selected to create a protein environment tailored for FeMo-co binding, such as α-Gly^{356} and α-Gly^{357} (which are needed to prevent steric hindrance with the metal cluster), α-Arg^{96} and α-Arg^{359} (which hydrogen bond to and stabilize the cofactor), or α-Gln^{191}, α-Glu^{440}, and α-Glu^{427} (which interact directly or through water molecules with the homocitrate moiety). As expected, residues α-His^{442}, α-Cys^{275}, and some other residues in the vicinity of FeMo-co are highly conserved across species.

Apo-NifDK (also denominated apo-dinitrogenase or apo-MoFe protein) refers to a cofactorless NifDK protein. Several forms of apo-NifDK have been reported to accumulate in the cell depending on the genetic background (Rubio and Ludden, 2005). For example, a Δ*nifH* mutation renders apo-NifDK lacking both the P-clusters and FeMo-co whereas a Δ*nifB* mutation renders apo-NifDK, which contains P-clusters but lacks FeMo-co. For the purpose of this chapter, we will use the term apo-NifDK when referring to the FeMo-co-less form found in Δ*nifB* strains (Schmid et al., 2002). This form of apo-NifDK can be readily activated by the simple addition of FeMo-co. In fact, apo-NifDK activation was used as an assay to isolate FeMo-co from pure NifDK protein (Pienkos et al., 1977).

Purified FeMo-co was found to be extremely sensitive to oxygen and unstable in protic solvents. Thus, FeMo-co extraction must be carried out in anaerobic N-methyl formamide (NMF) after denaturing and precipitating pure NifDK in a series of low and neutral pH solutions. FeMo-co isolated in this manner is stable indefinitely when stored as an anaerobic NMF solution under liquid nitrogen conditions. The isolation of FeMo-co is one of the seminal contributions to the field of nitrogenase biochemistry and to our understanding of complex metalloproteins assembly in general (see Chapter 2). FeMo-co isolation sets the basis for the *in vitro* FeMo-co insertion and the FeMo-co synthesis and insertion assays developed by Vinod Shah and now widely used in the field (Shah and Brill, 1977).

This chapter summarizes current knowledge on FeMo-co biosynthesis. As noted above, FeMo-co assembly occurs outside of NifDK in a complex biosynthetic pathway involving a series of biochemical activities that appear to

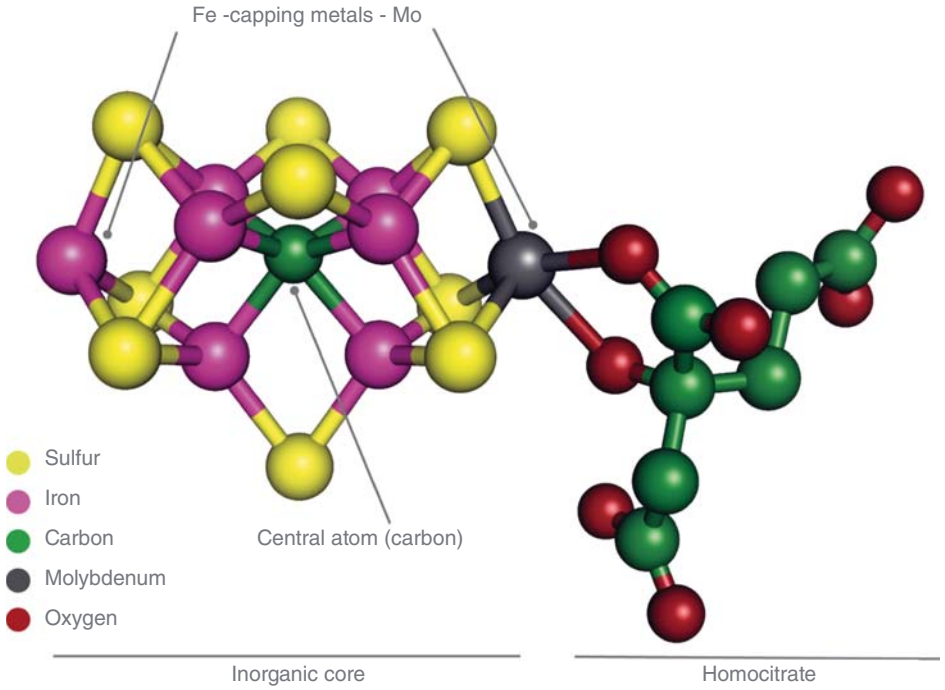

Figure 7.1 Structure of iron-molybdenum cofactor (FeMo-co) of nitrogenase.

be a common theme in complex metallocluster assembly in nature. FeMo-co biosynthesis requires enzymes, which provide substrates in the appropriate chemical forms and catalyze certain critical reactions such as carbide insertion, molecular scaffolds to aid in the step-wise assembly of FeMo-co, and metallocluster carrier proteins that escort FeMo-co biosynthetic intermediates in their transit between scaffolds (Table 7.1) (Rubio and Ludden, 2008; see Chapter 2).

Once fully assembled, FeMo-co is transferred from the FeMo-co "biosynthetic factory" into apo-NifDK, either via a hypothetical protein–protein interaction between NifEN and apo-NifDK (Hu and Ribbe, 2011) or mediated by FeMo-cofactor-binding proteins (Rubio and Ludden, 2008). The insertion of FeMo-co into apo-NifDK generates mature, functional holo-NifDK. Minor differences are observed in the βI, βII, βIII, αI, and αII domains of apo-NifDK upon FeMo-co insertion. However, the αIII domain undergoes major structural rearrangements. A comparison between the apo- and holo-NifDK structures revealed a widely conserved His triad (α-His^{274}, α-His^{442} and α-His^{451}) possibly involved in the formation of an insertion funnel in the structure of Δ*nifB* NifDK. The rearrangement of the αIII domain is hypothesized to generate an opening for FeMo-co insertion and to provide a positively charged path to drive FeMo-co entrance down to the cofactor binding site (Schmid et al., 2002). Site-directed mutagenesis studies on NifDK are consistent with the important role of the histidine residues along the insertion funnel to facilitate FeMo-co insertion (Hu and Ribbe, 2011).

7.2 NifU AND NifS

Many of the proteins involved in nitrogen fixation, including nitrogenase itself, are iron–sulfur (Fe–S) proteins. Given the large amount of Nif proteins expressed in nitrogen-fixing conditions, a specific [Fe–S] cluster biosynthetic system is found in model diazotrophic microorganisms in addition to the general [Fe–S] cluster biosynthetic machinery. This redundancy presents at least two major advantages: (i) it satisfies the high demand of [Fe–S] clusters needed for nitrogen fixation and (ii) it ensures that a deleterious mutation disturbing this specialized system only affects cell survival under diazotrophic growth conditions (Johnson et al., 2005)

NifU and NifS are required for the maturation of both NifH and NifDK. The critical observation to identify a role for these proteins was that whereas many mutations in *nif* genes affected either NifH or NifDK, mutations in either *nifU* or *nifS* resulted in a large decrease of activity in both nitrogenase components (Jacobson et al., 1989a). Since the presence of [Fe–S] clusters is common to both components it was proposed that NifU and NifS proteins had a role in the assembly of nitrogenase-specific [Fe–S] clusters. An additional key observation was the fact that although nitrogenase activity was severely affected in *nifU* and *nifS* mutants, it was not completely lost. This led to the identification of additional housekeeping NifU and NifS homologs, referred to as IscU and IscS, which were involved in supplying [Fe–S] clusters for general cellular functions (Zheng et al., 1998; see Chapter 6).

Table 7.1 Role of *nif* gene products in Mo-nitrogenase

Gene	Role of Gene Product
nifA	*nif*gene transcriptional activator
nifL	Anti-activator of *nif* gene transcription
nifY	In *K. pneumoniae* carries out same functions as *nafY*. Unknown function in *A. vinelandii*
nifU	Scaffold for [Fe–S] cluster biosynthesis. Forms complex with NifS
nifS	Cysteine desulfurase, serves as S donor for [Fe–S] cluster biosynthesis. Forms complex with NifU
nifX	Double role carrying NifB-co and serving as storage for VK-cluster (and probably other FeMo-co precursors)
fdxN	Donates electrons for FeMo-co biosynthesis
nifB	SAM-radical protein. Generates the complex FeS core of FeMo-co (including the central C atom)
nifV	Homocitrate synthase
nifQ	Donates molybdenum to the NifEN/NifH complex for FeMo-co biosynthesis
nifE	In combination with NifN, forms a scaffold protein involved in later steps of FeMo-co assembly
nifN	In combination with NifE, forms a scaffold protein involved in later steps of FeMo-co assembly
nafY	Double role stabilizing apo-NifDK and in FeMo-co insertion
nifZ	Involved in P-cluster formation
nifD	Dinitrogenase (MoFe protein) α-subunit. FeMo-co is buried within this subunit
nifK	Dinitrogenase (MoFe protein) β-subunit of. P-cluster is located at the interface of and subunits
nifM	Required for maturation of NifH (Fe protein). Similar to prolyl isomerases
nifH	Dinitrogenase reductase (Fe protein). Obligate electron donor to NifDK. Also required for P-cluster and FeMo-co syntheses

Genes from the nitrogen-fixing bacterium *A. vinelandii* are listed. The code is as follows: in bold are genes required for *in vivo* Mo-, V- and Fe-only nitrogenases; underlined are genes required for *in vitro* Mo-nitrogenase. Note: genes denoted in red together with those denoted in green are essential for full *in vivo* Mo-nitrogenase activity.

NifS is an 87-kDa pyridoxal phosphate (PLP)-containing homodimer (Zheng et al., 1993). Spectroscopic analyses showed that addition of L-cysteine altered the UV-visible properties of NifS, whereas none of the other biological amino acids was able to produce similar effects. Subsequent experiments demonstrated that NifS was a cysteine desulfurase that catalyzed a desulfurization reaction of L-cysteine, rendering L-alanine and sulfane as products. A highly conserved Cys^{325} residue located in the active site of the enzyme was found critical for NifS activity (Zheng et al., 1994). Based on sequence conservation, cysteine desulfurases are classified into two major groups. NifS falls within group I, with a SSGSAC(T/S)S conserved consensus sequence (Fontecave and Ollagnier-de-Choudens, 2008). Interestingly, a *cysE* homolog, encoding an *O*-acetyl serine synthase, the rate-limiting step for cysteine biosynthesis, is co-transcribed together with *nifS* (Evans et al., 1991).

NifU is a 66-kDa homodimer containing a stable [2Fe–2S] cluster per subunit (Fu et al., 1994). Primary sequence conservation analysis, site-directed mutagenesis experiments, and activity assays with separated purified domains confirmed the presence of three conserved domains in NifU (Agar et al., 2000). The central domain contains the permanent, redox-active, [2Fe–2S] cluster coordinated by four conserved cysteine residues, whereas the *N*-terminal and *C*-terminal domains present three and two conserved cysteine residues, respectively, for the assembly of transient [Fe–S] clusters (Smith et al., 2005). Spectroscopic and genetic analyses provided further evidence of formation of labile [2Fe–2S] clusters within both terminal domains of NifU, in reactions containing L-cysteine, Fe^{2+}, and NifS (Yuvaniyama et al., 2000).

A series of elegant experiments using apo-NifH as [Fe–S] cluster acceptor provided further details on the mechanism of NifU (Zheng et al., 1994; Dos Santos et al., 2004). NifS activity directs the assembly of transient [4Fe–4S] clusters on NifU, which are subsequently transferred to apo-NifH endowing protein activity. A NifUS complex formed during cluster assembly has been reported (Yuvaniyama et al., 2000), but NifS was not required for cluster transfer from the [Fe–S] donor NifU to the target apo-protein. Although *in vitro* loading of apo-NifH was possible simply by incubating with Fe^{2+} and S^{2-}, the reaction was significantly faster (at physiologically significant rates), specific, and more efficient (requiring only equimolar amounts of NifU) when using NifS, Fe^{2+}, and L-cysteine. All together, these results confirmed the role of NifS as donor of S^{2-} in order to sequentially load the scaffold NifU for the synthesis of simple [2Fe–2S] and [4Fe–4S] clusters required for maturation of both components of nitrogenase.

NifU and NifS are also involved in FeMo-co synthesis. Participation of these proteins as providers of [Fe–S] cluster substrates for FeMo-co biosynthesis was difficult to demonstrate because many FeMo-co biosynthetic proteins are Fe–S proteins themselves and mutations in *nifU* or *nifS* would have pleiotropic effects on the pathway. This puzzle was solved by investigating the capability of *nifUS* mutants to synthesize NifB-co, an early precursor to FeMo-co (see below). NifB-co biosynthesis was practically abolished in *nifUS* mutants (Zhao et al., 2007). Because NifU and NifS were shown not to be essential to render active NifB, the lack of NifB-co was attributed to a lack of [Fe–S] cluster precursors to assemble NifB-co (and hence FeMo-co).

NifB-co is a biosynthetic intermediate not only of FeMo-co but also of the FeV-co and FeFe-co of alternative nitrogenases. Consistently, *nifU* and *nifS* mutants were shown to be defective in Mo-nitrogenase, V-nitrogenase, and Fe-only nitrogenase activities (Kennedy and Dean, 1992).

7.3 NifB: FROM SIMPLE [Fe–S] CLUSTERS TO THE CORE OF FeMo-co

The *nifB* gene encodes a protein that includes an S-adenosyl methionine (SAM) radical motif CX_3CX_2C at the *N*-terminal region (Sofia et al., 2001). The *C*-terminal end of the protein comprises a NifX-like domain that is conserved in proteins with ability to bind FeMo-co and its biosynthetic precursors (Moreno-Vivian et al., 1989; Rubio et al., 2002). As mentioned above, NifB participates in an early biosynthetic step that is common to FeMo-co, FeV-co, and FeFe-co biosyntheses. Therefore, *A. vinelandii* mutants lacking *nifB* were incapable of diazotrophic growth under all conditions tested (Joerger and Bishop, 1988; Rodriguez-Quinones et al., 1993). Consistently, regulation of *nifB* expression by transcriptional activators of all three nitrogenases, NifA, VnfA, and AnfA, has been reported (Drummond et al., 1996).

NifB catalyzes the conversion of simple [2Fe–2S] or [4Fe–4S] clusters, donated by NifU, into a complex [Fe–S] cluster in a reaction that involves radical chemistry (Curatti et al., 2006). Interestingly, the metabolic product of NifB, termed NifB-co, was purified and studied before purification of active NifB was accomplished (Shah et al., 1994). NifB-co comprises the central [6Fe–9S–C] core of FeMo-co but does not contain a heterometal (e.g., Mo) or homocitrate (Shah et al., 1994; George et al., 2008). Early experiments showed that NifB-co served as precursor to FeMo-co in the *in vitro* FeMo-co synthesis assay (Shah et al., 1994) and that it was the source of most (if not all) Fe and S present in FeMo-co (Allen et al., 1995).

The NifB protein was first purified from *A. vinelandii* cells (Curatti et al., 2006). Isolated NifB was a 110-kDa homodimer containing ca. 12 Fe atoms and exhibiting a

UV–visible spectrum that is typical of [Fe–S] proteins. Changes in the NifB redox state and incubation with SAM altered the properties of its UV–visible spectrum, as expected for a redox-responsive SAM radical protein. Isolated NifB did not carry NifB-co nor was it readily active in supporting *in vitro* FeMo-co synthesis. However, after incubation with Fe^{2+} and S^{2-}, the Fe content increased to ca. 18 atoms and NifB became active (Curatti et al., 2006), providing the first demonstration of complete *in vitro* FeMo-co synthesis from its atomic components. The work of Curatti also laid the ground work for further mechanistic experiments by showing that radical chemistry was absolutely required for NifB activity. Later on, it was shown that the carbide atom at the center of FeMo-co had its origin in the methyl group of SAM (Wiig et al., 2012).

An interesting observation is that NifB-co could be inserted in the place of FeMo-co into nitrogenase *in vitro*. This artificial NifDK/NifB-co complex was capable of proton and acetylene reduction but not nitrogen fixation (Soboh et al., 2010). This observation emphasizes the importance of carrier proteins in redirecting metal precursors to the appropriate target proteins *in vivo* (see below).

7.4 NifQ: DIRECTING Mo TO FeMo-co SYNTHESIS

NifDK represents up to 5% of the total cellular protein content accumulated under diazotrophic growth. Thus, nitrogen-fixing *A. vinelandii* cells must cope with a large demand for Mo, a low abundance transition metal (1–2 ppm in soils). *A. vinelandii* produces siderophores, low molecular weight molecules with high affinity for metals, to aid in Mo (and Fe) acquisition (Kraepiel et al., 2009). Unfortunately, siderophores can bind to other metals, such as W, which can eventually be incorporated into FeMo-co rendering inactive nitrogenase (Siemann et al., 2003). To discriminate against tungstate, *A. vinelandii* carries ABC transport systems that are highly specific for molybdate (Mouncey et al., 1995). Three copies of the *modABC* operon are found in the *A. vinelandii* genome (Setubal et al., 2009), as opposed to a single copy in the closely related bacterium *Pseudomonas stutzeri*.

A. vinelandii has a unique Mo-accumulation system based on a Mo storage (MoSto) protein. MoSto is a $\alpha_3\beta_3$ heterohexamer of the *mosA* and *mosB* gene products with capacity to store up to 100 Mo atoms (Fenske et al., 2005) in the form of complexes of polynuclear oxoanions (Schemberg et al., 2007). In addition, cellular systems are in place to keep Mo homeostasis and to direct it to the corresponding Mo-dependent enzymes (Fig. 7.2). The molbindin ModG appears to be responsible for directing Mo to nitrogen assimilation pathways, such as nitrate reductase or nitrogenase (Mouncey et al., 1995). NifO has been related to Mo balance between nitrate reductase and nitrogenase. It was suggested that NifO would direct Mo toward FeMo-co synthesis, thus impairing development of nitrate reductase activity (Gutierrez et al., 1997).

The *nifQ* gene was identified by screening Nif mutants, the phenotype of which could be reverted by a large excess of molybdate or cysteine in the medium (Imperial et al., 1985). Although *nifQ* mutants did not accumulate molybdate they were not impaired in molybdate transport or in the activity of alternative nitrogenases (Joerger and Bishop, 1988; Rodriguez-Quinones et al., 1993) or Mo-co-containing enzymes, such as nitrate reductase (Pienkos et al., 1977).

NifQ proteins are found in all diazotrophic species of the Proteobacteria phylum, with the exception of some Rhizobia. NifQ proteins do not contain molbindin domains or show sequence similarity to MosA or MosB. They do contain a highly conserved *C*-terminal putative metal-binding motif $CX_4CX_2CX_5C$.

As isolated from *A. vinelandii,* NifQ was a monomeric 20-kDa, oxygen-sensitive protein, containing ca. 3 Fe atoms and 0.30 Mo atoms per monomer. NifQ displayed a UV–visible spectrum typical of (Fe–S) proteins. Electronic paramagnetic resonance (EPR) and electron spin echo (ESE)-EPR analyses revealed that NifQ carried a novel redox-responsive [Mo-3Fe–4S] cluster (Hernandez et al., 2008). *In vitro* FeMo-co synthesis assays with purified components demonstrated that NifQ served as a unique Mo source for FeMo-co synthesis. Comparison of Mo-content in Nif proteins before and after the FeMo-co synthesis reaction revealed that, only in the presence of NifH, Mo was effectively mobilized from NifQ to NifEN, demonstrating that all three proteins were required for Mo transfer (Hernandez et al., 2008).

The exact reaction(s) carried out by NifQ are not known. The complete processing of Mo from molybdate (Mo^{VI}) to the state found in FeMo-co (Mo^{IV}) requires at least three chemical transformations: (i) replacement of O ligands by S ligands, (ii) reduction of Mo from Mo^{VI} to Mo^{IV}, and (iii) insertion into an [Fe–S] environment. It has been suggested that the role of NifQ could be related to some (or all) of these changes (Hernandez et al., 2009).

7.5 NifV AND THE INCORPORATION OF HOMOCITRATE INTO FeMo-co

The *nifV* gene product is a homocitrate synthase that catalyzes the condensation of acetyl coenzyme A and α-ketoglutarate to render *R*-homocitrate (Zheng et al., 1997). The *nifV* mutants exhibited slow diazotrophic growth rates (McLean et al., 1983), a phenotype that could be reverted *in vivo* by supplementing the growth medium with homocitrate (Hoover et al., 1988). V- and

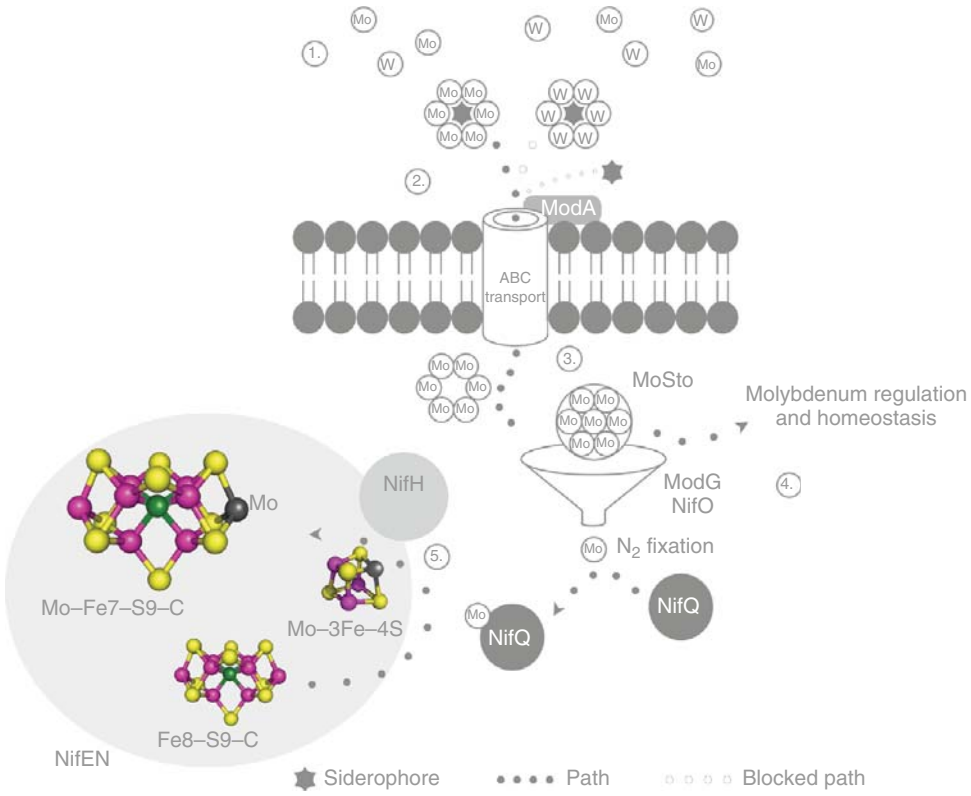

Figure 7.2 Molybdenum trafficking to FeMo-co can be divided into in five processes: (1) molybdate harvesting, (2) molybdate transport and discrimination against tungstate, (3) molybdenum accumulation and homeostasis, (4) molybdenum sorting to the appropriate pathway, and (5) molybdenum insertion into the cofactor.

Fe-nitrogenase-dependent growth was also impaired in these mutants (Kennedy and Dean, 1992), indicating that homocitrate was part of the FeV-co and FeFe-co cofactors as well.

Klebsiella pneumoniae nifV mutants have been shown to incorporate citrate into a non-functional form of FeMo-co *in vivo* (Liang et al., 1990). The situation was more complex in *A. vinelandii* where a mixture of organic acids replacing homocitrate in the cofactor was found (Ludden et al., 2004). *In vitro* FeMo-co synthesis assays carried out with analogous organic acids in the place of homocitrate resulted in the synthesis of cofactors with altered catalytic properties (Hoover et al., 1989). It is not clear how the nitrogen-fixing cell manages to discriminate between homocitrate and other analogous organic acids during FeMo-co synthesis. Homocitrate incorporation occurs within NifEN, presumably after Mo incorporation has taken place (Rangaraj and Ludden, 2002). It is possible that discrimination occurs within the NifEN/NifH complex. It is also possible that homocitrate concentration in the cell was so high that it would preclude incorporation of other organic acids.

7.6 NifEN: A NODE IN THE FeMo-co BIOSYNTHETIC PATHWAY

NifEN is a 200-kDa $\alpha_2\beta_2$ heterotetramer of the *nifE* and *nifN* gene products that carries two identical [4Fe–4S] clusters at the interface of both subunits (Goodwin et al., 1998). If isolated from the appropriate genetic backgrounds, NifEN preparations exhibit trapped FeMo-co biosynthetic intermediates (see below) (Hu et al., 2005; Soboh et al., 2006). NifEN is absolutely required for FeMo-co synthesis *in vivo* (Jacobson et al., 1989b) and *in vitro* (Curatti et al., 2007).

NifEN displays high similarity with NifDK at several levels, including amino acid sequence similarity (Brigle et al., 1987), position of their metal clusters within the protein (Kaiser et al., 2011), and the ability to catalyze acetylene and azide reduction albeit at very low rates (Hu et al., 2009). It was the amino acid sequence similarity of NifEN to NifDK that led to the proposal of NifEN acting as molecular scaffold for FeMo-co biosynthesis (Brigle et al., 1987).

NifEN acts as central node of the FeMo-co biosynthetic pathway, where additional Fe, Mo, and homocitrate are incorporated into NifB-co (Fig. 7.3) (Rubio and Ludden,

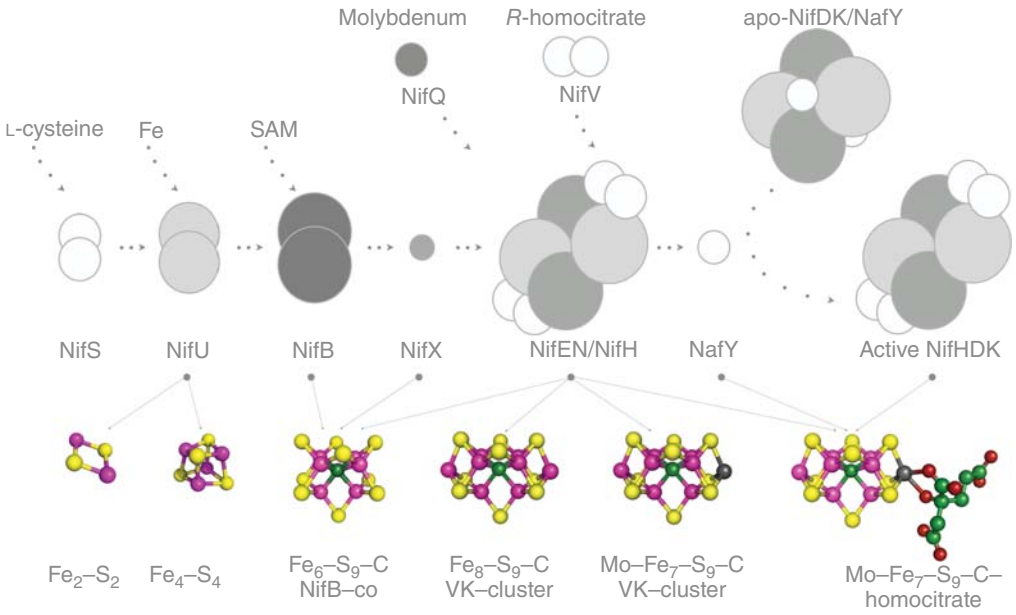

Figure 7.3 FeMo-co biosynthesis. This schematic model illustrates the enzymatic machinery (above) involved in different steps of FeMo-co assembly (below). Early steps involve NifS, NifU, and NifB for the assembly of NifB-co, the central Fe–S core of FeMo-co, and its transfer to the NifEN scaffold via NifX. Maturation to FeMo-co occurs within a putative NifEN/NifH complex by sequential addition of Fe, Mo, and homocitrate.

2008). Briefly, NifB-co is transferred from NifX to NifEN, where it is converted into the VK-cluster (named after Dr. Vinod K. Shah) (Hernandez et al., 2007). Although both NifB-co and the VK-cluster lack Mo and homocitrate and serve as precursors to FeMo-co, there are some differential properties that indicate they are not the same precursor. First, while NifB-co is EPR silent, the VK-cluster shows EPR signals both in reduced and oxidized states (Hernandez et al., 2007). Second, EXAFS analysis suggests that NifB-co is no larger than the central [6Fe–9S–C] core of FeMo-co (George et al., 2008), whereas the VK-cluster was proposed to be a larger [8Fe–9S] cluster (Hu et al., 2006). The recently solved NifEN crystal structure confirmed the assignment of 8 Fe atoms for the VK-cluster. Third, NifEN-mediated Fe incorporation into NifB-co at capping positions external to the [6Fe–9S–C] core was achieved *in vitro* (Rubio et al., unpublished results).

In addition to the VK-cluster, NifEN purified from a Δ*nifH* background has been shown to contain Mo in a separate [Mo–3Fe–4S] cluster environment (George et al., 2007). Occupancy levels for this cluster were low and dependent on the purification method used, probably due to cluster instability (Soboh et al., 2006). Nevertheless, it was shown to serve as Mo source during FeMo-co synthesis *in vitro*. The composition of this cluster resembles the one found in NifQ preparations and, since NifQ has been shown to be able to transfer Mo to NifEN *in vitro* (Hernandez et al., 2008), a logical proposal is that the [Mo–3Fe–4S] cluster within NifEN derives from the NifQ cluster. Another possibility is that this cluster represents a NifQ-independent Mo insertion pathway that would operate with lower efficiency. This pathway would be responsible for the reversion of the *nifQ* mutant phenotype by the presence of 1000-fold molybdate into the growth medium (Imperial et al., 1984; 1985).

Interestingly, NifEN is able to substitute for the homologous VnfEN protein of the V-nitrogenase (Wolfinger and Bishop, 1991). This finding raises questions regarding the specificity of NifEN in Mo insertion into FeMo-co and opens the possibility of other elements providing this specificity (Hernandez et al., 2009).

Finally, NifEN appears to be the site where homocitrate is incorporated into the cofactor in a reaction that requires NifH.

7.7 NifH: NITROGENASE MOONLIGHTING PROTEIN

NifH (also referred to as dinitrogenase reductase, Fe protein or nitrogenase component II) is the obligate electron donor to NifDK. NifH is a 60-kDa homodimer of the *nifH* gene product. The NifH structure revealed a twofold symmetric enzyme with $Mg^{2+} \cdot ATP$ binding sites located at the dimer interface within each monomer. Two cysteine residues from each NifH subunit coordinate a single [4Fe–4S] cluster at the subunit interface (Georgiadis et al., 1992). NifH undergoes conformational changes during $Mg^{2+} \cdot ATP$ binding and hydrolysis in a process coupled to electron transfer from the [4Fe–4S] cluster of NifH to the P-cluster of the NifDK component (Lanzilotta et al., 1998).

Three accessory proteins are necessary to synthesize active NifH, namely, NifU, NifS, and NifM (Jacobson et al., 1989a). NifM is similar to prolyl isomerases and has been proposed to induce a conformational change on NifH that precedes incorporation of its [4Fe–4S] cluster (Gavini et al., 2006). NifU and NifS are involved in the assembly and delivery of the NifH [4Fe–4S] cluster (Dos Santos et al., 2004).

NifH is a moonlighting protein with at least three essential roles in the nitrogenase system: (i) it is required for electron transfer to the NifDK component during catalysis, (ii) it is required to assemble P-clusters from pairs of [4Fe–4S] cluster precursors, and (iii) it is essential to FeMo-co synthesis, in which process it probably plays multiple roles.

Not all of NifH capabilities are required for the performance of all its functions. Many lines of evidence show that $Mg^{2+} \cdot ATP$ hydrolysis and electron transfer are required for catalysis but not for P-cluster or FeMo-co biosynthesis. First, *nifM* mutants were shown unable to fix nitrogen but able to support FeMo-co biosynthesis (Roberts et al., 1978). Second, [4Fe–4S] cluster-deficient apo-NifH (generated by chemical treatment of NifH to remove the metal clusters) was able to participate both in P-cluster synthesis and in FeMo-co synthesis (Rangaraj et al., 1997). Third, NifH variants with altered properties of $Mg^{2+} \cdot ATP$ binding and/or hydrolysis could carry out FeMo-co synthesis (Gavini and Burgess, 1992; Rangaraj et al., 1999). On the other hand, more recent experiments indicate that NifH must be able to hydrolyze $Mg^{2+} \cdot ATP$ and to transfer electrons in order to be active in FeMo-co biosynthesis (Hu et al., 2006).

NifH is absolutely required for FeMo-co biosynthesis. Neither Mo nor homocitrate is incorporated into the cofactor in the absence of NifH. However, the exact mechanism by which NifH exerts its role remains unclear. NifEN and NifH are able to interact transiently with each other (Rangaraj et al., 1999) and, in fact, Mo transfer from NifQ to NifEN occurs only in the presence of NifH (Hernandez et al., 2008). It has been proposed that NifH would play its role of facilitating Mo insertion into the VK-cluster simply by docking with NifEN and exerting some sort of conformational change on it (Rubio and Ludden, 2008).

The proposal of NifH being the element that selectively incorporates Mo into FeMo-co discriminating against other heterometals has long been discussed. Several observations do not support a role for NifH and other dinitrogenase reductases in specifying the heterometal to be inserted into the cofactor and point to other proteins (e.g., NifQ) being potentially responsible for heterometal discrimination. VnfH, the equivalent protein in V-nitrogenase, could replace NifH in FeMo-co biosynthesis (Chatterjee et al., 1997). Similarly, AnfH of the Fe-only nitrogenase supported FeMo-co synthesis *in vivo* (Gollan et al., 1993). Bishop and collaborators proved that NifH was able to support V-dependent diazotrophic growth in the absence of VnfH (Joerger et al., 1990).

Finally, it is well known that NifH must be present to render homocitrate-containing FeMo-co (Rangaraj and Ludden, 2002; Hu et al., 2006). However, incorporation of homocitrate into an isolated Mo-containing FeMo-co precursor has not yet been reported. Thus, a direct role for NifH in homocitrate incorporation into FeMo-co precursor remains hypothetical.

7.8 METALLOCLUSTER CARRIER (ESCORT) PROTEINS

Once a cofactor has been synthesized on a scaffold, it needs to be transferred to its target protein. When prosthetic groups are very labile and oxygen sensitive, direct diffusion is unlikely and the metal clusters are expected to be always protein-bound within the cell (Rubio et al., 2002). Additionally, there is a rapid demand for nitrogenase synthesis during diazotrophic growth, which, taken together, might explain the existence of proteins involved in metallocluster delivery.

The *nifX* gene is clustered into a single operon together with *nifEN*. The *nifENX* gene cluster is in fact widespread among bacteria, suggesting that three gene products have a related role. NifX is a ca 17-kDa single-domain protein. Although unable to bind ^{55}Fe or ^{99}Mo (Rangaraj et al., 2001; Rangaraj and Ludden, 2002) or assemble an [Fe–S] cluster, the product of the *nifX* gene has been shown to be able to ligate FeMo-co and FeMo-co precursors (Hernandez et al., 2007). Early studies speculated on a role of NifX in the incorporation of homocitrate into a FeMo-co precursor (Rangaraj and Ludden, 2002), or as a negative regulator of *nif*-gene expression in response to $[NH_4^+]$ and O_2 (Gosink et al., 1990). However, recent *in vitro* experiments have demonstrated different roles for NifX (Hernandez et al., 2007). First, it would work as donor of at least two FeMo-co precursors (NifB-co and VK-cluster) to NifEN. NifX and NifEN do not form a stable protein complex, but a transient interaction occurs for the metal cluster exchange to happen. Second, NifX would function as storage of FeMo-co precursors, redirecting labile metal clusters to NifEN. This might be especially relevant to buffer the flux of FeMo-co precursors under stress conditions, thus minimizing metal cluster losses.

NifX-like domains are present in a group of nitrogenase-related proteins, and thus serve to define a family of nitrogenase cofactor binding proteins, including VnfX and the *C*-terminal domains of NifB, NifY, NafY, and VnfY. NafY is probably the best characterized among them (Homer et al., 1995; Rubio et al., 2002; Rubio et al., 2004).

NafY is a ca. 26-kDa two-domain protein with a double role in apo-NifDK stabilization and in FeMo-co

insertion into apo-NifDK. Two functional domains can be defined in NafY, with each role mostly assigned to each domain. First, the 12-kDa *N*-terminal domain is sufficient to bind apo-NifDK in the absence of the rest of the protein. NMR solution structure of the *N*-terminal domain of NafY revealed that it contained a sterile alpha motif domain, a structure frequently involved in protein–protein interactions (Hernandez et al., 2011). This domain represented the first apo-NifDK binding structure known, other than NifH, and exhibited a novel fold for apo-NifDK binding, different from what is observed in the NifH structure (Georgiadis et al., 1992). Interestingly, excess of *N*-terminal NafY domain or full-length NafY had a negative effect on apo-NifDK reconstitution *in vitro*. Second, the 14-kDa *C*-terminal domain was shown to bind FeMo-co autonomously. The crystal structure of the core domain of NafY (defined as the *C*-terminal domain missing the last 13 amino acid residues) represents the only known FeMo-co binding fold different from that of NifDK (Dyer et al., 2003). Mutational analyses indicated direct implication of the His^{121} residue in FeMo-co binding (Rubio et al., 2004). These results suggest a model with a series of histidine residues involved in FeMo-co insertion into apo-NifDK. FeMo-co-bound to NafY via His^{121} would be donated to α-His^{362} (at the entrance of the insertion funnel in apo-NifDK), followed by entry into the positively charged environment created by the His triad (α-His^{274}, α-His^{442} and α-His^{451}) and finally donation to α-His^{442}, as one of the ligating residues of FeMo-co in NifDK (Schmid et al., 2002).

Given the low affinity of NafY for NifB-co and the ability of apo-NifDK to bind NifB-co (Soboh et al., 2010), this might be a physiological mechanism to couple FeMo-co synthesis to apo-NifDK activation, while preventing insertion of biosynthetic intermediates into the nitrogenase active site.

NifX and NafY are not strictly essential for *in vitro* FeMo-co synthesis or *in vivo* diazotrophic growth under standard laboratory conditions (Rubio et al., 2002; Curatti et al., 2007). However, several caveats need to be considered in order to appreciate their relevance. First, functional overlap among members of this family complicates the finding of a phenotype in deletion mutants. A BLAST search for NifX-like sequences reveals two additional homologs in the genome of *A. vinelandii* (Setubal et al., 2009), in addition to the above-mentioned members of this family. Thus, functional redundancy might obscure the observation of a phenotype in single mutant strains. Second, diazotrophic growth experiments of deletion mutant strains are typically carried out under optimal laboratory conditions. This might preclude the observation of a phenotype present under nutrient-limited environmental growth conditions. For instance, the double Δ*nifX* Δ*nafY* mutant or the triple Δ*nafY* Δ*nifY nifX::kan* mutant were impaired in diazotrophic growth under Mo starvation conditions (Rubio et al., 2002). Similar observations indicating the requirement of NifX under Fe-depleted conditions were reported in *Herbaspirillum seropedicae* (Klassen et al., 2003). Third, *in vitro* experiments proved the additive stimulatory effect of NifX and NafY on FeMo-co biosynthesis when present in the reaction mixture (Curatti et al., 2007). NifX and NafY were not required for NifB-co synthesis, but were able to independently increase apo-NifDK activation. Fourth, proteins involved in metal cluster storage and delivery have been described in other cofactor biosynthetic pathways, including the Mo-co carrier protein in *Chlamydomonas reinhardtii* (Fischer et al., 2006), the IscA and ErpA carriers in *E. coli* (Pinske and Sawers, 2012), and the mammalian MMS19 protein for [Fe–S] cluster assembly (Gari et al., 2012), to name a few. Similarly, enzyme-specific chaperones relevant to metal cofactor insertion into multisubunit metalloenzymes have been reported in other systems, such as the NarJ chaperone from *E. coli* (Vergnes et al., 2006) and the copper superoxide dismutase from *Saccharomyces cerevisiae* (Culotta et al., 1997). Hence, it is not surprising to find proteins with similar roles in the FeMo-co biosynthetic pathway.

7.9 CONCLUSION

The Mo-nitrogenase carries at its active site an FeMo-cofactor that is essential for nitrogen fixation activity. FeMo-co biosynthesis is a complex process involving a number of *nif* gene products that function as molecular scaffolds, metallocluster carriers, or substrate providers. Findings from biochemical and genetic studies using model organisms should be taken into account when designing a strategy to transfer *nif* genes into crop plants (e.g. cereals; see Chapter 108). The products of at least six genes: NifB, NifE, NifN, NifH, NifD and NifK have been shown to be absolutely required for FeMo-co biosynthesis and nitrogenase activity both *in vivo* and *in vitro*. On the other hand, it is likely that the products of some genes that are required for FeMo-co biosynthesis *in vivo* in model organisms could be replaced by the activities of plant counterparts. This group would include NifU, NifS, FdxN, NifQ and NifV, which provide simple [Fe–S] clusters, electrons for FeMo-co synthesis, molybdenum in the appropriate redox state, and homocitrate, respectively. Finally, the metallocluster carrier proteins NifX, NifY, and NafY aid in FeMo-co synthesis and insertion, but are certainly not essential and could be removed from the equation in initial approaches to engineer novel nitrogen-fixing organisms.

8.1 INTRODUCTION

Biological nitrogen fixation (BNF) is the purview of a single family of enzymes, nitrogenases, with three closely related subclasses of proteins. To date, all nitrogen fixation, as defined by dinitrogen gas (N_2) reduction to ammonia, is limited to this family of nitrogenases found in the diverse Archaea and bacteria. The three variants of nitrogenase are expressed from three gene clusters and are distinguished by characteristic amino acid sequence differences and metal composition (see Chapter 2). This chapter explores the distribution and ecological niches of the organisms equipped with two or all three of these enzymes.

Dinitrogen reduction by all three types of nitrogenase is performed by a two-protein component system requiring a metabolic source of electrons, for example, reduced ferredoxin or flavodoxin, and ATP. The reaction can be summarized by the general equation (Rees and Howard, 2000):

$$N_2 + (6+2n)H^+ + (6+2n)e^- + p(6+2n)ATP \rightarrow 2NH_3 + nH_2 + p(6+2n)ADP + p(6+2n)Pi$$

It is not our intention here to evaluate the mechanistic nuances of the reaction but to emphasize the generality of the overall reaction stoichiometry as discussed in sections below. The present understanding of the enzyme mechanism is that at least one equivalent of H_2 is produced for each mole of N_2 reduced; however, depending on other conditions of the reaction, such as enzyme component ratio and concentration, the ratio of H_2/ammonia can be significantly higher. Likewise, the ratio of ATP to electrons in products can vary from 1 to 50 in uncoupled reactions depending on a number of parameters (Rees and Howard, 2000).

The general structure and organization of the nitrogenases from all three classes are the same. Nitrogenase is composed of Component 1 and Component 2, which are generic terms encompassing all three classes. Component 1 has two different, but similar subunits, designated α and β, which are expressed from the genes *D* and *K* respectively. Two copies of these two subunits are paired to give a tetramer $(\alpha\text{–}\beta)_2$. Shared between the subunits in each α–β pair is the 8Fe:7S P-cluster, while the substrate reduction site in the α subunit is the 7Fe:M:9S:C:homocitrate cofactor shown in Figure 8.1 (see also Chapter 2).

The metal M can be Mo, V, or another Fe atom. It is this difference in metal composition, M (Mo, V, or Fe) at a single site in the cofactor that distinguishes the three cofactors.

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

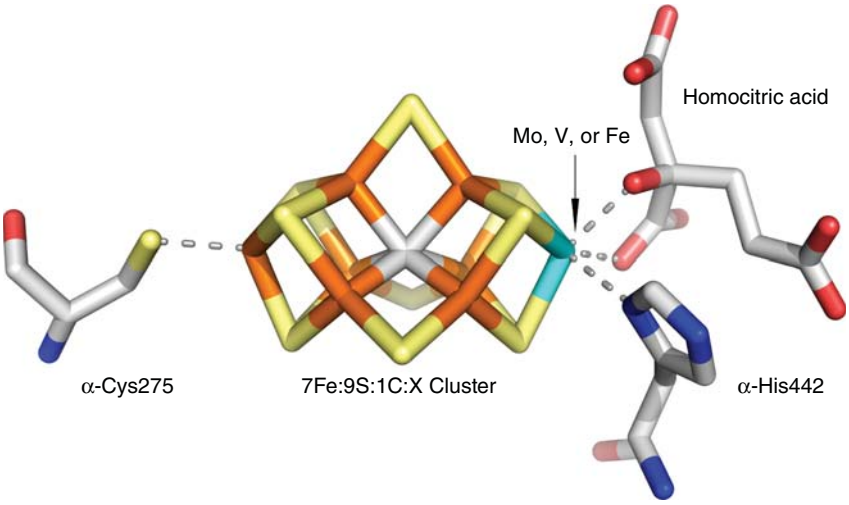

Figure 8.1 Stick figure for the nitrogenase cofactor with protein ligands, α-Cys275 and α-His442. The cofactor includes the organic acid, homocitric acid, and the metallic cluster where X (shown in cyan) = Mo, V, or Fe, depending on the nitrogenase type. The cluster contains the interstitial carbon atom (shown as the gray central atom), hexa-coordinated to six iron atoms (orange). Sulfur atoms are shown in yellow, oxygen atoms in red, and nitrogen atoms in blue. Figure 8.1 uses 1.0 Å coordinates (Protein Data Bank pdb3u7q) (Spatzel et al., 2011; Howard and Rees, 2006; Einsle et al., 2002).

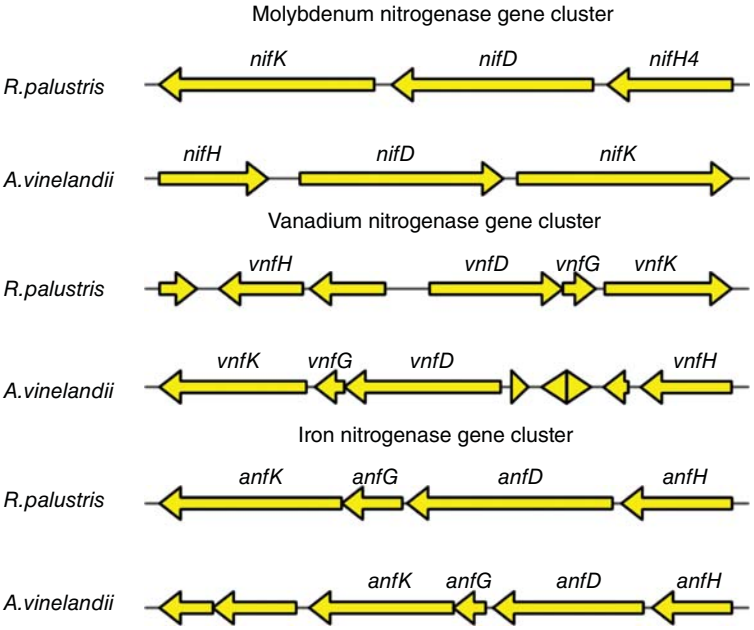

Figure 8.2 Diagrammatic representation of the arrangement of the genes encoding the subunits of Components 1 and 2 of the MoFe-, VFe-, and FeFe-nitrogenases on the chromosomes of *Rhodopseudomonas palustris* (Oda et al., 2005) and *Azotobacter vinelandii* (Setubal et al., 2009).

Associated with each cofactor type is a specific Component 1 with homologous α and β subunits, expressed from the appropriate genes *D* (α-subunit) and *K* (β-subunit) for each of the three classes. The genes are designated *nifD* and *K* for the Mo-containing cofactor, *vnfD* and *K* for the V-containing cofactor, and *anfD* and *K* for the all Fe-containing cofactor. These Component 1 proteins with their unique cofactor and subunits are identified as MoFe-protein, VFe-protein, or FeFe-protein. The Anf and Vnf classes also have a small subunit, designated δ (encoded by *anfG* or *vnfG*), whose function appears to be to stabilize the tetramer, a condition apparently not needed for the Nif class. The number of δ in the tetramer has been uncertain until recently where four were found for the VFe-protein (Lee et al., 2009).

The second component, the generic Component 2, is the Fe-protein having two identical subunits bridged by a single 4Fe:4S cluster (Hausinger and Howard, 1983; see also Chapter 2). The Fe-protein binds two ATPs (one in each subunit) and is the sole functional electron donor to the Component 1 in nitrogenase turnover. Each class of nitrogenase based on the cofactor has its own highly homologous Fe-protein expressed from the gene *H*, or *nifH*, *vnfH*, and *anfH* (Fig. 8.2). For electron transfer, the Fe-protein with two ATPs binds to each α–β pair in Component 1, to form a transient complex where ATP is hydrolyzed. Based upon the accounting for an active site with one Fe-protein bound to one α–β pair, there are at least 19 Fe required, or, for the full tetramer, 38 Fe.

A fundamental question arises from the observation that there are three highly similar classes of nitrogenase, differing primarily in the identity of the single metal at the active site cofactor – what is the survival advantage to having more than one type of nitrogenase? We explore here the variation of the distribution of the classes among diazotrophic species and their ecological niches.

8.2 ALTERNATE NITROGENASES AND THE METAL CONTENT OF THE COFACTOR

The connection between the metal content of the cofactor and the gene of origin, as indicated above, is based upon a limited number of isolated and characterized nitrogenases. The exploration of the general identity of nitrogenases, and of their phylogenetic relationships, relies entirely on the detection of the *nif*, *vnf*, or *anf* genes. Because all diazotrophic species whose genes have been studied contain *nif*, and many fewer contain *anf* or *vnf*, the latter two have been designated as "alternate" nitrogenases (see Chapter 2).

A widely accepted and reasonable assumption is that the expression of these genes is responsive to the metal availability, and, that in consequence each expressed nitrogenase binds a cofactor with the "matching" metal, that is, Mo, V, or Fe, as appropriate. This assumption has been shown to be valid in several diazotrophs, most prominently for *Azotobacter vinelandii* (Joerger et al. 1989, Jacobitz and Bishop 1992, Eady 1996, Premakumar et al. 1998, Howard and Rees, 2006), which under appropriate conditions expresses the three nitrogenases, each equipped with a cofactor with the expected metal composition. In the absence of analytical data on the cofactor for the great majority of nitrogenases, this expectation is assumed to be valid, and that is the case for the discussion presented in this chapter as well. This is a "working hypothesis," whose generality is untested. There are observations in the literature that raise doubts about its general validity (e.g., Pau et al., 1993; Eady, 1996). Where feasible, the assumption needs to be tested on a case-by-case basis by direct chemical analysis of the isolated proteins (Howard et al., 2013).

8.3 DISTINGUISHING FeFe-NITROGENASE FROM VFe-NITROGENASE

Critical to evaluating potential implications of nitrogenase classes and their distribution across ecological niches is to unambiguously identify these proteins in the various diazotrophs. For the most part, the identification depends on the interpretation of a partial or complete genomic sequence determination. Anf and Vnf are homologous proteins with a high percentage of amino acid residue identity. This raises the possibility of confusion in gene identification.

With the rapidly growing annotated databases of complete genomes of diazotrophs, the BLAST program (http://www.ncbi.nlm.nih.gov/BLAST/blastcgihelp.shtml) provides a rapid way to survey a wide range of organisms for the presence of alternate nitrogenases. For a protein of interest, BLAST uses a representative amino acid sequence to find and identify related sequences, and provides the statistical data for each of the matches. For nitrogenases, the long-studied *A. vinelandii* Nif, Vnf, and Anf proteins can serve as an excellent source of reference sequences. How well does the BLAST analysis perform in distinguishing AnfD from VnfD, or VnfD from NifD?

As described recently in detail (Howard et al., 2013), comparative analyses of nitrogenase sequences show that the sequences of the NifD, AnfD, and VnfD subfamilies, as well as those of the corresponding K subfamilies, can be unambiguously distinguished by their unique strong motif residues. A strong motif residue is defined as an amino acid found at a sequence-specific site in all members of a subfamily, but absent from that position in members of all other subfamilies (Bickel et al., 2002).

In a BLAST search for similarity to the *Enterobacter radicincitans* DSM 16656 α-subunit, AnfD (EJI90485.1), at least six proteins were incorrectly identified as AnfD (Table 8.1b). These sequences were observed to have high bit scores and >57% identity with the query sequence; these indices would seem to qualify them as authentic Anf group proteins. However, when evaluated by multiple sequence alignment and by strong motif residues, these proteins were clearly not Anf, and indeed, were Vnf (Table 8.1a). The subsets of residues from the presently recognized strong motifs for Anf and Vnf (Howard et al., 2013) were chosen to include residues over the full length of the proteins. The subsets included both overlapping residues (residue position that was a constituent of a strong motif in both Anf and Vnf, yet by definition of strong motifs, a different residue) and residue positions that were uniquely a strong motif for one of these two nitrogenase subfamilies. For the six proteins shown in Table 8.1b, none of the ten-member Anf strong motif residues were found, and all seven residues of the Vnf strong motif subset were present. This clearly places these proteins as Vnf. The latter sequences were interspersed in the search with several Vnf and Nif proteins, correctly identified, with equally compelling bit and percentage identity scores. In all, 48 sequences in this BLAST search were designated as AnfD. As discussed above, six of these were actually VnfD – a 12.5% error rate. These errors substantially skew the ratio of Anf/Vnf sequences. The results clearly demonstrate the care required to ensure the appropriate attribution of a protein sequence to a genotype.

Table 8.1 (a) Strong motif residues in AnfD and VnfD subfamilies. (b) Sequences identified in the BLAST analysis as AnfD, but which have none of the strong motif residues characteristic of AnfD sequences, but all the strong motif residues characteristic of VnfD sequences.

(a)

Residue # Anf sequence	35	36	37	57	87	235	257	345	376	409	433
Residue # Av1 sequence	48	49	50	69	99	252	274	364	394	427	451
Anf residue	G	Y	L	H	I		E	A	C	P	K
Vnf residue				L		H	N	T	G	V	M

(b)

8.4 WHY THREE NITROGENASES?

All nitrogen-fixing organisms that have been examined have genes encoding MoFe-nitrogenase. How do the two alternative nitrogenases contribute? In terms of total population size, the number of nitrogen fixers equipped solely with MoFe-nitrogenase outnumbers those that also contain alternate nitrogenases by orders of magnitude. There is no reported instance of a nitrogen fixer that contains solely VFe- or FeFe-nitrogenase, but lacks MoFe-nitrogenase. There are only a few microorganisms that have genes for all three nitrogenases. To date, the latter organisms are *A. vinelandii*, *Azotobacter paspali*, *Methanosarcina acetivorans*, and *Rhodopseudomonas palustris* (Bothe et al., 2010), a very short list. Of these organisms, *R. palustris* and the closely related *Rhodopseudomonas* strains have been the most broadly investigated and provide a useful case study of the lessons to be learned from the characterization of very closely related strains isolated from carefully examined sources, and subsequent attempts to explain or predict their ecological niches.

8.5 RHODOPSEUDOMONAS PALUSTRIS CGA009 AND CLOSELY RELATED STRAINS

A subject of study since the early years of the twentieth century, *R. palustris* CGA009 (van Niel, 1944) is famed for its exceptional metabolic versatility (Wall, 2004; Larimer et al., 2004). Sequencing of the *R. palustris* CGA009 genome revealed a full suite of genes for all three metallonitrogenases. *R. palustris* CGA009 is unique among purple phototrophic bacteria in having a VFe-nitrogenase (Larimer et al., 2004).

Complete genome sequences have been determined for four closely related *Rhodopseudomonas* strains: BisB18, Bis5, BisA53, and HaA2 (Oda et al., 2008). The sequence of strain TIE-1 was also available (Jiao et al., 2005). Table 8.2 describes the sources of these strains.

The 16s rRNA sequence identity between CGA009 and the five strains ranged from 100% for TIE-1 to 97.8 to 97.3% for the other four. Average percent amino acid identities between pairs of orthologs of the *Rhodopseudomonas* genomes for CGA-009, BisB18, BisB5, and BisA53, and HaA2 ranged from 69.6% (CGA009, BisB18) to 87.0% (HaA2, BisB5), with an overall average of ∼73%.

Whole-genome comparisons in the 1970s by DNA–DNA hybridization showed that members of same-named prokaryote species, in contrast to members of different-named species, share greater than 70% of their genome content (Johnson, 1973). Subsequently, the >70% metric was accepted formally by bacterial systematists (Wayne et al., 1987). Now, a difference of ∼1% in 16S rRNA sequence between strains is viewed as sufficient to assign them to different species (Stackebrandt and Ebers, 2006; see Chapter 3). Since the data provided above shows strain TIE-1 as the only strain to pass the 16S rRNA identity test, the other strains have been designated as *Rhodopseudomonas* spp.

A view in high detail of the similarities and differences between the proteomes of these strains provides insights into the relationship between these organisms and their ecological niches and the way to a more nuanced understanding of the distribution and roles of the nitrogenases.

As shown in Table 8.3, the five strains are clearly strongly related. However, in each strain, 10–18% of the genes are strain specific.

Strain CGA009 encodes MoFe-, FeFe-, and VFe-nitrogenases. Strains BisB18 and BisA53 encode

Table 8.2 *Rhodopseudomonas* sp. strains: Sources and Mo-, W-, and FeFe-Nitrogenase gene representation

Strain	Nitrogenase Genes	Source of Strain
CGA009	Mo, V, Fe	CGA009 is a chloramphenicol resistant derivative of CGA 001, from the culture collection of R.K. Clayton at Cornell University.*
TIE-1	Mo, Fe	Isolated from cultures of phototrophic Fe(II)-oxidizing bacteria enriched in a medium supplemented with 10 mM $FeCl_2$ inoculated with samples taken from an iron-rich mat from School Street Marsh in Woods Hole, MA.
HaA2	Mo	HaA2 came from a site roughly ~240 km from the first two locations, from a 1– to 2-mm-thick patch of leaf litter, roots, and sediment present ~2 cm below the surface of a shallow pond that was formed by the accumulation of rainwater in a depression.
BisB18 BisB5 BisA53	Mo, Fe Mo Mo, Fe	These strains were isolated from the top 0.5 cm of claylike sediment present 1–2 cm below the surface of a river along its bank. Strains BisB18 and BisB5 were isolated from the same 0.5 g of sediment sample. BisA53 was from a sample taken about 5 m away.

Table 8.3 Comparative gene inventories of five strains of *Rhodopseudomonas*

Strain	Total Number of Genes	Strain-Specific Genes*	Genes Shared by all Five Genomes*
CGA009	4833	585	2752
HaA2	4683	514	2740
BisB18	4886	859	2751
BisB5	4397	420	2746
BisA53	4884	794	2760

*Including paralogs.

Oda et al., 2008; Jiao et al., 2005.

MoFe- and FeFe-nitrogenase, and HaA2 and BisB5 encode only MoFe-nitrogenase.

The genomes of TIE-1 and CGA009 are 97.9% identical at the nucleotide level over 5.28 Mb of shared DNA. Notably, TIE-1 encodes only the MoFe- and FeFe-nitrogenases. Comparison of these highly homologous genomes shows that the VFe-nitrogenase gene cluster in CGA009 is part of an indel that is not present in the TIE-1 genome sequence, strongly indicating that the V-nitrogenase was acquired by lateral gene transfer, a deduction supported by its absence from the other *Rhodopseudomonas* strains (Oda et al., 2008), and more broadly, from purple phototrophic bacteria.

A comparison of the available data on the attributes of the environment from which each of the *Rhodopseudomonas* sp. strains was isolated (Table 8.2) and of the nitrogenase genes in each of the organisms strongly suggests that the attempt to predict the microenvironment from which one is sure to isolate a particular nitrogenase genotype would be unproductive. Oda et al. (2008) comment that "the *Rhodopseudomonas* isolates are different ecotypes that evolved by radiating into microenvironments with distinctive characteristics of light, oxygen, and nutrient availability while retaining a high degree of metabolic flexibility" and conclude that "Although the microenvironments from which each of these *Rhodopseudomonas* ecotypes derive are on a scale that may be too small to allow accurate measurement of their physical and chemical characteristics, we can perhaps infer these characteristics from the genome sequences."

Significant problems confront the attempt to describe a microenvironment as the environment "preferred" by a *Rhodopseudomonas* ecotype. *Rhodopseudomonas* spp. are motile. The genome of each of the six strains, listed in Table 8.2, encodes flagellin genes. It is likely that these organisms explore multiple microenvironments and, because of the great breadth of their metabolic capabilities, may do equally well under significantly different conditions. Moreover, the substantial number of genes specific to each strain suggests that the microenvironment "ideal" for each strain

may be distinctive, but the inspection of its genome is very unlikely to allow an *a priori* exclusive definition of that microenvironment.

8.6 CONTROL OF EXPRESSION OF NITROGENASE

Two linked questions need to be considered from the perspective of natural selection: what is the survival advantage of carrying multiple forms of nitrogenase, and if there is such an advantage, why is *nif* the sole nitrogenase in the great majority of diazotrophic species? To gain a glimpse of the answers one needs to start by considering when and how the nitrogenases are expressed. Understanding what controls the *in vivo* expression of each of the three nitrogenases is an essential part of understanding the relationship between a particular species and its ecological niche(s). An important caveat needs to be kept in mind while seeking answers: what we know, even when the knowledge is limited, is for a relatively small sample of the nitrogen-fixing species and generally those from less demanding environments. Fortunately, the number of diverse organisms under study and the variety of available experimental approaches are rapidly expanding, and enhance our ability to explore multiple fundamental questions.

Our present understanding of relevant regulatory processes in diazotrophs is that the intracellular metal composition and nitrogen compounds (principally ammonium ion and glutamine) independently regulate the level and class of nitrogenase expressed. The intracellular levels of both of these types of regulatory agents are indirectly dependent upon their transport from the environment. A full discussion of the role of nitrogenous compounds in regulating nitrogenase expression is outside the scope of this chapter and is addressed elsewhere (Dixon and Kahn, 2004). Understanding of the molecular basis of metal control for several species (Hamilton et al., 2011, Heiniger et al., 2012) is improving. Research on diazotrophs in a controlled laboratory environment found uniformly that the metal-dependent classes of nitrogenase were expressed in order of preference for Mo over V, and of Mo or V over Fe. When Mo was available, diazotropic growth and transcription analyses under nitrogen-fixing conditions showed that *nif* genes were expressed while neither *vnf* nor *anf* genes were expressed.

However, this generalization of the metal control of gene hierarchy appears to be much more complex when analyzed in detail in some species. For example, the mutant strain *R. palustris* ΔnifH nifD::Tn5 (strain with *nif* structural genes deleted or disrupted) expressed active FeFe- and VFe-proteins when grown diazotrophically in the presence of 15 nM molybdate salt; even the addition of Mo to concentrations as high as 100 μM did not substantially affect the growth rates, or rates of acetylene reduction when only the FeFe- or only the VFe-nitrogenase were expressed (Oda et al. 2005). In contrast, a *Rhodobacter capsulatus* ΔnifHDK mutant strain, similar to the *R. palustris* mutant strain, was unable to express its *anf* genes or grow diazotrophically at Mo concentrations of >10 nM (Schneider et al., 1991). Certainly there are species differences beyond just the nitrogenase genes at work here. It is well to note that in most, if not all, of these genetically manipulated strains, the actual proteins and their metal content have not been examined. It is evident that when the *nif* genes are deleted, no structural MoFe-protein is expressed. However, the metal content of the cofactor incorporated by the structural proteins expressed from *vnf* or *anf* genes in the presence of Mo has not always been determined (Oda et al., 2005). In at least one case, *A. vinelandii*, if the *nif* genes were deleted but the cells grown with Mo in the medium, the Mo form of the cofactor is inserted into the FeFe-protein and diazotrophic growth is enabled (Pau et al., 1993). In another species, *R. capsulatus*, tungsten will substitute for Mo in the cofactor although the resulting nitrogenase is only able to reduce protons to H_2 but not N_2 to ammonia (Siemann et al., 2003). These examples show that there may be surprises in store regarding which metals are used and which gene of origin, *nif*, *anf*, or *vnf*, is expressed to construct an active nitrogenase.

Biochemical studies on the reactions catalyzed by MoFe-protein, VFe-protein, and FeFe-protein and their associated Fe-proteins, each purified and with the metal defined, suggest differences in the relative ratio of H_2 and ammonia during turnover as well as in ATP used per electron transferred (Eady, 1996, 2003); also see the equation in the Section 8.1.

It is tempting to extrapolate these differences to suggest advantages of one enzyme class over another in terms of preferred ecological niches. For example, it has been suggested that the VFe-protein might be a more useful enzyme for an organism growing at 4°C as it retains a higher dinitrogen reduction fraction of activity than does the MoFe-protein at that temperature (Miller and Eady, 1988). As important as such studies are for understanding the enzymatic mechanism, they fall short of answering questions about the rationale of the ecological distribution of nitrogen fixation. As noted earlier, the alternate proteins are poorly characterized in terms of quaternary structure and the role or the stoichiometry of the δ subunit. Many of the conditions critical for exploring the relative efficiency of the three enzymes have not been reproduced, casting doubts on the reliability of such comparisons.

It is worthwhile enumerating the differences between *in vitro* measurements and nitrogen fixation *in vivo*.

1. The concentration of the proteins is orders of magnitude higher in a cell where ca. 5–10% of the cellular mass is represented by the nitrogenase proteins (Dingler et al., 1988; Jacobs et al., 1995). Because the complex between the Fe-protein and Component 1 is central to the overall

reaction, the effects of concentration are large and, perhaps surprisingly, catalysis is slower on a molar turnover basis at the high protein concentrations found in the cell.

2. The ratio of Fe-protein to Component 1 is near unity in the cell, while in *in vitro* studies the maximum activity is achieved at a higher ratio (Dingler et al., 1988; Jacobs et al., 1995). Again, the *in vivo* activity is lower at such component ratios.
3. *In vivo*, the penultimate electron donor (donor for the Fe-protein) is a flavodoxin or ferredoxin (connected to other cellular metabolism) that can reduce the Fe-protein by two electrons. *In vitro*, dithionite, a poorer reducing agent with many side products, is used and is only capable of reducing the Fe-protein by one electron. Hence, ATP hydrolysis in the *in vitro* assay might be twice the actual biological requirement; see equation Section 8.1.
4. ATP and a regenerating system are used *in vitro* to set the ADP/ATP ratio near zero, while *in vivo*, the cellular "energy charge" is set by the overall metabolism, and where ADP, a known inhibitor of nitrogenase, is present in substantial amounts (Upchurch and Mortenson, 1980). The "energy charge" is certainly a function of metabolic sources and must be a significant variable between niches, for example, phototrophs *versus* chemotrophs.

The intracellular concentrations of nitrogenase represent a marked difference between the conditions under which nitrogen fixation proceeds *in vivo* and those used to study the enzyme mechanism *in vitro*. Indeed, a projected efficiency based on the *in vitro* numbers would suggest that MoFe-nitrogenase was much preferred over the two alternate nitrogenases, yet when strains of *Azotobacter* were analyzed by growth rates in chemostats, the FeFe-protein system was essentially equal to the MoFe-protein (Bishop et al., 1986). More recent studies have shown that in *A. vinelandii*, transcription of the three metal classes of nitrogenase are different, possibly leading to different levels of cellular nitrogenase, and furthermore, the utilization of nitrogenous compounds is affected when cells shift to an alternate nitrogenase (Hamilton et al., 2011). Similar changes are seen in *R. palustris* along with more efficient uptake of extracellular ammonia (Oda et al., 2005).

These results clearly show the need for studies that more closely mimic the various ecological niches, such as the actual metal concentrations and their oxidation states, as well as energy sources, and the pH in the immediate environment. Evaluation of how the varied expression of the three nitrogenases provides "fitness" for an ecological niche and evolutionary survival would be greatly aided by determining growth rates in a chemostat under conditions simulating those of the potential niche.

8.7 GLOBAL DIVERSITY OF NITROGEN-FIXING ORGANISMS

It is plausible to assert that BNF is performed on Earth wherever life is found, as exemplified by the presence of diazotrophs in the Arctic tundra (Davey, 1982), the abyssopelagic zones of the Sargasso Sea (Hewson et al., 2007), and at the extreme temperatures of the sea hydrothermal vent fluids (Mehta and Baross, 2006). A caveat is that frequently little is known about the gene expression patterns of the diazotrophs in the various environments (Riemann et al., 2010), or even about the frequency of representation of Vnf and Anf relative to Nif.

From extensive studies of *nifH* phylotypes, Zehr et al. (2003) concluded that the distribution of nitrogen-fixing organisms, although strongly influenced by fixed nitrogen availability in the environment, is nonrandom and can be predicted on the basis of habitat characteristics. The phylotypes fall into four clusters (Chien and Zinder, 1996; Zehr et al., 2003). Cluster I is composed of bacterial *nifH* and some *vnfH* sequences. Cluster II contains bacterial and methanogenic (Archaeal) *anfH* sequences. Cluster III contains *nifH* sequences from anaerobic members of the Bacteria and Archaea. Cluster IV contains *nifH* paralogues that have no role in nitrogen fixation.

Gaby and Buckley (2011) utilized an aligned database of 16,989 *nifH* sequences, then available in public databases, to assess the diversity of diazotrophs across phylogenetic groups or across environments. Using a DNA barcode approach and clustering these sequences into molecular operational taxonomic units (OTUs; e.g., (Blaxter et al., 2005; Hao et al., 2012)), this study provided a glimpse of the diazotroph diversity in different environments and in different *nifH* lineages. Of the 16,989 sequences, 13% fell into Cluster III.

Soil, marine sources, microbial mats, and termite guts – ranked in order of the number of *nifH* sequences derived from the source environment – accounted for 64% of the sequences, with soil being by far the richest. Sequences from α, β, and γ *Proteobacteria* and from *Cyanobacteria* represented 46% and 30%, respectively, of the sequences from marine environment. Gaby and Buckley (2011) noted that these data are strongly influenced by site selection in the surveys of microbial diversity, and consequently should not be taken as a measure of global abundance. Rather, they noted, "they provide information on nitrogen-fixing organisms most commonly observed in sequence databases." Of the ten most observed taxa, five are from *Cyanobacteria*, and the other five from α, β, and γ *Proteobacteria*. Strikingly, five of the 10 top OTUs did not contain cultivated representatives. However, a detailed discussion of the results of this study provides valuable insights on the correlation between physiological and biochemical properties of diverse diazotrophs and the environments in which they are found

(Gaby and Buckley, 2011). Notably, this analysis did not include much information on Vnf or Anf nitrogenases. Apparently, it is difficult to resolve *nifH and vnfH* in some instances (Zehr et al., 2003).

Fortunately, some information pertaining to the distribution and phylogeny of organisms with genes for VFe- and FeFe-nitrogenases is available from other specific, focused studies, essentially "case histories."

8.8 ISOLATION OF DIAZOTROPHS CONTAINING Mo-INDEPENDENT NITROGENASES

Studies on global diversity of diazotrophs leave the impression that nitrogen fixers with alternate nitrogenases represent a very small fraction of such organisms. However, the results of studies employing standard microbiological methods of enrichment and cultivation in pure culture indicate that organisms with VFe- and/or FeFe-nitrogenases are present in many different aquatic and terrestrial environments.

Bishop and coworkers (Loveless et al., 1999; Betancourt et al., 2008) successfully isolated, by enrichment, pure strains of such organisms from a wide range of natural environments, including creek sediment, mangrove sediment, salt marsh, soil, "paraffin dirt" (Simoneit and Didyk, 1978), wood chip mulch, and so on. The alternate nitrogenases in each of these strains were identified by PCR amplification using either *vnfDGK* or *anfDGK* primers. The 16S rRNA analysis revealed that some three-quarters of these strains belonged within groups of long-studied γ-proteobacterial diazotrophs: *A. vinelandii*, *Azobacter beijerinckii*, and *Azomonas agilis.* In the study by Loveless et al. (1999), seven of the γ-proteobacterial diazotrophs, isolated from a variety of habitats, had the genes for MoFe-nitrogenase and VFe-nitrogenase, and grew well on V_2O_5 under Mo-deficient, nitrogen-fixing conditions, although with generation rates 20–30% slower than those seen in the presence of 1 mM Na_2MoO_4 or 10 mM NH_4^+. Four of these isolates also had the genes encoding FeFe-nitrogenase.

8.9 COINCIDENTALLY DISCOVERED NOVEL GENERA AND SPECIES WITH ALTERNATE NITROGENASES

Pelosinus fermentans (type strain $R7^T$), the first representative of a new genus (Shelobolina et al., 2007; Yutin and Galperin, 2013), was isolated from primary kaolin, a clay from an alluvial deposit in Southern Urals in Russia. Kaolin is a highly prized source of material for porcelain manufacture. Deposits of kaolin have also been found in China, England, and the United States. Kaolin contains (by weight) 0.25–1.5% Fe_2O_3 (Jepson, 1984). Climatic conditions favorable for weathering lead to removal of discoloring impurities, such as iron oxides and sulfides, and organic matter, and result in white kaolin (Elzea Kogel et al., 2002). These observations led to a project to isolate representative Fe(III)-reducing bacteria from kaolin clays that may play a role in the removal of the iron from kaolin. This effort led to the isolation, under strict anaerobic conditions, of an isolate, strain R7, that was capable of reducing Fe(III) only in the presence of a fermentable substrate (Shelobolina et al., 2007). Based on phylogenetic analysis and physiological tests, this strain was proposed to represent a new genus, *P. fermentans* gen. nov., sp. nov., type strain R7. The complete genome of strain R7 is available (Brown et al., 2012.), and it has the genes encoding MoFe- and FeFe-nitrogenases.

There is long-standing interest in bioremediation of uranium-contaminated waters by a wide variety of bacteria capable of reducing U(VI) to U(IV) (Wall and Krumholz, 2006). In oxic waters and soils, uranium is present as soluble uranyl ion (UO_2^{2+}) in the oxidation state U(VI). Reduction of U(VI) to U(IV) produces the insoluble mineral uraninite and thus the sequestration of uranium (Langmuir, 1978). The same opportunity for intervention is presented by Cr(VI), toxic, and mobile in groundwater. When reduced to the Cr(III) state, the metal complexes are much less toxic and form insoluble, stable precipitates under slightly acidic to neutral conditions in aquifers (Palmer and Wittbrodt, 1991; Cook, 2000).

To enrich for bacteria capable of reducing Cr(IV), contaminated groundwater from Hanford, Washington (USA), was amended with 30 mM lactate and 0.05 mM sulfate, in a reactor kept anaerobic with N_2 gas. Under these conditions of electron acceptor limitation, the enrichment led to a predominance of metal-reducing *Pelosinus* spp. (De León et al., 2012; Mosher et al., 2012). Four of the *Pelosinus* spp. strains (A11, A12, B3, and B4) were obtained in pure culture, their genomes were sequenced and found to be very similar, and each was tested for the ability to reduce Fe(III), monochromate, dichromate, and U(VI). *P. fermentans* strain A11 reduced all four, strain R7 (isolated from kaolin) and strain B3 were able to reduce Fe(III), monochromate, dichromate, but not U(VI), strain A12 only Fe(III), strain B3 Fe(III) and monochromate (Table I in Mosher et al., 2012). As far as nitrogenases are concerned, strain R7 has the genes for both MoFe- and FeFe-nitrogenases (genome data from Brown et al., (2012.)), as do all four Hanford strains.

8.10 ESTIMATES OF CURRENT GLOBAL NITROGEN FIXATION

Annual global nitrogen fixation, including an anthopogenic contribution of 210 Tg N/year, is estimated at 413 Tg N/year.

The subtotals (in Tg N/year) that make up these totals have large error bars (Fowler et al., 2013; Vitousek et al., 2013). The estimate for non-agricultural BNF on land is $58 \pm 50\%$ (i.e, between 29 to 87 Tg N/year) to which agricultural BNF adds $60 \pm 30\%$. Fertilizer production contributes $120 \pm 30\%$, combustion $30 \pm 10\%$, and lighting $5 \pm 50\%$. BNF in marine ecosystems contributes $140 \pm 50\%$ (Fowler et al., 2013).

In terrestrial systems, it is difficult to determine with precision the quantitative contribution made by BNF. BNF is broadly divided into symbiotic and free living. This division obscures the diversity of relationships between nitrogen-fixing microorganisms and plants. Reed and Cleveland (2011) provide a more nuanced description, but one that still adheres to this subdivision: "… we define symbiotic N_2 fixation as N_2 fixation that occurs via relationships between plants (e.g., legumes) and the N_2-fixing microbial symbionts occupying plant root nodules (e.g., *Rhizobia* or *Frankia*). In contrast, we classify all other forms of N_2 fixation (including N_2 fixation by epiphytes on plant leaf surfaces and the symbiotic N_2 fixation that occurs in lichens) as free-living N_2 fixation" (Reed and Cleveland, 2011). They also comment that the commonality and activity of alternative nitrogenases remains unknown.

In some instances, the presence of an alternative nitrogenase may be known, but goes without comment. *E. radicincitans* DSM16656^T, a proteobacterium now reclassified as *Kosakonia radicincitans* DSM16656^T (Brady et al., 2013), was isolated from the phyllosphere of winter wheat under temperate climatic conditions. Upon the inoculation of various plant species, this organism was reported to promote the growth of roots and shoots and increased yields (Remus et al., 2000). Its genome has genes for nitrogen fixation, phosphorus mobilization, and phytohormone production (Witzel et al., 2012). Nitrogenase genes for both MoFe-nitrogenase and FeFe-nitrogenase are present. Given the ease of detection of genes for VFe- and FeFe-nitrogenase, doubtless, over time a clearer picture will emerge of their distribution.

8.11 CONCLUDING REMARKS

In 1913, the Haber–Bosch process provided the first useful industrial process for reduction of N_2 to ammonia, a highly energy-demanding reaction requiring 200–500 atm at 500–600°C with an iron-based catalyst. Exactly one hundred years later, this process, now improved with a ruthenium-based catalyst, still requires high pressure and temperature (70–80 atm, 350–470°C) (Tanabe and Nishibayashi, 2013). By contrast, for the past 2 billion years, the microbial world has performed the synthesis of NH_3 from N_2 and H_2 at less than 1 atm and 25°C.

Demand for fixed nitrogen continues to rise, with current commercial ammonia production reaching 160 million tons per year. As a reference point, the mass of N_2 in the atmosphere is 3.9×10^9 Tg. There is no danger of running out of raw material.

"Human activity has greatly increased the rate of transfer of N_2 to the biosphere (industrial manufacture of fertilizer, fossil fuel combustion, nitrogen-fixing crops), resulting possibly in a global fertilization of the biosphere" (Jacob, 1999). With respect to symbiotic microorganisms, the rate of diversity decline among host organisms is accelerating in response to climate change. It is inevitable that the increasing inputs of nitrogen fertilizers, along with the impacts of climate change, will affect the global distribution and diversity of nitrogen-fixing prokaryotes, and the ongoing surveys of microbial diversity will serve as "shifting baselines" for future ecological studies.

Expression and Regulation of Nitrogen Fixation Genes and Nitrogenase

Chapter 9

Regulation of *nif* Gene Expression in *Azotobacter vinelandii*

César Poza-Carrión, Carlos Echavarri-Erasun, and Luis M. Rubio
Centro de Biotecnología y Genómica de Plantas, Universidad Politécnica de Madrid, Madrid, Spain

9.1 INTRODUCTION: *Azotobacter vinelandii* AS PARADIGM OF NITROGEN-FIXING BACTERIA

Only some bacteria and archaea are capable of performing biological nitrogen fixation. Organisms that grow on N_2 as sole nitrogen source are called diazotrophs, and play an essential role in the biosphere (Falkowski, 1997; Boyd et al., 2011; see Chapter 1). Most biological nitrogen fixation is catalyzed by the Mo nitrogenase, although some nitrogen-fixing bacteria additionally contain alternative V or Fe-only nitrogenases that are expressed when Mo is not available in the medium (Bishop and Joerger, 1990). Diazotrophs use large amounts of ATP to break the N_2 triple bond. The Mo nitrogenase requires a minimum of 16 molecules of ATP to fix one molecule of N_2 according to the following reaction (Seefeldt et al., 2009):

$$N_2 + 8e^- + 16\text{MgATP} + 8H^+ \rightarrow 2NH_3 + H_2 + 16\text{MgADP} + 16\text{Pi}$$

It should be noted that H_2 is an obligate subproduct of this reaction, thus decreasing the energetic efficiency of N_2 fixation (Simpson and Burris, 1984). Alternative nitrogenases direct more electrons to the reduction of H^+ than the Mo nitrogenase and, consequently, require the hydrolysis of 24–32 ATP molecules per N_2 fixed (Eady, 1996). All nitrogenases are slow enzymes because they must carry out a minimum of eight electron transfer events, each one occurring at a rate of $5s^{-1}$ (Thorneley and Lowe, 1983). As a result, N_2-fixing bacteria are required to produce large amounts of nitrogenase – up to 10% of the total protein content in the cell – to be competent enough for diazotrophic growth (Dingler et al., 1988). Moreover, the assembly of nitrogenase metal cofactors requires complex biosynthetic pathways involving a number of gene products (Rubio and Ludden, 2008; Hu and Ribbe, 2011; see Chapter 7), some of which must be recycled frequently (Martinez-Noel et al., 2011). It is probably due to these reasons that diazotrophic growth occurs only in narrow nutritional and physiological conditions (Postgate, 1998).

Owing to the extreme oxygen-labile nature of nitrogenase, most diazotrophic bacteria fix N_2 only when growing anaerobically. However, this is not the case of *Azotobacter vinelandii*, a strict aerobic bacterium able to grow diazotrophically almost as fast as when using NH_4^+. *A. vinelandii*, a gram-negative Pseudomonadaceae, has emerged as the leading model for free-living diazotrophic bacteria. There are good reasons for this choice: the convenience of its strictly aerobic metabolism (Burk, 1930) to set up laboratory cultures; the ability to grow of many carbon sources including sugars, alcohols, and organic acids (Wong and Maier, 1985); its genetic tractability (Dos Santos, 2011); and the great quantity and quality of nitrogenase enzymes produced (Dingler et al., 1988).

A. vinelandii ensures an anaerobic intracellular environment by virtually eliminating O_2 traces using highly active respiratory chains (Poole and Hill, 1997; Bertsova et al., 2001). It is also one of the few species carrying all three nitrogenase systems (Bishop and Joerger, 1990). When

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

growing under diazotrophic conditions, *A. vinelandii* selects the nitrogenase to express on the basis of metal availability. Priority is on Mo nitrogenase expression, because it is the most efficient in reducing N_2 into NH_3, minimizing H_2 production. In fact, *A. vinelandii* growing diazotrophically in the absence of Mo has been shown to express the urocanate hydratase (*hutU*) gene, which encodes an enzyme involved in amino acid catabolism, suggesting that *in vivo* performance of alternative nitrogenases may not be enough for optimal diazotrophic growth (Hamilton et al., 2011b). The presence of Mo in the medium represses the expression of alternative nitrogenases. In the absence of Mo, and depending on whether V is present in the medium, *A. vinelandii* expresses either the V or the Fe-only nitrogenase (Joerger et al., 1989b, 1990). The fact that *A. vinelandii* can manage the biosyntheses of three different nitrogenase active site cofactors (FeMo-co, FeV-co, and FeFe-co) differing only in one metal site demonstrates high adaptability to grow diazotrophically in poor environments.

9.2 METHODOLOGIES USED TO STUDY REGULATION OF *nif* GENE EXPRESSION IN *A. vinelandii*

Although *A. vinelandii* can accommodate from 4 up to 100 chromosome copies per cell, depending on the stage in the growth cycle (Maldonado et al., 1994), for the most part this bacterium behaves as haploid (Maldonado et al., 1992), allowing easier genetic manipulations. Chromosomal insertions, deletions, and gene replacement techniques are possible because of highly efficient double-recombination events (Dos Santos, 2011). These relatively easy genetic techniques came in handy to determine the *nif* gene map and operon distribution in the *A. vinelandii* genome (Joerger and Bishop, 1988; Jacobson et al., 1989a, b).

Mapping *nif* gene expression was first approached by Northern Blot analysis (Jacobson et al., 1986; Joerger and Bishop, 1988) and *lacZ* transcriptional fusion techniques (Rodriguez-Quinones et al., 1993). Co-transcription patterns within *nif* operons (Jacobson et al., 1986; Hamilton et al., 2011a) and identification of transcriptional regulatory elements (Bennett et al., 1988; Joerger et al., 1989a; Blanco et al., 1993; Walmsley et al., 1994; Drummond et al., 1996) followed. Dixon and collaborators have studied both NifA and NifL biochemistry and genetics extensively (Dixon and Kahn, 2004; Martinez-Argudo et al., 2004b). In addition, considerable efforts have been made to understand the formation of NifA-NifL-GlnK complexes by using protein–protein interaction techniques both *in vivo* (Rudnick et al., 2002) and *in vitro* (Little et al., 2002). More recently, massive sequencing techniques delivered the *A. vinelandii* genome (Setubal et al., 2009) sequence and the transcriptional profiles of *A. vinelandii* grown diazotrophically under different metal availability regimes (Hamilton et al., 2011b).

9.3 *nif* GENES

The synthesis of active Mo nitrogenase is a complex biological process. It involves a number of gene products functioning as nitrogenase component proteins, molecular scaffolds, metallocluster carrier proteins, and additional enzymes, which are required, not just for the synthesis of the nitrogenase complex itself, but also for the biosynthesis of its catalytic metal cofactors (see Chapter 7).

Mo nitrogenase genes in *A. vinelandii* are located in two chromosomal regions adjacent and equidistant from the replication origin (Setubal et al., 2009). From a genetic standpoint, such a position suggests a higher gene dosage during active cell growth (Setubal et al., 2009) or just a critical role of these genes in *A. vinelandii* life style. Interestingly, all genes known to be required for the Mo, V, and Fe-only nitrogenases (e.g., *nifU*, *nifS*, *nifV*, *nifM*, and *nifB*) are located in Mo nitrogenase regions (Joerger and Bishop, 1988; Jacobson et al., 1989a; Kennedy and Dean, 1992; Drummond et al., 1996).

The so-called major *nif* cluster contains at least five transcriptional units, namely *nifHDKTY*, *nifENX*, *orf5*, $iscA^{nif}nifUSVcysE1^{nif}nifWZMclpX2$, and *nifF*, in which *nif* genes are interspersed with a number of open reading frames (ORFs) of unknown function (Jacobson et al., 1989a, b). The minor *nif* cluster contains three operons, namely *rnfABCDGEH*, *nifLA* and *nifB fdxN nifOQ rhdN* $grx5^{nif}$, and the *nafY* gene (Joerger and Bishop, 1988; Rodriguez-Quinones et al., 1993; Rubio et al., 2002; Curatti et al., 2005).

Gene expression in *nif* operons is dependent on the RNA polymerase σ^{54} factor and on the NifA transcriptional activator (Fig. 9.1). The σ^{54} subunit (also known as RpoN, σ^N, or NtrA) recognizes a promoter-specific sequence located at positions −24 to −12 that conforms to the consensus sequence 5′-YTGGCACGR-N_3-TTGCW-3′ (Barrios et al., 1999). In *nif* operons, transcription initiation by the σ^{54}-dependent RNA polymerase requires that the enhancer-binding-protein (EBP) NifA binds to DNA regions known as upstream activator sequences (UAS), which conform to the consensus sequence 5′-TGT-N_{10}-ACA-3′ (Buck et al., 1986). There are cases in which additional DNA-binding proteins are needed, including the integration host factor (IHF) (Hoover et al., 1990). IHF is an asymmetric histone-like protein that binds and bends DNA in specific locations (consensus sequence 5′-WATCAANNNNTTR-3′) (Goosen and van de Putte, 1995).

The *nifHDKTY orf1orf2* operon contains the Mo nitrogenase structural genes *nifH*, *nifD*, and *nifK*, along with *nifT*, *nifY*, and two ORFs of unknown function. Despite being transcribed from the same promoter, transcript levels were up to 70 fold higher for *nifH*, *nifD*, and *nifK* than for the other co-transcribed genes (Hamilton et al., 2011b). Analysis of intergenic sequences within the operon revealed regions

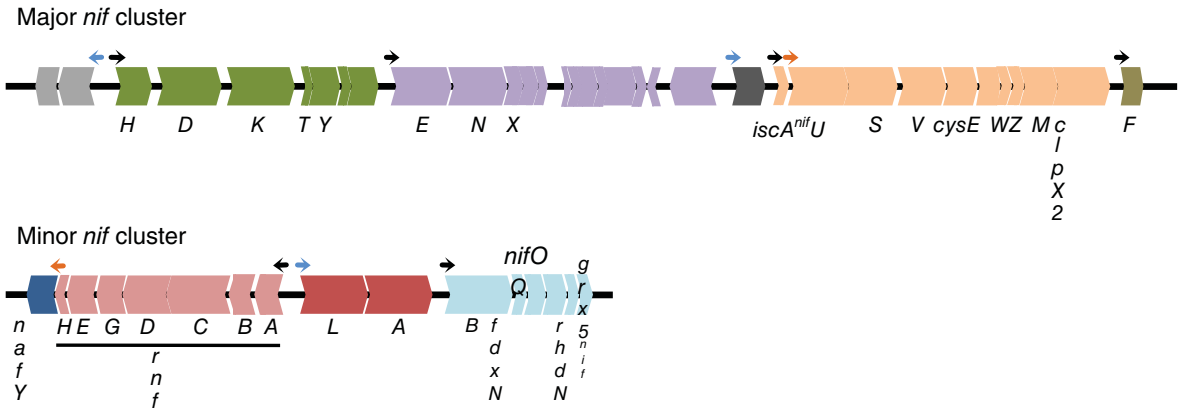

Figure 9.1 *A. vinelandii* Mo-nitrogenase *nif* gene clusters. Predicted σ^{54}–dependent promoter regions are depicted by arrows. Black arrows represent regions additionally containing NifA-UAS and IHF motifs; blue arrows represent regions containing NifA-UAS motifs; orange arrows represent regions lacking both NifA-UAS and IHF motifs.

capable of producing secondary structures that could explain the pattern of mRNA accumulation (Hamilton et al., 2011a). Importantly, overall *nifH* transcript levels also appeared to be higher than *nifDK* levels, revealing a mechanism to control the stoichiometry of nitrogenase component proteins.

The *nifENX orf3orf4* operon appears to have arisen from a duplication of the *nifHDK* operon (Fani et al., 2000). It contains the *nifE* and *nifN* genes, which products are homologous to NifD and NifK, respectively, and form a heterotetrameric $NifE_2N_2$ protein that functions as molecular scaffold for FeMo-co biosynthesis (Brigle et al., 1987; see Chapter 7). In addition, the operon contains the *nifX* gene, which encodes a FeMo-co precursor carrier protein, and two ORFs of unknown function. Although *nifENX* and *nifHDK* operons present similar 5′-untranslated region structures, *nifEN* levels are much lower than those of *nifDK*.

Not much is known about regulation of *orf5* expression except that it is apparently under the control of NifA and its mRNA accumulates in N_2-fixing conditions. However, *orf5* function is not essential for diazotrophic growth (Jacobson et al., 1989a).

The *iscA*^{nif} *nifUSV cysE1*^{nif} *nifWZM clpX2* operon includes a number of genes coding for proteins involved in the biosynthesis of nitrogenase metal cofactors and in the maturation of NifH and NifDK structural polypeptides. Operon expression is turned on once conditions for diazotrophic growth occur (Hamilton et al., 2011b), and its kinetics is similar to other *nif* operons (Poza-Carrión et al., 2014). The products of four genes in this operon (*nifU*, *nifS*, *nifV*, and *nifM*) are required for all three nitrogenases in *A. vinelandii* (Kennedy and Dean, 1992; see Chapter 7). Although *iscA*^{nif} shows the highest expression level in the operon (Hamilton et al., 2011b), its deletion did not impair diazotrophic growth (Jacobson et al., 1989a) probably because other proteins are able to replace its function as scaffold for [Fe–S] cluster biosynthesis. The *cysE1*^{nif} gene encodes a serine *O*-acetyltransferase, an enzyme that catalyzes the first step in L-cysteine biosynthesis; its function is not essential for diazotrophic growth under standard laboratory conditions (Jacobson et al., 1989a). Similarly, *clpX2* was shown to have a role in recycling NifB and NifEN polypeptides (Martinez-Noel et al., 2011) but its function is not essential for diazotrophic growth.

The flavodoxin-encoding gene *nifF* (Bennett et al., 1988) is in an independent transcriptional unit regulated by NifA and located downstream of *clpX2*.

In the minor *nif* cluster, the *rnfABCDGEH* operon encodes for a membrane-bound NADH oxidase complex. Mutational analysis suggested that *rnf* gene products were part of a redox regulatory mechanism controlling the rate of *nif* expression, probably via reduction of NifL (Curatti et al., 2005). In addition, *rnf* mutants exhibited lower rates of incorporation of the [4Fe–4S] cluster into NifH. Importantly, *rnf* gene expression occurs under conditions of N_2 fixation by all three nitrogenases (Hamilton et al., 2011b).

The *nafY* gene, encoding a FeMo-co insertase, is located downstream of the *rnf* operon but is transcribed from an independent promoter (Rubio et al., 2002). Expression of *nafY* is not absolutely dependent on NifA (hence the *naf* denomination), and *nafY* mRNA accumulates to substantial levels even when growing on NH_4^+ as nitrogen source (Poza-Carrión et al., 2014).

Genes in the *nifB fdxN nifOQ rhdN grx5*^{nif} operon are key to FeMo-co biosynthesis: *nifB* encodes a SAM-radical protein essential to assemble the metal core of FeMo-co, and *nifQ* encodes a protein required for Mo incorporation into the cofactor. Expression from the *nifB* promoter is activated by NifA, and also by the transcriptional activators of the alternative nitrogenases (Drummond et al., 1996). Expression levels within this operon have been investigated

in detail (Rodriguez-Quinones et al., 1993; Hamilton et al., 2011b). Although all these genes are co-transcribed, a sharp drop in expression was observed between the *nifO* and *nifQ* genes. Moreover, their expression pattern was different depending on metal availability in the medium (Mo, V, or only Fe), suggesting the existence of unknown elements that would regulate expression in this operon.

9.4 THE NifA-NifL-GlnK SYSTEM: A DYNAMIC SIGNAL INTEGRATING SYSTEM THAT MODULATES *nif* GENE EXPRESSION

The NifA-NifL-GlnK complex is key in regulating *nif* gene expression. In *A. vinelandii* this system integrates different environmental and intracellular signals including cell energy levels (ATP/ADP ratio), carbon/nitrogen balance, and redox state, to determine if diazotrophic growth is feasible. Different diazotrophic proteobacteria, such as *A. vinelandii*, *Klebsiella pneumonia*e, and *Pseudomonas stutzeri*, display significant differences in their signal integration mechanisms (Merrick and Edwards, 1995; Desnoues et al., 2003; Dixon and Kahn, 2004; Martinez-Argudo et al., 2005; See also Chapters 10, 34).

The biochemical basis of the NifA-NifL-GlnK complex relies on a series of sensing motifs that have been studied in detail (Little et al., 2002, 2012; Martinez-Argudo et al., 2004b) (Fig. 9.2).

NifL is an evolutionary relative of histidine protein kinases that acts as an anti-activator of NifA. The N-terminal domain of NifL is specialized in sensing intracellular redox potential. It contains two PAS motifs (Per-ARNT-Sim) (Hill et al., 1996; Macheroux et al., 1998), one of them carrying a flavin adenine dinucleotide (FAD) cofactor. These PAS domains undergo conformational changes, depending on the redox state of the cell. NifL presents an ATP-binding domain at its C-terminus that belongs to the GHKL (Gly-His-Lys-Leu) superfamily of ATPases (Blanco et al., 1993). This ATP-binding domain seems to perform two different functions: (i) it senses the energy status of the cell by binding ADP and (ii) it senses cellular nitrogen/carbon ratios through an interaction with GlnK, a PII-like protein (Little et al., 2000, Rudnick et al., 2002). Finally, a highly conserved histidine residue is located in the central region of NifL (Histidine-domain) where it seems to play an important role in the transmission of PAS and GHKL signals modulating the interaction of NifL with NifA (Little et al., 2007).

NifA is an EBP that activates transcription of σ^{54}-dependent promoters (Studholme and Dixon, 2003) (Fig. 9.2). The N-terminal part of NifA presents a GAF domain (cGMPphosphodiesterase adenylate cyclase FhlA domain) that binds 2-oxoglutarate (2-OG) for NifA allosteric control (Little and Dixon, 2003; Martinez-Argudo et al., 2004a). 2-OG is a Krebs cycle intermediate that provides not just a direct measure of cellular carbon status but also an indirect measure of cellular nitrogen status. This is because 2-OG is a substrate of the glutamine oxoglutarate aminotransferase (GOGAT) enzyme, being a main source of carbon skeletons for amino acid biosynthesis (Helling, 1998). In addition, NifA presents a central catalytic AAA^+ domain that can interact with the σ^{54} RNA polymerase subunit (Neuwald et al., 1999), and a C-terminal helix-turn-helix DNA-binding domain that recognizes NifA-UAS located 5′ of *nif* genes.

When *A. vinelandii* cells are growing under ideal diazotrophic conditions – nitrogen starvation and high respiratory rates – the level of oxygen is low and the levels of 2-OG and ATP are high. Allosteric binding of 2-OG to the GAF domain produces a conformational change in NifA that impairs NifL binding. Free NifA is able to activate *nif* gene expression through DNA binding and activation of the σ^{54} factor. On the other hand, at relatively low 2-OG levels or, most importantly, when NifL FAD group is oxidized by excess oxygen, NifL is competent enough to inhibit NifA activity (Fig. 9.3). However, additional fine-tuning applies, and is described below (Martinez-Argudo et al., 2005).

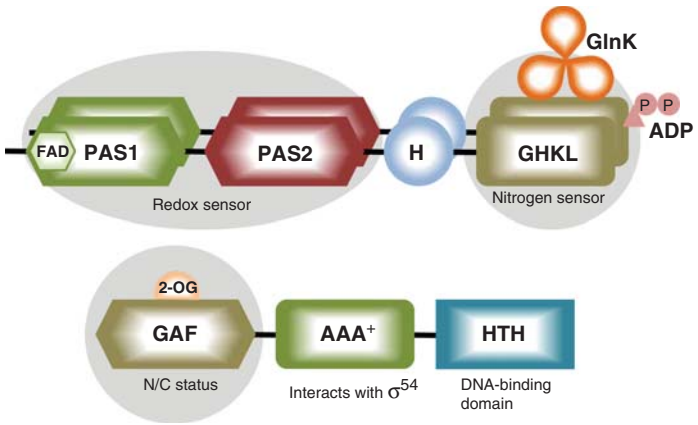

Figure 9.2 Schematic domain architecture of *A. vinelandii* NifL and NifA proteins.

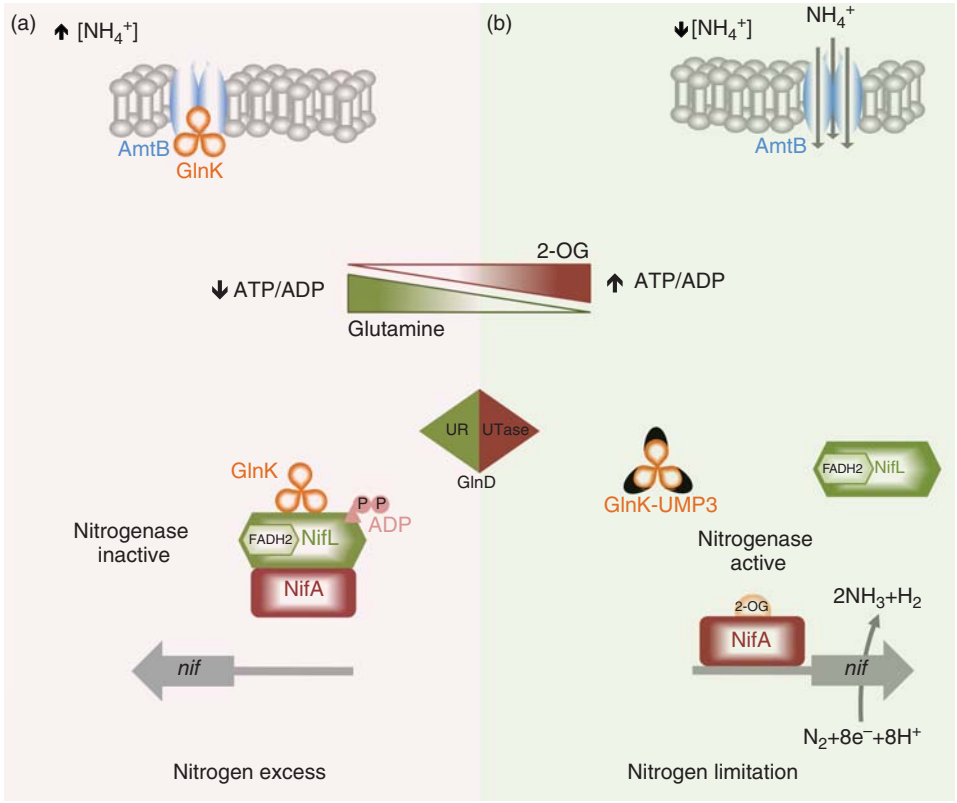

Figure 9.3 GlnK-NifL-NifA response to environmental and metabolic conditions in *A. vinelandii*. (a) Conditions of nitrogen excess result in high concentration of glutamine that leads to deuridylylation of GlnK by the uridylyl-removing (UR) activity of GlnD. The unmodified form of GlnK can interact with (1) AmtB to block active transport of ammonium and (2) with NifL in a GlnK-NifL-NifA ternary complex to block activation of *nif* gene transcription. (b) Conditions of nitrogen limitation result in high concentration of 2-OG that lead to uridylylation of GlnK (GlnK-UMP3) by the uridylyltransferase (UTase) activity of GlnD. The modified form of GlnK is unable to interact with either AmtB or NifL. In addition, high 2-OG levels induce a conformational change in NifA that prevents NifL inhibition and allows binding to specific UAS activating *nif* gene transcription.

A. vinelandii relies on GlnK (a member of the PII family of proteins) and GlnD (an uridylyltransferase/uridylyl-removing enzyme) to determine its cellular nitrogen/carbon balance (Meletzus et al., 1998). The *glnK* gene is co-transcribed with *amtB* in the *glnK amtB* operon and, contrary to the well-studied case of enteric bacteria, including the diazotrophic enterobacterium *K. pneumoniae*, its expression appears to be independent of NtrC (Meletzus et al., 1998). Regulation of *nif* expression in *A. vinelandii* diverges from other diazotrophs in that NtrC is not required for expression (Toukdarian and Kennedy, 1986). This suggests the existence of other proteins that may modulate *nif* transcription. In this context, new transcriptional regulatory regions in the *nifL* codifying region have been described (Mitra et al., 2005).

Uridylylation of GlnK by GlnD plays a key role in *nif* gene activation of expression (Little et al., 2002). GlnD mutants exhibited an Nif^- phenotype (Colnaghi et al., 2001; Rudnick et al., 2002). However, it is possible to revert this phenotype by certain suppressor mutations affecting glutamine synthetase activity (Rudnick et al., 2002).

Under conditions of nitrogen excess (high nitrogen/carbon ratio), non-uridylylated GlnK can interact with the C-terminal domain of NifL, increasing its inhibitory effect over NifA and forming a ternary complex (Fig. 9.3). *In vivo* and *in vitro* experiments have demonstrated this interaction (Little et al., 2002; Rudnick et al., 2002). Unmodified GlnK is also capable of interacting with the cytoplasmic ammonium transporter AmtB (Coutts et al., 2002).

On the other hand, under conditions of nitrogen limitation (low nitrogen/carbon balance) GlnD uridylylates GlnK ($GlnK\text{-}UMP_3$), which cannot interact with NifL. In addition, 2-OG binding to NifA prevents its inhibition by NifL. Interestingly, there is no evidence of NifL interaction with cytoplasmic membranes as it was shown in *K. pneumoniae* where NifL could be immobilized in the membrane, and therefore, hijacked from NifA, resulting in activation of *nif* transcription (Klopprogge et al., 2002).

9.5 PERSPECTIVES

Recently, whole Transcriptome Shotgun Sequencing (RNA seq) conducted on *A. vinelandii* growing diazotrophically with either Mo or V or Fe-only revealed the extent of cross-talk between the three different nitrogenase systems and their integration with central metabolic processes (Hamilton et al., 2011b). This analysis was performed comparing steady-state mRNA levels of NH_4^+-grown cells versus N_2-growth cells. How these mRNA levels are established and how they change over time has been shown recently (Poza-Carrión et al., 2014). This study of *nif* gene expression kinetics provides a detailed picture that reveals new regulatory elements. In this context, we have

observed that a *fdxN* mutant maintains very high levels of *nifA* expression (but not *nifL*) compared to the wild type. Likewise, sharp differences in mRNA levels from genes expressed from a common promoter could be explained by the existence of non-coding RNA elements, but this regulatory aspect has not yet been investigated.

When considering the transfer of *nif* genes to a new organism, a decision must be made on whether to completely imitate the regulatory scheme of a model diazotroph or to wipe out all intrinsic regulatory sequences and use a synthetic biology approach instead (Temme et al., 2012). The more we learn about *nif* regulation the more we will be able to tune our choices (see Chapter 108).

10.1 INTRODUCTION

The ability to use nitrogen gas as the sole nitrogen source confers to nitrogen-fixing bacteria an ecological and adaptive advantage for proliferating in natural ecosystems that in general are nitrogen-limiting environments. But, it also imposes considerable physiological constraints, due to the high-energy requirement for nitrogenase functioning, to the extreme oxygen sensitivity of the nitrogenase enzyme and to the complex regulatory mechanisms that prevent expression of the nitrogen-fixation (*nif*) genes under conditions noncompatible with the nitrogen-fixation process (Rees and Howard, 2000; Lawson and Smith, 2002; Dixon and Kahn, 2004). Indeed, diazotrophs are in most cases able to fix nitrogen only under nitrogen-limiting conditions in the presence of a suitable source of carbon and energy and in an environment where their nitrogenase enzyme can be protected from oxygen damage. Therefore, nitrogen-fixing bacteria have evolved several mechanisms to sense multiple environmental signals in order to adapt the nitrogen-fixation process to their physiological constraints (Dixon and Kahn, 2004; see also Chapter 9).

Pseudomonas stutzeri strain A1501, isolated from the rice rhizosphere in China, has emerged as an interesting model system of root-associated nitrogen-fixing bacteria (Qiu et al., 1981; Desnoues et al., 2003; Yan et al., 2013). This strain is one of the rare examples of nitrogen-fixation capacity within the *Pseudomonas* genus *sensu stricto* (Vermeiren et al., 1999; Lalucat et al., 2006; Yan et al., 2013).

P. stutzeri A1501 can survive in the soil, colonize the root surface, and invade endophytically the root tissues of the host plant (You et al., 1995; Rediers et al., 2003; Yan et al., 2013). Therefore, the potential of the strain to adapt to the nutritional environment of the rhizosphere is of particular importance. The nucleotide sequence of the complete genome of *P. stutzeri* A1501 has been determined (Yan et al., 2008). The genome of another nitrogen-fixing *P. stutzeri* strain DSM4166 isolated from the rhizosphere of a "high-fixing" *Sorghum nutans* cultivar in Germany (Krotzky and Werner, 1987) has also been determined (Yu et al., 2011). Interestingly, the nitrogen-fixation genes are carried on a 49-kb genomic island almost identical in both strains (Yan et al., 2013; see also Chapter 21).

The genes of the global regulatory networks controlling nitrogen and carbon sources utilization in *P. stutzeri* A1501 are located in the core genome (Fig. 10.1a). During evolution, A1501 acquired a nitrogen-fixation island with a *nif*-specific regulatory system from a diazotrophic common ancestor (Yan et al. 2008). Consequently, the expression of *nif* genes in *P. stutzeri* is controlled by two regulatory

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

systems of different evolutionary origins (Yan et al., 2010, 2013). In this review, we report recent advances made toward understanding the regulatory networks coupling carbon and nitrogen metabolism, including the discovery of small regulatory noncoding RNAs (ncRNAs), and their role in the control of nitrogen fixation of *P. stutzeri* A1501.

10.2 GLOBAL REGULATORY NETWORKS CONTROLLING NITROGEN FIXATION AND NITROGEN SOURCE UTILIZATION IN DIAZOTROPHIC PROTEOBACTERIA

Availability of a nitrogen source is a key regulatory signal controlling the nitrogen-fixation process through complex regulatory networks. Global regulation involves a number of signal transduction and effector proteins such as the *nif*-specific regulators, NifLA, and the global nitrogen regulators, AmtB–GlnK–NtrBC (Javelle et al., 2003; Merrick, 2004).

In several nitrogen-fixing Gammaproteobacteria (e.g., *Azotobacter vinelandii*, *P. stutzeri*, *Klebsiella pneumoniae*), the NifA activator and the antiactivator NifL proteins, encoded by the *nifLA* operon, control the expression of all other *nif* genes. This operon is in turn controlled by the general nitrogen regulatory protein NtrC and by the PII protein (GlnB or GlnK) in response to the fixed nitrogen status (Dixon, 1998; Martinez-Argudo et al., 2004; Xie et al., 2006; see Chapter 9).

One of the best-studied regulatory cascades is that established in *A. vinelandii* (Little et al., 2001, 2002). In this bacterium, 2-oxoglutarate is the metabolic signal controlling the interactions of GlnK with its target genes and acting as a regulator of the interaction between NifL and NifA. Under nitrogen-limiting conditions, GlnK is uridylylated and does not interact with NifLA, and NifA is activated by binding 2-oxoglutarate and can activate transcription of the *nif* operons. Under nitrogen excess GlnK binds to NifL and NifA, forming a complex that cannot activate the transcription of the *nif* operons (see Chapter 9).

10.3 THE NITROGEN REGULATORY CASCADE IN *P. stutzeri* A1501

The *P. stutzeri* A1501 strain is able to grow on ammonium ions or on various nitrogen sources and fix nitrogen under microaerobic and nitrogen-poor conditions (Desnoues et al., 2003). The nitrogen regulatory cascade in A1501 comprises the AmtB–GlnK–NtrBC global nitrogen regulation proteins, which sense the nitrogen signal and subsequently control expression of the *nif*-specific regulatory proteins NifLA (Xie et al., 2006; He et al., 2008; Zhang et al., 2012). These genes have been mapped on the chromosome of *P. stutzeri* A1501 and DSM4166 (Fig. 10.1a,b).

A1501 contains two ammonium transporter genes, *amtB1* and *amtB2*, linked to the *glnK* gene encoding a protein from the PII family (Fig. 10.1a). A *glnKamtB* gene cluster is commonly found in bacteria; but the tandem repeat of ammonium transporter genes found in *P. stutzeri* has not been found in other *Pseudomonas* species nor in the closely related *Azotobacter* (Fig. 10.1c,d) and may be unique to *P. stutzeri* (Vermeiren et al., 2002; He et al., 2008).

Construction of a double *amtB1–amtB2* deletion did not result in a mutant strain showing a growth defect, under the conditions tested, when compared to the growth of the wild-type strain (Zhang et al., 2012). Addition of ammonium

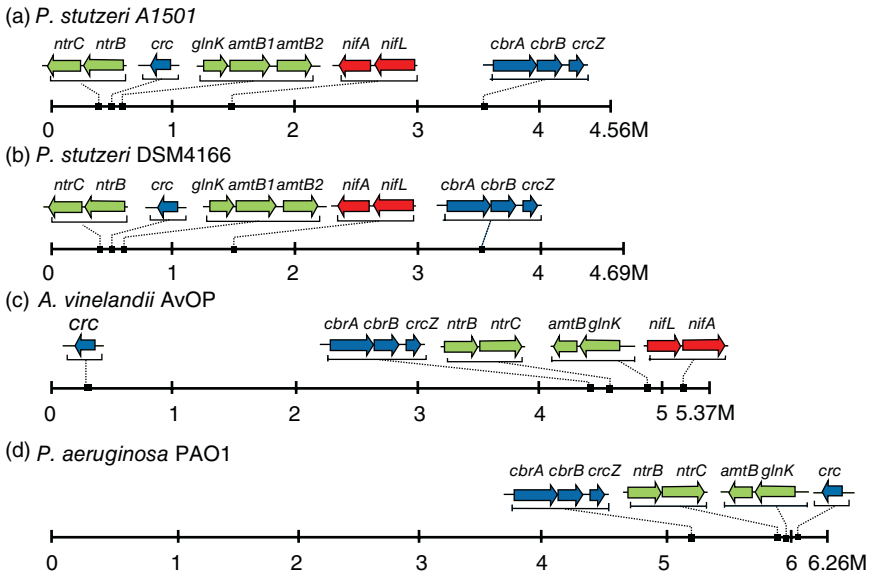

Figure 10.1 Localization of the gene clusters encoding regulatory proteins for nitrogen fixation, global nitrogen regulation, and carbon catabolite control on a linear map of the chromosome of three diazotrophic strains *P. stutzeri* A1501 (a), *P. stutzeri* DSM4166 (b), *A. vinelandii* AvOP (c), and one nondiazotrophic *P. aeruginosa* PAO1 (d).

to a nitrogen-fixing culture had a very small influence on nitrogenase activity in the *amtB* double deletion strain. In contrast, the wild-type strain showed significantly reduced nitrogenase activity, suggesting that the two AmtB proteins are involved in regulating the expression of the nitrogenase genes or nitrogenase activity in response to ammonium (Zhang et al., 2012).

Different strategies have been reported to obtain ammonium excretion by mutant strains (Christiansen-Weniger and Van Veen, 1991). For example, a *nifL* mutant of *A. vinelandii* has been found to excrete ammonium (Bali et al., 1992; Brewin et al., 1999). In the case of A1501, ammonium is excreted in the medium by the *amtB1–amtB2* double mutant strain under nitrogen-fixation conditions, and the amount of ammonium is increased when the strain expresses *nifA* constitutively (Zhang et al., 2012).

PII signal-transduction proteins are known to play a major role in the overall regulation of nitrogen metabolism, including nitrogen fixation (Merrick, 2004; Pedrosa and Elmerich, 2007). In *K. pneumoniae*, two paralogous gene copies *glnB* and *glnK* have been identified, whereas A1501 and *A. vinelandii* encode only a single PII protein termed GlnK (Ninfa and Atkinson, 2000; Rudnick et al., 2002; He et al., 2008). In the case of A1501, transcription of *glnK* is decreased in the presence of ammonium and is partly dependent on NtrC and RpoN under nitrogen-limiting conditions (He et al., 2008). Inactivation of *glnK* leads to a mutant strain devoid of nitrogenase activity and auxotrophic for glutamine (He et al., 2008). Using a *glnK–lacZ* fusion it has been shown that under nitrogen-limiting conditions, *glnK* is expressed from an RpoN-dependent promoter requiring NtrC as a transcriptional enhancer. An interaction between NifL and GlnK was observed in *P. stutzeri* (He et al., 2008), as also reported in *A. vinelandii* (Rudnick et al., 2002; see Chapter 9).

In Proteobacteria, such as *A. vinelandii* and *P. stutzeri*, GlnK is subject to reversible covalent modification by UTase/UR (uridylyltransferase/uridylyl-removing enzyme) encoded by the *glnD* gene (Arcondéguy et al., 2001). We observed that a mutation in the *glnD* gene of *P. stutzeri* prevented the activation of *nif* genes transcription, which resulted in a Nif$^-$ phenotype (unpublished data). It was hypothesized that the nonuridylylated form of GlnK interacts with NifL to inhibit NifA activity. This interaction was prevented when GlnK was fully uridylylated under nitrogen-fixation condition, as shown in *A. vinelandii* (Arcondéguy et al., 2001; see Chapter 9). A schematic representation of the transcriptional regulation of *nif* gene expression in A1501, mediated by the *nif*-specific and the Ntr regulatory systems, is shown in Figure 10.2.

It is particularly interesting to note that many genes of unknown function may play some essential role in controlling the expression of the *nif* genes or the activity of nitrogenase. Indeed, a transcriptome analysis revealed that the expression of a number of genes was significantly altered in response to ammonia sufficient or ammonia limiting conditions or after ammonia shock (Yan et al., 2010, 2013). Among differently regulated genes, nine transcriptional

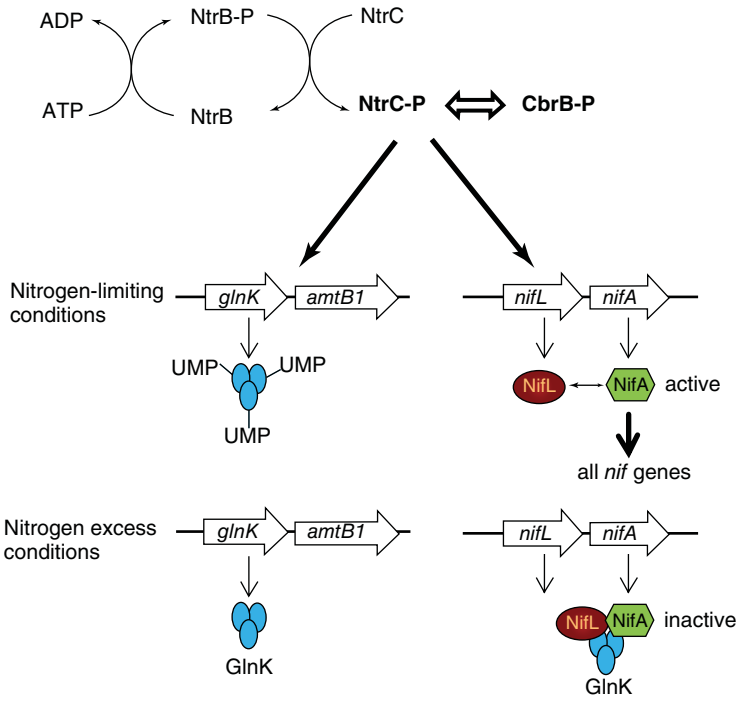

Figure 10.2 Cascade regulation of *nif* genes in *P. stutzeri* A1501 in response to the fixed nitrogen status. Under nitrogen-limiting conditions, glnK is uridylylated and NtrB phosphorylates NtrC, leading to activation of transcription of the *glnK*, *amtB*, and *nifLA* operons. Expression of GlnK prevents NifL from inhibiting NifA, leading to activation of *nif* transcription. Double solid arrow indicates that NtrC and CbrB may have partially overlapping functions. (*Source*: This figure was drawn according to the *Azotobacter* model proposed by Dixon and Kahn (2004) and adapted to data obtained in *P. stutzeri* A1501.)

regulators or outer membrane proteins were identified. The construction of mutant strains was performed, and it was shown that some showed a significant decrease in nitrogenase activity (Yan et al., 2010). However, the possible role of these genes in electron transfer, redox and nonredox catalysis, and sensing of regulatory processes requires further investigation.

10.4 CATABOLITE REPRESSION OF CARBON SOURCES UTILIZATION IN *Pseudomonas*

The rhizosphere is the primary site of interaction between microorganisms and host plants (Starkey, 1958). Bacterial growth in the rhizosphere depends on various carbon sources derived from root exudates (Starkey, 1958). In many cases, bacteria can selectively use a preferred carbon source by preventing the use of secondary substrates. This regulatory process is called catabolite repression control (CRC) and can be achieved by different regulatory mechanisms (Gorke and Stulke, 2008; Rojo, 2010). A classical example is the diauxic growth of *Escherichia coli* in media containing both glucose and lactose, discovered by Jacques Monod in 1941 (MacGregor et al., 1992; Gorke and Stulke, 2008). Catabolite repression is likely to play a role in natural habitats, where different bacterial species are in competition for available nutrients, by optimizing their metabolic versatility (Silby et al., 2011).

CcpA is the main regulator of catabolite repression found in *Bacillus subtilis* (Gorke and Stulke, 2008; Moreno et al., 2001). The Crc protein is the global transcription regulator involved in CRC in *Pseudomonas* (Gorke and Stulke, 2008; Rojo, 2010). Crc acts as a translational repressor by binding to target mRNAs. Crc activity is modulated by the products of the *cbrAB–crcZ* operon that has been particularly well studied in *Pseudomonas aeruginosa* (Sonnleitner and Haas, 2011). Changes in carbon and nitrogen concentration are sensed by the two-component system CbrA/CbrB, which controls expression of the small ncRNA CrcZ (407 nt). This small RNA by binding to the Crc protein can remove Crc from its target mRNA in the absence of the preferred carbon sources and relieve catabolite repression (Sonnleitner et al., 2009). Apart from catabolite repression, it was found that Crc also controls a number of other function, such as twitching motility, biofilm formation, virulence, and quorum sensing (Linares et al., 2010; O'Toole et al., 2000; Parvatiyar et al., 2005).

The two-component CbrA/CbrB system was initially shown to control the utilization of several amino acids and other nitrogenous compounds as sole source of carbon and nitrogen in *P. aeruginosa* (Nishijyo et al., 2001). Therefore, the involvement of *crc*, *CbrAB–crcZ* in carbon catabolite repression and in regulation of nitrogen fixation was investigated. These four genes are present in *Azotobacter* and *P. stutzeri* and have been mapped on their genomes (Fig. 10.1a–c).

10.5 CATABOLITE REPRESSION CONTROL: PROPERTIES OF A *CRC* MUTANT STRAIN OF *P. stutzeri* A1501

Like other metabolically versatile *Pseudomonas* species, *P. stutzeri* A1501 can assimilate a wide range of carbon compounds and live under a wide range of environmental conditions (Silby et al., 2011). Little is known of the role of Crc in the regulation of nitrogen fixation, despite the important role of carbon supply to this process. Especially the connections to nitrogen and carbon metabolism remain to be explored. Our recent studies aimed at assessing the regulatory role of Crc in nitrogen-fixing *P. stutzeri*, emphasizing the potential molecular mechanisms underlying cross talk between carbon and nitrogen metabolism.

P. stutzeri A1501, as many other *Pseudomonas* species, can utilize a variety of aromatic compounds. Our recent study of the β-ketoadipate pathway suggested that benzoate utilization was subject to catabolite repression (Li et al., 2010). Based on nucleotide sequence comparison, we identified a putative *crc* gene in the A1501 genome (Li et al., 2010; see Fig. 10.1a), whose translation product shared the highest similarity (88% amino acid identity) with the well-studied *P. aeruginosa* PAO1 Crc protein. To understand the role of the Crc-like protein of A1501 in catabolite repression, a mutant strain was constructed (Yan et al., 2012a). Subsequently, the *ben*, *cat*, *pca*, and *pob* genes, encoding key enzymes of the aromatic catabolic pathways, were selected for real-time polymerase chain reaction (RT-PCR) analysis. Expression of these selected genes was clearly higher in the *crc* mutant strain than in the parental strain, confirming our earlier observation that benzoate degradation in A1501 was subject to carbon catabolite repression. We further showed that in a medium containing both glucose and lactate, lactate was used more efficiently than glucose by the wild-type strain, indicating that lactate was the preferred carbon source for A1501 growth; whereas the *crc* mutant used glucose as efficiently as lactate.

Interestingly, the *crc* mutant was also impaired in its motility properties and in its competitive root colonization ability (manuscript in preparation). These additional phenotypes were in agreement with former reports on a *P. aeruginosa crc* mutant defective in type IV pilus-mediated twitching motility (Linares et al., 2010). Moreover, inactivation of *crc* resulted in reduced expression of the *glnK*, *ntrC*, *nifA*, and *nifH* genes, in agreement with the reduced nitrogenase activity (30%) compared with that of the wild-type A1501 strain (manuscript in preparation).

10.6 CATABOLITE REPRESSION CONTROL: TRANSCRIPTOME ANALYSIS

Transcriptome analysis and complementary phenotypic and physiologic assays have been performed in different bacteria (*B. subtilis*, *E. coli*) to identify the set of genes controlled by catabolite repression (Moreno et al., 2001; Yoshida et al., 2001; Liu et al., 2005). In the case of *Pseudomonas*, increasing evidence suggest that Crc affects not only specific catabolic pathways but also many other genes required for the interaction of the bacterium with the environment. A mutation in the *crc* gene of *Pseudomonas* was found to have pleiotropic effects, including quorum sensing, and susceptibility to antibiotics and virulence, all of which are important for the establishment of a successful association between the bacteria and their hosts (O'Toole et al., 2000; Parvatiyar et al., 2005; Gorke and Stulke, 2008; Linares et al., 2010).

In order to understand the role of Crc in the regulation of *nif* genes, we have compared the genome-wide transcriptional profile of A1501 wild type to that of a *crc* mutant under nitrogen-fixation conditions. A total of 498 genes were up- or downregulated in the *crc* mutant under nitrogen-fixation conditions. Among those, almost all the *nif* genes and general nitrogen regulatory genes were significantly downregulated. However, their mRNA did not reveal a putative Crc-binding site, suggesting that Crc impaired the expression of the *nif* genes through an unidentified indirect mechanism. Furthermore, a significant proportion (70%) of the 498 genes encoded proteins were involved in aromatic compound catabolism, energy generation, and amino acid biosynthesis and metabolism, and also in the group of stress response-related proteins such as a cold-shock protein (CspD), an osmotically inducible protein (OsmC), a superoxide dismutase (SodC), and two catalases (KatE and KatB), which may collectively contribute to the capacity to protect nitrogenase enzymes under microaerobic nitrogen-fixation conditions (Yan et al., 2012a). Taken together, these data revealed that Crc is a global regulator within the regulatory network coupling between carbon and nitrogen metabolism, which facilitates nitrogen fixation and environmental adaptation of root-associated *P. stutzeri* A1501. This study has extended our knowledge of the Crc regulon in pseudomonads (Fig. 10.3).

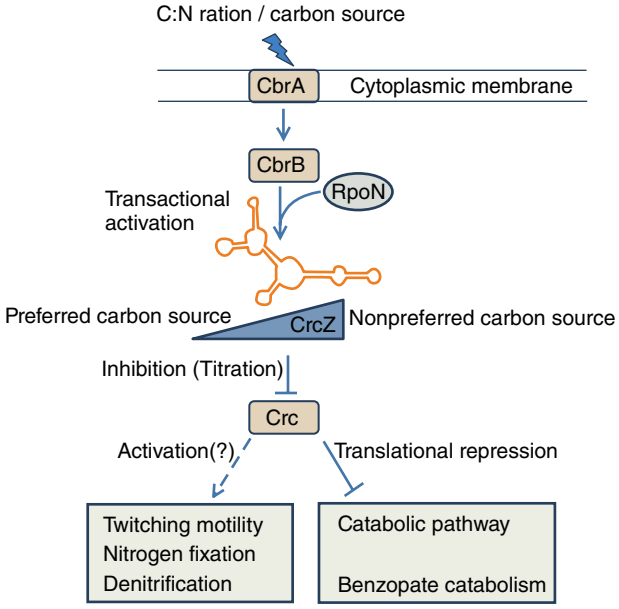

Figure 10.3 A model for the involvement of the CbrA/CbrB/CrcZ/Crc regulatory cascade in the regulation of twitching motility, nitrogen fixation, denitrification, and benzoate catabolism in *P. stutzeri* A1501. In response to a signal sensed by the CbrAB two-component system, the response–regulator CbrB is phosphorylated and activates the expression of CrcZ. CrcZ which harbors several Crc binding sites counteracts Crc function by sequestration of the protein. The question mark means that gene expression activation by Crc is likely to be indirect. (*Source*: This figure was drawn according to Sonnleitner and Haas (2011) and adapted to data obtained in *P. stutzeri* A1501.)

10.7 CATABOLITE REPRESSION: THE CbrA–CbrB SYSTEM IN *P. stutzeri* A1501

Available evidence suggests that in certain species of *Pseudomonas*, the CbrA/CbrB system functions as a global regulatory system required for the assimilation of carbon and nitrogen sources (Nishijyo et al., 2001; Li and Lu, 2007; Zhang and Rainey, 2008). The CbrA/CbrB system forms networks with other regulation systems, such as CrcZ and Crc, which play an important role in the process of microbial adaptation to the environment (Rojo, 2010). In *Pseudomonas putida*, lack of CbrB affects not only carbon metabolism and amino acid utilization but also apparently unrelated functions, such as tolerance to metals, motility, chemotaxis, and the transition from a planktonic lifestyle to the formation of surface-attached biofilm communities (Amador et al., 2010).

Multiple sequence alignment revealed that the CbrAB ortholog in *P. stutzeri* A1501 shared 78% and 84% amino acid identity with the well-characterized *P. aeruginosa* CbrA and CbrB proteins, respectively (unpublished data). A *cbrAB* double mutant strain of A1501 was constructed; its growth properties in LB or lactate containing minimal media did not differ from the wild type. An assay for 95 carbon or nitrogen substrates, using commercially Biolog plates, revealed that the *cbrAB* mutant strain had a growth defect on 20 carbon sources, including seven amino acids, two carbohydrates (α-D-glucose and maltose) and putrescine. In addition, the

cbrAB mutant displayed reduced nitrogenase activity and reduced motility phenotype (manuscript in preparation). However, the mechanism by which these regulators controls nitrogen fixation remain to be elucidated.

10.8 CbrAB AND NtrBC OVERLAPPING FUNCTIONS IN *P. stutzeri* A1501

Sequence comparison revealed that CbrAB belong to the NtrBC family. Although the signal sensed by the CbrAB system remains unknown, this system has been suggested to act coordinately with NtrBC to maintain the carbon–nitrogen balance (Nishijyo et al., 2001). In *Pseudomonas fluorescens*, the CbrAB system regulates operons for the utilization of amino acids that can be used as carbon and nitrogen sources, which are also regulated by the NtrBC system (Zhang and Rainey, 2008). Using catabolism of arginine and histidine as two models, further evidence supports the notion that the CbrAB and NtrBC two-component systems work coordinately to control the carbon and nitrogen metabolic flows in *P. aeruginosa* (Li and Lu, 2007).

To further document the role of CbrB and NtrC in *P. stutzeri* A1501, we compared properties of single *ntrC* and *cbrB* mutants and of an *ntrC/cbrB* double mutant (manuscript in preparation). Specific nitrogenase activity of the three mutant strains was significantly reduced compared to that of A1501, while the specific nitrogenase activity of the double mutant was much lower than that of two single mutant strains, suggesting that CbrB and NtrC may at least partially substitute for each other in the control of nitrogen fixation, as pointed out previously for *P. aeruginosa* in which NtrC and CbrB may have partially overlapping functions (Li and Lu, 2007). To further confirm this possibility, we constructed an *ntrC* mutant strain overexpressing the *cbrB* gene. As expected, overexpression of *cbrB* partially restored nitrogenase activity of the *ntrC* mutant strain. Given that CbrB may at least partially compensate for the regulatory defect caused by the *ntrC* mutation at some operons related with nitrogen fixation, it seemed attractive to speculate that the two-component system represents a link between carbon and nitrogen metabolisms (Fig. 10.4).

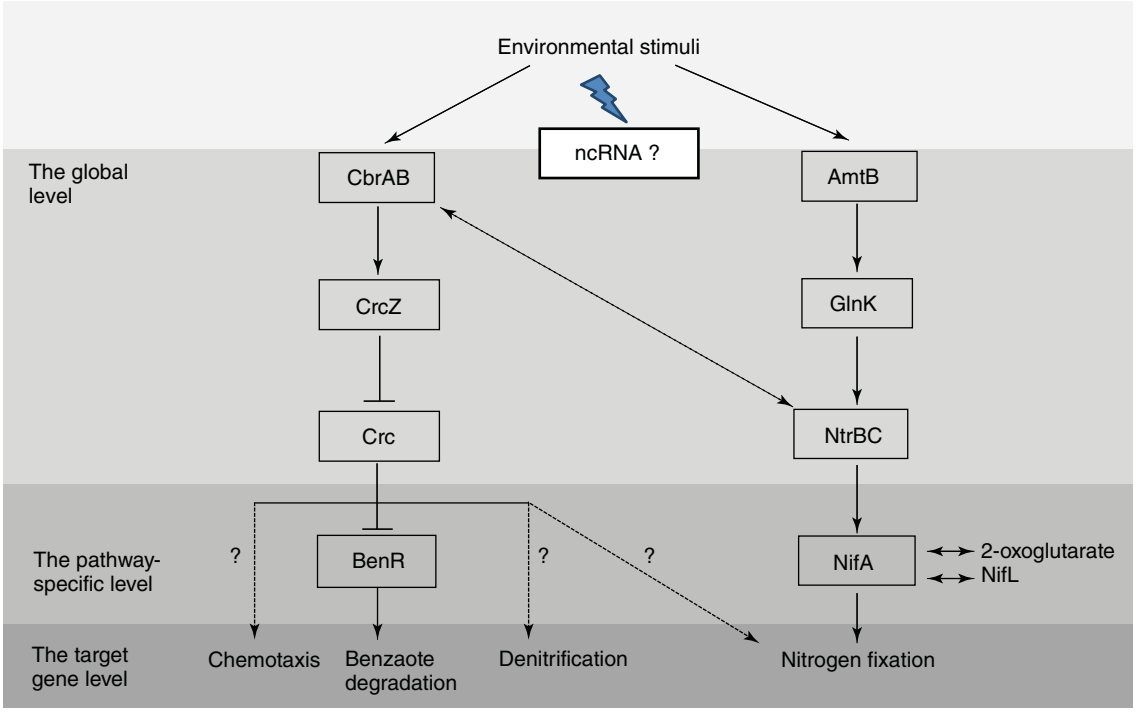

Figure 10.4 Regulatory networks operating in *P. stutzeri* A1501. There are two regulatory cascades in which three levels can be distinguished: (i) the global level: the PII protein, the two-component regulatory proteins and small regulatory ncRNAs, (ii) the specific-pathway level: the key regulators, and (iii) the target gene level: the genes involved in nitrogen fixation, denitrification, benzoate degradation, chemotaxis, and so on. Solid arrows indicate activation of gene expression. Repression is noted as "⊥." Double arrows show the interaction of NifL with NifA or binding of 2-oxoglutarate to NifA. Question marks represent the regulatory steps of unknown mechanism. Dotted double arrow represents a possible link between the two regulatory cascades. For details and references, see text.

10.9 SMALL REGULATORY NONCODING RNAs

Research on the discovery and characterization of small regulatory ncRNAs; also named sRNAs) in bacteria has exploded in recent years (Waters and Storz, 2009). In particular, a number of ncRNA molecules were identified in *Pseudomonas* species (Table 10.1). Active research is focused on the mechanisms by which these ncRNAs adjust bacterial physiology in response to environmental clues (Sonnleitner et al., 2012).

To date, very few small regulatory ncRNAs have been functionally characterized in nitrogen-fixing bacteria. Reports include an internal antisense RNA that regulates expression of the photosynthesis gene *isiA* in the cyanobacterium *Synechocystis* sp. PCC 6803 (Dühring et al., 2006), a ncRNA required for growth of freshwater cyanobacterium *Synechococcus elongatus* strains PCC 6301 under multiple stress conditions (Nakamura et al., 2007), and four *Rhizobium etli* ncRNAs varying during free-living growth and during interaction with the eukaryotic host plant (Vercruysse et al., 2010).

10.10 IDENTIFICATION OF ncRNA IN THE GENOME OF *P. stutzeri* A1501

The RNA transcripts synthesized by A1501 under nitrogen fixation and ammonium repression conditions were sequenced using Illumina (Solexa)'s high-throughput sequencing platform. A total of 53 ncRNAs induced under nitrogen-fixation conditions were identified. Among these candidates, 17 ncRNA-encoding genes had higher transcriptional levels (>2 fold) while 6 genes were down regulated (<0.5-fold) under nitrogen-fixation conditions (Yan et al., 2012b). The BLASTN searches of the 53 ncRNA sequences against GenBank database showed that (i) 12 ncRNAs were specific to A1501 because no homologous sequences were found in any other bacteria; (ii) 24 ncRNAs were only found in some *P. stutzeri* strains; and (iii) 17 ncRNAs were found to be conserved in other species of *Pseudomonas* or in other bacteria.

The BLASTN of Rfam database indicated that seven genes were highly conserved among bacteria and encoded previously known functional classes of ncRNAs (Table 10.1). In *P. aeruginosa*, the GacS/GacA two-component system positively controls the transcription of sRNA RsmZ, which is crucial for the expression of genes involved in virulence (Kay et al., 2005). The 6S RNA is a small ncRNA that interacts with σ^{70}-RNA polymerase and downregulates transcription at many promoters during the stationary phase. It has been proposed that 6S RNA mimics the conformation of DNA during transcription initiation, suggesting that the contacts between RNA polymerase and 6S RNA or DNA may be similar (Klocko and Wassarman, 2009). P15 is a ncRNA that was predicted using bioinformatic tools in the genome of the opportunistic pathogen *P. aeruginosa* and its expression verified by Northern blot analysis, but its function is unknown (Livny et al., 2006). The 407 nt ncRNA CrcZ comprises five CA-motifs and has been shown to antagonize the function of Crc in catabolite repression. In *P. aeruginosa*, the transcription of *crcZ* is driven by CbrAB in an RpoN-dependent manner (Sonnleitner et al., 2009). A conserved RpoN-binding site (GG-N10-GC) located in the promoter region of the A1501 *crcZ* gene was identified. Under nitrogen-fixation conditions, the expression of *crcZ* was almost completely repressed in the *rpoN* mutant of A1501 (Yan et al., 2012b; manuscript in preparation).

We employed the computational software sRNATarget to predict their potential targets. Some nitrogen-fixation-

related genes within the *nif*-island were predicted to be potential targets of 18 ncRNAs (13 upregulated ncRNAs and five down-regulated ncRNAs), suggesting that these ncRNAs are probably involved in the regulation of nitrogen fixation in *P. stutzeri* A1501. Further work is necessary to identify target genes of these ncRNAs and to determine as to whether they are involved in the regulation of nitrogen fixation in *P. stutzeri* and other diazotrophs.

10.11 CONCLUDING REMARKS

Diazotrophs have evolved transcriptional and posttranslational mechanisms to control the nitrogen-fixation process depending on environmental conditions. The mechanisms operating in *P. stutzeri* are extremely complex. They include the following: (i) a classical nitrogen regulatory cascade found in *Gammaproteobacteria*, involving two main systems, namely the *nif*-specific regulators, NifLA, and the global nitrogen regulators, AmtB–GlnK–NtrBC. The cascade found in *P. stutzeri* A1501 is close to that of *Azotobacter* (see Chapter 9). (ii) The CbrAB–CrcZ–Crc system for carbon catabolite repression. Data reported here strongly suggest that the catabolite repression cascade regulates also nitrogen fixation in *P. stutzeri* A1501. The involvement of this cascade in *Azotobacter* that is carrying the same genes is unknown. (iii) A complex network of ncRNAs. As the synthesis of several of them was specifically upregulated under nitrogen-fixation conditions, it is believed that some are playing a role in integrating nitrogen fixation with global cellular physiology. (iv) An unidentified mechanism (revealed by the analysis of the *amtB* mutant strains), that to some extent, controls nitrogenase activity and synthesis.

The complexity of the nitrogen-fixation regulatory network is schematized in Figure 10.4, with an emphasis on a possible cross talk between various regulatory systems as well on fine-tuning of nitrogen fixation with overall cellular physiology (Yan et al., 2012c).

Hopefully, the understanding of these complex regulations, especially during association with the host plant, should contribute to a rational exploitation of such fine-tuned interactions and provide various accessible alternative strategies for the genetically engineering of diazotrophic strains with higher potential in their transfer of fixed nitrogen to the host plant.

Chapter 11

Regulation of Nitrogen Fixation and Molybdenum Transport in *Rhodobacter capsulatus*

Bernd Masepohl
Biologie der Mikroorganismen, Ruhr-Universität Bochum, Bochum, Germany

11.1 INTRODUCTION

Rhodobacter capsulatus is a phototrophic Alphaproteobacterium capable of growing with atmospheric dinitrogen (N_2) as sole nitrogen source (Weaver et al., 1975). Nitrogen fixation, the reduction of N_2 to ammonia (NH_3), is catalyzed by two genetically distinct nitrogenases: a molybdenum-dependent nitrogenase (Mo-nitrogenase) and an alternative Mo-free iron-only nitrogenase (Fe-nitrogenase) (Schneider et al., 1991; Schüddekopf et al., 1993; see Chapter 2).

R. capsulatus carries more than 50 genes involved in nitrogen fixation, the majority of which is clustered in one of four chromosomal regions (Masepohl and Klipp, 1996; Strnad et al., 2010). Among these are the "classical" nitrogen fixation (*nif*) genes including the structural genes of Mo-nitrogenase, *nifHDK*, and genes involved in iron-molybdenum cofactor (FeMo-co) biosynthesis, *nifB*, *nifUSVW*, and *nifENX*. Apart from these *nif* genes, *R. capsulatus* contains alternative nitrogen fixation (*anf*) genes including the structural genes of Fe-nitrogenase, *anfHDGK* (Schüddekopf et al., 1993). The *rnf* (*Rhodobacter* nitrogen fixation) genes are essential for diazotrophic (N_2-dependent) growth using either Mo- or Fe-nitrogenase (Schmehl et al., 1993; Schüddekopf et al., 1993). The *rnf* genes, which were first described for *R. capsulatus*, but later on also identified in many other bacteria, encode a membrane complex involved in electron supply of both nitrogenases (Jouanneau et al., 1998; Kumagai et al., 1997; Saeki and Kumagai, 1998).

Mo-nitrogenase exhibits higher specific N_2-reducing activity than Fe-nitrogenase and thus appears to be the preferred enzyme providing sufficient molybdate supply (Schneider et al., 1997). In *R. capsulatus*, Mo-nitrogenase activity depends on two transporters with different molybdate affinities. At nanomolar molybdate concentrations in the environment, the high-affinity ATP-binding cassette (ABC) transporter ModABC is essential for Mo-nitrogenase activity (Wang et al., 1993). At micromolar molybdate concentrations, Mo-nitrogenase activity depends on the oxyanion permease PerO, which belongs to the ArsB/NhaD family (Gisin et al., 2010). To date, PerO is the only experimentally confirmed bacterial molybdate transporter outside the ABC transporter family.

This review summarizes our current knowledge on regulation of nitrogen fixation and molybdenum transport in *R. capsulatus*. Currently, more than 20 proteins are known or predicted to control expression and activity of Mo-nitrogenase, Fe-nitrogenase, and molybdate uptake (Table 11.1). This review focuses on nitrogen and molybdenum regulations, while the regulatory effects of oxygen and light will only briefly be touched upon.

11.2 TRANSCRIPTIONAL ACTIVATION OF NITROGEN FIXATION GENES

The *R. capsulatus* nitrogen regulation (*ntr*) genes *ntrB* and *ntrC* encode a cognate two-component system acting on top

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

TCS, two-component regulatory system; IHF, integration host factor.

of a regulatory cascade controlling expression of Mo- and Fe-nitrogenase (Fig. 11.1) (Cullen et al., 1996; Masepohl and Klipp, 1996). Under nitrogen-fixing conditions, the response regulator NtrC becomes phosphorylated, and thus, activated (Cullen et al., 1996). In the following step, NtrC∼P activates transcription of its target genes including *nifA1*, *nifA2*, and *anfA* (Table 11.2) (Bowman and Kranz, 1998). Importantly, *anfA* transcription is strongly repressed by molybdate, thus limiting Fe-nitrogenase expression to conditions unfavorable for Mo-nitrogenase. *R. capsulatus* NtrC activates target promoters recognized by RNA polymerase containing the housekeeping sigma factor RpoD, while NtrC proteins from other diazotrophs typically activate promoters depending on the alternative sigma factor RpoN (alias NtrA) (Foster-Hartnett et al., 1994; see Chapter 10).

NtrC is absolutely essential for diazotrophic growth of *R. capsulatus* using either the Mo- or the Fe-nitrogenase (Masepohl et al., 2001; Schüddekopf et al., 1993). The sensor kinase NtrB serves as a phosphodonor for NtrC as demonstrated by *in vitro* reconstitution of the two-component system (Cullen et al., 1996). In addition to NtrB, the sensor kinase NtrY is an efficient *in vivo* phosphodonor as implied by gene disruption studies (Fig. 11.1) (Drepper et al., 2006). In contrast to single mutants lacking either NtrB or NtrY, an *ntrB–ntrY* double mutant is no longer able to fix dinitrogen, suggesting that NtrB and NtrY are the only physiological phosphodonors for NtrC. In line with this assumption, acetyl phosphate does not phosphorylate *R. capsulatus* NtrC *in vitro*, while it is a substrate for enteric NtrC (Cullen et al., 1996).

The *R. capsulatus ntrYX* genes, which are located directly downstream of the *nifR3–ntrBC* genes, encode a two-component system involved in oxygen regulation of photosynthesis genes (Gregor et al., 2007). Transcription of the *ntrYX* operon is primarily driven by the *ntrY* promoter but, in addition, requires the *nifR3* promoter for maximum expression (Drepper et al., 2006). A similar order of *nifR3–ntrBC* and *ntrYX* genes is conserved in different bacteria. Recently, *Brucella abortus* NtrY was shown to contain a redox-sensing heme cofactor, which controls autokinase activity (Del Carmen Carrica et al., 2012). Only at low ambient oxygen concentrations, the heme iron is in its reduced

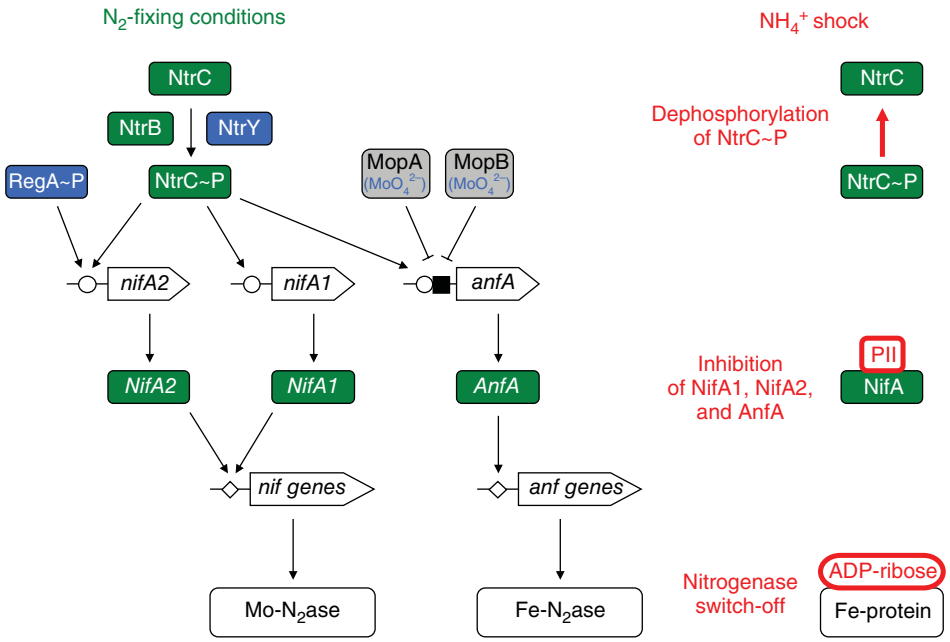

Figure 11.1 **Regulatory cascades controlling nitrogen fixation**. Proteins involved in nitrogen, oxygen, and molybdenum regulation of nitrogen fixation are shown in green, blue, and gray, respectively. Phosphorylation of the response regulator NtrC depends on two sensor kinases, NtrB and NtrY. NtrC~P activates RpoD-dependent promoters (open circles), while NifA1, NifA2, and AnfA activate RpoN-dependent promoters (open diamonds). MopA and MopB repress *anfA* by binding the *anfA* Mo-box (black square). Upon ammonium addition to an N_2-fixing culture, NtrC~P is dephosphorylated (and thus, inactivated) and, upon interaction with either of two PII proteins, GlnB and GlnK, NifA1 and NifA2 are inhibited. Nitrogenase switch-off involves ADP-ribosylation of the Fe-protein and an ADP-ribosylation-independent mechanism (not depicted in this figure). For further details, see text.

Table 11.2 Genes directly activated by NtrC

Target Genes	Accession Numbers	Known or Predicted Functions	References
nifA1	rcc03267	Activator of *nif* gene transcription	Masepohl et al. (1988)
nifA2	rcc00567	Activator of *nif* gene transcription	Masepohl et al. (1988)
anfA	rcc00584	Activator of *anf* gene transcription	Schüddekopf et al. (1993)
mopA–modABCD	rcc00561–rcc00565	Molybdate-responsive regulator and molybdate transporter	Wang et al. (1993)
glnB–glnA	rcc01673–rcc01674	PII-type signal transduction protein and glutamine synthetase	Foster-Hartnett and Kranz (1994)
glnK–amtB	rcc03387–rcc03386	PII-type signal transduction protein and ammonium transporter	Drepper et al. (2003)
amtY	rcc01792	Ammonium transporter	Yakunin and Hallenbeck (2002)
ureDABCEFG	rcc01217–rcc01224	Urease	Masepohl et al. (2001)

form, which is a prerequisite for autophosphorylation of NtrY and subsequent phosphotransfer to NtrX. It is tempting to speculate that in *R. capsulatus*, the phosphorylation states of NtrB and NtrY reflect the fixed nitrogen and ambient oxygen concentrations, respectively, and cross talk to NtrC integrates both signals (Fig. 11.1).

In addition to NtrC, the response regulator RegA acts as a coactivator of *nifA2* but not *nifA1* (Fig. 11.1) (Elsen et al., 2000). RegA and its cognate sensor kinase RegB comprise a global redox-responding two-component system involved in regulation of many important processes including photosynthesis, carbon fixation, and (via *nifA2*) nitrogen fixation (for a recent review, see Wu and Bauer, 2008). At low ambient oxygen concentrations, RegA becomes phosphorylated and, in turn, activates its target promoters. Apparently, *nifA2* regulation by NtrC and RegA provides another mechanism integrating nitrogen and oxygen signals. Furthermore, RegA directly interacts with the above-mentioned NtrX protein (Gregor et al., 2007). RegA–NtrX interaction likely reduces the amount of homomeric RegA protein and, hence, affects *nifA2* control in response to oxygen tension.

NifA1, NifA2, and AnfA activate transcription of all the other *nif* and *anf* genes required for expression and activity of the Mo- and Fe-nitrogenases. In contrast to

NtrC, which activates RpoD-dependent promoters, NifA1, NifA2, and AnfA activate RpoN-dependent promoters as is the case for their homologs in other diazotrophs (Hübner et al., 1993; Schüddekopf et al., 1993). The *rpoN* gene forms part of the RpoN-dependent *nifU2–rpoN* operon, and therefore, RpoN appears to be autoactivated under nitrogen-fixing conditions (Cullen et al., 1994; Preker et al., 1992). In addition to the RpoN-dependent promoter preceding the *nifU2–rpoN* operon, a weak constitutive promoter mediates basal expression of *rpoN* required to initiate the autoregulatory circuit.

11.3 AMMONIUM INHIBITION OF NITROGEN FIXATION

In ammonium-grown *R. capsulatus* cells, *nifR3-ntrBC* expression is comparably high as in nitrogen-fixing cells (Cullen et al., 1998). Furthermore, NtrC levels remain constant during growth with ammonium and dinitrogen, but transcriptional activation of *nifA1*, *nifA2*, and *anfA* occurs exclusively under nitrogen-fixing conditions. Altogether, these findings suggest that, in the presence of ammonium, NtrC predominantly occurs in its unphosphorylated (inactive) form.

Addition of ammonium to a nitrogen-fixing culture causes at least three effects as depicted in the regulatory model in Figure 11.1 (Drepper et al., 2003). First, an ammonium shock leads to dephosphorylation of NtrC∼P and, hence, inactivation of the regulator stopping further transcription of *nifA1*, *nifA2*, and *anfA*. Second, the transcriptional activators NifA1, NifA2, and AnfA are posttranslationally inhibited, thus preventing further transcription of Mo- and Fe-nitrogenase genes. Third, Mo- and Fe-nitrogenase activities are specifically inhibited by ammonium (Jouanneau et al., 1983; Masepohl et al., 1993). In addition, removal of light leading to energy deprivation also inhibits Mo-nitrogenase activity (Pierrard et al., 1993; Yakunin and Hallenbeck, 2002). In contrast to the well-studied nitrogen-signaling pathway, the energy-signaling pathway remains largely unknown.

Signal transduction after an ammonium shock involves two PII-like proteins, GlnB and GlnK (Fig. 11.2) (Drepper et al., 2003). A *glnB–glnK* double knockout strain is still able to synthesize active Mo- and Fe-nitrogenases demonstrating that none of the PII proteins is *per se* essential for nitrogen fixation. However, proper regulation of nitrogen fixation requires both proteins, which mutually depend on each other (Tremblay et al., 2007).

R. capsulatus GlnB and GlnK specifically interact with different protein partners involved in nitrogen regulation as shown by yeast two-hybrid studies (Pawlowski et al., 2003). Apart from the formation of homo- and heteromers, both PII proteins interact with NifA1, NifA2, and DraT (dinitrogenase reductase ADP-ribosyltransferase), the latter enzyme catalyzing ADP-ribosylation of the nitrogenase Fe-protein (see later). Furthermore, GlnB (but not GlnK) interacts with NtrB. Notably, none of the two signal transduction proteins interacts with AnfA [our unpublished results]. Interaction of the *R. capsulatus* PII proteins with their partners is likely to be modulated by 2-oxoglutarate, the ATP–ADP ratio, and by reversible uridylylation reflecting the cellular carbon, energy, and nitrogen status, as shown for PII proteins of diverse species (Fokina et al., 2010; Gerhardt et al., 2012; Jiang and Ninfa, 2009; Tremblay et al., 2007; Tremblay and Hallenbeck, 2009; Truan et al., 2010; Xu et al., 2001).

Disruption of the *R. capsulatus glnB* gene strongly diminishes ammonium inhibition of *nifA1* and *anfA* transcription, suggesting that GlnB is critical to keep NtrC in its unphosphorylated (inactive) form (Drepper et al., 2003). As mentioned earlier, GlnB specifically interacts with NtrB (Pawlowski et al., 2003). Taken together, it seems likely that dephosphorylation of *R. capsulatus* NtrC∼P involves an NtrB–GlnB complex as in *Escherichia coli* (Jiang et al., 1998; see also Chapter 9).

R. capsulatus synthesizes two highly similar NifA regulators, NifA1 and NifA2, which functionally replace each other in *nif* promoter activation (Masepohl et al., 1988; Paschen et al., 2001). Constitutive (NtrC-independent) expression of *nifA1* leads to accumulation of NifA1 protein in the presence of ammonium as shown by Western analysis. However, constitutive expression of *nifA1* or *nifA2* does not relieve ammonium inhibition of *nif* promoters, suggesting that both regulators are posttranslationally inhibited by ammonium. A *glnB–glnK* double mutant synthesizes huge amounts of Mo-nitrogenase in the presence of ammonium, while no expression is observed in single mutants implying that either GlnB or GlnK is sufficient for NifA1 and NifA2 inhibition (Drepper et al., 2003). As mentioned earlier, both regulators directly interact with GlnB and GlnK (Pawlowski et al., 2003). Altogether, these findings support the conclusion that upon an ammonium shock, GlnB and GlnK bind to NifA1 and NifA2 leading to inhibition of both activators.

Similar experiments with a strain constitutively expressing *anfA* indicate that AnfA is also inhibited upon ammonium addition, as described earlier for NifA1 and NifA2 (Drepper et al., 2003). In a *glnB–glnK* double mutant, however, Fe-nitrogenase expression is still inhibited by ammonium, suggesting that AnfA inhibition follows a mechanism other than that controlling NifA1 and NifA2.

Ammonium addition to a nitrogen-fixing *R. capsulatus* culture inhibits *in vivo* Mo-nitrogenase activity (Förster et al., 1999; Pierrard et al., 1993). Rapid and complete "switch-off" is observed in highly nitrogen-limited cultures, while moderately nitrogen-limited cultures only partly inhibit nitrogenase by the "magnitude response" reflecting the amount of added ammonium (Yakunin and Hallenbeck,

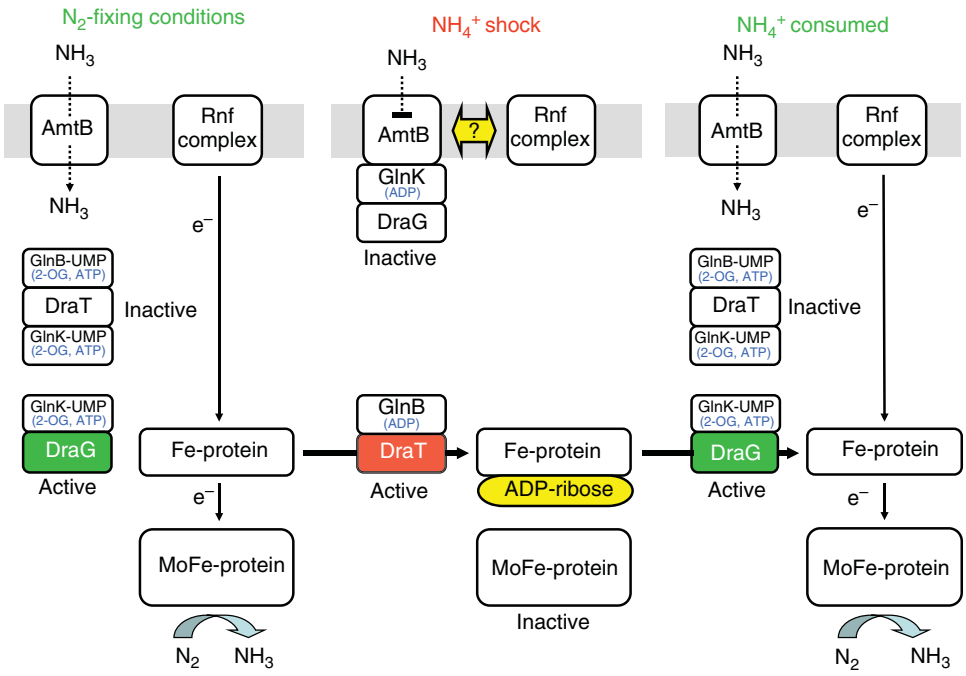

Figure 11.2 **Posttranslational control of nitrogenase activity**. N_2 fixation requires electron flow from the Rnf complex to the Fe-protein and further to the MoFe-protein. Upon an ammonium shock, DraT catalyses ADP-ribosylation of the Fe-protein, which in its modified form is no longer able to deliver electrons to the MoFe protein. When the ammonium is consumed, DraG removes the ADP-ribose moiety from the Fe-protein, thereby restoring its ability to transfer electrons to the MoFe-protein. Activities of DraT and DraG are controlled by various interactions with GlnB and GlnK. AmtB is involved in inactivation of DraG and the Rnf complex by membrane sequestration and yet an unknown mechanism (indicated by question mark), preventing electron transfer to the Fe-protein. For further details, see text.

1998). In *R. capsulatus*, switch-off involves two mechanisms, a slow DraT-dependent and a fast DraT-independent mechanism (Förster et al., 1999; Jouanneau et al., 1983; Pierrard et al., 1993; Tremblay and Hallenbeck, 2009; Yakunin and Hallenbeck, 1998). Similarly, other bacteria including *Azoarcus* and *Azospirillum brasilense* control nitrogenase switch-off by two mechanisms (Oetjen and Reinhold-Hurek, 2009; Zhang et al., 1996). By contrast, DraT-dependent switch-off is the only mechanism regulating nitrogenase activity in *Rhodospirillum rubrum* (Liang et al., 1991; Zhang et al., 1996; see Chapter 12).

DraT and DraG (dinitrogenase reductase activating glycohydrolase) form a two-enzyme system antagonistically, controlling activity of the nitrogenase Fe-protein (for a recent review, see Huergo et al., 2012). Upon ammonium addition, DraT is activated and, in turn, activated DraT modifies the Fe-protein by ADP-ribosylation. Fe-protein modification prevents association with the MoFe-protein and consequently stops electron supply to the MoFe-protein (Fig. 11.2). DraT activation is likely to require complex formation with GlnB-ADP as recently shown for *A. brasilense* DraT-GlnB by *in vitro* studies (Moure et al., 2013; see Chapter 13). Upon ammonium consumption, DraT is inactivated, while DraG becomes active. Activated DraG removes the ADP-ribosyl moiety from the Fe protein, thereby restoring its capacity to donate electrons to the MoFe-protein. DraT and DraG activities are controlled by various interactions with PII proteins, in which complex formation is modulated by small effector molecules and PII uridylylation (Fig. 11.2).

An *R. capsulatus* strain lacking DraT does no longer modify (ADP-ribosylate) NifH and AnfH, the dinitrogenase reductase components of the Mo- and Fe-nitrogenases, respectively, strongly indicating that, in addition to Mo-nitrogenase, the alternative nitrogenase is subject to posttranslational regulation (Masepohl et al., 1993). Mo-nitrogenase switch-off, however, is still observed in the *draT* mutant demonstrating the presence of a second, DraT-independent mechanism (Förster et al., 1999). In line with this finding, strains expressing mutant NifH proteins, which are no longer modified by DraT, still exhibit the switch-off response to ammonium (Pierrard et al., 1993).

The ammonium-induced switch-off is completely abolished in an *R. capsulatus* mutant lacking the ammonium transporter AmtB (Yakunin and Hallenbeck, 2002). AmtB is dispensable for growth with ammonium, but appears to be involved in ammonium retention under nitrogen-fixing conditions. In addition, AmtB might function as an ammonium sensor for the switch-off process. Upon ammonium addition, a ternary AmtB–GlnK–DraG complex is likely to be formed in *R. capsulatus* (Fig. 11.2) as described for *A. brasilense*

AmtB–GlnZ–DraG (Huergo et al., 2007; Rajendran et al., 2011; Tremblay and Hallenbeck, 2008; Tremblay et al., 2007). Assuming that membrane-bound DraG is inactive, DraT-mediated modification of the Fe-protein will not be reversed until DraG is released again.

As mentioned earlier, *amtB* disruption abolishes both the DraT-dependent and the DraT-independent ammonium responses (Yakunin and Hallenbeck, 2002). The DraT-independent switch-off mechanism probably prevents electron flow from the Rnf complex to the Fe-protein (Fig. 11.2) as recently suggested for *Azoarcus* (Sarkar et al., 2012).

11.4 MOLYBDENUM REPRESSION OF Fe-NITROGENASE AND Mo TRANSPORT

Expression of Fe-nitrogenase enables *R. capsulatus* to grow diazotrophically under conditions of Mo-starvation otherwise unfavorable for growth depending on Mo-nitrogenase. *In vivo* Fe-nitrogenase activity is maximal at ambient Mo concentrations below 1 nM, while activity gradually decreases with increasing Mo concentrations (Wang et al., 1993). Fe-nitrogenase activity is half-maximal at Mo concentrations of about 10 nM, and no longer detectable at 100 nM. This decrease results from Mo-dependent *anfA* repression, confining expression of the central transcriptional activator of Fe-nitrogenase genes, AnfA, to Mo-limiting conditions (Fig. 11.1) (Kutsche et al., 1996; Wiethaus et al., 2006).

Transcription of the *anfA* gene is repressed by two regulators, MopA and MopB, which are structurally and functionally similar to *E. coli* ModE (Fig. 11.1) (Hall et al., 1999; Kutsche et al., 1996; Wang et al., 1993; Wiethaus et al., 2009). ModE-like regulators, which consist of a C-terminal molybdate- and an N-terminal DNA-binding domain, act as one-component regulators sensing and responding to the cellular Mo status. Deletion of both, *mopA* and *mopB*, but not single gene mutations, abolishes *anfA* repression indicating that MopA and MopB substitute for each other regarding *anfA* repression (Kutsche et al., 1996; Wiethaus et al., 2006). Binding of molybdate by MopA and MopB increases affinity of the regulators for the *anfA* Mo-box, which overlaps the transcription start site (Kutsche et al., 1996; Müller et al., 2010; Wiethaus et al., 2006). Mo-boxes are conserved palindromic sequences found in various target promoters (Fig. 11.3). Notably, the isolated DNA-binding domain of MopB efficiently binds the *anfA* promoter *in vitro* (Müller et al., 2011). As one would expect for a truncated MopB protein lacking the Mo-sensing domain, binding of the *anfA* promoter is independent of Mo availability.

The *R. capsulatus mopA* gene forms part of the *mopA–modABC* operon, while *mopB* forms a monocistronic operon located upstream of *mopA* (Fig. 11.3) (Wiethaus et al., 2006). The *mopB* gene is constitutively expressed, while the *mopA–modABC* operon is repressed by MopA and MopB, thereby confining expression of MopA and the high-affinity molybdate transporter ModABC to Mo-limiting conditions. As mentioned earlier for the *anfA* Mo-box, MopA and MopB bind the *mopA* Mo-box, which overlaps the *mopA* transcription start site (Kutsche et al., 1996; Wiethaus et al., 2006).

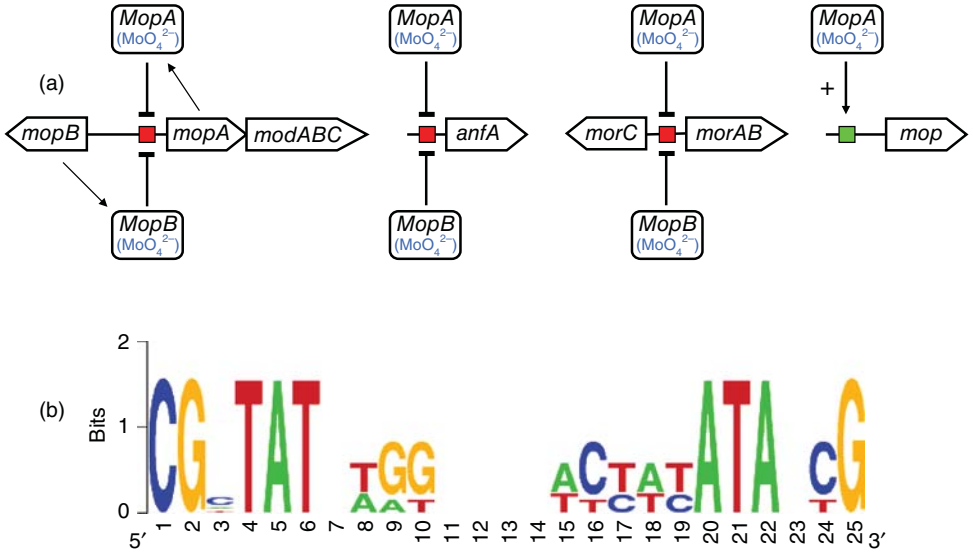

Figure 11.3 Gene regulation by MopA and MopB. (a) The molybdate-responsive one-component regulators MopA and MopB bind the Mo-repressed Mo-boxes upstream of *mopA*, *anfA*, and *morA* (given in red). MopA (but not MopB) binds the Mo-activated *mop* Mo-box (given in green). (b) The Mo-box consensus based on the *mopA*, *anfA*, *morA*, and *mop* Mo-boxes was generated using the weblogo.berkeley.edu program.

Remarkably, *R. capsulatus* wild-type cells exhibit significant Mo-nitrogenase activity even at ambient Mo concentrations as low as 1 nM (Wang et al., 1993). *In vivo* Mo-nitrogenase activity increases with increasing Mo concentrations reaching maximal levels at 100 nM. Mutants lacking ModABC require about 100-fold higher ambient Mo concentrations than the wild type to achieve comparable Mo-nitrogenase activities (Wang et al., 1993; Wiethaus et al., 2006). Double mutants lacking ModABC and the permease PerO require even higher Mo concentrations than *modABC* mutants to express active Mo-nitrogenase (Gisin et al., 2010). These and other findings support the conclusion that ModABC is essential for Mo uptake at nanomolar concentrations in the environment, while PerO is crucial for Mo import at micromolar concentrations. In addition to molybdate, PerO transports other oxyanions including tungstate, vanadate, and sulfate. In contrast to *modABC*, expression of *perO* appears to be independent of Mo availability (Gisin et al., 2010).

R. capsulatus harbors the divergently transcribed Mo-regulated (*mor*) genes, *morAB* and *morC*, coding for a putative ABC transporter exhibiting clear sequence similarity to ModABC (Wiethaus et al., 2006). Both MopA and MopB bind the *morA–morC* intergenic region, which encompasses a highly conserved Mo-box, and repress transcription of *morAB* and, to lesser extent, *morC*. In contrast to ModABC, however, MorABC is dispensable for Mo-nitrogenase activity.

MopA and MopB substitute (at least in part) for each other as repressor proteins controlling *anfA*, *mopA–modABC*, and *morAB* (Fig. 11.3). In addition, MopA acts as an activator of the *mop* gene, which encodes a hexameric molybdate-binding protein possibly involved in Mo-storage (Wiethaus et al., 2006, 2009). Remarkably, MopB does not substitute for MopA in *mop* activation. As one would expect for an activator-binding site, the *mop* Mo-box does not overlap the transcription start site but, instead, is located further upstream. A mutant *mop* promoter, in which the *mop* Mo-box is exchanged against the *anfA* Mo-box, is still activated by MopA demonstrating that an original repressor-binding site may well function as an activator-binding site, provided its correct positioning relative to the other *cis*-regulatory promoter elements (Müller et al., 2010).

The Mop protein specifically interacts with MopB but not with MopA (Wiethaus et al., 2009). It is tempting to speculate that Mop serves as an intracellular Mo buffer specifically donating molybdate to MopB. Alternatively, complex formation may prevent binding of target promoters by the regulator. In any case, Mop–MopB interaction is likely to modulate MopB-dependent gene regulation.

In summary, many details of the complex regulatory network controlling nitrogen metabolism in *R. capsulatus* have already been elucidated, but many open questions remain to be solved. Particularly, the regulatory effects of environmental signals other than nitrogen and molybdenum (e.g., light, oxygen, and iron) require future studies.

Chapter 12

Metabolic Regulation of Nitrogenase Activity in *Rhodospirillum rubrum*: The Role of PII Proteins and Membrane Sequestration

Stefan Nordlund
Department of Biochemistry and Biophysics, Stockholm University, Stockholm, Sweden

12.1 INTRODUCTION

In all diazotrophs, the expression of nitrogenase is regulated in response to the availability of biologically usable nitrogen and to the oxygen concentration in the cellular compartment where nitrogenase is located (Dixon and Kahn, 2004). This regulation can be understood as a means to economize the use of cellular energy, as the reaction catalyzed by nitrogenase has a high ATP demand, nitrogenase is present in high concentrations in the cell and is degraded in the presence of oxygen. Transcriptional regulation does however not lead to a rapid response, as would be required to react to sudden and short-term changes in the environment. In some diazotrophs however, there is yet another level of regulation, primarily sensing changes in the nitrogen supply and in the energy status. The response to an increased availability of nitrogen or a decrease in the energy level is inhibition of nitrogenase activity, a regulation at the metabolic level (Nordlund, 2000).

At the culture level, this control is displayed as the loss of nitrogenase activity when a source of combined nitrogen such as ammonium ions is added to the culture, or when the driving force for cellular ATP production is cut off (Nordlund, 2000). This phenomenon has been termed the "switch-off" effect and was first observed in *Rhodospirillum rubrum*.

In 1949, Kamen and Gest demonstrated that *R. rubrum* could fix nitrogen, and shortly after, they reported that when ammonium ions were added to a culture of nitrogen fixing *R. rubrum* the activity was inhibited, but recovered after a certain time (Gest, 1999; Gest and Kamen, 1949; Kamen, 1986). Schick some 20 years later rediscovered this effect and showed that the duration of inhibition was dependent on the concentration of ammonium ions added (Schick, 1971). Further studies showed that nitrogenase activity was not only inhibited *in vivo*, but the activity in extracts of cells to which NH_4^+ had been added was also lower (Neilson and Nordlund, 1975). Taken together, those reports laid the groundwork for the studies at the molecular level that were to follow.

12.2 THE "SWITCH-OFF" EFFECT AT THE MOLECULAR LEVEL

At the molecular level, the inhibition of nitrogenase activity is due to reversible modification of the Fe-protein of nitrogenase (Nordlund, 2000). In *R. rubrum*, the

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

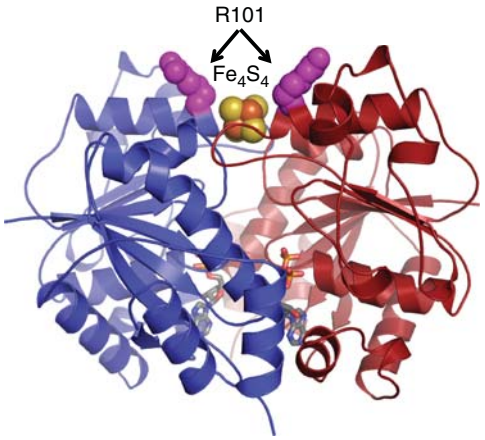

Figure 12.1 Structure of the Fe-protein of nitrogenase. The Fe_4S_4 cluster is indicated as well as the R101 residue (purple) in each subunit, of which only one is modified by ADP-ribosylation. At the bottom of the structure, the binding of one adenine nucleotide to each subunit is shown. This figure was produced using PyMOL. Fe-protein from PDB Id: 1N2C.

modification consists of an ADP-ribose moiety bound to arginine 101 (Pope et al., 1985a, b). The reaction leading to ADP-ribosylation is catalyzed by dinitrogenase reductase ADP-ribose transferase (DraT), whereas the removal of the modification is catalyzed by dinitrogenase reductase activating glycohydrolase (DraG) (Lowery and Ludden, 1988; Lowery et al., 1986; Saari et al., 1984, 1986; see also Chapter 11). With present knowledge about the nitrogenase complex and the docking between its two components, the MoFe-protein (dinitrogenase) and the Fe-protein (dinitrogenase reductase), the inhibitory effect of the modification is easily understood. Arg101 is located close to the Fe_4S_4 cluster donating electrons to the P-cluster in the MoFe-protein, and in the middle of the area involved in the docking to the MoFe-protein (Fig. 12.1). The effect of the ADP-ribosylation is thus that the two proteins cannot interact and no electron transfer can take place.

In Figure 12.2, the "switch-off" effect in *R. rubrum* is schematically depicted. At the addition of a "switch-off" effector, for example, NH_4^+ or glutamine, or the removal of the culture from the light, there is a rapid loss of nitrogenase activity. When the effector added has been metabolized or the light is turned on, nitrogenase activity is regained (Fig. 12.2a). This series of events is due to the modification of the Fe-protein catalyzed by DraT, leading to loss of nitrogenase activity followed by the removal of the ADP-ribose group in the reaction catalyzed by DraG (Fig. 12.2b).

The activity of DraT and DraG are in turn regulated so that they are not active at the same time (Fig. 12.2a). It has been shown that DraT is only active for a short time (Liang et al., 1991), whereas DraG is active except during "switch-off." Both of these regulatory enzymes are active as isolated, which means that the regulation of DraT is lost upon cell breakage.

12.3 THE DraT AND DraG PROTEINS

12.3.1 DraT

DraT is a monomeric protein with a molecular mass of 30 kda (Lowery and Ludden, 1988, 1989; Lowery et al., 1986), catalyzing the modification of the Fe-protein in a reaction where NAD^+ is the donor of the ADP-moiety. MgADP is required for the reaction with the *R. rubrum* Fe-protein as substrate, whereas MgATP is inhibitory. DraT will only ADP-ribosylate the Fe-protein, but not only the one from *R. rubrum*. It has however been shown that some NAD^+ analogs can serve as donor of the ADP-ribose group *in vitro*. When DraT was purified from *R. rubrum* it was noticed that the fraction with activity also contained a contamination running at about 13 kda on SDS-PAGE (Lowery and Ludden, 1988). This can now be explained as we have found that DraT from *R. rubrum* requires GlnB, a PII protein (see below), not only for activity but also for stability (Selao, Teixeira, Nordlund unpublished). In addition, our recent results suggest that binding to GlnB increases the affinity for NAD^+. So far no crystal structure of DraT is available, but it would obviously be important in elucidating its catalytic function and the regulation of its activity possibly by the interaction with GlnB.

To analyze the activity of DraT, the loss of nitrogenase activity can be used, and also more convenient, the fact that only one of the two identical subunits of the Fe-protein is modified (Fig. 12.2). This gives rise to two bands on SDS-PAGE gels using a low crosslinker concentration, with equal amounts of the two bands obtained with fully ADP-ribosylated Fe-protein (Kanemoto and Ludden, 1984).

12.3.2 DraG

R. rubrum DraG has also been purified and characterized. It is a monomeric protein, with a molecular mass of 32 kda (Saari et al., 1984, 1986; Zumft and Nordlund, 1981). In *R. rubrum* extracts, DraG is found associated with the chromatophore membrane; as a first step in the purification, it is solubilized by a washing with 0.5 M NaCl (Ludden and Burris, 1976; Nordlund et al., 1977). The catalysis of the hydrolysis of the ADP-ribose group from the Fe-protein requires the presence of MgATP and another divalent cation. We have shown that Mn^{2+} most likely is the ion functioning *in vivo*, but *in vitro* Fe^{2+} is equally efficient. There is no activity with only Mg^{2+} present *in vitro* (Nordlund and Noren, 1984). In contrast to DraT, DraG will use denatured ADP-ribosylated Fe-protein as substrate as well as some low molecular mass compounds (Pope et al., 1986; Saari et al., 1984, 1986).

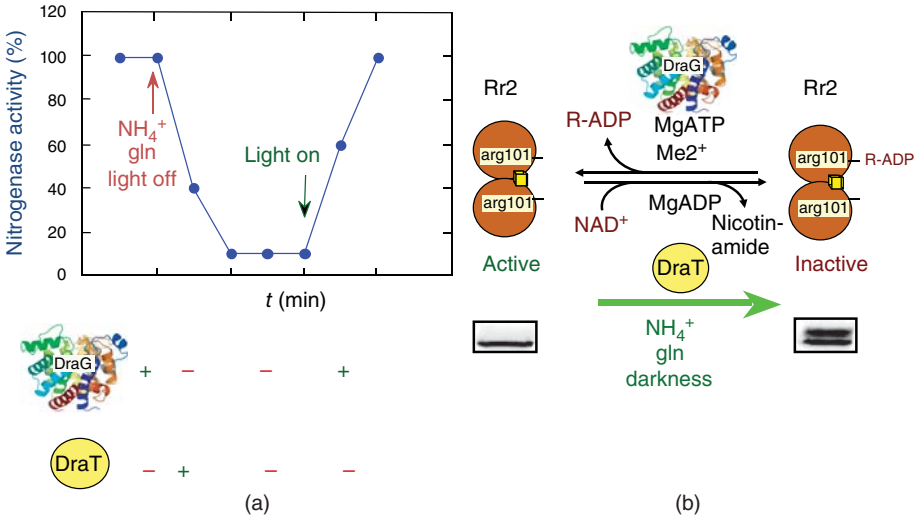

Figure 12.2 Schematic illustration of "switch-off" in *R. rubrum*. (a) The effect on nitrogenase activity upon addition (at red arrow) of ammonium ions (NH_4^+) or glutamine (gln) or turning off the light. Under the diagram, the activity of DraT and DraG before, during, and after the "switch-off" is indicated. (b) Schematic showing the reactions catalyzed by DraT and DraG. Rr2 denotes the Fe-protein from *R. rubrum*. Underneath Rr2, the appearance of the two bands on SDS-PAGE of modified Rr2 is shown.

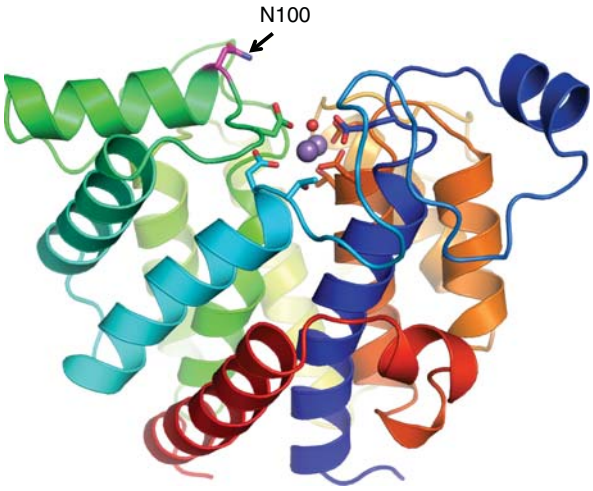

Figure 12.3 The structure of DraG from *R. rubrum*. Asparagine 100 is indicated and the two purple spheres are the two manganese ions in the active site. This figure was produced using PyMOL. DraG from PDB id: 2WOC.

A key to understanding the function of DraG is the 3D structure, which we were recently able to determine for *R. rubrum* DraG (Berthold et al., 2009). The structure (Fig. 12.3) shows an all helical compact protein composed of 16 helices. The active site is located deep in a grove between loops and contains two manganese ions. Based on a structure in which an ADP-ribose was trapped, a catalytic mechanism was proposed (Berthold et al., 2009). This was further verified by specific substitutions of key amino acids (Berthold et al., 2009) and has gained further support from computational studies (Himo, Manta, personal communication).

12.3.3 The *draT* Operon

Both DraT and DraG are constitutively expressed but at very low concentrations in the cell. The *draT* and *draG* genes form an operon located close to the *nifH* gene, encoding the Fe-protein. The *draT* operon is however transcribed in the opposite direction (Fitzmaurice et al., 1989; Liang et al., 1991). In addition to *draT* and *draG*, the *R. rubrum* operon contains a third gene *draB*, located downstream of *draG*, encoding a 16-kda peptide of unknown function (Zhang et al., 2001a).

12.4 REGULATION OF DraT AND DraG ACTIVITIES

One of the key challenges is to understand how DraT and DraG are regulated. Over the years, there have been many proposals, but today it is generally agreed that PII proteins and AmtB are both central to this regulation, at least during nitrogen "switch-off."

12.4.1 PII Proteins and AmtB

PII proteins are homotrimeric proteins of 42 kda that function in signal transduction in regulation and coordination of carbon and nitrogen metabolisms. They have been identified in diazotrophic *Archaea*, all bacterial domains, as well as in the chloroplast of plants and red algae (reviewed in Arcondeguy et al. (2001), Forchammer (2008), and Ninfa and Jiang (2005)). The structure of PII proteins has been solved from a number of organisms and shows a cylindrical core with three protruding loops on the top of the cylinder, the T-loops, one from each subunit. In addition, there are three ATP/ADP binding sites and three binding sites for 2-oxoglutarate. The

binding of these effector molecules induces different conformations of the T-loops. PII proteins interact with other proteins, thereby conveying a signal reflecting the metabolic carbon and nitrogen status as well as the cellular energy level. There are two different means by which PII proteins can be affected by the metabolic status; by binding ATP, ADP, and 2-oxoglutarate; and/or by covalent modification, uridylylation. Clearly, the ATP/ADP ratio reflects the energy status, whereas 2-oxoglutarate is an indicator of the carbon/nitrogen balance. In Protobacteria, the reversible uridylylation is catalyzed by the bifunctional enzyme GlnD and occurs at a conserved tyrosine in the T-loop. GlnD is regulated by the concentration of either glutamine or 2-oxoglutarate, depending on the organism and its metabolism, but in both cases reflecting the nitrogen status (Jiang et al., 1998; Jonsson and Nordlund, 2007). Uridylylation affects the binding of PII proteins to their targets, as this in most cases involves the T-loop.

One PII protein target is the ammonia channel AmtB, a trimeric membrane protein belonging to the Amt/Rh family of transport proteins and mediating transport of ammonia/ammonium ions into the cell (Forchammer, 2008; Khademi et al., 2004; Tremblay and Hallenbeck, 2009). It has been suggested that in addition to the role as a transporter, it is also involved in the regulation of metabolism in response to the extra cellular concentration of ammonium ions (Javelle et al., 2004). It is in this function that PII proteins have a role.

In some seminal work, it was shown that PII proteins form a complex with AmtB in *Escherichia coli*, and that this only occurs with the unmodified form of the PII protein. The structure of the complex has been determined and shows that each T-loop of the PII protein is inserted into one of the three subunits of AmtB, and that the PII protein thereby blocks the transport channels, hindering the influx of ammonia (Conroy et al., 2007; Durand and Merrick, 2006; Javelle and Merrick, 2005).

In most bacteria, there are more than one PII protein. In *E. coli* there are two paralogs, GlnB and GlnK, of which the latter is believed to be the physiologically AmtB-binding PII protein. In *R. rubrum*, there are three paralogs, GlnB, GlnJ, and GlnK (Zhang et al., 2001b). GlnJ is a K-type paralog, and its gene is located in the same operon as the gene encoding AmtB1, an organization that is quite common. There is also an AmtB2 protein in *R. rubrum*, but as for the GlnK protein, no function has yet been identified.

In *R. rubrum*, GlnJ in the unmodified form has been shown to bind to AmtB1, and this occurs under conditions of nitrogen sufficiency (Wang et al., 2005). The role of GlnB is most likely similar to the one in *E. coli*, that is, interacting with other PII protein targets such as GlnE and NtrB.

12.4.2 Regulation of DraT Activity

Upon the addition of "switch-off" effectors, DraT becomes active catalyzing the transfer of the ADP-ribose moiety from NAD^+ to arg101 in one of the subunits of the Fe-protein. However, as isolated DraT is inactive or shows very low activity, the latter may be due to the presence of a (contaminating) PII protein. Relatively little is known of the regulation of DraT, but our current model for nitrogen "switch-off" in *R. rubrum* stipulates that binding of GlnB to DraT leads to activation, presumably by increasing its affinity for NAD^+.

For energy "switch-off," even less is known. It has been shown that when subjecting a culture of *R. rubrum* to darkness, the ratio of NAD^+ to NADH is dramatically increased (Jackson and Crofts, 1968). One possible model would therefore be that the much higher NAD^+ concentration is sufficient to support high DraT activity, even without GlnB binding. It should be noted that we have shown that "switch-off" does not require deuridylylation of neither GlnB nor GlnJ in *R. rubrum* (Teixeira et al., 2010). As uridylylated GlnB/GlnJ has not been shown to be able to bind to AmtB1 or DraT, it can be assumed that GlnB–DraT interaction is not required for DraT activity during energy "switch-off."

12.4.3 Regulation of DraG Activity

It is a consensus today that DraG inactivation is due to sequestration to the chromatophore membrane upon exposure of a *R. rubrum* culture to "switch-off" conditions. Kim et al. (2004) showed that a DraG mutant in which N100 had been substituted for a lysine did not show normal "switch-off," that is, this strain would not show normal decrease in activity. We have made the same substitution and could verify the results by Zhang et al., but could also show that the DraG variant was active *in vitro* and did not bind to the chromatophore membrane. As N100 is located close to the entrance to the catalytic site of DraG, we postulate that upon binding to the membrane, the catalytic site is covered preventing access to the ADP-moiety of the modified Fe-protein. Other substitutions of N100 are also active *in vitro*, but in contrast they are sequestered to the membrane and the "switch-off" effect is normal in these mutants.

A major question is however the identity of the signal(s) that leads to binding to the membrane. A number of candidates have been suggested, but today we see two different processes in *R. rubrum*, one during nitrogen "switch-off" and the other for energy "switch-off." In both cases, we envisage that DraG binds to an unknown membrane protein that changes its conformation from nonbinding to binding of DraG under both conditions. Upon addition of a nitrogen effector, for example, NH_4^+, uridylylated GlnJ becomes deuridylylated in the reaction catalyzed by GlnD and in this form binds to AmtB1. Upon binding of GlnJ, AmtB1

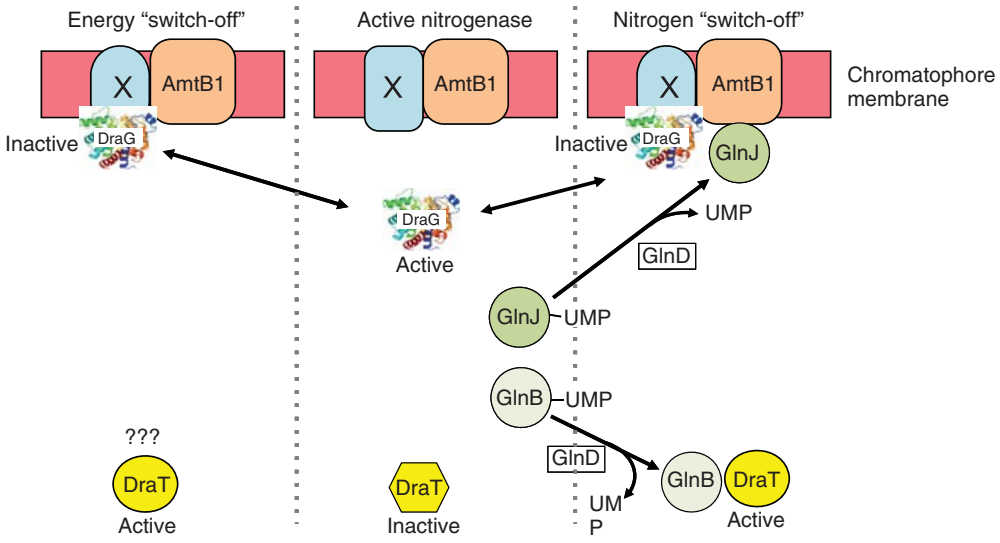

Figure 12.4 Schematic representation of our model of events taking place during "switch-off." In the middle, the situation during high nitrogenase activity is shown, both PII proteins, GlnB and GlnJ, are uridylylated and cannot bind to targets. DraT is inactive and DraG is active. The right part shows the situation during nitrogen "switch-off." GlnJ is bound to AmtB1 after deuridylylation by GlnD. AmtB1 affects the unknown protein (X), making it a binding partner for DraG, which then is inactive. GlnB interacts with DraT after deuridylylation by GlnD, activating DraT. The left part shows the situation during energy "switch-off." Much less is known, but we suggest that X has adopted the DraG-binding conformation because of a lowered membrane potential. The higher DraT activity may be due to an increase in the NAD^+/NADH ratio.

changes its conformation, which in turn causes the unknown DraG-binding protein to adopt a confirmation that promotes binding of DraG. When the NH_4^+ added is metabolized, GlnD catalyzes uridylylation of GlnJ, which then cannot bind to AmtB1. AmtB1 and therefore also the DraG-binding protein, go back to the original conformation. All leading to DraG being released from the membrane.

Much less is known about the process during energy "switch-off," but according to our model turning off the light leads to a change in the membrane potential that can be relayed to the unknown DraG-binding protein, causing a change in its conformation. The model is supported by the fact that even under nitrogen-sufficient conditions, that is, under conditions when neither AmtB1 nor GlnJ are expressed, DraG is found associated with the membrane.

Our model for the regulation of DraT and DraG activities is depicted in Figure 12.4, but it should be emphasized that there may be other factors involved, one such is the redox state of the Fe-protein (Halbleib et al., 2000). It has been shown that the reduced form is a better substrate for DraG, whereas the oxidized Fe-protein is the preferred substrate for DraT. Even if redox is not the major or required signal, it may have some influence during energy "switch-off" as we have shown that the physiological electron transfer leading to reduction of the Fe-protein in *R. rubrum* requires light (Edgren and Nordlund, 2004).

12.5 DraT AND DraG IN OTHER ORGANISMS

The "switch-off" effect has also been studied in other phototrophs, primarily in *Rhodobacter capsulatus* (Tremblay et al., 2007; Tremblay and Hallenbeck, 2008; see Chapter 11), and in *Rhodopseudomonas palustris* (Zumft and Castillo, 1978). In neither of these organisms have, however, detailed studies at the molecular level been reported. This is in contrast to the work on *Azospirillum brasilense*, from which detailed biochemical as well as structural studies have contributed substantially to our understanding of the processes during "switch-off" (Huergo et al., 2007. 2012; Li et al., 2009; Ljungström et al., 1989; Zhang et al., 1997). It should be noted that the model for *A. brasilense* differs in some aspects from the one we propose for *R. rubrum*. One difference is that DraG is inactivated by binding to an unidentified protein in the chromatophore membrane, whereas for *A. brasilense* it is has been suggested that binding to GlnZ leads to inactivation (Rajendranan et al., 2011; see Chapter 13).

As DraT and DraG are expressed under all conditions in *R. rubrum*, it could be suggested that these regulatory proteins have additional functions, perhaps in *R. rubrum* and also in other organisms. A list of some 40 organisms having a *draT* gene was recently published (Huergo et al., 2012). A recent search in the presently sequenced genomes shows that *draT* and *draG* can be found in about 60 genomes. Evidently,

a closer analysis is required to be able to draw conclusions on any possible additional function(s) of these proteins, for example, are they expressed, do they form an operon, and is the organism a diazotroph.

12.6 CONCLUDING REMARKS

Our knowledge about the "switch-off" effect has increased tremendously since the first demonstration by Gest and Kamen about 60 years ago, and even compared to the contribution by Schick 20 years later. Today, the molecular details of the proteins involved are in most cases known, but the interactions between DraT and DraG with their partners in the regulatory mechanism are yet to be clearly established. In spite of great similarities at the protein level, the models for "switch-off" in *R. rubrum* and *A. brasilense* show differences that need to be understood. A major question is the regulatory events at the molecular level during energy "switch-off," be it by darkness in *R. rubrum* or by oxygen removal in *A. brasilense*.

ACKNOWLEDGMENT

The work from my laboratory has been carried out by many coworkers financed by grants from the Swedish Research Council. I am especially grateful to Dr Agneta Norén. I also want to thank Dr Ray Dixon for very fruitful discussions.

13.1 INTRODUCTION

13.1.1 The *Azospirillum brasilense* Nitrogen-Fixation System

Azospirillum brasilense is an aerobic Alphaproteobacteria diazotroph. This bacterium lives in the soil on its own or is associated with the rhizosphere of various plants fixing nitrogen gas from the atmosphere. Therefore, *Azospirillum* has been utilized as nitrogen biofertilizer and plant growth promoting rhizobacterium (PGPR) by farmers worldwide to improve crop productivity (Bashan et al., 2004). The nitrogen-fixation genes (*nif*) are responsible for the nitrogen-fixation ability; these genes are highly conserved among all nitrogen-fixing bacteria. The most common form of nitrogenase is the iron-molybdenum form that is composed of dinitrogenase (MoFe protein or NifDK) and dinitrogenase reductase (Fe protein or NifH) (Dixon and Kahn, 2004).

The reduction of one N_2 to two NH_3 by nitrogenase requires the hydrolysis of at least 16 ATP molecules. In order to optimize the use of energy and fixed nitrogen, most diazotrophs can shut down or turn-on the nitrogen-fixation system according to the availability of nitrogen sources in the environment. Nitrogenase regulation can occur at both transcriptional and posttranslational levels (Dixon and Kahn, 2004; Huergo et al., 2012).

The transcriptional activator NifA coordinates the transcription of the *nif* genes in Proteobacteria (Dixon and Kahn, 2004). In *A. brasilense*, NifA is constitutively expressed (Fadel-Picheth et al., 1999), but the protein is inactive under conditions of excess O_2 or NH_4^+ (Arsene et al., 1996). Activation of NifA upon removal of NH_4^+ requires the signal transduction P_{II} protein GlnB (Arsene et al., 1996; Araujo et al., 2004; Sotomaior et al., 2012). A conserved NifA motif containing four cysteines is likely to be involved in the inactivation of NifA under high oxygen levels (Dixon and Kahn, 2004).

13.2 REVERSIBLE ADP-RIBOSYLATION REGULATES NITROGENASE ACTIVITY IN *A. brasilense* AT A POSTTRANSLATIONAL LEVEL

Once synthesized, the nitrogenase enzyme of *A. brasilense*, as well as of some other diazotrophs, is reversibly inactivated *in vivo* in response to the availability of NH_4^+ (Huergo et al., 2012). In *A. brasilense*, this inactivation

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

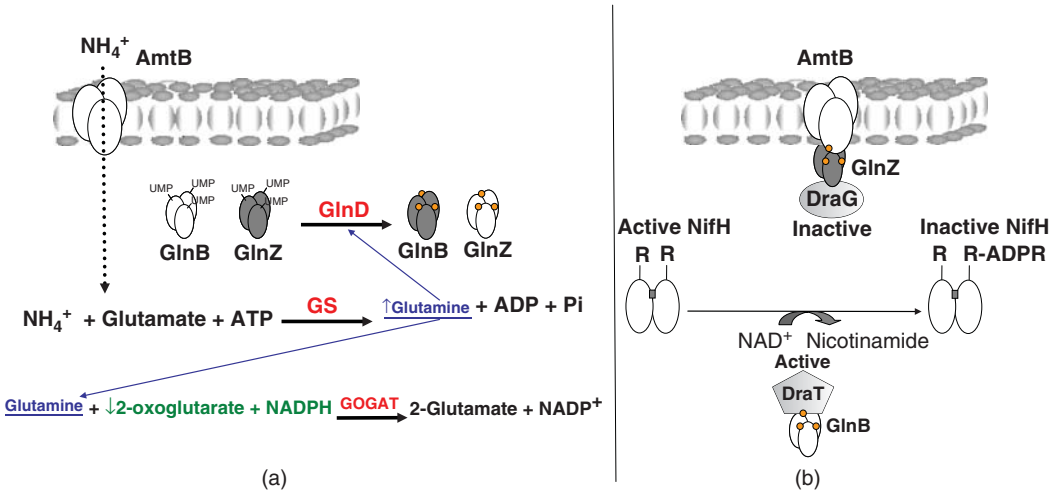

Figure 13.1 Role of the P_{II} proteins in the regulation of nitrogenase activity in *A. brasilense*. (a) When nitrogen-limited cells find ammonium in the external media, NH_4^+ is assimilated through the GS/GOGAT pathway causing an increase in the intracellular glutamine and a decrease in the 2-oxoglutarate. Glutamine binds to the GlnD enzyme, favoring the removal of UMP groups from the P_{II} (GlnB and GlnZ) T-loops. This decrease in the 2-oxoglutarate facilitates the binding of ADP (represent by orange dots) to P_{II}. (b) Few seconds after the ammonium shock, DraT is activated by the interaction with GlnB-promoting NifH-ADP-ribosylation and switching off nitrogenase activity. At the same time, DraG is inactivated by membrane sequestration through the formation of the AmtB–GlnZ–DraG ternary complex on the membrane.

involves ADP-ribosylation of the Fe-protein (dinitrogenase reductase NifH) that is catalyzed by dinitrogenase reductase ADP-ribosyltransferase (DraT) (Fig. 13.1b). Nitrogenase inactivation is reversed, after consumption of NH_4^+ by the cellular metabolism, through the action of dinitrogenase reductase activating glycohydrolase (DraG) (Huergo et al., 2012).

The activities of both DraT and DraG are oppositely regulated according to the levels of ammonium. Under nitrogen-fixation conditions, DraT is inactive and DraG is active. When external ammonium becomes available, DraT is activated while DraG is inactivated (Huergo et al., 2012). The activities of both DraT and DraG are regulated through interactions with P_{II} signal transduction proteins (Fig. 13.1; see also Chapters 11, 12).

Nitrogenase can also be ADP-ribosylated under low energy conditions such as anaerobiosis (in the organotroph *A. brasilense*) or darkness (in the phototroph *Rhodospirillum rubrum*; see Chapter 12). When oxygen or light return to optimum levels, the ADP-ribosyl attached to nitrogenase is removed by DraG. The mechanism that regulates DraT and DraG in response to the energy (oxygen or light) is still elusive. In contrast, much more is known about the ammonium signaling pathway. In the latter case, the P_{II} signaling proteins regulate DraT and DraG reciprocally (Huergo et al., 2012).

13.3 P_{II} PROTEINS REGULATE DraT AND DraG ACTIVITY

The P_{II} proteins constitute a family of highly conserved trimeric proteins that regulate the nitrogen and carbon metabolism in prokaryotes and plants (Huergo et al., 2013). P_{II} proteins can bind ATP, ADP, and 2-oxoglutarate (2-OG), and these molecules are called "P_{II} effectors" (Huergo et al., 2013). ATP and ADP bind to the same site at the interface between two subunits of P_{II} trimers in a competitive manner and with different affinities (Jiang and Ninfa, 2009). Each P_{II} trimer can bind up to three adenine nucleotide molecules; therefore, there are different possible combinations of bound ATP/ADP for P_{II} trimers (da Rocha et al., 2013). The three 2-OG binding sites are also located in the lateral clefts between P_{II} subunits, and 2-OG binding is dependent on the presence of bound MgATP (Truan et al., 2010; Fokina et al., 2010) (Fig. 13.2).

The effector ligands affect the P_{II} structure mainly at the base of a long, flexible loop known as "the T-loop" (Fig. 13.2). As a result, the energy landscape of T-loop conformations is differently affected by the different ligands modulating the ability of P_{II} to interact (through The T-loop) with various target proteins including enzymes, transcriptional factors, and transporters (Huergo et al., 2013). In some prokaryotes, the possible T-loop conformations and interactions are also influenced by covalent posttranslational modification of some of its residues.

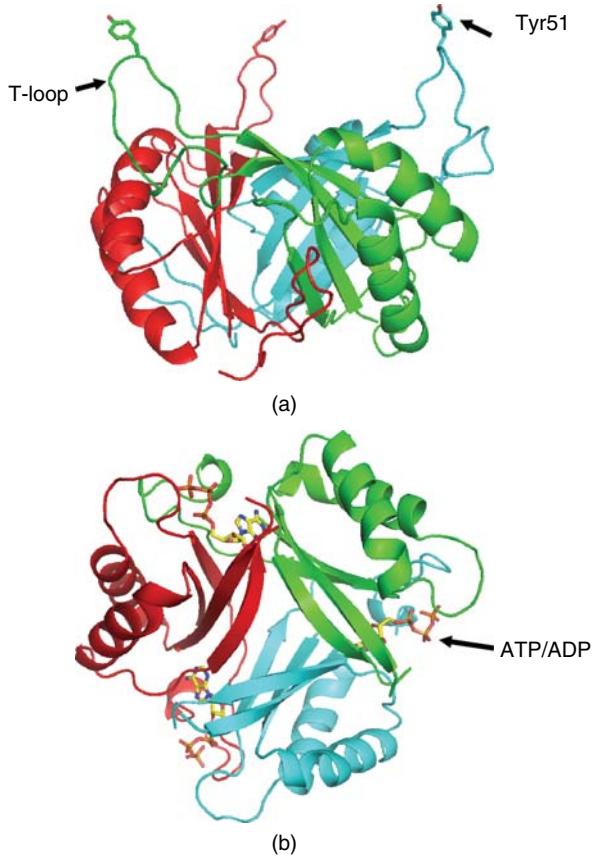

Figure 13.2 Characteristic structural elements the P_{II} proteins. (a) The arrows indicate the T-loop and the conserved Tyr51 residue. (b) The arrow indicates the lateral clefts between each P_{II} subunit where ATP and ADP bind competitively. (*Source*: From Huergo et al., FEMS Microbiol. Rev. 2013 37(2):251–283.)

Two P_{II} proteins, namely GlnB and GlnZ, are encoded by the *A. brasilense* genome (de Zamaroczy et al., 1996). Under nitrogen-limiting conditions, each monomer of GlnB and GlnZ is covalently modified by uridylylation of the T-loop residue Tyr51 (Fig. 13.1a). When ammonium is available in the environment, GlnB and GlnZ are de-uridylylated by GlnD, a bifunctional enzyme catalyzing the uridylylation/de-uridylylation process (Araujo et al., 2008). The switch between the GlnD opposing enzymatic activities is dictated by the intracellular availability of glutamine which, in turn, depends on the environmental levels of ammonium (Fig. 13.1a; see also Chapters 11, 12).

In vivo pull-down experiments in *A. brasilense* revealed physical interactions between DraT–GlnB and DraG–GlnZ, suggesting that DraT and DraG activities are controlled by interactions with the P_{II} proteins (Huergo et al., 2006a, b). The P_{II} effectors and uridylylation affect the complex formation between DraT–GlnB and DraG–GlnZ *in vitro* (Huergo et al., 2012). Both complexes are more stable when the P_{II} proteins are de-uridylylated (high nitrogen level) and when the ATP/ADP ratio and the 2-OG levels are low (Huergo et al., 2012). A decrease in the 2-OG levels signals abundance of available fixed nitrogen in Prokaryotes (Dodsworth et al., 2005; Yuan et al., 2009; Radchenko et al., 2010); therefore, the DraT–GlnB and DraG–GlnZ complexes are stabilized when the ammonium supply is abundant, that is, high glutamine and low 2-OG (Fig. 13.1a). The interaction between DraT and GlnB leads to DraT activation *in vitro*, promoting NifH ADP-ribosylation and thus nitrogenase inactivation when ammonium is sufficiently available in the environment (Moure et al., 2013). In order to avoid a futile cycle of nitrogenase ADP-ribosylation, DraG must be inactivated upon DraT activation. Hence, complex formation between DraG and GlnZ in response to increased ammonium and thus DraT activation must result in DraG inactivation. In order to understand how the interaction between DraG and GlnZ may affect DraG activity, the X-ray structure of the DraG–GlnZ complex was determined in the presence of ADP at 2.1 Å.

In contrast to all other known P_{II}–target protein complex studies, so far the DraG–GlnZ complex does not depend on the formation of contacts involving the T-loop. Indeed, a GlnZ variant carrying a T-loop deletion is still able to interact with DraG (Rajendran et al., 2011). Instead, a lateral surface region of the trimer comprising two GlnZ monomers is the site for DraG interaction (Fig. 13.3).

Comparison between the structures of GlnZ bound to Mg-ATP/2-OG and the structure of GlnZ bound to ADP within the DraG–GlnZ complex explains how increased 2-OG can negatively affect the DraG–GlnZ interaction. With Mg-ATP/2-OG bound, the GlnZ T-loops extend at nearly 90° to the GlnZ trimer axis, and this conformation would severely clash with bound DraG. By contrast, with bound ADP the largely disordered GlnZ T-loops appear to extend more parallel to the trimer axis and therefore avoid clashing into bound DraG (Fig. 13.4). On the other hand, comparison of the DraG structure with and without bound GlnZ does not show any significant conformational changes in DraG upon interaction with GlnZ. DraG activity, when assayed using a low molecular mass of artificial substrate *in vitro*, is unaffected in the presence of GlnZ (Li et al., 2009; Rajendran et al., 2011), indicating that the interaction with GlnZ does not affect the catalytic machinery nor prevent access of this low molecular mass substrate to the active site of DraG. *In vivo* DraG inactivation in response to ammonium is therefore not simply explained by GlnZ complex formation and requires additional considerations.

Experimental data indicate that a critical component for DraG inactivation is the ammonium transporter protein AmtB (Huergo et al., 2006b). The AmtB protein is an integral membrane protein that forms a pore to conduct ammonia across the cell membrane (Zheng et al., 2004; Fig. 13.1a). When the *amtB* gene of *A. brasilense* is disrupted, the cells fail to ADP-ribosylate nitrogenase but are unaffected in their

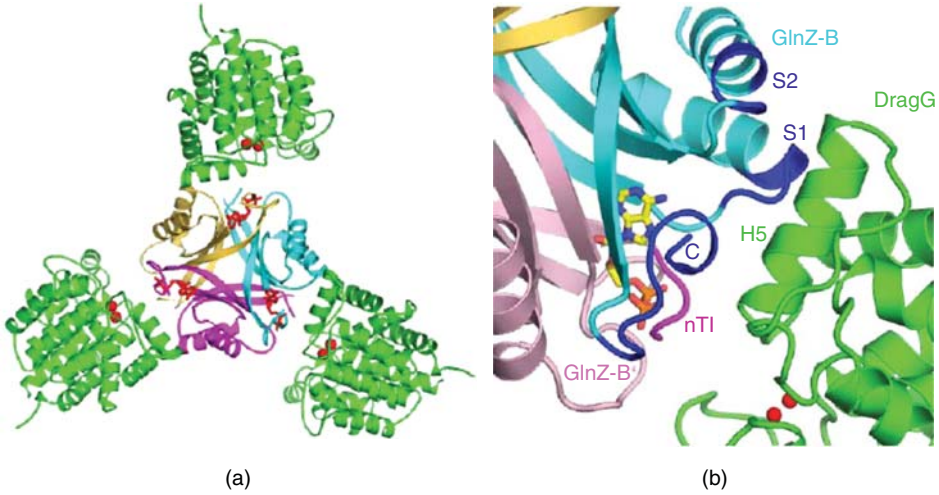

Figure 13.3 Structure of the trimeric *A. brasilense* DraG–GlnZ complex. (a) Cartoon representation of three DraG monomers (green) bound to the central GlnZ trimer (cyan, light pink, and orange). The ADP molecules bound in the lateral clefts between GlnZ chains are shown as red sticks, the two Mg^{2+} ions are present in the active site of each DraG monomer as red spheres. (b) Closeup of the DraG–GlnZ interface involving the two GlnZ monomers B and B′ (cyan and magenta, respectively). The DraG-interacting chain segments S1, S2, and C of monomer GlnZ-B are emphasized in dark blue; the N-terminal part of the interacting T-loop of chain GlnZ-B′ in magenta, and ADP is shown in yellow sticks. (*Source*: Figure 1 from Rajendran C PNAS 2011 108(47):18972–6.)

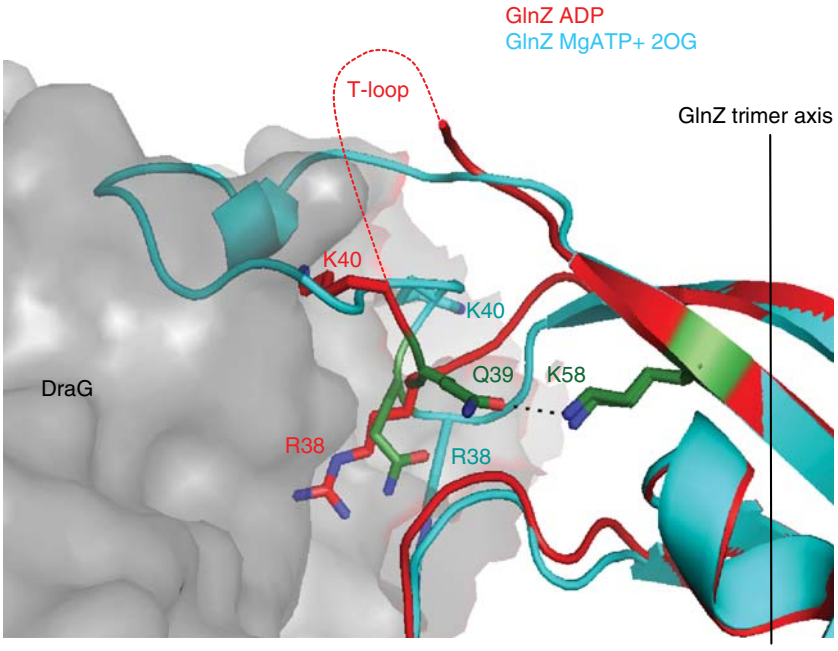

Figure 13.4 Comparison between the structures GlnZ bound to Mg-ATP and 2-OG, and the structure of GlnZ bound to ADP within the DraG–GlnZ complex. The structure of GlnZ bound to MgATP and 2-OG (cyan) was superimposed to the structure of the GlnZ bound to ADP within the DraG–GlnZ complex (red). The DraG surface is shown in gray. Key GlnZ residues that stabilize the different GlnZ T-loop conformations are indicated by sticks. The part of the GlnZ T-loop that was not resolved in the DraG–GlnZ is represented by a dashed red line.

capacity to take up ammonium from the media. The failure of the *amtB* mutant to modify nitrogenase correlates with defects in DraG inactivation rather than DraT activation (Huergo et al., 2006b). Interestingly, the GlnZ–DraG complex is still formed in the *amtB* mutant background (Huergo et al., 2006a), again supporting the fact that the GlnZ–DraG interaction is not sufficient for DraG inactivation.

The AmtB protein is the best described protein whose activity is regulated by the interaction with P_{II} proteins. When the ammonium level rises, there is a decrease in the intracellular 2-OG, which facilitates the occupancy of the P_{II} trimer by ADP (Radchenko et al., 2010; Gerhardt et al., 2012; da Rocha et al., 2013). Bound ADP stabilizes a P_{II} T-loop conformation that can bind at the cytoplasmic face of

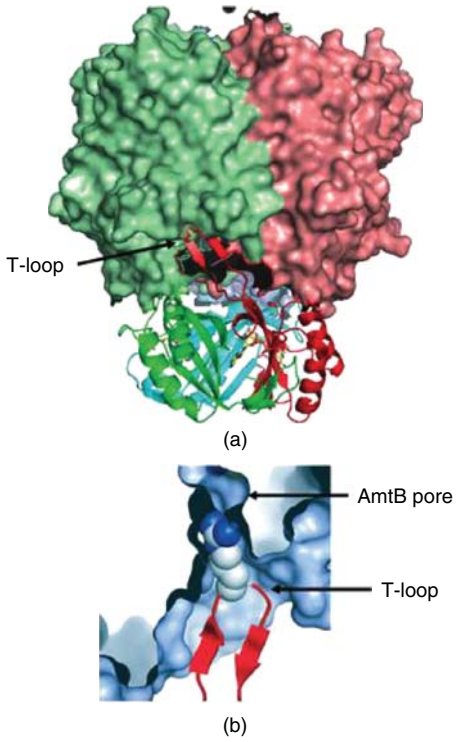

Figure 13.5 The *E. coli* AmtB–GlnK complex. (a) Overview of the complex. (b) Detail view of T-loop insertion of AmtB cytoplasmic channel exit. (*Source*: Figure 1B/Figure 5C from Conroy MJ et al. PNAS 2007, 104(4):1213–8.)

the ammonia pore of AmtB blocking the transporter activity (Coutts et al., 2002; Javelle et al., 2004; Conroy et al., 2007; Rodrigues et al., 2011) (Fig. 13.5).

In vitro analysis showed that in *A. brasilense*, the AmtB, GlnZ, and DraG proteins can form a ternary complex in the presence of ADP (Huergo et al., 2007). This is supported by *in vivo* data showing that DraG binds to the membrane in a GlnZ–AmtB dependent manner when the ammonium levels rise (Huergo et al., 2006b). Indeed, the AmtB–GlnZ–DraG ternary complex can be easily modeled based on the *Escherichia coli* AmtB–GlnK and *A. brasilense* GlnZ–DraG structures without structural clashes (Fig. 13.6).

The model structure of the AmtB–GlnZ–DraG complex clearly shows that the ADP-ribosylated NifH would not be able to access DraG, causing DraG inactivation by steric hindrance of its active site (Fig. 13.6). However, this also holds true for the GlnZ–DraG binary complex; a structural model of ADP-ribosylated NifH cannot be accommodated in the DraG active site without severe clashes between the NifH and GlnZ structures (Fig. 13.6) (Rajendran et al., 2011; Huergo et al., 2006a). If DraG–GlnZ complex formation, known to occur after an ammonium pulse in this genetic background, were sufficient to inactivate DraG, how could the *amtB* mutant fail to inactivate DraG?

The answer to this question may be related to the flexibility of the GlnZ T-loop. In the DraG–GlnZ complex, the GlnZ T-loop remains rather mobile as it cannot be seen in the electron density (Fig. 13.5). The intrinsic mobility of the GlnZ T-loop would be further restricted upon interaction with DraG imposing an entropic penalty on the formation of the DraG–GlnZ complex. Indeed, a GlnZ variant carrying a T-loop deletion binds more avidly to DraG. This is further supported by calorimetric analysis of the DraG–GlnZ complex (Rajendran et al., 2011) that shows a positive value for the term $-T\Delta S$ in the Gibbs free energy equation. As a result, the complex between DraG and GlnZ has an overall modest affinity (1.5 μM) and ADP-ribosylated NifH may be able to out-compete GlnZ for DraG binding, allowing

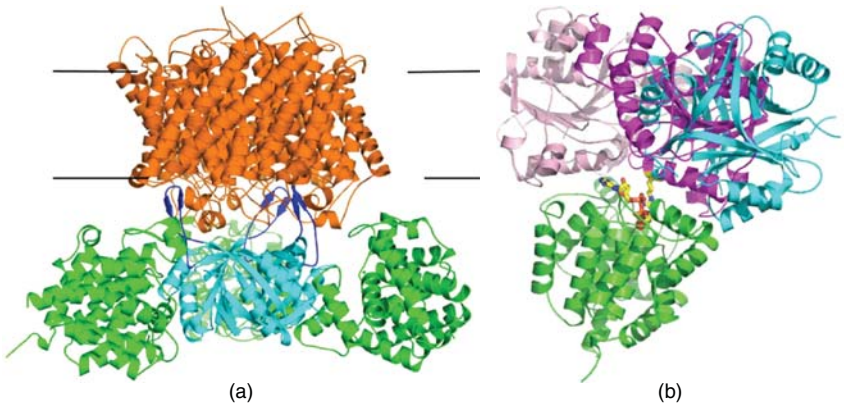

Figure 13.6 Cartoon representation of a putative *A. brasilense* AmtB–DraG–GlnZ ternary complex and a modeled DraG–NifH complex. (a) The *E. coli* AmtB (orange)–GlnK (cyan) complex (2NUU) was superimposed on the *A. brasilense* complex of DraG (green) with GlnZ (not shown for clarity) using their structurally very similar P_{II} trimers. The (ordered) GlnK T-loops are emphasized in dark blue. (b) Illustration of the steric overlap between the DraG (green)–GlnZ (cyan) complex and a modeled complex of DraG with a mono-ADP-ribosylated NifH dimer (light pink and magenta subunits). The ADP-ribosylated R101 side chain is shown in yellow stick representation, and the Mg^{2+} ion is shown at the DraG active site as a red sphere. (*Source*: Figure 4 from Rajendran C PNAS 2011 108(47):18972–6.)

the ADP-removal reaction to occur even after a rise in ammonium in an *amtB* background.

On the other hand, after an ammonium shock in the presence of AmtB, the AmtB–GlnZ–DraG complex forms and the GlnZ T-loop will be in a fixed position as it engages in interactions with the cytosolic face of AmtB (Fig. 13.6). This would reduce the entropic penalty for DraG binding such that DraG binding to AmtB-bound GlnZ would be considerably enhanced, and competition by ADP-ribosylated NifH would be more strongly prohibited.

13.4 CONCLUSIONS

The solution of the crystal structures of DraG and of the DraG–GlnZ complex has facilitated the comprehension of the nitrogenase ADP-ribosylation system in *A. brasilense.* These protein structures together with biochemical data and *in vivo* studies support a model where DraG is inactivated by the formation of a ternary complex involving DraG, the P_{II} protein GlnZ, and the ammonium transporter protein AmtB on the cell membrane (Fig. 13.1). The formation of the AmtB–GlnZ–DraG complex would impede the access of ADP-ribosylated NifH to the DraG active site, thereby inactivate DraG in response to ammonium.

The model for the regulation of DraG in *A. brasilense* presented here shares some similarities to the one proposed to operate in *R. rubrum* (Nordlund and Hogbom, 2013; see Chapter 12). In the latter organism, it is believed that both the AmtB and P_{II} participate in the inactivation of DraG in response to ammonium; this inactivation would also involve the binding of DraG to the cell membrane. However, the formation of a ternary complex between AmtB, P_{II}, and DraG has been excluded in the *R. rubrum* model. In contrast, DraG would bind to the membrane through direct contact with an unknown membrane protein (Nordlund and Hogbom, 2013).

Chapter 14

Fe Protein Overexpression Can Enhance the Nitrogenase Activity of *Azotobacter vinelandii*

Papri Nag* **and Subrata Pal**

Department of Life Science and Biotechnology, Jadavpur University, Raja SC Mullick Road, Kolkata, India

14.1 INTRODUCTION

Although biological nitrogen fixation (BNF) is widely known in bacterial species, only a few can carry out BNF under free living conditions. *Azotobacter vinelandii* is unique in its ability to fix nitrogen in aerobic free living conditions. Studies with *Azotobacter* have led to the elucidation of nitrogenase, its subunits and kinetics; see Chapter 9. Most bacteria capable of BNF have a single type of nitrogenase enzyme (Nitrogenase I) consisting of the Fe-protein and MoFe subunits (expressed from the *nifH* and *nifDK* genes, respectively) (Seefeldt et al., 2009; Robinson et al., 1986). However, *A. vinelandii* produces three types of nitrogenases under different conditions: Nitrogenase I is expressed under normal conditions; Nitrogenase II consists of the Fe- and VnFe-protein subunits under Mo-limiting conditions (Joerger et al., 1990); and Nitrogenase III consists only Fe in its dinitrogenase and dinitrogenase reductase subunits under Mo- and Vn-limiting conditions (Hales et al., 1986). Nitrogen fixation is a highly energy-dependent process and is also highly sensitive to oxidative conditions and the nutritional status of the cell. Nitrogenase I, which is most widely studied, is stringently regulated at the transcriptional level by NifA (enhancer-binding protein) and NifL (regulatory protein) with the help of Sigma54 (RNA polymerase) (Dixon and Kahn, 2004).

Nitrogenase-mediated BNF requires 16 molecules of MgATP for each molecule of NH_3 produced (Tezcan et al., 2005). Because of the high-energy requirement and slow turnover of Nitrogenase I (Dixon and Kahn, 2004), *Azotobacter* fixes nitrogen sufficient for its own needs only. It releases very small amounts of ammonium into the environment under favorable conditions, releasing most of the ammonium after death and lysis (Bali et al., 1992). Studies relating to the improvement of the nitrogen-fixing ability of diazotrophs have been focused on either physiological suppression of nitrogen assimilatory genes (Bali et al., 1992) or creating mutations and selecting higher nitrogen-fixing mutants (Gordon and Moore, 1981). Attempts to increase the NifA production in order to increase nitrogen-fixation efficiency (NFE) have revealed that complete deregulation of the system leads to the loss of survivability of the cells (Bali et al., 1992; Brewin et al., 1999). Hence, increasing the NFE in a controlled manner may be one of the solutions. The complexity of enhancing the nitrogen-fixing efficiency can be deduced from the fact that 82 genes are involved in

*Present address: National Institute of Plant Genome Research, Aruna Asaf Ali Marg, New Delhi, India

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

the entire process in addition to a variety of cellular housekeeping genes involved in carbohydrate metabolism, iron uptake, and oxygen stress (Dos Santos and Dean, 2011). Many of the proteins involved in the process are rich in iron (Hu and Ribbe, 2011; Raulfs et al., 2009). Moreover, the nitrogenase enzyme itself is oxygen labile. Thus, understanding the nitrogenase cycle and its physiological impact on the cell is important.

The Fe-protein subunit (encoded by *nifH* gene) of nitrogenase is central to the *A. vinelandii* nitrogenase cycle. Dinitrogenase (MoFe protein) can accept electrons only from the Fe protein (Rubio and Ludden, 2005), although the presence of other reductase-like ferrodoxins is also required (Egener et al., 2001). NifH and MgATP are also essential for the maturation of FeMo-co precursor into a fully assembled MoFe subunit (Rubio et al., 2002). The Fe protein probably acts as the Mo/homocitrate insertase of the NifEN-bound Mo-free FeMo-co precursor (Hu et al., 2006).

In our endeavor to increase the nitrogen-fixing efficiency of *A. vinelandii* (strain: UW), we chose to overexpress the *nifH* gene (Fe-protein subunit) from a heterologous promoter that can be induced. An RK2-based plasmid, pJB654, reported to exist stably in *A. vinelandii*, was selected as vector containing the *Pm* promoter, which is inducible with *meta*-toluic acid (Blatny et al., 1997). The *nifH* gene of *A. vinelandii* was inserted downstream of this promoter; and Fe-protein expression, acetylene reduction (nitrogen-fixation activity), and ammonium excretion were measured. We also assessed the amount of stress produced, as a result the higher nitrogen was fixed under induced conditions by determining the cellular levels of superoxide dismutase (SOD) and the levels of catechol were produced as a result of higher Fe uptake.

14.2 METHODS

14.2.1 Strains and Growth Conditions

Escherichia coli cells harboring plasmid pDB6 (pUC_{18} containing *A. vinelandii nifHDK* insert), pGEMT Easy (Promega), and pJB654 (broad host range expression vector containing the TOL promoter Pm and its regulator *xylS*, parDE, *oriV*, and *trfA* fragments) (Blatny et al., 1997) were grown with 50 μg ampicillin ml^{-1}. *E. coli* cells harboring plasmid RK2013 (Sia et al., 1995) were grown with 50 μg kanamycin ml^{-1}. *A. vinelandii* was grown in nitrogen-free modified Burk's medium (BN^-) (Page and Sadoff, 1976) at 30 °C with aeration and was maintained on agar plates of the same medium for up to 2 weeks. *E. coli* DH5α and HB101 were grown in Luria Bertini (LB) medium at 37 °C with aeration. Transconjugates were maintained on appropriate agar plates containing 50 μg/ml ampicillin or kanamycin. The growth characteristic of the transconjugants was compared with the parent strain UW in the presence of 4 μM *m*-toluic acid.

14.2.2 Construction of Recombinant Plasmids

The *A. vinelandii nifH* fragment (873 bp) was amplified with *Pfu*-I enzyme (Fermentas, Germany) from plasmid pDB6 (Jacobson et al., 1989) using the primers NifH1 (5′tcccc/gggatggctatgcgtcaatg3′) with a *Sma*I site and NifH2 (5′tag/gatcctagtcagacttcttcggc3′) with a *BamH*I site. The digested PCR product was subcloned into the pGEM-T Easy vector by TA cloning. The *Sma*I-*BamH*I fragment from pGEM-T-*nifH* was finally cloned into the broad host range expression vector pJB654 to generate plasmid pJB654-N. A schematic representation of the cloning steps is illustrated in Figure 14.1.

14.2.3 Conjugation of *A. vinelandii* UW with pJB654-N from DH5α

pJB654-N was transferred from *E. coli* DH5α to *A. vinelandii* UW by triparental mating using the helper plasmid pRK2013 (Ditta et al., 1980). *A. vinelandii* UW and *E. coli* DH5α carrying plasmid pJB654-N and helper *E. coli* (HB101) carrying plasmid pRK2301 were each cultured overnight at the appropriate temperatures and the cultures were adjusted

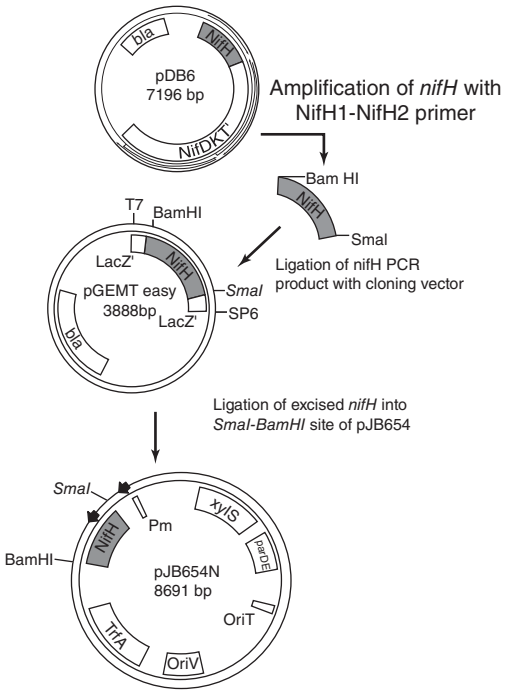

Figure 14.1 Schematic diagram showing the construction of pJB654-N. (*Source*: Adapted from Nag and Pal, 2013.)

to 10^9 cells ml^{-1}. The three types of cells were mixed in equal volumes in a 1.5-ml centrifuge tube and filtered through a 0.2-µm cellulose acetate filter membrane. The membrane was placed, bacterial side up, on a BN^- agar plate and incubated for 6–8 h at 30 °C. The cells were resuspended in 0.5-ml BN^- medium by rinsing the membrane. The transconjugates were plated, after dilutions, on BN^- agar plates with 50 µg ampicillin per milliliter. Transconjugants were restreaked four to five times on BN^- ampicillin plates in order to purify *A. vinelandii* cells harboring the plasmid pJB654-N. In order to examine the expression of the exogenous *nifH* fragment, PCR analysis was carried out with DNA extracted from the transconjugants using two sets of primers, Pm1 (5′′ggctatctctagaaaggcct3′) and NifH2.

14.2.4 Immunoblotting of NifH

Protein extraction was carried out using osmotic shock, and electrophoresis was achieved using a 10% SDS-polyacrylamide gel according to published protocols (Vázquez-laslop et al., 2001) with few modifications. Briefly, 2 ml cells were harvested, washed in an equal volume of PBS, and resuspended in a 200 µl of lysis buffer (40% glycerol in 33 mM Tris-Cl, pH 7.4 and 0.1 mM EDTA, pH 7.4). The cells were incubated at room temperature for 25–30 min and resuspended in 30 µl ice cold milli-Q water. 4 mM dithionite (DTH), 0.2 mg dithioerythritol (DTE) ml^{-1}, 20 µg lysozyme ml^{-1}, 0.1mg RNase ml^{-1}, and 0.1mg DNase ml^{-1} were sequentially added to the suspension. The mixture was incubated at room temperature for 20 min under vacuum, centrifuged at 10,000 *g*, and the supernatant was immediately used for anoxic nondenaturing acrylamide gel analysis (Allen et al., 1995). The running buffer was supplemented with 2 mM DTH, and the gel was pre-run for 45 min. Immunoblotting was carried out according to a published protocol (Sambrook et al., 1989) using an anti-*A. vinelandii* NifH antibody (Kindly supplied by Prof. P. W. Ludden, University of California, Berkeley).

14.2.5 Assay for Superoxide Dismutase

The procedure developed by Beauchamp and Fridovich (1971) was followed to assay the presence of SOD. The SOD band intensity was determined using the domain ImageJ program (Java version of NIH Image developed at the US National Institutes of Health and available on the Internet at http://rsb.info.nih.gov/ij/). Fluorescence intensity was measured as the area under peaks produced by NIH ImageJ.

14.2.6 Acetylene Reduction Assay

Cells were grown overnight in Burk's medium containing 29 mM NH_4Cl, harvested and washed with fresh ammonium-free medium, subcultured in the same ammonium-free medium, and incubated for the desired time (until log phase). The transconjugants were grown in ampicillin-containing medium and 4 µM *m*-toluic was acid added as the inducer. For acetylene reduction assay (Burris, 1972), 2 ml aliquots of *A. vinelandii* cells grown to mid-log phase were transferred to 27 ml sealed vials. About 10% of their air space was replaced with acetylene gas and incubated at 30 °C for 2–5 h. Using an airtight syringe 1 ml of gas from the head-space was injected into a Porapak N column of a gas chromatograph (model: NUCON 5765, India). The column temperature was 80 °C, and the temperature of the injector and detector was set at 120 °C. The amount of ethylene produced was calculated by the formula:

$$\text{Nanomoles of ethylene produced hour}^{-1}\text{mg}^{-1}\text{protein} = \frac{C \times P_s \times A_s \times V}{P_{std} \times A_{std} \times T \times P}.$$

where, C is the concentration of ethylene in standard; P_s is the peak height of sample; A_s is the attenuation used for sample; P_{std} is the peak height of standard; A_{std} is the attenuation used for sample; T is the time of incubation; and V is the volume of air space in the assay vial.

14.2.7 Ammonium Production Assay

The ammonium concentration in the medium was estimated as follows. Aliquots were taken at different times and *A. vinelandii* cells were spun down. Appropriate amounts of supernatant were assayed for ammonium by the indophenol method (Burris, 1972).

14.2.8 Spectrophotometric Assay for Siderophore (Catechol)

The cells were removed by centrifugation, and the culture supernatant fluid, containing the catechol released by the bacterial cells, was acidified to pH 1.8 with HCl and passed through a Millipore filter (pore size: 0.2 µm). The acidified culture fluid was scanned with a Hitachi U2800 spectrophotometer, absorbance at 310 nm being used to compare total catechol amounts (Page and Huyer, 1984).

14.3 RESULTS

The P_m-*nifH* construct introduced in the UW strain was verified by sequencing the *nifH* gene. The selected conjugant was designated UW/pJB654-N. The inducer of P_m promoter, *m*-toluic acid, is a substrate in the toluic acid pathway and was considered to be toxic to bacterial cells at high concentrations (Marques and Ramos, 1993). Therefore,

we assessed the effect of different concentrations of *m*-toluic acid on strain UW.

It was found that UW could grow in N-free medium containing *m*-toluic acid as the sole carbon source. This effect was diminished when sucrose was added to the medium, since the cells were utilizing sucrose preferentially. It was also found that the addition of the inducer improved the acetylene reduction capacity of strain UW. We used 4 μM *meta*-toluic acid for further analysis. As *m*-toluic acid alone was used by UW as a substrate, we had to normalize our analysis by growing the wild-type strain with the same concentration of the inducer. We performed uninduced control reactions as well. Immunoblots show that UW/pJB654-N produced twofold to threefold higher Fe protein at log phase (OD_{600nm}=0.9) and 1.2 fold higher Fe protein at stationary phase (OD_{600nm}=1.2) than UW cells (Fig. 14.2a). This led to higher nitrogen-fixation activity, as assessed by acetylene reduction and ammonium estimation assays. During log phase, 7.4 nM ethylene $hour^{-1}$ mg^{-1} protein was produced by UW/pJB654-N cells as compared to 2.64 nM ethylene $hour^{-1}$ mg^{-1} protein produced by UW. The acetylene reduced during stationary phase was less in both UW and UW/pJB654-N, though UW/pJB654-N (2.1 nM ethylene $hour^{-1}$ mg^{-1} protein) displayed higher acetylene reduction than UW (0.2 nM ethylene $hour^{-1}$ mg^{-1} protein) (Fig. 14.2b). In uninduced experiments, 60% more Fe protein was detected in UW/pJB654-N, but only a 5% higher acetylene reduction activity than UW (results not shown). We concluded that the increase in acetylene reduction activity in the UW/pJB654-N was due to the increased amount of Fe protein produced by the plasmid, as the endogenous *nifHDK* operon continued to be driven by its own promoter in both UW and UW/pJB654-N. In the log phase, uninduced UW and UW/pJB654-N cells released comparable amounts of ammonium. However, when the cells were grown in the presence of 4 μM *m*-toluic acid, the transconjugants released 1.67-fold more ammonium than UW at log phase, whereas this difference was much higher (2.16-fold) during the stationary phase (Fig. 14.2c).

As discussed earlier nitrogen fixation produces stress inside the cells, and this may be one of the reasons why increasing the NFE is so difficult. In order to assess whether the increase in acetylene reduction activity due to increased Fe protein produced additional stress, we analyzed the most common stress-related enzyme SOD. We were surprised to observe that the SOD activity of UW were higher than UW/pJB654-N in the log phase. The SOD activity of UW was approximately 25% higher than that of UW/pJB654-N. However, during the stationary phase, UW/pJB654-N expressed 70% more SOD as compared to UW. The uninduced control experiments showed almost no difference in SOD production between UW/pJB654-N and UW during the log phase. In the stationary phase of the uninduced experiments, UW/pJB654-N had 26% more SOD content as compared to UW (Fig. 14.3a).

Catechols are produced by *A. vinelandii* for uptake of Fe (Page and Huyer, 1984). *A. vinelandii* releases four siderophores: azotochelin, aminochelin, protochelin, and azotobactin, and a pseudo-siderophore dihydrobenzoic acid (DHBA) (Page and Huyer, 1984). UW/pJB654-N produced 55% more (40% more in uninduced conditions) catechol than UW (Fig. 14.3b). It is also known that catechols are usually produced in higher amounts as a result of metal depletion, which happens during the late stationary phase in laboratory conditions. Hence, we determined the amount of catechol produced during the stationary phase. UW/pJB654-N produced 110% more catechol than UW under induced conditions compared to only 28% in uninduced controls (Fig. 14.3b).

14.4 DISCUSSION

NFE may be enhanced under conditions of higher levels of Fe protein, provided excess ATP and high concentrations of FldHQ (flavodoxin hydroquinone) are available (Lowery et al., 2006). In our study, we show that NFE can be enhanced by overexpressing the Fe protein alone. We expressed *nifH* from the *Pm* promoter, which can be induced by *m*-toluic acid. Analysis of the genome sequence of *A. vinelandii* DJ (Setubal et al., 2009) revealed the presence of all the enzymes of at least one *m*-toluic acid degradation pathway. The metabolic intermediates of the *m*-toluic acid degradation enter the Krebs cycle (Marques and Ramos, 1993). A change in the ATP/ADP ratio could lead to an increase in nitrogenase activity (Lowery et al., 2006). In order to prove that the observed twofold higher acetylene reduction by UW/pJB654-N under induction by *m*-toluic acid was solely due to the increased amount of Fe protein, we added the same amount of the inducer to UW control cells. We also observed an increase in ammonium release. As *Azotobacter* utilizes ammonium for its growth and generally excretes little amounts of ammonium into their surroundings till their death and lysis (Bali et al., 1992), it was not a surprise when the amount of ammonium released by UW/pJB654-N was less (1.67-fold) as compared to the acetylene reduced (twofold higher). However, UW/pJB654-N released high amounts of ammonium during the stationary phase as expected.

Several pathways by which *A. vinelandii* protects nitrogenase from the irreversible oxidation of its components have been proposed (Maier and Moshiri, 2000). An interesting mechanism for the protection of nitrogenase is autoprotection, which involves the SOD and catalase/peroxidase enzymes of the cell. Fe protein could reduce oxygen to produce an O^- radicle and H_2O_2 (Thorneley and Ashby, 1989). These products are removed by

(b) Total catechol (OD_{310}) production by UW and UW/pJB654N. Data represent mean and standard error of two independent experiments with three replicates each. (c) Production of pigments by UW/pJB654N (left) and UW (right) at stationary phase after induction. Addition of *m*-toluic acid in Burk's N-free medium may provide an advantage to the cells by acting as an additional carbohydrate substrate. (*Source*: Adapted from Nag and Pal, 2013.)

SOD and catalase/ peroxides. It has been also suggested that SOD is important in the process of nitrogen fixation as evidenced by the higher levels of SOD in nitrogen-fixing cells (Becana and Rodríguez-Barrueco, 2006; Boogerd et al., 1998). We observed that under induced conditions in the log phase (OD_{600nm} = 0.75), SOD activity of UW was about 25% higher than that of UW/pJB654-N. However, at the stationary phase (OD_{600nm} = 1.20), SOD activity of UW was depleted faster than that of UW/pJB654-N to about 70% of the latter. This result correlates with the Fe-protein production by the UW/pJB654-N and UW strains. SOD levels of cells fixing nitrogen are higher than nonfixing cells (Maier and Moshiri, 2000; Dingler and oelze, 1987). UW cells displayed SOD levels 25% higher as compared to UW/pJB654-N, even though the latter had twofold to threefold higher NFE. However, UW/pJB654-N expressed 70% more SOD than UW during the early stationary phase.

Siderophores are low molecular weight derivatives of catechols or hydroxamiic acid released by bacterial cells. Siderophores help in the solubilization, chelation, and transport of iron into the cell (Neilands, 1995). Nitrogen fixation in *A. vinelandii* is sensitive to iron. It was found to be growth-limiting for the organism at a concentration as high as 12.5 μM (Fekete et al., 1983). From our results, the enhanced total catechol production in the recombinant cells is consistent with the higher requirement of iron for the nitrogenase activity of *A. vinelandii* (Tindale et al., 2000). The production of catechols is higher during early stationary phase, when the growth medium is depleted of iron. We also observed the formation of a dark color pigment during the late stationary phase (Fig. 14.3c). Similar to the results of Shivprasad and Page (1989), formation of this dark colored pigment was optimal in the stationary phase, and there was no correlation between nitrogenase activity and pigmentation (results not shown).

14.5 CONCLUSION

Our results have shown that increasing the level of Fe protein in the cell can enhance the nitrogen-fixation activity of *A. vinelandii*. To our knowledge, this is the first report of effectively increasing the nitrogenase activity by over-expressing only one of the subunits of the enzyme. This approach may be less toxic for the cell as indicated by the

SOD activity during the exponential phase of cell growth. It would be worthwhile to explore in future if engineering the relevant metabolic pathways for ATP production, SOD expression, and iron uptake can further lead to *Azotobacter* strains with enhanced nitrogenase activity.

ACKNOWLEDGMENTS

This work was supported by a University Grants Commission, India, fellowship to PN. We express our deep gratitude to P. W. Ludden for the anti-NifH antibody, W. J. Page for the UW strain, Svein Valla for the plasmid pJB654, D. R. Helinski for pRK2013, and D. R. Dean for the plasmid pDB6.

15.1 INTRODUCTION

Nitrogen fixation performed by symbiotic systems requires concerted gene expression in both partners. Many regulatory circuits operate inside the nodule to carry out both, bacterial differentiation into nitrogen-fixing bacteroids and expression of *nif* and *fix* genes where low-oxygen concentration operates as the most important regulatory signal. The limited oxygen atmosphere inside the nodule is the optimal environment for the nitrogenase to reduce dinitrogen to ammonia. However, metabolic adjustments are needed to optimize oxygen consumption in respiration under this condition. The requirement of a low-oxygen environment for nitrogen fixation and the demand for optimal respiration to produce ATP seem to be a paradoxical situation in nitrogen-fixing bacteria (Dixon and Kahn, 2004; Fischer, 1994; Udvardi and Poole, 2013). Inside the nodules, oxygen diffuses by binding reversibly to leghemoglobin, and the bacteroid respiration is made possible by the expression of a cbb_3-type terminal oxidase with high affinity for oxygen. This specialized cytochrome oxidase complex is encoded by the oxygen-regulated *fixNOQP* operon (Mandon et al., 1994; Preisig et al., 1993). Therefore, a detection-effector system that responds to changes in the oxygen level is necessary to activate transcription of these genes.

Most rhizobial genes involved in nitrogen fixation are integrated in two different networks in a species-specific manner (Fischer, 1994; Kaminski et al., 1998; Udvardi and Poole, 2013). One includes the NifA and RpoN regulators, while FixL, FixJ, and FixK comprise the other regulatory cascade, specific for symbiotic diazotrophs (Dixon and Kahn, 2004; Udvardi and Poole, 2013).

FixL and FixJ are members of the two-component regulatory systems, the main mechanism employed by bacteria to coordinate their responses to environmental changes. In general, FixL is a hemoprotein with histidine kinase activity able to sense oxygen concentration. When oxygen concentration drops, the redox state of the protoporphyrin in its heme domain changes and promotes the autophosphorylation of the histidine kinase domain. Once autophosphorylation occurs, the transphosphorylation of the FixJ receiver domain can take place (Agron et al., 1993). In these model systems, FixJ is a positive regulator of *fixK*, which is a second transcriptional regulator in the regulatory cascade in response to microaerobic conditions (Hertig et al., 1989; Anthamatten et al., 1992). FixK belongs to the cyclic AMP receptor protein/fumarate and nitrate reduction regulator (CRP/FNR) superfamily of transcriptional regulators (Fischer, 1994). The CRP/FNR regulators are key distributors of a variety of environmental signals, and some

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

of them are recognized as kaniglobal regulators (Körner et al., 2003). CRP and FNR from *Escherichia coli* are the two most well-studied members. CRP is a global regulator that is activated in the presence of the second messenger cAMP. CRP or CAP (catabolite activator protein) participates in the catabolic repression phenomena in *E. coli*, regulating the transcription of catabolite-sensitive genes by binding to DNA (Körner et al., 2003). The three dimensional structure of CRP and the CRP–DNA complex has been resolved and analyzed (Schultz et al., 1991; Parkinson et al., 1996a, b; Passner and Steitz, 1997). The CRP–DNA-binding site is a 22-bp palindromic sequence with the consensus sequence: AAATGTGATCTAGATCACATTT (Busby and Ebright, 1999). Fnr contains an O_2-sensitive $[4Fe–4S]^{2+}$ cluster that directly senses oxygen. In *E. coli*, it controls the expression of up to 100 genes in response to oxygen limitation (Kang et al., 2005; Kiley and Beinert, 2003). Under aerobic conditions, FNR is a monomer unable to activate transcription of its targets. However, in anaerobic conditions, the protein dimerizes and specifically binds to an imperfect palindrome known as the anaerobox [TTGATN4ATCAA] to activate or repress transcription of its regulatory targets (Spiro and Guest, 1987; Nees et al., 1988). During anaerobic conditions, each FNR monomer possesses an iron–sulfur cluster [4Fe–4S] coordinated by conserved cysteines in the N-terminal domain. The presence of iron–sulfur clusters [4Fe–4S] allows oxygen sensing; oxidation of the metal cluster promotes its disassembly and the formation of the apoprotein in aerobic conditions (Jervis and Green, 2007; Crack et al., 2008). Other important residues within the dimerization interface and near the cysteine cluster that regulates the dimer formation are serine 24 and aspartate 154 (Jervis et al., 2009; Moore and Kiley, 2001). The FNR tertiary structure has not been determined. Because of their sequence similarity, CRP has been used as template for structure modeling of FNR (Cherfils et al., 1989).

Similar to CRP targets, FNR-dependent promoters could be of three classes, named by analogy with the CRP promoters by the number and the position of the anaerobox. Class I is characterized for the presence of the FNR-binding site located near position −62. The FNR DNA-binding site in class II promoters is centered near position −41.5 overlapping the −35 box. Class III promoters have more than one FNR binding site that can be located in a class I– class I or class I–class II manner (Busby and Ebright, 1999). Three different activating regions (ARs) have been studied genetically and biochemically in *E. coli* FNR. AR1 comprises residues 71–75, 116–121, and 184–192 located in three adjacent exposed loops (Bell and Busby, 1994; Williams et al., 1997; Li et al., 1998). This structural region makes contact with the C-terminal domain of the RNA polymerase α subunit (αCTD) (Lee et al., 2000). The presence of an AR2 was uncovered by the analysis of FNR mutants that recovered activity despite the absence of a conventional AR1, in a genetic background where *rpoA* is affected or in mutants defective for iron–sulfur cluster assembly. Based on these studies, the role of residues 49 and 50 in AR2 was determined (Li et al., 1998; Ralph et al., 2001; Blake et al., 2002). Residues from 80 to 89 constitute the AR3 within a loop; this region is responsible for contacting the σ^{70} CTD, and in addition to the other ARs is crucial for transcription regulation at class II promoters. In the case of class I promoters, only AR1 is required for transcriptional regulation (Lamberg et al., 2002).

In Rhizobiales, different kinds of FNR-like proteins have been identified and grouped in three main subfamilies: FixK, FnrN, and NnrR (Körner et al., 2003). The study of these regulators has focused mainly on the identification of their regulatory targets and in some cases defining the DNA-binding site. Not too much attention has been paid to the regulatory mechanisms governing their activity. A notable exception is the regulator $FixK_2$ from *Bradyrhizobium japonicum* where studies on the biochemical properties of the purified protein have been reported (Mesa et al., 2005, 2009).

Interestingly, the FixK protein does not conserve the cysteines necessary to coordinate the iron–sulfur clusters in FNR. This particularity renders the protein unable to directly respond to the presence of oxygen. However, the role of FixK as a key distributor of the microaerobic response in rhizobia resembles the role of its homolog in *E. coli* that is required to switch from an aerobic lifestyle to an anaerobic one. Worth noting is the observation that the FixK target *fixN*, which encodes the subunit I of the cytochrome cbb_3 oxidase, has an anaerobox in its regulatory sequence (Batut et al., 1989). It has also been proposed based on model building of Fnr and FixK from *E. coli* and *Sinorhizobium meliloti*, respectively, that both regulators might bind the same DNA consensus sequence (Cherfils et al., 1989). More recent studies in *S. meliloti* and *B. japonicum* have explored the regulatory landscape of the FixK regulators in response to oxygen limitation, both under free living and symbiotic conditions. The presence of a conserved anaerobox is important for the recognition of direct targets for these regulators (Bobik et al., 2006; Mesa et al., 2008). The recognition of practically the same DNA sequences by Fnr and FixK proteins is attributed to the presence of the conserved motif EXXSR in the DNA-binding domain of both regulators (Lazazzera et al., 1993).

After the initial identification and characterization of the FixK regulator, another Fnr homolog has been found in *Rhizobium leguminosarum* bv. viciae. This protein was named FnrN and in contrast with FixK, this regulator is able to respond directly to oxygen limitation (Colonna-Romano et al., 1990; Schlüter et al., 1992). FnrN regulators conserve most of the cysteines that are important for oxygen sensing in Fnr of *E. coli*; however, their spacing in the N-terminal

motif is slightly different (Trageser and Unden, 1989; Khoroshilova et al., 1995).

Another Fnr-like regulator was found to integrate the low oxygen and N-oxides signal in *B. japonicum*. This protein belongs to the subfamily of NnrR regulators (Tosques et al., 1996; van Spanning et al., 1999). These regulators are responsible for the induction of the *nir* and *nor* genes, which encode important proteins involved in nitrogen oxide metabolism, in response to the presence of nitric oxide or chemically related species. The role of NnrR regulators in rhizobial models such as *S. meliloti* and *Rhizobium etli* CFN42 has also been explored (de Bruijn et al., 2006; Meilhoc et al., 2010; Gómez-Hernández et al., 2011).

The role of two novel Fnr-like regulators has been reported in *R. etli* CFN42. These two regulators were named StoRd and StoRf because they were found to be negative regulators of the symbiotic terminal oxidase cbb_3 (Granados-Baeza et al., 2007). Along with the dawn of high-throughput sequencing technologies in this decade, several members of the Fnr/CRP regulatory family have been identified in different rhizobia (Mesa et al., 2006; Granados-Baeza et al., 2007). This observation raises interesting questions regarding the significance of incorporating these types of regulators in the evolution of global regulatory circuits. Different regulatory mechanisms have evolved within the group of the Rhizobiales that involve Fnr-like regulators, mainly for the control of nitrogen fixation and denitrification processes and probably for other unexplored metabolic circuits. Even though over the years important genetic and physiological aspects on the role of FNR-like regulators in rhizobia have been reported, intriguing observations on the mechanism of action and implications of the highly variable regulatory circuits where these regulators are immersed are still pending further analysis. Undoubtedly, this is a fertile research area for the development and assessment of new hypothesis that certainly will enrich our knowledge of rhizobial physiology.

R. etli CFN42 induces the formation of nitrogen-fixing nodules on roots of *Phaseolus vulgaris* (bean) plants. In this strain, the genomic material is distributed in one chromosome and six large plasmids (pRet42a to pRet42f) whose sizes range from 184.4 to 642.5 kb. The genome of *R. etli* CFN42 encodes six *fnr*-related genes: *fixK*f, *fnrN*ch, *fnrN*d, *nnrR*, *stoR*d, and *stoR*f (González et al., 2006). Results in our laboratory have demonstrated that in *R. etli* a complex regulatory circuit controls the expression of *fix* genes that involves at least five transcriptional regulators of the Crp/Fnr family. The goal of this chapter is to review in a critical way what we have learned in the past decade about the role of Fnr-related regulators in controlling gene expression in *R. etli* and what features are conserved or have been adapted when compared with other model rhizobia.

15.2 REGULATION OF THE *R. etli fix* GENES: AN OVERVIEW

Although the presence of homologs of the *S. meliloti fixL, fixJ*, and *fixK* genes is a common feature among the different nitrogen fixers, the connectivity among regulatory cascades, the specific regulatory role of each element, and their target genes may vary (Anthamatten and Hennecke, 1991; Anthamatten et al., 1992; Bauer et al., 1998; Fischer, 1994; Kaminski et al., 1998).

Important differences between the mechanisms of regulation of *fix* gene expression in *S. meliloti* and *B. japonicum* have been reported in other rhizobia such as *R. etli* strains CFN42 and CNPAF512 and *R. leguminosarum* bv. viciae. In this regard, our work has mainly focused on the clarification of the regulatory scheme for *fix* genes in *R. etli* CFN42. Most of the *nif* and *fix* genes identified in this strain are located on the symbiotic plasmid (pSym or pRet42d) (Girard et al., 1991; Gonzalez et al., 2006; Soberón et al., 1999). Nevertheless, a *fix* reiterated region is localized on the plasmid pRet42f, previously considered a cryptic plasmid.

Detailed expression and epistasis analysis of the regulatory elements present in each reiteration have been carried out to establish the regulatory model of *fix* genes in *R. etli* CFN42 (Girard et al., 2000). The regulatory model of *R. etli* CFN42 *fix* genes integrates the participation of genes localized in different replicons. Furthermore, this scheme shows several novel characteristics when compared with the conventional systems *S. meliloti* and *B. japonicum*. In *R. etli*, the sensor histidine kinase FixL encoded on the pSym in other rhizobial species is located on pRet42f in a region containing copies of *fixK*, *fixNOQP*, and *fixGHIS* genes. Another puzzling aspect of the regulatory cascade in *R. etli* is the absence of a *fixJ* gene, a characteristic that is shared *with R. leguminosarum* bv. viciae. Both cytochrome oxidase complexes encoded by the reiterated operons *fixNOQP* are controlled by a novel *fixL–fixK*f cascade, where the response regulator in charge of activating *fixK*f expression is FxkR (*fxkR*-dubbed *fixK* regulator), which belongs to the OmpR/PhoB superfamily (Girard et al., 1996, 2000; González et al., 2003, 2006; Zamorano-Sánchez et al., 2012).

Although expression of both *fixN*f and *fixN*d requires FixKf, these genes exhibit a differential dependence on FixL. The expression of *fixN*f is fully dependent on FixL, while expression of the reiteration indispensable for symbiotic nitrogen fixation, *fixNOQP*d, can continue at adequate levels in the absence of FixL with the participation of *R. etli* CFN42 *fnrN* homologs (López et al., 2001). Thus, microaerobic expression of the *fixNOQP*d operon in *R. etli* is subjected to the direct regulatory input of three different activators: FixKf, FnrNchr, and FnrNd (Fig. 15.1).

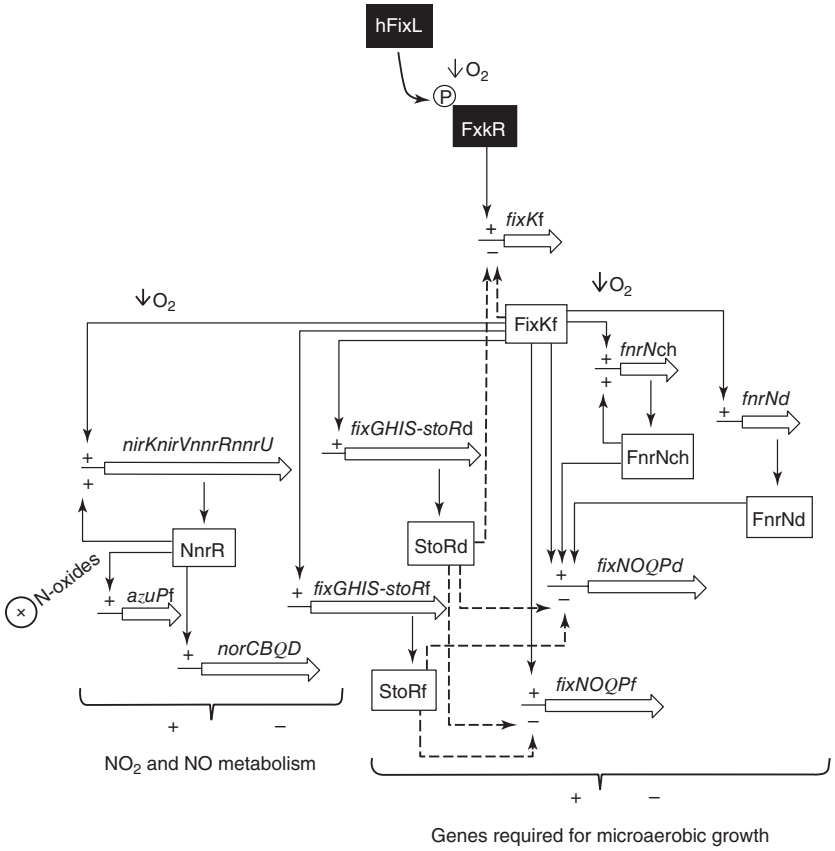

Figure 15.1 Regulatory model for *fix* gene expression in *R. etli* CFN42 under microaerobic conditions. The oxygen concentration is sensed by the two-component regulatory system hFixL-FxkR to activate FixKf, the master regulator for *fix* genes expression. The presence of N-oxides provokes the induction of the *nnrR* gene to activate the expression of genes encoding nitrite and NO-oxidases. ■ two-component regulatory system; □ FNR-like proteins; – positive regulation; --- negative regulation.

15.3 NOVEL ELEMENTS IN THE REGULATORY CASCADE OF *fix* GENES IN *Rhizobium etli*

After the release of the genome sequence of *R. etli* CFN42 in 2006 (González et al., 2006), we aimed to identify novel FNR-like regulators that might participate in nitrogen-fixation regulation. Two ORFs RHE_PD00288 and RHE_PF00499 annotated as *fnr* homologs are located downstream the *fixGHIS* operon reiterations on plasmid pRet42f and pRet42d. The genomic location of these genes suggested that they might participate in nitrogen fixation. We demonstrated that these two regulators are in an operon with *fixGHIS*, and that they operate as negative modulators of the expression of the *fixNOQP* reiterations. Negative regulation of the *fixNOQP* operons was not reported previously in model rhizobia (Fig. 15.1). These two novel reiterated regulators conserved 84% identity at the nucleotide level, and due to their role in controlling the expression of the symbiotic terminal oxidase, they were named StoRd and StoRf, respectively (Granados-Baeza et al., 2007). Apart from having very similar roles under free-living microaerobic conditions, StoRd and StoRf mutants behave different under symbiotic conditions. The physiologic studies of nitrogen fixation in *P. vulgaris* plants revealed that a mutant in StoRd produces more cbb_3 in nodules and had almost double nitrogenase activity and a 45% increase in total nitrogen content at 45 days after inoculation. On the other hand, the StoRf mutant was modestly impaired for nitrogen fixation and did not promote the same increase in cbb_3 in nodules (Granados-Baeza et al., 2007).

In *R. leguminosarum* bv. viciae, the expression of the *fixNOQP* reiterations under free living and symbiotic conditions depends on FixL and FnrN while FixK is only marginally involved (Schlüter et al., 1997). FixL, FnrN, and FixK proteins are highly conserved in *R. etli* when compared with their counterparts in *R. leguminosarum*; however, in this particular genetic background, FixKf is fundamental for the expression of *fixNOQP* genes under free living conditions. Nevertheless, under symbiotic conditions, the responsibility of promoting *fix* genes expression can rely on FixKf or on the FnrNch and FnrNd regulators (Girard et al., 2000; Lopez et al., 2001). All this aforementioned evidence shows that even though free-living microaerobic conditions have been helpful for the understanding of basic aspects of *fix* gene regulation, they do not mimic the nodule environment, and important differences in the regulation of *fix* genes can be observed in this particular niche. Because of this, it will be of great importance to expand the known repertoire of Fnr targets in *R. etli* during symbiosis with bean plants.

It also will be very interesting in terms of understanding the regulatory hierarchy of the FNR-like regulators, to know how frequently they are encountered together in the regulatory region of their target genes at different stages of the symbiosis. Furthermore, transcriptomic and proteomic analyses of nodules infected by strains mutated in FNR-like regulators will reveal important regulatory and metabolic networks that can limit nitrogenase activity and nitrogen assimilation.

15.4 NnrR LINKS THE LOW-OXYGEN AND N-OXIDE RESPONSE IN *Rhizobium etli*

Another conserved Fnr-like regulator indispensable for denitrification was found to integrate the low oxygen and N-oxides signal in *B. japonicum* (Mesa et al., 2003; de Bruijn et al., 2006). This protein belongs to the subfamily of NnrR regulators that control the expression of nitrite reductases and nitric oxide reductases in response to nitric oxide or chemically related species (Tosques et al., 1996; van Spanning et al., 1999).

R. etli is unable to use nitrate for respiration and does not encode a nitrate reductase gene. However, this bacterium encodes highly conserved homologs of the nitrite reductase (*nirK*) and the nitric oxide reductase complex (*norCBQD*). These genes are responsible for the generation and removal of nitric oxide in the nodules of *P. vulgaris*. The product of *norC* is required *in vivo* to detoxify NO. The balance between the activities of NirK and NorC determines the level of tolerance to $NO^{\cdot}$ in *R. etli* (Gómez-Hernández et al., 2011). Interestingly in *R. etli*, an *nnrR* homolog is part of an operon that includes *nirK*, *nirV*, and *nnrU* (*nirKV-nnrRU*). The *nirKnirV-nnrRU* and *norCBQD* operons are mainly expressed under low oxygen in *R. etli* and induced in the presence of nitrite or nitric oxide. Microaerobic expression of these genes requires the presence of FixKf while induction by nitric oxide or nitrite needs the presence of NnrR. Interestingly, the microaerobic expression of *norC* requires the presence of both FixKf and NnrR, while expression of *nirK* only requires FixKf (Gómez-Hernández et al., 2011) (Fig. 15.1). This suggests that FixKf can recognize the regulatory region of the *nirKV-nnrRU* operon and activate its expression, but cannot recognize the regulatory region of the *norCBQD* operon or activate its expression by itself. On the other hand, NnrR can recognize and activate transcription of *norCBQD* but requires the presence of nitric oxide to activate the expression of the *nirKV-nnrRU* operon. Binding affinity studies of Fixkf and NnrR to the regulatory region of these two operons will be fundamental for the understanding of site recognition and discrimination in bacteria that harbor several FNR-like regulators.

Two Fnr-binding sites (anaeroboxes), one of class II and one of class I, were found to be important for *nirK* expression. The class I box overlaps with a putative NifA-binding site and might play a role in positive and negative regulation of *nirK* expression. The class II anaerobox is an essential target site for *nirK* activation (Gómez-Hernández et al., 2011). Further experiments are needed to reveal the importance of these sequences for the induction of the *nirKV-nnrR* operon in the presence of nitric oxide. There is only one anaerobox upstream of *norC* [TTG-CGAATTAA-CAA], centered at position −43.5 bp from the transcriptional start site. However, its role in the expression and induction of the *norCBQD* operon in microaerobiosis in the presence or absence of nitric oxide has not been evaluated. Future efforts should be focus in the characterization of DNA recognition by NnrR in the presence or absence of nitric oxide.

15.5 CONSERVED FUNCTIONAL FEATURES IN FNR-RELATED PROTEINS OF *R. etli*

Important aminoacid residues for FNR activity have been reported in a few biological models. In an attempt to identify conserved aminoacids in FNR-like proteins from *R. etli*, we analyzed a multiple sequence alignment with FNR homologs for which a function had already been reported.

It is well known that cysteines are oxidizable targets that play important roles in protein oligomerization, sulfur cluster assembly, or protein function in general. As mentioned earlier, conserved cysteines in the amino terminal part of FNR homologs are important for oxygen sensing. In *R. etli*, the FnrN proteins are the only ones that conserved the cysteines required to ensemble the crucial iron–sulfur cluster. Similar to other FnrN proteins, they present a small difference in the spacing between second and third cysteines. StoRd has six cysteines while StoRf and FixKf have five cysteines. NnrR, similar to its homolog from *B. japonicum*, has no cysteines within its sequence. Cysteine residues are present along the sequence of these regulators, but none of them appeared to be highly conserved in all FNR-related proteins. It has been recently shown that Cys183 from $FixK_2$ is a target for oxidation not only *in vitro* but also *in vivo*. Oxidation of this residue inactivates $FixK_2$ (Mesa et al., 2009; Bonnet et al., 2013). This residue is in close proximity to the DNA-binding domain and is not conserved in any of the FNR-related proteins of *R. etli*. The role that these cysteines could play for the protein function is still unknown. None of the rhizobial proteins aligned, have a similar cysteine pattern as the one in the FLP, FlpA, and FlpB proteins that could suggest a regulatory mechanism involving sulfur bridge formation (Green et al., 2001).

The dimerization interface of *E. coli* FNR, from residues 140 to 159, is mainly composed of hydrophobic or aliphatic

aminoacids. Arginine residues in positions 140 and 145 together with the aspartate 154 regulate FNR activity in a positive and a negative way, respectively. From the FNR-like regulators of *R. etli*, only StoRd conserve the Arg140. Hydrophobicity is retained at positions 151 and 158 in all FNR-like proteins of *R. etli.* The hydrophobic character of residues that aligned with the proposed dimerization region of FNR from *E. coli* suggested that there might be a common interface in *R. etli* FNR homologs. Important differences between FNR-like proteins from *R. etli* and FNR from *E. coli* and more related homologs such as CydR from *Azotobacter vinelandi* might be the lack of Ser24 and Asp154 that are important for the dimerization regulatory mechanism (Jervis et al., 2009).

Aminoacids in the ARs of *E. coli* FNR are not highly conserved in the Fnr-like proteins of *R. etli*; nonetheless, some conserved aminoacids are present in more than one of the regulators.

The most conserved region of the FNR-like proteins is the DNA recognition motif: EXXSR. Glu209 and Arg213 of *E. coli* FNR make direct contact with the G–C and A–T pairs of the TTGAT sequence in the anaerobox region. Ser212 is responsible for the direct contact with the first T–A pair in the anaerobox consensus, in contrast to residues 209 and 213 this aminoacid is absent in the CRP–DNA recognition helix and provides a discriminatory contact for FNR together with Arg180 that is absent in FNR (reviewed by Green et al. (2001)). The DNA-binding motif of FNR from *E. coli*, ETVSR, is conserved in *R. etli* FnrN and FixKf proteins. StoRd and StoRf have a slightly different motif, EALSR, and in *R. etli* NnrR, as well as in their more closely related homologs, the first residue in the motif is a histidine instead of a glutamate residue (HTVSR). The serine and the arginine residues of the motif are conserved in all FNR-like proteins. Because Fnr-like proteins conserve the residues of the protein-DNA recognition helix (EXXSR) of FNR-like proteins, one could speculate that they can bind the Fnr-recognition site; however, the presence of these conserve residues is not always an indication of the ability of a protein to bind the anaerobox. An interesting case is that of FLP from *Lactobacillus casei.* Even though the recognition motif is conserved, this protein recognizes a different consensus, similar to but still different from that of FNR and CRP. It has been proposed that the presence of a proline instead of valine or arginine immediately before the glutamate of the recognition motif in FLP might be responsible for a change in the relative position of the recognition helix (Gostick et al., 1998). Interestingly StoR and SinR proteins have a proline before the first glutamate of the recognition motif. Whether they bind different consensus sequences and whether the proline has any role in its recognition still has to be demonstrated. FnrNd, FnrNch, and FixKf proteins have an isoleucine residue before the glutamate in the motif while NnrR has a leucine residue.

It is clear that even in the DNA recognition helix, the most conserved region of these proteins, there are some differences that might explain, at least to some extent, experimental observations regarding target specificity among the FNR-related proteins of *R. etli.*

Important questions are still pending for an answer: How different are the oxygen-sensing mechanisms of FnrN regulators in comparison with FNR from *E. coli*? Are all the Fnr-related regulators in this bacterium contacting the same subunits of the RNA polymerase? Are the cysteines present in the predicted dimerization interphase of StoRd and StoRf regulators playing any role in controlling oligomerization of these proteins? How does the presence of a Histidine instead of a Glutamate residue in NnrR-binding motif affect affinity or sequence discrimination? Does the Proline localized beside the binding motif of the StoRd and StoRf regulators have anything to do with the role of these proteins as negative regulators? These and many other questions could be formulated, and the ability to answer them will be instrumental for our understanding of the regulatory networks that the FNR-related regulators are involved in.

15.6 PREDICTION OF DNA-BINDING SPECIFICITY USING THREE-DIMENSIONAL MODELS OF FNR-RELATED PROTEINS OF *R. etli*

FixKf, FnrNch, and FnrNd share a highly conserved DNA-binding domain, whereas StoRd, StoRf, and NnrR regulators have notable differences in the conserved EXXSR motif. Both StoR regulators have a proline residue instead of a valine, lysine, or proline residue before the conserved glutamate in the binding motif. NnrR regulator has a histidine residue instead of the conserved glutamate. Furthermore, all the regulatory targets of NnrR known to date in *R. etli* have anaeroboxes with the consensus TTG-N8-CAA, but none of them have the TTGAT-N4-ATCAA consensus found in most of the *fix* genes. We hypothesized that the differences in the conserved DNA-binding motif can account for variations in binding affinity or target discrimination.

Recently, the crystal structure of $FixK_2$ of *B. japonicum* bound to a TTGAT-N4-ATCAA anaerobox was reported (Bonnet et al., 2013). Using the coordinates of this crystal [PDB 4I2O], we generated dimeric three-dimensional models of *R. etli* FixKf, FnrNch, StoRd, and NnrR using the software TFmodeller (Contreras-Moreira et al., 2007). The 3D footprint database is a useful tool recently developed for analyzing protein–DNA interfaces of crystal structures and three-dimensional models (Contreras-Moreira, 2010). Using the interactive footprint software of this database, we were able to analyze the protein–DNA contacts. The protein–DNA interfaces of the FixKf and FnrNch models are the same as in the $FixK_2$-anaerobox crystal structure.

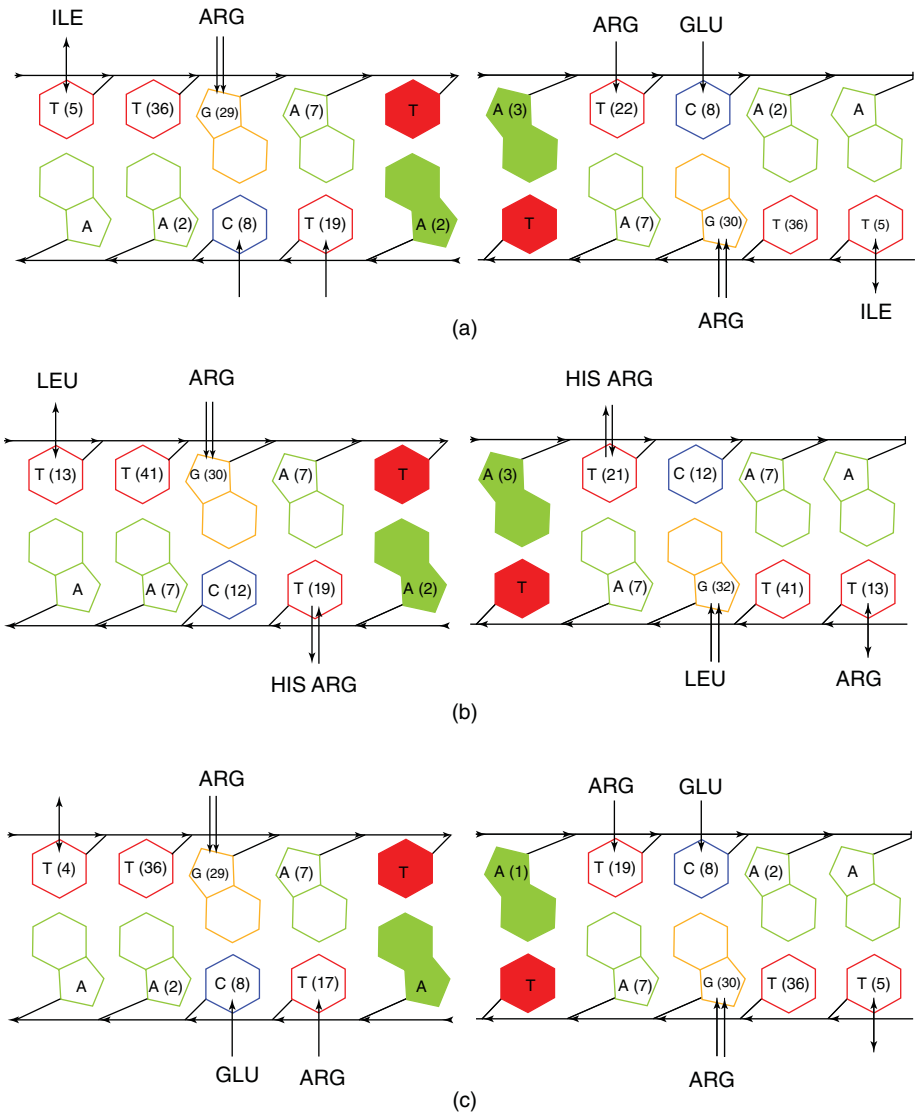

Figure 15.2 Protein–DNA interface of (a) FixKf, (b) NnrR, and (c) StoRd 3D models. Aminoacids of the conserved "VEXXSR" motif that contact the DNA are shown. Single-headed arrows symbolize a hydrogen bond formation, while double-headed arrows represent hydrophobic interactions. Full-colored nitrogen bases indicate predicted indirect contact with deformed DNA geometry. Numbers within the parenthesis inside the nucleotide bases indicate the number of side chain contacts.

Differences can be appreciated between the interface of the NnrR and StoRd model when compared to FixKf (Fig. 15.2). The presence of a histidine residue instead of a glutamate in NnrR results in the loss of a hydrogen bond with the 12th cytosine in the anaerobox (Fig. 15.2) and a new hydrophobic interaction is formed with the 11th thymine. The number of side chain contacts with the nitrogen bases is in general higher in the NnrR model when compared to FixKf (Fig. 15.2). In the case of StoRd, the only notable difference when compared with FixKf is that the presence of a proline instead of an isoleucine just before the conserved-binding motif is responsible for the loss of a hydrophobic contact with the first thymine of the anaerobox.

The algorithm of this footprinting software allows predicting the binding specificity of the regulators by the use of two types of position weight matrices (PWMs): contact and readout. The first one is calculated based on the number of contacts between side chains and nitrogen bases, while the readout PWMs are derived considering the array of scored atomic interactions at the interface and the set of sequence-dependent deformations inferred from the DNA coordinates (Contreras-Moreira, 2010). The predicted binding specificity of FixKf and StoRd is illustrated graphically by a consensus LOGO in Figure 15.3. From the *in silico* examination of the interfaces of FNR-like regulators in *R. etli*, one can suggest that specific changes in the binding motif, for instance the histidine and the proline in NnrR and StoRd, might be responsible for selective discrimination of specific targets. From the models it is also interesting to note that a hydrogen bond is formed between the arginine of the motif and the 11th thymine (5′ to 3′) of both strands of the anaerobox. In *norC*, for example, these nucleotides are substituted for guanine and adenine in each strand. Hydrogen bond formation does not occur when these

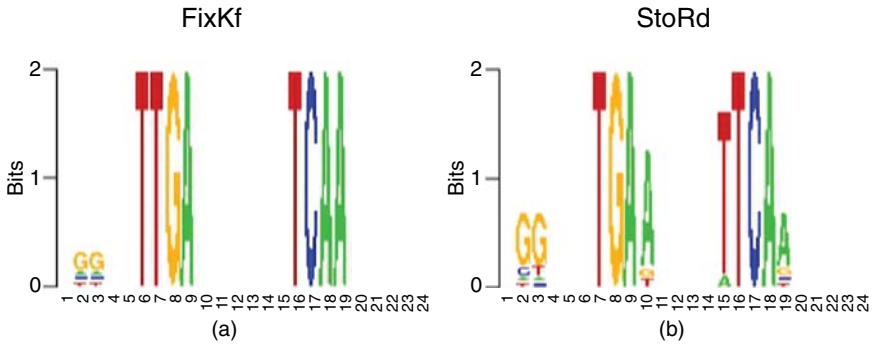

Figure 15.3 Binding specificity of FixKf (a) and StoRd (b) three-dimensional models. The LOGO represents the consensus predicted by the average of two types of position weight matrixes described in the text. It was generated by the web server 3D footprint using the "footprint your structure" software tool.

changes are incorporated *in silico*, although several side chain interactions with these nitrogen bases can be observed (data not shown). The absence of a thymine in position 11 allows the formation of a hydrophobic contact between the histidine in the motif of NnrR and the 13th position of the anaerobox. This interaction only occurs in the NnrR model (data not shown). Genetic and biochemical approaches will be necessary to analyze in deeper detail how modifications within the anaerobox sequence can affect binding affinity or shift sequence recognition by different FNR-like regulators.

15.7 PREDICTION OF FNR-RELATED TARGETS IN THE GENOME OF *R. etli* CFN42

FNR homologs of *R. etli* control the expression of genes that are important for respiration inside the nodule (*fixNOQP* and *fixGHIS* operons) and to alleviate nitrosative stress (*norCBQD*, *nirKVnnrRU* operons, *azuPf*, and *azuPd* genes). All these genes are expressed under microaerobic conditions both in culture and in symbiosis with legume plants. They have a conserved anaerobox with the consensus TTG-N_8-CAA. Furthermore, the presence of more than one anaerobox within the regulatory region of *nirK* allows fine-tuning of the transcription of this gene.

FNR from *E. coli* is known for being a global regulator that controls expression of several genes under anaerobic conditions. Recently, the chromosomal distribution of the targets of the regulator during exponential anaerobic growth was analyzed, and this study revealed 63 copies (Grainger et al., 2007). The presence of several FNR homologs in *R. etli* and the fact that variations in the DNA-binding domain may allow for sequence-affinity or sequence-discrimination differences make us speculate if different anaeroboxes or anaerobox-like sequences apart from the ones that have been previously described could be recognized by these regulators. A PWM was generated using the anaerobox sequence of the known targets of regulation of the six FNR-related proteins of *R. etli*. This matrix was used to scan the upstream region [−200 +1] of all genes of *R. etli* CFN42 using the matrix scan algorithm of the web server RSAT (http://rsat.ulb.ac.be/). This strategy revealed the presence of 303 putative anaeroboxes in the *R. etli* CFN42 genome. In some cases, two contiguous divergent genes shared one of these putative anaeroboxes. Anaeroboxes with the highest weight had the consensus TTG-N_8-CAA sequence. Other anaerobox-like sequences that lacked the consensus were predicted; however, until now there is no evidence that the FNR regulators can bind to them. The transcriptional profile under microaerobic conditions of a *R. etli* triple mutant in *fixL*, *fnrNd*, and *fnrNch* that no longer expresses the FNR-related proteins was compared to the wild-type strain. Apart from the known targets of regulation of these proteins, differences in the transcription of several genes were observed. Some of these genes have predicted anaeroboxes. Genes RHE_PD00022, *virB3a* (type IV secretion system protein), and $adhA_2$ (alcohol dehydrogenase) were downregulated in the absence of FNR regulators. These genes have anaeroboxes in their regulatory regions that highly resemble the anaerobox of known targets. Also genes with a less conserved anaerobox, lacking the consensus sequence TTG-N_8-CAA, were differentially expressed in the absence of FNR regulators. In this regard, it would be interesting to determine if these changes in expression are due to direct regulation and if these anaerobox-like motifs are important. Several genes with a highly conserved anaerobox were not clearly regulated by the FNR regulators under the conditions tested. It might be possible that the expression of some of these genes, although dependent at least on some level of the FNR regulators, have specific requirements that were not met in our experimental conditions. Interestingly, several highly conserved anaeroboxes (weight above five and with the consensus TTG-N_8-CAA) are located in plasmids pRet42d and pRet42f (16 and 18 unique sequences, respectively). The widespread transcription activity of the *R. etli* pRet42d observed under microaerobiosis (Girard et al., 1996) and the presence of several of the known targets of the FNR regulators on plasmid pRet42f suggest us that the occurrence of FNR regulators in these plasmids allowed the selection of adaptive *cis* mutations that favored survival

or increased fitness under microaerobic conditions either in free living or symbiotic bacteria. Same rational could apply for *fnrNch* in the chromosome of *R. etli*. Ulterior acquisition or recruitment of the megaplasmids brought robustness to the microaerobic response of this bacterium.

Some genes with unknown function were differentially regulated in the absence of the FNR proteins. A particularly interesting case is gene RHE_PD00022, transcription of this gene is drastically reduced in the absence of FNR regulators. The absence of either the FixL–FxkR two-component system or the FixKf regulator almost abolishes the expression of this gene. RHE_PD00022 gene has a canonical anaerobox with the consensus sequence TTGAT-N_4-ATCAA and is expressed at high levels both in culture at low-oxygen concentrations and in symbiosis. The predicted protein is annotated as a hypothetical protein and possesses three tandemly repeated BON (Bacterial OsmY and nodulation) domains. This type of domain is mostly unexplored and little is known about its function (Yeats and Bateman, 2003). The most well-characterized protein baring BON domains is OsmY, a protein that confers protection to osmotic stress in *E. coli* (Yim and Villarejo, 1992). The aminoacids conserved in the BON domain are suggestive of a binding function. It has been hypothesized that the BON domains of OsmY help to avoid shrinkage of the cell by contacting the phospholipid interphase within the periplasmic space (Oh et al., 2000; Liechty et al., 2000). Another BON-domain baring protein is NolX, a protein involved in the secretion of a pilus structure that determines host specificity in rhizobial nodule formation. The phyletic distribution of these proteins suggests that most Proteobacteria have one or two BON-domain baring proteins. These proteins are more extended in the *Burkholderia* genus. Unusually three repeated BON-domain architectures as the one in RHE_PD00022 are only present within *Burkholderia* proteins and proteins encoded in the symbiotic or pathogenicity plasmids of *Ralstonia* and *Rhizobiales*. This distribution strongly suggests a role for these proteins in cell–cell interaction or host invasion (Yeats and Bateman, 2003). Interestingly, gene RHE_PC00107 in pRet42c is predicted to have a CBS and a BON domain, these two domains are frequently found together. It also has a highly conserved anaerobox, and even though it did not appear to be differentially regulated in our expression analysis its neighbor $adhA_2$ (RHE_PC00106), which also has a highly conserved anaerobox, was dependent on FNR regulators. Gene RHE_PF00490 also has a CBS domain but lacks a BON domain. This gene also possesses a highly conserved anaerobox. These genes are encoded in plasmids that are crucial for symbiosis and nitrogen fixation; it will be of great relevance to analyze if they play a role in these crucial processes of rhizobial physiology.

15.8 CONCLUDING REMARKS

FNR-like regulators are crucial for nitrogen fixation in Rhizobia. FixK and/or FnrN are responsible for the activation of the *fix* genes in *S. meliloti*, *B. japonicum*, *R. leguminosarum*, and *R. etli*. However, in most of these bacteria, there is more than one regulator of this type and their function has not been clarified. From the study of the regulation of *fix* genes in *R. etli*, we have learned that several regulators of the same family can be used to shape an adapted regulatory circuit. The inclusion of regulators with similar specificities such as in the case of FixKf, FnrNch, and FnrNd can make a regulatory network more robust. However the ability of FnrN regulators to directly detect oxygen in addition might allow fine-tuning of the response by modifying the detection threshold of the oxygen signal. The responses to signals that are often encountered together in a particular environment probably evolve to include regulators that recognize very similar DNA targets although with some differences in specificity or affinity. It is well known that low oxygen and nitrogen oxide are signals that dwell within the nodules. It is tempting to speculate that a relatively small number of changes were required to modify the specificity for preexisting anaeroboxes that were recognized by a low-oxygen responsive regulator to now be targeted by a protein with a highly similar DNA-binding motif that has acquired the novel function of nitrogen oxide sensor. Having two different sensors for separate signals allows setting up a hierarchical response in a stepwise manner. NnrR and FixKf seem to fit in that kind of hierarchical response in *R. etli*.

StoRd and StoRf play a role as modulators within the regulatory cascade that control the expression of *fix* genes in *R. etli*; however, until know it has not been shown that these regulators can bind directly to the anaerobox. The identification of the binding site of these regulators in the regulatory region of their reported targets will shed light on the molecular mechanisms that promote positive and negative regulation at low oxygen levels in *R. etli*.

Several anaeroboxes have been predicted in the regulatory regions of the genes encoded in the genome of *R. etli*; however, only few efforts have been made so far to determine the functionality of these sequences. With the improvement and the development of novel genomics approaches, it has become an obligation to pursue a deeper but broader understanding of the role of FNR-like regulators in rhizobial physiology. The inclusion of several members of the FNR/CRP superfamily in the *fix* regulatory cascade of *R. etli* makes this regulatory model attractive for the study of the impact of cross talk and the mechanisms that have been selected to avoid its counterproductive effects.

Section 4

Taxonomy and Evolution of Nitrogen Fixing Organisms

Chapter 16

Exploring Alternative Paths for the Evolution of Biological Nitrogen Fixation

John W. Peters and Eric S. Boyd

Department of Chemistry and Biochemistry and Department of Microbiology and Immunology, Montana State University, Bozeman, MT, USA

16.1 INTRODUCTION

Biological nitrogen fixation is curiously restricted to prokaryotes and is associated with a diversity of microorganisms that represent a wide range of physiologies (Boyd et al., 2011a, 2011b; Dos Santos et al., 2012). Since nitrogenase is very sensitive to oxygen, different classes of organisms have evolved different mechanisms to catalyze nitrogen fixation in an oxic environment (Gallon, 1992; Berman-Frank et al., 2003). Probably the most recognized mechanism is associated with symbiotic nitrogen fixation where plants provide a microaerobic niche by producing leghemoglobin that sequesters oxygen in nodules, thereby maintaining very low oxygen tensions (Ott et al., 2005). Nitrogen fixation occurs under anoxic conditions in strict or facultative anaerobes and nonfilamentous cyanobacteria or in the heterocysts of filamentous cyanobacteria. In obligate aerobes, the nitrogen-fixation apparatus is protected by what has been described as respiratory protection whereby high rates of respiration ensure the consumption of oxygen at the cell membrane, thereby maintaining an oxygen-free cytoplasm. It is likely that these mechanisms emerged later in the evolutionary history of biological nitrogen fixation owing to the increased complexity of *nif* gene clusters in microorganisms adapted to fixing nitrogen in air (Boyd et al., 2011a). The simplest assemblages of specific genes associated with nitrogen fixation occur in strict anaerobes, but tracing the evolutionary trajectory and identifying the most ancient nitrogen fixers present in extant biology has been a challenge.

16.2 HOW ANCIENT IS BIOLOGICAL NITROGEN FIXATION?

Many would like to place biological nitrogen fixation as an ancient and perhaps even primordial process. This is due to the essential requirement of fixed nitrogen for life and the presumed limiting amount of fixed nitrogen in the early reducing Earth when the polyoxyanions of nitrogen (nitrate and nitrite) would likely be present in vanishing low quantities if at all (Falkowski, 1997; Fani et al., 2000). Apart from models based on atmospheric chemistry (Yung and McElroy, 1979; Kasting and Walker, 1981; Navarro-González et al., 2001), little is known, however, about the availability of ammonia or other reduced forms of nitrogen over the course of geological time. One can however ask the general question of whether the overall occurrence of the biochemical apparatus present in extant biology, nitrogenase, and its associated functionalities are consistent with a primordial origin by focusing the question of whether nitrogenase was likely to be a property of a Last Universal Common Ancestor (LUCA). Biological nitrogen fixation is not found associated with any eukaryote, but the process is widely distributed among bacteria with a very limited distribution among methanogenic archaea. Although widely distributed both

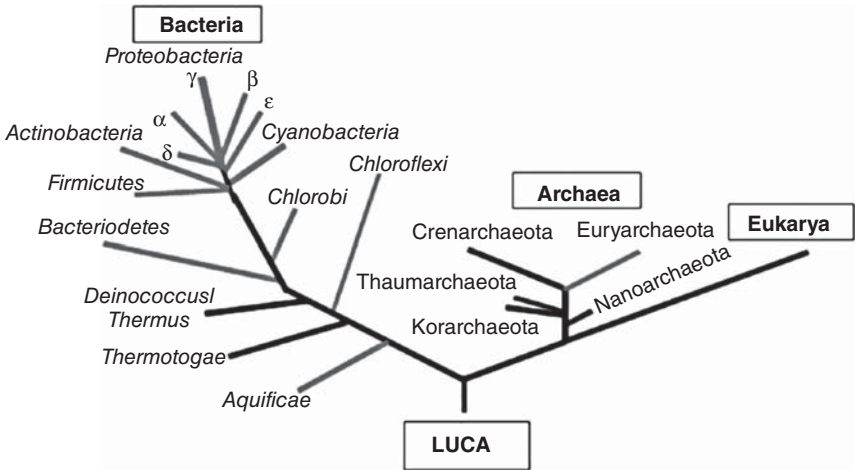

Figure 16.1 A taxonomic tree indicating lineages where representative organisms have been identified that harbor *nif* (overlaid in gray).

taxonomically (Boyd et al., 2011a) and ecologically (Zehr et al., 2003), the process is far less than universal and unlike processes and functionalities that we ascribe to properties of LUCA, the process is not commonly associated with deeply rooted lineages identified by 16S ribosomal DNA evolutionary trajectories (Fig. 16.1).

16.3 WHAT ARE THE MOST DEEPLY ROOTED ORGANISMS THAT HARBOR NITROGENASE AND PRESUMABLY FIX NITROGEN?

To answer this question, one must define a set of criteria to establish what genes are required for nitrogen fixation today, and hypothetically which were required to fix nitrogen in ancestral populations. This is not as simple as in many other systems where the presence of one or more specific gene products that encode the enzyme provides the basis for an active function. This is due to the requirement of additional gene products that are involved in the biosynthesis of the unique cofactors (Rubio and Ludden, 2005, 2008; see Chapter 7). From previous genomic, biochemical, and molecular genetic studies on biological nitrogen fixation from different microbial sources, we and others have established a criterion defining the minimal set of genes required to synthesize an active nitrogenase (Boyd et al., 2011a; Dos Santos et al., 2012). This criterion stipulates that the structural genes *nifH*, *nifD*, and *nifK* and three additional FeMo-cofactor biosynthetic genes *nifE*, *nifN*, and *nifB* must be present in an operon for it to be considered to encode for a functional nitrogenase. The criteria is based mainly on the observation that deletion mutation analysis of *nifE* and *nifN* (Ugalde et al., 1984; Jacobson et al., 1989; Roll et al., 1995; Hu et al., 2005) and *nifB* (Shah et al., 1994; Christiansen et al., 1998) results in the production of an inactive FeMo-cofactor-less nitrogenase. Moreover, the *nif* clusters of all sequenced nitrogen fixers that have been characterized minimally have these gene products (Boyd et al., 2011a). Using this criterion, we identified all putative diazotrophs with sequenced genomes and exploited specific genetic events (e.g., gene fusions, duplications) that were involved in the evolution of the biosynthetic pathways to identify which extant organisms harbor the oldest nitrogenase.

The first relationship that was exploited was the relationship between the structural gene products that encode the MoFe protein, NifDK, and the paralogous NifEN complex, which functions as a scaffold for FeMo-cofactor biosynthesis. Primary amino acid sequence comparisons of NifD, NifK, NifE, and NifN reveal significant homology, indicating that these gene products have evolved from a common ancestor. It has been suggested that two sets of gene duplications resulted in these four related gene products. The first duplication of *nifD*, which is presumed to be ancestral for reasons discussed later, was duplicated to *nifK* generating the heterotetrameric MoFe protein (Fani et al., 2000). Subsequently, *nifD* and *nifK* were duplicated in tandem to form *nifEN*, which encodes for a heterotetrameric complex that functions as a dedicated scaffold for FeMo-cofactor biosynthesis (see Chapter 7). Phylogenetic reconstruction of paralogous NifD, NifK, NifE, and NifN proteins reveals distinct clades that correspond with each protein, with NifE and NifN proteins nested among NifD and NifK proteins, respectively, consistent with this evolutionary trajectory (Boyd et al., 2011a, 2011b). With regard to the overarching question of the identity of the most ancient nitrogen fixers among sequenced extant organisms, the NifD and NifK proteins associated with hydrogenotrophic methanogens form basal branches (Fig. 16.2), suggesting that nitrogenase in these taxa is most reminiscent of the ancestor. Such results strongly suggest an origin for nitrogen fixation in an anoxic environment, which is consistent with the oxygen sensitivity of this enzyme complex, and our suggestion that the mechanisms organisms have adapted

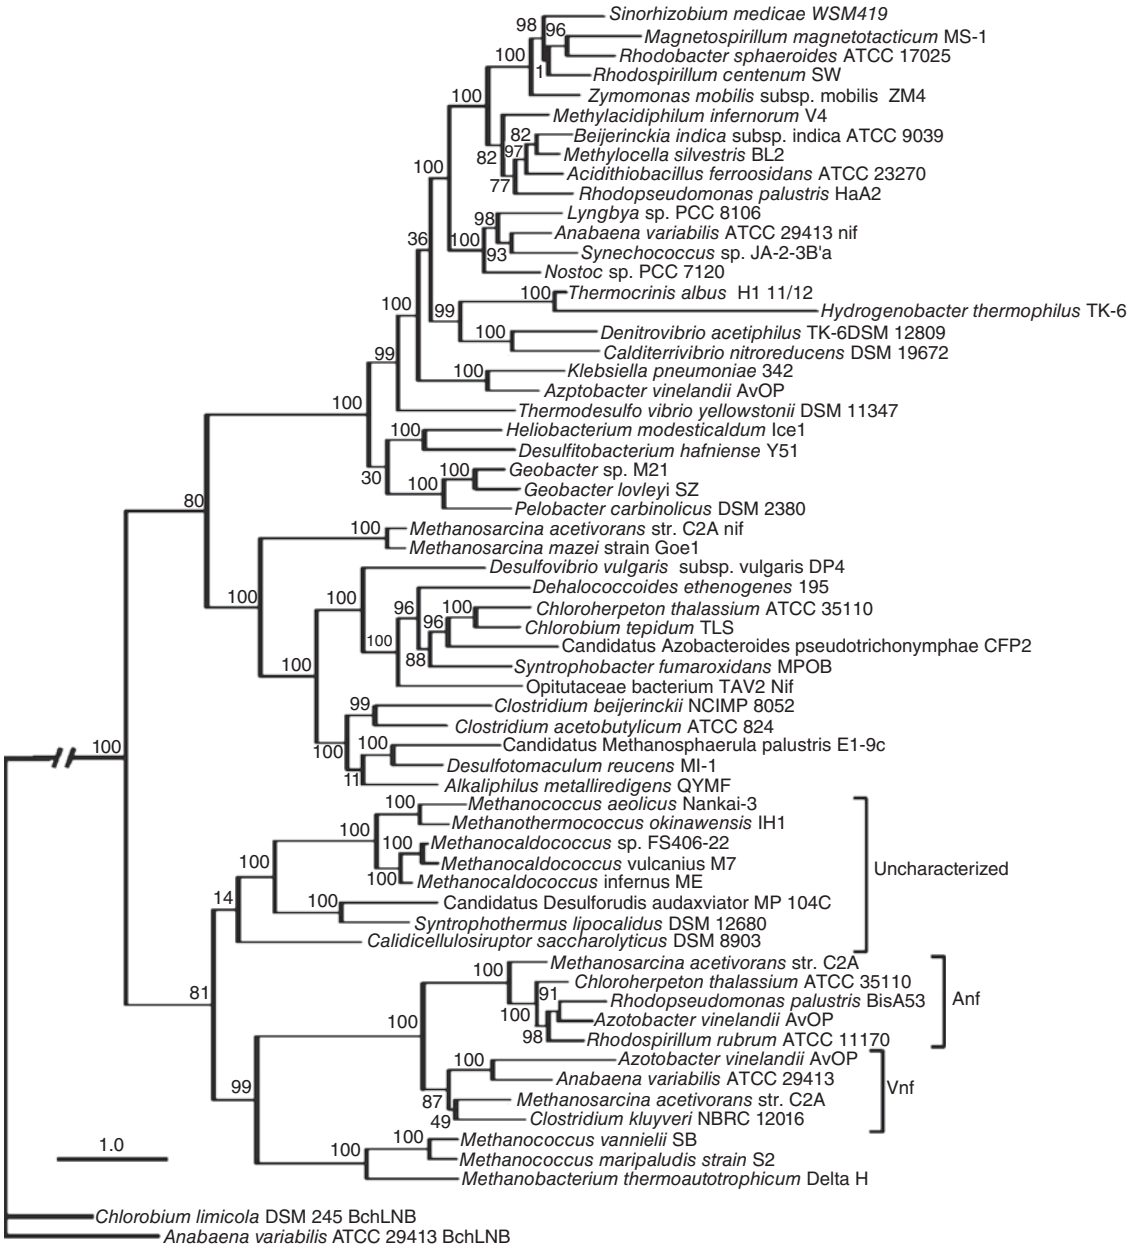

Figure 16.2 Maximum-likelihood phylogenetic reconstruction of a concatenation of Nif/Anf/Vnf and uncharacterized HDK proteins. Individual proteins were aligned, concatenated, and subjected to evolutionary reconstruction as described previously (Boyd et al., 2011b). The composition of the active-site clusters other than those that correspond to Nif (e.g., Vnf, Anf, uncharacterized) is overlaid on the phylogeny. Bootstrap values are indicated at the nodes.

to fix nitrogen in the presence of oxygen are more recent innovations.

Reinforcement of these results which implicate hydrogenotrophic methanogens as the oldest nitrogen-fixing organisms, the evolution of the essential NifB protein offers additional support. NifB is a radical generating *S*-adenosylmethionine (SAM)-dependent enzyme that is involved in generating the hexacoordinated carbide at the center of the FeMo-cofactor (Wiig et al., 2012), which is the presumed key structural determinant of nitrogenase function (see Chapter 7). Most NifB proteins of extant organisms exist as putative two-domain protein composed of a radical SAM functionality and a carrier functionality that is the result of a fusion between the core NifB protein and a carrier protein that still exists as a standalone functionality termed NifX (Rubio and Ludden, 2008). Methanogens lack the associated NifX domain as a component of NifB and as such would have emerged prior to the fusion of these two functionalities in the evolution of NifB (Boyd et al., 2011a).

16.4 ARE ALTERNATIVE NITROGENASES EVOLUTIONARY ANCESTORS OF Mo-NITROGENASE?

The evolutionary trajectory of the different metal-containing nitrogenases has been an interesting question since their discovery nearly 30 years ago now. It has been suggested that nitrogen fixation by alternative nitrogenases might have preceded Mo nitrogenase in the early Earth and were the dominant nitrogenases prior to the *Great Oxidation Event* and the advent of oxygenic photosynthesis (Anbar and Knoll, 2002; Raymond et al., 2004). This suggestion was largely based on the presumed limited availability of Mo under the reducing environment of the early Earth (Anbar et al., 2007; Anbar, 2008) where most Mo would have been complexed in insoluble Mo-sulfides (Helz et al., 1996). Although this logic is sound and the potential for alternative nitrogenases as ancestors of Mo-nitrogenase is a rational suggestion, there are a number of both direct and indirect observations that indicate that this is not likely to be the case.

The alternative nitrogenase functions with either V in the place of Mo (V-dependent nitrogenase) or in the absence of any heterometal (Fe-only nitrogenase). Biochemical studies indicate that alternative nitrogenases are less efficient owing primarily to the substitution of either V or Fe for Mo in the FeMo-cofactor such that V-nitrogenase and Fe-only nitrogenases function with either at FeV-cofactor or what has been termed an FeFe-cofactor, respectively (Eady, 1996). Alternative nitrogenases are found to occur only in a small number of organisms and, to date, have never been observed in genomes that do not also encode a Mo-nitrogenase (Raymond et al., 2004; Boyd et al., 2011a). Gene clusters encoding the structural components of the alternative nitrogenases only possess a fraction of the required cofactor biosynthetic genes required for FeMo-cofactor biosynthesis (Boyd et al., 2011b). Transcriptional analysis of the model nitrogen-fixing organism *Azotobacter vinelandii* indicating nitrogen fixation by alternative nitrogenases (Vnf or Anf dependent) involves the expression of a number of FeMo-cofactor synthetic gene products located in the *nif* operons and is also required for the expression of active Mo-nitrogenase (Wolfinger and Bishop, 1991; Hamilton et al., 2011). These observations make it difficult to rationalize an ancestry involving the features of an extant alternative nitrogenase without invoking fairly extensive gene loss and/or rearrangements.

Lacking key dedicated biosynthetic gene products (E, N, or B), alternative nitrogenase does not obey the criteria that were put forth above that define the ability to catalyze nitrogen fixation. Inclusion of Vnf and Anf structural genes (Anf/VnfD and K) in the internally rooted phylogenetic analysis of NifD, NifK, NifE, and NifN amino acid sequences reveal ambiguous results as to which form of nitrogenase is ancestral (Boyd et al., 2011a). Previous studies examining the evolutionary trajectories of NifD alone or concatenations of NifH and NifD also lead to ambiguous results (Raymond et al., 2004). Since all three nitrogenases (Mo-, V-, and Fe-only) have dedicated structural proteins (H, D, and K), we recently conducted a phylogenetic study in which alignments of all three protein sequences were concatenated (Boyd et al., 2011b). In this study, the phylogenetic relationships were better resolved and a clear pattern was revealed (Fig. 16.2). Well-supported phylogenetic trees indicate that the alternative nitrogenases are nested among basal branching Mo-nitrogenase representatives. The phylogenetic and bioinformatics studies, as are all of the studies described in the chapter, are limited by only being able to analyze sequenced extant organisms. However, the results are compelling and consistent with biochemical and physiological data that together provide a strong case for reevaluating the dogma associated with basing the ancestry of nitrogenase solely on the availability on Mo in the geologic record.

16.5 WHAT IS THE NATURE OF THE METAL COMPLEMENT OF "UNCHARACTERIZED NITROGENASES"?

The assignment of the metal cofactor at the active site of nitrogenase homologs as described in the aforementioned phylogenetic studies is based on patterns of clustering with representative homologs that have been biochemically characterized to some extent. There are, however, a number of deeply rooted lineages that do not contain characterized nitrogenase proteins (Mehta and Baross, 2006; Boyd et al., 2011b; Dos Santos et al., 2012) (Fig. 16.2). Some of these uncharacterized nitrogenases do not obey our established criteria and lack homologs of the biosynthetic gene, *nifN*, required to be considered as a *bona fide* nitrogenase.

As mentioned previously, alterative nitrogenases are less efficient as nitrogen reduction catalysts, and previous biochemical studies have also shown interesting differences in the reduction of other substrates, including hydrogen, acetylene, and carbon monoxide. Alternative nitrogenases produce a larger proportion of hydrogen as a product in the nitrogenase reaction than does Mo-nitrogenase (Eady, 1996). Acetylene reduction catalyzed by the Mo-nitrogenase results in ethylene as the sole product in contrast to the alternative nitrogenases that produce detectable quantities of ethane in addition to ethylene. The recent observation that nitrogenases are capable of hydrocarbon production with carbon monoxide as a substrate (Lee et al., 2010; Hu et al., 2011) indicates that Mo-nitrogenases and V-nitrogenases have differing catalytic efficiencies for hydrocarbon production with V-nitrogenase having higher catalytic rates. Interestingly, it has been shown that simple site-specific

amino acid substitutions of Mo-dependent nitrogenase can affect increased hydrocarbon production on the order of that observed for that of the V-dependent nitrogenase (Yang et al., 2012). These results indicate that the combination of the metal content and cofactor protein environment that make up the structural determinants account for the subtle differences in substrate reduction properties of the different metal-dependent nitrogenases. Recently, we conducted a fairly exhaustive study of the polypeptide environment of the deeply rooted uncharacterized nitrogenase based on homology models (McGlynn et al., 2012). This work clearly indicated that the uncharacterized nitrogenases were more likely to be Mo-dependent nitrogenases than alternative nitrogenases. Given the organisms that possess uncharacterized nitrogenases occupying anaerobic niches, the results of this work is in line with our previous studies indicating that the oldest extant nitrogen-fixing organisms are anaerobes and that biological nitrogen fixation had its origins in an anoxic environment (Boyd et al., 2011a, 2011b). In addition, the observation that these deeply rooted uncharacterized nitrogenases are likely to be Mo-dependent further supports our previous observations indicating that Mo-dependent nitrogenases are ancestral to the alternative nitrogenases.

16.6 IS THERE AN EVOLUTIONARY RELEVANCE TO NITROGENASE PROMISCUITY?

The ability of nitrogenases to reduce other substrates such as acetylene and cyanide and their ability to convert carbon monoxide to hydrocarbon products has enticed some to propose that nitrogenase may have its evolutionary roots in one or more of these catalytic activities (Fani et al., 2000; Hu et al., 2011). This is an interesting idea, given that the barrier for these reactions is lower and this might afford a somewhat stepwise path to achieving an enzyme capable of overcoming the enormous activation barrier of dinitrogen activation (Rees, 1993). Nitrogenase enzymes with the dedicated physiological function of reducing these types of substrates or analogous compounds have not been identified in extant biology, and it is difficult to envision conditions that would represent a strong selective pressure to evolve such enzymes. Recent work involving the observation that Mo- and V-dependent nitrogenases are capable of hydrocarbon production from carbon monoxide has been used to suggest a link between nitrogenase-dependent production of reduced carbon and nitrogen (Lee et al., 2010; Hu et al., 2011). Imagining a selective pressure that would lead to this complicated and presumably ATP-dependent mechanism for generating reduced carbon in early life is difficult, especially in light of the presence of other viable mechanisms present in extant biology. The Wood–Ljungdhal pathway is a prime example and the key enzyme, the carbon monoxide dehydrogenase/acetyl CoA synthase (Ragsdale, 1991), for example, has a much more common occurrence in deeply rooted microorganisms (Techtmann et al., 2012) than nitrogenase and is by all accounts a more ancient enzyme. We presume that nitrogenase evolved in response to selective pressure of fixed nitrogen availability, and nitrogenase promiscuity and the ability to reduce other substrates is a product of the evolution of a redox enzyme that can overcome the largest activation barrier in biology.

16.7 WHAT IS THE EVOLUTIONARY ORIGIN OF NITROGENASE?

The evolutionary origin of nitrogenase is a very interesting question and is framed by a number of traditional paradigms that are not strongly tied to the observations we can glean from extant biology. In today's world, the availability of fixed nitrogen limits global nutrition and so there is a natural desire to place the emergence of biological nitrogen fixation as a very early event and perhaps even a primordial process. However, even the simplest evolutionary observations such as the aforementioned limited distribution of biological nitrogen fixation in deeply rooted lineages is not consistent with biological nitrogen fixation being a property of LUCA. The history of nitrogen availability is not something that can, as of yet, be ascertained from the geologic record, so the time when the selective pressure was sufficient to affect the emergence of such a complicated biochemical process is unclear. Some insights however can be assembled from other evolutionary relationships including the closely related protein complexes associated with chlorophyll and bacteriochlorophyll biosynthesis and the related enzyme complex putatively involved in F430 biosynthesis found most commonly in methanogens (Raymond et al., 2004; Boyd et al., 2011b) (Fig. 16.3).

There is an emerging body of work on the biochemistry of the dark operative protochlorophyllide reductase complex involved in bacteriochlorophyll biosynthesis (Fujita and Bauer, 2000; Brocker et al., 2008, 2010; Sarma et al., 2008; Muraki et al., 2010; Moser et al., 2013). In brief, the enzyme catalyzes the stereo-specific reduction of the C17–C18 double bond of the D-ring of protochlorophyllide to form a chlorophyllide. Presumably, the nature of this stereo-specific reduction is facilitated by an analogous gated electron transfer mechanism required in biological nitrogen fixation and thus involves an analogous enzyme complex, which in bacteriochlorphyll biosynthesis involves an Fe-protein analogous component, BchL, and a MoFe protein analogous component, BchNB. At the site of active site cofactor binding in nitrogenase, BchNB possesses a

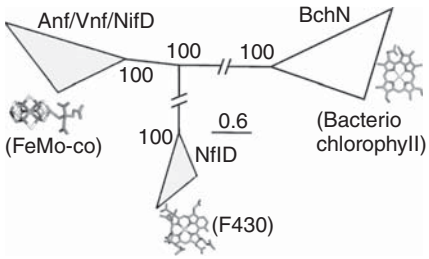

Figure 16.3 Phylogenetic relationships between Anf/Vnf/NifD, BchN, and NflD proteins indicate a clear evolutionary ancestor (Boyd et al., 2011b). Parsimony would suggest that the ancestor is similar to the NflD or BchN protein. The ancestor of these protein complexes (at the trifurcation point of the tree) likely encoded a single structural protein approximating NflD. An ancient duplication followed by independent evolution of the second NflD copy yielded the precursor to the heterotetrameric BchNB and NifDK complex. See Figure 16.4 for a schematic describing this evolutionary trajectory.

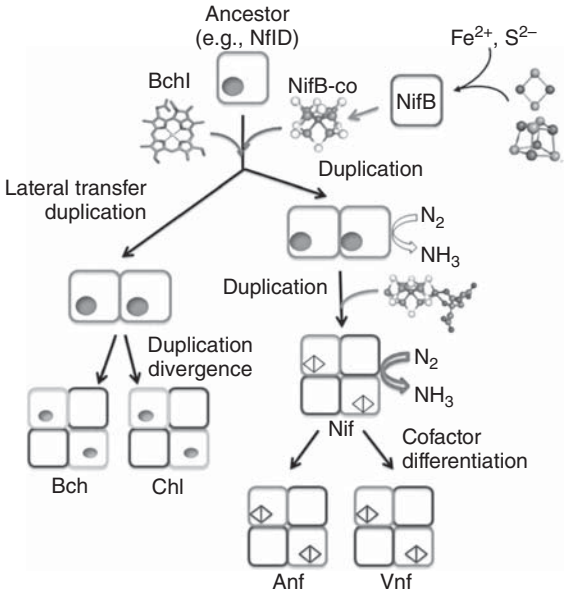

Figure 16.4 Hypothetical scheme depicting the evolution of nitrogenase from its protein ancestor. NifB, which catalyzes the formation of the FeMo-co precursor NifB-co from simple FeS clusters and/or ferrous iron/sulfide is presumed to have been paramount in providing the selective pressure to evolve a protonitrogenase. Here, NifB-co would have serendipitously nested in the cavity of the nitrogenase ancestor (e.g., BchNB- or NflD-like), which would have had the ability to reduce N_2, although without high efficiency. Duplication of nifDK and subsequent diversification resulting in nifEN yielded the ability to further mature NifB-co into FeMo-co.

cavity for protochlorophyllide binding, and substrate reduction involves BchL-dependent electron transfer reactions to affect substrate reduction.

From a structural perspective relating the arguably simpler protochlorophyllide reductase to the more complex cofactor-containing nitrogenase through parsimony would dictate invoking that the least common ancestor is the one with most simple components. That is to say, the simplest evolutionary trajectory is one in which the common ancestor approximates the structure of the protochlorophyllide reductase or a cofactor-less nitrogenase (Brocker et al., 2008; Muraki et al., 2010). The mechanism of cofactor biosynthesis is an additional source of insight when thinking of plausible scenarios for the evolution of nitrogenase (Rubio and Ludden, 2008; Hu and Ribbe, 2013). The final step in nitrogenase enzyme maturation is in fact the insertion of a preformed cofactor into a cofactor-less nitrogenase that for all intent and purposes approximates the salient structural features of the protochlorophyllide reductase (Schmid et al., 2002). Interestingly, neither the cofactor-less nitrogenase nor the cofactor on its own have nitrogen-reducing activity, observations that when considered in the context of evolution narrow down viable scenarios. We have spent considerable time attempting to envision evolutionary paths for nitrogenase in which a step-wise process could emerge such that structural determinants for catalysis derived from the cofactor and structural protein could be brought together to form an active nitrogen-reducing enzyme. When approached from this perspective, the most parsimonious scenario involves a common ancestor with an open cavity resembling protochlorophyllide reductase (Brocker et al., 2010; Muraki et al., 2010) (Fig. 16.4). This reductase serendipitously binds a modified iron–sulfur cluster fragment, and the result is a protonitrogenase with a selectable level of nitrogen-reducing activity. This could be in the form of a radical SAM-modified carbide iron–sulfur cluster similar to the cofactor intermediate proposed to form at an early state in FeMo-cofactor biosynthesis (Soboh et al., 2010; Wiig et al., 2012). In this scenario, additional selective pressure would exist to refine the process to the complicated biosynthetic pathway observed in extant biology.

17.1 INTRODUCTION

It has long been known that many species in the Leguminosae (Fabaceae) form a beneficial symbiotic interaction with N-fixing soil bacteria in the genus *Rhizobium*, as well as with other N-fixing bacteria in the Alphaproteobacteria class, such as *Bradyrhizobium*, *Azorhizobium*, *Ensifer* (*Sinorhizobium*), and *Mesorhizobium* (members of these genera are collectively termed "rhizobia"). This interaction involves the infection of legumes by the rhizobia and the development on their roots (and occasionally their stems) of structures termed nodules (see Chapter 4; Sections 9–12). The rhizobia proliferate within the developing nodules and establish an endosymbiosis within the plant cells, which allows the bacteria to fix N at a high rate, converting it to ammonia, which is then transferred to the host plant and used for its growth. Nodulated N-fixing symbioses have allowed legumes to colonize nutrient-poor soils, and many are pioneer species (Sprent, 2009). Nodulated legumes are considered to be the main contributors of biologically fixed N to pristine (i.e., unspoilt) ecosystems (Cleveland et al., 1999), and are thus essential to their ecology. Partly owing to its size and range of biomes, Brazil is one of the main centers of radiation of the Leguminosae in the World (Lewis et al., 2005), and it thus harbors an extraordinary diversity of legume species (including many endemics) that can

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

nodulate with many different rhizobial species (Sprent, 2009). Examples of Brazilian biomes where legume–rhizobial symbioses proliferate and even dominate are parts of Amazonia, the Cerrado, the Caatinga, and the Mata Atlantica (Moreira et al., 1992; de Faria et al., 1984; Sprent et al., 1996; Bontemps et al., 2010; dos Reis et al., 2010; Freitas et al., 2010). In addition to their ecological importance, several nodulated legumes are used as crops for human and animal consumption.

In the last 10–12 years, there has been increased focus on a newly described group of bacteria that can nodulate legumes. These are not related to conventional "rhizobia" in the Alphaproteobacterial genus *Rhizobium*, but are all in the Betaproteobacteria class, which contains genera such as *Burkholderia*, and are thus sometimes termed "beta-rhizobia" (Gyaneshwar et al., 2011; see also Chapter 89). Originally, it was doubted that legumes could be nodulated by bacteria in other classes of the proteobacteria, such as the Betaproteobacteria, although N_2 fixation is common in these classes, the bacteria within them had long been considered to be exclusively free-living and/or loosely associated with plants, and not considered as nodulating symbionts (Gyaneshwar et al., 2011; see Chapter 88). Nodules, with their ample supply of nutrients and their enclosed protective environment, are an attractive niche for a wide variety of nonsymbiotic bacteria that have the capability to colonize plants opportunistically (Sprent 2009; Lima et al., 2009), but most examples of "nonrhizobial" isolates from nodules have failed to fulfill "Koch's postulates" (i.e., they cannot renodulate their hosts). However, shortly after the first claims of legume-nodulating "β-rhizobia" emerged in 2001 for *Ralstonia taiwanensis* (now renamed *Cupriavidus taiwanensis*) isolated from invasive *Mimosa* spp. in Taiwan (Chen et al., 2001) and for *Burkholderia* spp. isolated from legumes in South Africa and French Guiana (Moulin et al., 2001), conclusive evidence for nodule formation and effective nitrogen fixation ability was obtained (Chen et al., 2003a, 2005a, b; Elliott et al., 2007a, b; see also Chapter 89). In all of these studies, green fluorescent protein (GFP) marked strains of *C. taiwanensis* and various *Burkholderia* strains were used to perform microscopical analyses of the nodulation processes on various legumes, but particularly on Brazilian native and invasive *Mimosa* spp., and they thus demonstrated that (i) Betaproteobacteria could fix N_2 symbiotically within nodules on these legumes and (ii) that the infection and development of N_2-fixing nodules with Betaproteobacteria were essentially the same as that described for many other legumes by "normal" rhizobia (Sprent, 2009).

The early studies of beta-rhizobia suggested that they might have a close affinity with the large legume genus *Mimosa* (Mimosoideae), which contains more than 500 species, with at least 300 of them native or endemic to Brazil, with the Cerrado and Caatinga as their main centers of radiation (Simon et al., 2011). This affinity has been demonstrated by recent studies by Bontemps et al. (2010) and dos Reis et al. (2010), in which it was shown that 70 *Mimosa* spp. (many of them endemics to the Cerrado and Caatinga) were almost exclusively nodulated by *Burkholderia*, see also Chapter 89. Therefore, based on these studies (and others, as we shall detail later in this review), it is reasonable to suggest that Brazil is a major center of symbiotic *Burkholderia* diversity, but there is at least one other, centered in South Africa, in which several endemic papilionoid legumes (*Cyclopia*, *Lebeckia*, *Rhynchosia*) are nodulated by strains closely related to *B. tuberum* (Elliott et al., 2007b; Gyaneshwar et al., 2011) or belonging to new species (De Meyer et al., 2013a, b). In this context, it is interesting to note that even *Mimosa*-nodulating *Burkholderia* strains, such as *B. phymatum* STM815 can be found associated with papilionoid legumes, such as common bean (Talbi et al., 2010). Indeed, papilionoid-nodulating *Burkholderia* may be of potential agricultural importance in poor soils, especially those that have high-salinity levels, or suffer from extremes of pH (high or low) (Gyaneshwar et al., 2011).

The aim of this chapter is to update the recent review by Gyaneshwar et al. (2011), particularly with regard to the following topics:

1. Several new species of *Burkholderia* have been described, and we shall put them into context with regard to their legume hosts and their geographical distribution, and also to evaluate how they might (or might not) assist in current attempts to divide the genus *Burkholderia* into two new genera, separating the "pathogenic" from the "beneficial" species (see also Chapter 89).
2. It is now clear that *Cupriavidus* symbioses are not confined to *C. taiwanensis*, and in addition to soil factors (such as pH and the presence of heavy metals) there are possible geographical and plant phylogenetic factors underlying these symbioses.
3. Evaluation of potentially new "rhizobial" taxa within the Betaproteobacteria (see also Chapter 89).
4. Coevolution between beta-rhizobia and their legume hosts, with particular reference to the Mimosoideae.

17.2 BURKHOLDERIAS ARE HIGHLY DIVERSIFIED SYMBIONTS OF LEGUMES

The legume-nodulating burkholderias are closely related to plant-beneficial, often diazotrophic, endophytic, and environmental *Burkholderia* species and strains, but not to the phytopathogenic/pathogenic group of burkholderias (including the "*B. cepacia* complex," Fig. 17.1) (Suarez-Moreno

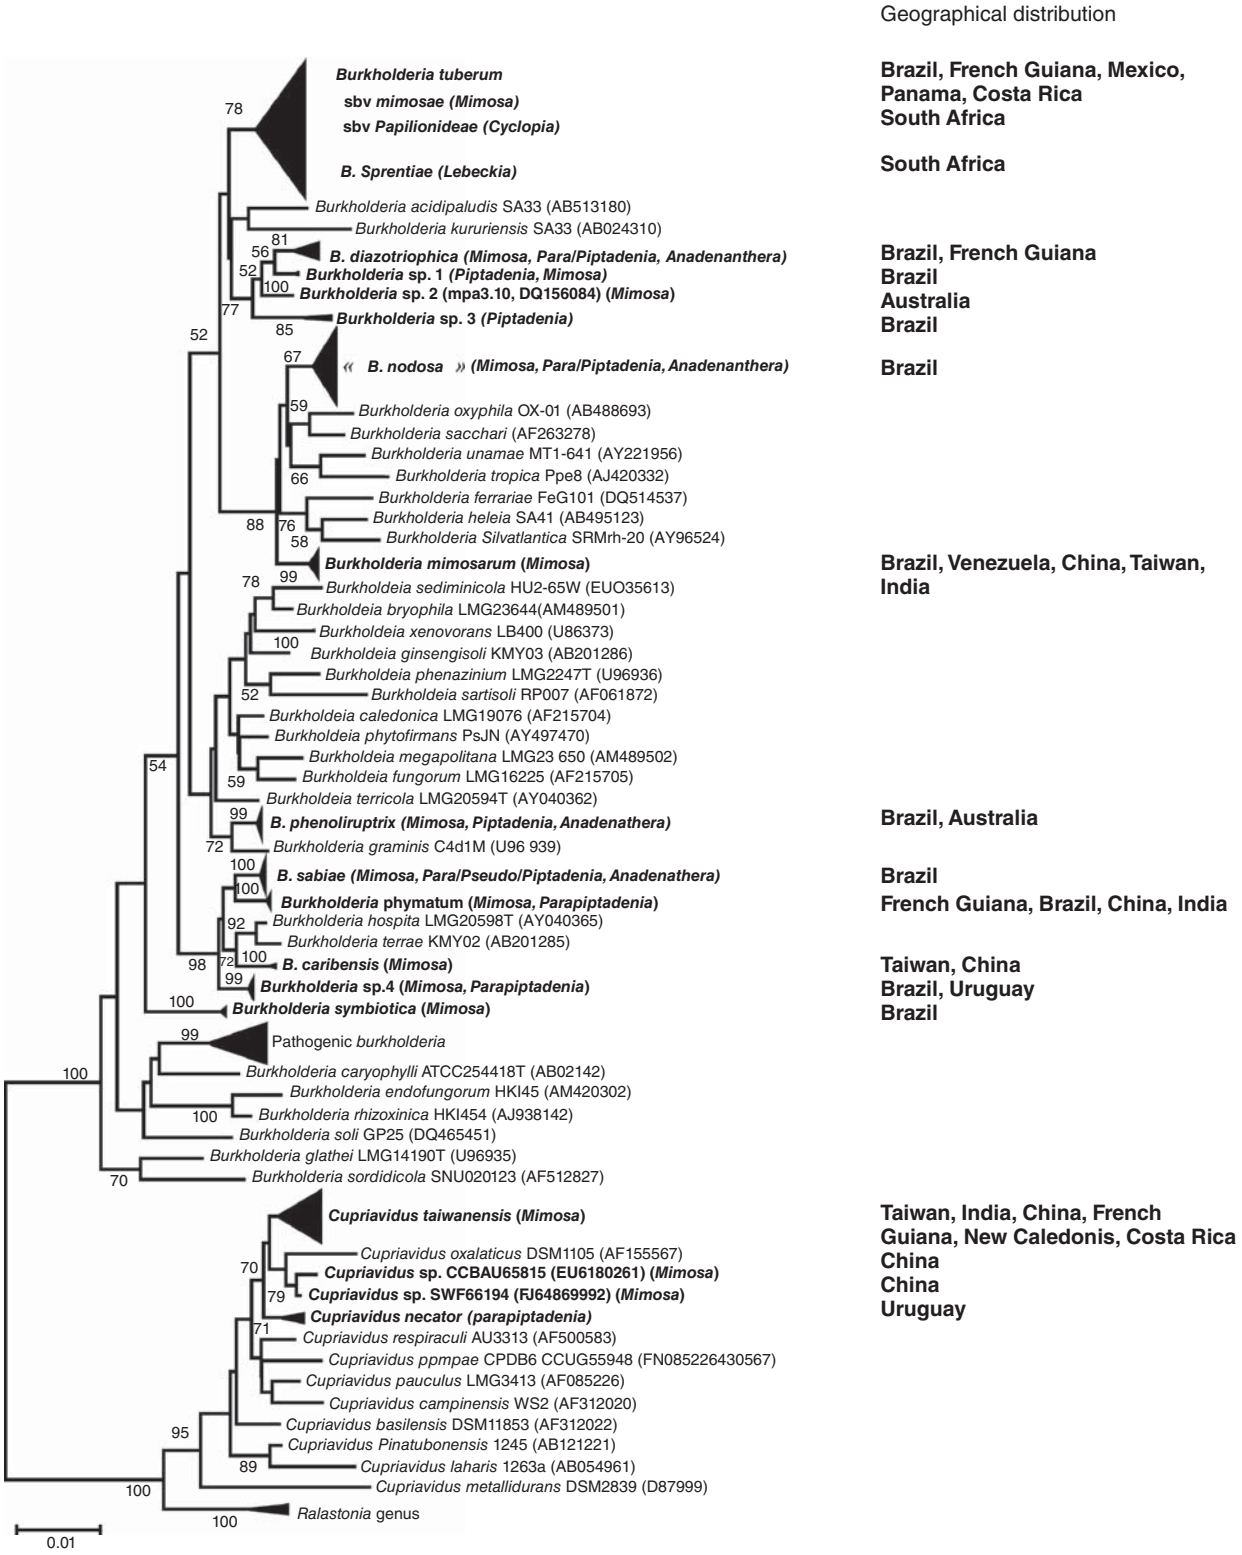

Figure 17.1 16S rRNA phylogeny of the *Burkholderia* genus. The tree was built using the neighbor-joining method, based on evolutionary distances computed using the maximum composite-likelihood method, with MEGA5 software. Bootstraps percent values (1000 replicates) are indicated at each tree node (if >50%). The analysis involved 299 nucleotide sequences, and 1273 positions in the final dataset. Some clades were summarized as triangles to simplify the figure. *Burkholderia* legume symbiont clades and species are indicated in bold. The legume host of origin of the isolates is indicated in parentheses, while their geographical origin is given at the right-hand side of the tree (see also Chapter 89).

et al., 2012). It is considered that the legume-nodulating burkholderias may have originated from the environmental/endophytic ones. A reasonable scenario is that approximately 50 mya, shortly after the first emergence of the legumes at 60 mya and coinciding with the evolution of their ability to nodulate (Doyle, 2011), the environmental/endophytic ancestors of the legume-nodulating burkholderias "added" *nod* genes (from an unknown donor) to their pre-existing *nif* genes (Bontemps et al., 2010). These potentially nodulating burkholderias then encountered several legume ancestors, became their symbionts, and then diversified in parallel with them. In the specific case of *Mimosa*, it is estimated to have emerged at approximately 30 mya, and then to have radiated within a number of centers in the Americas, but most notably in the Cerrado and Caatinga biomes of Brazil, resulting in >200 species residing within them (Simon et al., 2011), many of which have been shown to be nodulated by a wide range of *Burkholderia* genotypes, some new and some already described (Bontemps et al., 2010; dos Reis et al., 2010). It is thus reasonable to suggest that the ancestral *Mimosa* spp. encountered their ancestral *Burkholderia* symbionts in these biomes, and the two partners then diversified and coevolved with each other, thus resulting in the high diversity of both symbiotic partners now evident in both biomes (Bontemps et al., 2010). Similarly, in the Cape Floristic Region (the Fynbos) of South Africa, several genera of endemic legumes in the Papilionoideae have diversified and evolved to nodulate with a group of non-*Mimosa*-nodulating *Burkholderia* spp. that possess *nod* genes that are phylogenetically closely related to *B. tuberum* STM678 (Elliott et al., 2007b; Garau et al., 2009; Gyaneshwar et al., 2011; Howieson et al., 2013). Indeed, the number of symbiotic species of *Burkholderia* has increased concomitantly as new legume symbiont diversity studies are regularly and continually being published, and this number will undoubtedly continue to increase as more centers of diversity (particularly those in the tropics and subtropics) are investigated.

Up to now, 11 species of nodulating burkholderias have been described, but several clades remain to be named (Fig. 17.1). Here is a list of the presently recognized species, together with their geographical distribution, host range, and nodulation gene origin (as shown in Fig. 17.2). This information is summarized in Table 17.1 (see also Chapter 89).

Burkholderia caribensis (Chen et al., 2003b). Two strains of this previously described non-nodulating and non-diazotrophic species have been isolated as fully functional N-fixing *M. pudica* symbionts in Taiwan. They harbor *nodA* genes closely related to *C. taiwanensis* LMG19424 (Chen et al., 2003b). However, until now this has been the only report of nodulating *B. caribensis*, and so it would appear that the occurrence of strains of this species as legume-nodulating bacteria (LNB) is rather limited.

Burkholderia diazotrophica (Sheu et al., 2012b). This species was originally found in Brazil, Taiwan, and French Guiana in nodules of "widespread" *Mimosa* species, such as *M. pudica* and *M. candollei* (syn. *M. quadrivalvis* var. *leptocarpa*) (Bontemps et al., 2010; Mishra et al., 2012), but recently it has also been isolated from nodules of *Anadenanthera* (species *peregrina* and *colubrina*), *Parapiptadenia blanchetti*, *Piptadenia viridiflora*, and *P. gonoacantha* (Bournaud et al., 2013). They carry the widespread nodC3 variant (Fig. 17.2).

Burkholderia mimosarum (Chen et al., 2006): This species seems to have an affinity for the species *Mimosa pigra* in Taiwan, Venezuela, and Brazil (Chen et al., 2005a, b, Bontemps et al., 2010), although it has also been isolated from *M. pudica* in French Guiana (Mishra et al., 2012), China (Liu et al., 2012), and India (Gehlot et al., 2013). Its type strain, PAS44, has been shown to be highly competitive for nodulation against *C. taiwanensis* LMG19424 or against various strains of alpha-rhizobia (Elliott et al., 2009).

Burkholderia nodosa (Chen et al., 2007): This species has only been found in Brazil. It is a frequent symbiont of *Mimosa* spp. (Bontemps et al., 2010) as well as *Piptadenia*, *Parapiptadenia*, and *Anadenanthera* species (Bournaud et al., 2013).

Burkholderia phenoliruptrix (Bournaud et al., 2013; de Oliveira-Cunha et al., 2012). This species was originally described on the basis of a single nonsymbiotic isolate, which was notable for its phenol-degrading properties (Coenye et al., 2004). The nodulating capability of strains from this species was first shown by Chen et al. (2005a) for strain BR3462 (syn. BR3459a), which was isolated from *M. flocculosa* in Brazil, and later sequenced and described formally as belonging to *B. phenoliruptrix* (de Oliveira Cunha et al., 2012). Several further isolates of this species were identified from the nodules of *Mimosa* and "Piptadenia Group" species, and these also proved to be true efficient nodulators of their legume hosts (Bournaud et al., 2013; clade 7 in Bontemps et al., 2010). This species harbors strains with two *nodC* variants nodC3 and nodC4 (Fig. 17.2), one being vertically transmitted (nodC4) while the other seems to have been acquired by lateral transfer (nodC3) (Bournaud et al., 2013).

Burkholderia phymatum is one of the first described species (Moulin et al., 2001; Vandamme et al., 2002). Its type strain, STM815, has been found to be an efficient symbiont of many *Mimosa* species (Elliott et al., 2007a; dos Reis et al., 2010). Among diversity studies, this species has been reported to be widely associated with *Mimosa pudica* in French Guiana (Mishra et al., 2012), China (Liu et al., 2012), and India (Gehlot et al., 2013), and as a minor symbiont of *Parapiptadenia pterosperma* in Brazil (Bournaud et al., 2013). Despite its high nodulation competitiveness ability, this species has not yet been reported among diversity studies of rhizobial symbionts of *Mimosa* species in Brazil

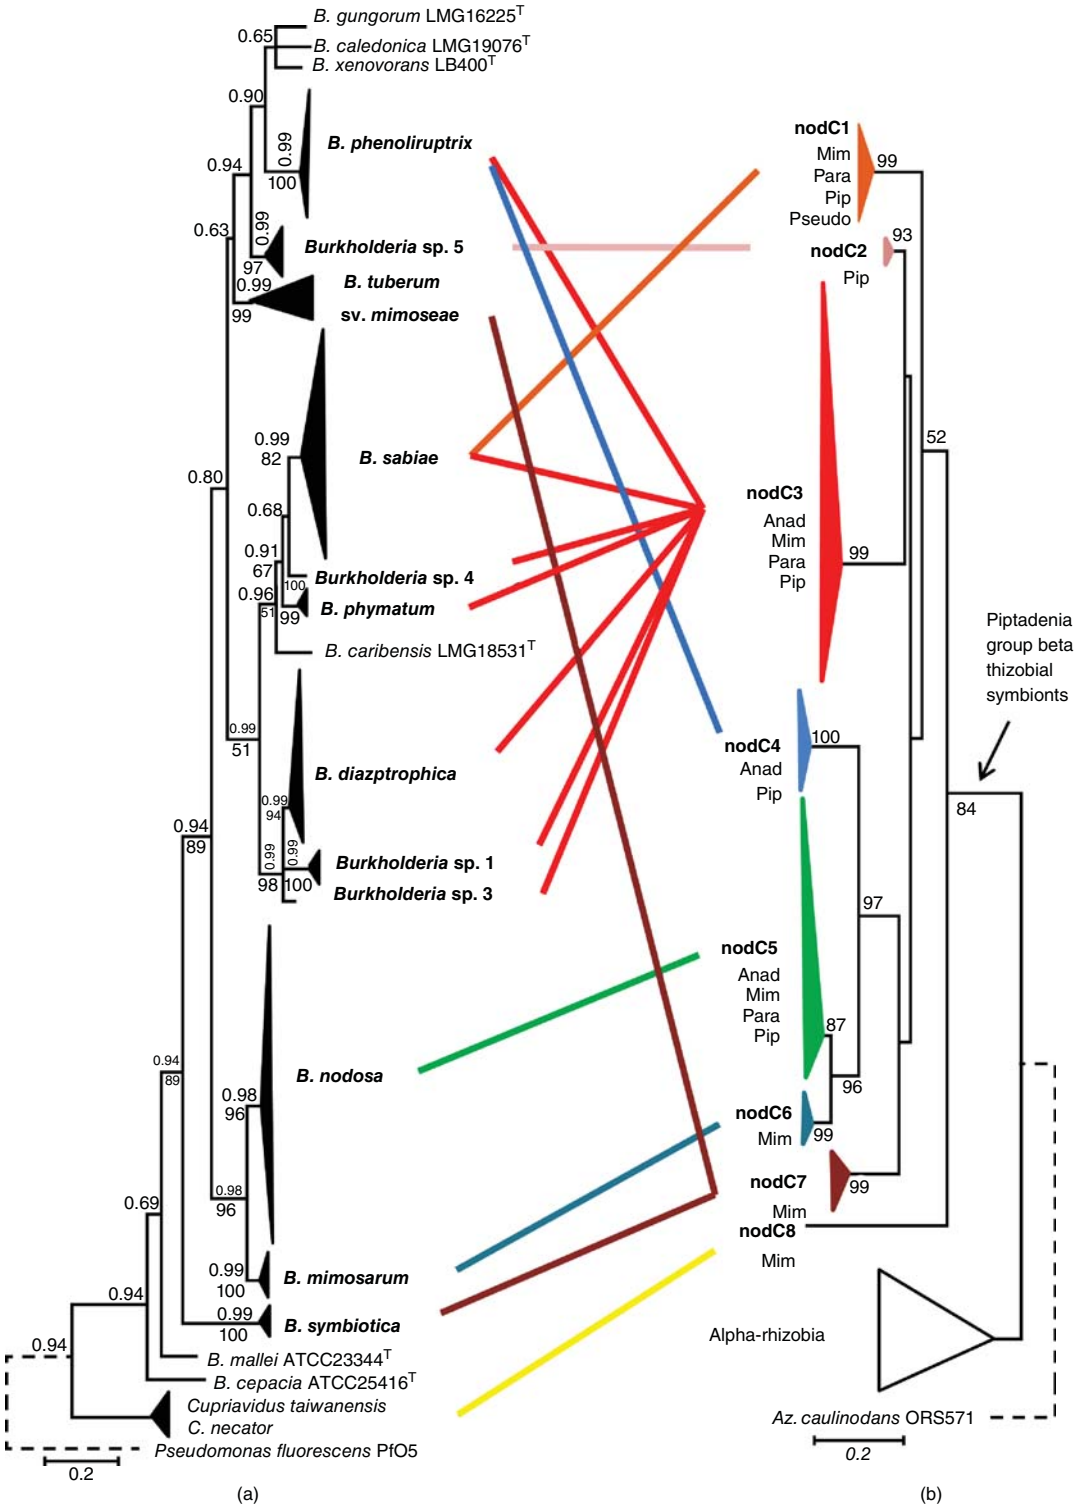

Figure 17.2 Comparison of taxonomic (a) and symbiotic (b) gene phylogenies in beta-rhizobial symbionts of the tribe Mimoseae. The figure is derived from Figure 2 of (Bournaud et al., 2013). The taxonomic marker phylogeny (a) was built using a Bayesian analysis on a partition of 16S rDNA and recA phylogenetic markers, while the symbiosis gene phylogeny was built using maximum likelihood on an alignment of the *nodC* gene. Details on analyses, strains used, and accession numbers can be found in (Bournaud et al., 2013). Legume genera associated with *nodC* clades are abbreviated as follows: Mim, *Mimosa*; Para, *Parapiptadenia*; Pip, *Piptadenia*; Pseudo, *Pseudopiptadenia*; and Anad, *Anadenanthera*.

(Bontemps et al., 2010). All strains isolated from nodules of the Mimoseae tribe harbor the nodC3 variant (Fig. 17.2).

Burkholderia rhynchosiae (De Meyer et al., 2013a). This species was isolated from *Rhynchosia ferulifolia* (tribe Phaseoleae, papilionoid) root nodules in South Africa (Garau et al., 2009). Its *nodA* genes are close to *B. tuberum* sbv *papilionoiideae*.

Burkholderia sabiae (Chen et al., 2008). This species was originally isolated from nodules of the tree "Sabiá" (*M. caesalpiniifolia*) in Brazil, but was also recently found to be a frequent symbiont of the Piptadenia Group (species of *Piptadenia*, *Parapiptadenia*, *Pseudopiptadenia*, *Anadenanthera*). The species hosts strains with two *nodC* variants (nodC1 and nodC3, Fig. 17.2).

Burkholderia sprentiae (De Meyer et al., 2013b). This species was isolated from *Lebeckia ambigua* root nodules from South Africa (Howieson et al., 2013). It is close to the species *B. tuberum*.

Burkholderia symbiotica (Sheu et al, 2012a). This species has only been reported in Brazil in nodules of the Caatinga endemics *Mimosa cordistipula* and *M. misera* (Bontemps et al., 2010; Sheu et al., 2012a). Members of this species carry the nodC7 variant.

Burkholderia tuberum (Vandamme et al., 2002) is a species belonging to a large clade of related symbionts that display two large symbiovars with distinct nodulation gene origins (Mishra et al., 2012): "sv. mimoseae" for symbionts of legumes in the tribe Mimoseae (Bontemps et al., 2010; Mishra et al., 2012), all carrying the nodC7 variant (Fig. 17.2); and "sv. papilionoideae" for South African papilionoid endemics (Howieson et al., 2013), carrying nodulation genes closer to alpha-rhizobia (Chen et al., 2003b). These symbiovars are not yet taxonomically approved, but, nevertheless, can be used to distinguish the two host range and nodulation gene origins. The *B. tuberum* "sv. *mimoseae*" strains have been reported only in the nodules of *Mimosa* species in Central and South America, that is, French Guiana (Mishra et al., 2012), Brazil (Bontemps et al., 2010), Mexico (Ormeno-Orrillo et al., 2012), Panama (Barrett and Parker, 2005), and Costa Rica (Barrett and Parker, 2006). They carry the nodC7 variant, which is only found in *Mimosa*-nodulating strains. For the *B. tuberum* sv. papilionoideae, evidence of effective nodulation on *Macroptilium atropurpureum* (Angus et al., 2013) and *Cyclopia* species (Elliott et al., 2007b) has been published. The large *Burkholderia* clade that includes *B. tuberum* clearly needs further taxonomic revision as it very likely contains more than one species. On this topic, a new species has already been defined as *B. sprentiae* (De Meyer et al., 2013b).

17.2.1 Unnamed New Species

Several strains of *Burkholderia* isolated from nodules of various members of the tribe Mimoseae probably belong to new species (see *Burkholderia* sp. 1–5 in Figs. 17.1 and 17.2; see also Chapter 89). This is the case with four clades of strains (*Burkholderia* sp. 1, 3, 4, 5) isolated in Brazil from *Piptadenia* and *Parapiptadenia* species (Bournaud et al., 2013), of which some are currently the focus of a taxonomic study aimed at describing a new species (Bournaud et al., unpublished), together with strains isolated from *M. pudica* in Australia (*Burkholderia* sp. 2, (Parker et al., 2007)). Other strains isolated from papilionoid legumes of the Fynbos in South Africa (in the genera *Rhynchosia*, *Lebeckia*) also probably belong to new species (Garau et al., 2009; Howieson et al., 2013).

17.2.2 Burkholderia: Toward the Borders between Mutualism and Pathogenicity?

Interestingly, no members of the phytopathogenic/pathogenic *Burkholderia* group (including the "*B. cepacia* complex") have, so far, been found to nodulate legumes, although they are frequently isolated from them as "passengers" or "endophytes" (Gyaneshwar et al., 2011; Suarez-Moreno et al., 2012). The only isolate of *B. cepacia* described as a nodule symbiont was isolated from a *Dalbergia* species in Madagascar (Rasolomampianina et al., 2005), but its nodulating ability could not be clearly established and the *nod* and *nif* genes could not be amplified from this strain (L. Moulin, unpublished data). Attempts to separate the two *Burkholderia* clades (pathogenic/nonpathogenic) are being undertaken, based either on multilocus sequence analyses (MLSA) or on different phenotypic tests, as well as their propensity for pathogenicity (Estrada-de los Santos et al., 2013; see Chapter 89). In spite of their proven potential for practical applications in agriculture (Suarez-Moreno et al., 2012), the use of *Burkholderia* strains for agronomy or ecology is currently not widely permitted owing to the presence of human and plant pathogens within the genus. It is, therefore, hoped that the establishment of the exact genetic boundaries between the pathogenic and nonpathogenic clades, and possibly the separation of them into two genera (Gyaneshwar et al., 2011), will assist in allowing the use of the mutualistic *Burkholderia* for plant growth improvements in agronomy and ecological restoration (see also Chapter 89).

17.3 ORIGIN AND DIVERSITY OF *Cupriavidus* LEGUME SYMBIONTS

Cupriavidus is closely related to *Burkholderia*, but unlike the latter genus it contains very few N-fixing species. The genus was redefined by Coenye et al. (2004), and several species from the genus *Ralstonia* were included in it, including (at that time) the sole diazotrophic *Ralstonia* species, *R. taiwanensis*. *Cupriavidus taiwanensis* has now been isolated from nodules on invasive *M. pudica* and *M. diplotricha* in many countries in SE Asia (China, India, Taiwan, Philippines, Table 17.1) and Australasia (Papua New Guinea, New Caledonia), and it may often predominate as symbionts of these *Mimosa* spp. in these countries (Chen et al., 2001, 2003a, b; 2005b; Elliott et al., 2009; Liu et al., 2012; Andrus et al., 2012; Klonowska et al., 2012; Gehlot et al., 2013). The predominance of *C. taiwanensis* in some environments appears somewhat surprising, as *M. pudica* and *M. diplotricha* also have the potential to nodulate with *Burkholderia*, and the latter will outcompete *C. taiwanensis* in laboratory-based experiments (Elliott et al., 2007a, 2009). On the other hand, under particular soil conditions, such as when N-levels are increased from close to zero, the competiveness of *C. taiwanensis* is increased relative to *Burkholderia* (Elliott et al., 2009), and this most likely explains why it is frequently found in nodules on *Mimosa* growing in high(er) fertility neutral-alkaline soils (Mishra et al., 2012; Liu et al., 2012; Gehlot et al., 2013). In addition to this, however, and as suggested by its name, an additional factor that can contribute to the competitive ability of *C. taiwanensis* in some environments (e.g., in New Caledonia) is its presence in the soil of high concentration of metals, particularly Cu and Zn, and also Fe (Chen et al., 2008; Klonowska et al., 2012).

So from where does *C. taiwanensis* originate? Although it is found throughout much of SE Asia and Australasia, both *M. pudica* and *M. diplotricha* are invasive plants that were taken to these environments over the last 500 years by European colonists from tropical coasts of the newly discovered New World (Chen et al., 2005b). This means that the symbionts of these plants in these invasive environments almost certainly came with them from the Americas, and this has been shown clearly for both *Burkholderia* spp. and *C. taiwanensis* (Chen et al., 2005a, b; Andam et al., 2007; Parker et al., 2007; Andrus et al., 2012), but where in the Americas did it originally evolve its nodulating ability? Based on its ability to nodulate *Mimosa*, the first places to look might be the centers of *Mimosa* radiation, such as the Cerrado and the Caatinga in Brazil, but, surprisingly, no *Cupriavidus* symbionts were found during the studies of Bontemps et al. (2010) and dos Reis et al. (2010), which suggests that they have a different center of origin to the *Mimosa*-nodulating burkholderias, and that unlike *Burkholderia* they may not have coevolved with *Mimosa*. Indeed, this is supported by the fact that *C. taiwanensis* has a much reduced host range in the genus *Mimosa* when compared to *B. phymatum* (Elliott et al., 2007a), and also by the fact that most Brazilian species (including Cerrado/Caatinga endemics) cannot nodulate effectively (or at all in some cases) with

C. taiwanensis (Elliott et al., 2007a; dos Reis et al., 2010). This reduced host range within the genus *Mimosa* might be linked to *C. taiwanensis* being a young symbiont (Amadou et al., 2008) relative to the *Mimosa*-nodulating burkholderias, which probably acquired their nodulating ability >50 mya (Bontemps et al., 2010). It is possible that *C. taiwanensis* recently acquired its symbiotic ability from promiscuous *Mimosa*-nodulating burkholderias that were spread with invasive/widespread *Mimosa* spp. (such as *M. pudica*) throughout tropical and subtropical South America (Andam et al., 2007; Gyaneshwar et al., 2011; Silva et al., 2012), but most particularly in the coastal lowlands where they predominate (Mishra et al., 2012).

On the other hand, there is a conflicting pattern for the origin of *nod* genes in *Cupriavidus* between *nodA* and *nodC* phylogenies. In the *nodA* phylogeny, *Cupriavidus* seems to have recently acquired a *nodA* gene from the ancestor of the *B. phymatum/B. sabiae* clade (Mishra et al., 2012), while in the *nodC* phylogeny *Cupriavidus* symbionts are outgrouped from all *Burkholderia*–Mimoseae symbionts, forming a separate clade (nodC8, Fig. 17.2b), and thus suggesting a much more ancient transfer of *nod* genes than the *nodA* phylogeny. The origin of nodulation in *Cupriavidus* could thus be more ancient than previously expected. This is supported by the recent description of other species of *Cupriavidus* that can nodulate legumes, such as *C. necator* and *C. necator*-like strains that have been shown to nodulate *Mimosa* spp. (and other legumes) in Brazil and Uruguay (da Silva et al., 2012; Taulé et al., 2012, Table 17.1). Interestingly, although the *C. necator* strains from da Silva et al. (2012) were isolated during soil "trapping" experiments with promiscuous legume hosts (*Leucaena leucocephala*, *Phaseolus vulgaris*) and, therefore, are not directly linked at this time to any particular host, their *nod* gene (*nodA*, *nodC*) and *nifH* sequences are similar to those of *C. taiwanensis* LMG19424^T and other *Mimosa*-nodulating beta-rhizobial strains (Fig. 17.2b), which suggests that their actual host(s) might also be *Mimosa* spp. Indeed, the soil used for the trapping experiments came from the south of the state of Minas Gerais (MG) (Florentino et al., 2012), and hence was within the endemic range of *Mimosa* in Brazil (Simon et al., 2011; dos Reis et al., 2010), but the soil used to trap the *C. necator* strains of da Silva et al. (2012) was not similar to Cerrado soil. In fact, its pH was neutral-alkaline rather than the highly acidic pH, which is more typical of Cerrado soils. It is known that *Mimosa*-nodulating *Burkholderia* generally prefer acidic soils, whereas symbiotic *Cupriavidus* prefer neutral-alkaline soils (Elliott et al., 2009; Mishra et al., 2012), so it is possible that *Mimosa* spp. that are endemic to neutral-alkaline non-Cerrado soils in MG are preferentially nodulated by *Cupriavidus* spp. Additional factors that may potentially favor *Cupriavidus* in the soils of the metal-mining state of MG are the presence of high levels of heavy metals, particularly of Zn and Cu (Chen et al., 2008; Ferreira et al., 2012; Klonowska et al., 2012).

Therefore, all the available information about the distribution of legume-nodulating *Cupriavidus* suggests that when considering where to search for the origins and/or the original hosts of *Cupriavidus* in tropical and subtropical America, two types of environments should be focused on (i) coastal lowlands and/or "disturbed" environments with neutral-alkaline soils with relatively high fertility, such as wasteground, where ruderal species, such as *M. pudica* and *M. diplotricha*, are dominant weeds and (ii) nonacidic soils anywhere in the native range American *Mimosa* (i.e., southern United States to northern Argentina; Simon et al., 2011) that have relatively high natural levels of Cu and Zn (and possibly also Fe). In the latter case, a strong possibility that is now emerging as a candidate for a center of *Cupriavidus* diversity is Uruguay (Battistoni, Fabiano, Cold, Taulé, unpublished), where there are several endemic *Mimosa* spp. that appear to be nodulated by *Cupriavidus* strains related to the *C. necator*-like strains that were isolated from *Parapiptadenia rigida* in the same geographical region (Taulé et al., 2012). These include *M. uruguensis*, which has previously been shown to nodulate effectively with *C. taiwanensis*, but not *B. phymatum* STM815 (Elliott et al., 2007a). Further work is being conducted to determine if Uruguayan *Mimosa* spp. are preferentially nodulated by *Cupriavidus*, and also if there are soil conditions that may have driven their coevolution.

On another aspect, *C. taiwanensis* pSym is used in experimental evolution studies aiming at turning a plant pathogen (*Ralstonia solanacearum*) into a legume symbiont (Marchetti et al., 2010; Guan et al., 2013).

17.4 NEW RHIZOBIAL TAXA IN THE BETA AND GAMMA SUBCLASSES OF PROTEOBACTERIA?

At present, the only confirmed LNB outside the Alphaproteobacteria belong to the closely related Betaproteobacterial genera *Burkholderia* and *Cupriavidus* (Gyaneshwar et al., 2011), but there have been many claims over the last 20 years for other "exotic" LNB. One possible candidate is *Herbaspirillum* (see Chapter 93). Both *Burkholderia* and *Cupriavidus* are related to it (Tayeb et al., 2008; Hassen et al., 2012), and it is known as a genus that has diazotrophic species that associate closely (often endophytically) with several nonlegumes and also promote their growth (Monteiro et al., 2012). Interestingly, plant-associated herbaspirilla are also found associated with legumes, particularly common bean (Schmidt et al., 2011; Monteiro et al., 2012), and have even been isolated from within their nodules (Valverde et al., 2003). However, convincing evidence that *Herbaspirillum* can actually nodulate legumes is still lacking, and there

is no indication from any of the genomes that have been sequenced so far that herbaspirilla have this capacity. For example, *H. lusitanum*, the species isolated from common bean nodules by Valverde et al. (2003), does not even have any N-fixation genes in its genome (Weiss et al., 2012), and although *H. seropedicae* can clearly fix N it is not known to harbor *nod* genes (Pedrosa et al., 2011). Nevertheless, the possibility that herbaspirilla might nodulate legumes has recently received a boost by the recent report by Hassen et al. (2012) of two *Herbaspirillum* strains that were isolated from the South African legume *Aspalathus linearis* (Papilionoideae), and which can also apparently nodulate this plant and fix N.

There have also been reports of other Betaproteobacterial genera, such as *Achromobacter* and *Janthinobacterium*, as being potentially effective nodulators of legumes (Benata et al., 2008; Lima et al., 2009; Azarias Guimaraes et al., 2012). Similarly, in the Gammaproteobacteria, there are claims of nodulating strains of *Pseudomonas* (Shiraishi et al., 2010; Huang et al., 2012) and *Stenotrophomonas* (Lima et al., 2009). However, it should be noted that in all these cases, including *Herbaspirillum* (Hassen et al., 2012), Kock's postulates appear to have not yet been fulfilled, that is, the inoculated strains have not been reisolated from the nodules and/or there is no microscopical evidence confirming their occupation of the infected cells of the nodules in a bacteroid form. Highly rigorous tests of the ability of several nodulating *Burkholderia* and *Cupriavidus* strains were performed before they were accepted as LNB (see Introduction), and in consideration that nodules are an excellent endophytic niche for many opportunistic nonsymbiotic bacteria (Gyaneshwar et al., 2011), it is reasonable to expect similarly rigorous tests to be applied to *Herbaspirillum*, *Achromobacter*, *Pseudomonas*, etc., before any of these "exotic" Beta- and Gammaproteobacteria can be fully accepted as being LNB.

17.5 HAS *Mimosa* COEVOLVED WITH ITS SYMBIONTS?

An earlier attempt at examining the symbiont preferences of *Mimosa* spp. in the context of the taxonomy of this large and complex legume genus broadly concluded that the Brazilian and South American species had an ability to nodulate effectively with the promiscuous beta-rhizobial strain *B. phymatum* STM815, whereas the Mexican species did not (Elliott et al., 2007a). Since then, a number of studies on *Mimosa* spp. and/or their symbionts have been undertaken (see also Chapter 89). First, Simon et al. (2011) have published a comprehensive molecular phylogeny using the *trnD-trnT* plastid sequences from 259 *Mimosa* spp., which has confirmed that the Brazilian and Mexican spp. are phylogenetically separate, and that they are grouped in several clades consisting of many closely related and highly endemic species that are confined to particular biomes, such as the Cerrado and Caatinga of Brazil and the Central Mexican highlands. Second, Bontemps et al. (2010) have shown that the symbionts of c. 47 of the Cerrado/Caatinga native and endemic *Mimosa* spp. are almost exclusively *Burkholderia*, and third, a study of several central Mexican endemic *Mimosa* spp. has shown that they are nodulated by Alphaproteobacteria in the genera *Rhizobium* and *Ensifer* (syn. *Sinorhizobium*) (Bontemps and Rogel, unpublished). Concomitantly with these diversity studies, it has also been demonstrated that the Cerrado/Caatinga endemics are not able to be nodulated effectively (or at all) by *B. phymatum* STM815 (dos Reis et al., 2010).

These data, taken together with those of Elliott et al. (2007a, 2009), suggest that the central Brazilian and central Mexican endemic *Mimosa* spp. have adopted very different symbionts, and that they are not capable of nodulating with each other's symbionts. This strongly suggests some degree of coevolution of these two geographically and taxonomically very separate groups of *Mimosa* spp. with their respective rhizobial symbionts. It is not clear about how and when the Brazilian and Mexican endemic *Mimosa* spp. became geographically separated from each other (Simon et al., 2011), but a reasonable scenario is that the ancestors that gave rise to these endemic *Mimosa* lineages reached central Brazil and central Mexico, where in both locations they became adapted to highland regions with poor soils (low N, low organic matter). In the case of Brazil, the soils will have been acidic and will have had a population of potential symbiotic bacteria that were adapted to those conditions (i.e., *Burkholderia* spp.), whereas in Mexico the soils will have been neutral/alkaline and housed Alphaproteobacterial symbionts (*Ensifer*, *Rhizobium*). Over evolutionary time, each group of mimosas will have radiated and speciated, resulting in a high level of endemicity in highland biomes in both countries; this endemicity will be related to many factors, including altitude (Simon and Proença, 2000). Given that each endemic species will, by definition, have been confined to a particular locality, it is likely that they will also have been obliged to adopt their rhizobial symbionts from that specific locality, be they *Burkholderia* (Brazil) or *Ensifer*/*Rhizobium* (Mexico). As they became increasingly cut off from their neighbors, each endemic *Mimosa* sp. and its symbiont will have evolved together, but separately, not only from their immediate neighbors, but also from their "widespread" relatives in the lowlands. Thus, we now see today in central Brazil, a set of highly endemic *Mimosa* spp. that have evolved over the last 10 my at altitudes >1000 m (Simon et al., 2011), and which have *Burkholderia* symbionts with a genotype that is also found only at these altitudes (Bontemps et al., 2010). The possibility that this is also the case with the (*Ensifer*/*Rhizobium*) symbionts of the Mexican highland endemics is currently being investigated

(Bontemps and Rogel, unpublished), but it is likely that the Mexican endemics are also nodulated by particular nod genotypes.

Although Brazil and Mexico contain the largest centers of radiation of the genus, *Mimosa* has other centers of endemicity in both the New World (e.g., Uruguay and subtropical South America, the Andes) and the Old World (India, Madagascar) (Simon et al., 2011; see Chapter 89). Little is so far known about these other centers, except that (as we have previously mentioned) Uruguayan endemics may be preferentially nodulated by *Cupriavidus* spp., and that two Indian species, *M. hamata* and *M. himalayana*, although they have only recently (6–10 mya) been separated from their central Brazilian relatives (Simon et al., 2011), are not nodulated by *Burkholderia*, but by *Ensifer* strains that are closely related to the symbionts of the "local" mimosoid legumes (Gehlot et al., 2013). This latter study further illustrates, along with the Brazilian highland endemics (Bontemps et al., 2010), that geographical isolation, even for a relatively short period (<10 my), of a legume population in a region whose soil is populated by a particular symbiont type will eventually oblige these legumes (in these cases *Mimosa* spp.) to form a symbiosis with them. Over time, continued isolation of both symbiotic partners will, inevitably, lead to their coevolution without any significant input from horizontal gene transfer (at least in the case of the bacterial partner).

17.6 IS THERE EVIDENCE OF COEVOLUTION BETWEEN LEGUMES IN THE TRIBE MIMOSEAE AND THEIR *Burkholderia* SYMBIONTS?

In the wider context of the tribe Mimoseae and the Piptadenia Group, to which *Mimosa* belongs (Jobson and Luckow, 2007), it is difficult, however, to discern any solid relationships between the various legume genera and the symbionts that have so far been isolated from them, except that, in general they have a preference for nodulating with *Burkholderia* strains that are similar to those that nodulate Brazilian and generally "Widespread" *Mimosa* spp. (Bournaud et al., 2013). So, although burkholderias have been shown to be diversified symbionts of legume species of the tribe Mimoseae, and that the onset of diversification of the plant and *Burkholderia* species might have occurred concomitantly (ca. 30 mya), no strict pattern of coevolution appears when plant and *Burkholderia* phylogenies are compared (Bournaud et al., 2013; see also Chapter 89). This pattern, if it has ever existed, is either not discernible owing to site effects and/or it has been disrupted by the broad range of partners chosen by both the legumes and the *Burkholderia* species, for example, *B. nodosa* and *B. sabiae* are found as symbionts of almost every genus and species of the Piptadenia Group, including *Mimosa*.

Although nodulation genes in *Burkholderia* strains isolated from *Mimosa* species have been shown to be vertically inherited (Bontemps et al., 2010), as more legume genera in the tribe Mimoseae are found to be nodulated by beta-rhizobia, this vertical pattern of nodulation gene transfer in mimoseae–burkholderias shows an increasingly more complex pattern (Fig. 17.2b). Some *nodC* variants (such as nodC3) are much more frequent within species than others, while other species (such as *B. phenoliruptrix* and *B. sabiae*) carry two *nodC* variants, indicating that horizontal transfer also played a role in the diversification of symbiosis in *Burkholderia* (Bournaud et al., 2013). It is now well established that horizontal gene transfer tends to erase evidence of coevolutionary relationships between plant radiation and speciation in rhizobia (Martinez-Romero, 2009), and this phenomenon can also be observed for beta-rhizobia. No strict correlation can be found between *nodC* clades and the host range or symbiotic ability of the burkholderias, as most *nodC* variants were found in strains nodulating the same genera and species. On the other hand, some *nodC* clades were found only in *Mimosa*-nodulating symbionts (nodC6, C7, C8, Fig. 17.2b), indicating possible host specificity, but this was only identified because *Burkholderia* strains were isolated from several endemic *Mimosa* species that had been separated from their widespread relatives for >10 my (see previous section). Clearly, more host range studies of strains from each species and carrying the different *nodC* variants are required to get a better idea of host specificity in this group of symbionts. In addition, although none of the other Piptadenia Group genera are anywhere near as rich in species as *Mimosa*, and some are also paraphyletic (e.g., *Piptadenia* s.l., and perhaps *Stryphnodendron*) (Jobson and Luckow, 2007), which hinders our ability to investigate them as deeply as it has been possible to do with a large monophyletic genus like *Mimosa*, it may be that further investigations within the Group, particularly into the symbionts of highly endemic species that are specific to very particular environments, will result in the identification of more specifically-related (and even novel) symbiotic genotypes.

17.7 CONCLUSION

Twelve years after the first description of beta-rhizobia, the biodiversity of this group of symbionts is emerging as highly diversified in several groups (especially in *Burkholderia*) with high affinities with legume species in the tribe Mimoseae and in several South African endemic species in the Papilionoideae. The-root nodulating ability of Betaproteobacteria may also be extended to new genera, such as *Herbaspirillum* and *Achromobacter*, although more data on their nodulation abilities are required to establish their status as true symbionts. As more biodiversity surveys of

symbionts of endemic legume species are achieved, the wider picture (including the possibility of host coevolution) of the beta-side of the extended rhizobial family will be revealed (see also Chapter 89).

ACKNOWLEDGMENTS

We thank our numerous colleagues in Brazil and elsewhere who have contributed so much to the research into "beta-rhizobia" over the last 10 years. EKJ thanks CAPES (Brazil) for a Visiting Researcher (Ciencia sem Fronteiras) fellowship. We thank funding agencies as ANR (LM project JCJC-2009 BETASYM), CNPq (Process No. 492683/04-2), EMBRAPA, IRD, and CIRAD for grants and PhD fellowships.

Chapter 18

Bradyrhizobium, the Ancestor of All Rhizobia: Phylogeny of Housekeeping and Nitrogen-Fixation Genes

Mariangela Hungria, Pâmela Menna, and Jakeline Renata Marçon Delamuta
Embrapa Soja, Londrina, PR, Brazil

18.1 INTRODUCTION

The widespread use of legumes (family Leguminosae = Fabaceae) as food crops, forages, and green manures is mainly associated with their ability to establish symbiotic associations with nodulating nitrogen-fixing bacteria collectively known as rhizobia. These bacteria have been subject of many studies, with an emphasis on their key role in the replacement of chemical N fertilizers, improving agricultural sustainability – especially in tropical nitrogen-impoverished soils – with profound environmental impacts, including lower emission of greenhouse gases and pollution of water by nitrate. One outstanding example is the case of the soybean (*Glycine max* [L.] Merr.) crop, discussed in Chapter 99. However, despite the global economic, environmental, and social importance, in comparison with other groups of bacteria, for example, human, plant, and animal pathogens, few studies have been performed on the taxonomy, phylogeny, and genomics of rhizobia (see Chapter 3).

The family Leguminosae encompasses over 18,000 species, classified into around 650 genera, occupying nearly all terrestrial biomes (Polhill and Raven, 1981). Rhizobia have been isolated from root nodules predominantly in the subfamilies Mimosoideae and Papilionoideae; root nodules are rare in the Caesalpinioideae (Allen and Allen, 1981). Unfortunately, still today information about nodulation capacity is lacking for nearly half of the genera of Leguminosae (Sprent, 2009). However, in comparison with the number of legumes known to nodulate, very few rhizobial species have been described – about a hundred (DSMZ, 2013). Nitrogen-fixing rhizobia belonging to the genus *Bradyrhizobium* are abundant in many soils, particularly in the tropics (e.g., Moreira et al., 1993; Menna et al., 2006, 2009a), and have been isolated from the nodules of highly divergent legume tribes, including herbaceous and woody species of tropical and temperate origins, aquatic legumes such as *Aeschynomene*, and the nonlegume *Parasponia andersonii* (Trinick, 1973; Sprent, 2001; Menna et al., 2006). Also, it has been isolated as an endophyte of nonlegumes (e.g., Chaintreuil et al., 2000; Tan et al., 2001) and detected in a variety of environmental metagenomes that have been published, confirming the broad distribution of the genus.

Bradyrhizobium represents the ancestor of all rhizobia (e.g., Lloret and Martínez-Romero, 2005); even though, the genus is far less studied than *Rhizobium* – probably due to its intrinsic physiological properties, with an emphasis on the slow growth rate *in vitro* that makes it more difficult to conduct genetic studies. In this chapter, we review phylogenetic insights into nitrogen-fixing *Bradyrhizobium*, highlighting results obtained by our group.

18.2 STATE OF THE ART OF THE GENUS *Bradyrhizobium*

Long before the nitrogen-fixation process was elucidated, the benefits of the biological process were recognized.

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

The Romans developed the idea of crop rotation with legumes and nonlegume plants to improve soil "health" and "quality." In 1813, interest in chemistry led Sir Humphrey Davy to report that the legumes "seemed to prepare the ground for the wheat," and he speculated that the nitrogen came from the atmosphere. At that time, it was a common practice to transfer soil from a field where legumes had been grown to areas being newly planted (e.g., to new pastures of alfalfa – *Medicago sativa* L. – in England), representing the first inoculations. In 1838, Boussingault, a French agricultural chemist showed that legumes had higher N levels than cereals and concluded that the atmosphere was the source. Unfortunately, in 1848, Liebig, an internationally eminent chemist, argued that the source of N was ammonia and not the atmosphere. Finally, in 1886, German scientists, Hellriegel and Wilfarth, demonstrated that the ability of legumes to convert N_2 from the atmosphere into compounds that could be used by the plant was due to the presence of swellings or nodules on the roots and of particular bacteria within these nodules (reviewed in Voelcker, 1896; Fred et al., 1932; Cooper, 2003; Hungria and Campo, 2004; Hungria et al., 2005; Ormeño-Orrillo et al., 2012; see also Chapter 88).

Shortly after, in 1888, the Dutch microbiologist Martinus Willem Beijerinck isolated bacteria from nodules of pea (*Pisum sativum* L.), which were termed *Bacillus radicicola*, and demonstrated that they had the ability to reinfect the host legume and fix nitrogen in symbiosis (Beijerinck, 1888, 1890). In 1890, German scientists, Nobbe and Hiltner, demonstrated the advantages of adding pure bacteria with the seed at sowing, and the discovery was patented, resulting in the first commercial product (Voelcker, 1896); we now understand that this inoculant for soybean carried bradyrhizobia.

Some 40 years later, a first systematic classification of nitrogen-fixing rhizobia was proposed, based on the cross-inoculation concept with respect to the host legume, resulting in six species of *Rhizobium*: *R. meliloti*, *R. trifolii*, *R. phaseoli*, *R. lupini*, *R. leguminosarum*, and *R. japonicum* (Fred et al., 1932).

Fifty years later, the taxonomy was redefined using numerical criteria, including several phenotypic and genetic properties. A new genus was created, *Bradyrhizobium* (*bradus*, from the Greek, meaning slow, referring to the growth rate *in vitro*) to accommodate rhizobia with the typical properties of alkaline reaction and slow growth rate in culture media containing mannitol as carbon source (Jordan, 1982). However, it is interesting to remember that the division of rhizobia into fast and slow growers *in vitro* had been proposed much earlier by Löhnis and Hansen (1921).

In relation to the evolution of rhizobia, in 1965 Norris suggested that *Bradyrhizobium* was the ancestor of alpha-rhizobia and originated in the tropics (Norris, 1965). Several decades later, studies with new molecular tools confirmed Norris's hypothesis (Provorov and Vorob'ev, 2000; Lloret and Martínez-Romero, 2005). Ancient and conserved molecules have been used as molecular clocks to estimate time divergence between lineages in response to changes that have occurred in their sequences. The ancestral gene of glutamine synthetase (GS) doubled before the separation of Prokaryotes and Eukaryotes (Pesole et al., 1995), and the comparison between the two paralogous genes GSI and GSII allowed estimates of the times of divergence between lineages of Alphaproteobacteria (Turner and Young. 2000; see Chapter 3). From this comparison, estimates for the two genes were similar in fast-growing rhizobia, and *Bradyrhizobium* was highlighted as the ancestor of all rhizobia. Interestingly, *Bradyrhizobium* is the only rhizobial genus that has preserved the ability to photosynthesize (see Chapter 28) and, together with *Azorhizobium*, can fix nitrogen both in free-living and in symbiotic conditions.

18.3 DESCRIBED SPECIES OF *Bradyrhizobium*

Initially, *Bradyrhizobium japonicum* was the only described species for the genus, encompassing symbionts of soybean; for symbionts of other legumes, the nomenclature used was *Bradyrhizobium* sp. followed by the host plant name (Jordan, 1982, 1984). The reports of large genetic and physiological variability among strains that nodulate soybean led to the description of *Bradyrhizobium elkanii* a few years later (Kuykendall et al., 1992).

Thereafter, other species were described, including symbionts of legumes other than soybean: *Bradyrhizobium yuanmingense*, symbiont of *Lespedeza* spp., a legume that grows in the northern hemisphere (Yao et al., 2002); *Bradyrhizobium canariense*, a symbiont of genistoid legumes from the Canary Islands (Vinuesa et al., 2005); *Bradyrhizobium pachyrhizi* and *Bradyrhizobium jicamae*, isolated from effective nodules of *Pachyrhizus erosus* (L.) Urb., commonly called jicama or Mexican yam and known for its tuberous roots (Ramírez-Bahena et al., 2009); *Bradyrhizobium cytisi* (Chahboune et al., 2011) and *Bradyrhizobium rifense* (Chahboune et al., 2012), isolated from effective nodules of *Cytisus villosus* Pourr. (a legume with broad distribution in the Mediterranean and northern Africa) grown in soils of Morocco; *Bradyrhizobium lablabi*, isolated from effective nodules of *Lablab purpureus* (L.) Sweet and peanut (*Arachis hypogaea* L.) in Anhui and Sichuan provinces of China (Chang et al., 2011); and *Bradyrhizobium arachidis*, also isolated from peanut in China (Wang et al., 2013b). There is also the reclassification of *Blastobacter denitrificans as Bradyrhizobium denitrificans*, for the aquatic symbiont of *Aeschynomene indica* (van Berkum et al., 2006, 2011).

In relation to the soybean, new species from China have been described: *Bradyrhizobium liaoningense* has been defined as an extra-slowly growing *Rhizobium* that nodulates primitive and modern soybean genotypes (Xu et al., 1995), and *Bradyrhizobium huanghuaihaiense* (Zhang et al., 2012) *and Bradyrhizobium daqingense* (Wang et al., 2013a), both effective nodulators of soybean. In addition, a new species has been recently described – *Bradyrhizobium diazoefficiens* – for the strains previously classified as *B. japonicum* group Ia (Delamuta et al., 2013).

The genus *Bradyrhizobium* also includes non-nodulating nonsymbiotic bacteria. *Bradyrhizobium betae* refers to endophytes isolated from sugar beet (*Beta vulgaris* L.) roots affected by tumor-like deformations (Rivas et al., 2004), and *Bradyrhizobium iriomotense* has also been isolated from a tumor-like root of the legume *Entada koshunensis* Hayata and Kaneh in Japan (Islam et al., 2008). There is also the reclassification of *Agromonas oligotrophica* into *B. oligotrophicum*, a nitrogen-fixing oligotrophic bacterium isolated from paddy soils in Japan (Ramírez-Bahena et al., 2013).

We may conclude that, despite *Bradyrhizobium* being the predominant symbiont of a variety of tropical legumes (e.g., Moreira et al., 1993; Menna et al., 2006, 2009a), in addition to the suggestion that diversity should be greater in tropical than in temperate regions (e.g., Oyaizu et al., 1992), in early 2013, only 15 species of *Bradyrhizobium* have been described as symbionts of legumes. This reinforces the suggestion that *Bradyrhizobium* diversity in the tropics is poorly documented (Zakhia and de Lajudie, 2001; Menna et al., 2006, 2009a, 2009b), and that hundreds of *Bradyrhizobium* species remain to be described (e.g., Willems et al., 2001a; Menna et al., 2006, 2009a, 2009b).

18.4 PHYLOGENY BASED ON THE ANALYSIS OF RIBOSOMAL GENES

Ribosomal sequences – with an emphasis on 16S rRNA – have become the basis of bacterial molecular phylogeny and taxonomy (Woese, 1987; Weisburg et al., 1991; Olsen and Woese, 1993; Willems and Collins, 1993; Garrity and Holt, 2001; see Chapter 3). Based on 16S rRNA (e.g., Wang and Martínez-Romero, 2000) and also on genomic analyses (e.g., Carvalho et al., 2010), rhizobia are currently positioned in four taxonomic branches: *Azorhizobium*, *Bradyrhizobium*, *Mesorhizobium*, and *Rhizobium–Sinorhizobium* (=*Ensifer*). These branches include nonsymbiotic relatives (oligotrophic soil and aquatic bacteria such as *Rhodopseudomonas palustris*, *Rhodoplanes roseus*, *Nitrobacter winogradskyi,* and *B. denitrificans*, and pathogens such as *Afipia* spp.), which may indicate common ancestry for rhizobial species and other parasitic and soil-borne bacteria.

Since the 1990s and early 2000s, partial or complete 16S rRNA sequences have been extensively applied to phylogeny studies of *Bradyrhizobium* (e.g., Young et al., 1991; Oyaizu et al., 1992; Yanagi and Yamasato, 1993; van Rossum et al., 1995; Urtz and Elkan, 1996; Moreira et al., 1998; Vinuesa et al., 1998; Wang et al., 1999; Chen et al., 2000; Jarabo-Lorenzo et al., 2000; Willems et al., 2001b; see Chapter 3). However, all of these, in addition to other later studies, have shown that despite a high level of diversity in morphological, physiological, and genetic properties (e.g., van Rossum et al., 1995; Moreira et al., 1993; So et al., 1994; Boddey and Hungria, 1997; Doignon-Bourcier et al., 1999; Chen et al., 2002), the diversity in the 16S rRNA sequences of *Bradyrhizobium* is low and distinguishes species poorly (e.g., Menna et al., 2006, 2009a; Delamuta et al., 2013). A phylogenetic tree of *Bradyrhizobium* species, based on 16S rRNA, is shown in Figure 18.1.

Other ribosomal genes can add information about phylogeny that helps to clarify the taxonomy of *Bradyrhizobium* species. The 23S rRNA is a long fragment of about 2.3 kb; it contains more information than 16S rRNA and has proven to be useful in the definition of several genera and species of bacteria (Ludwig and Schleifer, 1994) including rhizobia (Tesfaye et al., 1997; Terefework et al., 1998; Tesfaye and Holl, 1998; Qian et al., 2003; Germano et al., 2006). Furthermore, because the rate of sequence change seems to be faster in 23S rRNA than in 16S rRNA (Olsen and Woese, 1993), the former allows a finer definition of phylogenetic relationships

Analysis of the 16S–23S rRNA intergenic transcribed spacer (ITS) (also called intergenic spacer IGS) has proven to be useful in studies of phylogeny and taxonomy of *Bradyrhizobium*. Most bradyrhizobia carry only one copy of ITS; the sequence is long and with higher variability, making the region particularly useful for elucidation of phylogeny and taxonomy (Laguerre et al., 1996; Vinuesa et al., 1998; Doignon-Bourcier et al., 2000; van Berkum and Fuhrmann, 2000; Parker and Lunk, 2000; Willems et al., 2001a; Germano et al., 2006; Menna et al., 2009a). Recently, the genome sequencing of *B. japonicum* USDA 6^T revealed two copies of the rRNA gene cluster [*rrn*] in the chromosome (Kaneko et al., 2011), confirmed in the Brazilian strain CPAC 15 (=SEMIA 5079) belonging to the same species (Delamuta et al., 2013); however, the two copies are identical and, therefore, do not invalidate the use of the ITS region. A more defined phylogeny of *Bradyrhizobium* using the ITS genomic region was also obtained in studies performed by our group (Alberton et al., 2006; Germano et al., 2006; Menna et al., 2009a), reinforcing the utility of this locus.

Another advantage of analysis of the ITS relies in a direct relationship with results obtained in the DNA–DNA hybridization (DDH) technique. DDH is still required to define new species (Garrity and Holt, 2001), although an increasing number of arguments against its obligatory use have been raised, including the high cost and intensive

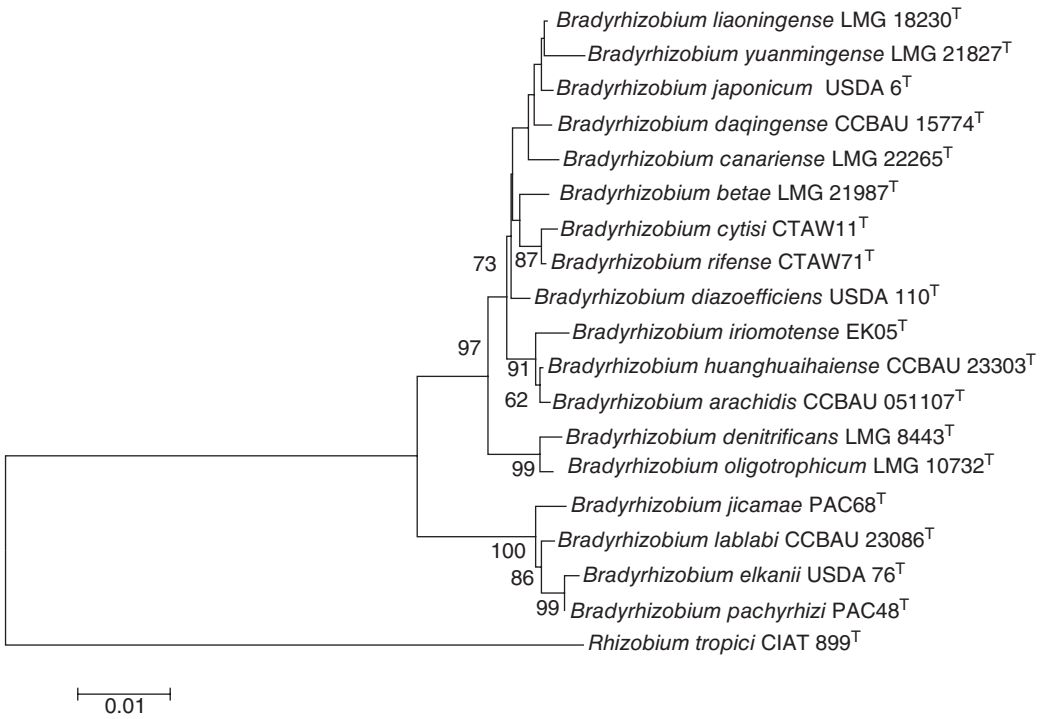

Figure 18.1 Neighbor-joining phylogeny based on 16S rRNA gene sequences showing the relationships between described species of the genus *Bradyrhizobium*. The percentages of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) are shown next to branches. The tree is drawn to scale, with branch lengths in the same units as those of the evolutionary distances used to infer the phylogenetic tree. Evolutionary distances were computed using the Tamura–Nei method and are in units of the number of base substitutions per site. Positions containing gaps and missing data were eliminated from the dataset (complete deletion option). Phylogenetic analyses were conducted in MEGA5. *Rhizobium tropici* was used as an outgroup. Bar, 1 substitution per 100 nucleotide positions.

work required for its development (e.g., Vandamme et al., 1996; Coenye et al., 2005; Ribeiro et al., 2012), the existence of more accurate approaches (e.g., Konstantinidis and Tiedje, 2004), and doubts about its adequacy (e.g., Achtman and Wagner, 2008). Replacements of DDH have been suggested, such as the use of the average nucleotide identity (ANI) of genome sequences. First, it was proposed that an ANI >94% would correspond to 70% of DDH (Konstantinidis and Tiedje, 2004), and later >95–96% was suggested as the threshold for species delineation (Richter and Rossello-Mora, 2009). With improved facilities available and lower costs of sequencing genomes, replacement of DNA–DNA by ANI is appealing. However, where numerous strains are to be studied, genome analysis is still problematical.

Therefore, when analysis of many genomes is impossible, meaningful results may be achieved from the ITS region, with strong correlations with DDH results (Willems et al., 2001a, 2003). According to Willems et al. (2003), strains of >95.5% similarity in their ITS sequences belong to the same genospecies, showing >60% DNA–DNA hybridization values.

Although 16S rRNA is highly conserved, genetic recombination and horizontal gene transfer may occur within the gene (van Berkum et al., 2003; Gevers et al., 2005). Therefore, the phylogenies of rhizobia based on 16S rRNA, 23S rRNA, or ITS genes may be discordant (van Berkum et al., 2003; Germano et al., 2006). A combined analysis of ribosomal genes was then proposed as a buffer to site-specific horizontal gene transfer, which, at the same time, would be useful to improve species definition, due to the longer sequence of nucleotides, or greater number of bands in RFLP analysis. This polyphasic approach has been used successfully with *Bradyrhizobium* (e.g., Ludwig and Schleifer, 1994; Vinuesa et al., 1998; Germano et al., 2006: Menna et al., 2009a), improving the definition of species.

18.5 THE USE OF THE MULTILOCUS SEQUENCE ANALYSIS (MLSA) APPROACH TO DEFINE TAXONOMY AND PHYLOGENY OF *Bradyrhizobium*

Based on the limitations of the analysis of 16S rRNA, with an emphasis on the lack of capacity of detecting differences among some species – as is the case with *Bradyrhizobium* – other genes with evolution rates faster than that

of 16S rRNA, but conserved enough to retain genetic information, have been proposed as alternative phylogenetic markers (e.g., Stackebrandt et al., 2002; Hernández-Lucas et al., 2004; Parker, 2004; Stepkowski et al., 2003; Martens et al., 2007, 2008; Alexandre et al., 2008; Roma-Neto et al., 2010). Multilocus sequence analysis (MLSA) was then proposed, encompassing the combined analysis of housekeeping genes, and it has been increasingly used to access phylogeny and taxonomy of prokaryotes. Requisites for the choice of the housekeeping genes have been suggested and include the following: (i) broad distribution within the taxa studied; (ii) even distribution in the genome (dispersed in at least 100 kb, to avoid horizontal gene transfer events); and (iii) a single copy within a given genome (Gevers et al., 2005; Martens et al., 2007, 2008). The MLSA has been applied also in studies with rhizobia, including the genera *Sinorhizobium* (e.g., Martens et al., 2007, 2008), *Rhizobium* (e.g., Ribeiro et al., 2009), and *Bradyrhizobium* (Moulin et al., 2004; Vinuesa et al., 2005; Menna et al., 2009a; Delamuta et al., 2013).

Among the housekeeping genes used in the MLSA for phylogenetic reconstructions of rhizobia are the *atpD*, *dnaJ*, *dnaK*, *gap*, *glnA*, *glnII*, *gltA*, *gyrB*, *pnp*, *recA*, *rpoA*, *rpoB,* and *thrC* genes (Turner and Young, 2000; Gaunt et al., 2001; Weir et al., 2004; Stepkowski et al., 2003, 2005; Vinuesa et al., 2005; Martens et al., 2007, 2008; Alexandre et al., 2008; Menna et al., 2009a; Ribeiro et al., 2009, 2012; Delamuta et al., 2013; see Chapter 3).

One question that is often raised concerns the number of genes that should be considered in the MLSA analysis. Martens et al. (2008) found high concordance between MLSA of five housekeeping genes and DNA–DNA hybridization. In *Bradyrhizobium*, the use of at least four housekeeping genes has been proposed (Stepkowski et al., 2003, 2005; Vinuesa et al., 2005); however, more recently, other studies have shown good resolution with only three genes (Menna et al., 2009a; Chahboune et al., 2011, 2012; Chang et al., 2011; Delamuta et al., 2012, 2013; Zhang et al., 2012). One important point to be considered is that the congruence of each gene with the 16S rRNA should be carefully analyzed, eliminating genes with evidence of horizontal gene transfer or atypical evolutionary history. One example was observed in the study by Menna et al. (2009a), in which four housekeeping genes were analyzed, *atpD*, *dnaK*, *glnII*, and *recA*; however, a specific group of *B. elkanii* strains showed high variability in the *atpD* gene, and, thus, the tree built with three genes reflected better the phylogenetic relationships of a large group of *Bradyrhizobium* strains studied than the tree built with all four genes.

For the last decade, we have been working with a large collection of *Bradyrhizobium*, most from Brazil and including about 180 strains isolated from 64 legume species belonging to 17 tribes of the three subfamilies of Leguminosae (Germano et al., 2006; Menna et al., 2009a, 2009b; Binde et al., 2009; Menna and Hungria, 2011; Delamuta et al., 2012, 2013). The results from these studies have clearly shown that the 16S rRNA defines poorly the phylogenetic relationships among *Bradyrhizobium* species. The additional analyses of other ribosomal DNA regions has substantially improved the definition of species (Germano et al., 2006; Menna et al., 2009a) and confirmed the results from Willems et al. (2001a) that ITS is a valuable gene for the taxonomic study of *Bradyrhizobium* (Menna et al., 2009a). MLSA has proven to be extremely valuable for defining taxonomic positions and phylogenetic relationships (Menna et al., 2009a; Delamuta et al., 2012, 2013), and, in Figure 18.2, there is a comparison of results obtained with the analysis of 16S rRNA and MLSA with three genes of a group of *Bradyrhizobium* strains.

18.6 PHYLOGENY OF NODULATION AND NITROGEN-FIXATION GENES IN *Bradyrhizobium*

In our studies with ribosomal and MLSA genes, we have seen poor correlations between taxonomic position and host range (Germano et al., 2006; Menna et al., 2006, 2009a; Binde et al., 2009). For example, several strains were identified that could nodulate and be effective in fixing nitrogen with legumes of different tribes and subfamilies, but there were also more specific groups of strains, such as those symbionts of soybean. To gain a better understanding of nitrogen-fixation ability, we studied *Bradyrhizobium nod* and *nif* genes (see Chapters 3, 8, 20, 77).

It is well known that the symbiosis is under the control of a finely tuned expression of common and host-specific nodulation genes and also of genes related to the assembly and activity of the nitrogenase, which, in the *Bradyrhizobium* strains investigated so far, are mostly clustered in a symbiotic island. It is noteworthy that, in *B. japonicum*, this symbiotic island is flanked by insertion sequence (IS) elements, with high capacity of horizontal gene transfer (Kaluza et al., 1985; Kaneko et al., 2002, 2011). To better understand the evolution of symbiotic genes in *Bradyrhizobium*, we studied 40 strains, symbionts of several legumes; for the nodulation trait we analyzed common [*nodA*], *Bradyrhizobium*-specific [*nodY/K*], and host-specific [*nodZ*] nodulation genes, and also *nifH* for the fixation ability (Menna and Hungria, 2011). One important point is that the chosen genes are distantly located in the symbiosis island of *B. japonicum* (Kaneko *et al*., 2002), avoiding interpretations based on horizontal gene transfer.

In general, clusterings of *nod* and *nif* trees were similar and clearly different from those of other rhizobial species, indicating a monophyletic origin of nodulation and nitrogen-fixation genes in *Bradyrhizobium*; however,

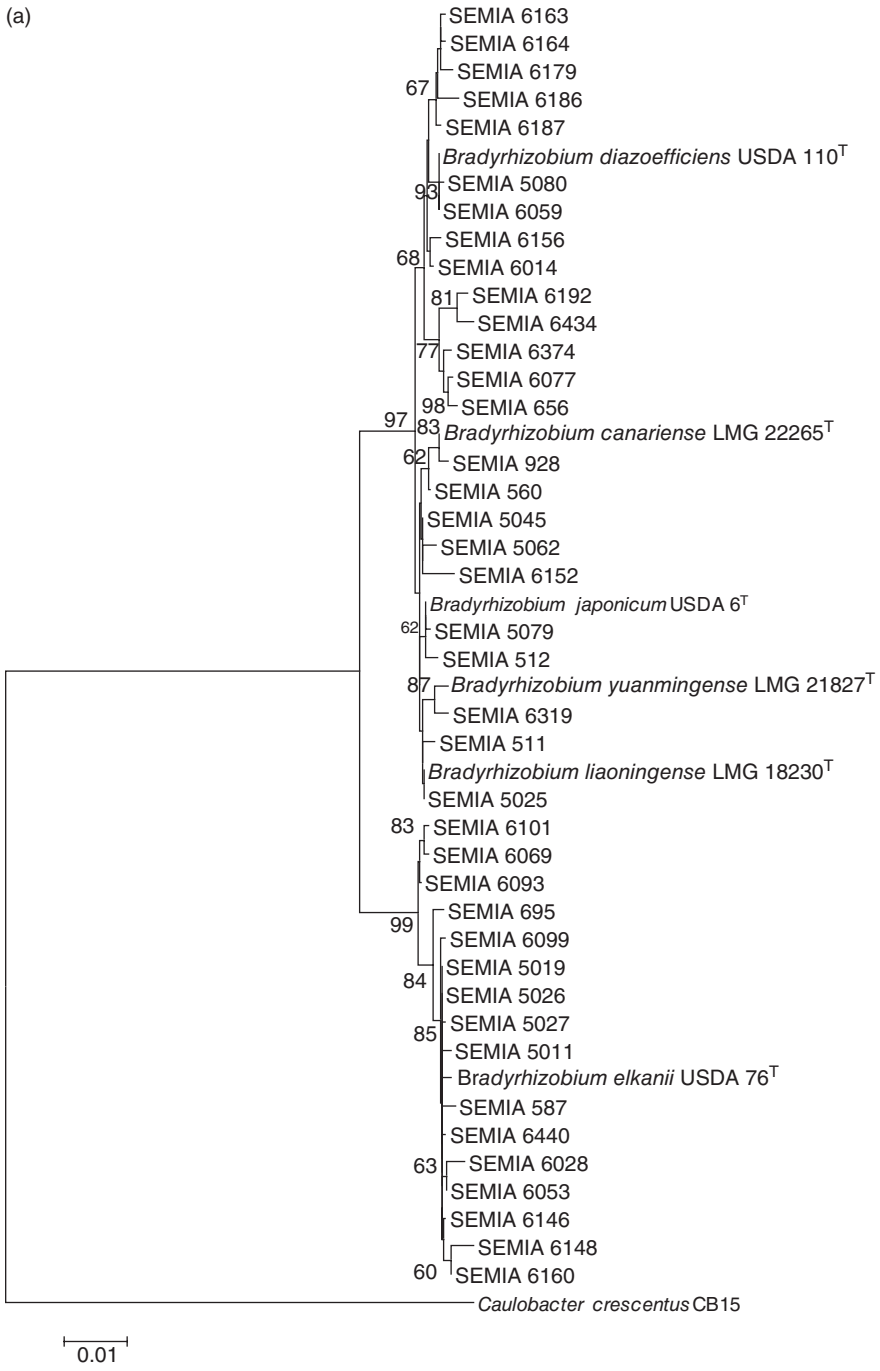

Figure 18.2 Evolutionary trees inferred using the neighbor-joining method for *Bradyrhizobium* strains based on the (a) 16S rRNA gene and (b) concatenated sequences of the *dnaK*, *glnII*, and *recA* genes. The percentages of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) are shown next to the branches. Evolutionary distances were computed using the maximum composite-likelihood method and are in units of the number of base substitutions per site. Positions containing gaps and missing data were eliminated from the dataset (complete deletion option). Phylogenetic analyses were conducted in MEGA4. Modified from Menna et al. (2009a).

congruence of these genes with housekeeping genes was low (Menna and Hungria, 2011).

The hypothesis of monophyletic origin of nodulation genes has been raised in studies in which *nodA* of several *Bradyrhizobium* strains fitted into a defined phylogenetic group, in some cases showing correlation with the geographic origin (Stepkowski et al., 2007; Steenkamp et al., 2008; Menna and Hungria, 2011). Figure 18.3 shows the results obtained with strains from our study (Menna and Hungria, 2011). One interesting feature of *nodA* is that it has 209–211 amino acids (Menna and Hungria, 2011), whereas in *Mesorhizobium*, *Rhizobium*, and *Sinorhizobium* the gene has 195–198 amino acids (Moulin et al., 2004; Stepkowski et al., 2007). The loss at the N-terminal end of the NodA protein in other rhizobial genera might suggest that the gene is undergoing an evolutionary progression toward a shorter sequence, which also gives support to the theory that *Bradyrhizobium* is the ancestor of all rhizobia.

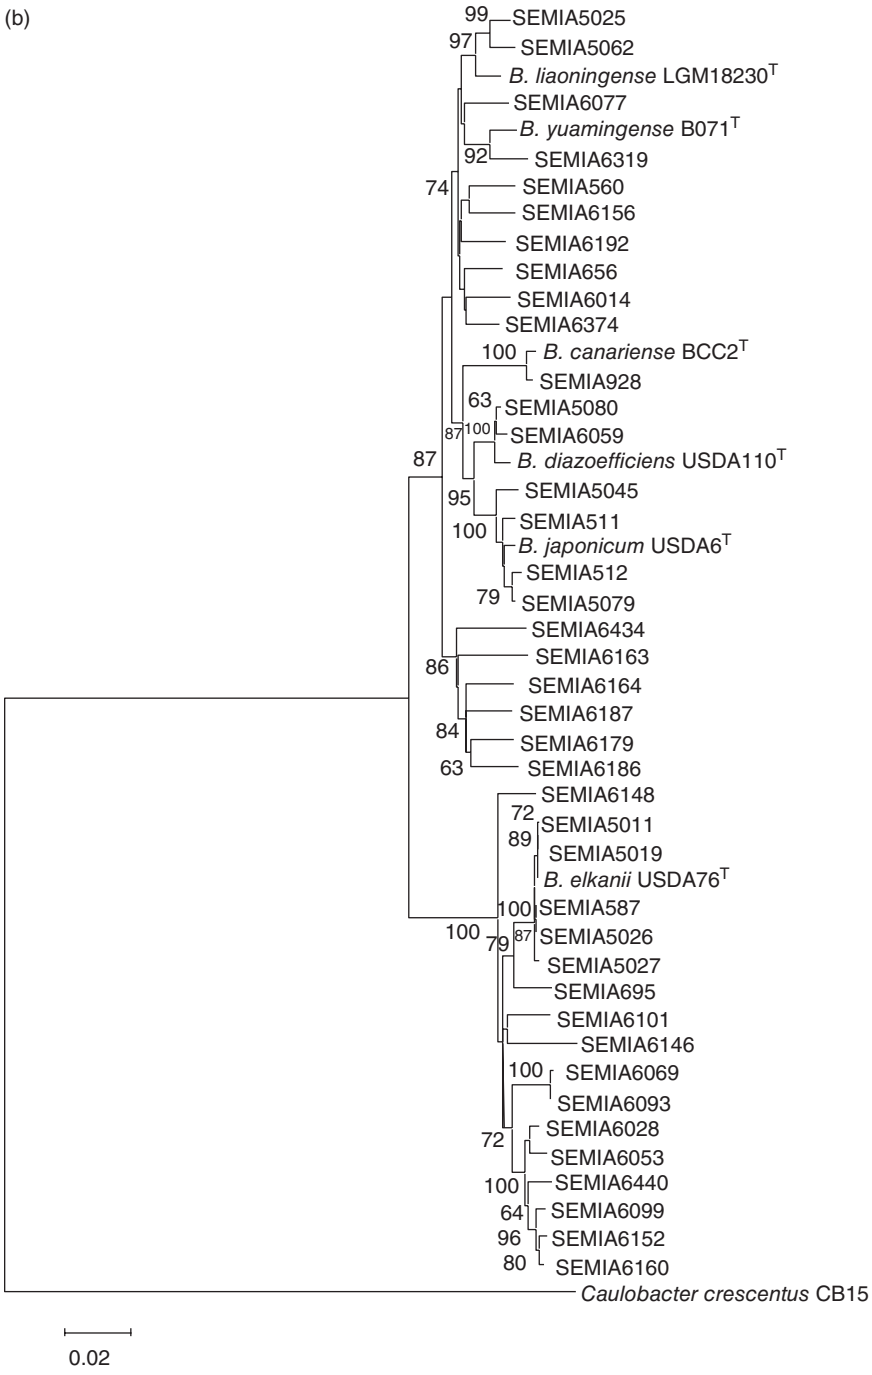

Figure 18.2 (*Continued*)

The results from our study (Menna and Hungria, 2011) have pointed out that *Bradyrhizobium* adopted different nodulation/nitrogen fixation strategies. The first and predominant one included evolution toward increased host range, emphasized by the greater diversity of *nod* genes, with an emphasis on *nodZ*. *nodZ* is unusual in comparison to other common nodulation genes such as *nodABC*, as its expression is constitutive and independent of *nodD*; chemical analysis has suggested that NodZ is essential for fucosylation of the terminal reducing *N*-acetylglucosamine of the lipochitin oligosaccharides (LCOs) of Nod factors (Stacey et al., 1994). The role of host specificity of NodZ has been confirmed in experiments on host range (López-Lara et al., 1996). Two strategies have been detected so far for NodZ. The first and predominant strategy shows high diversity of *nodZ* among *Bradyrhizobium* (Steenkamp et al., 2008; Menna and Hungria, 2011) giving support to the hypothesis that the variability in the decorated nodulation

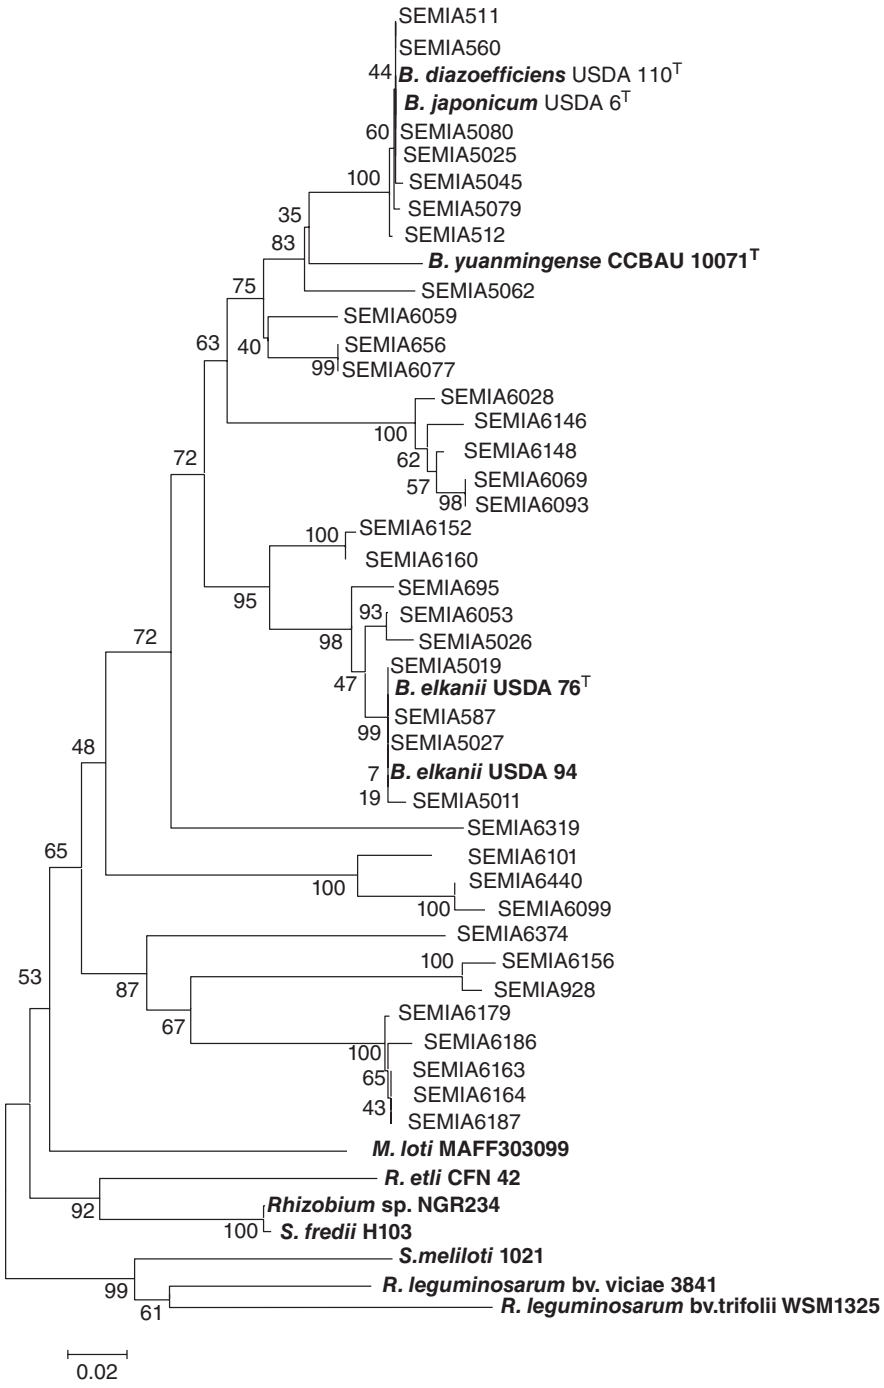

Figure 18.3 Phylogenetic relations of *Bradyrhizobium* SEMIAs and type/reference strains based on *nodA* partial sequences. Type/reference strains are highlighted in bold. Phylogeny was inferred using the neighbor-joining method. The percentages of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) are shown next to branches. Evolutionary distances were computed using the maximum composite-likelihood method and are in units of the number of base substitutions per site. Phylogenetic analyses were conducted in MEGA4. After Menna and Hungria (2011).

factors might represent an important adaptation strategy, enabling nodulation of a variety of legumes. The second strategy, less common, shows the absence of *nodZ*, and one example is a group of symbionts of *Acacia* sp. (Menna and Hungria, 2011), which might indicate that a specific fucosylation of the LCOs may not be necessary for nodulation of the host plant, probably due to close coevolution of the symbiotic partners.

However, we identified another group of strains with a different evolution story. A group of symbionts from *A. mearnsii* showed high congruence between the 16S rRNA and the *nodY/K*, *nodA,* and *nifH* genes, in addition to a shorter *nodY/K* and the absence of *nodZ*, strongly indicating a finely-tuned coevolution of the host plant and symbionts. In addition, the *B. japonicum* symbionts from soybean also showed high congruence of *nod* and *nif* genes with the

16S rRNA, albeit to a lesser extent (Menna and Hungria, 2011). Lastly, our study also identified some symbionts of *Arachis* spp. which occupied isolated positions in all *nod* and *nifH* trees, with no relation with the core genes, apparently resulting from horizontal gene transfer.

In conclusion, despite reinforcing the theory of monophyletic origin of the symbiosis island in *Bradyrhizobium*, our study pointed out that horizontal gene transfer is common in a variety of groups, whereas, in others, vertical transfer represents the main genetic event, altogether contributing to a high level of diversity in *Bradyrhizobium* (Menna and Hungria, 2011).

Finally, we must comment that absence of the common *nodABC* genes and of *nodY/K* has been reported for photosynthetic *Bradyrhizobium* strains BTAi1 and ORS278, symbionts from *Aeschynomene* stem nodules (Giraud et al., 2007; see Chapter 28), and other *Bradyrhizobium* strains from our study (Menna and Hungria, 2011). These results indicate that an alternative mechanism for initiating transcription of nodulation genes is not exclusive to the stem-nodulating group, opening an interesting field of research. It is interesting to note that very few *Bradyrhizobium* genomes have been sequenced so far (Kaneko et al., 2002, 2011; Giraud et al., 2007; Tian et al., 2012), and new facilities and lower costs will likely increase our knowledge of the genomics of these strains in the foreseeable future.

18.7 CONCLUDING REMARKS

The family Leguminosae encompasses over 18,000 species, of which about 3000 are capable of nodulating with rhizobia, but information is lacking for nearly 40% of the legume genera. Evidence indicates that *Bradyrhizobium* is the ancestor of all rhizobia, and strains belonging to the genus have been isolated from a variety of legumes and ecosystems, being particularly abundant in the tropics. However, few *Bradyrhizobium* species have been described so far, in part, due to the high conservation of the 16S rRNA gene. The use of other ribosomal and housekeeping genes, with an emphasis on the MLSA method, is facilitating the detection of genetic diversity and the description of new *Bradyrhizobium* species. Analyses of nodulation and nitrogen-fixation genes have shown a predominance of monophyletic evolution of *nod/nif* genes, but with low congruence with the 16S rRNA gene. However, there are also a few groups with specific evolution stories toward higher or lower host specificity. Considering the high number of host legumes in symbioses with *Bradyrhizobium*, very few genetic studies have been performed so far with the genus. Progress is expected in the next few years with the help of the new molecular tools available today, with an emphasis on genomics.

ACKNOWLEDGMENTS

19.1 INTRODUCTION

The legume–*Rhizobium* symbiosis is characterized by the formation of a new root organ, the nodule, in which bacteria fix atmospheric dinitrogen and exchange it for photosynthates and other nutrients provided by the host legume. The symbiosis enables legumes to produce protein-rich seed and foliage that are critical to many human and animal diets.

Improvement of crop yield within the context of low-input agriculture is an ongoing concern for breeding programs, in which biological nitrogen fixation can play an important contribution. Nitrogen efficiency for several legumes can vary more than 10-fold providing a potential for optimization. However, while superior N_2-fixing strains have been isolated and tested under controlled environmental conditions, the problem to exploit these strains is the inability to control infection of legume roots in the field by indigenous strains that in many cases induce nodules but fix nitrogen poorly.

The mutual interaction is initiated by the exchange of signals between the plant and the bacteria. A rhizobial lipochito-oligosaccharide molecule called Nod factor, produced in response to (iso)flavonoids exuded by the root, is perceived by two plant LysM receptor kinases. The chemical structure of nodulation factors shares a common backbone of *N*-acetylglucosamine residues, which, in addition, feature diverse substitutions at the reducing and nonreducing ends of the molecule (see Chapters 50 and 51). Perception of Nod factor by the legume host triggers different responses that mediate changes in young epidermal cells and, at the same time, is necessary for the molecular events that will induce cortical cells to reinitiate cell division leading to nodule organogenesis. These responses can occur independently of each other, as it has been shown by the phenotype of different mutants, where bacterial infection – related to the epidermal responses – is observed in the absence of nodule formation and vice versa (Madsen et al., 2010; Oldroyd et al., 2011).

Early nodulation events act to inhibit nodulation of developmentally younger root tissues to maintain a homeostatic balance of shoot and root development. The regulatory circuit is called "autoregulation of nodulation" (AON) (Reid et al., 2013). It has been shown that the AON starts to be active after root hair curling but before the initiation of visible cortical and pericycle cell divisions. Therefore, it is expected that competitiveness for infection will be expressed at very early stages of interaction. Once a certain strain triggers infection, then AON systemic mechanisms may prevent infection by other strains. The legume–rhizobia association is highly specific such that a limited set of rhizobial species

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

will establish symbiosis with only a limited number of host plants; however, the mechanisms whereby the host legume controls nodulation by specific strains are poorly understood. This chapter examines the relevant accomplishments to better understand the basis of controlling nodule formation in legumes, and also an attempt has been made to consider how manipulation of the host–bacteria interactions may contribute to overcome the problem of competitiveness for nodulation. The detailed mechanisms involved in the plant response to rhizobial signals are not discussed here, but references can be found in the literature cited.

19.2 Nod FACTOR RECOGNITION

The chemical structure of the rhizobially produced lipochito-oligosaccaride, which is recognized by the host LysM-containing receptor kinases Nfr1 and Nfr5, is a major determinant of host specificity. Thus, the *Sinorhizobium meliloti nodH* mutant that lacks a C-6 sulfate at the reducing end is unable to induce a response on its natural host *Medicago truncatula* (Roche et al., 1991; see Chapter 51).

Radutoiu et al. (2007) have shown that expression of *Lotus japonicus* Nfr1 and Nfr5 in *M. truncatula* and *Lotus filicaulis* extends their host range to include bacterial strains *Mesorhizobium loti* and *R. leguminosarum* bv. viciae strain DZL, which usually only infect *L. japonicus*. They proposed that differences in decorations of the Nod-factors synthesized by *M. loti* and DZL influence affinity at the NFR5 LysM2 domain, which is also associated to a specific amino acid present in this domain.

Two cases that reveal natural variation in nodulation specificity in pea highlight the significance of fitness between the Nod factor decorations and its receptors. The Afghanistan pea cultivar is resistant to nodulation by European *Rhizobium leguminosarum* strains but is efficiently nodulated by strains isolated from Israel. Strains of *R. leguminosarum* bv. viciae that can nodulate cv. Afghanistan produce a Nod factor that has an O-linked acetyl group on the terminal reducing end residue. Acetylation requires a bacterial gene called *nod*X. Further investigations demonstrated that the introduction into the European strains of the ability to acetylate the nodulation factor lifts the restriction and makes them able to nodulate cv. Afghanistan (Firmin et al., 1993). The resistance to nodulation in Afghanistan segregates as a single genetic locus, in a region where there are multiple Nod factor receptor-like genes (Gualtieri et al., 2002).

Another instance of regulation of nodule formation associates the efficiency of nodulation by nodE mutants of *R. leguminosarum* bv. viciae to one haplotype of Sym37 in peas. Sym37 belongs to the family of receptor kinases that includes *L. japonicus* NFR1 and *M. truncatula* LYK3, contains three LysM ectodomains, which in *L. japonicus* have been implicated in binding of Nod factors (Broghammer et al., 2012; Ronghui et al., 2011). *NodE* mutants are unable to form C18:4 acyl chains and, therefore, produce only C18:1-containing Nod factors. Because the six polymorphic residues of Sym37 are spread across the three LysM domains, it is possible that such substitutions may cause important structural changes that affect recognition.

LysM-containing receptor-like kinases (LYKs) are found only in plants including the primitive plant genera *Physcomitrella* and *Selaginella.* It has been proposed that a more recent specialization took place in legumes in order to provide specificity and efficiency to the recognition of rhizobial nodulation signals (Zhang et al., 2009).

19.3 MECHANISMS USING PLANT IMMUNE RESPONSES

Analysis of host genes induced in response to rhizobial infection has revealed that several of the upregulated genes are also genes involved in the mechanisms of plant defense response to pathogens. Peltzer-Meschini et al. (2008) has described genes homologous to soybean Rpg1-b to be highly induced in *Phaseolus vulgaris* at early stages after infection with its cognate *Rhizobium etli*. An interesting case is the pair of genes NSP1 and NSP2 of the group of GRAS transcription factors from *M. truncatula*, which are essential for the Nod factor signaling pathway, whereas their orthologs from rice are induced by perception of a chitooligosaccharide elicitor. The current scenario indicates that legumes activate quite similar mechanisms to respond to pathogens and symbiotic microbes (Kalo et al., 2005; Samac and Graham, 2007), and that in nature legumes genes have been recruited from the plant resistance pathway to control nodulation. This has been clearly documented in soybean in which several genes have been identified to restrict nodulation with specific rhizobial strains. The genetic analysis of the loci that in soybean causes ineffective nodulation has revealed they map in a region of the genome that contain sequences determinant of resistance to pathogenic microorganism, including the genes Rj2 and Rfg1, which restrict nodulation with *Bradyrhizobium japonicum* strain USDA122 and *Sinorhizobium fredi* strain USDA257, respectively (Caldwell, 1966; Trese, 1995). In a recent report by Yang et al. (2010), it was shown that Rj2 and Rfg1 are allelic genes encoding a member of the Toll-interleukin receptor nucleotide binding site/leucine-rich repeat (TIR-NBS-LRR) class of plant resistance proteins. This study indicated that successful nodulation requires rhizobia to evade the plant immune responses triggered by microbial infection, and define a way outside the Nod-factor-mediated mechanism to control nodulation by specific strains.

19.4 THE SYMBIOTIC INTERACTION OF *Phaseolus vulgaris* IN THE REGIONS OF HOST DIVERSIFICATION

Common beans (*P. vulgaris* L.) is one of the most ancient crops in America with a proposed Mesoamerican origin and two major centers of bean genetic diversification (BD), namely the Mesoamerican center (Mexico, Central America, and Colombia) and the Andean center in South America (Ecuador, Perú, and Argentina) (Gepts, 1998; Bitocchi et al., 2012). *P. vulgaris* can be nodulated by a number of diverse rhizobial genotypes, among which *R. etli* bv. phaseoli is the predominant species found associated with common beans from Mexico, Colombia, and the South Andes. The occurrence of host-dependent competitiveness in the interaction between common bean and *R. etli* was shown in our laboratory (Aguilar et al., 2004). Coinoculation of common beans from each BD center with an equicellular mixture of sympatric and allopatric *R. etli* strains representative of the Mesoamerican and Southern Andean lineages revealed a distinct host-dependent competitiveness: beans from the Mesoamerican genetic pool were almost exclusively nodulated by strains from their host region, whereas nodules of beans from the Southern Andes were largely occupied by the geographically cognate *R. etli* lineages. The different strains of *R. etli* from the Mesoamerican and Andean regions could be distinguished on the basis of the types of *nod*C gene they contain, which for convenience have been denominated α and δ, respectively (Fig. 19.1).

Attempts to investigate whether the diversity in nodulation behavior by different genotypes of *R. etli* was due to differences in the chemical structure of the nodulation factor revealed no significant difference between them. Indeed, it was found that in general the length of the glucosamine oligosaccharide backbone was predominantly pentameric. The C6 of the nonreducing end residue was frequently, but not always, O-carbamoylated. Carbamoylation was detected in all the strains we examined as well as in the *R. etli* type strain CFN42. The N-acyl moiety comprises monounsaturated C_{16} or/and C_{18} fatty acids. Linked to the C6 of the reducing terminal glucosamine residue, a 4-O-acetyl fucose residue was found in all the strains but strain 55N1 which in detailed analyses consistently showed an absence of the O-acetyl decoration (Gil-Serrano, Megias, and Aguilar, unpublished). Therefore, no obvious detectable changes in the Nod factor structures associated with either α or δ *R. etli* strains were found in our analysis, which suggested that differences in affinity between genotype of *R. etli* and common beans is not determined by chemical modifications of the Nod factor.

Common bean is able to establish effective symbiosis with a diversity of rhizobial phylotypes that produce different Nod factors. However, there are clear differences among them in their competitiveness for infection. For instance, the *nol*L mutant strain *R. etli* CFN289 – unlike its parental strain CE3 – produces a Nod factor that lacks an acetyl group at the fucosyl residue at the reducing end of the signal molecule (Corvera et al., 1999). The *nol*L mutant strain induces effective nodules although it is less efficient at nodulation of common beans, and it competes very poorly for nodule occupancy as compared with the wild-type strain (Fig. 19.2).

In order to assess if acetylfucosylation of the Nod factor was important for the nodulation preference between lineages of *R. etli* and beans from the same region of diversification, competitiveness assays were performed with a mixture of strains *nodC* type α and type δ strains that produce Nod factor with and without the acetyl-group at the fucosyl site. The *R. etli nol*L mutant strain (acetyl-minus) was found to be less competitive in comparison with its parental strain CE3 as well as with the *nod*C type α strain SC15 (Fig. 19.2). In case of a mixture of strains α (CE3) and δ (136N2), respectively, that are able to acetyl-decorate their Nod factor at the reducing terminal, the occupancy of nodules was found to be as expected: the strain α CE3 was highly competitive against strain delta 136N2 in the Mesoamerican bean variety cultivar Nag12. In contrast, the *nol*L strain displayed a significantly impaired competitive ability, only 22% of nodules were occupied by CFNX289 (Fig. 19.2). This suggests that the α strain CFNX289, which produces Nod factor without acetylation, is unable to compete and occupy nodules as efficiently as the δ strain 136N2, which produces acetylated Nod factor. However, when competitiveness was assessed between two strains α (CFNX259) and δ (55N1), both of them unable to produce acetylated Nod factor, the strain CFNX259 displayed a clear competitive ability (Fig. 19.2). Taken together, these results suggest that the acetylfucose substitution is involved in the nodulation competitiveness and that the high competitiveness observed with the *nol*L strain CFNX259 against the strain 55N1 suggests that factors other than acetylfucosylation may be also involved in the nodulation preference between host and rhizobia from the same center of genetic diversification.

Common beans have been considered a poor nitrogen-fixing legume, and attempts to introduce superior common bean nodulating strains by inoculation faced the problem how to control infection in the field, since the resulting nodules were mostly formed by highly competitive, but less efficient, indigenous strains. Apparent competitiveness of rhizobia may vary depending on the plant genotype used as a host, which suggests the occurrence of plant genotype × rhizobial strain effects.

Our results are consistent with a competitiveness that is expressed at early stages of interaction, in which the decoration of the nodulation factor is important as well as other factors that affect competitiveness. These results suggest the occurrence of checkpoints other than the nodulation factor in the establishment of preferential nodulation of Mesoamerican beans by cognate *R. etli* strains.

The molecular basis of mutual affinity between common beans and rhizobia from the same center of diversification

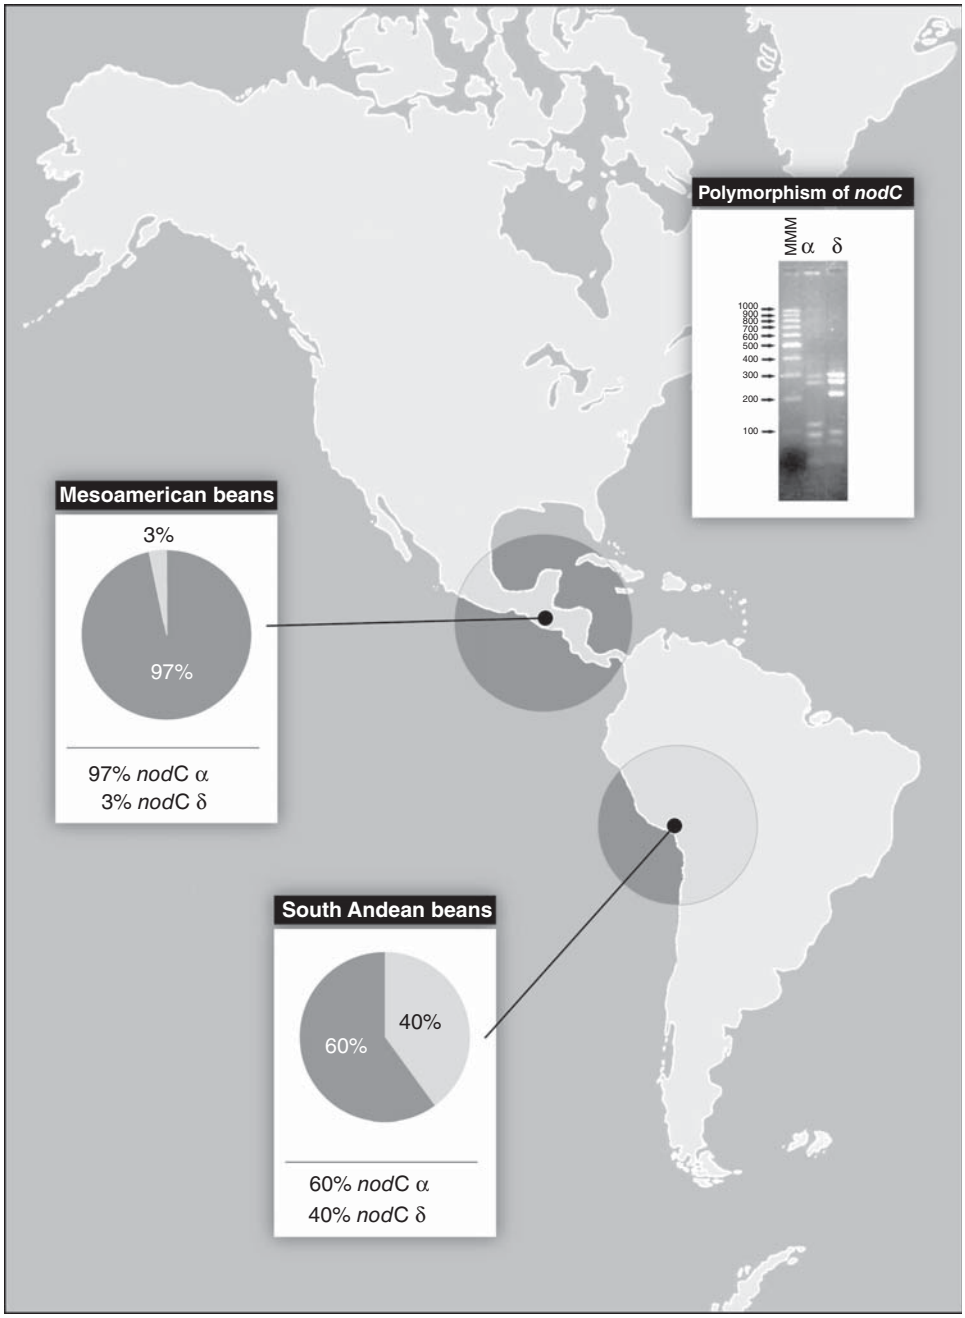

Figure 19.1 Affinity of common beans from the Mesoamerican and South Andean centers of diversification and *R. etli*. Lineages of *R. etli* from Mesoamerica and South Andes regions were distinguished by their *nod*C polymorphism and identified as *nod*Cα and *nod*Cδ, respectively. Nodule occupancy by *nod*Cα and *nod*Cδ strains in coinoculation assays of common beans from the Mesoamerica and South Andean regions is shown as a "cake" graph.

is still unknown. In order to gain insight into the strain preference by beans belonging to the Mesoamerican pool, a survey of genes was performed by applying a suppressive hybridization approach in which a Mesoamerican variety was infected with *R. etli* strains from the Andean and Mesoamerican regions, respectively (Peltzer-Meschini et al., 2008). Among the genes differentially expressed, NF-YC1 encoding for a protein highly homologous to the C subunit of the NF-Y heterotrimeric transcription factor was detected (Zanetti et al., 2010; Battaglia et al., 2014). A relative early accumulation of NF-YC1 transcripts in Mesoamerican beans in response to *R. etli nod*Cα strains was found. Overexpression of NF-YC1 caused no significant change in the preferential pattern of nodulation, whereas it

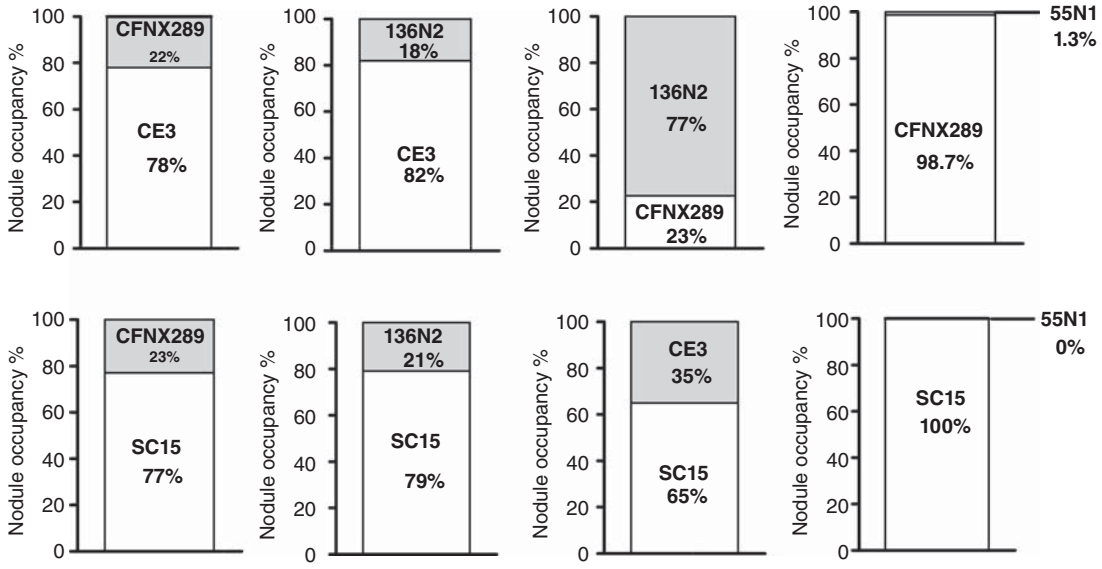

Figure 19.2 Nodule occupancy in the Mesoamerican bean variety cv. Nag12 infected with mixed inoculums of *R. etli* strains. Strains CE3, CFNX289, and SC15 are lineages *nod*Cα, whereas strains 55N1 and 136N2 are *nod*Cδ. Strain CFNX289, which is an *in vitro* induced *nol*L mutant derived from CE3 and strain 55N1, which is an isolate from the South Andean region carrying an intrinsic *nol*L mutation, produce Nod factor without acetylation of the fucosyl residue at the reducing end of the lipochito-oligosaccharide molecule. Bars represent percentage of nodule occupation after inoculation with a two-strain mixture.

promoted the formation of higher number of nodules with the nodCδ strains. Because Zanetti et al. found a relationship between expression of NF-YC1 and genes participating in the G2/M transition of the cell cycle, they suggested that NF-YC1 promotes earlier nodulation by the activation of cortical cell division. Therefore, these results indicate that the occurrence of functional compatibility, probably recruited during the coevolution of both symbionts, leads the interaction to proceed faster toward infection and nodule occupation as compared with the association with allopatric strains. This kind of mechanism defines a natural strategy that the host established in order to select its partner.

19.5 THE NEED OF FACTORS OTHER Nod FACTOR FOR SPECIFICITY IN NODULATION

Studies on the symbiosis between species of Lotus and rhizobia seem to indicate that other factors in addition to nodulation factor are required for efficient recognition and nodulation. *L. japonicus* and *Lotus pedunculatus* produce effective nodules when infected by *M. loti* and *Bradyrhizobium* sp. strains, respectively. In cross-infection assays, it was shown that both of them pass the epidermal stage of recognition. Analysis of the chemical structure of nodulation factors produced by *M. loti* and *Bradyrhizobium* revealed differences among them, particularly decorations at the nonreducing end of the signal molecule. Similarly, differences in the extracellular LysM domain of Nfr1 and Nfr5 from *L. japonicus* and *L. pedunculatus* were shown by gene sequencing. Interestingly, genetic transformation by using *Agrobacterium rhizogenes* and chimera receptors as well as wild-type receptors resulted in no change of the infection pattern in *Lotus* species. These observations led the authors to conclude that an additional checkpoint determine successful nodulation (Bek et al., 2010). Although the functions of other components in the microsymbiont remain to be determined, it should be kept in mind that in addition to nodulation factors, surface rhizobial compounds such as exo- and lipooligosaccarides are also important in nodulation (see Chapter 36).

19.6 CONCLUSIONS

In order to improve nitrogen fixation, it is desirable that at early stages, the legume plant selects a rhizobia partner such that later on their association – directed by bacterially produced signal molecules – results in the formation of the nodule able to efficiency fix and deliver nitrogen. It has been shown that in natural soils, high doses of inoculants with selected strains are needed in order to displace the indigenous, less efficient, strains (Streeter, 1994; Aguilar et al., 2001); however, to achieve high level of inoculums is not practical. The process of infection displays sophistication and selectivity in favor of a single rhizobial species, but it cannot ensure the exclusion of ineffective variants that will be of no benefit for the host: once established inside the nodule, poor or ineffective rhizobia may be sanctioned by the plant (Kiers and Denison, 2010).

The perception of the nodulation factor by plant receptors opens biotechnological possibilities to target and modify a key event in the control of nodulation by specific strains,

whereas the notion that soybean plays control of nodulation by using plant resistance genes suggests yet another strategy to be exploited. The compatibility that became established between host and rhizobia through coevolution in the same region of differentiation must also be taken in consideration. The affinity detected in common beans from the two major center of diversification toward their sympatric *R. etli* strains opens new avenues to identify allelic variations in the host that contribute to such compatibility. Progress in the sequencing of the genomes of beans from both center of domestication, which is close to completion, will allow comparisons and therefore identification of candidate genes likely involved in this mutual affinity. These studies may lead to define genes and genetic markers useful in breeding programs for improved nitrogen fixation.

Rhizobia in the rhizosphere of legume are influenced by exudate compounds, some of which may act as chemoattractants (Cooper, 2007). Therefore, a combination of a legume able to produce and exude a certain compound and an elite strain able to interact positively with the latter could improve competitiveness and suppress infection by low-performing strains.

Overall, it is tempting to speculate that the application of the significant progresses made in our knowledge of the symbiosis will lead to have customized varieties that express interaction with elite rhizobial strains in the future.

Chapter 20

Assessment of Nitrogenase Diversity in the Environment

John Christian Gaby

Daniel H. Buckley
Department of Crop and Soil Sciences, Cornell University, Ithaca, NY, USA

20.1 INTRODUCTION

Biological nitrogen fixation emerged early in the history of life as a fundamental link in the global nitrogen cycle. This process is carried out by diverse diazotrophic microorganisms found exclusively in the domains Bacteria and Archaea. Although most described diazotrophs are found in the Proteobacteria, nitrogen fixation is widespread among prokaryotes and is found in at least 14 bacterial and archaeal phyla (Dos Santos et al., 2012; see Chapter 3). Described species of diazotrophs conserve energy through a wide variety of mechanisms and they can be heterotrophs, lithotrophs, or phototrophs. Diazotrophic species can also have diverse relationships with oxygen, and both obligate and facultative aerobes as well as many anaerobes have been described. In addition, diazotrophs can vary dramatically in their ecology, occurring as free-living organisms in a wide range of environments and also participating in a diverse array of symbiotic associations.

The nitrogenase enzyme catalyzes the conversion of dinitrogen gas to ammonium and comprises protein subunits encoded by the genes *nifH*, *nifD*, and *nifK*. The genes *nifD* and *nifK* encode proteins, which form the heterotetrameric core of the enzyme, also called the MoFe protein because of the requirement for a MoFe cofactor. The *nifH* gene encodes the dinitrogenase reductase subunit, also called the Fe protein. Of these three genes, *nifH* is the most widely sequenced and has become the marker gene of choice for studying the ecology and diversity of nitrogen-fixing organisms (Zehr et al., 2003; Gaby and Buckley, 2011). A typical approach used to explore diazotroph diversity is to generate *nifH* amplicons from environmental samples by using polymerase chain reaction (PCR) with primers that target the *nifH* gene (Zehr and McReynolds, 1989; Marusina et al., 2001; Poly et al., 2001; Ando et al., 2006). The sequences of these *nifH* amplicons can then be analyzed to explore the phylogeny and diversity of diazotrophs present.

The phylogeny of the *nifH* gene and its paralogs may be divided into five principal clusters. According to the designation of Chien and Zinder (1994), conventional nitrogenases fall into two clusters. Cluster I contains primarily aerobes and facultative anaerobes, many of which are found in the phyla Proteobacteria and Cyanobacteria. The second cluster of conventional nitrogenases, cluster III, contains strict anaerobes from diverse phyla and includes methanogenic Archaea, clostridia, spirochetes, and sulfur- and sulfate-reducing Deltaproteobacteria. Cluster II contains alternative nitrogenases, paralogs of *nifH*, which differ from conventional nitrogenase because they use different metal cofactors. There are two alternative nitrogenases, one of which has an FeFe cofactor, whereas the other has a VFe cofactor (see Chapter 2). The FeFe nitrogenase forms cluster II, whereas the VFe *nifH* does not form a coherent cluster, associating mostly with cluster I sequences in phylogenetic trees. Cluster IV contains *nifH* paralogs present in methanogens, and these genes have not been shown to function in nitrogen fixation (Staples et al., 2007). Cluster V contains *nifH* paralogs involved in bacteriochlorophyll synthesis (Raymond et al., 2004).

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

Awareness of the presence of these paralogs is essential when working with PCR primers for *nifH* because paralogous gene sequences can be amplified by many *nifH* primer sets (Ohkuma et al., 1999; Yamada et al., 2007) and can be confused with *nifH* if phylogenetic analysis is not conducted to identify and remove these paralogs prior to analysis of *nifH* diversity.

This chapter provides a summary of our current understanding of the global diversity of nitrogen fixers. It is clear that we still have much to learn about diazotroph diversity and ecology, but advances in technology are contributing to a rapid pace of new discoveries. Next-generation sequencing technologies can now be applied to surveys of *nifH* diversity (e.g., Farnelid et al., 2011, 2013; Mao et al., 2011), and quantitative PCR assays have been developed to assess *nifH* gene abundance in the environment (e.g., Church et al., 2005; Wallenstein and Vilgalys, 2005; Hayden et al., 2010). Application of these new tools is facilitated by the availability of a *nifH* sequence database.

20.2 DATABASES AVAILABLE FOR *nifH*

The availability of an aligned *nifH* sequence database facilitates the analysis of diazotroph diversity and phylogeny as well as the evaluation and design of PCR primers that target *nifH*. There are three publicly available collections of aligned *nifH* sequences. The first is available from the Functional Gene Pipeline/Repository, known as FunGene (Cole et al., 2009). The sequences in FunGene are pulled from public databases and aligned using HMMer. The FunGene sequence compilation is available in FASTA format, but this collection lacks sequence-associated metadata. A second *nifH* sequence collection is available from the Zehr research group (http://pmc.ucsc.edu/~wwwzehr/research/database/) in ARB database format. This database is compiled using a set of representative NifH protein sequences using BLAST to identify NifH in public repositories. A third *nifH* database was created by the authors of this chapter (Gaby and Buckley, 2011, 2012, 2014). This third database was also created in the ARB environment (Ludwig et al., 2004), which allows a user to access sequences and the associated metadata through a graphical user interface. In addition to *nifH* sequences, this database includes linked *nifH*, *nifD*, *nifK*, and 16S rRNA gene records from sequenced genomes. The database includes a comprehensive annotated phylogenetic tree of all *nifH* sequences and trees of the full-length sequences for *nifH*, *nifD*, *nifK*, and 16S rRNA genes. These trees can be used to organize and navigate sequence data. In the following sections, we will explore the diversity of the 32954 *nifH* sequences available in this *nifH* database (http://www.css.cornell.edu/faculty/buckley/nifH_database_2012.arb) as of May 16, 2012.

20.3 DESCRIPTION OF THE *nifH* DATABASE

The *nifH* gene is one of the most frequently sequenced of microbial functional genes (Fig. 20.1). The number of *nifH* genes available in public sequence databases has increased dramatically over time and is continuing to accelerate with the development of next-generation sequencing platforms. In fact, more than 90% of *nifH* sequences in the database have been deposited since 2005 (Fig. 20.2). Sequences in the database are derived from 1211 studies each contributing between 1 and 1299 sequences. There are 584 studies that contributed only 1 sequence (48% of the total number of

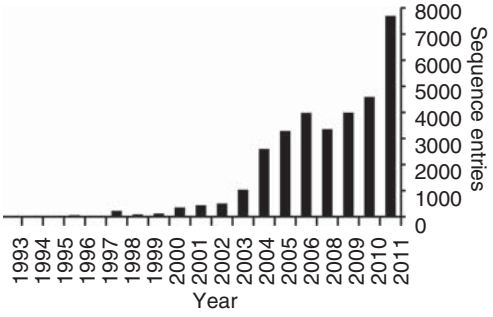

Figure 20.2 The number of *nifH* sequences submitted yearly to GenBank.

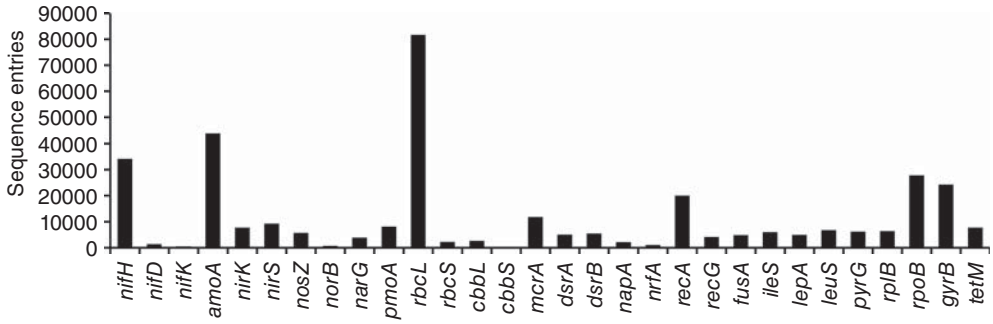

Figure 20.1 The number of sequences available in GenBank for highly sequenced functional genes as of July 12, 2012.

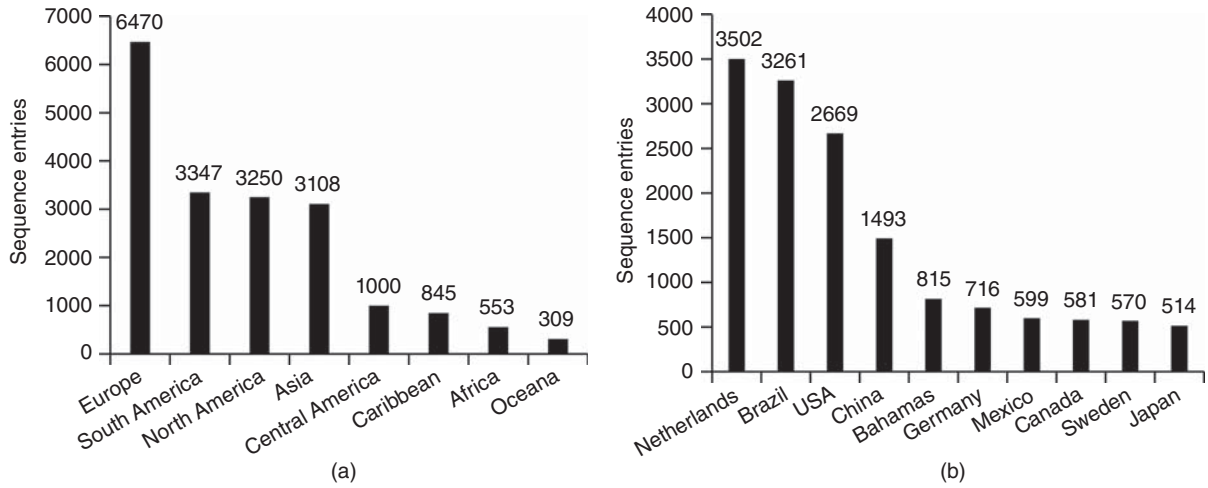

Figure 20.3 The number of *nifH* sequences obtained from the most frequently sampled world regions (a) and countries (b).

studies and 1.8% of the sequences in the database), and these represent sequences that originate from isolated strains. In contrast, the 10 studies that contributed the most sequences account for 8516 sequences in total (26% of all sequences in the database) and the top 35 studies contributed 50% of all sequences.

Evaluation of sequence-associated metadata reveals that, while a vast diversity of nitrogen-fixing microorganisms have been identified through analysis of *nifH*, global sampling efforts have been geographically biased. The *nifH* data disproportionately represent North America and Europe and underrepresent the Southern Hemisphere (Fig. 20.3). It is noteworthy that more than two-thirds of the *nifH* sequences from South America come from a single Brazilian study (Fig. 20.3b). The majority of *nifH* sequences that are available have been generated by a relatively small number of research groups.

20.4 DEFINING *nifH* DIVERSITY

In order to estimate the global richness of nitrogen fixers, it is necessary to establish units for measuring diversity. The conventional approach is to establish an operational taxonomic unit (OTU) based on a defined threshold of nucleotide sequence similarity.

Often an OTU similarity threshold is selected to correspond to a level of sequence similarity that effectively delimits microbial species. In the case of 16S rRNA gene sequences, the most common OTU definition is based on 97% sequence similarity (Stackebrandt and Goebel, 1994). In contrast, a 95% sequence similarity threshold has been proposed as the species-level cutoff for most conserved, protein-encoding genes (Konstantinidis and Tiedje, 2005).

One strategy for selecting an *nifH* OTU definition is to select an *nifH* sequence similarity threshold that roughly

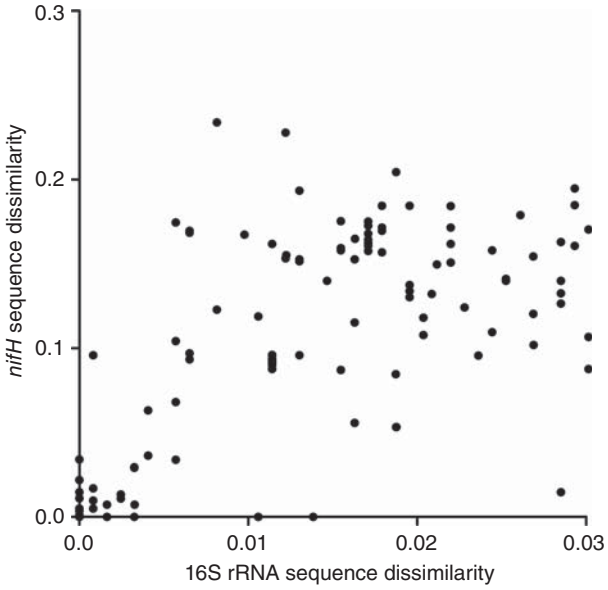

Figure 20.4 The similarity of *nifH* gene sequences for pairs of strains that have less than 3% 16S rRNA sequence similarity. Sequence dissimilarities are calculated from the pairwise comparison of nucleotide sequence divergence for both the *nifH* and 16S rRNA genes from sequenced genomes.

corresponds with the 16S rRNA OTU definition. Pairwise analysis of full-length *nifH* and 16S rRNA genes from sequenced genomes reveals that this approach is somewhat problematic (Fig. 20.4). Strains that fall into the same $OTU_{0.03}$ as defined by 16S rRNA dissimilarity can have *nifH* genes with as much as 23% 16S rRNA sequence dissimilarity (Fig. 20.4); hence, any *nifH* OTU definition is unlikely to correspond closely with species as defined by the 16S rRNA gene. Nonetheless, in order to estimate the diversity of nitrogen-fixing taxa, which have been sampled

globally, and to determine the extent to which sampling efforts have recovered extant nitrogen fixer diversity, it is necessary to establish an OTU definition that can capture meaningful units of diversity even if these units do not correspond with microbial species. From these results, a 10% dissimilarity cutoff ($OTU_{0.10}$) was arbitrarily selected as an appropriate operational taxonomic cutoff to define *nifH* sequence diversity, although in most cases it will be more informative to evaluate sequence diversity across several sequence similarity thresholds.

20.5 PHYLOGENETIC DIVERSITY

Nitrogenase *nifH* sequences characterized to date are not distributed evenly across the various clusters and subclusters that comprise the *nifH* phylogeny (Fig. 20.5). Cluster I *nifH* sequences are most common in the *nifH* database representing 19365 or 59% of available sequences. Most of the cluster I sequences (10653 sequences) belong to members of the Alpha-, Beta-, and Gammaproteobacteria, and these fall primarily into subclusters 1J and 1K. Another large group (4530 sequences) of cluster I *nifH* sequences belong to the Cyanobacteria, which are found exclusively in subcluster 1B. The final major group (1925 sequences) of cluster I *nifH* sequences comprises Deltaproteobacteria of the Desulfuromonadales, which form subcluster 1A (Fig. 20.5). In comparison, cluster III sequences are less abundant in the database (3461 sequences). This is likely due to the fact that anoxic environments, which tend to contain ample cluster III nitrogenase sequences, have been sampled for *nifH* far less frequently than arable soils and oxygenated water samples in which cluster I sequences are seen to dominate (Table 20.1).

There were 10833 sequences that shared the same alignment frame (*Azotobacter vinelandii* positions 133–454), and these sequences were used to estimate *nifH* sequence diversity (Fig. 20.6). This set contains a total of 8193 unique *nifH* sequences that cluster into 2341 $OTU_{0.10}$ and 809 $OTU_{0.20}$. Considerable differences can be observed in the richness of the *nifH* clusters and subclusters (Fig. 20.7). At $OTU_{0.10}$, there are significant differences in Chao1 richness estimates between Cyanobacteria (216, 195 LCI, lower 95% confidence interval; 258 HCI, higher 95% confidence interval) and the Alpha-, Beta-, and Gammaproteobacteria (919, 806 LCI, 1076 HCI) and cluster III (2226, 1952 LCI, 2573 HCI) when controlling for sampling intensity (2089th sample; Fig. 20.7a). Cluster III has by far the greatest richness despite having been sampled at half the depth of the Alpha-, Beta-, and Gammaproteobacteria (Fig. 20.7a). In fact, when $OTU_{0.20}$ is used to evaluate the number of deep evolutionary lineages, the difference in richness between cluster III (639, 596 LCI, 702 HCI) and the Alpha-, Beta-, and Gammaproteobacteria (154, 138 LCI, 195 HCI) and the Cyanobacteria (47, 44 LCI, 66 HCI; Fig. 20.7) is even greater (Fig. 20.7b). Cluster III is composed of anaerobic nitrogen fixers (Zehr et al., 2003), and in general anoxic environments such as wetlands and sediments are undersampled relative to oxic environments (Table 20.1). Studies on the evolution of nitrogen fixation support the emergence of nitrogenase in the methanogenic Archaea with subsequent horizontal gene transfer to Bacteria (Boyd et al., 2011). Hence, it is likely that nitrogen fixation originally emerged among strict anaerobes, and this may explain the degree of evolutionary diversity present in cluster III relative to cluster I.

20.6 ENVIRONMENTAL DIVERSITY

Given that habitat sampling has been uneven (Table 20.1), the richness of *nifH* associated with three well-sampled habitats (soils, the marine water column, and microbial mats) was evaluated. To perform the assessment, the Chao1 richness index was calculated with the program DOTUR (Schloss and Handelsman, 2005) using sequence data available in the *nifH* database. Habitats were established by text searches of the sequence record metadata. The results of the assessment show that soil harbors a greater diversity of nitrogen fixers than the photic zone of the ocean (Fig. 20.8). When 2855 sequences are compared to achieve even sampling intensity, the Chao1 richness estimate at $OTU_{0.10}$ for soil (1671, 1496 LCI, 1897 HCI) was significantly higher than for the marine water column (1042, 901 LCI, 1237 HCI). In the case of microbial mats, at a sampling intensity of 1222 sequences, the Chao1 richness estimate for mats (702, 575 LCI, 894 HCI) was not significantly different from the marine water column (760, 608 LCI, 991 HCI), but both mats and the marine water column were significantly lower than soil (1193, 1016 LCI, 1435 HCI; Fig. 20.8).

Diazotroph diversity in marine systems differs dramatically from soils and not just in the total richness of the community as described earlier. The *nifH* sequences from marine samples also display a striking pattern of dominance with a few OTUs from Cyanobacteria present at very high abundance (Gaby and Buckley, 2011). In fact, 5 of the 10 most abundant *nifH* $OTU_{0.10}$ in the database belong to marine Cyanobacteria including species related to *Trichodesmium* and UCYN-A. These five cyanobacterial OTUs alone account for approximately 37% of the marine *nifH* sequences that were used in diversity estimates (i.e., having an alignment frame that overlaps positions 133–454). In contrast, soils and microbial mat communities have few dominant diazotrophs. Soils most frequently contain diverse OTUs belonging to Proteobacteria (subclusters 1J, 1K, and 1A) while microbial mats contain a wide diversity of OTUs from cluster III and Cyanobacteria (Gaby and Buckley, 2011).

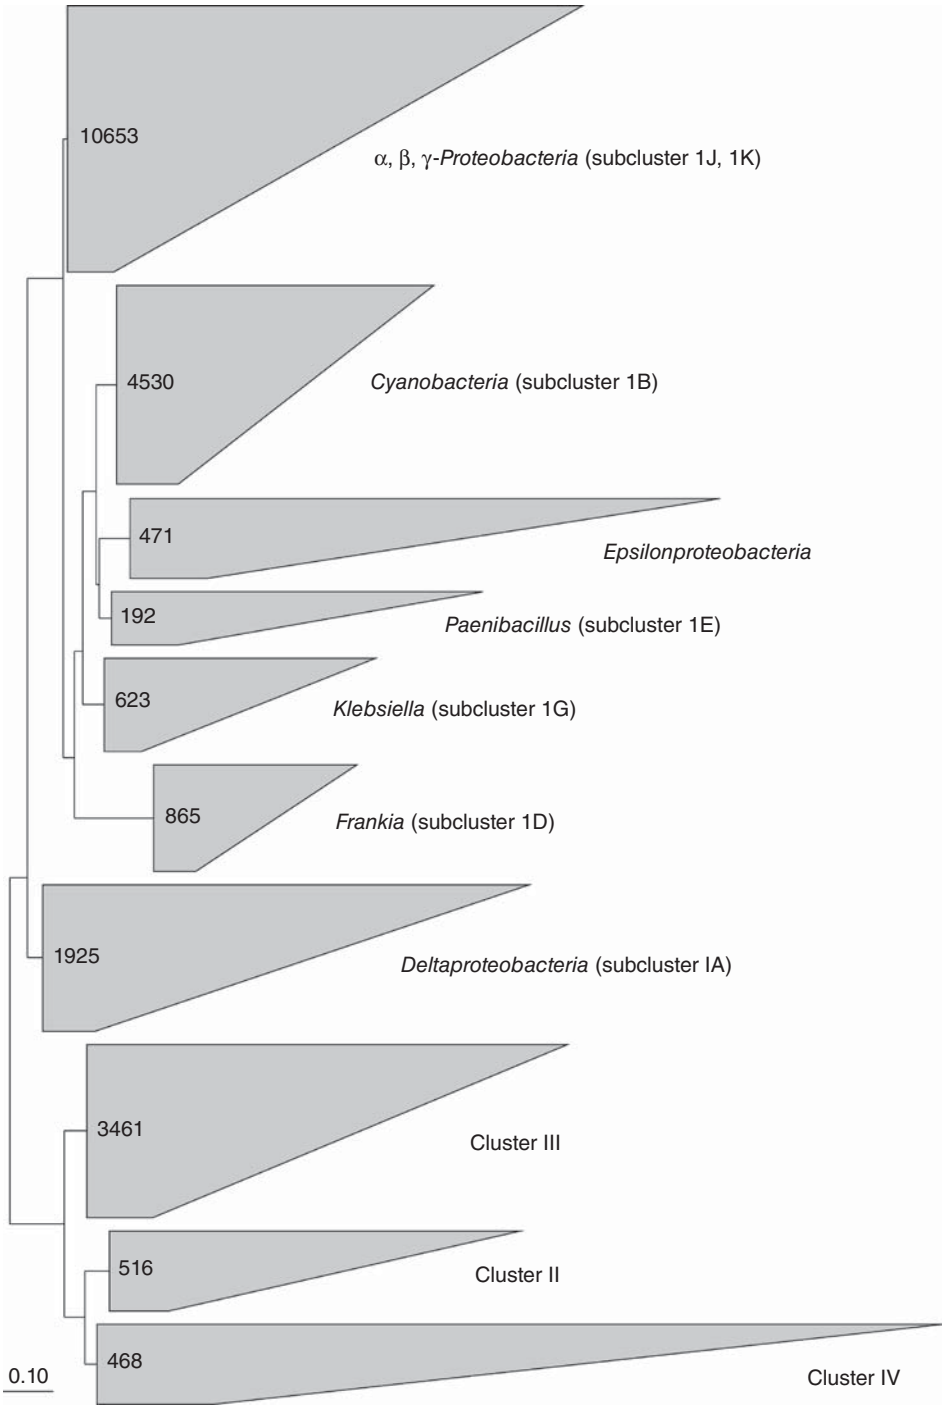

Figure 20.5 Phylogenetic tree showing the major clusters and subclusters of *nifH* sequences. The tree was constructed using a neighbor-joining tree as the base to which most sequences were added using the quick-add-by-parsimony function of ARB. The numbers within the trapezoids are the number of sequences within that phylogenetic group. The selection of groups was informed by groupings formed at an $OTU_{0.40}$ cutoff.

20.7 *nifH* PRIMER ASSESSMENT

Our ability to assess diazotroph diversity is influenced strongly by the availability and efficacy of *nifH* PCR primers. While nitrogenase genes are frequently recovered in metagenomic surveys, diazotrophs are often present as minority populations in microbial communities and so *nifH* genes are often undersampled in approaches that

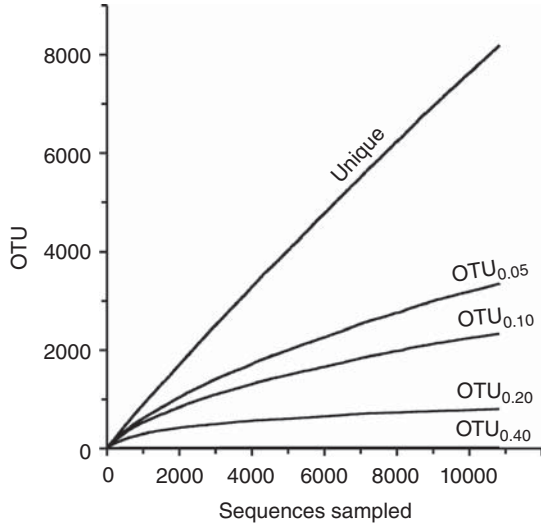

Figure 20.6 Chao1 richness estimates with 95% confidence intervals for all 10833 *nifH* sequences that share an alignment frame spanning positions 133–454 (*Azotobacter vinelandii* numbering). Each line depicts a different sequence dissimilarity OTU clustering threshold as indicated by labeling in subscript.

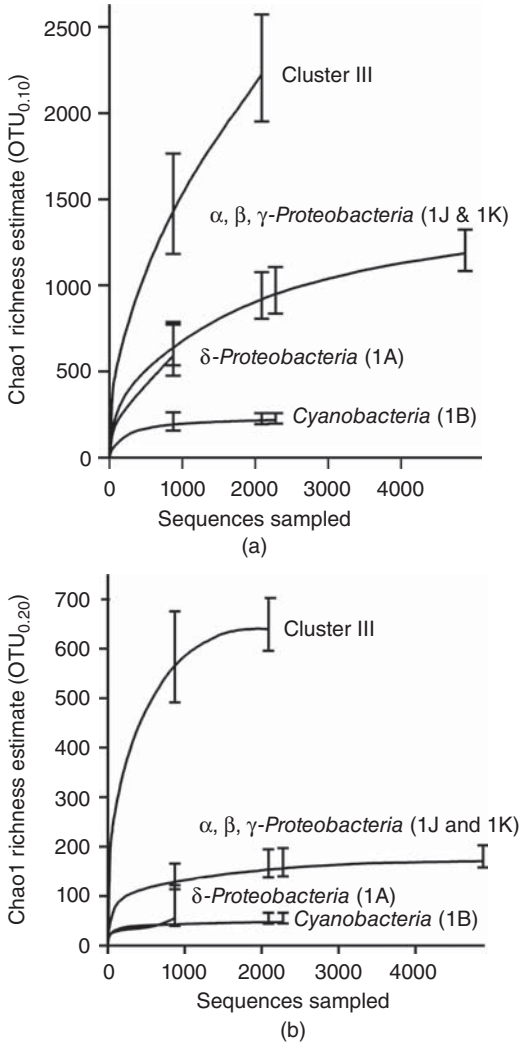

Figure 20.7 Chao1 richness estimates at a cutoff of $OTU_{0.10}$ (a) and $OTU_{0.20}$ (b) for the phylogenetic groups labeled in the figure. Bars indicate 95% confidence intervals at the sampling endpoints for each group.

employ shotgun sequencing. Diazotroph diversity can also be assessed by the enrichment and isolation of diazotrophs from environmental samples, but it is well known that cultivation imposes a strong bias on diversity estimates (Staley and Konopka, 1985). Most cultivated nitrogen fixers are heavily concentrated in the Proteobacteria (Dos Santos et al., 2012). Hence, PCR amplification of *nifH* remains an important tool for assessing diazotroph diversity.

For genes such as *nifH* that exhibit a moderate-to-high level of nucleotide variation across taxa, a degenerate primer is required to obtain "universal" coverage of taxa. The first degenerate *nifH* primer set to be designed, nifH2/nifH1 (Zehr and McReynolds, 1989), was designed primarily to target marine sequences, but since these primers target highly conserved regions of the *nifH* gene they still perform well when evaluated against a wide diversity of *nifH* sequences hitting 92% of 23847 *nifH* sequences (Gaby and Buckley, 2012). However, not all universal *nifH* primers are equally effective (Gaby and Buckley, 2012).

At least 53 universal *nifH* primers have been employed in the evaluation of *nifH* diversity (Gaby and Buckley, 2012).

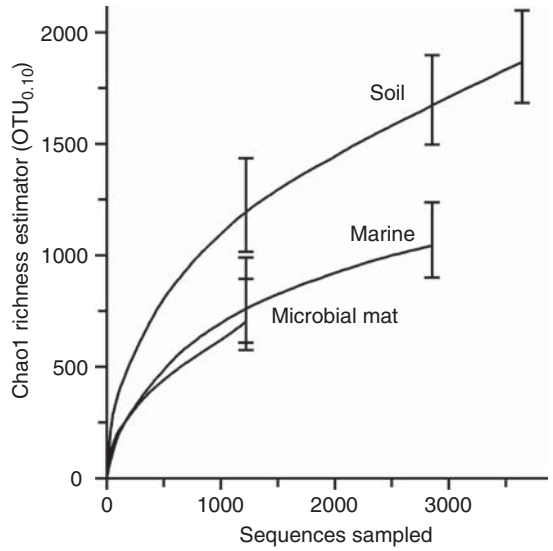

Figure 20.8 Chao1 richness estimates at an $OTU_{0.10}$ cutoff for the habitats labeled in the figure. Bars indicate 95% confidence intervals at the sampling endpoints for each group.

These primers were evaluated against the *nifH* database. While accounting for partial *nifH* sequence fragments, a total of 15 primers were found to target more than 90% of *nifH* sequences. In contrast, 23 primers were found to target less than 50% of *nifH* sequences (Gaby and Buckley, 2012). However, primers are used in pairs, and the coverage of the pair is the union of the coverage of each individual primer. Here, we report universal primer sets with high coverage as well as the commonly used primer set PolF/PolR (Table 20.2). The primer sets vary somewhat in their coverage within clusters and subclusters (Table 20.2). This result suggests that certain primer sets may be better suited to particular environments. It should be noted that this *in silico* approach to assessing primer coverage assumes that all template mismatches along the primer have equal impacts on amplification efficiency. In reality, however, mismatch position within a PCR primer can greatly affect priming efficiency (Bru et al., 2008).

While the *in silico* results are informative, the true test of primer efficacy comes at the laboratory bench, and so the primers were evaluated against a series of DNA samples from known nitrogen fixers and soils. Not all of the primer sets performed equally well in the empirical test despite having high coverage (Table 20.2). The IGK3/DVV primer set gave the best amplification from the widest diversity of templates (Gaby and Buckley, 2012). The F2/R6 primer set, despite having better *in silico* coverage than the IGK/DVV primer set, performed somewhat worse than IGK3/DVV (Table 20.2). The IGK3/DVV combination was not evaluated *in silico*, but the IGK3 primer has higher individual coverage than the IGK primer, and thus the coverage of the IGK3/DVV set is expected to be higher than IGK/DVV.

20.8 CONCLUSIONS

It is clear that the diversity of nitrogen-fixing organisms remains poorly characterized particularly with respect to

Table 20.2 Theoretical target group coverage and empirical results obtained for universal *nifH* primer sets

				Target Group Coverage*						Empirical Results†

*Target group coverage indicates the percentage of each target group in the *nifH* database that is hit by each universal *nifH* primer pair. Target group abbreviations are as follows: all *nifH* sequences (***nifH***), proteobacterial sequences from subclusters 1J and 1K (**Pr**), cyanobacterial sequences (**Cy**), subcluster 1A sequences (**1A**), cluster III sequences (**III**), and non-*nifH* cluster IV sequences (**IV**).

†DNA samples used for empirical tests of PCR primer pair specificity are as follows: *Desulfovibrio vulgaris* – cluster III (**Dv**), *Geobacter uraniireducens* – subcluster 1A (**Gu**), *Azotobacter vinelandii* – proteobacterial subclusters IJ and IK (**Av**), *Frankia* sp. CcI3 – subcluster 1D (**Fs**), *Xanthobacter autotrophicus* – proteobacterial subclusters IJ and IK (**Xa**), *Rhodobacter sphaeroides* – proteobacterial subclusters IJ and IK (**Rs**), *Escherichia coli* – negative control (**Ec**), agricultural soil (**AS**), and no-template control (**NT**). The symbols used to describe empirical results are product of correct size (+), no product produced (−), nonspecific amplification producing multiple bands or a single band of the wrong size (**ns**), a smeared band of indiscriminate size overlapping in size with the expected product (**s**). Note that the blank cells indicate that the evaluation was not performed.

‡Primer pairs are Ueda19F/407R (Ueda et al., 1995), IGK/DVV (Ando et al., 2006), F2/R6 (Marusina et al., 2001), nifH2/nifH1 (Zehr and Mcreynolds, 1989), and PolF/PolR (Poly et al., 2001).

anaerobic nitrogen fixers in *nifH* cluster III. Although the continuation of molecular surveys may eventually result in a comprehensive list of extant nitrogen-fixing taxa, most *nifH* OTUs are not represented by cultivated isolates, and hence the full breadth of physiological diversity among diazotrophs remains unconstrained (Gaby and Buckley, 2011). Diazotroph ecology, while commonly studied in the photic zone of the ocean and in arable soils, remains poorly characterized in many habitats. Studies of diazotroph ecology require careful selection and application of appropriate molecular tools and the availability of well-curated reference databases (Gaby and Buckley, 2014). The emergence of low-cost sequencing technologies and further development of molecular tools for characterizing the distribution and diversity of *nifH* in the environment can be expected to vastly improve our knowledge of nitrogenase diversity in the years to come.

Genomics of Nitrogen Fixing Organisms

Chapter 21

Genetic Regulation of Symbiosis Island Transfer in *Mesorhizobium loti*

Joshua P. Ramsay

21.1 DISCOVERY AND FIELD TRANSFER OF THE *Mesorhizobium loti* SYMBIOSIS ISLAND

The symbiosis island of *Mesorhizobium loti* is a mobile genetic element discovered in New Zealand through its ability to convert native nonsymbiotic mesorhizobia to symbionts of the pasture legume *Lotus corniculatus* (Birdsfoot trefoil) (Sullivan et al., 1995; Sullivan and Ronson, 1998). A field trial to determine the agricultural efficacy of *L. corniculatus* in acidic tussock grassland soils was established using seed coated with the symbiont strain *M. loti* ICMP3153. The site lacked native rhizobia capable of nodulating *L. corniculatus* as *Lotus* species had not been grown there previously. Following a 7-year period, up to 19% of *L. corniculatus* nodules were found to have been formed by a diverse group of native mesorhizobial species that had acquired the capacity for symbiosis with *L. corniculatus* (Sullivan et al., 1995). Investigation at the molecular level revealed that these newly evolved *M. loti* symbionts had acquired a ~500-kb chromosomal region encoding genes involved in nodulation and nitrogen fixation (Sullivan and Ronson, 1998; Sullivan et al., 2002). This chromosomal element encoded a phage-related integrase at one end, was inserted adjacent to the *M. loti* phe-tRNA gene, and was flanked by perfect direct repeat sequences, features common to pathogenicity islands. Due to these similarities, it was named the "symbiosis island" (Sullivan and Ronson, 1998).

In subsequent field experiments in which *M. loti* strain R7A (a descendant of the ICMP3153 strain reisolated from the original field experiment) was again introduced into a site devoid of natural symbionts, it was found that over a 4-year period 75% of root nodules were formed by diverse native mesorhizobial species that had acquired the symbiosis island, although the original inoculant strain R7A was still present in the rhizosphere of the plants. Diverse symbionts were first detected 2 years after inoculation (Fig. 21.1; G. Stuart, J. Sullivan and C. Ronson, unpublished data). A similar phenomenon has been documented in Western Australian soils, where a symbiosis island identified in *M. ciceri* bv. *biserrulae* strain WSM1271 was found to transfer to indigenous mesorhizobia. The evolved symbionts were able to supplant strain WSM1271 in nodules, but in this case the evolved symbionts exhibited suboptimal nitrogen-fixing ability, negatively impacting plant growth (Beaber et al., 2002). These events suggest that there are selective advantages other than just nitrogen fixation and symbiosis that ultimately favor the evolved isolates in these soils, at least during the relatively short time-frame of these studies.

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

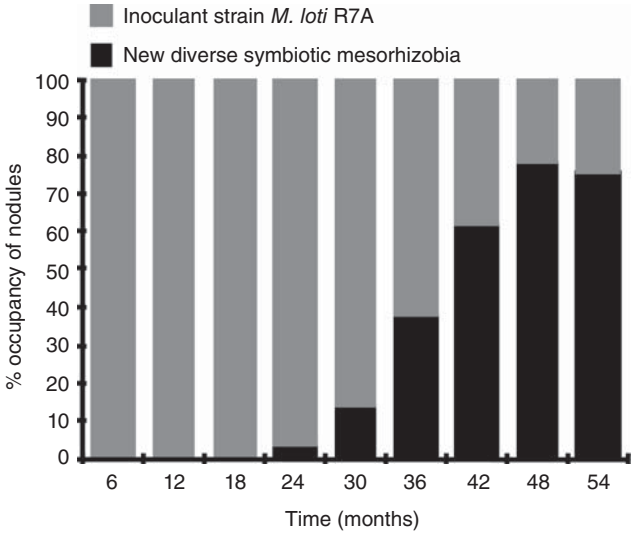

Figure 21.1 Kinetics of nodule formation by symbionts that have acquired the symbiosis island from *M. loti* strain R7A in the field.

21.2 INTEGRATION AND EXCISION OF THE SYMBIOSIS ISLAND

The symbiosis island (ICE*Ml*Sym^{R7A}) of *M. loti* strain R7A belongs to the widespread group of mobile genetic elements called integrative and conjugative elements (ICEs) (Burrus and Waldor, 2004). The integration of ICE*Ml*Sym^{R7A} DNA into the host chromosome requires an integrase IntS that catalyses recombination between 17-bp sequences that form a direct DNA repeat flanking the integrated ICE*Ml*Sym^{R7A} (Ramsay et al., 2006; Sullivan and Ronson, 1998) (Fig. 21.2). The 17-bp direct repeat sequences and surrounding regions, collectively named attachment (*att*) sites, are required for both integration and excision. The attachment sites *attL* and *attR* flank the integrated form of ICE*Ml*Sym^{R7A}, while *attP* and *attB* are used to denote the circularized ICE*Ml*Sym^{R7A} and bacterial *att* sites, respectively. The excision of ICE*Ml*Sym^{R7A} leads to the formation of *attP* and *attB*, which can be detected using polymerase chain reaction (PCR). The frequency of excision of ICE*Ml*Sym^{R7A} in the cell population can be quantified, using quantitative polymerase chain reaction (QPCR), to estimate the abundance of *attP* and *attB* relative to the total number of chromosomes present. In aerated liquid culture conditions (TY broth), the excision products *attP* and *attB* are detected in ~0.06% of cells in exponentially growing cultures and in ~6% of stationary-phase cells. Using the QPCR technique, it was discovered that efficient excision of ICE*Ml*Sym^{R7A} requires the expression of the recombination directionality factor *rdfS*, which is encoded in a gene cluster carrying genes involved in conjugation (including *rlxS*), presumably coordinating these processes. Overexpression of *rdfS* results in the loss of ICE*Ml*Sym^{R7A} from *M. loti*, producing a nonsymbiotic strain (R7ANS) (Ramsay, et al., 2006).

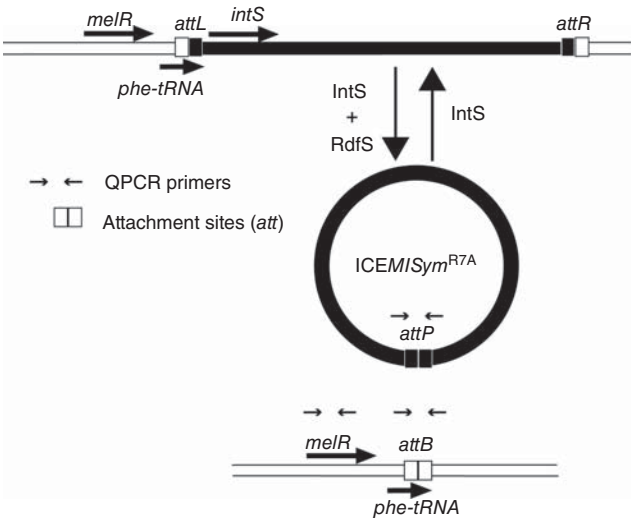

Figure 21.2 Schematic of integration and excision of ICE*Ml*Sym^{R7A}.

21.3 SYMBIOSIS ISLAND TRANSFER IS REGULATED BY QUORUM SENSING

Bacterial cell–cell communication or "quorum sensing" (QS) regulates numerous phenotypes in rhizobia, including horizontal gene transfer. QS-induced plasmid transfer has been characterized in both Gram-negative and Gram-positive bacterial species. For some plasmids, the QS regulatory factors and their cognate signaling molecules (sometimes referred to as pheromones or quoromones) can specifically induce transfer between plasmid-carrying and plasmid-free cells (Danino et al., 2003; Dunny, 2007; Wisniewski-Dye and Downie, 2002; see Chapter 37). ICE*Ml*Sym^{R7A} encodes a QS system related to that of the Ti plasmid of *Agrobacterium tumefaciens* and pRL1JI of *Rhizobium leguminosarum* (Ramsay et al., 2009; Ramsay, et al., 2006). In the plasmid systems, quorum-dependent transcriptional activation is carried out by a DNA-binding protein TraR. In the presence of the membrane-diffusible autoinducer molecule *N*-(3-oxooctanoyl)-L-homoserine lactone (3-oxo-C8-HSL), TraR is able to activate transcription of transfer genes and transcription of the 3-oxo-C8-HSL synthase-encoding gene *traI* in a positive-feedback loop (Frederix and Downie, 2011).

The TraR protein of ICE*Ml*Sym^{R7A} shares 29% and 32% amino acid identity with the Ti and pRL1JI plasmids, respectively, while the plasmid TraR proteins share 29% identity, suggesting that the three systems share a similar level

of evolutionary divergence. ICE*Ml*Sym^{R7A} also encodes two predicted *N*-acyl homoserine lactone (AHL) synthase genes *traI1* and *traI2*. TraI1 predominantly produces *N*-(3-oxohexanoyl)-L-homoserine lactone (3-oxo-C6-HSL), the cognate signal of ICE*Ml*Sym^{R7A} TraR. The predicted TraI2 protein contains all conserved residues known to be involved in catalysis for the LuxI/TraI AHL synthase family; however, no functional role or autoinducer synthase activity has been detected (Ramsay et al., 2009). The TraI1 and TraI2 sequences are more related to each other than they are to other database sequences, suggesting that *traI2* may be the product of a gene duplication event. It is possible that *traI2* has become a pseudogene, or it may be involved in the production in of an as-yet unknown signaling molecule. The TraR protein of ICE*Ml*Sym^{R7A} activates transcription of the *traI1* and *traI2* genes on ICE*Ml*Sym^{R7A}, resulting in a positive-feedback loop through activation of TraI1 expression and 3-oxo-C6-HSL production (Fig. 21.3). Predicted TraR-binding sites (*tra*-boxes) are located upstream of both *traI1* and *traI2* (Ramsay, et al., 2009).

Introduction of a plasmid-borne copy of ICE*Ml*Sym^{R7A} *traR* (pJRTraR) results in the excision and stable maintenance of ICE*Ml*Sym^{R7A} in 100% of cells, a 1000-fold increase in the production of 3-oxo-C6-HSL and a 40-fold increase in conjugative transfer (Ramsay et al., 2013; Ramsay et al., 2009; Ramsay et al., 2006). In contrast, addition of exogenous AHLs to high levels has no effect on these properties, suggesting that expression of *traR* or TraR activity is usually suppressed. Interestingly, the stable maintenance of ICE*Ml*Sym^{R7A} in the presence of pJRTraR requires a functional copy of *rlxS*, which encodes the ICE*Ml*Sym^{R7A} relaxase protein required for conjugation. This suggests that while ICE*Ml*Sym^{R7A} is excised, it replicates via rolling-circle replication, a feature that has been subsequently observed for ICEs in Gram-positive species (Thomas et al., 2013). The notion that an ICE is able to be stably maintained via an extrachromosomal replication mechanism challenges the assumption that excision is merely a transient event (Burrus et al., 2002). Indeed, recent studies of ICEs in *Pseudomonas* suggest that a minority of ICE-carrying cells may differentiate (sometimes terminally) into nongrowing "mating bodies" in which ICEs remain excised and conjugate to other cells (Reinhard et al., 2013).

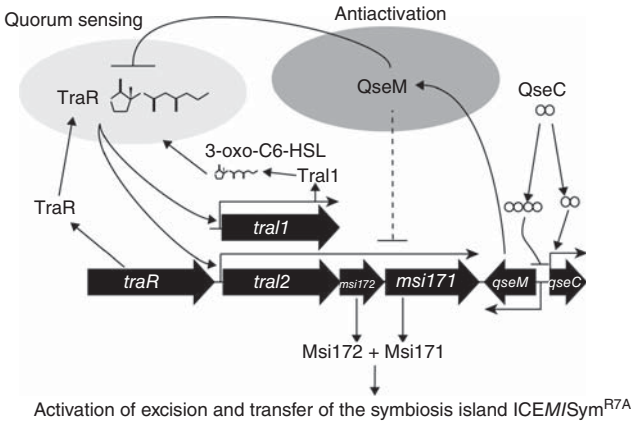

Figure 21.3 Regulation of ICE*Ml*Sym^{R7A} by quorum sensing and antiactivation.

21.4 QUORUM SENSING INDUCES A NOVEL ACTIVATOR OF SYMBIOSIS ISLAND EXCISION AND TRANSFER

The increased 3-oxo-C6-HSL production observed in cells carrying pJRTraR results from transcriptional activation of *traI1* and autoinduction by TraR-3-oxo-C6-HSL. The activation of excision and conjugative transfer by TraR requires transcriptional activation of the *traI2-msi172-msi171* operon and, specifically, the presence of *msi172* and *msi171*. Nonpolar deletions in *msi172* or *msi171* result in a total loss of excision and conjugative transfer but do not affect AHL production (Ramsay et al., 2009), effectively uncoupling QS from the regulatory cascade. The predicted protein products of *msi172* and *msi171* belong to the large uncharacterized protein family DUF2285, conserved on ICE*Ml*Sym^{R7A}-related elements found throughout the Proteobacteria. Our molecular investigations suggest that *msi172* and *msi171* work together to directly activate expression of *rdfS* promoter, indicating they may encode factors involved in transcriptional activation (Ramsay et al., 2013; Ramsay et al., 2009). Comparisons between related ICE elements reveal that the QS genes *traR* and *traI1/2* are infrequently associated with *msi172-msi171* and *rdfS*, suggesting that addition of QS regulation to this circuit is a recent evolutionary event (Ramsay, et al., 2013).

21.5 THE QS CIRCUIT IS CONTROLLED BY AN ANTIACTIVATOR

The large increase in AHL production and ICE*Ml*Sym^{R7A} excision and transfer that results from ectopic *traR* expression through pJRtraR indicates that the stoichiometry of TraR with other negative regulatory factor(s) is critical for the observed suppression of the QS autoinduction circuit in wild-type cells. On the Ti and pRL1JI plasmids, the TraM protein inhibits QS through direct antiactivation of the TraR protein (Fuqua et al., 1995). *M. loti* lacks TraM; however, ICE*Ml*Sym^{R7A} encodes an unrelated antiactivator of TraR, the QseM protein. The *qseM* gene is encoded downstream of and transcribed toward *traR* in a configuration similar to that of the *traM* gene on pRL1JI. Deletion of *qseM* results in activation of 3-oxo-C6-HSL production, and ICE*Ml*Sym^{R7A}

excision and conjugation, essentially producing a phenocopy of a strain carrying pJRTraR (Ramsay et al., 2013). Mutation of *traR* in the *qseM*-deleted strain results in a loss of this activation, confirming the dependence of this activation on TraR. Bacterial two-hybrid analysis has demonstrated that QseM can directly interact with the TraR protein in a heterologous *Escherichia coli* background. However, the interaction with TraR appears to be AHL-dependent, unlike that observed between TraR and TraM, also in *E. coli*. This suggests that the mechanism of TraR antiactivation by QseM may be distinct. QseM shows no sequence similarity to TraM; however, it is similar in size and our preliminary analysis of purified QseM suggests that like TraM it is α-helical in structure (Ramsay et al., 2013; J. Ramsay, A. Major, K. Krause and C. Ronson, unpublished data).

Overexpression of QseM suppresses excision of ICE*Ml*Sym^{R7A} excision (<0.1%) to levels significantly below that observed in wild-type cultures. Surprisingly however mutation of *traR* has only a marginal effect on the frequency of ICE*Ml*Sym^{R7A} excision, although it does result in significantly lowered rates of conjugative transfer (Ramsay et al., 2013; Ramsay et al., 2009). This is a clear evidence that QseM has additional targets other than TraR. Interestingly, the QseM protein contains weak but convincing sequence similarity to the DUF2285 family (and similarity to the protein product of *msi171*), and several QseM homologs are annotated as belonging to this family. It is possible that an ancestor of the QseM family of proteins diverged from the DUF2285 family and evolved antagonistic activity against excision-activating relatives such as Msi172 and Msi171 (Ramsay et al., 2013). We are currently investigating the possibility that Msi172 and Msi171 are the secondary targets of QseM.

21.6 A MOLECULAR SWITCH CONTROLS THE PRODUCTION OF THE ANTIACTIVATOR

Our dissection of the regulatory circuits controlling ICE*Ml*Sym^{R7A} excision and transfer has revealed that there is a delicate balance between repression by the QseM protein and runaway positive autoinduction of the QS system. This implies that at the top of the regulatory hierarchy, the switch to the excised and transferring state is controlled by the stoichiometry of TraR-3-oxo-C6-HSL and QseM. Our analyses of *traR* expression indicate that it is transcribed at a low basal level throughout growth, and that both *traR* transcriptional activation and mRNA abundance are unaffected by activation of QS or the presence of QseM (Ramsay et al., 2013). It remains possible that the expression of *traR* is activated by some as yet undiscovered factor. More however is understood about the expression of *qseM*, which is controlled by the DNA-binding protein QseC.

The *qseC* gene is divergently transcribed from *qseM* as a leaderless mRNA. QseC binds two adjacent operator sequences between *qseM* and *qseC* and is able to both activate its own expression and repress expression of *qseM* (Fig. 21.4). QseC binds the *qseM*-proximal operator O_L at low concentrations, while the *qseC*-proximal operator O_R is only bound in the presence of QseC-bound O_L. This suggests that with increasing QseC concentration, O_L is initially bound and that O_R is bound secondarily in a cooperative manner. The -35 region of the *qseC* promoter is located immediately downstream of the O_L operator sequence, consistent with positive autoinduction of *qseC* expression through recruitment of the RNA polymerase holoenzyme (RNAP) to the -35 site within O_R. The *qseM*-35 region is

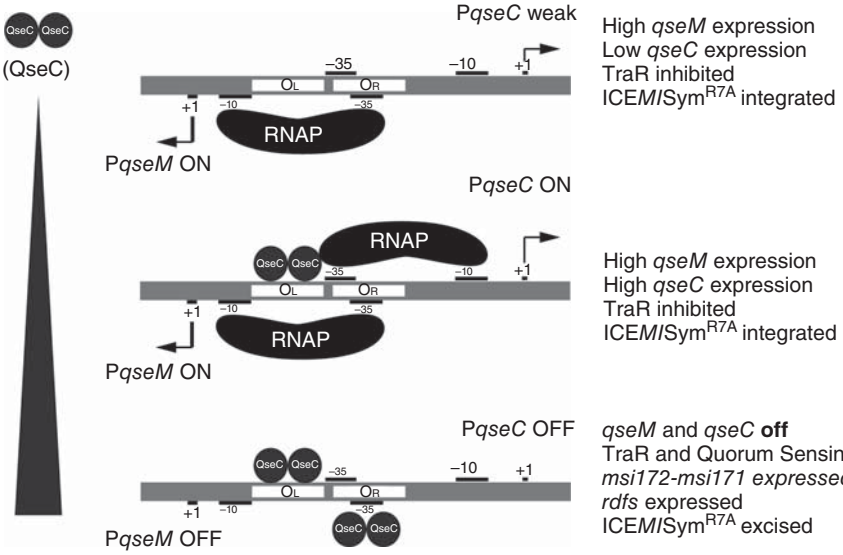

Figure 21.4 Regulation of *qseC* and *qseM* expressions by the QseC switch.

also within O_R, however, due to the divergent orientation of *qseM*, the access of RNAP to the *qseM* promoter is likely blocked by QseC binding to O_R, consistent with the observed increase in *qseM* expression in a *qseC* mutant. In a *qseC* mutant, pJRTraR is unable to induce 3-oxo-C6-HSL production or elevate the frequency of excision and conjugative transfer. Consistent with our model, this suggests that in the absence of QseC, QseM dominates the balance between QseM and TraR-3-oxo-C6-HSL, preventing positive autoinduction of QS. When this model is considered with respect to the excision frequencies observed in wild-type cells (~0.06% in log phase and ~6% in stationary phase), it is tempting to conclude that in the ~6% of cells containing ICE*Ml*Sym^{R7A}, the QseC concentration is high enough to repress expression of *qseM*, resulting in the de-repression of the QS-positive induction circuit and subsequent activation of *msi172-msi171* and *rdfS* expression (Ramsay et al., 2013).

21.7 CONCLUDING REMARKS

Although ICE*Ml*Sym^{R7A} excision and transfer is regulated by QS and can occur at very high levels if the QS system is de-repressed, the further tier of regulation provided by QseM–QseC ensures that only low levels of AHL are produced by the population, and that most cells remain blind to this signal, whatever its level. As mentioned earlier, while TraR is largely dispensable for the basal frequency of excision observed in R7A, it is absolutely required for transfer. This demonstrates that TraR-activated expression and induction of transfer is occurring in R7A, albeit at a low frequency, with low population-level AHL production (Ramsay et al., 2009). Therefore, it seems plausible that the QseM–QseC switch facilitates bimodal induction of QS in the population, allowing the coordination of transfer from only the subpopulation of *qseM*-repressed cells. Other physiological factors, such as stress or the availability of suitable recipients, could introduce conditionality on the QS system and/or repression by QseM, by modulating the proportion of cells receptive to be induced by QS. This mechanism could allow ICE*Ml*Sym^{R7A} to maximize its potential for propagation from both vertical and horizontal descents by appropriately partitioning a subpopulation of cells for transfer in response to environmental conditions.

22.1 INTRODUCTION

This chapter presents an updated and expanded description of the *Azotobacter vinelandii* strain DJ genome. The first description of this genome was published in 2009 (Setubal et al., 2009). In that publication, the focus was on the following sets of genes: respiration and respiratory protection genes, nitrogen-fixation-related genes, genes related to other oxygen-sensitive processes (CODH, FDH, and hydrogenases), alginate genes, and polymer production and encystment genes. Here, we update information related to genome annotation and phylogeny, and include new material that was not part of that paper because of space limitations.

We do not repeat information from the above paper related to the gene categories listed. The reader interested in learning about these genes should consult the original paper and a follow-up review that contains more information on the genomics of nitrogen fixation, with a focus on *A. vinelandii* (O'Carroll and Dos Santos, 2011).

22.2 MATERIALS AND METHODS

The phylogenetic trees were built using 20 genomes (Table 22.1). For both trees, we used OrthoMCL (Li et al., 2003) to obtain families of orthologous proteins. For the phylogeny of Pseudomonadaceae (Fig. 22.1), OrthoMCL provided 1303 families containing exactly one representative member of each ingroup genome and at most one from the outgroup genome (out of 10,026 families). Each one of these groups was aligned with Muscle (Edgar, 2004), and the noninformative columns were removed by Gblocks (Castresana, 2000). All alignments were concatenated, totaling 399,671 columns, and this final concatenated alignment was used as input to RAxML (Stamatakis, 2006) with the PROTGAMMAWAGF model to build the tree. Bootstrap support values were obtained with 100 replicates. The same method was used to build the tree in Figure 22.2, but in this case we used 6 genomes, 15 families (out of 4989), and 4421 columns. Note that only 80 *Azotobacter chroococcum* protein sequences are available in GenBank.

Gene-sharing information shown in Table 22.3 was obtained from orthoMCL results. AlienHunter (AH) (Vernikos and Parkhill, 2006) was used to identify anomalous regions in the *A. vinelandii* DJ genome. These regions have unusual sequence composition and are considered anomalous if the AH score is above that of an automatically calculated threshold, based on the background sequence composition of the whole genome. For the *A. vinelandii* DJ genome, this threshold was 13.02, and 54 anomalous regions were found. Alignment between chromosomes was carried out using the script Promer from the MUMmer package

(Kurtz et al., 2004). Promer performs alignments between translated nucleotide sequences. Promer was not sensitive enough to pick up the alignment between the *iscAnif* gene present in *Teredinibacter turnerae* T7901 genome and that of *A. vinelandii* DJ; this detection required a BLAST search. Clustered regularly interspaced short palindromic repeats (CRISPRs) were found using the CRISPRfinder server (Grissa et al., 2007).

22.3 RESULTS AND DISCUSSION

22.3.1 Genome Features and Phylogeny

The basic genome features of *A. vinelandii* DJ are shown in Table 22.2. They are the same as those reported previously (Setubal et al., 2009), with additional information on group II introns and CRISPRs.

>Setubal et al. (2009) presented a maximum-likelihood phylogeny of Pseudomonadaceae. Figure 22.1 presents a new phylogeny of Pseudomonadaceae, obtained by the same method. This phylogeny has the following novel features compared with the one published previously: it includes two *Cellvibrio* genomes, which are also Pseudomonadaceae but for which in 2009 there were no complete genomes available; five new *Pseudomonas stutzeri* genomes, in addition to *P. stutzeri* A1501; and some newly sequenced *Pseudomonas* species. With the exception of *P. stutzeri*, for all other *Pseudomonas* species we used just one representative per species. This phylogeny is in complete agreement with that from Setubal et al. (2009). The addition of new genomes shows that the *Pseudomonas* species separate into two basic groups: one containing all *P. stutzeri* species and the other containing the remaining *Pseudomonas* species. *A. vinelandii* DJ localizes externally to the *Pseudomonas* species but internally with respect to the two *Cellvibrio* species.

P. stutzeri A1501 is a nitrogen fixer (Yan et al., 2008). Among the five new *P. stutzeri* strains that we included in the phylogenetic inference only one other strain also fixes nitrogen: *P. stutzeri* DSM 4166, an isolate from the rhizosphere of a *Sorghum nutans* cultivar (Yu et al., 2011; see also Chapter 10).

We further investigated the phylogeny of *A. vinelandii* by using the relatively few protein sequences publicly available from *A. chroococcum*. *A. chroococcum* was the first *Azotobacter* species to be described and is commonly found in soils worldwide; it is also a nitrogen fixer (Page, 1987). The resulting phylogeny is shown in Figure 22.2. As expected, *A. chroococcum* groups with *A. vinelandii* DJ, with both species appearing separate from the *Pseudomonas* group.

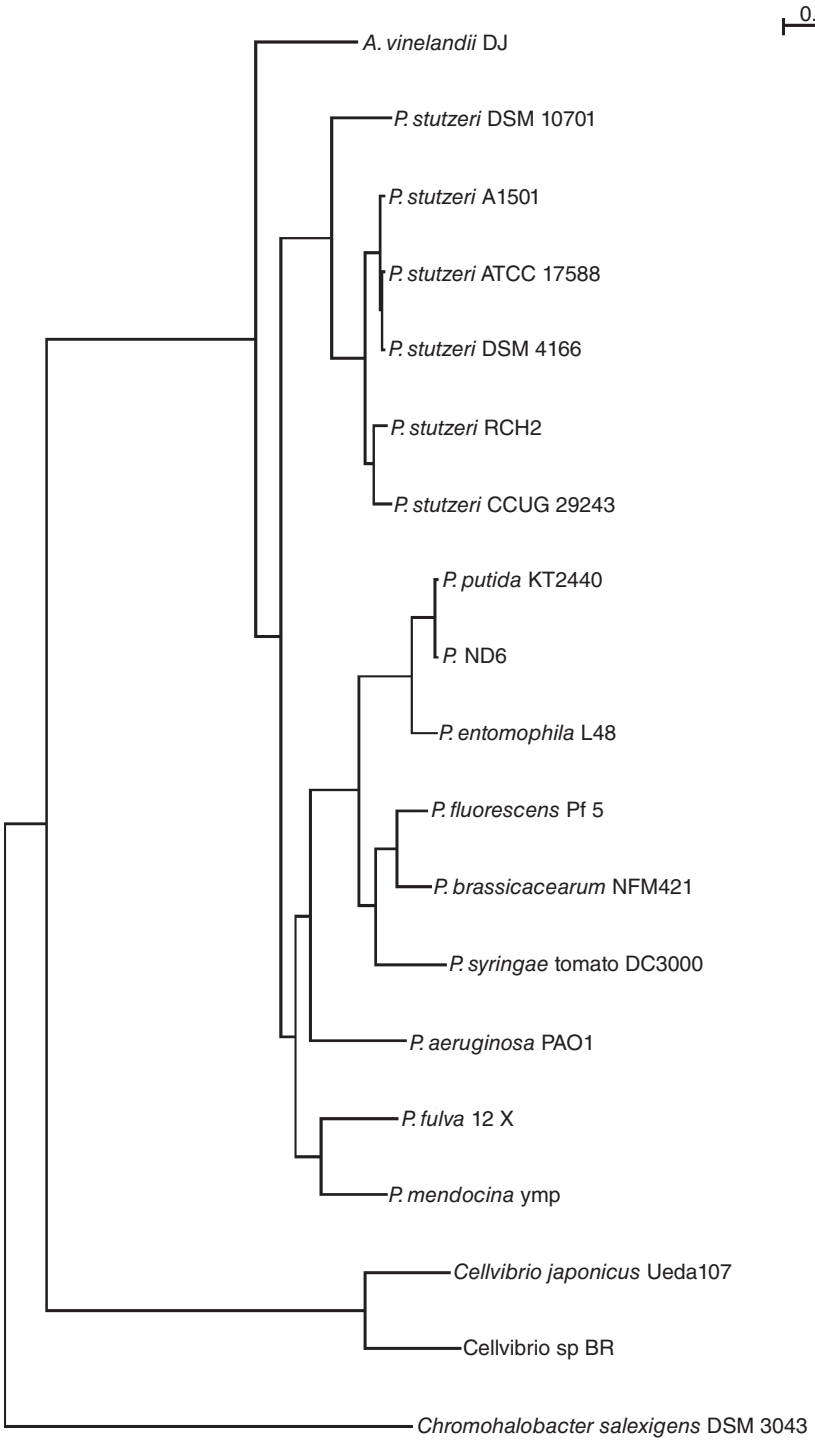

Figure 22.1 A maximum-likelihood phylogenetic tree including representatives from all Pseudomonadaceae species whose genome has been completely sequenced. *Chromohalobacter salexigens* DSM 3043 was used as outgroup. All branches received 100% bootstrap support. The scale shows the number of substitutions per site in branch lengths.

The proximity between *Azotobacter* and *Pseudomonas* shown in these trees justifies the question of whether the genus *Azotobacter* should be reclassified as *Pseudomonas*. Ozen and Ussery (2012) have studied this question, performing extensive comparative analyses. They reached the conclusion that there is "a high similarity between *A. vinelandii* and the *Pseudomonas* genus, suggesting that *Azotobacter* might actually be a *Pseudomonas*." The two trees that we present here show clearly that the two *Azotobacter* species, while related to the sequenced *Pseudomonas*, form a distinct group. Whether or not the *Azotobacter* genus should be reclassified as *Pseudomonas* is a question that we do not address here further.

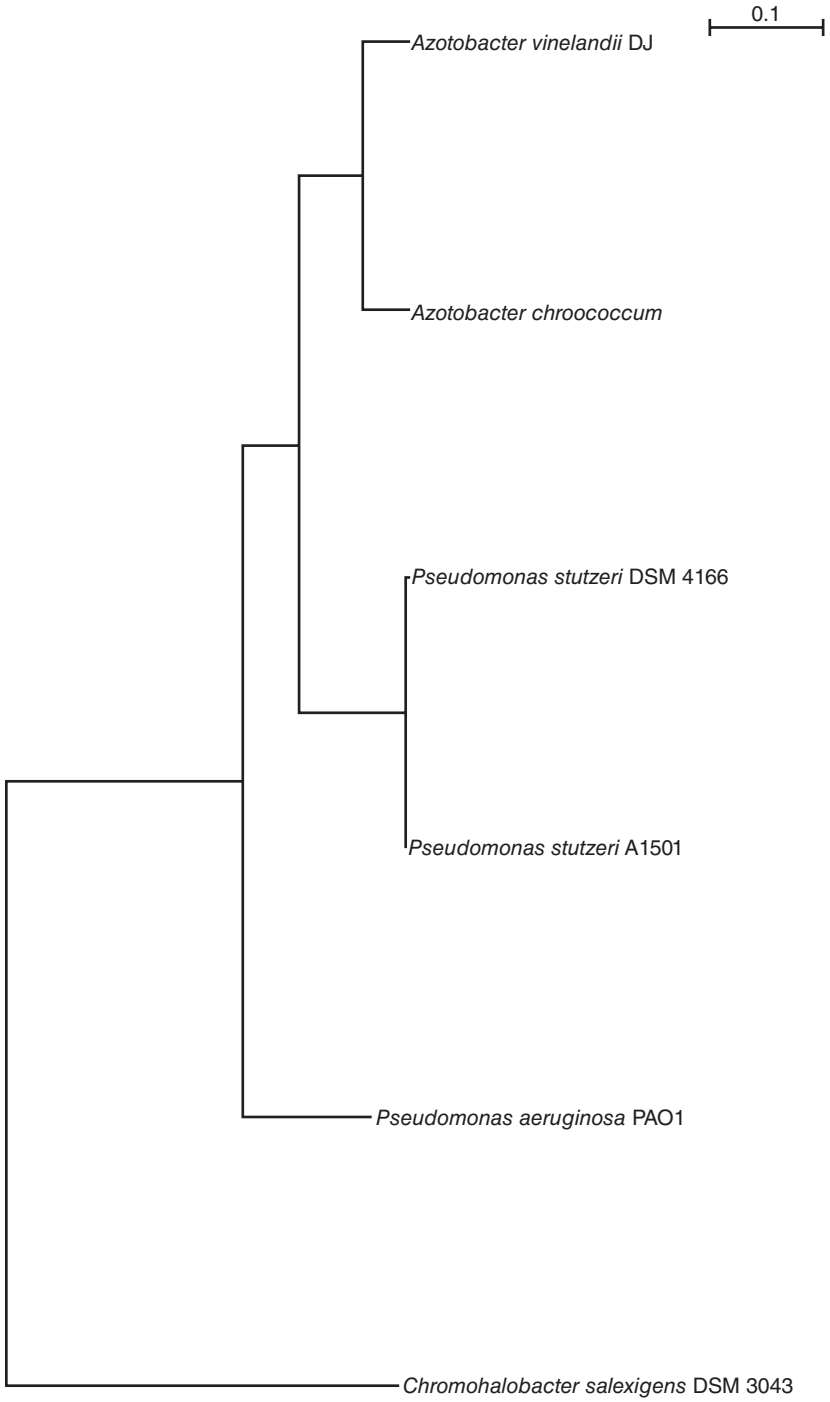

Figure 22.2 A maximum-likelihood phylogenetic tree for some Pseudomonadaceae species including *Azotobacter chroococcum*. All branches received 100% bootstrap support. The scale shows the number of substitutions per site in branch lengths.

22.3.2 Sharing of Nitrogen Fixation-Related Genes

Of all the genomes used to build the phylogeny in Figure 22.1, only *A. vinelandii* DJ, *P. stutzeri* A1501, and *P. stutzeri* DSM 4166 are diazotrophs. We have determined which genes are shared by these three genomes such that none of these genes is also present in the remaining genomes. The results are shown in Table 22.3. With the exception of transposase genes, these three genomes share exactly two regions. One is the major *nif* region (Avin_13060 to Avin_01710); the other is a region (Avin_50900 to Avin_51060) composed of two subregions: the *rnf1* region (Avin_50900 to Avin_50980) and the minor *nif* region

Table 22.2 Basic genome features of *Azotobacter vinelandi* DJ

(Avin_50990 to Avin_51060). Both sets of genes are related to nitrogen fixation (Curatti et al., 2005; O'Carroll and Dos Santos, 2011).

22.3.3 The Origin of Nitrogen Fixation Genes in *A. vinelandii*

There is considerable interest in the origins of nitrogen fixation (Raymond et al., 2004; Kechris et al., 2006; see also Chapters 8, 16, 20). One hypothesis is that nitrogen fixation appeared after the emergence of bacteriochlorophyll biosynthesis and then spread by horizontal gene transfer (HGT) to various microbial lineages (Boyd et al., 2011). The availability of the *A. vinelandii* DJ genome sequence and that of other related organisms presents an opportunity to investigate the issue of HGT for this particular group.

Figure 22.3 shows a graph of anomalous regions in terms of nucleotide composition of the *A. vinelandii* DJ genome. Many of these regions are candidates for having been horizontally transferred; however, none of the nitrogen-fixation genes is contained in any of these regions. This evidence, coupled with the results on gene sharing with the diazotrophic *P. stutzeri* species presented in the previous section, suggests that nitrogen-fixation genes were present in the common ancestor of *A. vinelandii* and *P. stutzeri*, having been lost in the nondiazotrophic *P. stutzeri* species. This means, in turn, that if HGT indeed took place in this lineage, it happened either in that ancestor or earlier.

In order to explore this question further, we have determined which organisms share nitrogen-fixation genes with high similarity to those of *A. vinelandii* and *P. stutzeri*. We carried out this by running BLAST (Altschul et al., 1997) searches using as queries the protein sequences for *A. vinelandii* DJ genes *nifHDKENB* against the nr database from GenBank. These genes have been suggested as a minimum gene set for the computational identification of diazotrophs from whole genome sequences (Dos Santos et al., 2012). Partial results can be seen in Table 22.4. *T. turnerae* T7901 is shown because it gave the best (by bitscore) BLAST hit for all six query sequences among the non-Pseudomonadaceae.

T. turnerae is a marine intracellular endosymbiont Gammaproteobacterium in the order Alteromonadales (NCBI taxonomy). The genome of strain T7901 has been sequenced (Yang et al., 2009), and the similarity of its nitrogen-fixation genes to those of *Azotobacter* and *P. stutzeri* was noted in that publication. Yang et al. (2009) suggested that "the *nif* cluster in *T. turnerae* was acquired via horizontal gene transfer from a *Pseudomonas*-like bacterium." In this context we note that, similar to the *A. vinelandii* results above, none of the *nif* genes in *T. turnerae* T7901 lie in an anomalous region (data not shown). Moreover, an alignment of the *A. vinelandii* DJ genome with that from *T. turnerae* T7901 shows that there is local synteny between the major *nif* regions in both genomes and between the minor *nif* regions in both genomes (Figs. 22.4 and 22.5). In the case of the major *nif* region, the *T. turnerae* chromosome contains an insertion and a deletion with respect to the *A. vinelandii* sequence (Fig. 22.4). The insertion runs from position 1,603,694 to position 1,625,049 in *T. turnerae* genome coordinates and contains genes unrelated to nitrogen fixation, some of which are found scattered in the *A. vinelandii* DJ genome. The deletion occurs between *A. vinelandii* genome coordinates 148,689 and 153,036 (or from Avin_01540 to Avin_01600). This region includes five hypothetical proteins and one ATP-binding cassette (ABC) transporter. This deletion suggests that these genes may not be strictly necessary for nitrogen fixation. In the case of the second region (Fig. 22.5), it essentially corresponds to the second shared region between *A. vinelandii* DJ and the two *P. stutzeri* diazotroph genomes already noted earlier, which includes the minor *nif* region.

These alignments (as well as the global alignment between the two chromosomes – data not shown) are characteristic of genomes that share a common ancestor but which have diverged for a long enough time such that many rearrangements have taken place, but still preserving small syntenic blocks. These results suggest that it is more likely that *T. turnerae*, *A. vinelandii*, and *P. stutzeri* inherited their nitrogen-fixation genes from a common ancestor. If this hypothesis is correct, then we can ask the question: which ancestor, if any, acquired its nitrogen-fixation genes through HGT? Our BLAST search did reveal a few more interesting links, as described next.

We investigated 15 additional non-Pseudomonadaceae species in the BLAST search, selected using the following criteria: only species containing at least five of the six minimum-set genes were selected; and all alignments had to have at least 60% amino acid identity (Table 22.5). Of

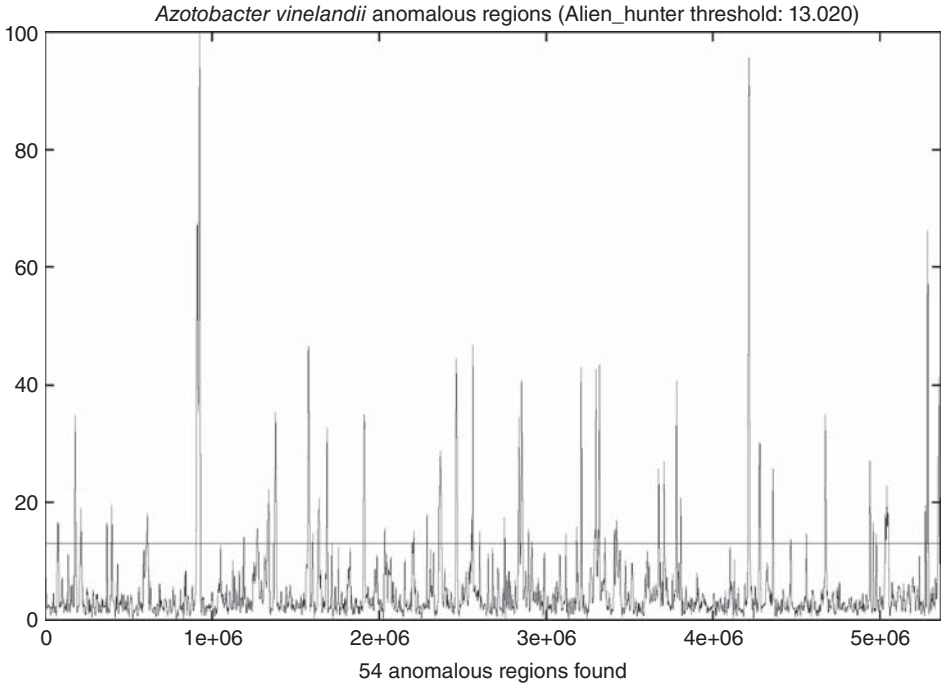

Figure 22.3 Anomalous regions in the genome of *A. vinelandii* DJ genome. The *x*-axis represents genome coordinates and the *y*-axis represents AlienHunter scores, calculated for each 5 kbp-length window with an offset of 2.5 kbp.

these 16 species (including *T. turnerae*), 12 are Gammaproteobacteria (with seven species in the order Chromatiales), and four are Betaproteobacteria.

Our interpretation of these results is that the presence of nitrogen-fixation genes in *A. vinelandii* is the result of vertical inheritance up to an unidentified Gammaproteobacterium ancestor. Because that hypothesized ancestor is also the ancestor of many nondiazotrophs, such a hypothesis requires that nitrogen-fixation genes were lost in many descendant lineages of that ancestor. The above-mentioned evidence suggests that HGT may have happened between that Gammaproteobacterium ancestor and a Betaproteobacterium ancestor, given that the connection between these two groups was one of the "highways" for HGT proposed by Beiko et al. (2005). Additional research is required to determine whether nitrogen-fixation genes were indeed exchanged in ancient HGT events between Betaproteobacteria and Gammaproteobacteria.

Table 22.4 Similarity of *A. vinelandii* DJ protein sequences given by percent identity with sequences from the following organisms: *P. stutzeri* A1501, *P. stutzeri* DSM 4166, and *Teredinibacter turnerae* T7901

nif Gene	A1501	DSM 4166	*Teredinibacter turnerae* T7901
H	92	92*	90
D	91	91	86
K	91	90	82
E	89	88	83
N	81	80	67
B	86*	86	89

The results were obtained with BLAST. For those marked with an asterisk, it was necessary to use tBLASTn to obtain the correct result because of annotation problems. All alignments covered 100% or nearly 100% of both query and subject sequences.

22.3.4 Other Features of the *A. vinelandii* DJ Genome

The *A. vinelandii* DJ genome has the remarkable property that it contains eight group II introns (Fig. 22.6), more than any other bacterial genome (Dai et al., 2003). (The database on which this statement is based was last updated in 2008.) Group II introns are a class of RNAs that can perform a self-splicing reaction. Bacterial group II introns almost always encode reverse transcriptase ORFs (Open Reading Frames) and are active mobile elements (Dai and Zimmerly, 2002). All of the identified group II introns in *A. vinelandii* DJ encode reverse transcriptase ORFs. These introns have been carefully annotated and are part of the *A. vinelandii* DJ GenBank record.

Another notable feature of the *A. vinelandii* DJ genome is that it contains three sets of CRISPRs. CRISPRs are thought to constitute a kind of RNA-interference-based immune system for prokaryotes (Makarova et al., 2006). We report them here primarily because they are not currently annotated in the *A. vinelandii* DJ GenBank record. Two of the sets display the expected structure for CRISPRs: from position 3261022 to position 3263057, with 30 spacers, and from position 3265050 to position 3266352, with 19 spacers. A third set has "questionable structure" (Grissa et al., 2007),

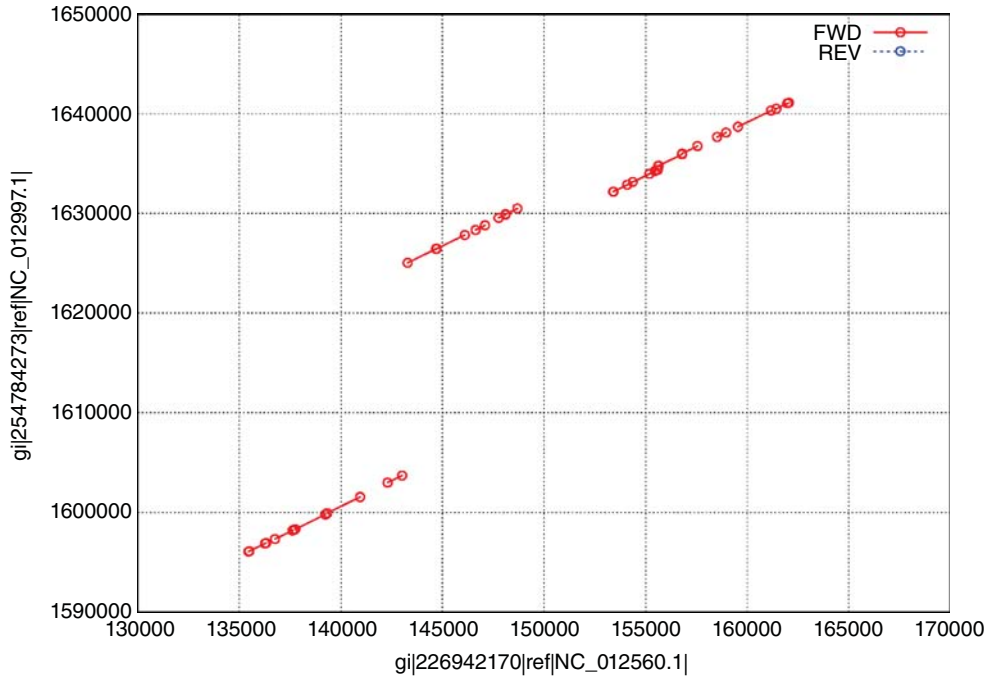

Figure 22.4 Alignment between the chromosome sequence of *A. vinelandii* DJ (*x*-axis) and the chromosome sequence of *T. turnerae* T7901 (*y*-axis). Only the regions delimited by the positions shown in both axes are shown. The region shared by both corresponds to the major *nif* region, with the modifications noted in the text.

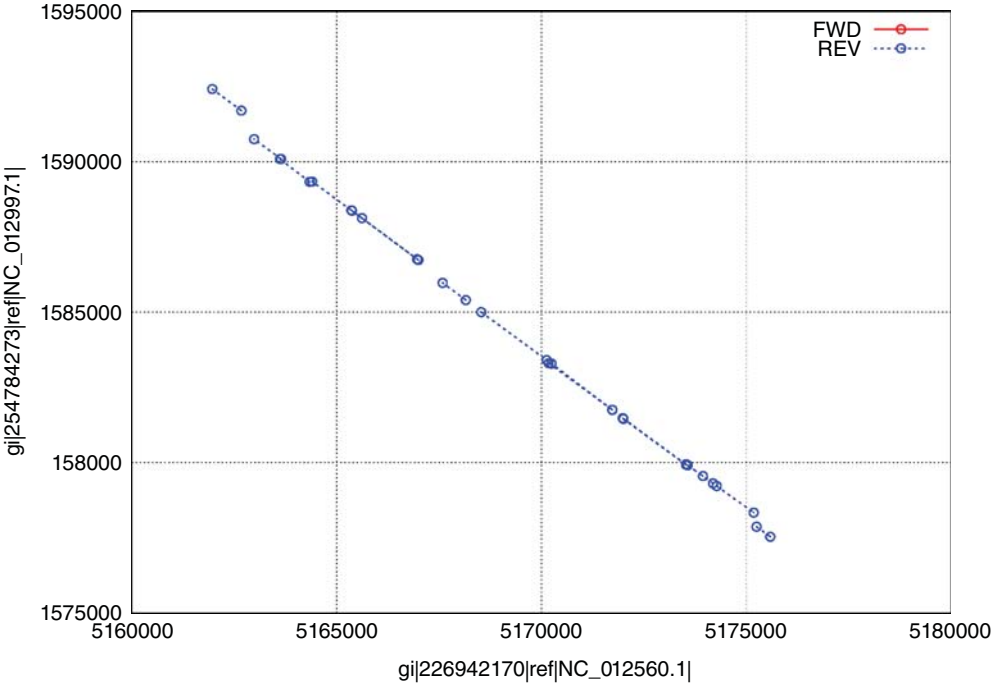

Figure 22.5 Alignment between the chromosome sequence of *A. vinelandii* DJ (*x*-axis) and the chromosome sequence of *T. turnerae* T7901 (*y*-axis). Only the regions delimited by the positions shown in both axes are shown. The region shared by both (which corresponds to Avin_50910 to Avin_51060) includes the minor *nif* region.

The first column contains the organism found (with proteobacterial class in parentheses), and the cells in that row show percent identity/bit score for each hit. For criteria in selecting hits, see the text. Asterisks indicate Betaproteobacteria. BLAST search was done on March 25, 2013.

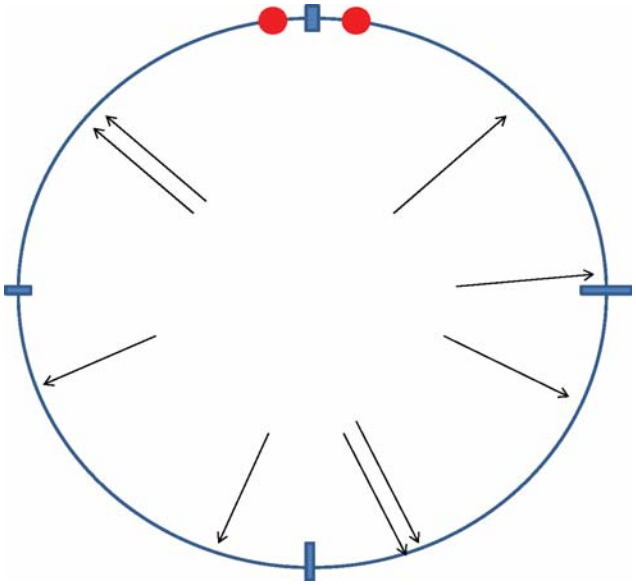

Figure 22.6 Approximate positions of group II introns in the chromosome sequence of *A. vinelandii* DJ (arrows). The two red dots represent the location of the minor (left) and major (right) *nif* regions. At the top is position 1.

and is located from position 3171496 to position 3171619, with two spacers. In addition, the genome contains two cas (CRISPR-associated) groups of protein-coding genes: Avin_17170 to Avin_17240 (spanning region 1,699,773 through 1,707,301 bp) and Avin_31570 to Avin_31630 (spanning region 3,266,532–3,273,695 bp). The second cas operon is thus immediately downstream from the second CRISPR set noted earlier. These data are strong evidence that *A. vinelandii* DJ has a functioning CRISPR-Cas system (CASS).

It has been proposed that a CASS can work as a defensive mechanism against bacteriophage invasion (Makarova et al., 2006). The *A. vinelandii* DJ genome has 40 protein-coding genes annotated with the word "phage." Several of these are scattered throughout the genome and do not form a complete prophage. But 21 of those genes can be found in the region defined by genes Avin_37340 to Avin_37610 (approximately 22 kbp). Part of this region (~5.5 kbp) does match (by MEGABLAST (Altschul et al., 1997)) part of *Pseudomonas aeruginosa* phage phiCTX (Nakayama et al., 1999). But this may be an ancient insertion (the region was not picked up by AH as anomalous), and the whole region may no longer contain a functional prophage. It is a matter however that deserves further investigation.

22.4 CONCLUSION

A. vinelandii is an important model organism for the study of nitrogen fixation and iron–sulfur clusters. The publication of the *A. vinelandii* DJ genome has enabled or facilitated various kinds of studies in these areas. Notable among them was the first transcriptome analysis of *A. vinelandii*, by Hamilton et al. (2011), who studied expression levels of the three nitrogen-fixation systems Nif, Anf, and Vnf that exist in *A. vinelandii* (see also Chapter 9).

Here, results concerning the genome of *A. vinelandii* DJ have been presented, updated, and expanded. Among these, the possible origin of its nitrogen-fixing genes was investigated, which led to the hypothesis that they were inherited

from a common ancestor of *A. vinelandii*, *P. stutzeri*, and *T. turnerae*. Information on the presence of group II introns and the CASS system has also been provided. It is hoped that the results presented here will further facilitate research that depends on the *A. vinelandii* DJ genome.

23.1 INTRODUCTION

Microvirga lotononidis WSM3557^T is the type strain of a recently described rhizobial species that is an effective nitrogen (N_2)-fixing microsymbiont of the symbiotically specific African crotalarioid legume *Listia angolensis* (Ardley et al., 2012). We have been studying species of *Listia* (previously *Lotononis* (Boatwright et al., 2011)) because of their potential as pasture legumes in southern Australian agricultural systems. These systems have traditionally relied on biological nitrogen fixation from rhizobial symbioses with introduced legumes, such as medics and subterranean clover, to build up and maintain soil nitrogen for crop and animal production (Howieson et al., 2000; Loi et al., 2005). Since 1975, however, a significant decrease in annual rainfall combined with a decline in its reliability, along with the development of dryland salinity (George et al., 2008), has compromised the effectiveness of annual legumes in these systems. In response, researchers have sought to improve sustainable agricultural productivity by introducing novel perennial pasture legumes (such as *Listia*) and the associated rhizobia that are climatically and edaphically suited to the arid climate and acid, infertile soils of southern Australian farming systems (Howieson et al., 2008).

Listia spp. are water-logging and drought-tolerant form of lupinoid nodules and are infected via epidermal entry, rather than by root hair curling (Ardley et al., 2013; Yates et al., 2007). Most *Listia* species are specifically nodulated by strains of pigmented methylobacteria, but *L. angolensis* forms N_2-fixing nodules only with species of the Gram-negative alphaproteobacterial genus *Microvirga*, a member of the family Methylobacteriaceae (Ardley et al., 2013; Yates et al., 2007). Three of the eight currently described *Microvirga* species are root-nodulating bacteria (RNB) (Ardley et al., 2012). Since this chapter was written, a fourth rhizobial species of *Microvirga, M. vignae*, has been described in Radl et al. (2014).

Nonsymbiotic species of *Microvirga* have been isolated from Australian geothermal waters, a Japanese hot spring, Chinese rice field soil, and Korean atmospheric samples (Kanso and Patel, 2003; Takeda et al., 2004; Weon et al., 2010; Zhang et al., 2009). The rhizobial species *M. lotononidis* and *M. zambiensis* were isolated from *L. angolensis* root nodules collected in Zambia, while *M. texensis* is the specific microsymbiont of the genistoid legume *Lupinus texensis* growing in Texas, USA (Andam and Parker, 2007; Ardley et al., 2012). Additionally, authenticated rhizobial strains subsequently identified as belonging to *Microvirga* have been isolated from nodules of *Phaseolus vulgaris* growing

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

in Ethiopia and from northern Australian *Indigofera linifolia* (Ardley et al., 2013; Lafay and Burdon, 2007; Wolde-Meskel et al., 2005). Strains of a novel species of *Microvirga*, with the proposed name of *Microvirga vignae*, are also being developed as rhizobial inoculants for cowpea (*Vigna unguiculata*) in Brazil (Jerri Zilli, pers. comm.). Both *M. lotononidis* WSM3557^T and *M. texensis* Lut6^T have a narrow host range, although WSM3557^T is able to nodulate species of *Leobordea* (previously *Lotononis* (Boatwright et al., 2011)) and *Lotononis* and is effective for N_2 fixation with *Leobordea bolusii*, *L. platycarpa*, and *Lotononis crumanina* (Andam and Parker, 2007; Ardley et al., 2012, 2013).

Most described species of *Microvirga* are either light pink or orange pigmented; absorption spectra of acetone:methanol extracts of *M. lotononidis* WSM3557^T, *M. texensis* Lut6^T, and *M. subterranean* FaiI4^T are consistent with the presence of carotenoids, but not bacteriochlorophyll (Ardley, 2012; Kanso and Patel, 2003). Many are moderately thermophilic and can grow at temperatures of up to 45 °C (Ardley et al., 2012; Kanso and Patel, 2003; Weon et al., 2010). WSM3557^T is fast-growing, forming 0.5–1.5 mm diameter colonies within 2–3 days at the optimum temperature of 41 °C, and can grow at temperatures of up to 45 °C. Colonies are pale pink, opaque, and moderately mucoid on ½ Lupin Agar (½ LA) (Ardley et al., 2012). Lut6^T is also fast-growing, forming dry, pale orange colonies of 0.5–1.5 mm diameter within 2–3 days at the optimum temperature of 39 °C, with a maximum temperature for growth of 43 °C.

Both *M. lotononidis* WSM3557^T and *M. texensis* Lut6^T were selected for sequencing as part of the "Analysis of the clover, pea/bean and lupin microsymbiont genetic pool by studying isolates from distinct Vavilov centres of diversity" Community Sequencing Program (http://genome.jgi.doe.gov/Anaofodiversity/Anaofodiversity.info.html; Joint Genome Institute (JGI) Project IDs: 403024 and 403026, respectively) at the U.S. Department of Energy, JGI. The genome projects for WSM3557^T and Lut6^T are deposited in the Genomes OnLine Database (GOLD) (Liolios et al., 2008), with the accession numbers Gi06493 and Gi06478, respectively. Improved high-quality draft genome sequences are deposited in the Integrated Microbial Genomes (IMG) system (http://img.jgi.doe.gov/cgi-bin/w/main.cgi). *M. lotononidis* WSM3557^T and *M. texensis* Lut6^T have been assigned the IMG Taxon OIDs 2508501114 and 2508501050, respectively.

The basic features of the WSM3557^T genome sequence information and annotation have now been described (Reeve et al., 2014). In presenting our findings to date in this chapter, we have focused on the genomic architecture of WSM3557^T and the presence of genes in this novel microsymbiont that are putatively involved in symbiotic interactions, along with several features that are unusual in rhizobia and found in this genome.

23.2 METHODS

Growth conditions and DNA isolation were according to Reeve et al. (2014); namely, WSM3557^T was grown to mid-logarithmic phase in TY rich media (Reeve et al., 1999) on a gyratory shaker at 28 °C and DNA was isolated from 60 ml of cells using a CTAB (cetyl trimethyl ammonium bromide) bacterial genomic DNA isolation method (http://my.jgi.doe.gov/general/protocols.html).

The draft genome of *Microvirga lotononidis* WSM3557^T was generated at the JGI using a combination of Illumina (Bennett, 2004) and 454 technologies (Margulies et al., 2005). For this genome, we constructed and sequenced an Illumina GAii shotgun library, which generated 71,475,016 reads totaling 5432.1 Mb, and 1 paired-end 454 Titanium library with an average insert size of 10 kb, which generated 582,107 reads totaling 113.9 Mb. All general aspects of library construction and sequencing performed at the JGI can be found at http://www.jgi.doe.gov/. The initial draft assembly contained 444 contigs in 1 scaffold. Illumina sequencing data was assembled with VELVET, version 1.0.13 (Zerbino and Birney, 2008), and the consensus sequence was computationally shredded into 1.5 kb overlapping fake reads (shreds). We integrated Illumina VELVET consensus shreds and the read pairs in the 454 paired-end library using parallel phrap, version SPS – 4.24 (High Performance Software, LLC). The software Consed (Ewing and Green, 1998; Ewing et al., 1998; Gordon et al., 1998) was used in the following finishing process. Illumina data was used to correct potential base errors and increase consensus quality using the software Polisher developed at JGI (Alla Lapidus, unpublished). Possible misassemblies were corrected using gapResolution (Cliff Han, unpublished), Dupfinisher (Han and Chain, 2006), or sequencing cloned bridging polymerase chain reaction (PCR) fragments with subcloning. Gaps between contigs were closed by editing in Consed, by PCR, and by Bubble PCR (J-F Cheng, unpublished) primer walks. A total of 303 additional reactions were necessary to close gaps and to raise the quality of the finished sequence. The estimated genome size is 7.2 Mb, and the final assembly is based on 59.7 Mb of 454 draft data that provides an average 8.3× coverage of the genome and 2160 Mb of Illumina draft data, which provides an average 300× coverage of the genome.

The methods for genome annotation are detailed in Reeve et al. (2014). Specifically, genes were identified using Prodigal (Hyatt et al., 2010) and annotated using the IMG annotation pipeline (Mavromatis et al., 2009). The predicted coding sequences (CDSs) were translated and used to search the National Center for Biotechnology Information (NCBI) nonredundant database, UniProt, TIGRFam, Pfam, PRIAM, Kyoto Encyclopedia of Genes and Genomes (KEGG), Clusters of Orthologous Group (COG), and InterPro databases. These data sources were combined to assert a product description for each predicted protein.

Noncoding genes and miscellaneous features were predicted using tRNAscan-SE (Lowe and Eddy, 1997), RNAMMer (Lagesen et al., 2007), Rfam (Griffiths-Jones et al., 2003), TMHMM (Krogh et al., 2001), and SignalP (Bendtsen et al., 2004). Additional gene prediction analyses and functional annotation were performed within the IMG (Expert Review) platform (http://img.jgi.doe.gov/er) (Markowitz et al., 2009). Further examination of the WSM3557^T genome used the analysis tools provided within the IMG platform (http://img.jgi.doe.gov/cgi-bin/w/main.cgi).

Plasmid profiling was performed using a modified Eckhardt procedure (Priefer, 1984).

23.3 RESULTS AND DISCUSSION

23.3.1 Structural Organization of the WSM3557^T Genome

The improved high-quality draft genome of WSM3557^T consists of 7,082,538 bp, with 63.08% G + C content, and is composed of 18 scaffolds of 104 contigs (Reeve et al., 2014). The genome is intermediate in size for root nodule bacteria, being smaller than *Bradyrhizobium japonicum* USDA 110 (9.105 Mbp) (Kaneko et al., 2002) and the *Methylobacterium* strains *M. nodulans* ORS 2060^T (8.839 Mbp) and *M.* sp. 4-46 (7.737 Mbp) (Marx et al., 2012), but larger than *Ensifer* (*Sinorhizobium*) *medicae* WSM419 (6.817 Mbp) (Reeve et al., 2010), *Rhizobium etli* CFN42 (6.53 Mbp) (González et al., 2006), and *Azorhizobium caulinodans* ORS 571 (5.37 Mbp) (Lee et al., 2008). From a total of 7036 genes, 6952 were protein encoding and 84 were RNA-only encoding genes (Reeve et al., 2014). There is one rRNA operon, with one full-length and one partial 23S rRNA gene and three partial 5S rRNA genes. The rRNA operon is on scaffold MLG.10 and includes genes for three tRNAs (tRNA-ala, tRNA-ile, and tRNA-met). There are 53 additional tRNA genes and the total represents 45 tRNA species. WSM3557^T is a selenocysteine synthesizer, possessing genes that encode seryl-tRNA synthetase (MicloDRAFT_00050960), selenophosphate synthase (MicloDRAFT_00024690), and seryl-tRNA (Sec) selenium transferase (MicloDRAFT_00024720). The distribution of genes into COGs functional categories is presented in Table 23.1. The number and percentage of genes assigned to each COG functional category is similar to that found in other sequenced

Table 23.1 Number of protein-coding genes of *Microvirga* sp. WSM3557^T associated with the general COG functional categories

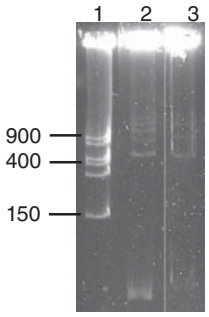

Figure 23.1 Eckhardt gel plasmid profiles of rhizobial *Microvirga* strains. The *Rhizobium leguminosarum* strain VF39 was used as a marker. The size of specific VF39 plasmids (kb) is shown. Lane 1, VF39; lane 2, Lut6^T; lane 3, WSM3557^T.

rhizobial strains, although a comparatively large number of genes (431; 7.57%) are associated with replication, recombination, and repair.

The plasmid profile of WSM3557^T shows that it possesses a multipartite genome architecture. Both WSM3557^T and *M. lupini* Lut6^T have multiple replicons (Fig. 23.1).

According to the gel image, WSM3557^T contains four plasmids, ranging in size from greater than 900 Kbp to less than 150 Kbp. Lut6^T harbors six plasmids, including three that are greater than 900 Kbp in size.

This number of plasmids in WSM3557^T is congruent with the presence of four copies of each of the *repABC* genes, which are present on large, low copy-number plasmids and on some secondary chromosomes in a number of alphaproteobacterial genera, and are responsible for the replication and segregation properties of these replicons (Cervantes-Rivera et al., 2011). In scaffold MLG.13, *repABC* are present in a cluster (MicloDRAFT_00032150–MicloDRAFT_00032180), together with a gene encoding the antisense RNA that modulates *repC* expression (Venkova-Canova et al., 2004). The presence of large plasmids in WSM3557^T and Lut6^T makes them notably different from the closely related and comparatively slow-growing genera *Bradyrhizobium* and *Methylobacterium*, which have large chromosomes, with small plasmids present in some strains (Cytryn et al., 2008; Marx et al., 2012).

A detailed analysis of the different replicons of WSM3557^T and Lut6^T would require their genomic structures to be fully resolved before they can be aligned and compared. However, a dot plot analysis of the assembled scaffolds of WSM3557^T and Lut6^T, using MUMmer (Kurtz et al., 2004), revealed considerable disruptions of synteny, indicating a high level of evolutionary divergence between the two strains. Dot plots of WSM3557^T mapped to the complete genome sequences of *Bradyrhizobium japonicum* USDA 110 and *Methylobacterium nodulans* ORS 2060^T showed no synteny.

23.3.2 Symbiotic Loci

For all known legume–rhizobia associations except that of *Aeschynomene* spp. and particular strains of *Bradyrhizobium* (Bonaldi et al., 2011), symbiosis is initiated when plant-derived flavonoids induce expression of rhizobial nodulation (*nod*, *nol*, and *noe*) genes and the subsequent synthesis of lipochito-oligosaccharide (LCO) Nod factors (see Chapters 50, 51). Regulation of *nod* gene expression is mediated by the transcriptional regulator NodD, the LCO backbone is encoded by the canonical *nodABC* genes, and other nodulation loci encode substituent groups that decorate the LCO core (Perret et al., 2000). The Nod factors induce plant genes that control and coordinate the processes of bacterial infection and nodule organogenesis (Oldroyd et al., 2011). Within the nodule, the rhizobia differentiate into N_2-fixing bacteroids and transcription of the nitrogen fixation (*nif* and *fix*) genes is induced (Terpolilli et al., 2012; see Sections 9–12).

Although the molecular basis of the dialog between *L. angolensis* and *M. lotononidis* has yet to be determined, the WSM3557^T genome possesses genes encoding synthesis of LCO structures and substituent groups, suggesting that a Nod factor is required in the establishment of this symbiosis. Genome regions containing symbiotic loci have a mosaic structure, with a large number of transposases, integrases, and inactivated derivatives present. Many of the genes required for nodulation and nitrogen fixation are clustered on the scaffold MLG.4 (146,360 bp, G + C = 0.62%).

23.3.3 Nodulation Genes

The gene neighborhood of WSM3557^T nodulation loci harbored on the MLG.4 scaffold is shown in Figure 23.2.

Organization of the *nod* cluster is similar to that seen in *Methylobacterium nodulans* ORS 2060^T, which specifically nodulates some species of *Crotalaria* (Sy et al., 2001), and the pigmented *Methylobacterium* sp. strains 4-46 and WSM2598, which are microsymbionts of *Listia bainesii* (Ardley et al., 2013; Fleischman and Kramer, 1998; Yates et al., 2007). These strains and other sequenced strains that share high sequence similarity with WSM3557^T *nod* genes are included for comparison in Figure 23.2.

The WSM3557^T genome contains one copy of the transcriptional regulator *nodD* (MicloDRAFT_00005370), which is upstream and transcribed in the opposite direction to a *nodYABC* operon (MicloDRAFT_00005280–MicloDRAFT_00005310). The NodD protein shares highest identity with NodD of rhizobial South African *Burkholderia* strains. No other homologs of *nodD* have been found in the WSM3557^T genome. WSM3557^T *nodY* is homologous with *Bradyrhizobium nodY*, which encodes a signal transduction response regulator and until now has been found exclusively in bradyrhizobia (Menna and

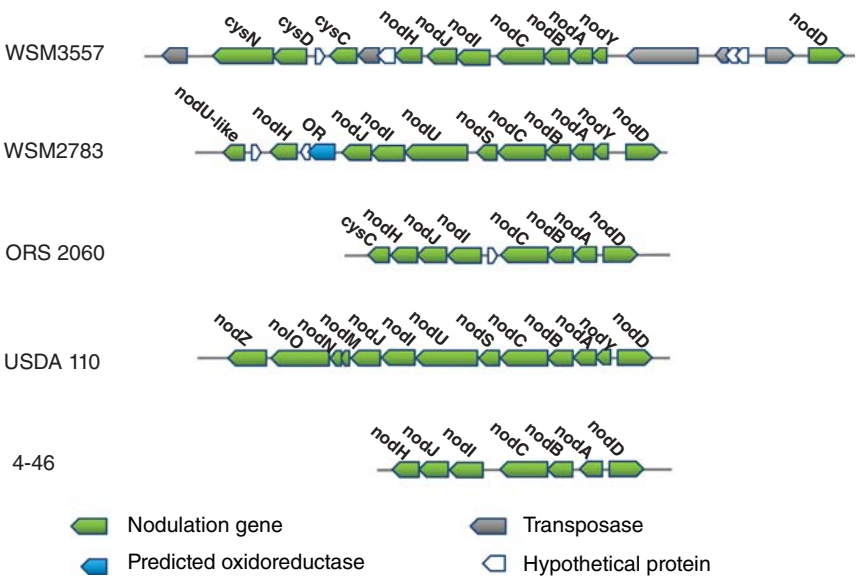

Figure 23.2 Physical map of nodulation loci of the sequenced genomes *Microvirga lotononidis* WSM3557^T, *Methylobacterium nodulans* ORS 2060, *Methylobacterium* sp. 4-46, *Bradyrhizobium japonicum* USDA 110, and *Bradyrhizobium* sp. WSM2783. Arrows show the direction of transcription.

Hungria, 2011). The highest identity (55%) is with NodY of *Bradyrhizobium* sp. WSM2783, which nodulates species of *Leobordea* and *Lotononis* (Ardley et al., 2013). NodA of WSM3557^T clusters with that of other rhizobia that nodulate African genistoid legumes, sharing 85%, 84%, and 81% identity with NodA of *Bradyrhizobium* sp. WSM2783, *Burkholderia* sp. STM678 (which nodulates species in tribe Podalyrieae from the South African Cape Fynbos biome (Gyaneshwar et al., 2011)), and *M. nodulans* ORS 2060^T, respectively. The WSM3557^T NodB has highest identity (71%) with *Bradyrhizobium* sp. WSM2783, while NodC shares highest identity (81%) with *Sinorhizobium fredii* HH103.

Immediately downstream of *nodYABC* are *nodIJ*, *nodH*, a gene encoding a protein of unknown function, *cysC, cysDN,* and genes encoding transposases (MicloDRAFT_00005190–MicloDRAFT_00005270). NodI and NodJ share highest identity of 87.5% and 81.6%, respectively, with *Rhizobium giardinii* bv. *giardinii* H152^T. The highest identities for WSM3557^T NodH are 83%, 80.2%, and 76.2% with *Bradyrhizobium* sp. WSM2783, *Microvirga texensis* Lut6^T, and *M. nodulans* ORS 2060^T NodH, respectively. The open reading frame (ORF) immediately downstream of *nodH* encodes a hypothetical protein with no homology to any known bacterial proteins. BLASTP analysis gave less than 30% identity with proteins from all organisms in the NCBI database. WSM3557^T CysC shares highest identity (59.3%) with *Hyphomicrobium* sp. MC1, while CysD and CysN share highest identity (83.5% and 61.4%, respectively) with *Methylobacterium* sp. strains 4-46 and WSM2598. In the methylobacterial strains, *cysDN* (and *cysC* in 4-46 and WSM2598) are not grouped in the nodulation gene cluster, but found elsewhere in the genome. The *cysCDN* genes, along with *nodH*, encode products required for Nod factor sulfation. *cysDNC* are homologs of *nodPQ* and encode subunits of adenosine triphosphate (ATP) sulfurylase (CysDN) and adenosine 5′-phosphosulfate (APS) kinase (CysC), which associate into a multifunctional protein complex and catalyze formation of an activated sulfate group (Schwedock et al., 1994). The activated sulfate group is then transferred to the Nod factor by the sulfotransferase NodH (Schultze et al., 1995). The Nod factors produced by WSM3557^T and the pigmented methylobacteria have not yet been characterized. However, the Nod factor structures of ORS 2060^T were identified as chitopentamers containing a $C_{18:1}$ or $C_{16:0}$ fatty acyl chain and sulfated at the reducing end (Renier et al., 2008). From their similarity with ORS 2060^T *nod* genes, it is reasonable to assume that the *nod* genes of WSM3557^T, 4-46, and WSM2598 also encode sulfated Nod factors, which may be required for nodulation of *Listia* species.

23.3.4 Genes Required for Nitrogen Fixation

The WSM3557^T MLG.4 scaffold also contains loci that are homologs of genes required for nitrogen fixation in other rhizobia. These are organized into two gene clusters. The first containing *nifA-nifB-fdxN-nifZT* (MicloDRAFT_00006160–MicloDRAFT_00006200) is 74,979 bp downstream of *nodD*. The second cluster is 10,434 bp downstream of *nifT* and contains *nifHDKENX1X2-fdxB* (MicloDRAFT_00006320–MicloDRAFT_00006400). The encoded proteins all share high identity with homologs found

in *M. lupini* Lut6^T (>91%) and in *Rhizobium mesoamericanum* STM6155 and various sequenced *Sinorhizobium* and *Mesorhizobium* strains (>76%). Another cluster of *nif/fix* genes is located on the scaffold MLG.1, and contains the *fixABCX* operon and an operon consisting of a gene encoding a scaffold protein (of the HesB/IscA family) for iron-sulfur cluster assembly and *nifSV-cysE-nifW* (MicloDRAFT_00000030–MicloDRAFT_00000110). Genes in this cluster also share high identity [>80%] with homologs in *M. lupini* Lut6^T and *Sinorhizobium* and *Mesorhizobium* strains. Scaffold MLG.9 contains a homolog of *nifU* (MicloDRAFT_00017310), along with the *fixNOQP-fixGHIS* and *fixKLJ* clusters (MicloDRAFT_00022650–MicloDRAFT_00022770) that are essential for microoxic respiration (Kaneko et al., 2011). The encoded MLG.9 nitrogen-fixation proteins share highest identity with homologs found in *M. lupini* Lut6^T (72.9–93.8%) or in strains of *Azorhizobium, Bradyrhiz*obium, *Methylobacterium*, *Starkeya*, and *Xanthobacter* (53.3–81.4%).

The alternative sigma factor RpoN is essential for N_2 fixation (Fischer, 1994). The WSM3557^T genome has two copies of the *rpoN* gene. *rpoN1* (MicloDRAFT_00017570) is found in scaffold MLG.9 between the *nifU* and *fixN* genes, while *rpoN2* (MicloDRAFT_00070370) is clustered with *nifQ* (MicloDRAFT_00070390) in scaffold MLG.17. *Rhizobium etli* strain CNPAF512 also contains two copies of *rpoN*; *rpoN1* is required for housekeeping functions, while *rpoN2* is essential for symbiotic nitrogen fixation (Michiels et al., 1998). Similar differential regulation of the two *rpoN* gene copies may occur in WSM3557^T. This is supported by the different phylogenies of the *Microvirga* WSM3557^T and Lut6^T *rpoN* copies. The *rpoN1* gene of both WSM3557^T and Lut6^T has highest identity (54.7–57.3%) with strains of methylobacteria and with *Azorhizobium doebereinerae* UFLA1-100. In contrast, *rpoN2* of Lut6^T (which in this genome is clustered with other nitrogen-fixation genes on scaffold MLH112) and *rpoN2* of WSM3557^T have highest identity (77.2–80.3%) with strains of *Mesorhizobium* and *Sinorhizobium.* There also appears to be disparate phylogenies between the WSM3557^T *nif/fixABCX* genes present on the MLG.1, 4, and 17 scaffolds and the *fix* genes required for microoxic respiration that are on the MLG.9 scaffold. The *nif* genes are involved in the synthesis, assembly, and functioning of the nitrogenase complex (Rubio and Ludden, 2008), while the *fixABCX* genes are postulated to encode a product that could facilitate the transfer of electrons to nitrogenase (Earl et al., 1987; Fischer, 1994; Scott and Ludwig, 2004). The close affinity of the MLG.1, 4, and 17 *nif* and *fix* genes to those of *Sinorhizobium* and *Mesorhizobium* suggests that these genes were acquired through horizontal transfer.

23.3.5 Additional Genes Required for Symbiosis Are Present on Scaffold MLG.4

Other loci putatively involved in symbiosis, such as the *dct* and *groESL* genes, have been identified on the *M. lotononidis* WSM3557^T scaffold MLG.4.

The *dctA* gene encodes a C4-dicarboxylate transport protein responsible for transport of host plant-supplied carbon to bacteroids and is required for symbiotic nitrogen fixation in rhizobia, while *dctB* and *dctD* encode a two-component regulatory system that regulates expression of DctA; homologs of these genes appear to be ubiquitous in rhizobia (Ronson et al., 1984; Yurgel and Kahn, 2004). In WSM3557^T, *dctA* and the adjacent divergently transcribed *dctBD* (MicloDRAFT_00005410–MicloDRAFT_00005430) are located in close proximity to *nodD*. Highest identity of the WSM3557^T DctA, B, and D (78.6–85.1%) is to homologs from strains of *Mesorhizobium loti.* Two additional copies of *dctA* (MicloDRAFT_00022000, MicloDRAFT_00061080) have been identified in the WSM3557^T genome, however, neither of these is associated with the corresponding two-component regulatory system *dctBD* and they share 57.24% and 49.12% identity, respectively, with the MLG.4 DctA.

GroEL chaperonins are required for the formation of a functional nitrogenase in *Bradyrhizobium japonicum* (Fischer et al., 1999). There are five pairs of chaperonin *groES-groEL* genes present in the WSM3557^T genome; one pair (MicloDRAFT_00005680–MicloDRAFT_00005670) is clustered with other symbiotic loci on MLG.4 indicating its potential role in symbiosis, while the other pairs (MicloDRAFT_00011830–MicloDRAFT_00011840; MicloDRAFT_00043640–MicloDRAFT_00043630; MicloDRAFT_00008770–MicloDRAFT_00008780; MicloDRAFT_00052250–MicloDRAFT_00052240) are on separate scaffolds.

23.3.6 Secretion Systems

23.3.6.1 Type I Secretion System. Type I secretion system (T1SS) genes are present in most rhizobia (Schmeisser et al., 2009). The secretion machinery consists of three proteins localized in the cell envelope: a specific outer membrane protein (OMP) and two cytoplasmic membrane proteins, one is an ATP-binding cassette (ABC) transporter protein and the other is a membrane fusion adaptor protein (Delepelaire, 2004). A number of T1SS homologs have been identified in WSM3557^T, including one TolC-like OMP (MicloDRAFT_00054540) and six copies each of PrtD family ABC transporter proteins and HlyD/PrtE family membrane fusion adaptor proteins that occur as pairs (MicloDRAFT_00007510/MicloDRAFT_00007520; MicloDRAFT_00037970/MicloDRAFT_00037980; MicloDRAFT_00053240/MicloDRAFT_00053250; MicloDRA

FT_00054970/MicloDRAFT_00054980; MicloDRAFT_00055180/MicloDRAFT_00055190; MicloDRAFT_00057510/MicloDRAFT_00057520). Proteins secreted by the T1SS vary greatly in size (Delepelaire, 2004) and include repeats-in-toxin (RTX) exoproteins, a family of proteins with diverse biological functions, which can act as virulence factors (Linhartová et al., 2010). A variable number of genes encoding RTX toxins and related Ca^{2+}-binding proteins (COG2931) are found in sequenced rhizobial genomes in the JGI database. They are not present in *Azorhizobium caulinodans* ORS 571^T or *A. doebereinerae* UFLA1-100^T, or in any rhizobial *Burkholderia* strains. *Bradyrhizobium*, *Cupriavidus taiwanensis*, *Mesorhizobium*, *Methylobacterium*, *Rhizobium*, and *Sinorhizobium* strains have from 1 to 10 *rtx* genes. In contrast, the *Microvirga* strains possess a remarkably large number of genes encoding RTX toxins and the related Ca^{2+}-binding proteins: 36 and 58, respectively, for WSM3557^T and Lut6^T.

23.3.6.2 Type II Secretion Systems. Although the type II general secretion pathway (Sandkvist, 2001) is absent in WSM3557^T and Lut6^T, both the general export pathway (GEP Sec) and the twin arginine translocation (TAT) pathway are present in both strains.

23.3.6.3 Type III Secretion System. Type III secretion systems (T3SSs) are used by plant and animal pathogens to translocate bacterial proteins into host cells where they mediate cellular functions, often to suppress host immune responses (Jones and Dangl, 2006). Rhizobial T3SS loci were first identified in the *Sinorhizobium fredii* strain NGR234 (Freiberg et al., 1997) and have since been found in strains of *Bradyrhizobium*, *Mesorhizobium*, *Sinorhizobium*, and *Rhizobium etli* (Deakin and Broughton, 2009). They are symbiotically active and have been shown to modulate nodulation in host plants, either positively or negatively (Krause et al., 2002; Marie et al., 2003; Okazaki et al., 2010).

Gene clusters encoding T3SS components are found in both WSM3557^T and Lut6^T. In WSM3557^T, T3SS loci are found in scaffolds MLG.2 and MLG.12. Homologs of *ttsI*, which encodes a response regulator (Marie et al., 2004), and *rhcC2*, which encodes an OMP of the secretion machinery (Schmeisser et al., 2009), are located on MLG.12 (MicloDRAFT_00026870 and MicloDRAFT_00026880). The remaining T3SS gene cluster (MicloDRAFT_00002700–MicloDRAFT_00002940), encoding essential components of the secretion apparatus and secreted proteins, is located on the small (26,102 bp) scaffold MLG.2. The organization of the gene clusters is similar to that of the T3SS loci found in the symbiotic plasmid of NGR234 (Schmeisser et al., 2009) and in *Mesorhizobium loti* MAFF30399 (Sánchez et al., 2009), except that *nolU* is absent (Fig. 23.3).

23.3.6.4 Type IV Secretion System. Type IV secretion systems (T4SSs) are ancestrally related to bacterial conjugation machines and mediate the transfer of DNA and protein substrates to phylogenetically diverse prokaryotic and eukaryotic target cells (Christie et al., 2005). The paradigmatic *Rhizobium radiobacter* (formerly *Agrobacterium tumefaciens*) T4SS machine is formed by the 12 VirBD4 proteins (Christie, 2004). Both *M. lotononidis* WSM3557^T and *M. texensis* Lut6^T possess *virBD4* loci. In WSM3557^T, these are found on scaffold MLG.13 in an operon (MicloDRAFT_00030620–MicloDRAFT_00030730) that is highly similar to the gene arrangement of the T4SS loci harbored in plasmid pAtK84c of *Rhizobium rhizogenes* strain K84 and plasmid pMLa of *M. loti*

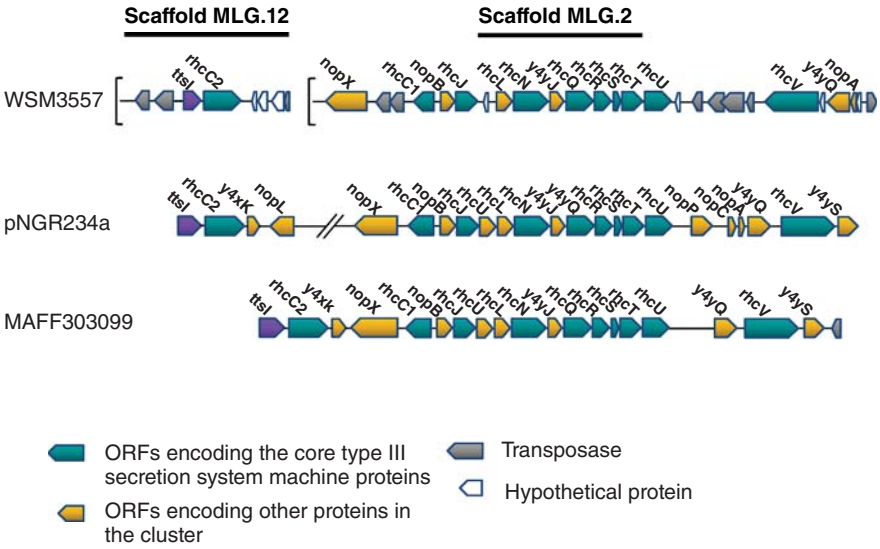

Figure 23.3 Type III secretion system loci of *Microvirga lotononidis* WSM3557^T, *Mesorhizobium loti* MAFF30399, and *Sinorhizobium fredii* NGR234.

MAFF30399. Two genes encoding hypothetical proteins (MicloDRAFT_00030680 and MicloDRAFT_00030690) are within this operon. *virB5* (MicloDRAFT_00030770) is found in an adjacent, divergently transcribed operon. WSM3557^T lacks *virB7*, which in *R. radiobacter* encodes an outer membrane T-DNA transfer lipoprotein required for T-pilus biogenesis (Christie et al., 2005). WSM3557^T VirBD4 shares highest identity with homologs in Lut6^T (78.7–95%) and in *R. rhizogenes* K84 and *Methylocystis* sp. Rockwell ATCC 49242 (39.8–65.9%). Genes encoding VirD (other than VirD4) and VirE are not present.

In *A. tumefaciens,* the virulence protein homologs VirJ/AcvB have been shown to be involved in the T4SS (Pan et al., 1995; Pantoja et al., 2002). *M. lotononidis* WSM3557^T scaffold MLG.13 also contains the *acvB* ortholog MicloDRAFT_00044170, located downstream of MicloDRAFT_00044180, an ortholog of the *Sinorhizobium medicae* WSM419 low pH-inducible gene *lpiA* (Reeve et al., 2006). The AcvB and LpiA proteins have been implicated in the modification of membrane lipid structure (Reeve et al., 2006; Sohlenkamp et al., 2007). Analysis of sequenced bacterial genomes reveals that the *acvB/lpiA* operon is highly conserved in Gram-negative pathogens and symbionts, suggesting the importance of these proteins in prokaryotic/eukaryotic interactions.

23.4 CONCLUSIONS

Rhizobial species of *Microvirga* constitute a novel group of nitrogen-fixing legume-symbiotic Alphaproteobacteria. *Microvirga* strains are uncommon microsymbionts of legumes, yet *M. lotononidis* WSM3557^T and *M. texensis* Lut6^T form highly specific and effective N_2-fixing symbioses with *Listia angolensis* and *Lupinus texensis*, respectively. Our studies have shown that the *M. lotononidis – Listia angolensis* symbiosis is an example of symbiotic specificity in an epidermally infected legume; however, the molecular basis of this specificity has not yet been determined.

Analysis of the sequenced genome of WSM3557^T suggests that this strain has acquired symbiotic loci by horizontal gene transfer from rhizobial donor strains. Symbiotic loci in WSM3557^T that show evidence of horizontal gene transfer include genes required for C4-dicarboxylate transport, the synthesis, assembly, and functioning of the molybdenum nitrogenase complex and Nod factor synthesis. Nod factor proteins have highest similarity with *Bradyrhizobium*, *Methylobacterium*, and *Sinorhizobium* Nod proteins. The FixNOPQ proteins required for microoxic respiration are most closely related to those of *Azorhizobium*. In contrast, other Nif, Fix, and Dct proteins appear to be most similar to those of *Mesorhizobium* and *Sinorhizobium*. WSM3557^T also appears to have acquired a T3SS from a mesorhizobial species. Whether the WSM3557^T T3SS has a role in modulating legume symbiosis remains to be determined. Likewise, the role of the large number of predicted RTX-like calcium-binding secreted proteins has not yet been examined.

Future studies of WSM3557^T will include functional analyses of the genes and regulons important to symbiotic performance and saprophytic competence. Exploitation of the genome sequence of WSM3557^T will be pivotal to gaining an understanding of the symbiotic process in symbiotically specific epidermally infected legumes. The proposed research is expected to deliver significant new information on legumes and rhizobia that are new to agriculture, new to science, and predicted to be important components of environmentally sustainable agriculture.

24.1 INTRODUCTION

An actinobacterium from the genus *Frankia* was first isolated in 1978 (Callaham et al., 1978) despite hundreds of prior attempts that failed, in hindsight, because of the slow growth rate of the organisms, presence of fast-growing contaminants in plant tissues, and the fact some lineages have evolved toward obligate symbiosis (Baker and Torrey, 1979). In addition, some of the genomes that have been sequenced have a large number of active genetic elements that may confer instability (Bickhart et al., 2009). For the same reasons, genetic transformation systems have not been developed despite numerous attempts using regenerated protoplasts (Normand et al., 1987; Tisa and Ensign, 1987) or electroporation (Cournoyer and Normand, 1992; Myers and Tisa, 2003). Attempts using complementation of *Rhizobium nodB* and *nodC* mutants with *Frankia* DNA banks in cosmid vectors have also failed (Ceremonie et al., 1998).

Apart from obvious basic physiological processes, including nitrogen fixation, hydrogen uptake, and bacteriohopane biosynthesis, bacterial symbiotic determinants are not known so far, even though the infection process and its ultimate outcome bear many similarities with those of the rhizobia (*sensu lato*) in legumes. Nodule establishment starts with either a deformed root hair entry or an intercellular penetration, followed by an infection thread, induction at a distance of cell differentiation, and emergence of a nodule invaded by frankial cells that differentiate into specialized forms (Benson and Silvester, 1993). The symbiotic program of host plants *Alnus* and *Casuarina* has been monitored by an expressed-sequence-tag (EST) approach and found to involve most of the determinants known in legumes (Hocher et al., 2011), with a special mention for SymRK that was found necessary for triggering infection by *Frankia* (Gherbi et al., 2008; see also Chapters 42, 43, 55).

The host plant symbiotic lock is thus beginning to be known; however, the identity of the bacterial symbiotic key remains elusive. Although some work has been done to identify the compound(s) that deform root hairs in *Alnus* (Van Ghelue et al., 1997; Ceremonie et al., 1999), they can only be postulated to be small hydrophilic molecules (below 2000 Da) that resists autoclaving and the chitinases tested.

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

In addition, some genomic and proteomic work has shown that frankiae devote a considerably smaller portion of their genome to making secreted proteins than do other bacteria, including polysaccharide hydrolases and other hydrolases (Mastronunzio et al., 2009). This observation has led to the hypothesis that the frankial symbiosis proceeds partly by avoiding triggering plant defense responses during infection (Mastronunzio et al., 2009).

On the basis of 16S rRNA sequencing, four clusters of *Frankia* strains have been recognized: (i) those infective on members of the Betulaceae (*Alnus*), Casuarinaceae (*Casuarina*, *Allocasuarina*), and Myricaceae (*Morella*, *Myrica*); (ii) those present in nodules of members of the Rosaceae (*Cercocarpus*, *Chamaebatia*, *Dryas*, *Purshia*), Datiscaceae (*Datisca*), Coriariaceae (*Coriaria*), and the North American *Ceanothus* (Rhamnaceae) that have not been grown in pure culture; (iii) those infective on members of the Elaeagnaceae (*Elaeagnus*, *Hippophae*, *Shepherdia*), *Gymnostoma*, and certain southern hemisphere Rhamnaceae (*Colletia*, *Discaria*, *Talguenia*, *Trevoa*); and (iv) strains of noninfective or noneffective (defective) saprophytes (Normand et al., 1996).

The different *Frankia* strain groups have contrasted lifestyles that range from obligate symbiotic to facultatively symbiotic to nonsymbiotic. **Obligate** symbionts have resisted, so far, all attempts at cultivation in pure culture and are apparently absent from soils that are devoid of their host plants; this is the case for the cluster 2 strains tested so far, of many *Casuarina*-infective and *Allocasuarina*-infective cluster 1b strains and cluster 1a *Alnus*-infective strains that produce many sporangia in nodules called Sp + (Simonet et al., 1999; Vanden Heuvel et al., 2004). Some other lineages are **facultative/limited**. They contain some strains that can be cultivated *in vitro* yet are not detected by trapping from soils lacking their host plants, and have several phylogenetic neighbors that resist attempts at growth in pure culture. This is the case for *Casuarina*-infective and *Allocasuarina*-infective cluster 1b strains (Diem et al., 1983; Paschke and Dawson, 1993). Other strains are **facultative symbionts** that can be cultivated readily and grown in soils in the absence of their host plants; this is the case of *Alnus*-infective cluster 1a strains (Berry and Torrey, 1979; Callaham et al., 1978). Other facultative strains that are abundant in soils in the absence of their normal hosts can sometimes be recovered from plants with which they do not usually form symbiotic nodules have been designated atypical; this is the case of cluster 3 strains (Gauthier et al., 1981). Finally, some strains are **asymbiotic/defective** or saprophytic, but nevertheless have been recovered from nodules of actinorhizal plants and grow well *in vitro* but cannot fulfill Koch's postulates (Hameed et al., 1994). The significance of the latter strains to the symbiosis is unknown, for instance strain CN3 obtained from *Coriaria nepalensis* nodules but unable to nodulate any plant (Mirza et al., 1992) or EuI1c obtained from *Elaeagnus umbellata* that can only induce nonefficient nodules on its host (Baker et al., 1980; Tisa et al., 1983).

Part of the rationale for undertaking the different *Frankia* genome sequencing projects was to identify the bacterial symbiotic determinants and determine evolutionary context for host range and plant–microbe interactions. This concerned a range of plants differing in the symbiotic relationship.

24.2 GENOMES OBTAINED AND UNDERWAY

The first publication of *Frankia* genomes centered on three strains differing in their symbiotic relationships, two were **facultative** (*Frankia* EAN1pec, cluster 3 and *Frankia alni* ACN14a, cluster 1a) and the last one was **facultative/limited** (*Frankia* CcI3, cluster 1b) (Normand et al., 2007).

A fourth genome was published (Persson et al., 2011) from an **obligate** symbiont, strain Dg1 growing in *Datisca glomerata*. Recently, two more genomes were published representing another cluster 1a mid-host range *Frankia*, strain QA3 (Sen et al., 2013) and the first cluster 4 **asymbiotic** atypical *Frankia*, strain CN3 (Ghodbhane-Gtari et al., 2013).

Symbiotic status ranges from obligatively symbiotic (or completely symbiotic, cluster 2) to asymbiotic/defective (saprophytic, cluster 4) with three intermediate categories with varying degrees of autonomy.

Several other genomes are on the way to being published and many should have been published when this chapter appears.

A trend that emerges from Table 24.1 is the link between genome size and symbiotic status although the number of genomes characterized is still small. Smaller genomes appear to have contracted through a combination of gene deletion associated with genome instability (Fig. 24.1). Interestingly, most of the larger genomes have an abundance of duplicated genes, as well as signs of genome instability, that has led to genome expansion (Normand et al, 2007). There is still only a single genome in cluster 2 as well as in cluster 1b that comprises *Casuarina*-infective strains. In cluster 1, the two genomes sequenced are close to one another, but this is not true in cluster 4. The latter may not form a real cluster, since the initial phylogenetic study (Normand et al., 1996) was based on incomplete (<1000 nt) sequences comprising probably numerous sequencing errors with long branches.

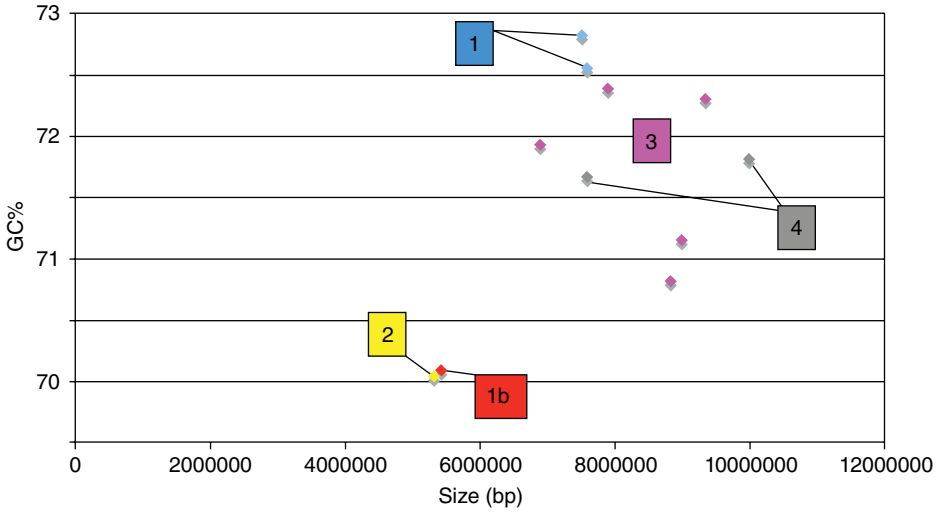

Figure 24.1 Genome sizes (*x*-axis) versus mol% G + C. Genomes from obligately symbiotic (cluster 2) or partially autonomous (cluster 1b) strains are the smallest (5.3–5.5 Mb) and have the lowest G + C% (70%). At the other extreme of the range are the saprophytic strains (asymbiotic/defective, cluster 4) with the largest genomes (up to 9.9 Mb). The other two groups, mostly symbiotic (cluster 1, *Alnus*-infective) and facultatively symbiotic (cluster 3), have intermediate sizes. Cluster 1 strains have the highest G + C% (>72.5%).

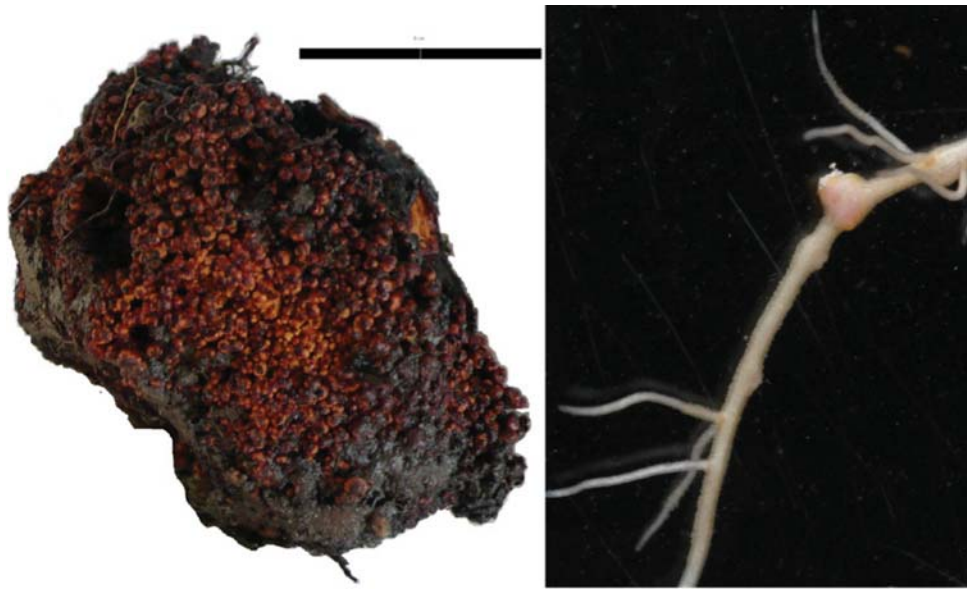

Figure 24.2 *Alnus glutinosa* nodules. Old perennial nodule on a black alder root from a field-grown individual (a; bar = 5 cm). A young *A. glutinosa* root (b) grown *in vitro* and inoculated with *Frankia alni* strain ACN14a that deforms root hairs, penetrates, and induces prenodular swellings that develop into small nodules (reddish swellings, upper right).

24.3 LINK WITH HOST RANGE

24.3.1 Host Biogeography

Cluster 2 (obligate) strains have a scattered distribution, since they appear to be absent from soils in the absence of their host plants, as shown by most trapping studies (personal observations). The host plants are similarly disjunct: *Datisca* spp. are present in California and Pakistan; *Coriaria* in Southern Europe, Eastern Asia, Mexico, North Africa, New Zealand; nodulated Rosaceous *Dryas* in North America and Northern Asia, and the other Rosaceous genera *Purshia*, *Chamaebatia*, and *Cercocarpus* in North America. Furthermore, it is difficult to be certain about the infectivity of these uncultivated symbionts, and it is only their genetic proximity and a few cross-compatibility tests that make us think these strains are relatively nondiverse.

For the most part, cluster 1b strains are uncultivated as isolation attempts from most *Casuarina* spp. and *Allocasuarina* spp. nodules have been unsuccessful. Isolates closely related to CcI3 have been obtained mainly from *C. equisetifolia* and related species, most of which have been deliberately planted outside their region of origin, Australia (Simonet et al., 1999). The isolates as well as the unisolated endophytes are phylogenetically close to one

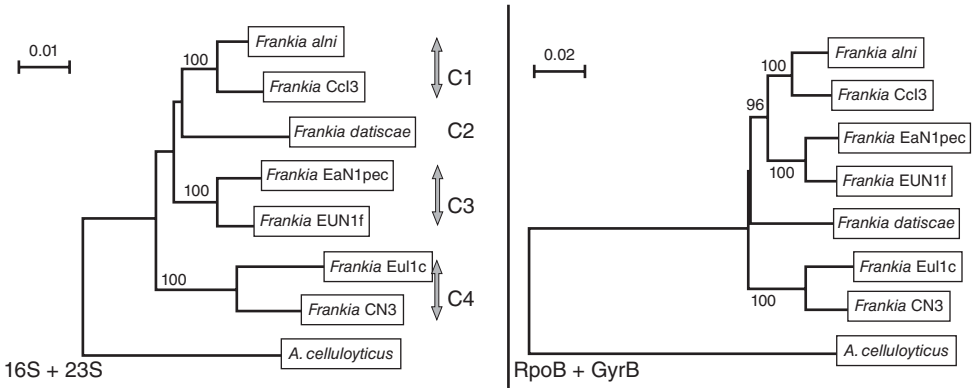

Figure 24.3 Different genes yield different topologies. In the case of *Frankia*, using *Acidothermus cellulolyticus* as outgroup, a combination of 16S + 23S rRNA puts the cluster 4 as the first to emerge, followed by cluster 3, cluster 2, and cluster 1. Conversely, a combination of RpoB + GyrB puts the cluster 4 as the first to emerge, followed by cluster 2, cluster 3, and cluster 1. A more robust multigene phylogeny should help discern the evolutionary history of *Frankia*.

another and are absent from soils where their host plants are not growing (Zimpfer et al., 1999). Presently, *Casuarina* trees grow in most tropical regions of the world and are planted extensively along seacoasts to stabilize the coastal dunes. In these situations, "casuarinas-infective strain isolates" can be found in soils only in close proximity to the trees (Zimpfer et al., 1999).

Cluster 1a strains, such as *Frankia alni* ACN14a, are infective on *Alnus* spp. as well as on *Myrica gale* and *Morella* sp. Alders are circumpolar plants that have adapted to specific niches. Black alder (*A. glutinosa*) may be the best-known actinorhizal plant; it grows along river banks where it sometimes produces large perennial structures (Fig. 24.2). Other *Alnus* species grow in nitrogen-poor biotopes in temperate locations around the globe.

Cluster 3 strains infect plants from the Elaeagnaceae that are also present in temperate ecosystems around the world, predominantly in Asia, Europe, North America, and North Africa. They also infect certain plants from the Rhamnaceae in South America, the Myricaceae, and *Gymnostoma* in Oceania. Finally, they are found as "atypical" strains on *Casuarina* and *Alnus* (Benson and Silvester, 1993).

Myrica gale or *Morella* species that can be nodulated by cluster 1 and 3 strains have a worldwide distribution (Benson and Silvester, 1993).

24.3.2 Core Genome

Several versions of the core *Frankia* genome can be computed: one that would contain genes present in all *Frankia* strains, and the other that is more specific would contain all genes present in strains that are partly or completely symbiotic, presumably including the symbiotic determinants. As the number of sequenced genomes increases over the years, the number of potentially symbiotic genes should approach an asymptote.

At a threshold level of 70% of similarity in amino acid sequences, the four published genomes share a core of around 860 CDS that represent 12.5% of the *F. alni* genome. This number increases to 1765 CDS when the threshold is lowered to 50% (25.7% of genome).

When a set of actinobacteria comprising phylogenetic neighbors *Acidothermus* and *Geodermatophilus* is used, and all shared genes are subtracted from this set, one obtains the frankial specific genome. At a threshold of 70%, that set is composed of 594 CDS or 8.65% of the genome; at a level of 50%, there are 783 CDS or 11.4% of the genome; and at a threshold of 30%, there are 650 CDS or 9.46%, including the *nif* genes.

Having numerous genomes allows one to infer phylogenies beyond what is possible with the 16S rRNA gene that is often used singly for that purpose (Fig. 24.3).

24.4 CONCLUSION

The emerging dataset represented by the *Frankia* genomes has allowed the identification of some tendencies. The first conclusion is that there is a marked variation in genome size that ranges from 5.3 Mb for the cluster 2 genome to 9.98 Mb for a cluster 4 genome. The second conclusion is that size variation is correlated with the closeness of the symbiotic relation and with the G + C% content (Normand et al., 2007).

Evolution of the symbiosis has resulted in a range of phenotypes from fully effective to asymbiotic/defective (atypical), from nodulating to saprophytic, and from obligate to facultative. There seems to be a geographical component to at least some of the phenotypes. Thus, geographically isolated plants, such as *Casuarina* sp. evolved in Australia and some Pacific islands, with fossil evidence for the Casuarinaceae in South America and New Zealand. *Casuarina* symbionts, which have a narrow host range,

appear limited to soils beneath their hosts as casuarinas planted outside their native range generally do not nodulate (Zimpfer et al., 1999). In the case of the obligate symbionts found in nodules from the North American *Ceanothus* sp., the Rosaceae, Datiscaceae, and Coriariaceae, the plants have developed as disjunct populations, in relative isolation from related plants, leading to the hypothesis that geographical isolation leads to an increasing dependence on symbiosis (Simonet et al., 1999). Plants that are widely distributed (*Alnus*, members of the Elaeagnaceae and Myricaceae) are infected by *Frankia* lineages that retain a wide distribution, even in the absence of cognate hosts (Benson et al., 2004).

The coming increase in sequenced genomes from strains with new phenotypes should help buttress and refine these findings.

25.1 INTRODUCTION

Bacteria of the genus *Azospirillum* (Alphaproteobacteria) have been known for many years as plant growth-promoting rhizobacteria (PGPR; see Chapter 90). These free-living nitrogen-fixing and highly motile bacteria can be isolated from the rhizosphere of many grasses and cereals, under tropical and temperate climates (Döbereiner et al., 1976; Patriquin et al., 1983; see Chapter 88). Azospirilla are predominantly root surface-colonizing bacteria, but some strains can also colonize the interior of roots (Elbeltagy et al., 2001; Rothballer et al., 2003). Through the establishment of cooperation (associative symbiosis) with plants, Azospirilla exert beneficial effects on plant growth and yield of many agronomically important crops such as rice, maize, and wheat while benefiting in return from root exudates (Okon, 1985; Veresoglou and Menexes, 2010; see Chapter 90). This plant's stimulatory effect has been attributed to several mechanisms, the two main properties that define the genus being the most documented: production of plant growth-promoting substances (such as auxins) and biological nitrogen (N) fixation. Apart from these two mechanisms, other properties are thought to be implicated in plant growth promotion, and it is likely that the *Azospirillum* effect results from a combination of different mechanisms (Bashan and de-Bashan, 2010). Moreover, *Azospirillum* spp. can, to a lesser extent, enhance plant health by inhibiting plant parasites (Miché et al., 2000) and/or by stimulating the plant defense (Yasuda et al., 2009).

In order to rationalize the use of *Azospirillum*, genetic studies have mainly focused on plant beneficial traits (nitrogen fixation, auxin biosynthesis) and properties linked to root colonization and survival in the rhizosphere (Bashan et al., 2004; Steenhoudt and Vanderleyden, 2000; Fibach-Paldi et al., 2012). Despite these studies, the growth response of plants to *Azospirillum* inoculation is not completely predictable and differential varietal response has been reported for several crops, including wheat, sorghum, corn, and rice (Drogue et al., 2012; García de Salamone et al., 2010; Sasaki et al., 2010; Saubidet and Barneix, 1998; Vargas et al., 2012;

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

Veresoglou and Menexes, 2010; see Chapter 90). To provide new insights into the *Azospirillum*–plant cooperation, genomes of several *Azospirillum* strains belonging to different species were recently sequenced and published. This review aims at summarizing the most important features revealed by comparative genome analyses.

25.1.1 Size and Architecture of *Azospirillum* Genomes

Pioneer studies have revealed that *Azospirillum* genomes are consisting of multiple replicons, and their sizes vary among species from 4.8 to 9.7 Mpb (Caballero-Mellado et al., 1999; Martin-Didonet et al., 2000). Until now, the genomes of five strains belonging to different species, isolated from various host plants and locations, were sequenced and published: (i) *Azospirillum* sp. B510, a strain isolated from disinfected rice stems in Japan and closely related to the species *Azospirillum oryzae* and *Azospirillum zeae* (Elbeltagy et al., 2001; Kaneko et al., 2010; Wisniewski-Dyé et al., 2012); (ii) *Azospirillum amazonense* Y2 isolated from the gramineous plant *Hyparrhenia rufa* in Brazil (Magalhães et al., 1983; Sant'Anna et al., 2011)); (iii) *Azospirillum brasilense* Sp245 isolated from wheat in Brazil (Baldani et al., 1986; Wisniewski-Dyé et al., 2011); (iv) *A. brasilense* CBG497 isolated from maize grown on an alkaline soil (pH 8) in the northeast of Mexico and used as a commercial biofertilizer (Garcia-Olivares et al., 2007; Wisniewski-Dyé et al., 2012); and (v) *Azospirillum lipoferum* 4B isolated from rice in France (Thomas-Bauzon et al., 1982; Wisniewski-Dyé et al., 2011). Genome size ranges from 6.5 Mbp (*A. brasilense* CBG497) to 7.6 Mbp (*Azospirillum* sp. B510) (Table 25.1). All sequenced genomes are composed of multiple circular replicons, whose number varies from four (*A. amazonense* Y2) to seven (Table 25.1).

Separation of plasmids by the Eckhardt method and pulsed-field gel electrophoresis (PFGE) analyses performed on other unsequenced strains repeatedly demonstrate the presence of multiple replicons (our unpublished data), implying that a composite genome architecture is a rule for members of the *Azospirillum* genus. Thus, *Azospirillum* genome architecture is more similar to the one observed in rhizobia (Rhizobiaceae family) (Crossman et al., 2008; González et al., 2006) than to the one observed in its closest relatives. Indeed, genomes of others, Rhodospirillaceae (such as *Rhodospirillum*, *Magnetospirillum*), display sizes from 4.3 to 5 Mpb composed of a unique chromosome or a chromosome and a tiny plasmid (<50 kb).

For all strains (except *A. amazonense* Y2 for which the information is not available), the analyses of GC skew shift point (Lobry, 1996) and stress-induced destabilization site (SIDD) (http://www.genomecenter.ucdavis.edu/benham/sidd/websidd.php) allowed to locate the putative chromosomal origin (*Cori*) of replication on the largest replicon (ca. 3 Mbp). The *Cori* region contains three to four DnaA boxes, and it is found adjacent to the *hemA* locus that is similar to the *Cori* pattern of many other Alphaproteobacteria (Brassinga et al., 2001). All the other replicons have *repABC/parAB* plasmid-type replication systems; with a clear SIDD site and the presence of several short (direct, inverted, tandem) repeats and palindromes, as well as a gene encoding a protein highly similar to the replication initiator protein. Some of the latter have been classified as chromids (up to five in the genomes of *A. lipoferum* 4B and *Azospirillum* sp. B510), that is, they display plasmid-type maintenance replication systems, presence of essential genes, and a nucleotide composition close to that of the chromosome (Harrison et al., 2010; Acosta-Cruz et al., 2012; Wisniewski-Dyé et al., 2011; Wisniewski-Dyé et al., 2012). In finished and closed genomes, a total of eight or nine ribosomal operons have been detected on the chromosome and on various chromids (Table 25.1); interestingly, the p1 chromid always bears the highest number of ribosomal operons (up to four in *Azospirillum* sp. B510). The smallest replicon, p6, is a typical plasmid and exhibits the lowest average GC content, which suggests an external origin by horizontal gene transfer (HGT); such an observation was previously made for two other Alphaproteobacteria interacting with plants, *Rhizobium etli* and *Rhizobium leguminosarum* (Crossman et al., 2008). Chromids and plasmids comprise the largest proportion of the total genome, with 55.2% for *A. brasilense* CBG497, 56.4% for *A. lipoferum* 4B and *Azospirillum* sp. B510, and 59.8% for *A. brasilense* Sp245. Therefore, in addition to possessing the largest number of chromids among all prokaryotic genomes sequenced to date, *Azospirillum* has the biggest proportion of its genome on nonchromosomal replicons (Wisniewski-Dyé et al., 2012).

25.1.2 Genome Plasticity and Horizontal Gene Transfer

A comparison of three *Azospirillum* genomes (those of *Azospirillum* sp. B510, *A. lipoferum* 4B, and *A. brasilense* Sp245) revealed very little synteny between replicons (Wisniewski-Dyé et al., 2011). Indeed, alignment of *Azospirillum* sp. B510 and *A. lipoferum* 4B genomes displayed little synteny on the chromosome and none on the other replicons despite an average nucleotide identity (ANI) of 91% and a relative distance of 0.01 between the two genomes (Fig. 25.1). Alignment of *A. lipoferum* 4B and *A. brasilense* Sp245 genomes revealed no synteny despite an ANI value of 89% and a relative distance of 0.10 (Fig. 25.1).

When such a comparison was made on two rhizobia of comparable genetic relatedness (*Rhizobium etli* CFN42/*R. leguminosarum* biovar *viciae* 3841, ANI = 89%), a strong synteny was observed on nearly all replicons (Wisniewski-Dyé et al., 2011). This indicates that *Azospirillum* genomes have undergone numerous rearrangements

Table 25.1 Genomic features of *Azospirillum* genomes sequenced to date

nk, not known.

*Those replicons carry ribosomal operons (sometimes partial). This information is partial for *A. brasilense* CBG497.

†When the size is indicated in bold, the chromid definition applies to the corresponding replicon, that is, plasmid-type maintenance replication systems, presence of essential genes, and a nucleotide composition close to that of the chromosome (Harrison et al., 2010; Wisniewski-Dyé et al., 2011).

‡The third criteria of chromid definition (nucleotide composition close to that of the chromosome) does not apply for these two replicons.

§The number of ORFs corresponds to the one established after the sequence was imported and annotated into the MaGe platform (Vallenet et al., 2009).

**According to PFGE data, the sequence of size of this replicon is 650 kb versus a sequenced size of 488 kb; consequently, genome coverage is estimated at 97–98% (Wisniewski-Dyé et al., 2012).

††Sizes of replicons are indicative as no information on genome architecture was provided when the genome was sequenced (Sant'Anna et al., 2011); hence, data on the sizes of replicons and on the presence of ribosomal operons are derived from PFGE analyses and hybridization with a 16 s rDNA probe performed anteriorly (Martin-Didonet et al., 2000). The low number of ORFs is far to what is expected for a 7.3 Mbp genome size and might be attributable to the draft status of this genome (1617 contigs) (Sant'Anna et al., 2011). The eventual chromid status of the replicons could not be assigned for the same reason.

compared to rhizobial genomes usually recognized for their plasticity. Experimental evidence had already highlighted the extraordinary genome plasticity of *Azospirillum*. For instance, the appearance of phenotypic variants was correlated with plasmid loss or reorganization (Vial et al., 2006), while plasmid content of strain *A. brasilense* Sp245 collected from several laboratories showed discrepancies (Pothier et al., 2008). Moreover, the presence of bacteriophages was evidenced, with some strains hosting gene-transfer agents that typically package bacterial genome fragments (Boyer et al., 2008). In addition, a thorough analysis of *Azospirillum* sp. B510 and *A. lipoferum* 4B genomes disclosed the presence of many (direct and palindromic) repetitive sequences of a size superior to 80 pb as well as clustered regularly interspaced short palindromic repeats (CRISPR) sequences that could act as recombination hotspots; insertion sequences (IS) are also scattered throughout all replicons and represent up to 4.47% of the genome in *Azospirillum* sp. B510 (310 IS, including 176 full IS) (Wisniewski-Dyé et al., 2011). However, despite experimental evidence of genome plasticity and presence of relevant elements in the genomes, the detailed mechanisms underlying genomic rearrangements remain to be elucidated.

Interestingly, although being multireplicon Alphaproteobacteria interacting with plants (such as rhizobia), the genus *Azospirillum* belongs to the family Rhodospirillaceae whose nearly all other known representatives live in aquatic habitats. In order to determine which genes *Azospirillum* shares with its aquatic relatives and what was the origin of its additional genes, a robust scheme for detecting ancestral genes and those acquired by HGT genes was developed (Wisniewski-Dyé et al., 2011). Briefly, proteins were assigned as being ancestral or horizontally transferred, with varying degrees of confidence, based on the

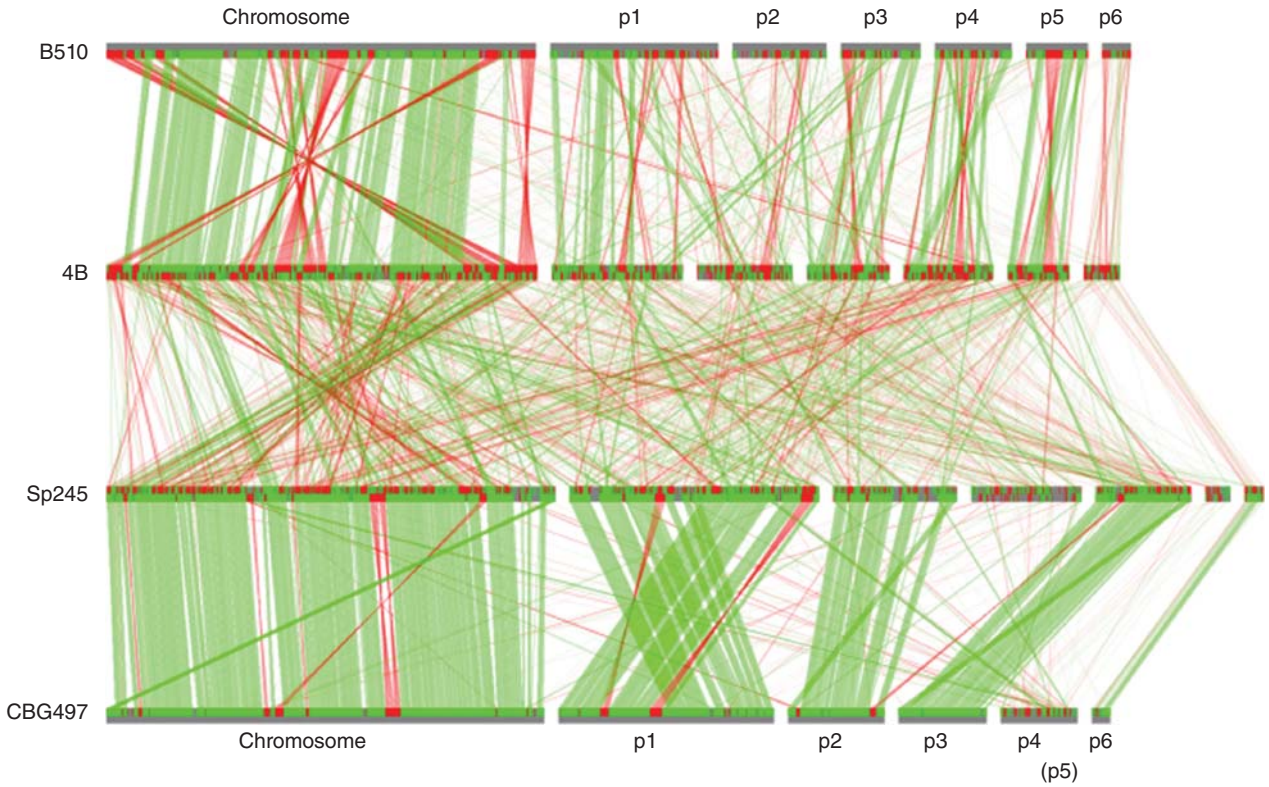

Figure 25.1 Whole genome alignments of *Azospirillum* replicons. Each line represents one gene; a green line indicates that the two orthologs are in the same orientation, whereas a red line indicates that the two orthologs are in an opposite orientation.

presence of members of Rhodospirillales and Rhodospirillaceae in the top eight BLAST hits. With this scheme, most protein-coding genes of *Azospirillum* could be classified as ancestral or HGT and, remarkably, nearly half of the genes whose origins could be resolved appear to be horizontally transferred (Wisniewski-Dyé et al., 2011). When the genomes of other Rhodospirillaceae were subjected to the same analysis, a substantially lower HGT level was revealed, whereas the number of ancestral genes in all organisms was comparable. The ancestral set of genes principally contained genes involved in "housekeeping" functions such as translation, posttranslational modification, cell motility, and nucleotide and coenzyme transport and metabolism. The HGT set contained a large proportion of genes involved in specific dispensable functions, such as defense mechanisms, cell wall biogenesis, transport and metabolism of amino acids, carbohydrates, inorganic ions, and secondary metabolites. A great proportion of HGT genes exhibit similarity with genes of terrestrial and plant-associated bacteria, notably Rhizobiales and Burkholderiales. Thus, HGT, likely promoted by conjugation or transduction events, may have been a major driving force in the transition of *Azospirillum* from aquatic to terrestrial environments, as well as in adaptation to the plant rhizosphere, an environment rich in amino acids, carbohydrates, inorganic ions, and secondary metabolites. Moreover, separation of *Azospirillum* from their close aquatic relatives coincided approximately with the emergence of vascular plants on land, about 400 million years ago (Wisniewski-Dyé et al., 2011).

25.1.3 The *Azospirillum* Core Genome

A reciprocal best blast hit criterion has been used previously to identify the most probable set of orthologous proteins shared by four fully sequenced *Azospirillum* strains. A total of 2328 proteins (named the AZO-core) appeared to be shared by the four strains, representing between 30% and 38% of the total encoded proteins within a genome (Wisniewski-Dyé et al., 2012). The repartition among replicons showed that the AZO-core was mainly chromosomally encoded (from 62% to 65% according to the strain considered), whereas the nonchromosomal proportion of AZO-core was unevenly distributed among strains. Not surprisingly, the AZO-core set revealed to be dominated by proteins of ancestral origin (74%) but contains more than a fifth (22%) of proteins encoded by horizontally acquired genes and a small proportion of proteins encoded by genes whose origin could not be resolved (4%; see also Chapters 26, 27).

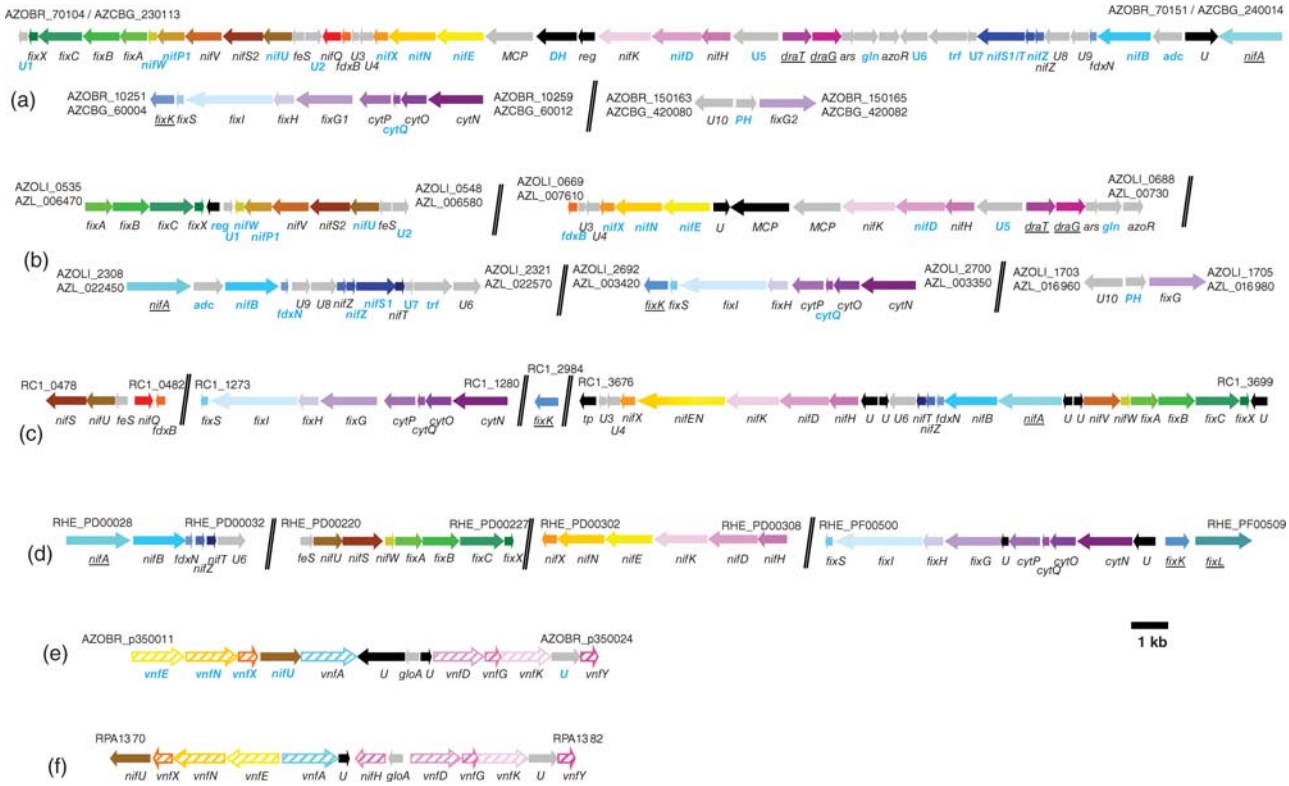

Figure 25.2 Organization of *Azospirillum* nitrogen fixation genes. Genes encoding FeMo nitrogenase of *Azospirillum brasilense* Sp245 and CBG497 (a); *A. lipoferum* 4B and *Azospirillum* sp. B510 (b); *Rhodospirillum centenum* SW (c); *Rhizobium etli* CFN42 (d). Genes encoding vanadium nitrogenase of *Azospirillum brasilense* Sp245 (e) and *Rhodopseudomonas palustris* CGA009 (f). Genes involved in nitrogen fixation are represented by colored arrows. Black and gray arrows represent genes unrelated to nitrogen fixation: black arrows represent genes that are unique to one strain whereas gray arrows represent conserved genes. For black and gray arrows, the meaning of gene names is as follows: *adc* (putative adenylate/guanylate cyclase), *ars* (putative arsenate reductase), *azoR* (NADH-azoreductase), *DH* (dehydrogenase), *feS* (Fe-S cluster assembly protein), *gln* (putative glutamine amidotransferase), *gloA* (lactoylglutathione lyase), *MCP* (putative methyl-accepting chemotaxis receptor), *PH* (phosphohydrolase), *reg* (putative regulator), *tp* (transposase), *trf* (putative aminotransferase), and *U* (protein of unknown function). A gene name depicted in black indicates an ancestral gene, whereas a gene name appearing in blue indicates a gene that has been horizontally acquired (Wisniewski-Dyé et al., 2011). Gene names that are underlined encode regulators of nitrogen fixation; *rpoN* (encoding sigma 54) is not depicted in this figure. Sp245 possesses two chromosomally encoded copies of *nifQ* (AZOBR_70116 represented here, and AZOBR_90008); homologs of AZOBR_90008 can be found in *A. lipoferum* (AZOLI_0980), *R. centenum* SW (RC1_0481), and *R. etli* CFN42 (RHE_PD00259) and are not represented here. All strains contain at least one copy of *nifP* (not always depicted here); *Azospirillum* strains contain two copies of *nifP* (only one is represented here). *R. etli* CFN42 lacks a *nifV* homolog. *draT* and *draG* are absent from the genomes of *R. centenum* SW and that of Rhizobiales.

The majority of genes for nitrogen fixation, one of the main features that define the *Azospirillum* genus, belong to the AZO-core. However, discrepancies in gene organization are found from one strain to another. In the two *A. brasilense* strains (Sp245 and CBG497), nitrogen-fixation genes lie on two chromosomal clusters (a big cluster of ca. 41.4 kb, and a second cluster of ca. 9.3 kb), whereas in *A. lipoferum* 4B and *Azospirillum* sp. B510, five chromosomal clusters have been identified (Fig. 25.2). Genes encoding the main structural components as well as regulators of nitrogen fixation genes (such as *fixK*, *nifA*, *draT*, *draG,* and *rpoN*) fall into the ancestral set (Fig. 25.2).

Rhodospirillum centenum SW lacks *draT* and *draG* allowing the posttranslational regulation of dinitrogenase reductase by adenosine diphosphate (ADP)-ribosylation (see Chapters 12, 13), but these genes are present in other *Rhodospirillum* strains and in *Magnetospirillum*. This regulation mechanism is also absent from the genomes of Rhizobiales but additional regulators, that are absent in *Azospirillum* (such as FixL and FixJ), have been reported. Interestingly, several nitrogen-fixation genes, although present in some aquatic relatives, fall into the HGT set due to strong homology with genes of other nitrogen fixers (Fig. 25.2). The unique structural gene falling into this category (i.e., *nifD* encoding the alpha chain of FeMo nitrogenase) may have been acquired from Rhizobiales, whereas all others are related to accessory functions (such as nitrogenase carrier protein NifX and FeMo-cofactor scaffold and assembly proteins NifN and NifB). Thus, although

encoding an ancestral function, nitrogen-fixation genes may have several origins in *Azospirillum*.

Among the 2328 proteins of the AZO-core, half (1151) of them was shown to be shared by *Azospirillum* strains and by the phylogenetically related *R. centenum* SW, and encode mainly "housekeeping" functions. Genes belonging to the AZO-core that are absent in *R. centenum* SW have been mainly acquired horizontally (53%) or are shared with other aquatic relatives (40%) or their origin could not be resolved (7%). Those genes are principally involved in signal transduction, regulation of transcription, carbohydrate transport and metabolism, and amino acid transport and metabolism; this latter category also includes organic acids, compounds that are abundant in the rhizosphere. Transporters, especially ATP binding cassette (ABC) transporters, are overrepresented. They can serve to internalize the wide diversity of organic and mineral compounds present in the rhizosphere, such as organic compounds exuded by plant roots, or to expel putative plant toxic compounds via multidrug resistance (MDR) efflux pumps. Thus, compared to its closest aquatic relative *R. centenum*, *Azospirillum* is more adapted to life in fluctuating environments such as the rhizosphere.

As for genes involved in direct plant growth promotion, only the pyrroloquinoline quinone (PQQ) operon, allowing the synthesis of the cofactor PQQ, a compound displaying plant growth-promoting properties belongs to the AZO-core (Choi et al., 2008); other genes belong to the accessory genome and may have been acquired specifically after speciation events or by individual strains (see later).

25.1.4 Accessory Genome and Its Relevance for Interaction with Plants and for Host Specificity

Chemotaxis toward plant-exuded compounds and motility are primordial for the initiation of root colonization in a wide range of rhizobacteria. The AZO-core contains genes implicated in flagellum biosynthesis and four common chemotaxis operons, whereas one and two additional chemotaxis operons are carried by the genomes of *A. lipoferum* 4B and *Azospirillum* sp. B510, respectively (Wisniewski-Dyé et al., 2011). Consequently, those two strains contain a significant number of unique genes encoding methyl-accepting proteins, able to detect various physicochemical cues and to relay information to the flagellar motors via a signal transduction cascade. Once colonization is achieved, polysaccharides and other adhesion structures mediate bacterial attachment to plant roots. Next to a common set of genes involved in the biosynthesis of exopolysaccharide (EPS) and lipopolysaccharide (LPS) such as *noeL*, *noeJ,* and *rmlD* (Jofré et al., 2004; Lerner et al., 2009), the presence of several unique genes suggests that EPS and LPS components might differ from one *Azospirillum* strain to another, a feature previously reported for LPS (Jofré et al., 2004). Cellulose synthesis allows bacteria to bind tightly to the roots (Rodriguez-Navarro et al., 2007), and genes involved in cellulose synthesis and acquired by HGT (Fig. 25.3) are found exclusively in *A. lipoferum* 4B and *Azospirillum* sp. B510.

TAD (Tight ADhesion) pili, present exclusively in the *A. brasilense* species, play an essential role in biofilm formation, colonization, and pathogenesis in various genera (Tomich et al., 2007), and their role in biofilm formation on abiotic surfaces was recently assessed in *A. brasilense* Sp245 (Wisniewski-Dyé et al., 2011). Cellulases and hemicellulases likely contribute to endophytic plant colonization, a property described for *A. brasilense* Sp245 and *Azospirillum* sp. B510 (Assmus et al., 1995; Elbeltagy et al., 2001). A weak cellulolytic activity was detected for those two strains and for *A. lipoferum* 4B (not known as an endophyte), and a substantial number of glycosyl hydrolases (from 26 to 34) were identified in *Azospirillum* genomes, with some CAZy families being restricted to a species (Wisniewski-Dyé et al., 2011). Altogether, these features might be relevant for the colonization of specific hosts.

While various studies showed evidence that the plant growth-promoting effects of *Azospirillum* depend on both host plant genotypes and bacterial strains (Sasaki et al., 2010; Saubidet and Barneix, 1998; Vargas et al., 2012; Veresoglou and Menexes, 2010), the molecular bases of these host-specific responses are still not elucidated. It was recently suggested that host specificity of phytostimulating cooperations could be the result of successive genotype-dependent responses in the three-step establishment of such symbioses: (i) attraction of bacteria from the surrounding soil to the rhizosphere; (ii) attachment to the root surface; and finally, (iii) functioning of cooperation that becomes effective (Drogue et al., 2012). In the case of *Azospirillum*, this effective functioning is thought to occur through nitrogen fixation and modulation of the plant hormonal balance (Bashan and de Bashan, 2010; Wisniewski-Dyé et al., 2013), two properties that are differentially distributed among *Azospirillum* genomes.

Indeed, next to nitrogen-fixation genes that have been inherited vertically and that are chromosomally encoded, *A. brasilense* Sp245 possesses a second cluster for nitrogen fixation, encoding a vanadium nitrogenase, and located on a chromid (Fig. 25.2e). This cluster, bordered by a gene encoding an integrase, seems to have been horizontally acquired from *Rhodopseudomonas palustris*; synteny analysis between the two operons indicates that this region has undergone rearrangements (Fig. 25.2). Its absence from the genome of *A. brasilense* CBG497 suggests that its acquisition by HGT is rather recent. Whether this vanadium nitrogenase is expressed and what are its inducing conditions remain to be determined as a proteomic analysis of *A. brasilense* Sp245 cells grown under nitrogen-fixation

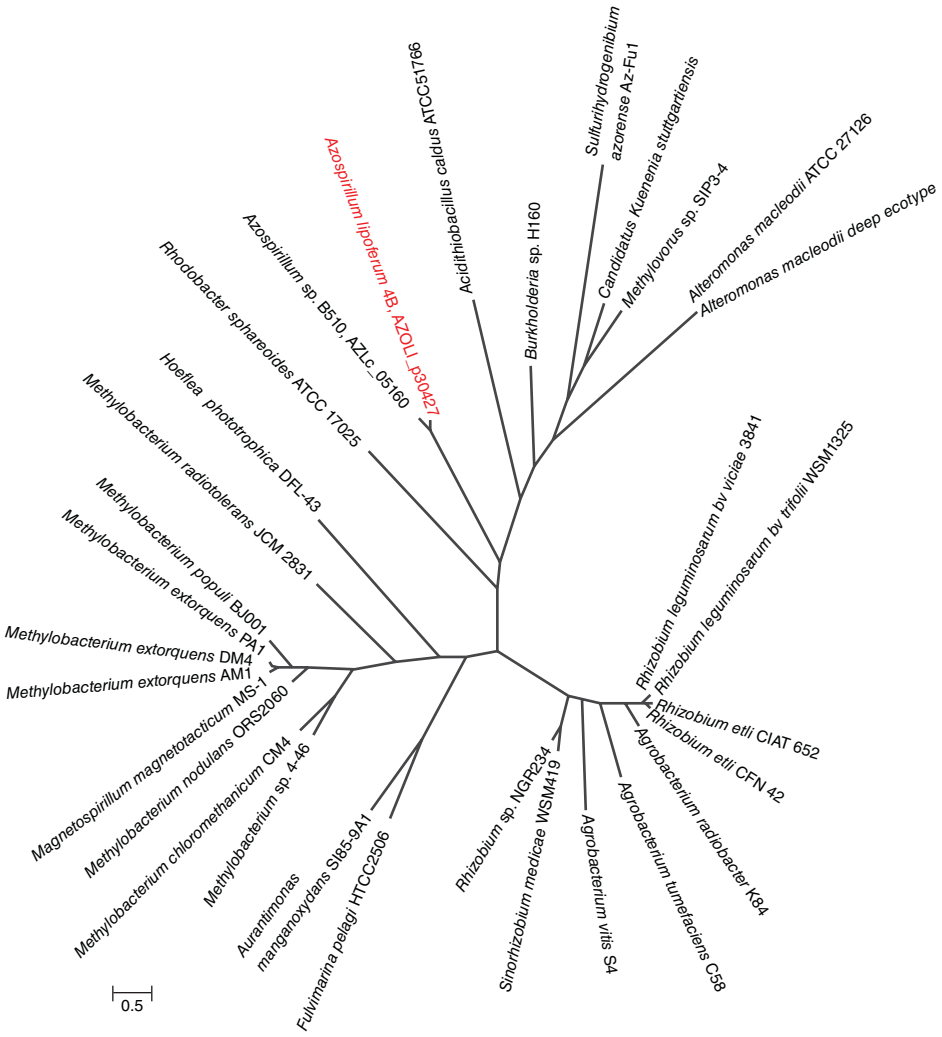

Figure 25.3 Phylogenetic tree for cellulose synthase of *Azospirillum lipoferum* 4B. Tree was built from aligned sequence of the *A. lipoferum* 4B query (*celB*, AZOLI_p30427) and 30 most similar sequences were determined by BLAST.

conditions did not allow to detect this low-abundant protein (Wisniewski-Dyé et al., 2011).

Interestingly, *A. lipoferum* 4B and *Azospirillum* sp. B510 may have acquired the ability to secrete gluconic acid and hence to solubilize inorganic phosphates, another important trait for enhancement of plant nutrition and scarcely reported for the *Azospirillum* genus (Rodriguez et al., 2004).

Apart from plant nutrition improvements, *Azospirillum* can modulate the plant hormonal balance via the synthesis or via the degradation of phytohormones or precursors of phytohormones (Bashan et al., 2010; Wisniewski-Dyé et al., 2013).

A. brasilense Sp245 is well known to produce indole-3-acetic acid (IAA) from tryptophan (Trp) through the indole-3-pyruvate (IPyA) biosynthetic pathway (Spaepen et al., 2007; see Chapter 91). One key gene of this pathway, *ppdC*/*ipdC*, encoding IPyA decarboxylase, is present in the sequenced genomes of the two *A. brasilense* strains but absent from those of *A. lipoferum* 4B and *Azospirillum* sp. B510 (Fig. 25.4).

The first and third steps of the IPyA pathway are catalyzed by enzymes, respectively, aromatic aminotransferases and NAD-dependent aldehyde dehydrogenase, which are common and nonspecific enzymes. Recently, the contribution of *hisC1*, which encodes an aromatic amino acid aminotransferase-1 (AAT1), to IAA biosynthesis was shown to occur in *A. brasilense* Sp7 (Castro-Guerrero et al., 2011); homologs sharing identity levels higher than 75% with AAT1 from Sp7 were found in all four *Azospirillum* genomes. Other metabolic pathways are known to contribute to IAA biosynthesis; an *ipdC* knockout mutant of *A. brasilense* Sp245 still produced 10% of the wild-type IAA level (Spaepen et al., 2007). Genetic determinants putatively involved in other pathways and classified as HGT were highlighted in specific strains (Fig. 25.4) (Wisniewski-Dyé et al., 2011). Functional studies are required to validate the involvement of those genetic determinants in IAA biosynthesis in those strains, as high-performance liquid chromatography (HPLC) analyses revealed the ability to

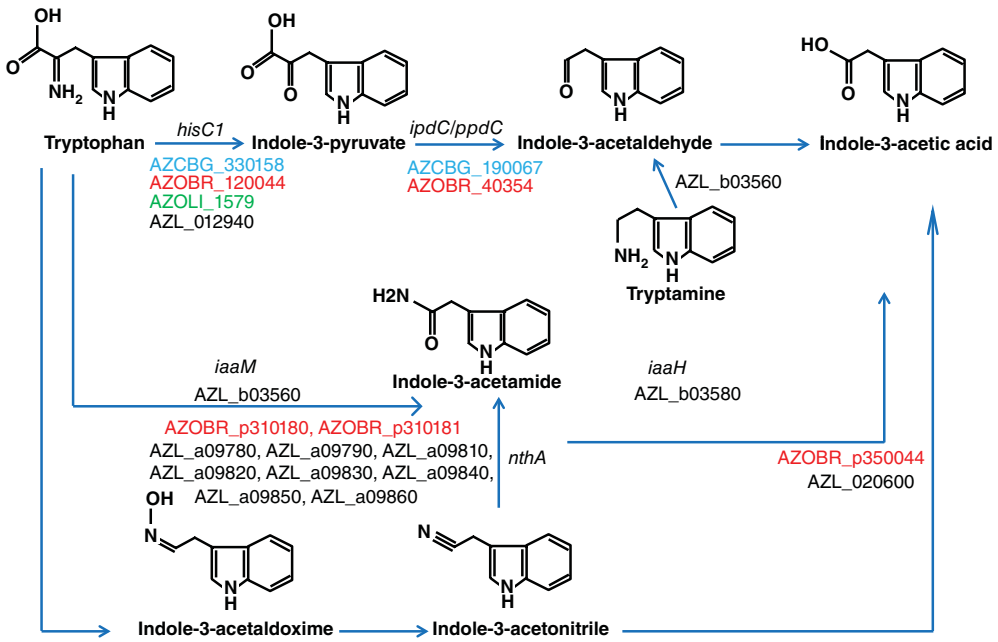

Figure 25.4 *Azospirillum* genes putatively involved in IAA biosynthesis. Genes from *A. brasilense* CBG497 and Sp245 are indicated in blue and red, respectively. Genes from *A. lipoferum* 4B are indicated in green. Genes from *Azospirillum* sp. B510 are indicated in black.

produce IAA in the presence of tryptophan for *A. brasilense* Sp245 and CBG497 but this production was shown to be negligible for *A. lipoferum* 4B and *Azospirillum* sp. B510 (our unpublished data). Interestingly, *A. lipoferum* 4B and *Azospirillum* sp. B510, although not carrying the *ipdC* gene, are able to metabolize IAA; this property previously reported for some rhizobacteria such as *Pseudomonas putida* relies on the presence of the *iac* genes (for IAA catabolism) (Leveau and Gerards, 2008) whose homologs are present only in *A. lipoferum* 4B and *Azospirillum* sp. B510 and have been classified as HGT.

The deamination of 1-aminocyclopropane-1-carboxylic acid (ACC), the immediate precursor of plant ethylene, is another key activity involved in the modulation of the plant hormonal balance by rhizobacteria. Because ethylene inhibits root growth and may be produced in too large amounts during plant stress response, bacterial ACC deamination can enhance both root system development and plant stress tolerance (Glick et al., 2007). The *acdS* gene, encoding ACC deaminase activity, is harbored by strains of the *A. lipoferum* species and has been acquired by HGT (Prigent-Combaret et al., 2008; Wisniewski-Dyé et al., 2011).

The plant hormonal balance might also be modulated by the degradation of salicylate into catechol via salicylate 1-monooxygenase (EC 1.14.13.1). The corresponding gene has been identified in *A. lipoferum* 4B and in *A. brasilense* genomes and may be the result of two independent acquisitions through HGT (Wisniewski-Dyé et al., 2011). However, only *A. lipoferum* 4B harbors the metabolic pathway for catechol degradation and thus may use salicylate as a source of energy and carbon.

25.1.5 Accessory Genome and Rhizosphere Competence

25.1.5.1 Carbon, Nitrogen, and Phosphate Acquisition. Many genes encoding functions critical for survival in the rhizosphere, such as catabolic properties, are strain specific and are often among those acquired by HGT (Wisniewski-Dyé et al., 2011). A complete ribose degradation pathway was identified in *A. lipoferum* 4B and *Azospirillum* sp. B510 involving a ribokinase (*rsbK*), a deoxyribokinase/ribokinase (*deoK*), and a deoxyribose mutarotase (*deoM*). The catabolic pathway of myoinositol was identified only in *Azospirillum* sp. B510. This strain may use the aliphatic amine methylamine as a nitrogen source; the eight-gene cluster necessary for glutamate-mediated methylamine utilization (composed of *mgdABCD*, *gms*, and *mgsABC*) is present in methylotrophs such as *Methyloversatilis universalis* FAM5 (Latypova et al., 2009) and also in various Rhizobiales from which it may have been acquired. *A. lipoferum* 4B and *Azospirillum* sp. B510 have the ability to degrade the organophosphonate 2-aminoethylphosphonate. Organophosphonates are primarily components of phosphonolipids, and also as constituents of polysaccharides, glycoproteins, glycolipids, and several antibiotics.

The accessory genome also encodes metabolic properties of ancestral origin that have been retained in some

strains. One such example is autotrophy achieved by enzymes of the Calvin–Benson–Bassham (CBB) cycle, whose corresponding operon is present in *A. lipoferum* 4B and in *A. amazonense* Y2. Chemolithoautotrophic growth using CO_2 as a carbon source and H_2 as an energy source was observed for these two strains (our unpublished data). *A. lipoferum* 4B also displays formate-dependent autotrophic growth. Occurrence of the *cbb* operon, investigated using a PCR approach targeting *cbbL* (encoding ribulose-1,5-bisphosphate carboxylase), was shown to occur in 12 out of 40 *Azospirillum* strains isolated from various host plants and geographic locations (our unpublished data). The fact that strains evolving in an environment rich in organic compounds, such as the rhizosphere, have kept the ability to fix CO_2 is puzzling but this property is not restricted to the *Azospirillum* genus. Whether the presence of the *cbb* operon is due to a stochastic inheritance from a phototrophic ancestor or the result of an adaptive evolution to a particular ecological environment is unknown.

25.1.5.2 Degradation of Plant Aromatic Compounds. Aromatic compounds (i.e., organic molecules containing one or more aromatic rings mainly produced by plants) are abundant in plant exudates and may serve as carbon source for microbes. The aerobic catabolism of aromatic compounds usually involves the oxygenolytic hydroxylation of the aromatic ring, producing central dihydroxylated aromatic intermediates (such as catechol and protocatechuate). These intermediates are then cleaved by different types of ring-cleavage dioxygenases, generating aliphatic compounds that funnel into the tricarboxylic acid (TCA) cycle through a small number of central pathways. *A. lipoferum* 4B and *Azospirillum* sp. B510 can degrade catechol and protocatechuate via the β-ketoadipate pathway; they also possess enzymes allowing the conversion of benzoate and 4-hydroxybenzoate into protocatechuate. In addition, *Azospirillum* sp. B510 can convert benzoate into catechol. Both strains can also metabolize gentisate (2,5-dihydroxybenzoate), and adjacent to the cognate cluster, a gene encoding a hydroxybenzoate transporter displaying strong identity with PcaK of *Ralstonia*, a chemoreceptor for aromatic acids (Harwood et al., 1994) is found. Additional hydroxybenzoate transporters are encoded by the genome of *Azospirillum* sp. B510. *A. brasilense* strains seem to be less versatile as only the meta-cleavage pathway of protocatechuate degradation has been identified; catabolism of gallate and methylgallate might be present but one of the key enzymes (EC 4.2.1.83) could not be identified. Experimentally, growth on protocatechuate as the sole carbon source was observed for all strains but *A. brasilense* CBG497 (Wisniewski-Dyé et al., 2012).

The phenylacetate catabolic pathway is the central route where catabolic pathways of many aromatic compounds converge and are directed to the TCA cycle (Fuchs et al., 2011). Within the genomes of *Azospirillum*, only *A. lipoferum* 4B and *Azospirillum* sp. B510 strain harbor the complete *paa* catabolic cluster; 11 of these genes are located on the p4/d replicon, whereas *paaX*, *paaY*, and *paaF* (which is duplicated) are located onto the chromosome, thus constituting five different clusters, an organization previously reported in *Pseudomonas putida* (Luengo et al., 2001). Seven of the genes located on p4 cluster have been classified as horizontally transferred, whereas the four others have been classified as ancestral (Wisniewski-Dyé et al., 2011), suggesting a complex evolution of this catabolic pathway. The functionality of the *paa* genes was confirmed as both strains were able to grow on phenylacetic acid as the sole carbon source, whereas *A. brasilense* strains showed no growth (Wisniewski-Dyé et al., 2012).

Thus, *A. lipoferum* 4B and *Azospirillum* sp. B510 seem to be more versatile for aromatic compound degradation than *A. brasilense* strains; indeed, in addition to the aforementioned pathways, several aromatic ring-hydroxylating dioxygenases could be identified. Whether this versatility is related to the composition of the host plant exudates and is a result of niche-specific adaptation remains to be elucidated.

25.1.5.3 Response to Stress and Iron Acquisition. *Azospirillum* must cope with reactive oxygen species (ROS) produced by plants, as a defense mechanism against both pathogenic and symbiotic bacteria (Lamb and Dixon, 1997; Santos et al., 2001). Comparative genomic analysis shows that next to common mechanisms, several enzymes involved in the oxidative stress response differ among *Azospirillum* species. A gene encoding a superoxide dismutase (SodA) is found uniquely in *A. brasilense* strains, whereas a gene encoding a catalase is present in *A. lipoferum* 4B and in *Azospirillum* sp. B510. Moreover, a bifunctional catalase-peroxidase (KatG) is only found in *A. lipoferum* 4B and displays 80% identity with KatG of *Rhizobium etli*, known to play a role in survival during stationary phase (Vargas et al., 2003). The genome of *Azospirillum* sp. B510 also harbors extra genes encoding glutathione-*S*-transferases, two being classified as HGT (AZL_014610 and AZL_e01570); such enzymes can detoxify a large variety of compounds by covalent linking of glutathione to hydrophobic substrates (Vuilleumier and Pagni, 2002). Having endophytic properties, this strain can be more exposed to plant secondary metabolites and such enzymes could confer the ability to cope with those compounds.

Several open reading frames (ORF)s in all four *Azospirillum* sequenced genomes have been annotated as laccase-like. Laccases- or laccase-like multicopper oxidases (EC 1.10.3.2) catalyze the oxidation of various substrates, such as phenols, diamines, and metals, coupled with the reduction of molecular oxygen to water. Bacterial laccases are involved in various functions such as copper resistance,

manganese oxidation, pigmentation, oxidation of toxic compounds, and destruction of ROS and are considered as an advantageous trait for a rhizosphere bacterium (Sharma et al., 2007). However, only one ORF (AZOLI_p30139 in *A. lipoferum* 4B and AZL_c02540 in *Azospirillum* sp. B510) possesses two typical copper-binding motifs (Kellner et al., 2008). Interestingly, the first report of a prokaryotic laccase is from *A. lipoferum* 4B (Givaudan et al., 1993), where it was shown to play a role in melanization and utilization of plant phenolic compounds (Faure et al., 1994). Moreover, laccase-positive strains are less sensitive to the inhibitory action of quinone analogs due to rearrangements of their respiratory chain, a feature that might be a competitive advantage in the rhizosphere in the presence of quinone compounds (Alexandre et al., 1999).

Discrepancies between *Azospirillum* strains are observed for iron acquisition, at the level of siderophore biosynthesis and uptake, and could be relevant as plant colonization ability is linked to iron acquisition systems (Molina et al., 2005). A 14 kb region, predicted to be involved in pyochelin biosynthesis, appeared to be exclusively present in the *A. lipoferum* 4B genome. The corresponding genes, classified as HGT, show protein identity levels greater than 45% and a high degree of synteny with those of the strain *Pseudomonas fluorescens* Pf-5. A cluster of genes involved in enterobactin biosynthesis was specifically found in the two *A. brasilense* strains (Sp245 and CBG497).

25.1.5.4 Type VI Secretion System. Components of a type VI secretion system (T6SS) have been identified in the four assembled published genomes and classified as HGT; however, the T6SS components display discrepancies among strains (Wisniewski-Dyé et al., 2011; 2012). T6SS are involved in a broad variety of bacterial functions: pathogenesis (by delivering effectors to target eukaryotic cells), biofilm formation, stress sensing, and toxicity toward other bacteria (Bernard et al., 2010; MacIntyre et al., 2010). Upregulation of *A. brasilense* Sp245 T6SS genes in response to exposure to IAA, as could happen in the rhizosphere, is in favor of a role in plant–bacteria interactions (Van Puyvelde et al., 2011).

25.2 CONCLUDING REMARKS

The availability of *Azospirillum* and host plant genomes offers new perspectives; indeed, transcriptome and functional analyses can now be carried out in order to characterize key genetic determinants involved in the *Azospirillum*–plant association and to elucidate the molecular bases underlying its specificity. Furthermore, the access to new *Azospirillum* genomes should provide important clues to evolutionary dynamics and events that lead to specific adaptation to a host plant.

26.1 INTRODUCTION

The species concept is challenged by genomes of certain bacterial species: in fact, in many cases the genomic variability at the level of many bacterial species has led to a new definition of the so-called "pangenome" (Medini et al., 2005). In particular, the pangenome of a species is composed of a "core" fraction conserved in all the strains and a "dispensable" fraction present only in a strain(s) subset; the dispensable genome can be additionally divided into "accessory" and "unique," the latter comprising of only the single strain-specific genomic regions. In most bacterial species, the dispensable genome has a size comparable to the core fraction, thus complicating the definition of the bacterial species (Gogarten and Townsend, 2005; Kislyuk et al., 2011). The genes encoded by the dispensable genome fraction are thought to account for the adaptation of each strain to different niches and are most likely being originated by relatively recent horizontal gene transfer (HGT) events (Medini et al., 2008).

The ratio between the core and dispensable fraction in the pangenome of a species is also useful in determining the lifestyle(s) of that species. In fact, pangenomes can be classified either as "open" or "closed" by looking at the pangenome growth curve; "open" pangenomes have virtually no upper limit to the number of genes in the pangenome, while for "closed" pangenomes this limit is reached within a limited number of strains. Open pangenomes belong to species able to live in different ecological niches and being more exposed to HGT events. On the contrary the closed pangenomes are typical of pathogens and obligate symbionts (Tettelin et al., 2008). The pangenome broad structure is therefore useful in determining the general lifestyle of a species without the need to look at gene annotations.

Another important factor for the determination of a species lifestyle is the presence of additional replicons

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

other than the chromosome. In fact, many bacterial species possess additional replicons with sizes comparable to the chromosome, called "megaplasmids"; a particular kind of megaplasmids, harboring core genes and having plasmid-like partitioning systems, have been recently defined as "chromids," showing that they are genera-specific elements, whereas the megaplasmids, being more recent in evolutionary terms, may be used to define the species boundary inside genera (Harrison et al., 2010;). In many bacterial species it has been shown that megaplasmids and chromids have rather specific functional signatures, such as the symbiotic megaplasmids in rhizobial species harboring most of the genes needed for an effective symbiosis (Barnett et al., 2001; Reeve et al., 2010), their presence being therefore strongly related with the species lifestyle. The yet unknown role of the different replicons (chromosome, chromids and megaplasmids) in the microevolution of bacterial species has been recently elucidated in *Sinorhizobium meliloti* in two distinct studies (Epstein et al., 2012; Galardini et al., 2013). This alphaproteobacterium is a nitrogen fixer symbiont of *Medicago* plants and has been an ideal model system to understand bacterial microevolution and the role of each replicon in intraspecies differentiation. From an ecological point of view, *S. meliloti* is found as a free-living organism in temperate soils around the globe, as a symbiont in root nodules of *Medicago* plants, and as an endophyte in several plant species (Chi et al., 2005; Pini et al., 2012). The genome of the *S. meliloti* type strain Rm1021, the first to be sequenced, possesses a chromosome, a chromid (pSymB), and a megaplasmid (pSymA) (Galibert et al., 2001); the pSymA megaplasmid contains most of the genes needed to establish an effective symbiosis and other genes related to nitrogen metabolism (Barnett et al., 2001), while the pSymB chromid is mostly deputed to support the saprophytic phenotype of the species in the soil environment and it contains many important core genes; for this reason it has been classified as a chromid (Finan et al., 2001; Harrison et al., 2010). Such functional diversification has been found appropriate also in other sequenced *S. meliloti* strains (Galardini et al., 2011; Schneiker-Bekel et al., 2011); moreover, the presence of conserved core genes on the pSymB chromid leads to the hypothesis that the chromosome and the pSymB chromid may be genus specific and relative more ancient than the megaplasmid pSymA, which may be selected during strain differentiation.

This chapter discusses the recent findings on the pangenome of the *S. meliloti* species, focusing not only on the core/dispensable fraction in the whole pangenome, but also on their role in each replicon in the context of species microevolution (Epstein et al., 2012; Galardini et al., 2013; Sugawara et al., 2013).

26.2 THE OPEN PANGENOME OF *S.meliloti* AGREES WITH THE SPECIES LIFESTYLE

The pangenome of a panel of 14 *S. meliloti* strains has been recently analyzed in a study aimed at determining whether the pangenome of this species was open or closed (Galardini et al., 2013). The general features of these *S. meliloti* genomes are outlined in Table 26.1: the overall genome size varies across the strains, from the 6.69 Mb of strain Rm1021 to the 8.94 Mb of strain 5A14, while the GC content shows a lower variability, ranging from 61.3% in strain Rm1021 to 62.0% in strains 5A14, AE608H and BL225C. The gene density appears to be conserved as well across the strains, even though with a higher variability, ranging from 82.53% in strain AK83 to 86.40% in strain SM11.

As expected, the pangenome of the *S. meliloti* species is open, in accordance to the species free-living and in association with plants either through symbiosis or endophytism lifestyles. The pangenome rarefaction curve (Fig. 26.1) suggests that the dispensable genome size increases with an almost constant rate with the addition of new genomes to the dataset, while the core genome size decreases with a slower rate: in particular, the accessory component of the dispensable genome grows faster than the unique component.

The pangenome of other 33 *S. meliloti* strains has also been determined recently, showing a relatively similar core genome size (4680 OGs, against the 3989 found in the 14

strains analysis) and also a similar variability in the unique genome size for each strain (varying from 25 to 840 OGs) (Sugawara et al., 2013); the pangenome rarefaction curve has not been computed for these strains, but the similar size of the core and unique genome suggests that it may be similar to the one computed for the other 14 strains.

26.3 REPLICON DIVERSITY: THE CHROMID HAS AN IMPORTANT ROLE IN INTRASPECIES DIFFERENTIATION

Both the pSymB chromid and the pSymA megaplasmid have a higher genetic diversity in the *S. meliloti* pangenome than the chromosome. This feature has been observed when comparing 24 *S. meliloti* strains against the reference genome of strain Rm1021, where the average nucleotide diversity is found to be 6.1 and 3.6 times greater than the one observed in the chromosome for the pSymA megaplasmid and for the pSymB chromid, respectively. As expected, the chromosome is found to be the most conserved replicon at the nucleotide level, but with two distinct levels of nucleotide conservation, higher for the first half of the replicon (from the origin to the replication terminus) and lower for the second half. This lower nucleotide variability among the analyzed strains may be related to a putative selective sweep on the second half of the chromosome (Epstein et al., 2012). This finding suggests that the chromosome controls the genetic hitchhiking (at least on part of the replicon), thus reducing intraspecies variability and ensuring a more strictly vertical inheritance.

Given the stability of the chromosome, the question of which replicon contributes the most to intraspecies differentiation remains open for either the pSymA megaplasmid or the pSymB chromid. To answer this question, the core and dispensable genome fractions analyzed by Galardini and colleagues (Galardini et al., 2013) were divided according to the replicon of origin. The genome structure of each strain was estimated by mapping the draft contigs against the complete genomes. As indicated in Table 26.2, in all the draft genomes the replicon sizes were conserved; the replicon-specific dendrograms suggest that the pSymB chromid may be the replicon that most contributes to the intraspecies differentiation in *S. meliloti*, in both the core and accessory pangenome fractions, showing the highest number of clusters (Fig. 26.2).

On the other hand, the pSymA megaplasmid shows the same strain composition in each genome fraction, showing also geographical clusterization for some strains; both findings suggest a more recent evolutionary origin for this replicon.

26.4 ANCIENT VERSUS RECENT: DIFFERENT TIMING OF HGT EVENTS

Genes in the *S. meliloti* pangenome show different taxonomic homologies with respect to their replicon of origin. When looking at the similarity with other bacterial species from different phyla, genes from the pSymB chromid appear to have a bigger homology signal to proteins belonging to β and γ *proteobacteria* classes than genes belonging to the chromosome and the pSymA megaplasmid (Fig. 26.3).

Table 26.2 Real and estimated replicons size (in Megabases) in the 14 *S. meliloti* strains

Not mapped	0.08	0.16	0.50	0.30	0.28	0.15	0.27	0.40	0.36	0.25	—	—	—	—

The replicons of strains Rm1021, AK83, BL225C and SM11 are known from their complete genomic sequence, while for the other strains the average mapped bases to each replicon of the four complete genomes are indicated.

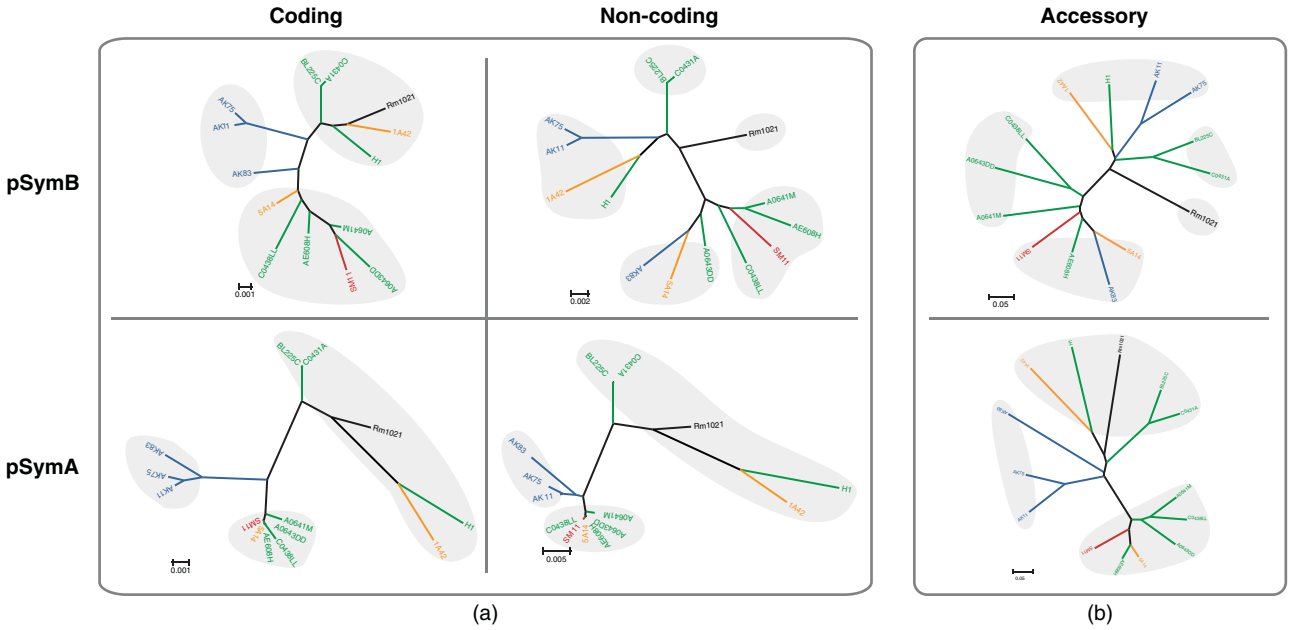

Figure 26.2 Dendrograms of the pangenome content with respect to the pSymB chromid and the pSymA megaplasmid.

Genes belonging to the pSymB chromid have higher phylogenetic similarities than the other replicons also for the phyla *Actinobacteria*, *Bacteroidetes*, *Chloroflexi*, *Cyanobacteria*, *Fibrobacteres,* and *Firmicutes* (Galardini et al., 2013). This broad range of phylogenetic similarities of chromid genes may indicate that a significant fraction of the pSymB chromid has originated by relatively ancient HGT events and may therefore have contributed to the emergence of a new taxa such as the *Sinorhizobium* genus (Harrison et al., 2010).

On the other hand, more recent HGT events with the near *Sinorhizobium medicae* species are more common on the pSymA megaplasmid (77.3% of all the predicted HGT events), while the chromosome shows only one gene transferred through HGT, thus confirming the selective control on this replicon (Epstein et al., 2012). Moreover, many of the genes being transferred through HGT between *S. meliloti* and *S. medicae* are grouped in clusters, confirming that megaplasmid pSymA evolutionary history may be mainly due to recent gene transfer events.

26.5 REPLICON-SPECIFIC FEATURES OF THE *S.meliloti* PANGENOME

Each replicon of the *S. meliloti* pangenome (partially) acts as an independent evolutionary unit and has a distinct role in both functional and evolutionary aspects. In particular, the chromosome is mainly composed by core genes with a limited variability between strains and whose function is mostly related to housekeeping functions; the lower variability and low number of HGT events (both from/to distant taxa and near species) indicate that this replicon

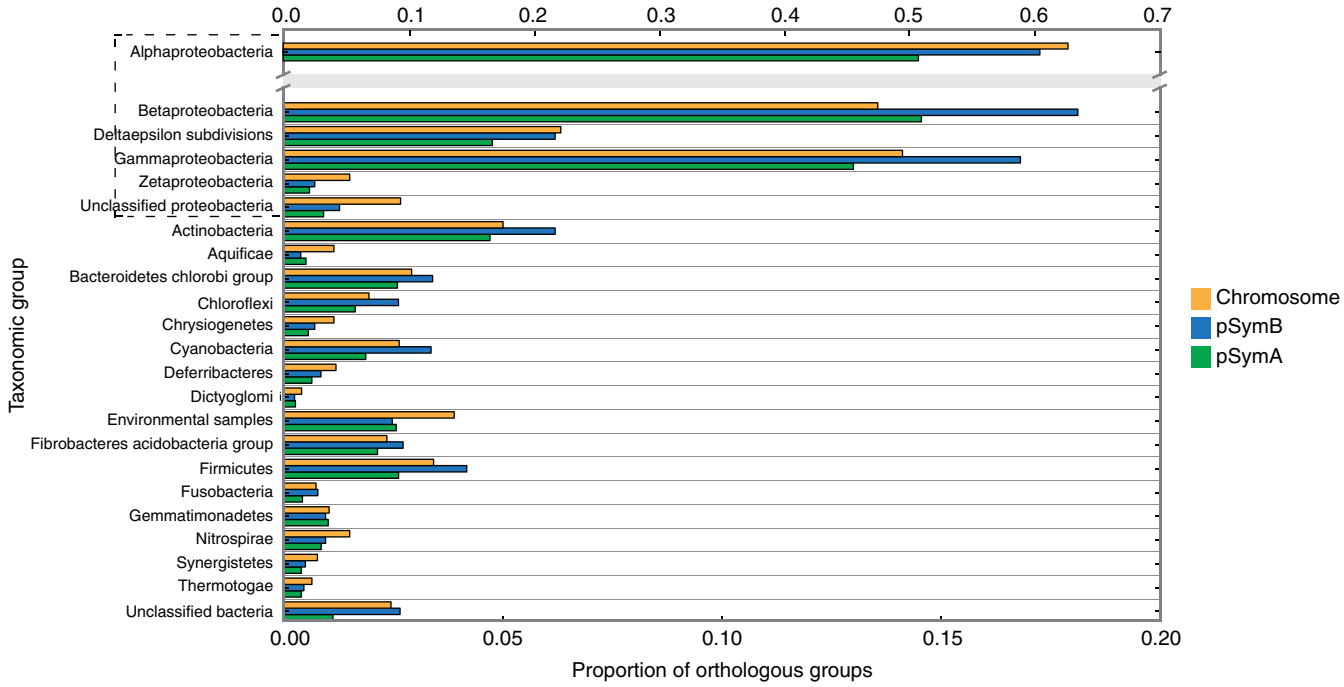

Figure 26.3 Taxonomic distribution of OGs belonging to different replicons.

evolves mostly through vertical inheritance. The pSymA megaplasmid harbors most of the genes needed to establish an efficient symbiosis (Barnett et al., 2001) and contains mostly dispensable genes; the similar phylogenetic pattern observed for both core and dispensable genes suggests that most of the gene content of this replicon may have originated by relatively recent HGT events, a feature confirmed by the higher number of genes transferred from/to *S. medicae* than the other replicons. Unexpectedly, the role of the pSymB chromid appears to be related to species differentiation; whether this role is found also in other species or at other taxonomical levels is unknown and yet to be established. The higher homology of its genes to distant bacterial taxa, compared to the other replicons, indicates that this replicon most probably has originated by relatively ancient HGT events that may be at the root of the genus *Sinorhizobium*.

26.6 CONCLUSIONS AND FUTURE PERSPECTIVES

The traditional view of bacterial genomes, composed by one chromosome and optionally several small plasmids does not take into account many bacterial species, often associated with multiple diverse lifestyles, such as the facultative plant symbiont *S. meliloti*. The peculiar characteristics of each of the three *S. meliloti* replicons have been analyzed for their functional features (Barnett et al., 2001; Finan et al., 2001; Harrison et al., 2010). However, until recently, the analysis of the evolutionary and phylogenetic role of each replicon has been missing. Here, we have discussed recent studies showing that the chromosome is the most conserved replicon of the *S. meliloti*, while the pSymA megaplasmid has a higher variability but a phylogenetic coherence between core and dispensable fraction that suggests recent HGT events; on the contrary, the pSymB chromid appears to drive the intraspecies differentiation and may originate at the *genus* level from ancient HGT events.

These replicon-dependent features of the *S. meliloti* species may also be shared by other bacterial species with open pangenomes and multipartite genomes, which are very common among rhizobial species. Similar studies on different species may confirm these observations and open the way to the definition of new rules describing the evolution of complex bacterial genomes, with the chromosome as a stable "container" of core functions, the chromid as an important source of genus-specific functions and intraspecies variants, and the megaplasmid as a fluid container of specific functions related to lifestyles.

27.1 INTRODUCTION

The advent of next-generation sequencing (NGS) technology has recently boosted the number of genome sequencing projects publicly available (Pagani et al., 2012). This trend is also observed in the *Rhizobiales,* an order of the *Alphaproteobacteria*-containing bacteria of contrasting ecologies and lifestyles. They exhibit a wide range of genome sizes, ranging from <1.2 to >8.8 Mb. Different genome architectures can be found among the *Rhizobiales*. Some contain large megaplasmids >1.5 Mb, which carry essential core genes such as chromosomes, but replicate via repABC-like systems (Landeta et al., 2011). The term "chromid" has been suggested for this type of replicons (Harrison et al., 2010). Others carry secondary linear chromosomes that show lower proportion of shared genes and lower levels of synteny (Slater et al., 2009). The lifestyles of these bacteria comprise facultative intracellular vertebrate pathogens (*Brucella*, *Bartonella*), facultative N2-fixing root-nodule bacteria or plant pathogens (*Agrobacterium*, *Azorhizobium*, *Bradyrhizobium*, *Rhizobium*, *Mesorhizobium*, *Sinorhizobium*), photosynthetic bacteria such as *Rhodopseudomonas*, or methylotrophs such as *Methylobacterium*, to mention but a few. Many of these bacteria establish long-term, often chronic infections of hosts, ranging from pericellular colonization (*Agrobacterium*) to facultative intracellular multiplication such as root nodule bacteria (rhizobia) or *Brucella* spp. (Batut et al., 2004). Therefore, these bacteria represent an ecologically and genomically heterogeneous group of organisms exhibiting an abundance of adaptations (Ettema and Andersson, 2009). For example, *Rhodopseudomonas palustris* has the ability to switch between the four different modes of metabolism that support life: photoautotrophic, photoheterotrophic, chemoautotrophic, and chemoheterotrophic (Larimer et al., 2004). Other genomes, such as those of the *Bartonellaceae*, are small and show limited metabolic diversity. They show evidence of genome reduction as an adaptation to host-associated intracellular lifestyles (Sallstrom and Andersson, 2005). The abundance of whole genome sequence data currently available for the *Rhizobiales* represents a powerful resource for comparative genomics to study the evolution of host–microbe interactions and niche adaptation.

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

A fundamental necessity for such studies is the inference of orthology relationships among the proteomes under analysis (Fitch, 1970; Koonin, 2005; Sonnhammer and Koonin, 2002). The correct inference of orthologous groups is critical in phylogenetic reconstruction, genome annotation, structural genomics, and experimental target selection, among others. Orthologous genes have diverged from their common ancestors by a speciation event and tend to maintain their functionality across large evolutionary distances, while paralogs tend to diverge over time via sub-functionalization or neo-functionalization pathways, thus acquiring new functions (Koonin, 2005). Xenology is the homology relationship resulting from horizontal gene transfer (HGT), which is a major force driving genome evolution in microbes (Gogarten and Townsend, 2005; Treangen and Rocha, 2011). Many microbial species, both eukaryotic and prokaryotic, have a mosaic genome structure, consisting of conserved syntenic regions alternating with highly divergent genomic islands acquired by HGT (Dobrindt et al., 2004; Rolland et al., 2009; Welch et al., 2002; see Chapters 25, 26), which generally insert into the recipient genome via site-specific recombination. A well-characterized island in the *Rhizobiales* is the symbiotic island of *M. loti* (Sullivan et al., 1995; Sullivan and Ronson, 1998; see Chapter 21). It was the seminal comparative genomics work of Tettelin and colleagues on multiple *Streptococcus agalactiae* strains (Tettelin et al., 2005) that revealed that this species "can be described by a pangenome consisting of a core genome shared by all isolates, accounting for approximately 80% of any single genome, plus a dispensable genome consisting of partially shared and strain-specific genes". A similar pangenome structure has been observed in many other bacterial groups, making the terms core- and pangenome common in microbial comparative gemonics (Koonin and Wolf, 2008; Medini et al., 2005; Rasko et al., 2008). The core genome genes generally encode essential genes of the central metabolism, replication, transcription and translation machinery, as well as DNA recombination and repair functions. Orthologous core genome genes are the most suitable for inferring species phylogenies or estimating population genetics parameters, as they convey the information of speciation events, tend to be selectively neutral, and are less prone to HGT (Vinuesa, 2010). Genes in the dispensable genome are frequently found associated with mobile genetic elements and often encode key adaptive traits for specific niches or habitats, defining the unique phenotypic attributes of particular groups of strains (Gogarten and Townsend, 2005; Medini et al., 2005; Tettelin et al., 2008; Galardini et al., 2011; Rasko et al., 2008; see Chapter 25).

We have recently developed a computationally efficient, versatile, and user-friendly bioinformatic pipeline for microbial pangenomics and comparative genomics, which we refer to as "GET_HOMOLOGUES" (Contreras-Moreira and Vinuesa, 2013). In this chapter we illustrate some of its features by performing several pangenomic analyses on 68 representative and completely sequenced *Rhizobiales*. We first compute robust consensus core- and pangenome sets of homologous gene families and estimate the size of these genome fractions. Whole genome phylogenies are inferred on the basis of either the conserved core genome, or the pangenome phylogeny, based on the presence–absence matrix of homologous gene families across genomes. The results are discussed in broad genomic, ecological, and evolutionary contexts.

27.2 METHODS

GET_HOMOLOGUES is an open source software package released under the GNU license, written in Perl (http://www.perl.org/), and R (R Development Core Team, 2012) for the automatic, customizable, and efficient computation of clusters of homologous gene families and downstream pangenomic and comparative genomics analyses on UNIX and Linux machines. It builds upon popular orthology-calling approaches based on heuristic pair-wise best-match methods (Altenhoff and Dessimoz, 2012; Kristensen et al., 2011). The input sequences can be either in FASTA (proteomes) or GenBank formats. Sequences are automatically extracted and the proteomes subjected to pair-wise BLAST+ (Camacho et al., 2009) analysis. The main script *get_homologues.pl* can cluster BLAST results using our own implementation of the bidirectional best-hit (BDBH) algorithm (Overbeek et al., 1999; Tatusov et al., 1997), or by calling the COGtriangles (Kristensen et al., 2010) or OrthoMCL (OMCL) (Li et al., 2003) clustering algorithms. Table 27.1 provides a short description of the main features of these algorithms.

The stringency of the resulting clusters of homologous proteins can be fine-tuned by controlling certain parameters such as E-value cut-off, pair-wise alignment coverage cut-off, and/or by scanning the Pfam (Finn et al., 2008) domain composition of proteins using hmmscan from the HMMER3 package (Eddy, 2009). A unique feature of GET_HOMOLOGUES is that clusters of homologous gene families can be made very robust by computing consensus clusters from those generated by any combination of the clustering algorithms and filtering criteria mentioned above. Several auxiliary scripts are provided to download selected genomes from NCBI and extract sequences in FASTA format (*download_genomes_NCBI.pl*), compare, filter and interrogate clusters of homologous sequences (*compare_clusters.pl*), compute and graphically display the core and pangenome sets, and perform comparative genomics analyses and (*plot_pancore_matrix.pl* and *parse_pangenome_matrix.pl*). The exponential (Tettelin et al., 2005) and binomial mixture models (Snipen et al., 2009) can be fitted to the data to estimate theoretical core and pangenome sizes, and high quality graphics

Table 27.1 Description of the clustering algorithms implemented in GET_HOMOLOGUES

Algorithm	Description
BDBH	Starting from a reference genome, keep adding genomes stepwise while storing the sequence clusters that result of merging the latest bidirectional best hits.
COGtriangle	Merges triangles of intergenomic symmetrical best matches, as described in (Kristensen et al., 2010). Note that a single sequence might occasionally be included in several COGS clusters with option −x.
OMCL	OrthoMCL v1.4, uses the Markov Cluster Algorithm to group sequences, with inflation (−F) controlling cluster granularity, as described in Li et al. (2003).

generated by calling R functions. Pangenome trees can be computed from pangenomic presence–absence data using the parsimony optimality criterion as implemented in pars from the PHYLIP package (Felsenstein, 2004). Basic comparative genomics analyses can be performed to identify lineage-specific genes or gene family expansions. The software is designed to take advantage of modern multiprocessor personal computers or servers, as well as computer clusters running the open source batch-queuing system Grid Engine, to parallelize time-consuming BLAST and hmmscan runs. Large genome sets can be analyzed even on machines with modest RAM resources (<10 GB) by invoking the BerkeleyDB option, which trades RAM usage for CPU usage, and/or by invoking a heuristic BDBH version that minimizes the number of BLAST searches between proteomes (Contreras-Moreira and Vinuesa, 2013). The clusters of homologous gene families are output in standard multi-FASTA format, or in an extended OrthoXML format (Schmitt et al., 2011), to facilitate exchange of orthologous sequence data, in compliance with recent community standards (Dessimoz et al., 2012). The software package is available for 32 and 64 bit processors on Linux and Mac OS X machines. It includes a user manual with detailed hands-on tutorials, and an installation script that checks for optional software dependencies and guides the user on how to proceed to install them. This script also supports downloading and formatting the current version of Pfam. The latest version of the package can be downloaded at http://www.eead.csic.es/compbio/soft/gethoms.php and http://maya.ccg.unam.mx/soft/gethoms.php.

27.3 RESULTS AND DISCUSSION

27.3.1 Computation, Graphical Display, and Statistical Analysis of the Core and Pangenome of 68 *Rhizobiales*

A total of 68 genomes of the *Rhizobiales* were downloaded from GenBank's FTP site using the auxiliary script *download_genomes_NCBI.pl*, bundled with the GET_HOMOLOGUES package. The main script *get_homologues.pl* was called under default settings BlastP Expectation value: −E 0.00001; alignment coverage: −C 75; reporting all clusters: −t 0, OMCL inflation parameter: −F 1.5] to compute families of homologous gene sequences with each of the three clustering methods implemented in GET_HOMOLOGUES (Table 27.1). As summarized by the Venn analysis shown in Figure 27.1a, each clustering method produced notoriously different results, as expected from their algorithmic differences, some of which are explained below. A unique feature of GET_HOMOLOGUES is the possibility to compute consensus clusters, that is, to filter out those families consistently recovered by all or any combination of the three clustering methods (Table 27.1). Such clusters are therefore very robust, although highly conservative. In the analysis presented in Figure 27.1a, a consensus core-genome consisting of 323 gene families was computed out of the intersection of the three algorithms for the 68 *Rhizobiales* genomes analyzed. Note that the COGtriangles method computes the largest set of unique clusters (Fig. 27.1a). This is due to the fact that many of them are singletons, that is, clusters containing less than three members. By definition, the COGtriangles algorithm requires at least three proteins in different species to form a cluster (Kristensen et al., 2010; Tatusov et al., 1997). On the other extreme, the BDBH algorithm produced the lowest number of unique clusters. This is expected since BDBH has the limitation of requiring the presence of a homologous sequence in the reference genome to consider the cluster (Contreras-Moreira and Vinuesa, 2013).

This type of consensus analysis can also be applied for the pangenome. We computed an intersection of 14,297 clusters out of those generated by the COGtriangles and OMCL algorithms (Fig. 27.1b). These do not require a reference genome, as opposed to the BDBH algorithm, and hence are better suited for pangenome analyses than the latter. These core- and pangenome consensus clusters were generated using the auxiliary script *compare_clusters.pl* from the output generated by *get_homologues.pl*. The former script also generates the Venn analysis and diagrams depicted in Figure 27.1a and b.

Exponential decay or binomial mixture models can be fitted to the core-genome cluster data with the aid of the auxiliary script *plot_pancore_matrix.pl* based on the core_genome.tab matrix files generated by *get_homologues.pl*.

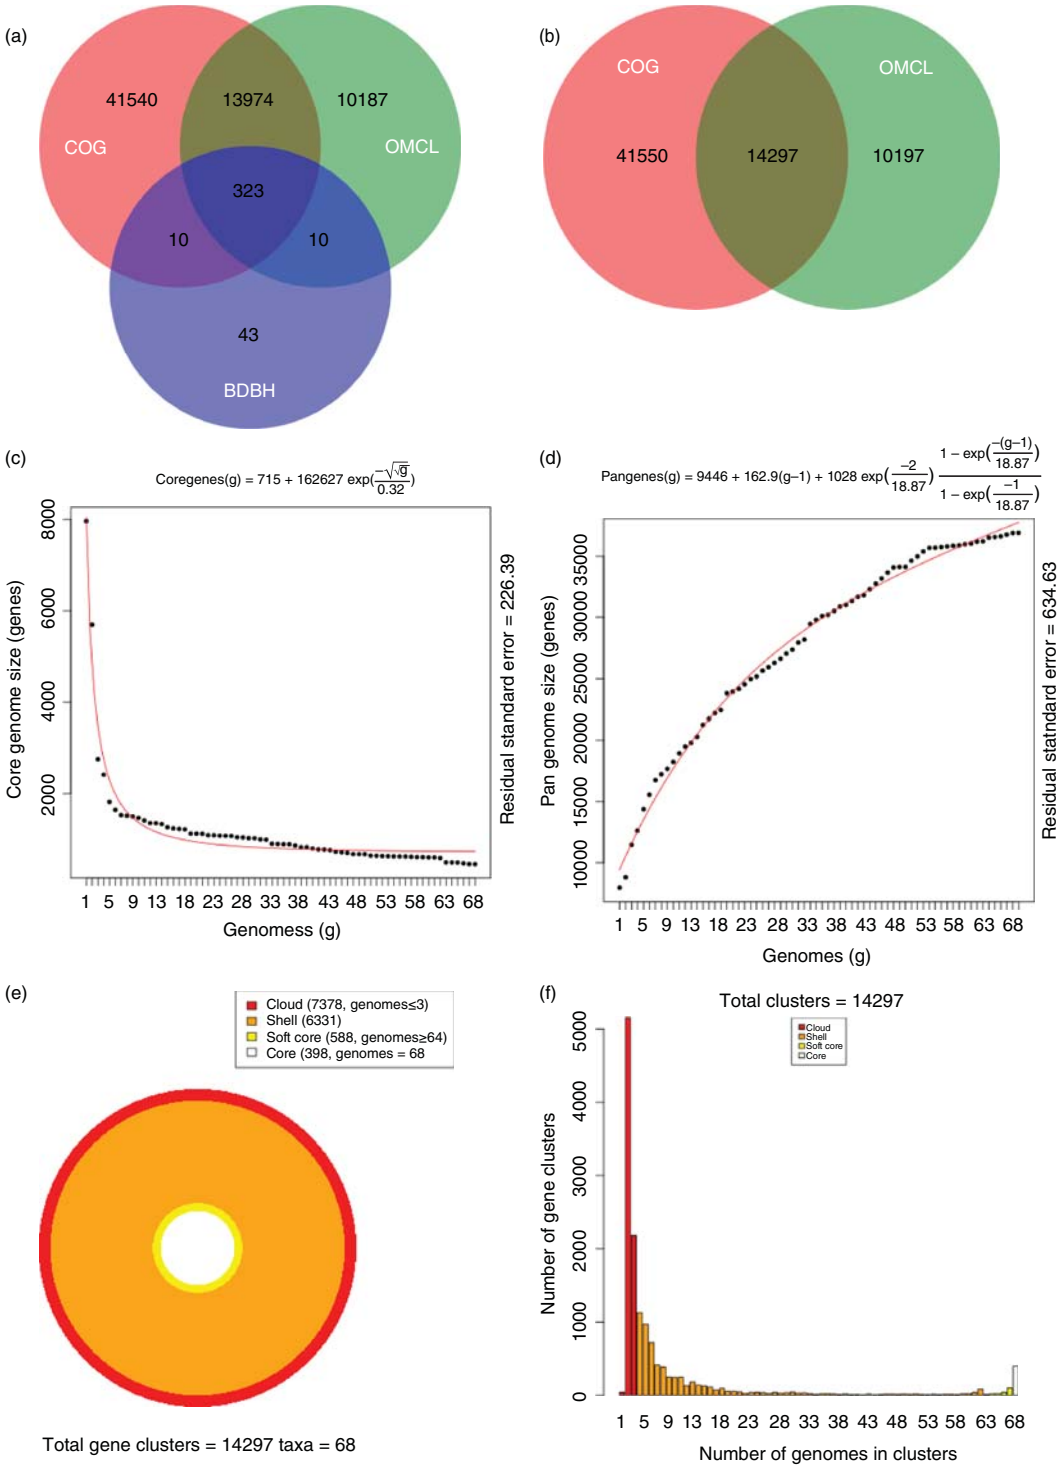

Figure 27.1 Pangenome analysis of 68 fully sequenced *Rhizobiales* genomes. (a) Venn analysis of the clusters generated by the BDBH, COGtriangles, and OrthoMCL algorithms for BLASTP results with E-value <10E − 5 and alignment coverage >75%. This produces an empirical consensus core-genome of 323 gene families. (b) Venn analysis of the clusters generated by the COGtriangles and OrthoMCL, which results in a consensus pangenome of 14,297 homologous gene families. (c) Theoretical estimation of the core-genome size of the *Rhizobiales* based on a Willenbrock model fit to OrthoMCL clusters, resulting in 715 gene families. (d) Tettelin fit to OrthoMCL clusters to estimate the size of the *Rhizobiales* pan-genome. (e) Circle plot of the observed sizes of the core, soft core, shell, and cloud genome fractions. (f) Distribution of cluster sizes as a function of the number of genomes they contain.

Figure 27.1c shows the plot of the exponential decay model of Willenbrock (Willenbrock et al., 2007) fitted to the core genome data for the OMCL algorithm. Notice that this function predicts a theoretical core genome with a size of 715 genes, which doubles the strict core size estimate made by the intersection of the three algorithms. This result highlights the complexities associated with theoretical core- and pangenome size estimations. The *plot_pancore_matrix.pl* script can also plot pangenome curves fitted with the exponential model proposed by Tettelin and colleagues (Tettelin et al., 2005). This analysis, run on the OMCL clusters, predicts that the theoretical pangenome of the *Rhizobiales* contains $\gg$40,000 genes, with $\sim$163 new genes being added on average to its pangenome with each new genome sequenced for bacteria from this order (Fig. 27.1d).

The auxiliary script *parse_pangenome_matrix.pl* is useful for both pangenome and basic comparative genomics analyses. Figure 27.1e shows a circle-plot showing the relative sizes of the strict and soft core-genomes, the shell-genome, and the cloud-genome compartments, as computed from the consensus clusters derived from the COGtriangles and OMCL algorithms. The soft-core is arbitrarily defined as the genes present in 95% or more of the genomes analyzed, as previously suggested by Kaas and colleagues (Kaas et al., 2012). The definition of a soft core genome is useful to get more robust core estimates when the dataset includes draft genomes, since those will, by necessity, miss some genes entirely, or contain truncated genes at the contig or scaffold ends. In our case study, 588 gene families were found in 64 or more genomes. The shell genome contains 6331 clusters present in >3 and <64 genomes. Finally, the most abundant class is that conformed by the so-called cloud genome, containing 7378 clusters in three or less genomes. Figure 27.1f shows the distribution of numbers of gene families as a function of their presence in 1–68 genomes. Such a distribution of the prokaryotic gene space was already observed in many other studies dealing with bacterial genomes at different levels of taxonomic depth, in which a minuscule fraction of genes is highly conserved in their phyletic distribution, while a much larger fraction (an order of magnitude in this case study of 68 *Rhizobiales*) is moderately conserved, and an even greater number of clusters is rarely encountered. In their seminal review on bacterial and archaeal genomics, Koonin and Wolf defined these components of prokaryotic gene space as the core, shell, and cloud compartments, respectively (Koonin and Wolf, 2008), which can be best described as the sum of three exponential decay functions. GET_HOMOLOGUES defines these compartments empirically, as follows: *Core* – genes contained in all considered genomes/taxa. *Soft core* – genes contained in 95% of the considered genomes/taxa, as in the work of Kaas and collaborators (Kaas et al., 2012). *Cloud* – genes present only in a few genomes/taxa. The cutoff was defined as the most populated non-core cluster class and its immediate neighboring classes. *Shell* – remaining genes, present in several genomes/taxa.

Snipen and colleagues criticized the use of exponential functions to estimate the sizes of the core and pangenomes (Snipen et al., 2009). This criticism stems from the fact that such models assume that the pangenome is composed of two types or classes of genes according to their phyletic distribution: a set of conserved core genes and a much larger set of dispensable genes. They extended the binomial mixture model originally proposed by Hogg and colleagues (Hogg et al., 2007), and found that for all genome sets analyzed in their study, the optimal mixture model has at least three components (Snipen et al., 2009). This is clearly in line with the above-mentioned study of Koonin and Wolf (Koonin and Wolf, 2008) and the results presented in Figure 27.1f. Such binomial mixture models are implemented in the *parse_pangenome_matrix.pl* script. The Bayesian information criterion indicates that for the 68 *Rhizobiales* dataset the optimal number of components for the mixture model is 8, producing an estimate of a theoretical core genome of size 270 and a pangenome of size 14,847 (Table 27.2).

Table 27.2 Binomial mixture model estimates of theoretical core- and pangenome sizes based on the consensus clusters generated by the COGtriangles and OrthoMCL algorithms

No. of Components	Core Size	Pan Size	BIC	Log Likelihood
2	402	14,300	256,835.864570013	−128,403.5805775
3	397	14,402	112,809.978810426	−56,381.0698927027
4	402	14,636	87,755.4665386494	−43,844.2459518106
5	397	14,765	81,400.9034621089	−40,657.3966085363
6	398	14,788	79,675.520958282	−39,785.1375516189
7	285	14,791	79,294.4986777406	−39,585.0586063441
8	**270**	**14,847**	**78,892.9034020882**	**−39,374.6931635139**
9	236	14,845	78,961.3328191793	−39,399.3400670554
10	262	14,838	78,916.2721469761	−39,367.2419259498

The row highlighted in bold indicates the best mixture model estimate, which corresponds to that with the lowest Bayesian information criterion value (BIC).

Particularly the estimate of the pangenome size seems too conservative when compared with the empirical observation of 14,297 consensus families estimated from the intersection of the COGtriangles and OMCL algorithms (Fig. 27.1b). However, the mixture model analysis and that presented in Figure 27.1e and f clearly show that the pangenome of the *Rhizobiales* has more than just two general categories of genes.

27.3.2 Phylogenomics of the *Rhizobiales* Based on a Supermatrix of the Core Genome

An important application of the consensus core genome clusters of orthologous gene families is their use in the phylogeny estimation of the order *Rhizobiales*. Each of the 323 families of the strict consensus core contains 68 sequences, one from each genome. These single copy orthologous gene families were individually aligned using muscle (Edgar, 2004) and the resulting alignments concatenated. The resulting supermatrix was then subjected to maximum likelihood phylogeny estimation using PhyML 3.0 (Guindon et al., 2010) under the LG model, with among-site rate variation estimated by fitting a gamma distribution with five rate classes, and empirical amino acid frequencies estimated from the data. The resulting core genome phylogeny for 68 *Rhizobiales* with midpoint rooting is shown in Figure 27.2.

Notice the high resolution of the phylogenetic hypothesis, as most bipartitions have Shimodaria-Hasegawa-like support values of 1. Two major clades are observed based on

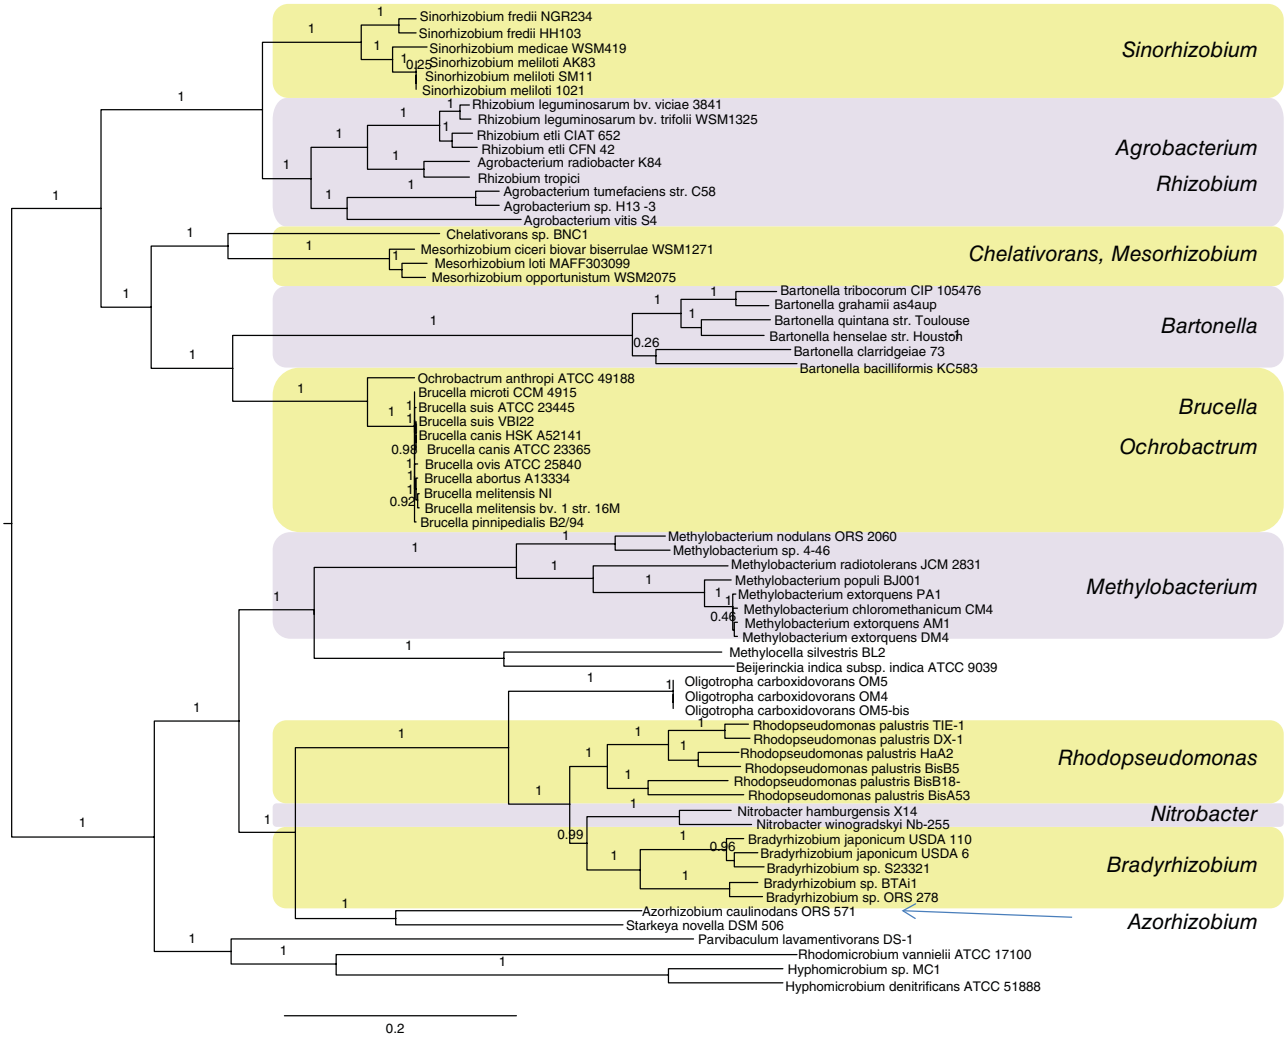

Figure 27.2 Phylogenomic analysis of the *Rhizobiales* based on a supermatrix of 323 consensus clusters of single copy orthologous genes derived from the intersection of the BDBH, COGtriangles, and OrthoMLC results. The phylogeny was estimated under the maximum likelihood criterion using the LG + G model with empirically estimated amino acid frequencies and rooted using midpoint rooting. The scale represents the estimated number of substitutions per site. Numbers on tree bipartitions indicate the Shimodaria-Hasegawa-like support values.

the midpoint rooting, which is consistent with the topology of a large genomic phylogeny for the Alphaproteobacteria (Williams et al., 2007). The first one groups genera in the families *Brucellaceae*, *Bartonellaceae, Phylobacteriaceae, and Rhizobiaceae*. They all form monophyletic entities, and therefore their classification in the corresponding families is consistent with the phylogenomic hypothesis presented in Figure 27.2. Two things are notorious in this clade: the long branch subtending the *Bartonella* cluster and the very limited genetic diversity found within the genus *Brucella* for the core genome loci. The former observation is typical of bacterial species undergoing genome reduction and degradation as a result of adaptation to intracellular lifestyle (Sallstrom and Andersson, 2005), while the latter is typical of clonal population structures, as reported for *Brucella* spp. based on multilocus sequence analysis (Whatmore et al., 2007).

The major groupings in the second clade correspond to the families *Bradyrhizobiaceae* and *Methylobacteriaceae*. These and the other families clustered in this clade are monophyletic, which again makes taxonomy consistent with the phylogenomic hypothesis presented in Figure 27.2. However, it is striking that the genetic diversity of the *R. palustris* clade is larger than that of the neighbor *Bradyrhizobium* spp. clade, as judged from the (patristic) distances measured on the tree. This suggests that *R. palustris* represents a species assemblage, rather than a proper species. A combination of multilocus sequence-based phylogenetic and population genetic analyses should illuminate this issue (Vinuesa, 2010; Vinuesa et al., 2005).

27.3.3 Pangenome Phylogeny of the *Rhizobiales* Based on the Pangenome Matrix

As discussed above, and shown in Figure 27.1e and f, the core-genome represents only a minor fraction of the whole genome of an individual strain or of the pangenome of a certain species or higher taxon, as the order *Rhizobiales* analyzed herein. It is well known that adaptive evolution in prokaryotes is largely determined by gain and loss of genes (Doolittle, 2005; Gogarten and Townsend, 2005; Koonin and Wolf, 2008; Ochman et al., 2000), which have drastically shaped genome evolution in *Alphaproteobacteria* (Boussau et al., 2004). It would therefore be instructive to get an estimate of phylogeny based on the pangenome matrix, that is, the matrix of presence–absence data for each gene family. The rationale here is that the more similar two strains are in genome composition, the higher the likelihood that they will share the same or a similar niche (Gogarten and Townsend, 2005; Lukjancenko et al., 2010; Snel et al., 1999; Snipen and Ussery, 2010). The *parse_pangenome_matrix.pl* script will use the pangenome_matrix.tab file generated by *compare_clusters.pl* to compute a pangenome tree using the parsimony criterion, as implemented in pars from the PHYLIP package (Felsenstein, 2004). Figure 27.3 shows the pangenome parsimony tree computed from the consensus pangenome matrix for 68 *Rhizobiales* from the 14,297 consensus clusters generated by the COG and OMCL algorithms. Relationships within generic lineages remain largely consistent with those revealed by the core-genome phylogeny. However, some changes are apparent. For example, the *Brucella/Ochrobactrum* clade (containing facultative intracellular pathogens of humans and animals) is now sister to the *Mesorhizobium/Agrobacterium-Rhizobium/Sinorhizobium* clade, which groups the plant symbionts or pathogens with larger genomes. The strong genome reduction experienced by the *Bartonella* clade causes it to cluster in a basal position to the above-mentioned groups. Another interesting difference is that on the pangenome phylogeny *Bradyrhizobium* is sister to *Rhodopseudomonas*, while *Nitrobacter* clusters with *Oligotropha*. The former genera contain metabolically highly versatile organisms, exhibiting some of the largest genomes in the *Alphaproteobacteria*.

The *parse_pangenome_matrix.pl* script can also be used to identify lineage-specific gene families or family expansions. Owing to space constraints, such analyses are not presented herein. The reader is referred to the original publication describing GET_HOMOLOGUES for an example of how to use the pangenome phylogeny to guide the definition of pairs of groups to identify lineage-specific gene families or family expansions (Contreras-Moreira and Vinuesa, 2013).

27.3.4 Analyzing Large Datasets Using the Berkeley-DB and/or the Heuristic BDBH Algorithm Implementation

An important feature of the *get_homologues.pl* script is that it can call the standard Berkeley DB (BDB) database via the core DB_File Perl module. BDB is a software library that provides a high performance embedded database for key/value data. *get_homologues.pl* can be called with the −s flag to store sequence data temporarily in this database to reduce the memory footprint at the expense of larger CPU time. This allows the analysis of dozens of bacterial genomes on modest desktop computers with <10 GB RAM. Figure 27.4 shows a graph of memory usage by get_homologues.pl when called with BDB and without (default).

To speed up the process of analyzing hundreds of genomes, the script can be called with the −b option, which will run a heuristic version of the BDBH algorithm that runs a minimum number of BLAST searches. As explained in detail in the manual provided with the software package,

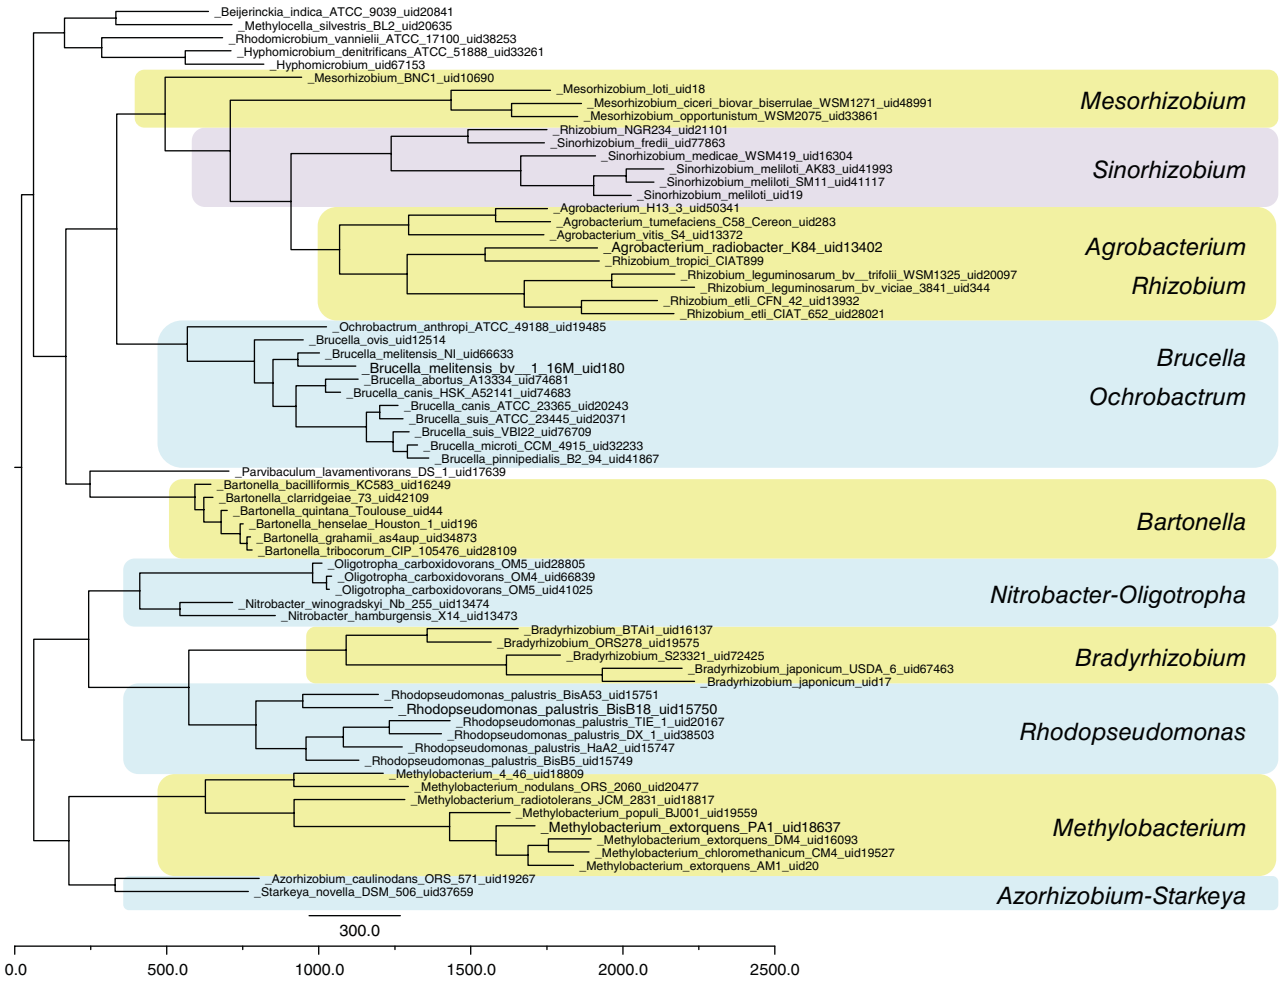

Figure 27.3 Pangenome tree based on the consensus pangenomic matrix (presence–absence matrix) containing 14,297 gene families derived from the intersection of COGtriangles and OrthoMLC clusters. The tree was recovered under the parsimony criterion. The scale indicates the number of gene clusters.

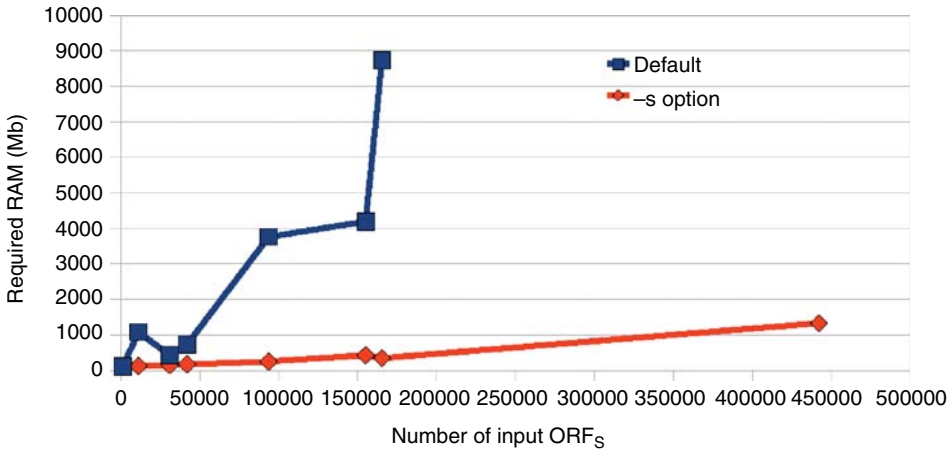

Figure 27.4 RAM requirement in Mb of the main script *get_homologues.pl* as a function of the number of genes to be analyzed when run in default mode or with the −s option enabled, which calls Berkeley DB to temporarily store data to disk to free RAM memory.

this option is probably only useful for the calculation of conservative core genomes.

27.4 CONCLUSIONS AND PERSPECTIVES

As briefly demonstrated in this work, the GET_HOMOLOGUES software package allows an easy, flexible, and thorough analysis of microbial pangenomes, computing very robust consensus core- and pangenomes and allowing for basic comparative genomics studies. The software is designed to take advantage of modern multiprocessor and multicore architectures, as well as of computer clusters to parallelize time-consuming hmmscan and BLAST jobs. The optional use of BDB to reduce the memory footprint permits the analysis of hundreds of genomes with moderate RAM resources. Altogether, these features allow non-bioinformaticians to easily perform sophisticated pangenome and basic comparative genomics analyses on large collections of complete or draft genomes, similar to those recently reported for different *Rhizobiales* (Sugawara et al., 2013; Tian et al., 2012). The robust consensus core genomes computed by the software permits refined phylogenomic analyses to be performed, as shown herein. The user of GET_HOMOLOGUES can upload selected gene families to our primers4clades server to select degenerate polymerase chain reaction (PCR) primers based on our extended CODEHOP algorithm for diversity and gene-based metagenomic studies (Contreras-Moreira et al., 2009; Sachman-Ruiz et al., 2011). We are currently developing computational pipelines that use the consensus orthologous gene families obtained by GET_HOMOLOGUES with the degenerate primer design capabilities of the primers4clades algorithm to develop highly informative markers for molecular ecology and systematics of rhizobia and other bacteria (Vinuesa, 2011).

28.1 INTRODUCTION

Rhizobia define a polyphyletic group of soil bacteria able to fix nitrogen and to interact in a symbiotic way with some plants of the legume family (Sprent, 2008). This interaction starts in the soil where plants and rhizobia exchange diffusible signal molecules, essentially plant flavonoid molecules (see Chapter 50) and lipochitooligosaccharides referred to as *Nod factors* (for nodulation factor) secreted by the bacteria (see Chapter 51). Once the reciprocal recognition is achieved, infection occurs and the plant develops nodules, which are new root organs hosting the bacteria. In the nodules, the symbiotic association is based on a nutrient exchange: the bacteria provide assimilable nitrogen to the plant under the form of ammonium, and in return, the plant supplies energy and carbon source to the bacteria (White et al., 2007). In the nodules, the bacteroid's metabolism is highly simplified compared to the free-living state, and seems to be totally reoriented in order to perform an efficient nitrogen fixation. The reduction of dinitrogen (N_2) to NH_3, which arises in rhizobia only during symbiosis, is an extremely energy-consuming process requiring both reducing equivalent and adenosine triphosphate (ATP) (White et al., 2007). These requirements are provided by the plant in the form of dicarboxylic acids. The bacteria assimilate this carbon source via the tricarboxylic acid (TCA) cycle and the malate dehydrogenase routes (White et al., 2007). Part of the resulting reducing equivalents is then converted into ATP through the microaerobic respiratory chains. These statements are likely true for all rhizobia–legume interactions. Nevertheless, variations occur around this theme.

We have been interested in a rhizobium/legume symbiosis established between photosynthetic bradyrhizobia and tropical aquatic legumes of the *Aeschynomene* genus. Five traits make this interaction atypical. First, bacteria involved in this interaction are photosynthetic. This feature

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

is very rare among rhizobia and is only shared by some *Methylobacterium* strains nodulating *Lotonis* species (Norris, 1958; Jaftha et al., 2002). Second, plants of this genus are able to form symbiosis on both stem and root system (Heagerup, 1928; Alazard, 1985) (see Chapter 45 of this book). Third, these bacteria are able to reduce dinitrogen in their free-living state (Alazard, 1990). Fourth, they are also found as endophytic organisms associated with the wild rice [*Oryza brevigulata*] that grows spontaneously in natural wetland sites in close association with *Aeschynomene* species (Chaintreuil et al., 2000). The fifth and last exceptional aspect of these rhizobia is that the genomes of two strains [ORS278 and BTAi1] do not contain the canonical *nodABC* genes required to produce Nod factors (Giraud et al., 2007). Strikingly, despite this lack, their ability to form symbiotic association with *Aeschynomene* legume plants is not compromised. The wide range of environments that they are able to colonize – soil and wetland environments rhizosphere, shoot and root surfaces, cortical tissues, stem and root nodules – implies that they have evolved metabolic adaptations to ensure survival under these different conditions. The aim of this chapter is to review the current knowledge on photosynthetic *Bradyrhizobium* metabolism during stem and root nodule symbioses. More general aspects of rhizobial bacteroid metabolism have been recently reviewed by Terpolilli and coworkers (2012).

28.2 PHOTOSYNTHESIS AND SYMBIOSIS

Unlike cyanobacteria, the stem-nodulating bradyrhizobial symbionts of *Aeschynomene* are anoxygenic photosynthetic bacteria; this means that photosynthesis and nitrogen fixation can occur simultaneously in the same bacterial cell without risk of damage of the nitrogenase by oxygen released by the photosystem (PS). The PS of the bradyrhizobia and purple bacteria are very close but differ as the bradyrhizobial PS is not functional under anaerobic conditions (Giraud et al., 2000). It is composed of a photochemical reaction center and light-harvesting (LH) complexes. The genes necessary for the formation of the PS are clustered in a 45-kb region that is syntenic to the photosynthesis gene cluster of *Rhodopseudomonas palustris*, a bacteria phylogenetically close to *Bradyrhizobium* (Giraud and Fleischman, 2004). This cluster is illustrated in Figure 28.1a; it includes genes involved in photopigment synthesis (bacteriochlorophyll (*bch*) and carotenoids (*crt*)), genes encoding the LH polypeptides (*pufBA*), genes encoding the reaction center subunits (*pufLM*), and various regulators (*ppsR1, ppsR2, BrBphP* and *aerR*); see (Elsen et al., 2005 and Fig. 28.1a). Several independent studies indicate that this PS is functional during stem nodule symbiosis and contributes to the nitrogen fixation efficiency: (i) bacteroids isolated from stem nodules express a PS (Giraud et al., 2000), (ii) illumination of stem nodules with near-infrared light that is absorbed by bacteriochlorophyll but not chlorophyll enhances nitrogen fixation (Evans et al., 1990), and (iii) the growth of the plants inoculated with a photosynthetic mutant is 50% less than that of plants inoculated with the wild-type strain (Giraud et al., 2000); see Fig. 28.2.

It is clear that the plant benefits from the advantages conferred by this bacterial photosynthetic activity. Indeed, the energy collected by the bacterial PS can be used for stimulating nitrogen fixation and represents energy saving for the plant. This functional advantage could explain why essentially all the bradyrhizobia isolated from stem-nodulating *Aeschynomene* species have been found to be photosynthetic (Miché et al., 2010). On the other hand, this raises the question why the other stem-nodulating legume species, such as *Sesbania rostrata,* are interacting with non-photosynthetic symbiotic bacteria.

Regulation of PS formation in *Bradyrhizobium* is quite unusual in comparison to what is known in purple bacteria, since PS formation requires a low oxygen tension but also specific light conditions (Giraud and Fleischman, 2004). The fine control of PS formation by light requires a light sensor – the bacteriophytochrome (BrBphP; see Fig. 28.1a) that switches between two photo-interconvertible forms (Pr and Pfr) absorbing red and far-red light respectively

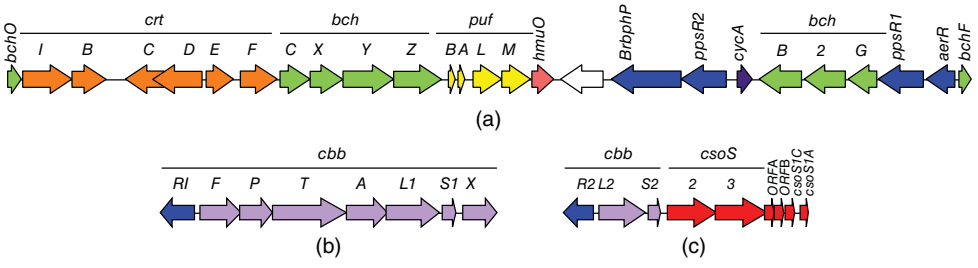

Figure 28.1 Organization of the photosynthesis gene cluster (a), the Calvin cycle gene cluster (b), and the carboxyzome gene cluster including the RuBisCO2 encoding genes (c). In (a) genes involved in carotenoid, bacteriochlorophyl synthesis are represented in orange and green, respectively; the *puf* genes encoding light harvesting polypeptides and reaction center subunits are colored in yellow. In (b,c) genes encoding enzymes of the CBB cycle and carboxyzome are colored in purple and red, respectively. In (a–c) genes encoding the regulator are represented in blue.

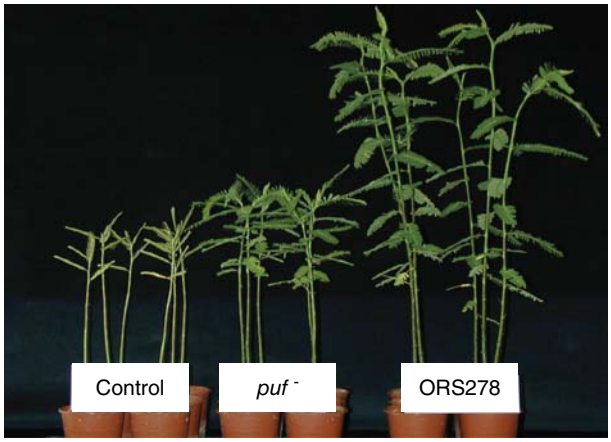

Figure 28.2 Bacterial photosynthesis is required for efficient symbiosis between *Aeschynomene sensitiva* and *Bradyrhizobium sp*. Strain ORS278. *A. sensitiva* plants were stem inoculated with WT or Δ*pufLM* ORS278 or not inoculated (control) and imaged 5 weeks after inoculation.

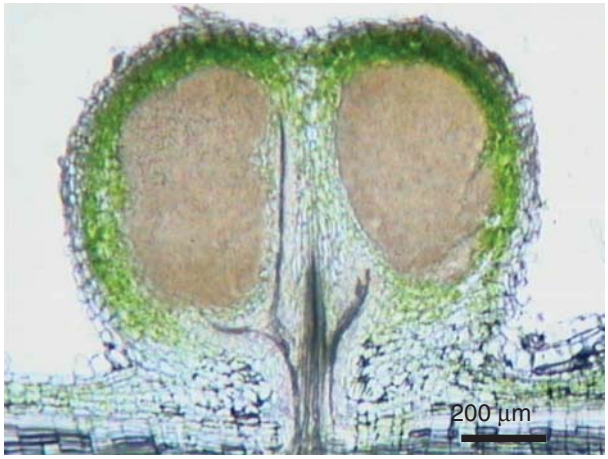
(Giraud et al., 2002). When BrBpHP is in its active Pr form, it allows the expression of the PS genes by antagonizing the transcriptional repressor PpsR2 (see Fig. 28.1a). At the same time, PpsR1 (see Fig. 28.1a), another transcriptional factor of the PpsR family, binds to the same promoter regions and activates the expression of the PS genes depending on the oxygen tension level. In other words, PS formation in *Bradyrhizobium* is under the dual control of two PpsR transcriptional factors that play antagonist roles and the actions of which are modulated by oxygen tension and light (Jaubert et al., 2004; Elsen et al., 2005). This atypical regulation of PS formation seems to be perfectly adapted to promote PS synthesis during stem symbiosis. Indeed, on the one hand, leghemoglobin maintains an oxygen tension that is compatible with the nitrogenase functioning and also with the activation of PS synthesis genes. On the other hand, the light perceived by the bacteria is first filtered through the nodule cortex (see Fig. 28.3), which contains chloroplasts preferentially absorbing blue and red light while transmitting far-red light. The enrichment in far-red light in the nodule tissue will then trigger PS synthesis thanks to the switch of the bacteriophytochrome into its active Pr form.

On the contrary, in the root nodules, i.e., when the root system is developed in the dark, no PS is formed. This means that light control by BrBpHP allows the bacteria to switch from dark heterotrophy during root symbiosis to the more energetically favorable photoheterotrophy during stem symbiosis. Interestingly, when the root system is exposed to light, for example, when plants are cultivated in Gibson tubes, both chloroplast formation in the root nodule cortex and bacterial PS formation occur (Fig. 28.3). This clearly indicates that light regulates plant energetic metabolism also through the induction of chloroplast differentiation in the nodule cortex covering the infected zone (see Fig. 28.3).

(a)



(b)

Figure 28.3 *Aeschynomene* root nodules exposed to light develop chloroplasts in the nodule cortex surrounding the infected zone. *Aeschynomene indica* root system (a) and transversal section of an *A. indica* root nodule (b).

To our knowledge, nodules containing chloroplast have only been described in *S. rostrata* (Dreyfus and Dommergues, 1981; James et al., 1996). We can easily deduce that the plant benefits from producing photosynthetates in the vicinity of the symbiotic cells, the nodule thus becoming an energetically independent functional unit. Furthermore, it is also worth highlighting that the photosynthetic apparatus of plants and bacteria that contain chlorophyll and bacteriochlorophyll, respectively, are not in competition for light because these photopigments absorb at different wavelengths. Their concomitant actions optimize light collection over a broader spectrum.

Beside the control of PS synthesis, one can expect that light controls other aspects of bacteroid metabolism. Indeed, it has been shown in *R. palustris* that the bacteriophytochrome RpBphP1, the homolog of BrBphP1, activates PS formation and also downregulates respiratory activity by repressing the synthesis of the alpha-ketoglutarate dehydrogenase complex, a central enzyme of the TCA cycle

(Kojadinovic et al., 2008). Indeed, the growth defect also observed for ORS278 strain when the cells are exposed to an inactinic far-red (770 nm) light (Verméglio André, personal communication) suggests that this dual control of both photosynthesis and TCA cycle should also occur *in nodulo* to enhance the most favorable bioenergetic process upon light exposure.

In nature, stem nodules are subjected to the alternation of day and night, meaning that the energetic metabolism of bacteroids is likely to drastically fluctuate over a 24-h period. Cyanobacteria possess an internal biological clock composed of three proteins – KaiA, KaiB, and KaiC – that enables them to anticipate and adjust their metabolism to the predictable diurnal cycle (Dong and Golden, 2008). Interestingly, sequence genome analysis reveals that photosynthetic bradyrhizobia possess two *kaiBC* operons, such genes not being found in non-photosynthetic rhizobia. It would then be particularly interesting to investigate whether these *kaiBC* genes are functional and allow a circadian control of certain aspects of bacteroid metabolism during stem symbiosis.

28.3 THE CALVIN CYCLE AND SYMBIOSIS

The Calvin–Benson–Bassham cycle (CBB cycle) is the major metabolic pathway responsible for biomass production at the global level. In algae, plants, and some prokaryotes, it allows CO_2 fixation and carbon incorporation in the biomass. The key enzyme of the CBB cycle is ribulose-bis-phosphate carboxylase oxygenase (RuBisCO). This enzyme converts one CO_2 and one ribulose-bis-phosphate molecule into two molecules of 3-phosphoglycerate. The rest of the metabolic pathway achieves the regeneration of the CO_2 acceptor. In addition to RuBisCO, only one other enzyme, the ribulose monophosphate kinase, is specific for the CBB cycle. The other reactions/enzymes are shared with sugar-related anabolic or catabolic pathways such as pentose phosphate, glycolysis, or neoglucogenesis. The CBB cycle is often associated with photosynthesis; however, one should keep in mind that many microorganisms do not necessarily combine photosynthetic ability with CO_2 fixation. For instance, the CBB cycle is functional in the photosynthetic *Bradyrhizobium* sp. BTAi1 (Hungria et al., 1993), as well as in the non-photosynthetic *Sinorhizobium meliloti* 1021 strain (Pickering and Oresnik, 2008) and *Bradyrhizobium japonicum* strain SR (Maier, 1981).

In photosynthetic bradyrhizobia, the genome of which has been sequenced, most genes involved in the CBB cycle are clustered in an operon-like structure and are located in close vicinity of the photosynthesis gene cluster. This cluster contains the so-called *cbb* genes, including *cbbL1* and *cbbS1,* encoding the large and the small subunits of the RuBisCO, respectively (see Fig. 28.1b). Interestingly, another gene set encoding a RuBisCO enzyme, named RuBisCO2, is present in the ORS278 strain genome (see Fig. 28.1c). This second copy is included in a cluster that also encodes carboxysome components. Carboxysomes are proteic microcompartments responsible for CO_2 concentration around RuBisCO (Price et al., 2008). This second gene cluster has likely been recently acquired as it harbors several typical features of lateral gene transfer (Giraud et al., 2007).

In this bacterium, only the RuBisCO encoded by genes located in the vicinity of the photosynthetic gene cluster is required to form an effective symbiosis with *Aeschynomene indica* (Gourion et al., 2011). A *cbbL1* mutant is not altered in its capacity to infect plants and to trigger nodule formation, but in contrast to the wild type (WT), plants infected by this mutant display a reduced nitrogen fixation activity. They form more nodules that are a mixture of reddish (functional) and yellowish (non-functional) organs. Expression studies using a promoter/reporter fusion confirm that *cbbL1* is constitutively expressed during the symbiotic process and the corresponding protein has been detected within nodules. In contrast, neither promoter activity nor protein could be detected for *cbbL2* in the same condition, i.e., in root nodules developed in the dark.

CO_2 fixation via the CBB cycle requires a substantial amount of ATP and reducing equivalents. In nodules developed in the dark, bacteria cannot use their photosynthetic ability to produce the energy necessary to run the CBB cycle. Instead, it is very likely that they rely on the plant partner for their energy supply. It is thus difficult to imagine that bacteria use the CBB cycle as a carbon supply machinery under symbiotic condition in darkness. Indeed, it would be futile for the bacteria to oxidize plant-derived organic carbon to generate energy dedicated to reduce CO_2 for forming organic carbon. The CBB cycle is used by some microorganisms as an electron sink, with CO_2 then acting as an electron acceptor (Joshi and Tabita, 1996; McKinlay and Harwood, 2010). Such a strategy would only make sense in environments where CO_2 is available and in which bacteria produce an excessive amount of reducing equivalents compared to their respiratory chain capacity. In nodules, bacteria are likely to encounter such conditions. Indeed, the respiratory chain capacity of the bacteria is reduced due to a low oxygen concentration and the TCA cycle produces a substantial amount of reducing equivalents and CO_2. If we consider the "electron sink hypothesis," the need of CO_2 as an electron acceptor should be only transient, mainly during the first steps of establishment of the symbiotic process before bacteroid differentiation, because when the bacteroids become functional, nitrogen fixation consumes a consequent amount of reducing equivalent and could take over the cofactor recycling. We could also imagine that other bacteria developed different strategies to solve the redox imbalance problem. Other metabolic pathways such as poly-ß-hydroxybutyrate

(PHB) synthesis could have an effect similar to CBB cycle activity (Terpolilli et al., 2012).

Alternative roles of RuBisCO in the symbiotic process cannot be excluded. Among them are the production of essential intermediary metabolite(s) by the CBB cycle or the photorespiration or the reduction of O_2 concentration by the RuBisCO Oxygenase activity to prevent nitrogenase damage.

Until now, the importance of RuBisCO for the symbiotic process has only been described in *Bradyrhizobium* sp ORS278. Nevertheless, the facts that (i) the phenotype does not involve the photosynthetic capacity of this bacterium, (ii) the *cbb* genes are widespread among rhizobia and, as mentioned earlier, (iii) the CBB cycle is functional in other rhizobia raise the question of the potential role of the CBB cycle in other symbiotic systems.

28.4 ADDITIONAL ASPECTS OF BACTEROID CENTRAL METABOLISM

Recent insights into the bacteroid metabolism during root symbiosis come from the screening of a large *Tn5* insertional library (>15,000 mutants) of the *Bradyrhizobium* ORS278 strain for their inability to fix nitrogen (Bonaldi et al., 2010).

From this genome-wide mutational analysis, major metabolic routes employed by *photosynthetic* bradyrhizobia during root symbiosis with *Aeschynomene* spp. have been revealed. These include the TCA cycle, glycolysis/neoglucogenesis pathways, PHB and glycogen biosynthesis/degradation, and as discussed above, the CBB cycle. This indicates that the central carbon metabolism of photosynthetic bradyrhizobia during root nodule symbiosis should not be drastically different from that of other rhizobia. All the genes encoding enzymes of the central metabolism required for efficient nitrogen fixation are listed in Table 28.1; for a complete list of genes involved in the symbiotic process refer to Bonaldi et al. (2010).

Below we highlight some original aspects or complementary information that could be deduced from this genetic screen:

- The TCA cycle plays a central role in the metabolism of rhizobium during symbiosis because it allows the metabolization of the dicarboxylic acids that represent the main carbon source provided by the host plant. The identification of Fix^- mutants in genes encoding several key enzymes of the TCA cycle indicates that the functioning of this cycle is indispensable for an efficient symbiosis between photosynthetic *bradyrhizobia* and *Aeschynomene*. Interestingly, these mutants displayed the same Fix^- phenotype when inoculated on the stem, suggesting that despite their ability to develop a photosynthetic apparatus and to fix CO_2, photosynthetic bradyrhizobia require to be fed by the plants with an appropriate carbon source.
- Operation of the TCA cycle requires anaplerotic synthesis of acetyl-CoA. It has been proposed that acetyl-CoA is mainly generated in bacteroids from the combined activities of malic enzyme and pyruvate dehydrogenase (PDH) complexes. An ORS278 mutant strain affected in BRADO3367, which encodes an NAD^+ dependant malic enzyme (annotated DME), has been identified. Interestingly this mutant is only slightly affected in its symbiotic efficiency, since it retained 86% of the WT nitrogenase activity. The Tn*5* insertion site is located at the beginning of the *dme* gene excluding the possibility that the mutated protein maintained a residual malic enzyme activity. As described in other rhizobia, strain ORS278 possesses an additional malic enzyme (BRADO5322), which is $NADP^+$ dependent (annotated TME). We therefore speculate that TME is functional during symbiosis and partially rescues the DME mutation. Because in *S. meliloti* TME fails to replace DME in N_2-fixing bacteroids (Mitsch et al., 2007), TME enzymes would play different physiological roles in both organisms.
- The ORS278 genome displays two *lpd* genes (BRADO0409 and BRADO4083, 43% identical) that encode dihydrolipoamide dehydrogenase. LpD together with PdhA, PdhB, and PdhC forms the PDH complex. When interacting with SucA and SucB, it forms the α-ketoglutarate dehydrogenase complex. BRADO4083 is located just downstream of the *pdhABC* operon, and BRADO0409 is located just downstream of the *sucAB* operon. Interestingly, we identified mutants in both *lpd* genes and they displayed a very different symbiotic phenotype. Mutants in BRADO4083 were drastically impaired in their N_2 fixation capacity, whereas mutants in BRADO0409 retained 85% of the WT nitrogenase activity. These results suggest that the LpD activity of BRADO0409 cannot replace that of BRADO4083 for the formation of a functional PDH. In contrast, BRADO4083 could rescue the mutation in BRADO0409 resulting in a partially functional α-ketoglutarate dehydrogenase. Alternatively, the α-ketoglutarate dehydrogenase complex might not be essential for symbiosis. This possibility is supported by the lack of symbiosis defective mutants in our collection that are affected in aconitase, isocitrate dehydrogenase and α-ketoglutarate dehydrogenase activity. Similarly, in *B. japonicum,* these key enzymes of the TCA cycle are dispensable for nitrogen fixation (Thöny-Meyer and Künzler, 1996; Green and Emerich, 1997; Shah and Emerich, 2006), suggesting that both organisms do not require an intact TCA cycle to meet their energy needs.

Table 28.1 Genes involved in symbiotic nitrogen fixation in *Bradyrhizobium sp.* ORS278

	Relative Nitrogenase Activity
Nitrogenase biosynthesis	
nifH (BRADO5394)	80%
nifN (BRADO5436)	ND
nifE (BRADO5437)	ND
nifK (BRADO5438)	ND
Electron transfers	
put.electron transfer flavoprotein deshydrogenase (BRADO2020)	19%
cycK (BRADO2734)	27%
put. pyruvate ferredoxin/flavodoxin oxidoreductase (BRADO4317)	ND
etfA (BRADO6491)	24%
etfB (BRADO6492)	26%
Tricarboxylic acid cycle	
sucC (BRADO0404)	ND
sucD (BRADO0405)	ND
sdhA (BRADO234)	ND
furnA (BRADO5016)	4%
IpD (BRADO0409)	85%
Pyruvate and carbohydrates metabolism	
IpD (BRADO4083)	ND
pdhA (BRADO4087)	6%
pdhB (BRADO4086)	ND
dme (BRADO3367)	86%
ena (BRADO4094)	ND
gpmA (BRADO0157)	5%
ppdK (BRADO2034)	34%
put.amylomaltase (BRADO5815)	6%
cbbK (BRADO1122)	80%
cbbE (BRADO2842)	ND
cbbL1 (BRADO1659)	40%
Amino acids biosynthesis	
hisB (BRADO0212)	54%
aatA (BRADO5973)	50%
Nucleotides biosynthesis	
purK (BRADO1205)	58%
purC (BRADO2776)	32%
Cofactors biosynthesis	
nadB (BRADO2036)	59%
put.RibBA-like protein (BRADO2133)	4%
Transporters	
pstC (BRADO1675)	3%
pstB (BRADO1677)	ND
put.ABC transporter (BRADO3096)	22%
put.ABC transporter (BRADO4782)	5%
put.permease (BRADO5117)	ND
put.ABC transporter (BRADO6119)	4%
Others	
Int (BRADO0045)	69%
put.peptidylpropyl isomerase (BRADO0589)	17%
put.acylCoA dehydrogenase (BRADO2179)	6%
put.hydrolase (BRADO2938)	18%
put.sulfite reductase (BRADO3794)	47%
put.D-alanyl-D-alanine carboxypeptidase (BRADO4549)	10%

Table 28.1 (*Continued*)

	Relative Nitrogenase Activity
put.PhnMprotein (BRADO5368)	3%
mutL (BRADO6079)	26%
mutA (BRADO2682)	13%

The list is restricted to genes encoding enzymes of the central metabolism required for nitrogen fixation but not for nodule development. The nitrogenase activities of the corresponding mutant were determined using acetylene reduction assays and are expressed as percentages of the WT control. ND stands for not detected.

- To cope with the lack of sugars provided by the plants, it is known that Rhizobium uses the gluconeogenesis pathway to synthesize the pool of essential sugars that they need. Several ORS278 Fix- mutant strains affected in three key gluconeogenic enzymes were isolated: enolase (Eno-BRADO4094), phosphoglyceromutase (GpmA-BRADO0157), and pyruvate phosphate dikinase (PPDK-BRADO2034). This also highlights the essential role of this pathway during the *Bradyrhizobium–Aeschynomene* symbiosis. Interestingly, it has been observed that the *ppdK* mutant retained 34% of the WT nitrogenase activity, whereas the *eno* and *gpmA* mutants were completely Fix$^-$. The partial activity of the *ppdK* mutant most likely results from an alternative route for phosphoenol pyruvate (PEP) formation, involving the PEP carboxykinase (PCK). It is notable that *ppdK* mutants of *S. meliloti* are not altered in their symbiotic performances whereas *pcK* mutants are strongly altered in nitrogen fixation, indicating that PEP is mainly formed via PCK (Osterås et al., 1997). In contrast to *S. meliloti,* we can propose that the main gluconeogenesis pathway in ORS278 involves the combined action of PPDK and malic enzyme. This is probably also the case for *B. japonicum* since *ppdk* is highly induced in bacteroids (a > 30 fold change) in comparison with microaerobic cultures (Pessi et al., 2007).
- As previously stated, the accumulation of storage compounds such as PHB or glycogen could be a strategy used by the bacteria to re-equilibrate the redox state of the cofactor pools produced by the TCA cycle. Accumulation of PHB granules can clearly be seen in bacteroids isolated from mature root nodules of *A. indica* or *A. afraspera* (Bonaldi et al., 2011). In addition, ORS278 mutants in key enzymes of glycogen or PHB catabolism are drastically impaired in nitrogen fixation. This suggests that the accumulation of these storage compounds and/or their subsequent metabolization is important for an efficient symbiosis.

28.5 PLANT CONTROL OF BACTEROID MORPHOTYPES

During the Rhizobium–legume symbiosis, bacteria are ultimately internalized in their host cells and undergo further morphological and metabolic differentiation. One remarkable feature of the photosynthetic *Bradyrhizobium/Aeschynomene* symbiosis is the synchrony of this differentiation, which occurs between the fourth and the fifth day post-inoculation and is rapidly followed by the beginning of detectable nitrogen fixation activity (Bonaldi et al., 2011).

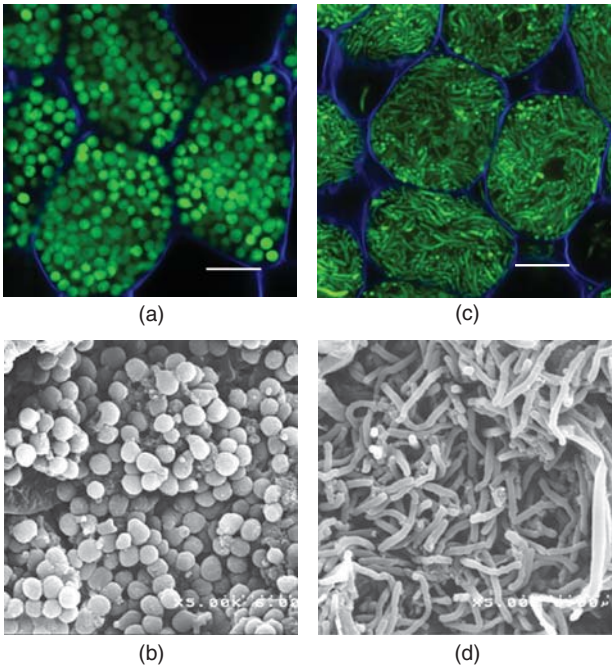


Figure 28.4 Various shapes of *Bradyrhizobium* sp. ORS285 strain bacteroids. ORS285 bacteroids are spherical in symbiotic cells of *Aeschynomene indica* (a,b) while elongated in *A. afraspera* (c,d). Images (a) and (c) were obtained with confocal microscope after calcofluor white staining of the cross sections of nodules and using a GFP-labeled *Bradyrhizobium* sp. ORS285 strain. Images (b) and (d) were obtained with scanning electron microscopy (b,d).

Interestingly, despite the taxonomical proximity between host plants, the morphology of bacteroids is drastically different depending on the host. Indeed, bacteroids are elongated in *A. afraspera* nodules, while they become spherical when in symbiosis with *A. indica* or *A. evenia* (Bonaldi et al., 2011) (see Fig. 28.4).

This is the first symbiotic system in which such closely related plants can trigger such drastically different shapes of the same bacteria. These observations indicate that in accordance with what has been previously described in the *Medicago–Sinorhizobium* system (Van de Velde et al., 2010); the bacteroid morphotype of photosynthetic bradyrhizobia is controlled by the plants. Mechanism(s) underlying this process remain(s) to be clarified, as well as the potential involvement of NCR-like or antimicrobial peptides (Van de Velde et al., 2010). This also raises the question of potential differences in symbiotic efficiency and bacteroid metabolism associated to these different bacteroid shapes.

28.6 CONCLUSIONS

To conclude, knowledge on photosynthetic *Bradyrhizobium*/*Aeschynomene* symbiotic systems is clearly far behind what is known about "classical" well-studied models. Nevertheless, several examples presented in this chapter highlight the utility to study such exotic models. Indeed, it has revealed atypical features of the symbiotic process not encountered in "classical models." Furthermore, it offers the possibility to investigate Rhizobium/legume interactions in relatively simple models, in which Nod factor signalization is not required. Now, the perspective of transferring symbiotic nitrogen fixation capacity to non-legume plants is returning in the discussions (Charpentier and Oldroyd, 2010). The possibility to bypass the requirements for Nod factor and for the associated signalization pathway is therefore of great interest (see also Chapter 108). Finally, we think these exotic models are of special interest to study differentiation aspects and associated variations thanks to the possibility to generate elongated or spherical bacteroids with the same bacterial strain in closely related plants.

ACKNOWLEDGMENTS

The authors are grateful to André Verméglio, CEA Cadarache France, for sharing unpublished data, for critical reading of the manuscript, and for his massive contribution to the field of photosynthetic bradyrhizobium metabolism. The authors also thank Pascal Ratet (CNRS Gif sur Yvette, France for critical reading of the manuscript). This work was supported by grants from the French national research agency (ANR-NEWNOD-2006-BLAN-0095 and ANR-SESAM-2010-BLAN-170801).

29.1 INTRODUCTION

The extant Alphaproteobacteria are phylogenetic relatives of mitochondria. In contrast to the latter, however, most species of this phylum possess cytoplasmic membrane-bound respiratory chains that are stunningly complex. There is diversity not only in the quinone-reducing enzymes but also in the routes electrons take from the quinols to their final destination, that is, the electron transport chain is often highly branched. A bacterium that reflects this complex situation in an almost unrivaled way is *Bradyrhizobium japonicum*. Under anoxic conditions, it is able to respire with nitrate as the terminal electron acceptor in a process called denitrification (Bedmar et al., 2005). The enzymes involved (nitrate, nitrite, nitric oxide, and nitrous oxide reductases) will not be the subjects of this article. Instead, the focus is on the respiratory oxygen reductases, generally called terminal oxidases, of which there are not less than eight in *B. japonicum* (Göttfert et al., 2004; Bühler et al., 2010). Six of them belong to the family of heme-copper oxygen reductases, and two are members of the copper-free cytochrome *bd* family. The level of information on the eight oxidases differs substantially, ranging from certain biochemical and molecular genetic details down to simple predictions derived from gene sequences.

Generation of reducing equivalents in *B. japonicum* occurs by oxidation of a huge array of known or potential carbon substrates (heterotrophy) and a few inorganic molecules (lithotrophy). While fermentation has never been reported, anaerobic nitrate respiration is possible (see earlier), but the main mode of consuming the reductants is clearly by electron transfer to oxygen as the terminal acceptor. The ubiquinone Q-10 is the major membrane-bound link in *B. japonicum* between the dehydrogenases and the terminal oxidases (Auling et al., 1988). Ubiquinols are oxidized either directly by quinol oxidases or via a chain that involves the ubiquinol:cytochrome *c* oxidoreductase (complex III; bc_1 complex), at least one *c*-type cytochrome, and finally the cytochrome *c* oxidases. Members of the alternative oxidase (AOX) family, originally thought to be restricted to mitochondria but recently found in prokaryotes as well (McDonald and Vanlerberghe, 2005), do not seem to exist in *B. japonicum*.

Incentives to study respiration in *B. japonicum* came from observations on the particular life styles of this bacterium. Being a soil bacterium, its aerobic energy metabolism is conceptually similar to that of many other aerobic prokaryotes in that habitat. The situation changes dramatically, however, when *B. japonicum* lives endosymbiotically within the cytoplasm of root nodule cells of

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

its hosts (soybean, mung bean, cowpea, siratro). Herein, the bacteria – then called bacteroids – face an ambient concentration of free oxygen that is about four orders of magnitude lower than in the free-living state (~25 nM vs. 250 μM O_2); yet, they must be able to respire under these conditions (Hennecke, 1993). The search for a high-affinity, bacteroid-specific, and symbiotically essential oxidase has led to the discovery of the cbb_3-type cytochrome oxidase which, incidentally, turned out to be the prototype of a new subfamily within the heme-copper oxidase superfamily (Preisig et al., 1993, 1996a; Ducluzeau et al., 2008). Micro-oxia in root nodules is maintained because most of the oxygen is bound to the plant-derived leghemoglobin. Oxygen that dissociates from oxy-leghemoglobin is then respired by bacteroids with the help of cytochrome cbb_3, thus creating a nearly anoxic cytoplasm inside of the bacteria. This condition is perfectly suited for the function of nitrogenase.

This article not only addresses the diversity of terminal oxidases in *B. japonicum* but also the question how these enzymes are assembled in the membrane together with their cofactors. Proteins that act as chaperones or assembly factors play an important role in this context. Given that *B. japonicum* possesses eight terminal oxidases, this bacterium would seem to be a rather inconvenient choice for biogenesis studies. Fortunately, however, the expected complexity is partly alleviated by the fact that two of the eight oxidases, cytochromes aa_3 and cbb_3, predominate in aerobic culture and in symbiosis, respectively (Bühler et al., 2010). Mutations in the structural genes of cytochromes aa_3 and cbb_3 cause clearly discernible phenotypes, that is, defective cytochrome oxidase activity and symbiotic nitrogen fixation, respectively. These traits allow genetic studies on biogenesis proteins that are specifically destined to assemble either of the two oxidases.

29.2 THE DIVERSITY OF TERMINAL OXIDASES IN *B. japonicum*

Two illustrations may guide the reader through this section. Figure 29.1 shows the arrangement of genes for all of the eight terminal oxidases in *B. japonicum*. They form apparent operons in all cases. Only in one case (second row from top), the subunit structural genes are not contiguous but are interrupted by genes for cofactor synthesis and assembly (blr1172, blr1174). Genes whose products carry cofactors (diverse hemes and/or copper) are color-coded. Genes in the immediate neighborhood of these operons were omitted for clarity although they are occasionally relevant for the regulation, assembly, or *in vivo* functions of the associated oxidase.

Figure 29.2 illustrates the highly branched respiratory chain of *B. japonicum* and the placement of seven of the eight oxygen reductases at the end of the respective electron transport pathways. The heme-copper oxidase encoded by the bll4481-to-4479 genes (see top row in Fig. 29.1) could not be placed here for lack of evidence as to whether it is a quinol oxidase or a cytochrome oxidase. Further details on the contents of Figures 29.1 and 29.2 follow next, where many of the interpretations given were also influenced by available structural and biochemical data on related oxidases from other bacteria.

29.3 THE HEME-COPPER OXIDASES

The heme-Cu_B-containing subunit I is the common denominator in six of the eight terminal oxidases (Fig. 29.1), and five of them could be placed into the scheme of Figure 29.2 (highlighted in pink). The three cytochrome oxidases on the right (Fig. 29.2) receive the electrons from the bc_1 complex via *c*-type cytochromes. Which of the *c*-type cytochromes might be involved will be discussed later. Akin to many aerobic and photosynthetic bacteria, the bc_1 complex is composed of three subunits: the Rieske iron–sulfur protein, the cytochrome *b*, and cytochrome c_1. A peculiarity in *B. japonicum* is that the three proteins are encoded by a bicistronic operon (*fbcFH*) where *fbcF* codes for the Rieske protein and *fbcH* for a large precursor that must be proteolytically cleaved to release apocytochrome *b* and apocytochrome c_1 during the process of membrane insertion (Thöny-Meyer et al., 1989, 1991). *B. japonicum* mutants of *fbcFH* have a severe defect in root-nodule colonization and symbiotic nitrogen fixation, which had been taken previously as the first evidence for the existence of a bc_1-dependent electron transport chain – now known to lead to cytochrome cbb_3 – that is essential for the symbiotic life style (Fig. 29.2).

29.3.1 Cytochrome aa_3 and Its Apparent Homolog

The four-subunit cytochrome aa_3 encoded by *coxA* (subunit I), *coxB* (subunit II), *coxC* (subunit III), and *coxF* (probable subunit IV) (Fig. 29.1) is the most prominent terminal oxidase in aerobically grown *B. japonicum* cells (Bott et al., 1990; Gabel and Maier, 1990; Bühler et al., 2010). It accounts for practically all of the cytochrome oxidase activity in membranes of such cells when either reduced cytochrome *c* (from horse heart) or *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) is used as the electron donor. This means there is very little, if any, background activity in air-grown *B. japonicum coxA* or *coxB* mutants that might stem from other cytochrome oxidases. Curiously though, the mutants are hardly affected

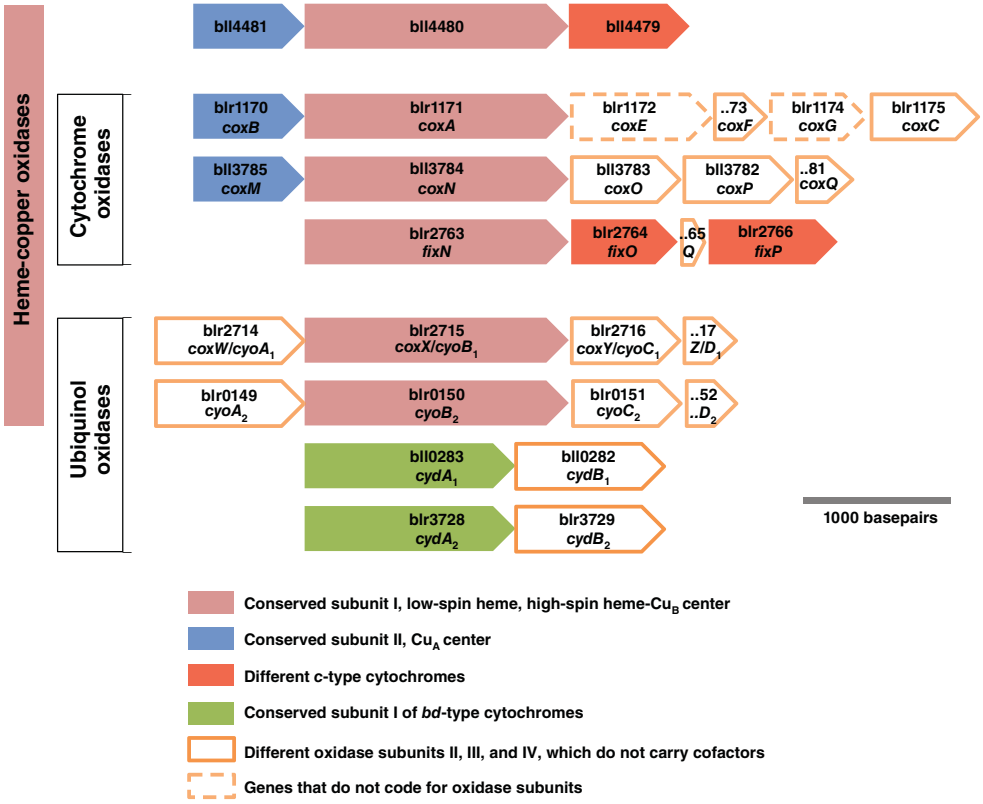

Figure 29.1 Gene clusters for the eight terminal oxidases in *B. japonicum*. The color code at the bottom is self-explanatory. The genes are marked with their numbers and, where available, with their names.

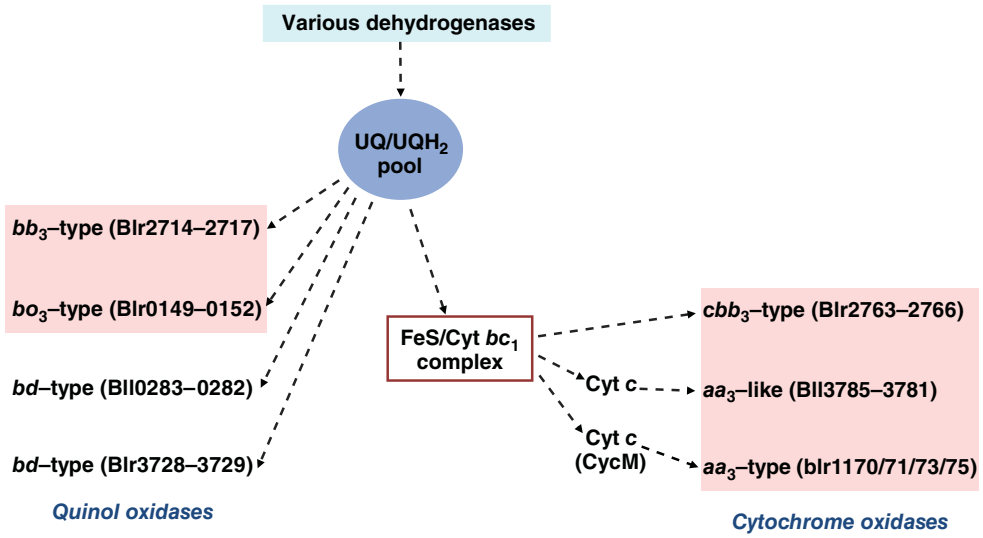

Figure 29.2 The branched respiratory chain of *B. japonicum*. The branches terminate either with quinol oxidases (left) or with cytochrome oxidases (right). Terminal oxidases that belong to the class of heme-copper oxidases are highlighted in pink color.

in aerobic growth that is interpreted to mean that respiration is sustained by the collective activity of ubiquinol oxidases expressed in such cells (Fig. 29.2, on the left). The mutants are also efficient in symbiotic nitrogen fixation, just like the wild type, which precludes a role of cytochrome aa_3 in symbiosis. In fact, expression of the *coxBACF* genes is downregulated in bacteroids of soybean root nodules (Gabel and Maier, 1993; Bühler et al., 2010).

Figure 29.3 Amino acid sequence motif of the copper A center in subunit II of heme-copper cytochrome oxidases. The alignment shows the respective sequence motifs from *P. denitrificans* (Pd) and *B. japonicum* (Bj). Compare Figure 29.1 for an affiliation of subunit-II proteins CoxB, CoxM, and Bll4481.

Extensive bioinformatic analyses of the *B. japonicum* cytochrome aa_3 subunits (sequence conservation, transmembrane helices, cofactor binding sites, domain topology) combined with few biochemical data strongly suggest that this oxidase and the redox centers in it have a structure similar to that of the *Paracoccus denitrificans* cytochrome aa_3 (Iwata et al., 1995). Accordingly, the low-spin heme-A iron and the metals of the binuclear heme A_3–Cu_B center in subunit I are liganded by two and four defined histidine residues, respectively. Subunit II carries a binuclear Cu–Cu center (Cu_A), which is complexed by six absolutely conserved amino acids as shown in Figure 29.3. Subunits III and IV do not carry cofactors.

There is evidence to suggest that cytochrome aa_3 forms a membrane-integral supercomplex together with the ubiquinol:cytochrome *c* oxidoreductase and the CycM protein, a membrane-anchored mono-heme cytochrome *c* that replaces soluble periplasmic cytochrome *c* in the transfer of electrons to the terminal oxidase (Fig. 29.2) (Bott et al., 1990, 1991).

The *B. japonicum* genome carries paralogs of the *coxBACF* genes, which had been named *coxMNOPQ* (Bott et al., 1992) (Figs. 29.1–29.3). A subunit III-like protein is encoded twice (*coxO* and *coxP*). The two genes might have been generated by duplication of a common ancestor during evolution. In all growth conditions tested, free-living and symbiotic, the *coxMNOPQ* genes are poorly expressed (Bühler et al., 2010), and mutations in them have so far not caused a phenotype other than wild-type (Bott et al., 1992). This has hampered any progress in the description of the biochemical and spectral properties of the encoded terminal oxidase, and its physiologic function remains enigmatic.

29.3.2 Cytochrome *cbb*$_3$

The common denominator in respiratory heme-copper oxidases is the membrane-integral subunit I, which is also present in the cbb_3-type oxidase (FixN or CcoN). Instead of heme A, however, it carries a low-spin heme B and a high-spin heme B-Cu_B center where reduction of O_2 to H_2O takes place (Buschmann et al., 2010). An exceptional property of cbb_3-type oxidases is subunit II (FixO/CcoO), which is a mono-heme cytochrome *c* instead of a Cu_A-containing subunit II. The FixP/CcoP subunit is usually a membrane-anchored di-heme cytochrome *c*, which is thought to relay electrons delivered by the cytochrome bc_1 complex (Fig. 29.2). The small, nonessential subunit FixQ/CcoQ might be involved in the assembly of the enzyme complex (Ekici et al., 2012a).

Research with the *B. japonicum* genes and enzyme has shown that (i) the *fixNOQP* operon is highly induced and essential in symbiosis (Preisig et al., 1993; Zufferey et al., 1996; Nellen-Anthamatten et al., 1998), (ii) the enzyme has a high affinity for molecular oxygen ($K_M = 7$ nM (Preisig et al., 1996a)), and (iii) the oxidase is capable of pumping protons over the membrane with an efficiency of 0.5 H^+/e^- (Arslan et al., 2000). All of these properties are compatible with the function of cytochrome cbb_3 as an oxygen reductase that sustains bacteroid respiration and energy conservation in the micro-oxic environment within root nodules. The recent report on the structure of a bacterial cytochrome cbb_3 has led to a possible explanation as to why the enzyme has a high affinity for oxygen (Buschmann et al., 2010). The authors noticed a distortion of heme in the heme B-Cu_B active site, which might facilitate O_2 access and binding.

29.3.3 In a Class of Its Own: bll4481–4479

The top row of Figure 29.1 shows genes whose deduced products clearly suggest the existence in *B. japonicum* of yet another heme-copper oxidase with a conserved heme-Cu_B-containing subunit I (bll4480) and a conserved Cu_A-containing subunit II (bll4481; see also Fig. 29.3). Evidence for associated subunits III and IV is missing; instead, the bll4481/4480 genes form an apparent operon together with the downstream gene bll4479, which codes for a di-heme *c*-type cytochrome (Fig. 29.1). This observation plus some other genes in the immediate vicinity of the operon (not shown) provide weak hints that this is a terminal oxygen reductase that receives the electrons from a pyrroloquinoline quinone (PQQ)-dependent dehydrogenase. The carbon substrate for such a specific oxidation pathway is completely unknown, and the analysis of knockout mutants of this gene region has so far not led to a discernible phenotype (Bühler et al., 2010). Likewise, it remains enigmatic as to whether the electron flow to this oxidase occurs via a quinol or via a reduced cytochrome *c*. Therefore, a placement in the scheme of Figure 29.2 was not possible.

29.3.4 Two Homologous Heme-Copper Ubiquinol Oxidases

An inspection of the genome has unveiled the existence of two homologous four-subunit oxidases in which the presence of a cofactor-free subunit II (i.e., without Cu_A) indicates that

they use ubiquinol rather than cytochrome *c* as the electron donor (Figs. 29.1 and 29.2). The only cofactor-containing protein is the heme-Cu_B-containing subunit I. Only one of the two quinol oxidases (blr2714–2717) has been characterized to some extent (Surpin et al., 1996; Surpin and Maier, 1999). The corresponding genes were previously named *coxWXYZ*, which is an inappropriate nomenclature because they do not code for a cytochrome oxidase. Based on spectral properties, the oxidase was classified as a bb_3-type oxygen reductase (Surpin et al., 1996). Interestingly, a *coxWXYZ* mutant had a marginally decreased symbiotic nitrogen-fixation activity (70% residual nitrogenase activity as compared with the wild type). Hence, apart from cytochrome cbb_3, the *coxWXYZ*-encoded ubiquinol oxidase might partially contribute to the respiratory activity of *B. japonicum* at some stage during nodule colonization (Surpin and Maier, 1999).

29.4 TWO CYTOCHROME *bd*-FAMILY MEMBERS

Completely unrelated to the heme-copper oxidases are the so-called *bd*-type quinol oxidases (Jünemann, 1997). The two-subunit *bd*-type oxygen reductases do not contain copper as cofactor, and their subunits do not share significant sequence similarity with subunits of the heme-copper oxidases. As the name says, they contain hemes B (two) and D (one) as cofactors, where the active site is generally composed of heme B_{595} and heme D in which the iron atoms of the two tetrapyrroles form a binuclear center (Borisov et al., 2011). The *B. japonicum* genome obviously encodes two homologs of this enzyme class (Fig. 29.1). Unfortunately, it is not known under which growth conditions these genes are expressed, which makes it difficult to attribute a specific function to them. Intriguingly, the bll0283-0282 genes are clustered together with genes for a malate degradation pathway (not shown). Yet, a mutant of bll0283 ($cydA_1$) was found to be unaffected both in free-living growth on malate and in symbiosis (Arslan, 2001). Heterologous expression of the *B. japonicum* $cydA_1B_1$ genes in an *Escherichia coli* strain that was depleted of its own three terminal oxidases revealed the spectrophotometric features of a *bd*-type oxidase, which underlined the functionality of *B. japonicum* $cydA_1B_1$ in *E. coli* (Arslan, 2001).

29.5 FACTORS INVOLVED IN THE BIOGENESIS OF CYTOCHROMES aa_3 AND cbb_3

The following paragraphs in this section describe all of the proteins that are relevant for the biogenesis of cytochrome oxidases, with special emphasis on those from *B. japonicum*. These are compiled in Table 29.1.

29.5.1 Surf1

Subunit I of aa_3-type heme-copper oxidases contains two molecules of heme A deeply buried within a hydrophobic pocket and functioning as cofactors for the O_2 reduction site. Heme A is synthesized from heme O by an enzyme termed heme A synthase and integrated into subunit I with the aid of a protein termed Surf1. Members of the Surf1 family of proteins are approximately 30-kDa inner mitochondrial membrane/periplasmic, membrane-anchored proteins exclusive to mitochondria/Alphaproteobacteria. They contain two transmembrane helices connected by a large loop facing the intermembrane space/periplasm (reviewed by (Hannappel et al., 2012)). Mutations in the *SURF1* gene are a frequent cause of Leigh's disease in children (Tiranti et al., 1998; Zhu et al., 1998; Darin et al., 2003), a usually fatal neurological disorder associated with severe cytochrome oxidase deficiency (Leigh, 1951). Surf1 proteins are not essential for cytochrome oxidase assembly but deletion of their genes substantially decreases activity of their associated oxidase (~60% loss in *P. denitrificans* (Bundschuh et al., 2008) and 80–90% in human tissues (Van Coster et al., 1991; Tiranti et al., 1999; Williams et al., 2004; Stiburek et al., 2005)) and causes a specific decrease in the heme A cofactor in aa_3-type cytochrome oxidase (Smith et al., 2005; Bundschuh et al., 2008). Surf1 copurifies with subunit I (Hannappel et al., 2012), and the transfer of heme A from heme A synthase to Surf1 has been demonstrated *in vitro* (Hannappel et al., 2011). The exact role of Surf1 in COX assembly is still unclear but it may facilitate heme A insertion into subunit I in one or more of the following ways: (i) protection of subunit I during heme A insertion; (ii) regulation of heme A synthase activity by controlling the release of heme A to subunit I; or (iii) insertion of heme A into subunit I. Given that free heme is toxic to the cell (Kumar and Bandyopadhyay, 2005; Anzaldi and Skaar, 2010), Surf1 may also be important to chaperone heme A and prevent it from being free within the membrane.

B. japonicum has two homologs of *surf1* within its genome. The first homolog, blr1177, is located at the end of the operon-encoding cytochrome *c* oxidase subunits I–III (*coxA*, *coxB*, *coxC*), *coxG*, and *coxE* (for heme O synthase) (see Fig. 29.1 for comparison). The second homolog, blr0153, is located downstream of the *cyo* operon-encoding subunits I–IV ($cyoA_2$-D_2) of a quinol oxidase (cf. Fig. 29.1). Other bacteria also have more than one homolog of *surf1* within their genome. In *P. denitrificans* there are two homologs of *surf1*; the first termed *surf1c* is located in an operon encoding the subunits of aa_3-type cytochrome oxidase, and the second termed *surf1q* is located in an operon encoding a ba_3-type quinol oxidase (Bundschuh et al., 2008). Deletion of either *surf1* homolog results in an exclusive loss of activity of its associated oxidase (Bundschuh et al., 2008). In *B. japonicum*, we have constructed

This table lists all genes confirmed or thought to be important for synthesis of the cytochrome oxidases in *B. japonicum*. This table also lists whether or not a mutant has been constructed, the Fix phenotype of the mutant, and relevant references.

deletion mutants of blr1177 and blr0153 and named them Δ*surf1c* and Δ*surf1q* in accordance with the aforementioned *P. denitrificans* homologs. As in *P. denitrificans*, deletion of *surf1c* (blr1177) but not deletion of blr0153 (*surf1q*) causes loss of activity of the aa_3-type cytochrome oxidase (Z. Youard and E. Rigozzi, unpublished results). We were unable to test the effect of the two mutations on activity of the cyo_2-encoded quinol oxidase because it is unknown at present under what conditions this oxidase is important for growth of *B. japonicum*.

29.5.2 Ccm System

As was described earlier, the symbiotically essential cbb_3-type cytochrome oxidase contains two subunits that are *c*-type cytochromes (FixO and FixP). Therefore, biogenesis factors involved in cytochrome *c* formation are symbiotically relevant as well. All *c*-type cytochromes contain at least one B-type heme that is linked covalently to the polypeptide by one to two thioether bonds. Attachment of the vinyls at positions 2 and 4 of the tetrapyrrole ring of heme to the thiols of the two cysteines (Cys_1 and Cys_2) of the heme-binding motif (C_1XXC_2H) of *c*-type apocytochromes (apocyt *c*) requires a series of membrane-associated biogenesis proteins. In Alphaproteobacteria and Gammaproteobacteria, archaea, mitochondria of plants, red algae, and in *Deinococcus* species, this pathway is referred to as the cytochrome *c* maturation (Ccm) system or System I (reviewed by (Sanders et al., 2010)).

The Ccm system can be separated into three operational modules (I–III) and consists of up to 10 membrane-bound proteins including CcmABCDEFGHI encoded by the *ccm* operon and CcdA (DsbD in some species). Module I consists of five components, CcmABCDE, of which the first four components (CcmABCD) are possibly involved in transporting and loading heme B onto CcmE (Schulz et al., 1999; Ren and Thöny-Meyer, 2001). CcmE seems to function as a chaperone to supply heme for module III and apocyt *c* (Mavridou et al., 2012). Module II consists of CcdA/DsbD, CcmG, and CcmH, and its proposed function is to prepare apocyt *c* for heme binding by reducing the cysteines of the heme-binding motifs to allow addition of heme B. It has been proposed that oxidation of these cysteines into intramolecular disulfide bonds occurs upon Sec-dependent translocation of apocyt *c* across the membrane via the extracytoplasmic DsbA-DsbB oxidative protein-folding pathway. CcdA/DsbD, CcmG, and CcmH are reducing agents that contain thioredoxin-like motifs (CXXC) for the reduction of disulfide bridges. Module III catalyses ligation of heme B to apocyt *c* to form holocytochrome *c* (holocyt *c*). The components of Module III appear to differ between species.

In *R. capsulatus*, for example, the activity of Module III has been attributed to CcmF, CcmH, and CcmI. The function of each component in Module III has not yet been determined, and various theories have been put forward to explain their importance for heme ligation. The Ccm system of *B. japonicum* has not been as well studied as the *E. coli* and *R. capsulatus* systems partly due to the difficulty of biochemical characterization within this species (lack of nonpolar *ccm* mutants, low abundance of Ccm proteins, and lack of a system for native overexpression). The *ccm* homologs in *B. japonicum* are organized into separated gene clusters, *cycABCXY* and *cycHJKL* (Ramseier et al., 1991; Ritz et al., 1993, 1995; Fabianek et al., 1997).

29.5.3 TlpA

Thioredoxins are ubiquitous proteins that share a common 3D architecture known as the thioredoxin fold, consisting of four α-helices and five β-sheets, and a highly conserved active-site sequence (Cys-Gly-Pro-Cys) (reviewed by Zeller and Klug (2006)). If soluble in the cytoplasm, these proteins form part of the thioredoxin system in which electrons are passed from NADPH to thioredoxin via thioredoxin reductase. Thioredoxin proteins have a low redox potential and are efficient reductants for disulfide bonds. Together with the glutaredoxins, thioredoxins help to maintain the intracellular reducing environment and play an important role in regulation of enzyme activity through redox-dependent signal transduction, a process termed the thiol switch (reviewed by Paget and Buttner (2003)).

In *B. japonicum* a thioredoxin-like protein, TlpA, was identified that shares approximately 31% amino acid sequence identity with various eukaryotic and prokaryotic thioredoxins and protein disulfide isomerases (Loferer et al., 1993). It possesses the same characteristic active-site sequence of all members of the thioredoxin family but is larger than other bacterial thioredoxins (23 kDa) and anchored to the cytoplasmic membrane with its active site-containing domain facing the periplasm. The *tlpA* mutant shows a pleiotropic phenotype with strongly decreased cytochrome *c* oxidase activity and defective development of nitrogen-fixing symbiosis with soybean compared to the wild type (Loferer et al., 1993).

Deletion of *tlpA* does not affect the expression or membrane insertion of the apoprotein of subunit I (CoxA), but it causes a decrease in the steady-state level of subunit I, suggesting that TlpA is involved in assembly/maturation or stabilization of cytochrome aa_3 (Loferer et al., 1993). Biochemical evidence from TlpA overexpressed in *E. coli* and purified without its membrane anchor ($TlpA_{sol}$) shows that it is a monomer in solution and catalytically active in reducing disulfides and oxidizing vicinal cysteine residues of heterologous proteins *in vitro* and can thus be classified as a protein thiol:disulfide oxidoreductase (Loferer and Hennecke, 1994). Further studies revealed that TlpA was a reductant, supporting the idea that the primary role *in vivo* of TlpA was to keep thiols of target proteins reduced (Loferer et al., 1995). One strong candidate for a TlpA target protein is ScoI. ScoI is proposed to function as a copper chaperone or disulfide reductase for delivery of copper into the active site of cytochrome aa_3. Regardless of the exact function of ScoI, its activity depends on the cysteines in its active site being in the reduced dithiol form for binding of copper (Bühler et al., 2010; Mohorko et al., 2012). In fact, TlpA was recently shown to reduce ScoI *in vitro* with a reaction rate constant ($9.4 \times 10^4\ M^{-1}\ s^{-1}$) that is typical for physiologically relevant disulfide exchange reactions, and it was determined that the redox potential of TlpA was more negative than that of ScoI ($E^{0'}$ −256 mV vs. −160 mV) (Mohorko et al., 2012). In the same study, a transient heterodisulfide bond was observed between Cys107 of the active site of TlpA and Cys78 of the copper-binding site of ScoI (Mohorko et al., 2012). This supports that ScoI is a biologically relevant target for TlpA, and that TlpA is important for recycling the active-site cysteines of ScoI prior to binding of copper.

A number of issues are currently being addressed, such as the identification of the system that is responsible for reducing/regeneration of the TlpA active-site cysteines, the identity of the target protein/s of TlpA responsible for the symbiosis-defective phenotype of the *tlpA* mutant, and finally, whether other proteins are also targeted by TlpA. Some of these issues will be reiterated after the discussion of ScoI function (see later). The X-ray structure of $TlpA_{sol}$ has been determined, and a number of residues have been identified that may play an important role in target recognition and activity of TlpA (Capitani et al., 2001).

29.5.4 ScoI

ScoI, also called SenC or PrrC, is a homolog of the mitochondrial copper chaperone Sco1 (reviewed by Robinson and Winge (2010)). Sco proteins (synthesis of cytochrome *c* oxidase) are cytoplasmic/inner mitochondrial membrane-anchored proteins with a large soluble domain that faces the periplasm/inner membrane space. Sco proteins bind to one copper ion via a CXXXC motif and a conserved histidine ligand. Sco proteins are widespread in eukaryotic and prokaryotic organisms, and some species possess more than one Sco homolog (Banci et al., 2011). Sco proteins have been implicated in the assembly of both aa_3 and cbb_3 type oxidases, meaning either that the targets of Sco differ between species, depending on the oxidases they possess (Frangipani and Haas, 2009; Arunothayanan et al., 2010; Lohmeyer et al., 2012; Thompson et al., 2012; Serventi et al., 2012), or that Sco is hierarchically positioned in such a way that it serves the disparate Cu sites of both oxidase types.

There is evidence for a direct interaction between yeast Sco1 and subunit II of aa_3-COX, and overexpression of Sco1 rescues the aa_3-COX activity of yeast mutants lacking Cox17. These results are the sole basis for a proposed model by which Sco proteins aid the assembly of aa_3-type oxidases by transferring copper directly to the Cu_A center (Robinson and Winge, 2010). Contradictorily, direct transfer of copper from Sco1 to the Cu_A center of the ba_3-type oxidase of *Thermus thermophilus* was not observed, leading to the proposal of an alternative model by which Sco proteins reduce a disulfide bridge within the Cu_A-binding site of subunit II, allowing insertion of Cu by a newly discovered, periplasmic chaperone PCu_AC (Abriata et al., 2008).

In some bacteria (see earlier), Sco proteins are important for the assembly of cbb_3-type COX even though these oxidases lack the Cu_A center and possess only the Cu_B center. In *R. capsulatus*, a species that lacks aa_3-type COX and instead uses a cbb_3-type COX and a quinol oxidase as terminal oxidases (Thöny-Meyer et al., 1994; Ekici et al., 2012a), deletion of the Sco homolog SenC results in reduced cbb_3 COX activity that is restorable by the addition of copper (Lohmeyer et al., 2012). Copper-dependent rescue of cbb_3 activity was also observed in a *senC* mutant of *Pseudomonas aeruginosa* (Frangipani and Haas, 2009). The ability of copper to rescue cbb_3 activity of *sco* mutants supports a possible role for Sco in the delivery of copper to the Cu_B site of cbb_3 COX. *In vitro* cross-linking has shown that SenC of *R. capsulatus* may directly interact with the cbb_3 oxidase during biosynthesis. Delivery of copper to the Cu_B center is likely to involve a different mechanism compared to that for delivery to the Cu_A center, because the Cu_B center is deeply buried within the hydrophobic membrane unlike Cu_A that is located on a surface-exposed, periplasmic domain of subunit II. Further chaperoning proteins may therefore be involved in the delivery to the disparate copper sites (see Sections 29.5.5–29.5.7).

In *B. japonicum*, the Sco homolog ScoI binds copper *in vitro*, and the thiols of two cysteine residues, numbers 74 and 78, were shown to be essential for binding (Bühler et al., 2010). Deletion of the *scoI* gene blr1131 results in loss of aa_3-type cytochrome oxidase assembly and activity, and also appears to affect assembly/activity of the cbb_3 oxidase, but only when *B. japonicum* was examined in the symbiotic state (Serventi et al., 2012). A similar condition-dependent phenotype was observed for *pcuC* mutants, as will be discussed next.

29.5.5 PcuC

B. japonicum PcuC is a homolog of PCu_AC, a copper chaperone first identified by Banci and coworkers in a search of the gene neighborhood of *scoI* for new proteins involved in copper delivery to cytochrome *c* oxidase (Banci et al., 2005). The PCu_AC family of proteins are periplasmic and share a common metal-binding motif $H(M)X_{10}MX_{21\text{-}22}HXM$. This motif is located within a soluble C-terminal cupredoxin-like fold and binds to a single Cu(I) via the methionine and histidine side chains (Banci et al., 2005). The solution structures have been determined for both *Deinococcus radiodurans* (Banci et al., 2005) and *Thermus thermophilus* PCu_AC in both the apo-bound and Cu(I)-bound forms (Abriata et al., 2008). PCu_AC does not have a homolog in mitochondria, but it has been suggested that it performs a similar role to the mitochondrial protein Cox17. Cox17 is a soluble intermembrane protein proposed to transfer copper to Sco1 and Cox11 for assembly of the Cu_A and Cu_B centers, respectively, of cytochrome *c* oxidase (Horng et al., 2004; Banci et al., 2007, 2008).

In *B. japonicum*, there are two genes for homologs of PCu_AC: *pcuC* and blr7088. The gene *pcuC* is contained within an operon of five genes (*pcuABCDE*) (bll4882-4878) that are upregulated under copper starvation (Serventi et al., 2012). Genes *pcuA* and *pcuD* are predicted to encode soluble periplasmic proteins, and *pcuB* and *pcuE* are predicted to encode membrane integral proteins (Serventi et al., 2012). Gene *pcuA* contains a CXXC sequence and is conserved among the rhizobia, *pcuD* is of unknown function, *pcuB* encodes a TonB-dependent receptor, and finally *pcuE* encodes a protein similar to *B. subtilis* YcnJ or a fusion of CopC/CopD (Serventi et al., 2012). Blr7088 is located adjacent to the *nirK* gene (blr7089) encoding nitrite reductase. Despite being located next to *nirK*, mutation of blr7088 has neither any effect on anoxic growth with nitrate as the terminal electron acceptor nor any effect on aa_3-type cytochrome *c* oxidase activity or symbiotic nitrogen fixation (Serventi et al., 2012).

Deletion of the *pcuABCDE* operon results in a pleiotrophic phenotype compared to wild type, with impaired growth under copper starvation, impaired growth under conditions of anoxic nitrate respiration, a 75% decrease in symbiotic nitrogen-fixation activity, and a complete lack of activity of the aa_3-type cytochrome *c* oxidase (Serventi et al., 2012). Surprisingly, *pcuC* is plainly responsible for all of the aforementioned phenotypes (except perhaps the defect in growth under anoxic nitrate respiration where the exact contribution of each gene to this phenotype could not be clearly determined) (Serventi et al., 2012). The lack of a clear copper phenotype for the other genes does not exclude them from copper metabolism as they may be redundant in function or only important in environmental niches where copper concentrations are too low to be effectively mimicked by laboratory media.

Similar to other members of the PCu_AC family, PcuC binds a single Cu(I) in a 1:1 ratio (Serventi et al., 2012). The impaired nitrate respiration of the *pcuC* mutant suggests that PcuC may also be involved in the delivery of copper

to nitrite reductase NirK (Serventi et al., 2012). The importance of PcuC for symbiotic nitrogen fixation also points to PcuC being involved in copper delivery to the Cu_B center of the symbiotic cbb_3-type cytochrome oxidase. Enigmatically, membranes prepared from a *pcuC* mutant grown anaerobically with nitrate as the terminal electron acceptor (a situation under which nearly all cytochrome *c* oxidase activity is due to the cbb_3 oxidase) show wild-type levels of oxidase activity while those prepared from root-nodule bacteroids show strongly impaired activity (Serventi et al., 2012). This implies that PcuC plays an important role in copper delivery to the cbb_3 oxidase but only during endosymbiosis. How is this possible? It may be that PcuC is important for cbb_3 activity under both growth conditions, but that the copper available in the denitrification growth medium (0.2 μM; below this level even wild-type cells do not grow) was high enough to bypass the need for PcuC (Serventi et al., 2012). Increasing the copper concentration within the plant growth medium does not successfully restore cbb_3 oxidase activity of *pcuC* mutant bacteroids, but it is difficult (if not technically insurmountable) to determine how much copper is available to *B. japonicum* symbionts growing within nodules, how it is supplied by the plant, and whether increasing copper in the plant growth medium would increase copper availability for the bacteroid (Serventi et al., 2012).

The involvement of PCu_AC in cbb_3 oxidase assembly is not unique to *B. japonicum*. In *R. sphaeroides*, Thompson et al. have recently shown that PCu_AC is involved in the formation of both the Cu_A center of the aa_3-type oxidase and the Cu_B center of the cbb_3 oxidase (Thompson et al., 2012). They also found that, to a lesser degree, and despite the presence of Cox11, PCu_AC is also involved in formation of the Cu_B center of the aa_3-type oxidase. They have proposed that Cu_B is predominantly assembled by Cox11, but that PCu_AC helps to supply copper under low-copper conditions (Thompson et al., 2012). The exact copper center (Cu_A or Cu_B of the aa_3-type COX) that *B. japonicum* PcuC is supplying copper is currently unknown, and it is uncertain whether PcuC plays a direct role in construction of the copper centers or, alternatively, whether it supplies copper to another downstream protein that carries out this role. If PcuC does supply copper to another downstream chaperone, then ScoI would be a likely candidate. Future work must determine whether or not this is indeed the case.

29.5.6 CoxG/Cox11

CoxG, also termed CtaG in some Alphaproteobacteria, is a homolog of the mitochondrial protein Cox11 (Cox11p in yeast) and is involved in copper trafficking to the Cu_B site of aa_3 COX subunit I. For simplicity, we refer to all eukaryotic homologs as Cox11 and all prokaryotic homologs as CoxG in this review. (Note that CoxG/CtaG/Cox11 is unrelated to CtaG of *Bacillus subtilis*, which is involved in formation of a caa_3-type cytochrome (Bengtsson et al., 2004)).

Cox11 was first revealed to be required for the assembly of cytochrome *c* oxidase in yeast, *Saccharomyces cerevisiae*, where mutants lacking Cox11 exhibit a deficiency in cytochrome *c* oxidase activity (Tzagoloff et al., 1990). Subsequently in *R. sphaeroides*, it was shown that cytochrome aa_3 isolated from a Δ*coxG* mutant specifically lacked the Cu_B center (Hiser et al., 2000). The cytochrome *c* oxidase still contained both hemes but electron paramagnetic resonance spectroscopy showed that heme a_3, associated with the Cu_B binuclear center, was misaligned (Hiser et al., 2000).

The exact timing of Cu_B site formation is still unclear, but because Cu_B is deeply buried within subunit I in the cytoplasmic membrane/inner mitochondrial membrane and in a binuclear complex with heme A_3, it is presumed that the formation of the Cu_B center takes place at around the same time as insertion of heme A_3. In *S. cerevisiae*, Cox11 was found to be associated with the mitochondrial translation machinery, suggesting that Cu_B may be formed by a transient interaction between Cox11 and the nascent Cox1 protein during insertion of Cox1 into the inner mitochondrial membrane (Khalimonchuk et al., 2005). Additional evidence for an association of Cox11 with the translation machinery comes from *Schizosaccharomyces pombe* where Cox11 is encoded as a fusion (but later separated by proteolytic cleavage) with ribosomal component Rsm22 (Carr et al., 2005).

Cox11/CoxG is anchored to the inner mitochondrial membrane/bacterial cytoplasmic membrane by a single N-terminal transmembrane domain and has a soluble C-terminal domain that faces the intermembrane space/periplasm (Tzagoloff et al., 1990; Banci et al., 2004; Carr et al., 2005). The C-terminal domains of all Cox11/CoxG proteins are highly conserved.

Biochemical analysis of yeast Cox11 has determined that it is a dimer in both the apo-bound and Cu(I)-bound forms, and that Cox11 binds to one Cu(I) ion per monomer via three thiolate ligands (Carr et al., 2002). The two copper ligands in the Cox11 dimer form a binuclear cluster, and mutation of any of the three conserved Cys residues, two within a highly conserved CFCF motif in the middle of the C-terminal domain of Cox11 and a third at the C-terminus of the transmembrane domain, was found to decrease Cu(I) binding and oxidase activity (Carr et al., 2002; Banting and Glerum, 2006).

The solution structure of the monomeric, metal-free soluble domain of *Sinorhizobium meliloti* CoxG (apo-CoxG) was determined, and Cu(I) binding to CoxG was confirmed to involve formation of a binuclear Cu(I) cluster but composed of only two cysteines in the CFCF motif (Banci et al., 2004). The third conserved cysteine was proposed to form an intermolecular disulfide bond between CoxG monomers essential for function (Banci et al., 2004). Recently, contrary

to earlier reports, Thompson et al. found that in *Rhodobacter sphaeroides*, this cysteine is not required for dimerization of CoxG or for binding of copper. They instead propose that this cysteine is involved in transfer of Cu(I) from the copper binding site of CoxG to the Cu_B site of subunit I (Thompson et al., 2010).

In *B. japonicum*, *coxG* is located within the *cox* operon encoding cytochrome *c* oxidase subunits I–III (*coxA–C*), heme O synthase (*coxE*), and Surf1c (*shb1*) (Fig. 29.1). A knockout mutation of *coxG* results, as one would expect, in loss of cytochrome aa_3 assembly and activity, but surprisingly does not affect symbiotic nitrogen fixation that depends on the activity of cytochrome cbb_3 (Bühler et al., 2010). If *B. japonicum coxG* is required for cytochrome aa_3 assembly, then why is it not also an important chaperone for assembly of the Cu_B-containing cytochrome cbb_3?

29.5.7 FixGHIS

The *fixGHIS* gene cluster (termed *ccoGHIS* in *R. capsulatus* and *rdxBHIS* in *R. sphaeroides*) is required for assembly of the cbb_3 oxidase in rhizobia and *R. capsulatus/sphaeroides*. In most bacteria in which the *fixGHIS* gene cluster has so far been identified, it is located immediately downstream of the *fixNOQP* operon for the cbb_3 oxidase (Kahn et al., 1989; Mandon et al., 1993; Preisig et al., 1993; Thöny-Meyer et al., 1994; Ducluzeau et al., 2008). The *fixGHIS* gene cluster was first characterized in *Sinorhizobium meliloti* where transposon disruption of the *fixG*, *fixH*, *or fixI* genes gave the same defective symbiotic nitrogen fixation (Fix^-) phenotype as mutants of the *fixNOQP* genes (Kahn et al., 1989). In *B. japonicum*, the mutation of *fixGHIS* results in the Fix^- phenotype and in decreased cytochrome oxidase activity measured in cells grown under micro-oxic conditions (Preisig et al., 1996b). Membranes isolated from the *B. japonicum fixGHIS* mutant have only trace amounts of the cbb_3 oxidase showing that one or more of the FixGHIS proteins are important for its assembly (Preisig et al., 1996b). In *Azorhirobium caulinodans*, *fixGHI* is not essential for symbiotic nitrogen fixation (Mandon et al., 1993), but it was later discovered that this species utilizes two separate oxidases for symbiotic nitrogen fixation: a cbb_3 oxidase and a *bd* oxidase (loss of only one oxidase reduces nitrogen fixation by 20–30%) (Kaminski et al., 1996). In *R. sphaeroides*, genetic disruption of the FixG homolog RdxA established that it was not essential for nitrogen fixation (Neidle and Kaplan, 1992). However, unlike *B. japonicum* and *S. meliloti*, *R. sphaeroides* possesses a second homolog of *fixG* that may functionally compensate for loss of RdxA (Neidle and Kaplan, 1992).

The *fixGHIS* gene cluster encodes four predicted integral membrane proteins (Kahn et al., 1989). FixG is predicted to have five transmembrane helices, and contains two cysteine-rich motifs like those found in bacterial ferredoxins for coordination of iron-sulfur [4Fe–4S] clusters. In *R. sphaeroides*, the FixG homolog RdxA is inserted into the inner membrane in such a way that the cysteine-rich motifs project into the cytoplasm (Neidle and Kaplan, 1992). FixG may be involved in a redox process coupled to cation transport catalyzed by FixI (Kahn et al., 1989). Likewise, Preisig et al. proposed that FixG performs an oxidoreductase role based on the resemblance of its cysteine-rich motifs to the [4Fe–4S] cluster-binding motifs of ferredoxin proteins, and that it might be involved in intracellular oxidation of Cu(I) to Cu(II) following transport of Cu(I) across the membrane by FixI (Preisig et al., 1996b).

FixH, aside from two putative transmembrane helices, does not contain any defined motifs, cofactor/metal-binding sites, or homology with any proteins of known function (Kahn et al., 1989; Preisig et al., 1996b). In *R. capsulatus* deletion of the *fixH* homolog *ccoH* caused a large decrease in the amount of cbb_3 oxidase in the membrane despite normal wild-type levels of transcription of the *ccoNOQP* operon (Koch et al., 2000). This suggests that CcoH is important for posttranslational assembly of the cbb_3 oxidase. The function of FixH is still unknown, but Pawlik et al. found that CcoH interacts with CcoP (subunit III) of the cbb_3 oxidase and that it appears to remain tightly associated with CcoP even once the cbb_3 oxidase is fully assembled (Pawlik et al., 2010).

FixI is thought to be important for copper homeostasis due to its homology to the copper uptake protein CopA of *Enterococcus hirae*. CopA is a member of the P-type ATPase family that is involved in transport of heavy metal ions in prokaryotes and eukaryotes (reviewed by Solioz and Stoyanov (2003)). FixI possesses all of the characteristic sequence motifs of the P-type ATPase family including the CXXC motif thought to be the metal-binding site, the TGE motif that forms part of the phosphatase domain, the CPC motif involved in ion transduction, the DKTGT motif containing an aspartyl residue that is the site of phosphorylation, and the VGDG motif that forms part of the kinase domain (Kahn et al., 1989; Preisig et al., 1996b). In *R. capsulatus ccoI* was also found to be required for assembly of the cbb_3 oxidase, and this phenotype could be mimicked by copper starvation of wild-type *R. capsulatus*, suggesting that CcoI may be important for copper transport (Koch et al., 2000). A likely target for FixI/CcoI-mediated copper delivery is subunit I (FixN/CcoN) of the cbb_3 oxidase that contains a Cu_B center. There is evidence that if CcoI is a copper transporter, then it may not be dedicated solely to copper delivery to the cbb_3 oxidase. In *Rubrivivax gelatinosus*, it has recently been reported that the CcoI homolog in this species, CtpA, may be involved in delivery of copper to other Cu-enzymes including the aa_3-type oxidase and nitrous oxide reductase NosZ (Hassani et al., 2010). There is also evidence that more than one transporter is involved

in copper delivery to the cbb_3 oxidase. Recently, a novel major-facilitator superfamily (MFS)-type transporter CcoA was implicated in copper delivery to the cbb_3 COX in *R. capsulatus* (see Section 29.5.8).

FixS contains a putative N-terminal membrane anchor, but does not contain any other obvious sequence motifs and is not similar to any proteins of known function (Kahn et al., 1989; Preisig et al., 1996b). Mutation of *ccoS* in *R. capsulatus* did not affect presence of cbb_3 oxidase in the membrane but rendered it inactive due to absence of the cofactors in CcoN (Kulajta et al., 2006). In summary, there is evidence that at least *fixH*, *fixI,* and *fixS* play crucial roles in the assembly of the cbb_3 oxidase.

29.5.8 CcoA

Recent research in the purple nonsulfur bacterium *Rhodobacter capsulatus* has identified an MFS-type transporter termed CcoA required for assembly of cbb_3-COX (Ekici et al., 2012b). CcoA was identified by screening a library of cbb_3-COX defective mutants for restoration of cbb_3-COX activity by Cu^{2+} supplementation. In the absence of CcoA, cellular copper content was found to be decreased and assembly and activity of cbb_3-COX was defective (Ekici et al., 2012b). Although several homologs of *ccoA* are found in *B. japonicum*, none of them are upregulated under copper starvation. Instead we believe that another gene, bll0889, may encode an ortholog of *ccoA*. Gene bll0889 is predicted to encode an MFS-type transporter and is located within a cluster of seven genes, all upregulated (but none as strongly as bll0889) under extreme copper starvation (Serventi et al., 2012).

29.6 FUTURE PERSPECTIVES

Several burning questions remain to be answered, of which a selection of two is given here:

1. What is the function of the oxygen reductases other than cytochromes aa_3 and cbb_3 in the physiology of *B. japonicum*? Will it be possible to identify specific growth conditions and specific substrates for heterotrophic or lithotrophic oxidation, which require a particular cytochrome/ubiquinol oxidase in a conceptually similar manner as the cbb_3-type oxidase is required for micro-oxic respiration in symbiosis?
2. How is copper taken up into free-living cells or endosymbiotic bacteroids, and how is it delivered to target cuproproteins such as the heme-copper oxidases? Although a number of metallochaperones have meanwhile been identified, the situation is far from being clear with regard to how they cooperate. For example, the intriguing similarity of phenotypes displayed by *tlpA*, *scoI*, and *pcuC* mutants would argue for a concerted action of all three proteins. Are they hierarchically arranged so that copper can be relayed from one protein to the next? Which of the proteins decisively discriminates between the final metallation of the Cu_A and Cu_B centers? More biochemical work, such as establishing a copper transfer assay with purified components *in vitro*, will be needed.

Chapter 30

Rhizobial Extracytoplasmic Function (ECF) σ Factors and Their Role in Oxidative Stress Response of *Bradyrhizobium japonicum*

Nadezda Masloboeva, Hauke Hennecke, and Hans-Martin Fischer
Department of Biology, ETH, Institute of Microbiology, Zurich, Switzerland

30.1 GENE REGULATION MEDIATED BY σ FACTORS

Bacterial σ factors determine promoter specificity of RNA polymerase (RNAP). They are divided into two structurally and functionally distinct groups, the σ^{54} and the σ^{70} (Wösten, 1998; Gruber and Gross, 2003). Transcription by RNAP containing σ^{54} is initiated from promoters that show high conservation around positions −24 and −14 relative to the transcription initiation site and obligatorily requires an enhancer-binding protein (EBP) and adenosine triphosphate (ATP) hydrolysis (for reviews, see (Ghosh et al., 2010; Bush and Dixon, 2012)). Many genes involved in nitrogen fixation in rhizobia and other diazotrophs are preceded by −24/−14-type promoters and thus transcribed by RNAP associated with σ^{54}.

The σ factors of the σ^{70} type are ubiquitous bacterial proteins comprising two to four structurally and functionally conserved domains (Gruber and Gross, 2003; Paget and Helmann, 2003). Extensive analysis of σ^{70}-type factors has revealed the roles of different domains in promoter recognition and initiation of transcription (Fig. 30.1). For example, domains σ_4 and σ_2 of σ^{70}-type σ factors make contacts with conserved promoter elements around positions −35 and −10, respectively, relative to the transcription initiation site (for reviews, see (Paget and Helmann, 2003; Österberg et al., 2011; Decker and Hinton, 2013)). Four distinct subgroups of σ^{70} factors are defined based on structural and functional features. Sigma factors of groups 1 and 2 possess all four conserved domains and comprise the largest σ factor proteins (ca. 70 kDa). While group 1 consists of essential primary σ factors, groups 2–4 include alternative σ factors required for specific bacterial functions that may or may not be essential. Sigma factors RpoD and RpoS of *Escherichia coli* are classical examples of group 1 and group 2 σ factors, respectively.

The σ factors of group 3 are significantly smaller in size (ca. 20–35 kDa) than those belonging to groups 1 and 2 because they lack domain σ_1 (Fig. 30.1). Members of this group control diverse cellular functions such as sporulation, heat shock protection, and flagella biosynthesis. Prominent examples of group 3 are the *Bacillus subtilis* factor SigH (σ^H) involved in the initiation of sporulation, the *E. coli* heat shock σ factor RpoH, and the *E. coli* FliA σ factor, which directs transcription of flagella and chemotaxis genes.

The largest group among σ^{70}-type factors is group 4, which comprises small σ factors (ca. 20–25 kDa) consisting only of domains σ_4 and σ_2 (Fig. 30.1). Group 4 σ factorsare highly diverse with regard to function and amino acid

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

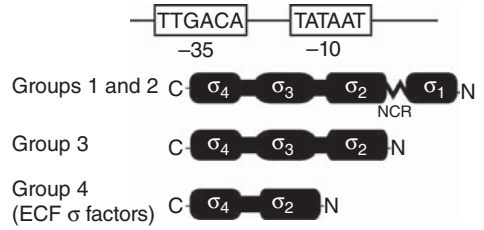

Figure 30.1 Classification and simplified domain architecture of σ^{70}-type σ factors. The role of domains σ_2 and σ_4 in recognition of −10 and −35 promoter elements is indicated. NCR indicates a nonconserved linker region between domains σ_2 and σ_1 of group 1 and 2 σ^{70} proteins. See text for further details.

sequence. Many σ factors of this group respond to signals from the extracytoplasmic compartment, and hence members of group 4 are referred to as extracytoplasmic function (ECF) σ factors. ECF σ factors control genes involved in different cellular functions, such as stress responses, metal homeostasis, virulence-related traits, and cell envelope structure. The number of ECF σ factors varies widely among bacterial species. For example, bacteria belonging to the *Chlamydiae* phylum or *Borrelia* genus lack this type of σ factor, *Staphylococcus* spp. harbor 1, *E. coli* 2, *B. subtilis* 7, *Mycobacterium tuberculosis* 10, *Caulobacter crescentus* 13, *Pseudomonas aeruginosa* 18, and *Streptomyces coelicolor* 50 ECF σ factors (Helmann, 2002; Staroń et al., 2009). ECF σ factors, particularly those present in rhizobia, are the focus of this chapter.

30.2 DIVERSITY AND COMMON FEATURES OF ECF σ FACTORS

Apart from their common structural organization, most ECF σ factors share four features: (i) ECF σ factors in complex with RNAP often transcribe their own gene and thus create a positive-feedback loop. (ii) In general, ECF σ factors control relatively small regulons. (iii) Activity of ECF σ factors is often controlled negatively via protein–protein interaction with an anti-σ factor. Usually, in the absence of stimuli, association of an ECF σ factor with RNAP is prevented by binding to its cognate anti-σ factor. In the presence of an appropriate stimulus, the ECF σ factor is released from the σ–anti-σ factor complex and binds to RNAP. (iv) Genes coding for ECF σ and anti-σ factors often form an operon and thus are tightly coregulated.

The diversity of bacterial ECF σ factors has been addressed only relatively recently in systematic analyses. In a bioinformatics analysis of ECF σ factors retrieved from sequenced bacterial genomes, more than 40 distinct classes of ECF σ factors were defined based on amino acid sequence similarity and domain structure of the associated anti-σ factors (Staroń et al., 2009). The study revealed that ECF σ factors exhibit a conserved domain structure and are ubiquitous in bacterial species while anti-σ factors show a surprising structural diversity. Many (but not all) anti-σ factors consist of a cytoplasmic portion that mediates ECF σ factor inhibition and an inner membrane or periplasmic domain that can sense extracytoplasmic signals. Great diversity of anti-σ factors likely reflects their ability to sense various stimuli and transduce the signals to the cognate ECF σ factors.

30.3 σ FACTORS IN RHIZOBIA

Transcription of many genes involved in nitrogen fixation is under control of a redox-responsive EBP-family protein NifA that acts in concert with RNAP containing σ^{54}. Accordingly, much attention was given to rhizobial σ^{54} factors (also named RpoN) in the pre-genomic era (Ronson et al., 1987; Kullik et al., 1991; Stigter et al., 1993; Fischer, 1994; Michiels et al., 1998a,b; Clark et al., 2001). Notably, several rhizobial species, including *B. japonicum*, *Mesorhizobium loti,* and *Rhizobium etli*, possess two variants of σ^{54} (Table 30.1).

Apart from the σ^{54} factors, rhizobia possess different numbers of σ^{70} factors (Table 30.1). Similar to most bacteria, rhizobial genomes encode one primary σ factor. The primary σ factors of *B. japonicum*, *R. etli*, and *S. meliloti* are very similar to that of *E. coli*, except for an extended σ_1 region that makes rhizobial proteins larger than the *E. coli* ortholog (about 80 kDa instead of 70 kDa) (Rushing and Long, 1995; Luka et al., 1996; Beck et al., 1997).

Unlike *E. coli*, rhizobia do not encode group 2 σ^{70} factors, but they often possess multiple paralogs of group 3 σ factors (Table 30.1). These σ factors, named RpoH according to the *E. coli* heat shock σ factor, display distinct functions and modes of regulation. Of the three *rpoH* genes in *B. japonicum*, $rpoH_2$ is essential for growth but the remaining two *rpoH* genes are dispensable for free-living growth and symbiosis (Narberhaus et al., 1997). In *S. meliloti,* $RpoH_1$ is required for efficient symbiosis while deletion of the other *rpoH* paralog does not lead to any discernible phenotype (Mitsui et al., 2004; Barnett et al., 2012).

While ECF σ factors belonging to group 4 are most abundant among (putative) rhizobial σ factors, comparatively little information is available about their function(s) and mode of regulation (Table 30.2).

In *B. japonicum*, two ECF σ factors EcfS (Bll4928) and EcfG (Blr7797) were shown to be required for an efficient symbiotic interaction with soybean host plants (Gourion et al., 2009; Stockwell et al., 2012). EcfG represents the general stress response σ factor that is regulated by its anti-σ factor NepR (Bsr7796) and its anti-anti-σ factor PhyR (Bll7795). EcfG-dependent gene expression can be induced by nutrient starvation (Francez-Charlot et al., 2009; Gourion et al., 2009). EcfS is negatively controlled by the putative anti-σ factor TmrS, which is cotranscribed with *ecfS*; yet no

Table 30.1 Numbers of σ^{54}- and σ^{70}-type σ factors in six rhizobial species and in *E. coli*

Organism*	Number of (Predicted) σ Factors in Individual Families and Groups					
	σ^{54} Family	σ^{70} Family				
	Total No.	Total No.	Group 1 (SigA, RpoD)	Group 2	Group 3 (RpoHs)	Group 4 (ECFs)

*Listed are rhizobial species whose ECF σ factors were analyzed by (Staroń et al., 2009).

†Group numbers according to the classification of (Staroń et al., 2009).

‡The designation of *B. japonicum* USDA 110 σ factors belonging to ECF group 16 and 33, which are discussed in detail in this chapter, are specified below the respective numbers.

information about the inducing signal(s) is available. More recently, two additional ECF σ factors of *B. japonicum*, EcfQ (Bll1028), and EcfF (Blr3038), were studied, and it turned out that they contribute to the oxidative stress response in this bacterium (Masloboeva et al., 2012; see below).

A general stress response ECF σ factor, RpoE2 (SMc01506), was also studied in *S. meliloti* (see Chapter 40). Deletion of *rpoE*2 had no effect on symbiotic properties and on the tolerance of free-living cells to various stress conditions (Sauviac et al., 2007; Bastiat et al., 2010). In *S. meliloti*, RpoE2 is regulated by the NepR-type anti-σ factors RsiA1 and RsiA2 (SMc01505, SMc04884) and the PhyR-type anti-anti-σ factors RsiB1 and RsiB2 (SMc01504, SMc00794), which are both present as two paralogs (Bastiat et al., 2010). Recently, two additional ECF σ factors of *S. meliloti*, RpoE1, and RpoE4, were characterized and shown to be activated in stationary phase likely by endogenously produced sulfite (Bastiat et al., 2012). An exhaustive mutagenesis approach is currently applied to all *S. meliloti* ECF σ factor genes in the laboratory of S.R. Long, Stanford University, CA, USA [http://www.isv.cnrs-gif.fr/colloque-AK2012/program.html].

In *R. leguminosarum* bv. viciae, the ECF σ factor RpoI is required for synthesis of the vicibactin siderophore and iron uptake. It is similar to ECF-type σ factors PvdS, PfrI, and PdrA of *Pseudomonas* spp. and, to a weaker extent, also to *E. coli* FecI (Yeoman et al., 1999; Carter et al., 2002). The mechanism of how RpoI is regulated has not been unraveled. In the following sections, the role of oxidative stress as an inducer of ECF σ factor-mediated responses is discussed.

30.4 DIVERSITY AND SOURCES OF REACTIVE OXYGEN SPECIES (ROS)

Key biological processes such as respiration and defense reactions are dependent on molecular oxygen (O_2). Molecular oxygen contains two unpaired, spin-aligned electrons in its outer *p* molecular orbitals. Such orbital occupancy enables O_2 to accept electrons or energy to generate type

I or type II reactive oxygen species (ROS), respectively (for review, see (Cadenas, 1989; Ziegelhoffer and Donohue, 2009)). A one-electron reduction of O_2 results in the formation of a superoxide anion radical (superoxide, $O_2^{\bullet -}$). Further reduction by the transfer of a second electron produces a peroxide anion (O_2^{2-}), which exists as hydrogen peroxide (H_2O_2) in biological systems. In turn, H_2O_2 reacts with iron ions (Fe^{2+}) in the Fenton reaction that leads to the formation of hydroxyl radicals ($OH^{\bullet}$). The type II ROS singlet oxygen ($^1O_2$) is produced as a result of energy transfer to O_2. Different ROS have distinct properties such as chemical reactivity, half-life, and solubility (Halliwell and Gutteridge, 1999). Most reactive among ROS are hydroxyl radicals whereas superoxide is much less deleterious, because it does not penetrate membrane bilayers due to its negative charge. Because of the rapid interconversion of different ROS in biological systems, it is difficult to assign specific effects to individual ROS.

While the respiratory chain of aerobic organisms is a major source of type I ROS, type II ROS are predominantly generated by excited chromophores in photosynthetic microorganisms and plants (Imlay, 2013). A mixture of ROS is generated deliberately in numerous biological processes. Among them is the respiratory burst by stimulated phagocytes that generate ROS via NADH oxidase. Likewise ROS can be detected during the initial steps of plant–pathogen and plant–symbiont interactions where ROS not only play a role in host defense reactions but also act as signaling molecules (for reviews, see (Nanda et al., 2010; Puppo et al., 2013)).

30.5 ROS IN THE *RHIZOBIUM*–LEGUME SYMBIOSIS

Rhizobial lipochito-oligosaccharide signal molecules (Nod factors) and initial contact of rhizobial cells with the epidermis of roots induces host defense reactions including production of ROS (H_2O_2, superoxide) and nitric oxide (NO) (for reviews, see (Pauly et al., 2006; Chang et al., 2009; Nanda et al., 2010; Saeki, 2011; Puppo et al., 2013; see Chapter 64)). Unlike the response to pathogens, however, the response to symbiotic rhizobia is transient and eventually suppressed by proficient symbionts (Santos et al., 2001; El Yahyaoui et al., 2004; Kouchi et al., 2004; Zamioudis and Pieterse, 2012). Notably, H_2O_2 seems to act also as a developmental signal for invading bacteria as indicated by the delayed nodulation phenotype of a *S. meliloti* strain overexpressing a catalase gene (Jamet et al., 2003). Thus, at the early stage of the rhizobia–legume interaction, bacterial antioxidant defense reactions are crucial to overcome the oxidative stress imposed by the host (Santos et al., 2000; Bueno et al., 2001).

The threat imposed on rhizobial symbionts by ROS persists also in mature nodules because of the high abundance of leghemoglobin. This plant-derived hemoprotein functions as an oxygen buffer. It maintains the concentration of free oxygen in the low nanomolar range, which protects oxygen-labile nitrogenase from irreversible inactivation and yet enables bacteroids to generate ATP via microaerobic respiration with the specialized FixNOQP cytochrome oxidase that has a high oxygen affinity. Auto-oxidation of leghemoglobin is probably a major source of superoxide in nodules (Puppo et al., 1991; Gunther et al., 2007). Moreover, transition metals that are abundant in nodules in combination with preformed H_2O_2 might generate hydroxyl radicals, ferryl heme proteins, and protein radicals (Becana and Klucas, 1992; Davies and Puppo, 1992; Moreau et al., 1996).

Finally, elevated concentrations of peroxides and protein carbonyls were reported to occur during natural and stress-induced nodule senescence possibly due to increased concentrations of free iron that serves as a catalyst for ROS generation (Escuredo et al., 1996; Gogorcena et al., 1997; Evans et al., 1999; Becana and Klucas, 1992; Mathieu et al., 1998).

30.6 ROS DETOXIFICATION IN THE *RHIZOBIUM*–LEGUME SYMBIOSIS

ApartRhizobia possess multiple enzymatic antioxidant defense systems with some of them also required for the development and/or proper functioning of symbiosis (for reviews, see (Becana et al., 2010; Puppo et al., 2013)). *S. meliloti* possesses two superoxide dismutase enzymes (SodA and SodC; (Santos et al., 1999; Santos et al., 2000; Flechard et al., 2009)) plus three catalases, that is, two monofunctional hydroperoxidases (KatA, KatC) and a bifunctional catalase-peroxidase (KatB) (Hérouart et al., 1996; Ardissone et al., 2004). In this bacterium, deletion of an individual catalase gene does not cause a symbiotic defect, but double-deletion mutants lacking KatA plus KatC or KatB plus KatC are impaired in nodule formation and nitrogen fixation (Sigaud et al., 1999; Jamet et al., 2003). Reduced nitrogen-fixation activity was also observed when the symbiotic properties of a *katG, prxS* (encoding a peroxiredoxin) double mutant of *Rhizobium etli* were tested on its host plant *Phaseolus vulgaris* (Dombrecht et al., 2005).

Apart from ubiquitous ROS detoxifying systems, rhizobial genomes encode additional enzymes that might play a role in ROS elimination. For example, the *S. meliloti* genome encodes three alkyl hydroperoxide reductases that also might use H_2O_2 as a substrate (Seaver and Imlay, 2001). In addition, *S. meliloti* secretes a putative chloroperoxidase (Smc01944) upon exposure to various hydroperoxides, and expression of a peroxiredoxin-encoding gene (*prxS*) is induced during symbiosis (Barloy-Hubler et al., 2004; Dombrecht et al., 2005).

With regard to mechanisms regulating oxidative stress response in rhizobia, only limited information is available. In *S. meliloti*, transcription factor (TF) OxyR controls expression of two (*katA* and *katB*) of the three catalase genes (Jamet et al., 2005; Luo et al., 2005)) while ECF σ factor RpoE2 is needed for synthesis of superoxide dismutase SodC and

the third catalase KatC (Flechard et al., 2009). Likewise, the *S. meliloti* OhrR TF negatively regulates expression of the symbiotically dispensable organic hydroperoxide resistance gene *ohr*, and possibly also that of the secreted peroxidase expression of above-mentioned Smc01944 ((Barloy-Hubler et al., 2004; Fontenelle et al., 2011)). In *R. etli*, regulation of catalase gene *katG* might be similar as in *E. coli.* Adjacent to *katG*, an OxyR-like regulatory protein is encoded and the *katG* promoter region contains sequence motifs characteristic of OxyR-binding sites (Vargas Mdel et al., 2003). By contrast, synthesis of KatG in *B. japonicum*, which is required for detoxification of H_2O_2 in aerobically growing cells, does not require the OxyR transcriptional activator (Panek and O'Brian, 2004).

30.7 REACTIVE OXYGEN SPECIES (ROS)-INDUCIBLE ECF σ FACTORS OF *Bradyrhizobium japonicum*

Global transcription profiling of *B. japonicum* cells grown microoxically (0.5% O_2 in N_2) and stressed with hydrogen peroxide revealed 225 regulated genes of which more than 10% have predicted regulatory functions (Fig. 30.2; (Masloboeva et al., 2012)).

This suggests a complex structure of the regulatory network that underlies the oxidative stress response in this bacterium. Within the subset of regulatory genes are two ECF σ factor genes, *ecfQ* (bll1028) and *ecfF* (blr3038), both of which are highly induced not only by hydrogen peroxide but also after exposure to singlet oxygen. Further studies revealed that *ecfQ* and *ecfF* mutants show enhanced sensitivity to singlet oxygen but not to other ROS. Neither *ecfQ* nor *ecfF* is required for an effective symbiosis of *B. japonicum* with different host plants, which is in line with bacteria

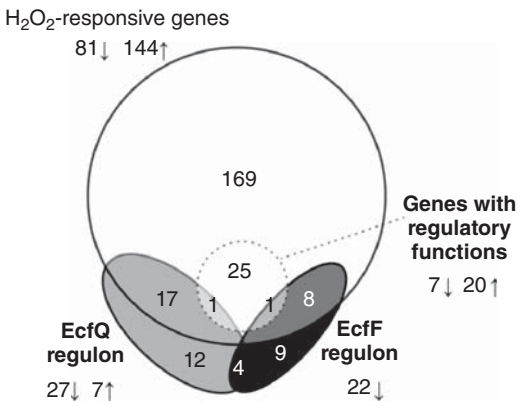

Figure 30.2 Venn diagram representing H_2O_2-responsive genes of *B. japonicum* cells and the genes of (minimally overlapping) EcfQ and EcfF regulons, all determined with cells grown under microoxic conditions. The dashed circle includes H_2O_2-responsive genes with predicted regulatory functions such as various transcription activators or ECF σ factors EcfQ and EcfF. Numbers of downregulated (↓) and upregulated (↑) genes are indicated.

being challenged by superoxide and hydrogen peroxide, but not singlet oxygen, during infection and symbiosis.

Mechanisms controlling expression and activity of EcfQ and EcfF are different. Unlike with *ecfF*, no (putative) anti-σ factor is encoded adjacent to *ecfQ*, and thus it is not known whether activity of EcfQ is controlled at the protein level. Transcription of *ecfQ* might be controlled by a yet to be identified TF, which may bind to conserved DNA motifs located upstream of the transcription start site. By contrast, EcfF is regulated in a manner typical for Ecf σ factors. It drives transcription of its own gene, and its activity is negatively regulated via direct interaction with the transmembrane anti-σ factor OsrA, which is encoded in the *ecfF-osrA* operon. Under nonstress conditions, EcfF activity is inhibited by binding to OsrA. Upon ROS exposure, EcfF is released from the complex thereby becoming available for association with RNAP core enzyme. Cysteine residue 179 of OsrA was shown to be crucial for EcfF activation and thus is an attractive candidate for sensing oxidative stress, yet the molecular details of this process remain to be unraveled (Fig. 30.3).

Using microarray analysis, we determined putative target genes of EcfF and EcfQ in cells grown microoxically. It turned out that both σ factors control rather small, largely distinct sets of genes (Fig. 30.2). The combined EcfQ and EcfF regulons include 13% of the members of the H_2O_2-responsive regulon. Transcriptional control of other H_2O_2-responsive genes outside of the EcfQ-/Ecf-regulons is likely mediated by TFs identified in the H_2O_2-responsive regulon. An example is the *B. japonicum* regulatory protein $FixK_2$, which was shown to be modulated posttranscriptionally by H_2O_2 (Mesa et al., 2009).

Although the regulon of EcfQ is functionally rather undefined (almost 70% of its members are hypothetical or unknown proteins), more than 70% of the proteins encoded by members of the EcfF regulon are functionally annotated. Remarkably, three (Bll5855, Blr7043, and Blr7044) of five methionine-sulfoxide (MetSO) reductases encoded in the *B. japonicum* genome belong to the EcfF regulon. Two of them (Bll5855, Blr7044) are cytoplasmic enzymes, while the third (Blr7043) is predicted to localize to the periplasm (Fig. 30.3). Notably, ECF σ factor-dependent genes for MetSO reductases have been identified previously in two Betaproteobacteria, *Neisseria gonorrhoeae* (Gunesekere et al., 2006) and *Neisseria meningitidis* (Hopman et al., 2010).

The function of MetSO reductases as antioxidant repair enzyme is well documented for a variety of bacterial species (see (Moskovitz, 2005) and references therein). Repair of oxidized methionines by MetSO reductases depends on electron donors which, under physiological conditions, are thioredoxin-like proteins (for review, see (Ezraty et al., 2005)). Accordingly, for repair of MetSOs in the periplasm, additional components are required to transfer electrons across the cytoplasmic membrane and deliver them to MetSO reductases functioning in the periplasm. A well-characterized example of such an electron transfer system is the DsbDC pair of proteins of *E. coli*, which is

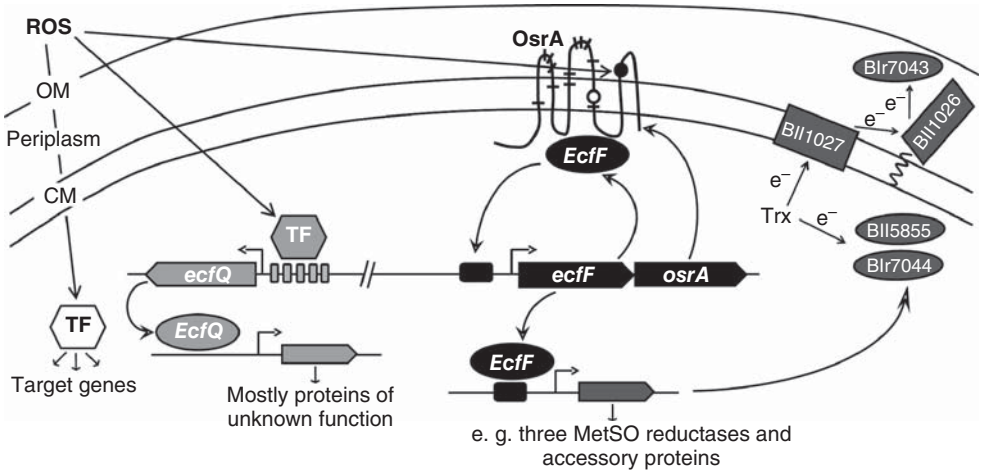

Figure 30.3 The role of ECF σ factors EcfQ and EcfF in the oxidative stress response of *B. japonicum*. The model summarizes the current knowledge about regulation by the two ECF σ factors, both of which contribute to the singlet oxygen tolerance of *B. japonicum*. Both σ factors are induced by reactive oxygen species (ROS). Transcriptional activation of *ecfQ*, which lacks an associated anti-σ factor gene, is postulated to be mediated by a hypothetical transcription factor (TF; gray hexagon) that binds to conserved DNA motifs in the *ecfQ* promoter region (gray boxes). Members of the EcfQ reglon are functionally largely unknown. EcfF is encoded in an autoregulated operon together with the gene for its cognate anti-σ factor OsrA whose predicted transmembrane topology is depicted. OsrA comprises a striking accumulation of methionine residues (bars), which may become oxidized by ROS and thus could be involved in sensing. In fact, a role in H_2O_2 sensing was shown for cysteine 179 (solid circle) while cysteine 129 (open circle) is needed for interaction with EcfF. Upon exposure to ROS, OsrA-bound EcfF is released and associates with RNA polymerase core to initiate transcription from EcfF-dependent promoters (black rectangles). Among EcfF target genes are those of three methionine sulfoxide (MetSO) reductases (Bll5855, Blr7043, Blr7044) and accessory proteins (Bll1026, Bll1027) involved in electron transfer across the cytoplasmic membrane to the periplasmic MetSO reductase. In addition to *ecfQ* and *ecfF*, more than 20 transcription factor genes are induced by ROS, whose products (TF; white hexagon) in turn activate the respective target genes.

needed for reduction or isomerization of disulfide bonds in the periplasm (Kadokura and Beckwith, 2010). Given that bll1026 and bll1027 are members of the EcfF regulon and encode a membrane-anchored periplasmic thioredoxin and an integral membrane protein with a DsbD β core domain, respectively, it is tempting to speculate that these proteins mediate electron transfer from a cytoplasmic electron donor across the membrane to the periplasmic MetSO reductase Blr7043 (Fig. 30.3).

30.8 PARALOGS AND ORTHOLOGS OF ECFF AND ECFQ

According to the classification of ECF σ factors by Staroń and coworkers (Staroń et al., 2009), EcfQ and EcfF of *B. japonicum* belong to groups ECF33 and ECF16, respectively (Table 30.2). Based on the (limited) number of rhizobial species included in the analysis, group 33 ECF σ factors are less prevalent in rhizobia than members of group 16. *B. japonicum* and the related photosynthetic *Bradyrhizobium* sp. BTAi1 each encode two paralogs of EcfQ and EcfF (Blr3042 and EcfS, respectively, in *B. japonicum*). Moreover, in both species, the genes for the group 16 σ factors (EcfF and EcfS) are followed by genes encoding transmembrane anti-σ factors (OsrA and TmrS in *B. japonicum*). By contrast, among the group 33 ECF σ factors, only one paralog comes as a cognate anti-σ–σ-factor pair (Blr3042 and Blr3043 in *B. japonicum*), whereas no anti-σ factor is associated with the second paralog (EcfQ). This may indicate a greater regulatory heterogeneity within group 33 σ factors than in group 16; yet more studies are needed to validate this hypothesis.

The increased singlet sensitivity of *B. japonicum* mutants lacking either EcfQ or EcfF indicates that these σ factors cannot replace each other in this aspect. The same applies to their paralogs Blr3042 and EcfS, which, however, is not surprising because neither of them is induced by oxidative stress. Likewise, EcfF cannot take over the crucial symbiotic role of its paralog EcfS (Stockwell et al., 2012), which is in agreement with the minimal overlap of the respective regulons (Masloboeva et al., 2012). The significance of singlet oxygen tolerance is probably more obvious for the photosynthetic bacterium *Bradyrhizobium* sp. BTAi1 because photosynthesis is a major source of singlet oxygen. Accordingly, it would be interesting to determine the photosynthetic and symbiotic phenotype of *Bradyrhizobium* sp. BTAi1 mutants lacking the orthologs of EcfQ and/or EcfF.

In conclusion, it becomes obvious that currently the genetic and functional diversity of rhizobial ECF σ factors is

only poorly explored. More systematic analyses are needed to get better insight into the complexity of the regulatory networks, which is reminiscent of the diversity in regulatory circuits that control nitrogen fixation and accessory symbiotic genes in rhizobia. Regarding *B. japonicum* EcfQ and EcfS, the elucidation of sensing and signaling mechanisms and the assignment of functions to target genes are obvious, challenging goals of future research.

31.1 INTRODUCTION

Plants can obtain nitrogen through associations with a variety of nitrogen-fixing bacteria. These nitrogen fixers can be loosely associated rhizosphere bacteria, endophytes that are living at low density inside plant tissues, or nodule-inducing bacteria that colonize plants at very high density. Although only a marginal fraction of the total nitrogen needs of plants can be obtained through the first two types of associations, nodulation can support all or a least a major part of its needs. This ability relies on the intimate contact between thousands of intracellular (endosymbiotic) bacteria and their host cells in the root nodules, the symbiotic nodule cells. Mature legume nodules contain several thousand symbiotic cells, each harboring thousands of intracellular, nitrogen-fixing rhizobia called bacteroids. The cytosolic space of the symbiotic cells is *quasi* entirely filled with bacteroids. These symbiotic cells are adapted to the symbiosis, to the metabolic exchange with the nitrogen-fixing rhizobia, and to the accommodation of this large bacterial population. Thus, the symbiotic cells need to maintain a homeostatic interaction with this large bacterial population, whereby elimination of the endosymbionts by defense reactions or, on the contrary, uncontrolled bacterial proliferation and collapse of the host cells have to be avoided. Because the symbiotic nodule cells are at the heart of the

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

Rhizobium–legume symbiosis, the mechanisms to reach homeostasis in the symbiotic cells as well as the bacterial adaptations required for their maintenance are now the subject of intense research.

The differentiation of the symbiotic nodule cells from their dividing progenitor cells in the nodule meristem involves genome doublings by endoreduplication cycles resulting in polyploid, giant symbiotic cells. The rhizobia proliferate in the infection threads, which are first initiated in root hairs and then ramify through the growing nodule. Differentiating host cells are penetrated by infection threads and bacteria are released from them through an endocytosis-like process, leaving the intracellular bacteria in membrane-enclosed organelle-like structures called symbiosomes. The symbiosome bacteria differentiate subsequently to nitrogen-fixing bacteroids. These bacteroids have a specific physiology and metabolism adapted to the symbiotic life and nitrogen fixation, which are dramatically different from those of a free-living bacterium. This differentiated state is obtained by a global transcriptome switch, which is primarily regulated by the rhizobial two-component regulator FixLJ. FixLJ is a sensor of the low-oxygen concentration that is prevalent in nodules (Kereszt et al., 2011).

In addition, the differentiation of bacteroids is often, but not always, accompanied by a morphological and cytological metamorphosis whereby the bacteroid cell becomes enlarged, its envelope fragilized, and its genome amplified and condensed. Three different bacteroid morphotypes have been described (Sen et al., 1986; Vasse et al., 1990; Mergaert et al., 2006; Bonaldi et al., 2011): elongated bacteroids which are sometimes also branched (designated below as the E-morphotype), enlarged spherical bacteroids (S-morphotype), and finally bacteroids that remain unmodified and have a rod-shaped morphology similar to free-growing rhizobia (U-morphotype). The metamorphosis to E- or S-morphotype bacteroids takes place in the symbiotic cells after the endocytotic release of rod-shaped *Rhizobium* bacteria in symbiosome vesicles (Vasse et al., 1990; Bonaldi et al., 2011). *Rhizobium* strains that can nodulate legumes of different clades adopt a bacteroid morphotype that is determined by the host. This indicates that the bacteroid morphotype is controlled by the host plant and results from host factors that induce the bacteroid metamorphosis (Sen et al., 1986; Mergaert et al., 2006; Bonaldi et al., 2011; see Chapter 28).

In *Medicago* and related legumes of the inverted repeat-lacking clade (IRLC), which form E-type bacteroids, a class of peptides named NCR (nodule-specific cysteine-rich) peptides control the bacteroid differentiation (Van de Velde et al., 2010). The NCR gene family has been identified in all investigated legume species of the IRLC clade but not in other plant species outside of this clade. Genome and transcriptome analyses have demonstrated that these genes are lacking in the non-IRLC legumes such as *Lotus japonicus*, *Glycine max*, or *Phaseolus vulgaris* (Mergaert et al., 2003; Alunni et al., 2007). A peculiar feature of the family in *Medicago truncatula* is that it is composed of about 600 genes that are all exclusively expressed in nodules (Mergaert et al., 2003; Alunni et al., 2007; Young et al., 2011). Within nodules, the NCR peptides are only produced by the infected symbiotic cells and are transported to the bacteroid-containing symbiosomes (Fig. 31.1). In the *M. truncatula dnf1* mutant that cannot transport NCR peptides anymore to the symbiosomes, bacteroid differentiation is aborted (Fig. 31.1) (Van de Velde et al., 2010; Wang et al., 2010). NCR peptides can induce typical features of E-morphotype bacteroids *in vitro* on cultured *Rhizobium* or *in planta* when expressed in transgenic *L. japonicus* plants, which form usually U-morphotype bacteroids (Van de Velde et al., 2010; Haag et al., 2011). Some NCR peptides accumulate to a significant extent in the cytosol of mature bacteroids (Van de Velde et al., 2010), suggesting that these peptides may have additional functions other than inducing the morphological transformation, and notably, it has been suggested that these intracellular NCR peptides may affect the bacteroid metabolism (Kereszt et al., 2011).

However, NCR peptides are similar to the defensin type of antimicrobial peptides (AMPs), and some NCR peptides have been found to have antimicrobial activity, killing *Rhizobium* when applied at high concentration. To counteract the antimicrobial activity of the NCR peptides, *Sinorhizobium meliloti*, the symbiont of *Medicago*, requires the BacA protein. In the absence of this protein, the bacteroids do not differentiate and are immediately killed by the NCR peptides in the nodule as soon as they are released in the symbiosomes (Haag et al., 2011). Here, we report on the current state of the art on the role of BacA and its homologs in other bacteria.

31.2 *BacA* IS REQUIRED IN LEGUMES FORMING E- OR S-MORPHOTYPE BACTEROIDS BUT NOT IN OTHER LEGUMES

The first rhizobial *bacA* gene was identified in a screen of *S. meliloti* mutants inducing ineffective (Fix^-) nodules on *Medicago sativa* (Glazebrook et al., 1993). In *Medicago* nodules formed by the *S. meliloti bacA* mutant, the bacteria infect the plant cells but do not elongate into the typical E-morphotype shape, and the rod-shaped bacteria in the symbiosomes quickly degenerate and lyse (Figs. 31.1 and 31.2) (Glazebrook et al., 1993; Maunoury et al., 2010; Haag et al., 2011). The gene's name reflects its role in bacteroid differentiation.

More recently, *bacA* genes in other *Rhizobium* species have also been investigated. It has been demonstrated

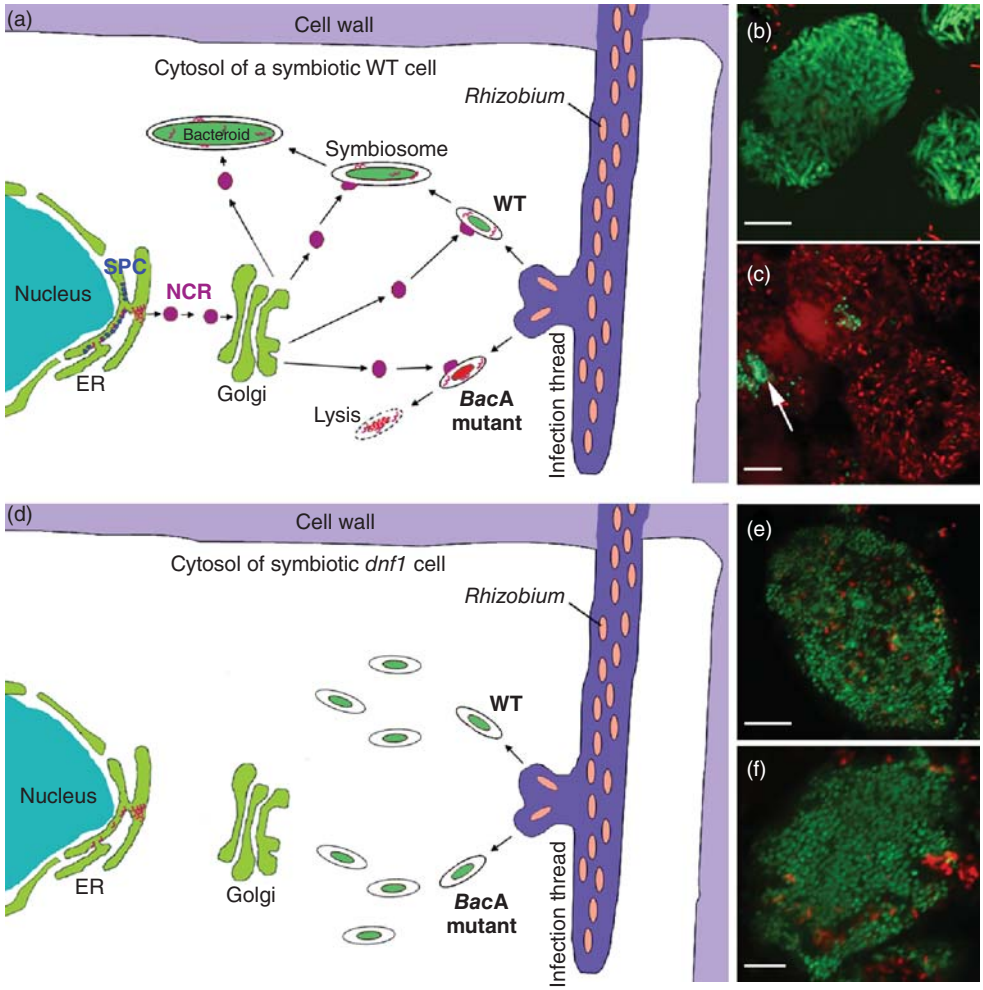

Figure 31.1 BacA is required for survival in the symbiotic nodule cells. (a) In a *M. truncatula* wild-type nodule cell, the *S. meliloti* wild-type (WT) and *bacA* mutant bacteria are released from the infection threads into membrane-bound symbiosomes. The bacteria are then challenged with host NCR peptides (purple), which are synthesized on the endoplasmic reticulum (ER) and transported to the symbiosomes via vesicle transport and a symbiotic nodule-cell-specific secretory pathway. This pathway requires an ER-located nodule-specific SPC containing the DNF1 subunit. The NCR peptides mediate the differentiation of the WT strain into a nitrogen-fixing bacteroid (green bacteroids), resulting in the chronic infection. In contrast, the *bacA*-deficient mutant is hypersensitive toward the host NCR peptides and is killed and then lysed (red symbiosome bacteria) rather than forming the chronic infection. (b) WT *S. meliloti* in WT host cells with live/dead staining, marking live bacteria in green and dead bacteria in red. The WT *S. meliloti* are healthy and differentiated. (c) Staining as in (b) of *bacA* mutant *S. meliloti* in WT host cells. The bacteria are nondifferentiated and dead except for the infection thread-located ones (arrow). (d) In an *M. truncatula dnf1* mutant nodule cell, the *S. meliloti* WT and *bacA* mutant bacteria are released from the infection threads into membrane-bound symbiosomes. The NCR peptides are not transported to the symbiosomes but remain blocked in the ER because of the absence of the DNF1 SPC subunit. Therefore, both WT and *bacA* mutant bacteria remain alive (green) within the symbiosomes but do not differentiate. (e) Staining as in (b) of WT *S. meliloti* in *dnf1* mutant host cells. The bacteria are alive but nondifferentiated. (f) Staining as in (b) of *bacA* mutant *S. meliloti* in *dnf1* mutant host cells. The bacteria are alive but nondifferentiated. Scale bars are 10 μm.

that the *bacA* gene of *Mesorhizobium huakuii* and two different *Rhizobium leguminosarum* bv. *viciae* strains were required for the formation of Fix$^+$ nodules on the legumes *Astragalus sinicus* and *Pisum sativum*, respectively (Tan et al., 2009; Karunakaran et al., 2010). Both legumes are closely related to *Medicago*, belonging to the IRLC legumes (Wojciechowski et al., 2004) and forming E-morphotype bacteroids. Histological analysis of *Pisum* nodules revealed that the *bacA*-deficient *R. leguminosarum* bv. *viciae* did not differentiate into bacteroids and could not survive in the symbiotic nodule cells but lysed after their release from the infection threads (Karunakaran et al., 2010), a phenotype similar to the *S. meliloti* mutant in *Medicago*.

In contrast, the *bacA* genes of *Mesorhizobium loti*, *Rhizobium leguminosarum* bv. *phaseoli*, *Rhizobium etli,* or

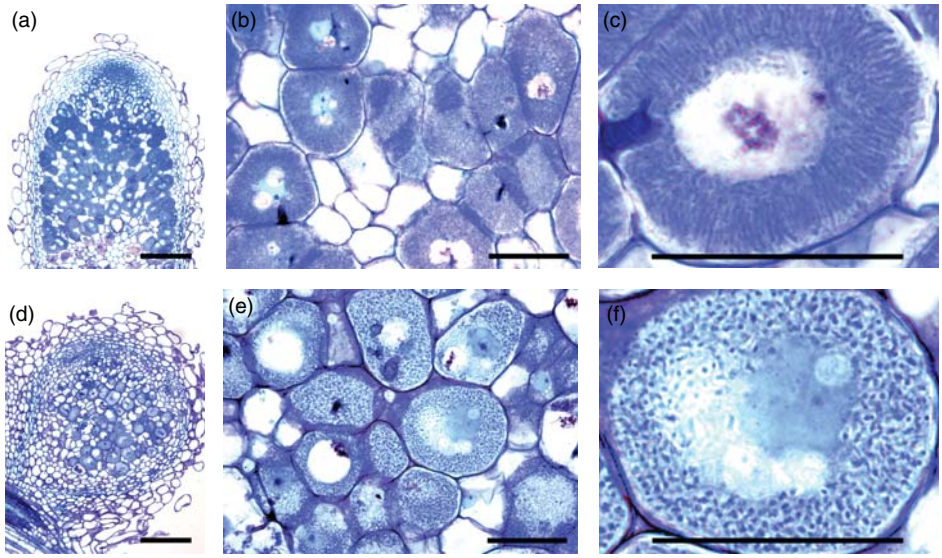

Figure 31.2 BacA is required for bacteroid differentiation in *Medicago*. Semi-thin sections stained with toluidine blue are shown of *M. truncatula* nodules infected with wild-type (WT) *S. meliloti* (a–c) or its *bacA* mutant (d–f). (a,d) Whole nodules. (b,e) Enlargement of a region containing symbiotic nodule cells. (c,f) Closeup of a single symbiotic cell, showing the elongated (E-morphotype) bacteroids in the WT infected cell (c) and the nondifferentiated bacteria in the cell infected with the *bacA* mutant (f). Scale bars are 200 µm (a,d) or 50 µm (b,c,e,f).

Sinorhizobium fredii strain NGR234 are dispensable for the formation of a functional symbiosis on various plants such as *L. japonicus*, *P. vulgaris*, *Lablab purpureus*, *Leucaena leucocephala*, *Tephrosia vogelii*, and *Vigna unguiculata* (Maruya and Saeki, 2010; Karunakaran et al., 2010; Ardissone et al., 2011). Contrary to the IRLC legumes, all these legumes form U-morphotype bacteroids and lack NCR peptides.

An eloquent example for the *bacA* requirement in symbiosis is provided by the *R. leguminosarum* bv. *viciae* strain A34 and the *R. leguminosarum* bv. *phaseoli* strain 4292, which have the same genetic background except for their symbiotic plasmids. These strains have opposing requirements for the *bacA* gene in symbiosis with *P. sativum*, which requires *bacA* and forms E-morphotype bacteroids, and with *P. vulgaris*, which does not require *bacA* and forms U-morphotype bacteroids (Karunakaran et al., 2010).

Bradyrhizobium species have a gene that is only distantly related to *bacA*, named *bclA* (see later). We have found that this *bacA*-like gene is required in *Bradyrhizobium* sp. for effective symbiosis on *Aeschynomene indica* or *Aeschynomene afraspera* whose bacteroids have the S- or E-morphotype, respectively (see Chapter 28). Mutants in the *bclA* gene do not differentiate and remain rod shaped in the symbiosomes (IG, PM, unpublished results). Strikingly, in *Bradyrhizobium japonicum*, the gene is not required for symbiosis with *G. max*, which forms U-morphotype bacteroids (IG, PM, unpublished results).

Taking together, these examples give ample evidence for a correlation between the need of the *bacA* or *bclA* gene and the formation of E- or S-morphotype bacteroids while the gene is dispensable when U-morphotype bacteroids are formed.

31.3 *BacA* PROVIDES PROTECTION AGAINST NCR PEPTIDES *in vitro* AND IN NODULES

NCR peptides induce E-morphotype bacteroid formation in IRLC legumes and unpublished evidence has demonstrated that a similar type of peptides is involved in bacteroid differentiation in *Aeschynomene* legumes. Thus the requirement of BacA or BclA proteins only for E- or S-morphotype bacteroid formation suggests that this protein plays a central role in the rhizobial response toward the NCR peptides (Kereszt et al., 2011). Two hypotheses have been put forward that could take into account the requirement of BacA (Haag et al., 2011). The protein could be directly required for the bacterial metamorphosis. However, synthetic NCR peptides induce *in vitro* bacterial elongation and DNA amplification to the same extent in the *S. meliloti bacA* mutant as in the wild-type (WT) strain, suggesting that BacA is not required for the differentiation process *per se* (Haag et al., 2011). The second possibility tested is related to the antimicrobial activity of NCR peptides. Indeed, NCR peptides resemble defensins, which are cysteine-rich AMPs of the innate immune system in animals and plants (Mergaert et al., 2003; Alunni et al., 2007). This type of immunity effector forms an early barrier against infections and has the capacity to kill invading microbes (Maróti et al., 2011). A subset of the NCR peptides possesses antimicrobial activity *in vitro* and treatment of *S. meliloti* and even other bacteria with these NCR peptides (at concentrations higher than those used for inducing bacterial differentiation) kills the microbes (Van de Velde et al., 2010; Haag et al., 2011; Tiricz et al., 2013). The killing activity of the NCR peptides is related to the damage they provoke on the bacterial membrane in a similar way as the defensins. Importantly, the *S. meliloti bacA*

mutant is between 10-fold and 100-fold more sensitive toward the antimicrobial action of NCR peptides (Haag et al., 2011; 2012). The hypersensitivity of the *bacA* mutant was not only specific to NCR peptides but applies also to the human β-defensin 2 (Arnold et al., 2013). This hypersensitivity provides a likely explanation for the mutant's symbiotic phenotype and suggests that BacA is required to survive the challenge with NCR peptides in the symbiotic nodule cells. Testing this hypothesis *in vivo*, in *M. truncatula* nodules, it was first shown that the *S. meliloti bacA* mutant bacteria, like WT, are challenged with NCR peptides once they are released from infection threads in the symbiotic nodule cells (Haag et al., 2011). With a live/dead staining procedure that marks bacteria with a different dye according to whether they are alive or dead (see Fig. 31.1), it has been found that *bacA* mutant bacteria are healthy in the infection threads but are rapidly killed after their uptake in symbiotic cells, while a WT strain remains, as expected, viable and differentiated. Moreover, the *bacA* mutant is able to survive in the symbiotic nodule cells of the *M. truncatula dnf1* mutant (Haag et al., 2011), which is affected in a nodule-specific signal peptidase complex (SPC) (Wang et al., 2010) and which cannot transport NCR peptides to the symbiosomes (Van de Velde et al., 2010). These observations are consistent with a role of BacA in preventing bacterial death by the potentially toxic NCR peptides and permitting the bacterial differentiation (Fig. 31.1). Perhaps the cell elongation and genome amplification are secondary effects of a bacterial defense response toward the antimicrobial activity of the peptides.

By synthesizing alternative versions of the NCR247 peptide with different disulfide bridge configurations between its four cysteine residues, it has been demonstrated that the peptide with disulfide bridges between cysteines 1–2 and 3–4 is significantly more active than the peptide with disulfide bridges between cysteines 1–3 and 2–4 for both induction of cell elongation and DNA amplification at low-peptide concentrations and for antimicrobial activity at higher peptide concentrations (Haag et al., 2012). Furthermore, substitution of the cysteine residues with serine diminishes the antimicrobial potency of NCR247 peptide, whereas chemically reducing the peptide by dithiothreitol treatment increases its antimicrobial potency significantly (Haag et al., 2012). This is similar to the behavior observed for the human β-defensin 1, which is produced in the colon and thought to be stored in an inactive oxidized form and to be activated by reduction through the action of thioredoxin proteins (Schroeder et al., 2011). Thioredoxins are ubiquitous redox proteins that regulate the oxidation state of cysteine residues and disulfide bridges in proteins. Intriguingly, *Medicago* nodules express a pair of unusual thioredoxins, Trx s1 and Trx s2 (Alkhalfioui et al., 2008). They are nodule specific and are thus coregulated with NCR genes. These thioredoxins differ from classical thioredoxins by the presence of an N-terminal signal peptide for the secretory pathway, such as the NCR peptides, which indicates that they are potentially cotransported with the NCR peptides to the symbiosomes. Thus, an interesting hypothesis is that these thioredoxins regulate the oxidative state of the peptides and thereby control their activity.

Importantly, no difference in sensitivity against either the chemically reduced NCR247 peptide or the linear peptide in which the cysteine residues were replaced with serine has been observed between WT *S. meliloti* and the *bacA* mutant (Haag et al., 2012). This suggests that the natural form of the NCR peptides is the oxidized one and raises the possibility that BacA can directly or indirectly influence the oxidation state of the NCR peptides in the periplasm of the bacteroids and promote the formation of the less detrimental oxidized state, thereby limiting damage of the inner membrane.

31.4 *BacA* HOMOLOGS ARE REQUIRED IN PATHOGENS FOR CHRONIC INFECTION

Apart from its role in intracellular accommodation of rhizobia during symbiosis with legume plants, BacA or BacA-like homologs have been identified and characterized in several pathogenic bacteria, in which they play critical roles during the interaction with their eukaryotic host. Notably, functional studies have been performed on BacA homologs from avian pathogenic *E. coli* (APEC) and in the mammalian pathogens *Mycobacterium tuberculosis* and *Brucella abortus*.

APEC can colonize the respiratory tract and cause pneumonia in poultry, and in addition, they are often associated with internal organ infections. In its most acute form, colibacillosis caused by APEC triggers septicemia, often resulting in sudden death of infected birds (Dziva and Stevens, 2008). As other pathogenic *E. coli*, APEC remains exclusively extracellular and the pathogen resides in the host tissues without penetrating the cells. In a signature-tagged mutagenesis screen for altered pathogenicity on chicken, a mutant in the BacA homolog (in *E. coli* named SbmA) was identified. The mutant has been shown to be attenuated in the colonization of different internal organs as compared to the WT strain, indicating that BacA is required for survival in the host and establishment of chronic infection even in the context of a nonintracellular pathogen (Li et al., 2005).

Brucella abortus is a zoonotic pathogen that causes brucellosis (Malta fever) in humans and spontaneous abortions in animal hosts such as cattle. It infects its host intracellularly through an endocytotic process and survives in phagocytic cells such as macrophages (Roop et al., 2009). A *B. abortus* BacA homolog has been identified, and the corresponding mutant displayed reduced intracellular survival

in macrophages compared to the WT strain. Moreover, bacterial clearance from infected BALB/c mice was increased in the *bacA* mutant by five orders of magnitude at 8-week postinoculation. Taken together, these results indicate that, similar to the *Rhizobium*–legume symbiosis, BacA is required for intracellular accommodation of *Brucella* and the establishment of a chronic infection (LeVier et al., 2000).

Mycobacterium tuberculosis, the causal agent of tuberculosis in humans, is a respiratory pathogen that colonizes the lung through intracellular infection. The bacterium can enter alveolar epithelial cells and macrophages and survive despite the high levels of defensins and other AMPs produced in these cells (Tan et al., 2006; Rivas-Santiago et al., 2005; Rivas-Santiago et al., 2006). In a murine infection model, *M. tuberculosis* can reside in the lung and spleen for months and lead subsequently to host death. Although the *M. tuberculosis bacA* mutant was not compromised in infection of both organs over more than 200 days, it induced significantly retarded host mortality compared to the WT strain in a long-term time-to-death experiment (Domenech et al., 2009).

Conservation of BacA function across bacterial species has been evaluated in different combinations of trans-complementation assays. Expression of the BacA homologs of either *E. coli* or *B. abortus* in the *S. meliloti bacA* mutant was able to complement its symbiotic defects and restored the formation of functional, nitrogen-fixing nodules on *M. sativa* (Ichige and Walker, 1997; Wehmeier et al., 2010). Even the *M. tuberculosis* BacA homolog rescued the *S. meliloti bacA* mutant phenotype on *M. sativa*, although only partially. In this case, nodules were not functional and did not support growth of the plants but the nodules were much more infected than in the case of the mutant, suggesting that the bacteria persisted in the nodules contrary to the *bacA* mutant, which is quickly degraded in the plant cells. Moreover, *bacA* mutant bacteria carrying the *M. tuberculosis* gene were enlarged although they displayed aberrant morphologies and did not become elongated as WT bacteroids (Arnold et al., 2013).

These examples from human and animal pathogens highlight the requirement of a functional BacA protein for inter- and intracellular accommodation of bacteria within eukaryotic cells and tissues and for maintenance of chronic infections. Similar to *S. meliloti* dealing with NCR peptides in *Medicago* nodules, these pathogens colonizing host tissues are facing the host innate immune system comprising AMPs such as defensins (Roop et al., 2009; Tan et al., 2006; Rivas-Santiago et al., 2005; Rivas-Santiago et al., 2006). It is tempting to speculate that the BacA proteins of the pathogens are important to resist to these AMPs and are therefore key in the establishment of chronic infections. In agreement with this possibility, it was shown that the *M. tuberculosis bacA* mutant has impaired tolerance to human β-defensin 2 (Arnold et al., 2013). Moreover, the *Mycobacterium* and *Brucella bacA* homologs can restore the sensitivity toward NCR peptides or human β-defensin 2 of the *S. meliloti bacA* mutant to WT levels (Haag et al., 2011; Arnold et al., 2013).

31.5 BacA IS AN ABC TRANSPORTER. BUT WHAT DOES IT TRANSPORT?

BacA and SbmA proteins have eight transmembrane domains, but they lack any other identified functional domain. However, there is a class of BacA-like proteins homologous to BacA and SbmA, which have an additional ATPase domain. The above-mentioned *Bradyrhizobium* and *Mycobacterium* genes belong to this class, and also *S. meliloti* and *E. coli* have apart from *bacA* or *sbmA* an additional *bacA*-like gene named *exsE* and *yddA*, respectively. Albeit they are divergent (LeVier and Walker, 2001), the BacA-like proteins show large regions of similarity with BacA and SbmA. In particular, transmembrane predictions revealed that all members have six transmembrane domains at conserved positions in the protein, shared with BacA and SbmA, suggesting that these proteins have similar topologies. Importantly, this class of BacA-like proteins has a fused, C-terminal ATPase domain that is typical for ATP-binding cassette (ABC) transporters (LeVier and Walker, 2001). The function of the *M. tuberculosis* BacA-like protein is abolished by deletion of its ATPase domain or by introduction of a point mutation in a conserved residue in this domain, which is known to be important for transport activity in other ABC transporters (Arnold et al., 2013). This observation suggests that BacA-like proteins indeed function as ABC proteins. Thus, potentially also the BacA/SbmA proteins are ABC transporters although their ATPase domain remains to be identified. No candidate gene has been identified in the vicinity of the *bacA*/*sbmA* genes. A recent study in *E. coli* suggested that transport by SbmA is driven by the membrane potential rather than by ATP hydrolysis, providing an explanation for the absence of an ATPase domain in SbmA (Runti et al., 2013).

Certain AMPs such as microcin B17, microcin J25, and proline-rich cathelicidin type of AMPs are internalized and have intracellular targets leading to bacterial death. These AMPs kill bacteria without affecting the bacterial membrane integrity in contrast to NCR peptides or defensins (Scocchi et al., 2011). The uptake of these peptides is mediated, at least in part, by the BacA/SbmA and BacA-like proteins, and mutations strongly reduce peptide uptake and thus confer resistance to the peptides. This has led to the suggestion that BacA/SbmA/BacA-like proteins are peptide transporters (Laviña et al., 1986; Yorgey et al., 1994; Salomon and Farias, 1995; Mattiuzzo et al., 2007; Pränting et al., 2008; Marlow et al., 2009; Karunakaran et al., 2010;

Ardissone et al., 2011; Arnold et al., 2013). Thus, the BacA/SbmA/BacA-like transporters have opposing effects on the bacterial sensitivity toward peptides with intracellular targets like the proline-rich cathelicidins and toward membrane-disrupting peptides such as NCR peptides or defensins. A possible explanation is that the internalization of AMPs by the transporter facilitates their contact with their target for AMPs with intracellular action and, on the contrary, takes them away from their membrane targets for membrane-disrupting AMPs. It is interesting to note that other ABC transporter systems are described that provide resistance to membrane-disrupting AMPs. The SapABCDF transporters in *Salmonella Typhimurium* (Para-Lopez et al., 1993; Para-Lopez et al., 1994) or the plant pathogen *Dickeya dadantii* (previously named *Erwinia chrysanthemi*) (Lopez-Solanilla et al., 1998) and the *Salmonella* YejABEF transporter (Eswarappa et al., 2008) have been proposed to import host-produced membrane-damaging AMPs taking them away from their membrane target site.

The BacA/SbmA/BacA-like proteins also mediate the uptake and sensitivity to the glycopeptide antibiotic bleomycin (Yorgey et al., 1994; Ichige and Walker, 1997; Marlow et al., 2009; Wehmeier et al., 2010; Domenech et al., 2009; Tan et al., 2009; Karunakaran et al., 2010; Maruya and Saeki, 2010) and sensitivity toward several aminoglycoside antibiotics (Ichige and Walker, 1997). Moreover, the *M. tuberculosis* BacA-like protein has recently been reported to facilitate vitamin B_{12} uptake (Gopinath et al., 2013). Although vitamin B_{12} is required for bacteroid differentiation (Campbell et al., 2006; Taga and Walker, 2010), it is unlikely that the symbiotic role of BacA or BclA is the uptake of plant-provided vitamin B_{12} because rhizobia can produce this cofactor and, more importantly, plants do not use or produce it (Roth et al., 1996).

As aminoglycoside uptake is driven by membrane potential (Taber et al., 1987) and in light of the structural diversity of all the compounds whose uptake is affected by the BacA/SbmA/BacA-like proteins, an alternative to the peptide uptake hypothesis could be that the proteins affect the membrane potential or membrane composition in a direct or indirect process. An altered membrane could have changed interaction properties with membrane-damaging peptides such as NCR peptides or defensins.

Support for a role of BacA in the determination of cell envelope features derives from the observations that the *S. meliloti* mutant has an increased sensitivity to detergents and ethanol (Ferguson et al., 2002). Similar behavior was described for *bacA* mutants in *M. huakuii* (Tan et al., 2009), *M. loti* (Maruya and Saeki, 2010), *R. leguminosarum*, or *R. etli* (Karunakaran et al., 2010). The *bacA* mutation in *S. meliloti* and *B. abortus* also reduces by about half the modification of the outer-membrane lipopolysaccharide (LPS) with typical very long-chain fatty acids (VLCFA) (Ferguson et al., 2004). Therefore, it has been proposed that BacA could be involved in the export of fatty acids out of the cytoplasm where they are synthesized (Ferguson et al., 2004). Also in *M. huakuii*, the bacA mutation affects the VLCFA content in LPS (Tan et al., 2009). However, no major changes associated with the cell envelope, including sensitivity to ethanol and detergents and lipid content of cell membranes, were detected in *bacA* or *bacA*-like deficient *Sinorhizobium fredii* strain NGR234 and *M. tuberculosis* (Domenech et al., 2009; Ardissone et al., 2011). Moreover, the symbiotic defect of the *S. meliloti bacA* mutant does not seem to be directly linked to the VLCFA LPS defect because additional mutants in the *acpXL* and *lpxXL* genes, which completely lack VLCFA in their LPS, are much less severely affected than the *bacA* mutant and can form nitrogen-fixing nodules (Ferguson et al., 2005) although bacteroid abnormalities have been observed with, for example, the formation of hypertrophied bacteroids (Haag et al., 2009).

In addition, the BacA-mediated uptake of cathelicidin type of AMPs such as the peptide Bac7 by *S. meliloti* can also be uncoupled from its symbiotic role because two point mutants in the *bacA* gene were identified that are symbiotically defective but maintain the capacity to take up the Bac7 peptide (Marlow et al., 2009). Similarly, the *M. tuberculosis bacA*-like gene can restore the resistance defect of the *S. meliloti bacA* mutant toward the NCR247 peptide as well as human β-defensin 2. Nevertheless, the *M. tuberculosis bacA*-like gene is only partially able to support symbiosis and bacteroid development (Arnold et al., 2013). Probably, the multifaceted phenotypes of the *bacA* mutant together with the complex mixture of NCR peptides produced by the symbiotic nodule cells has to be taken into account to fully explain the essential role of BacA in symbiosis.

31.6 GENERAL ENVELOPE STRESS RESPONSE FUNCTION OF BacA/SbmA?

Bacteria which interact with eukaryotic cells are often confronted with AMPs produced by the host cells. Many of these bacteria have evolved resistance mechanisms permitting them to survive these peptides. Examples are the SapABCDF and YejABEF transporters described earlier. Another frequently observed mechanism is the modification of the electrical charge of the bacterial envelope, rendering it less negative and thereby reducing electrostatic interactions with the cationic AMPs (Maróti et al., 2011). Related to this, it is interesting to note that the LPS of bacteroids in *Medicago* and pea nodules becomes more hydrophobic and displays different epitopes when compared to cultured bacteria (Kannenberg et al., 1994; Kannenberg and Carlson, 2001; Ferguson et al., 2005). This LPS modification could reflect an adaptive response of the bacteroids to the exposure with the NCR peptides.

The bacterial resistance mechanisms are usually induced after perception of the AMPs. The presence of AMPs can be directly sensed with AMP-binding two-component

regulators (Bader et al., 2005; Gryllos et al., 2008) or with ABC transporter-derived sensors, which in that case do not have a transporter function anymore but a role as receptor and signal transduction protein (Hiron et al., 2011; Falord et al., 2012). Alternatively, bacteria can sense the membrane damage provoked by the membrane-disrupting peptides through different envelope (or extracytoplasmic) stress response (ESR) systems. ESR pathways detect and induce appropriate responses to stresses that affect the bacterial membranes and periplasmic and membrane proteins, including membrane stresses provoked by AMPs (Majdalani and Gottesman, 2005; Rowley et al., 2006; Bury-Moné et al., 2009). Generally, bacteria have different coexisting ESR systems. AMP-responsive ESRs include, in *E. coli* and *S. Typhimurium*, the Rcs phosphorelay system (Farris et al., 2010), the CpxAR two-component system (Weatherspoon-Griffin et al., 2011), and the extracytoplasmic function sigma factor σ^E-regulon (Humphreys et al., 1999; Crouch et al., 2005).

Interestingly, *SbmA* is part of the ESR σ^E-regulon in *E. coli* (Rowley et al., 2006; Bury-Moné et al., 2009), suggesting that the SbmA protein has a role in ESR that needs to be further defined. σ^E and its homologs control to various degrees pathogenesis. For example, σ^E mutants of *S. Typhimurium* are defective for intracellular survival in macrophage and epithelial host cell lines and have a strongly attenuated virulence on mice (Humphreys et al., 1999; Crouch et al., 2005). The attenuated virulence of the σ^E-mutant of *S. Typhimurium* has been attributed to its inability to protect itself against the host-produced AMPs (Crouch et al., 2005). The mutant phenotypes are, in part, depending on the σ^E-regulated genes *htrA* (*degP*) and *surA*, encoding a periplasmic serine protease and a periplasmic peptidyl-prolyl-isomerase, respectively. But other σ^E-regulated genes are possibly important since σ^E mutants are more affected than individual *htrA* or *surA* mutants. A good candidate among them could be *sbmA* in light of the above-described critical function of SbmA/BacA proteins in symbiotic and pathogenic interactions.

Interestingly, a genetic link between *bacA* and *degP* was also demonstrated in *S. meliloti* (Glazebrook et al., 1996), suggesting that in *S. meliloti*, *bacA* is also implicated in ESR. However, the biochemical link between *bacA* and *degP* remains to be further unraveled.

The association of SbmA in *E. coli* and potentially also BacA in *S. meliloti* with ESR suggests that these proteins are part of a membrane stress-sensing system, or that they function in the bacterial response to alleviate this stress. The above-mentioned hypersensitivity of *bacA* mutants toward the membrane-damaging stresses induced by ethanol or detergents is in agreement with this.

The σ^E-regulon in *E. coli* includes also the *dsbC* gene (Rowley et al., 2006; Bury-Moné et al., 2009), which is involved in oxidative protein folding in the periplasm (Depuydt et al., 2011). It is unknown whether SbmA is also involved in oxidative folding, but a speculative link could be that BacA keeps NCR peptides in an oxidized and less damaging state in the periplasm as is suggested earlier (Haag et al., 2012).

ESR regulators have been described in several *Rhizobium* species (Bastiat et al., 2010; Sauviac et al., 2007; Gourion et al., 2009; Martínez-Salazar et al., 2009; see Chapter 40). But none of them were reported to regulate the *bacA* gene, and thus the regulon to which rhizobial *bacA* belongs remains to be discovered but could be very informative to understand better how BacA functions, both as a household function and in symbiosis.

31.7 CONCLUSION

BacA in *Rhizobium* species is critical for chronic intracellular infections of legume hosts, which produce AMPs in the symbiotic cells. BacA homologs are also contributing to the pathogenesis and chronic infection in pathogens, and they do this most likely by protecting the bacteria against the host AMPs. However, how BacA/SbmA proteins function mechanistically remains unknown. We propose the following hypotheses: (i) the proteins could be part of a peptide uptake system, leading to internalization of AMPs, which would move them away from membrane targets but bring them in proximity to intracellular targets; (ii) on the contrary, it cannot be excluded that they are exporters, affecting the bacterial envelop and thereby indirectly promoting the uptake of certain peptides with intracellular mode of killing and reducing the affinity of membrane-damaging peptides for the bacterial envelope; (iii) alternatively, they could export compounds that directly modifies the peptides (e.g., oxidizing peptides so that they are less harmful); or (iv) they could function as sensors rather than transporters, activating other resistance determinants. Testing these possibilities is a challenge for the future. Understanding the household function of *bacA* in *Rhizobium* and its regulation in stress response or other cellular functions could be an important clue for understanding its interference with the action of NCR peptides and other AMPs.

32.1 INTRODUCTION

Gram-negative soil bacteria that form a symbiotic relationship with legumes are collectively referred to as rhizobia. They are classified as Alphaproteobacteria and Betaproteobacteria (Moulin et al., 2001; Peter et al., 1996; Sadowsky et al., 2013; Skerman et al., 1980) (Fig. 32.1).

Their nitrogen-fixing capacities are of tremendous environmental importance to the global nitrogen cycling balance (Cheng, 2008) and the agricultural economy (Sessitsch et al., 2002). The rhizobia–legume symbiosis is initiated by a dialog between the legume plant and the compatible *Rhizobium* in the soil (Deakin and Broughton, 2009; Gage, 2004; Jones et al., 2007). Plants liberate flavonoids and also other compounds (such as B vitamins) into the rhizosphere. These signaling molecules upregulate rhizobial *nod* genes, subsequently lipochitooligosaccharidic nodulation factors (Nod factors) are produced that trigger the nodulation pathway in susceptible legumes (Oldroyd et al., 2011; see Chapters 50, 51). As a result, rhizobia enter the plant root through root hairs, make their way to the cortex, multiply, and initiate the formation of specialized root structures called nodules facilitating the access to mineral nitrogen via the root (Gage, 2004). Although some rhizobia are able to reduce atmospheric nitrogen to ammonia under free living conditions, the reduced oxygen tension found within root nodules maximizes the process of nitrogen fixation (Downie, 2005). Interestingly, the specificity of this interaction is determined by a number of molecular keys that are linked to the synthesis of Nod factors (i.e., lipochitooligosaccharides and their decorations), the receptors of plant signaling molecules (i.e., NodD proteins), and the arsenal of secretory components encoded by the various rhizobia (Table 32.1).

These are perhaps major determinants of host range (Berck et al., 1999; Broughton et al., 2000). However, it can be assumed that host range is also a result of rhizosphere fitness and a mix of other genetically encoded determinants that are not fully understood yet and only will be unraveled once we have a broader understanding of rhizobial "omics."

It is perhaps noteworthy that many rhizobia have evolved mechanisms that allow them to nodulate a larger variety of legume plants. These strains are called broad host range strains and are promiscuous with respect to the selection of their host plants. A detailed overview on the best studied model organism is given in the reviews (Berck et al., 1999; Marie et al., 2001). While the basic principles that are linked to host range determination are only now falling into place, the observation of this phenomenon has been made over a hundred years ago (Hiltner and Störmer, 1903; Wilson, 1939). While Hiltner and his team were perhaps the first to report on host range restrictions, Wilson and his team carefully analyzed the host range properties of rhizobia, which they had isolated from 31 different legumes genera and from 160 different legume species.

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

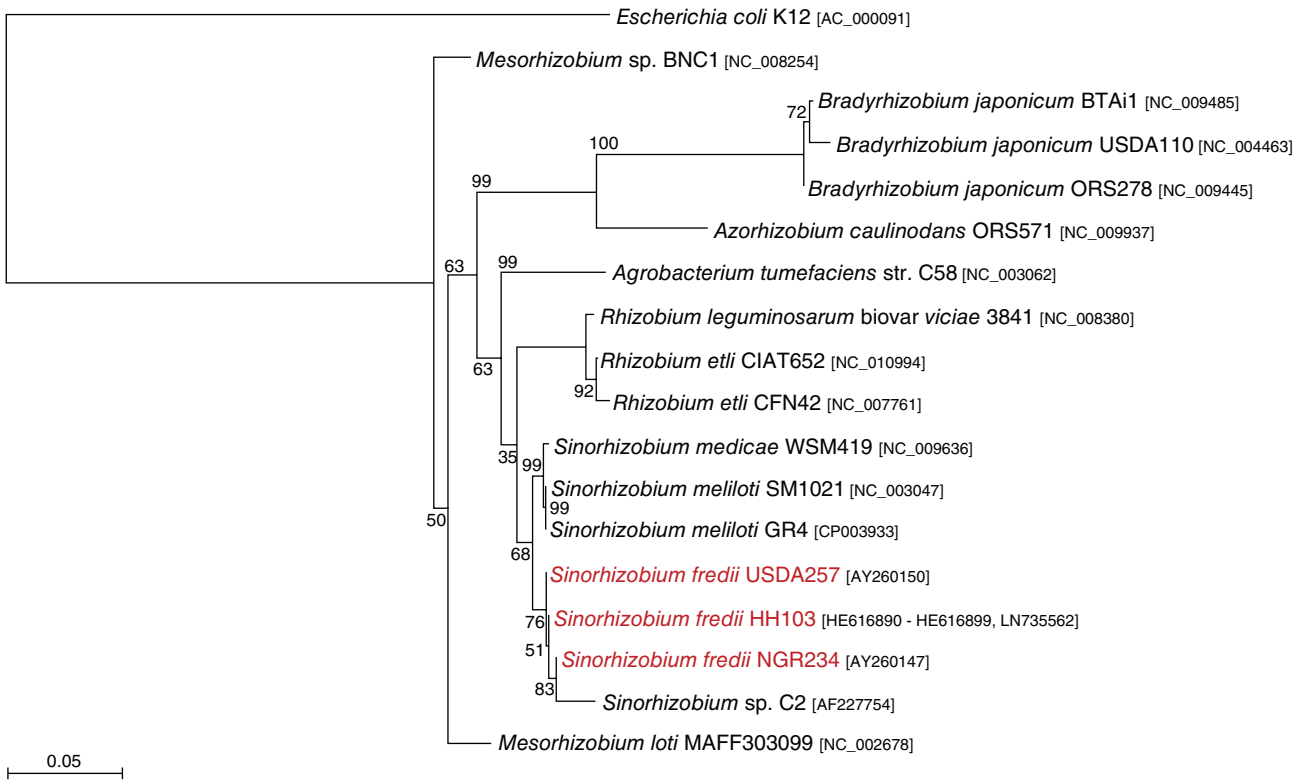

Figure 32.1 Phylogenetic relationships of 16S rRNA genes from selected rhizobial species as determined by the maximum-likelihood analysis. The percentage of bootstrap resamplings is indicated at the different nodes. The scale bar represents the expected number of changes per nucleotide position.

They clearly demonstrated that all the obtained isolates nodulated legumes of different tribes. The average number of plant species nodulated by a particular strain was 33%, clearly suggesting that rhizobial promiscuity is perhaps widely distributed in nature, and that this phenomenon is more the rule than the exception (Wilson, 1939).

Within this framework, currently three *Sinorhizobium fredii* isolates are studied that are known broad host strains (Fig. 32.1). These are the closely related *S. fredii* isolates NGR234, USDA257, and HH103 (Marie et al., 2001). However, the latter isolate shows a rather narrow host range. In the following section, key traits of these different *S. fredii* isolates are highlighted.

32.2 KEY TRAITS OF THE ALPHAPROTEOBACTERIA *Sinorhizobium fredii* NGR234, USDA257, AND HH103

32.2.1 *Sinorhizobium fredii* NGR234

Within the large group of the rhizobia, NGR234 (Fig. 32.1) portrays an outstanding candidate forming nitrogen-fixing root nodules with over 110 genera of legumes as well as with the nonlegume *Parasponia andersonii* (Pueppke and Broughton, 1999). NGR234 was first uncovered in 1965 in Papua New Guinea and isolated from *Lablab purpureus* nodules as the only fast-growing strain among 30 isolates (Trinick, 1980). Shortly after this discovery, its broad host range attracted great interest since no other plant symbiont was discovered having as many symbiotic partners as NGR234. Nevertheless, the molecular mechanisms behind this exceptionally wide host range are not fully evident, therefore qualifying NGR234 as the ideal prokaryotic model organism for studies with relevance to symbiotic determinants (Broughton et al., 2000).

Early studies with derivates and spontaneous resistance mutants of NGR234 yielded evidence that genes required for an effective symbiosis with leguminous plants are located exclusively on the symbiotic plasmid (pNGR234*a*) (Freiberg et al., 1996; Freiberg et al., 1997; Perret et al., 1991). A NGR234 derivate (ANU265) that was deprived of pNGR234*a* by heat curing was not impaired in its growth but failed to nodulate any of its hosts (Morrison et al., 1983). Consequently, the 0.5 Mb symbiotic plasmid of NGR234 lacks essential genes required for growth and survival control but comprises symbiotic determinants, for example, genes for nodulation (*nod*) and synthesis of Nod factors as well as genes for nitrogen fixation (*nif/fix*) (Freiberg et al., 1997).

Table 32.1 Identified secretion systems and assumed bacterial determinants of host range in the *Rhizobium*–legume symbiosis

Determinant	Identified as a Determinant of Host Specificity?	Type/Origin	Examples/Structure	Mode of Action	Source
Flavonoids	Yes/no	Plant signals (inducers or inhibitors)	e.g., Flavone, flavonole, flavanone, isoflavonoids and nonflavonoid substances	Flavonoids induce *nodD* expression and interact with NodD proteins building up a complex	Perret et al. (2000); Hirsch et al. (2001)
NodD protein	Yes	Rhizobial sensor of plant signals and transcriptional activator	LysR-like transcriptional regulator	NodD protein binds to *nod* boxes and regulates transcription of nodulation genes (*nod*, *nol*, *noe*), which are subsequently involved in synthesis of Nod factors	Schlaman et al. (1992); Fisher et al. (1993)
Nod factors	Yes	Rhizobial signal molecules	Lipochitooligosaccharide backbone with different decorations	Nod factors are recognized by the plant and induce early nodule development/rhizobial infection	Relic et al. (1993, 1994)
NodO protein	Yes	Rhizobial secreted protein	Calcium-binding protein	NodD-dependent expression of NodO, it can either facilitate Nod factor uptake, amplify the perceived Nod factor, or bypass the Nod receptor	de Maagd et al. (1989); Walker and Downie (2000)
Surface polysaccharides	Yes	Rhizobial surface compounds	EPS, LPS, KPS	Surface polysaccharides are involved in early stages of the infection processes (plant root invasion/nodulation) and facilitate the infection thread penetration	Fraysse et al. (2003); Downie (2010); Skorupa et al. (2006)
T3SS and effector proteins	Yes	Export of rhizobial effector proteins	e.g., NopL, NopP	T3SSs control the translocation of effector proteins that affect nodule initiation, these can, e.g., block plant defense mechanisms or induce certain symbiotic actions	Viprey et al. (1998); Deakin and Broghton (2009); Perret et al. (2000)
Protein secretion systems	?	Export of multifaceted proteins	T1SS–T6SS	Secretion systems translocate different classes of rhizobial proteins into the surrounding environment or into the eukaryotic host	Fauvart and Michiels (2008); Krehenbrink and Downie (2008)
Cell–cell communication	?	QS: different signaling molecules	QS: Autoinducer, e.g., *N*-AHLs	*N*-AHL-mediated signaling for coordinated expression of genes for successful infection	Zhang et al., 1993; Brelles-Marino and Bedmar (2001); Gonzalez and Marketon (2003)
		QQ: rhizobial (secreted) proteins	QQ: AHLases, amidases, oxidoreductases, hydrolases	QQ-based blockade of QS in other microorganisms for competition purposes	Uroz et al. (2005); Dong et al. (2000)

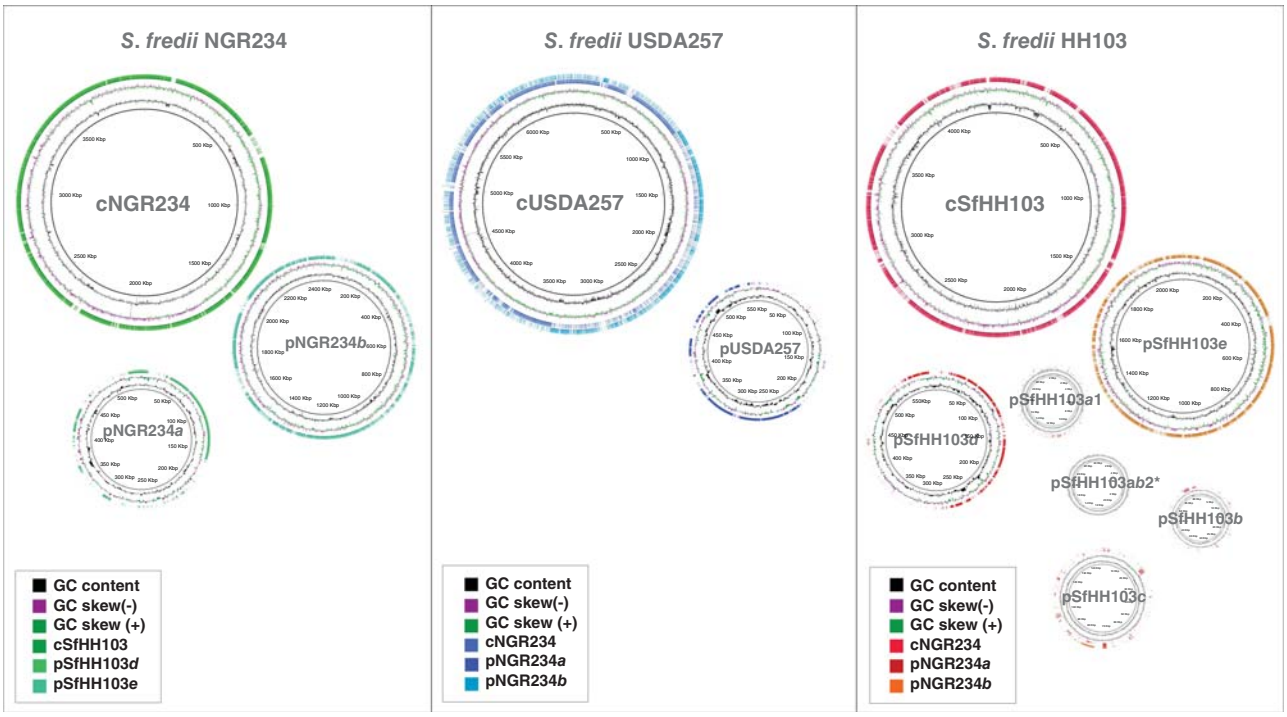

Figure 32.2 Genome maps and BlastN comparisons of NGR234, USDA257, and HH103. The innermost rings indicate the GC content (black) and GC skew (purple/green). The outermost rings represent the shared identity to the best matching replicon of the other *S. fredii* strain; the homologous regions between the two replicons are depicted in color. Shared identities in NGR234: the chromosome cNGR234 has the highest similarity to the chromosome cSfHH103, the sym plasmid pNGR234*a* has the highest similarity to pSfHH103*d*, the megaplasmid pNGR234*b* has the highest similarity to pSfHH103*e*; shared identities in USDA257: the chromosome cUSDA257 shares the highest similarity to chromosome cNGR234 and megaplasmid pNGR234*b*, the plasmid pUSDA257 has the highest similarity to pNGR234*a*; shared identities in HH103: the chromosome cSfHH103 has the highest similarity to chromosome cNGR234, the small plasmids pSfHH103*a*1-*e* share only weak similarities to NGR234's genome (cNGR234/pNGR234*a*/pNGR234*b*), the sym plasmid pSfHH103*d* has the highest similarity to sym plasmid pNGR234*a*, the megaplasmid pSfHH103*e* has the highest similarity to megaplasmid pNGR234*b*. *Plasmid pSfHH103*a*2 was not considered in the comparisons. Genome sequences were derived from the corresponding GenBank entries, genome maps were created using BRIG (Blast Ring Image Generator; http://sourceforge.net/projects/brig).

In a symbiotic relationship, root hair curling, induction of nodulation, and the entry of bacteria into the root are strictly dependent on the secreted Nod factors (see Chapters 51, 59, 63), thus they play a key role in the host range of symbiotic soil bacteria such as NGR234 (Viprey et al., 2000).

Most intriguing was the discovery of the first type III secretion system (T3SS) in a rhizobial genome by the work of Freiberg and colleagues. This was uncovered during the sequencing of the pNGR234*a* replicon, which was the first rhizobial replicon to be sequenced in 1997 (Freiberg et al., 1997). Later during the course of sequencing the whole 6.9 Mb NGR234 genome, a second copy of a T3SS was identified (Schmeisser et al., 2009). However, the molecular function of this second T3SS with relevance to root colonization, infection, and nodule formation is not yet clear. The NGR234 genome is divided into three replicons, a 0.5 Mb symbiotic plasmid (pNGR234*a*), a 2.4 Mb megaplasmid (pNGR234*b*), and the bacterial chromosome (cNGR234) with a size of 3.9 Mb (Fig. 32.2).

Among many other striking features, NGR234 encodes for a wealth of secretion-related proteins, which play an important role in the infection of plant hosts (Deakin and Broughton, 2009; Schmeisser et al., 2009). The genome revealed the presence of many proteins involved in type I (T1SS) and type II secretion (T2SS); apart from the above-mentioned T3SS, two complete conjugative type IV secretion systems (T4SS) were observed. No type V or VI transporters (T5SS/T6SS) were found within this genome (Table 32.2). Altogether, a relatively high number of 129 genes, which are spread over the three replicons of NGR234, are in some form involved in secretory processes in this microbe (Schmeisser et al., 2009).

Rhizobial cells have to be present in large numbers in and around plant root hairs as well as in nodules in order to achieve a successful symbiotic interaction (Bauer and Mathesius, 2004). To monitor their own population in the rhizosphere and to subsequently increase the cell density, cell-to-cell signaling processes are needed. Among

Table 32.2 Putative secretion-associated genes and proteins identified in *S. fredii* NGR234, USDA257, and HH103 (Data derived from Schmeisser et al., 2009; modified; Schuldes et al., 2012; Weidner et al., 2012).

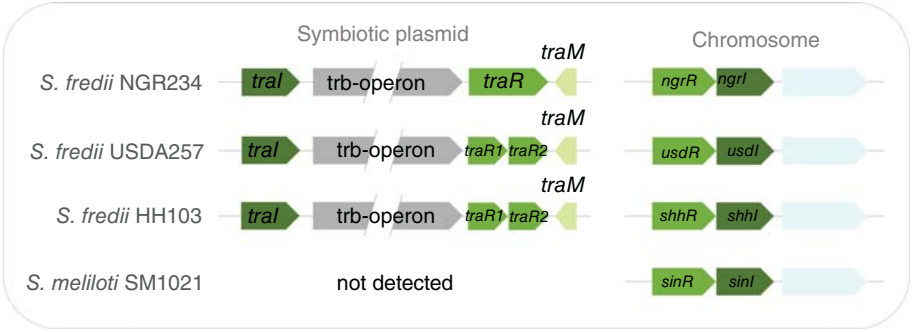

Figure 32.3 Cell–cell communication systems identified in the genomes of broad host strains *S. fredii* NGR234, USDA257, and HH103 and the narrow host strain *S. meliloti* SM1021. Left: Conventional QS system responsible for synthesis of AHLs is found on the symbiotic plasmid of NGR234, USDA257, and HH103. USDA257's putative regulators traR1 and traR2 have not yet been functionally confirmed. The narrow host range strain *S. meliloti* SM1021 lacks *traI/traR* homologs. In all three strains, the AHL synthase TraI directs the synthesis of AHL, which associates with the response regulator TraR. TraM functions as a suppressor, preventing TraR from activating target genes under noninducing conditions. The flanked *trb*-conjugal operon is shaded gray. Right: Second, novel QS system identified on the chromosome of all four rhizobial strains. It is composed of the autoinducer synthase gene (*ngrI*, *usdI*, *shhI*, and *sinI*) and the response regulator (*ngrR*, *usdR*, *shhR*, and *sinR*) in an inverted order and a hypothetical protein (blue) of unknown function. This system is most likely producing a coumestrol autoinducer type I signal.

Rhizobiaceae, diverse quorum sensing (QS) systems are prevalently used to exchange signaling molecules such as *N*-acyl homoserine lactones (*N*-AHLs) (Loh et al., 2002; Wisniewski-Dye and Downie, 2002; see Chapter 37). With respect to cell–cell communication, NGR234 carries two QS systems that are responsible for the autoinducer synthesis and recognition (Fig. 32.3). In 2003, He and colleagues already described the NGR234 QS regulators TraI and TraR producing and operating with 3-oxooctanoyl-homoserine lactone (He et al., 2003). This TraI/TraR system together with its suppressor TraM flanks the conjugal transfer operon and can be found on pNGR234*a*. A second putative QS system composed of NgrI/NgrR was identified being located on NGR234's chromosome most likely producing coumestrol autoinducer I type molecules (Krysciak et al., 2011). A recent genome wide RNA-seq analysis of NGR234-ΔtraI and NGR234-ΔngrI mutants identified major traits in NGR234 that were controlled by the autoinducer synthases TraI and NgrI. Beside many genes and operons regulated either by TraI/R or NgrI/R, a common set of 186 genes was differentially regulated by both QS regulons including flagellar biosynthesis genes and genes linked to exopolysaccharide biosynthesis (Krysciak et al., 2014).

Regarding the multiple proteins and gene operons participating in QS in NGR234, this microbe also developed quorum quenching (QQ) strategies to disarm QS molecules in order to compete with other bacterial species in nutrient and energy-limited niches (Teplitski et al., 2011). Using a genome-wide functional analysis conducted in 2011 in our

laboratory, we could demonstrate that NGR234 carries a surprisingly large number of genes encoding enzymes involved in the degradation or modification of *N*-AHLs. NGR234's most promising QQ-associated proteins DlhR and QsdR1 exhibited a clear QQ activity in all biosensor tests. Furthermore, these proteins contributed to the rhizosphere fitness of NGR234 and are possibly involved in the degradation of plant-derived molecules in the rhizosphere, emphasizing the ecological importance of QQ during root colonization (Krysciak et al., 2011).

32.2.2 *Sinorhizobium fredii* USDA257

The phylogenetically closely related strain USDA257 (Fig. 32.1) was isolated from a soybean plant (*Glycine soja*) growing in China (Keyser et al., 1982) and is perhaps the best studied broad host model organism nodulating soybeans effectively. This fast-growing isolate, which was generally considered to be a soybean symbiont, nodulates an exact subset of 79 genera of NGR234 plant hosts. Consequently, USDA257 was classified as a member of the broad host range rhizobia (Pueppke and Broughton, 1999).

The complete genome sequence of USDA257 revealed the presence of only two replicons: the chromosome of USDA257 (cUSDA257) and the plasmid (pUSDA257) in total 7.03 Mb (Schuldes et al., 2012) (Fig. 32.2). Similar to NGR234's symbiotic plasmid, pUSDA257 lacks essential genes for the control of survival and growth but encodes many genes linked to symbiosis (*nod*/*nif*/*fix*). In addition to the plasmid-borne *nif* and *fix* genes, a significant number of *nif* and *fix* genes are located on the chromosome of USDA257. Furthermore, USDA257 is perhaps able to grow on a wide range of substrates, including aromatic compounds (Schuldes et al., 2012). Similar to NGR234, the genome of USDA257 encodes for a surprisingly high number of secretion-associated genes and proteins. In total 154 genes could be identified being putatively linked to secretory processes (Table 32.2). Unlike NGR234, USDA257 does not appear to encode a functional T2SS but in return comprises a cluster of T6SS-related genes, which is very unique and has been found only in a few rhizobial species such as *R. leguminosarum*, *B. japonicum*, and *Mesorhizobium loti* (Records, 2011). Furthermore, the genome of USDA257 harbors two complete sets of T3SSs, one located on the chromosome and one on the symbiotic plasmid. This unique feature makes USDA257 and NGR234 to our knowledge the only known rhizobial strains with two copies of T3SSs (Table 32.2) (Schuldes et al., 2012).

A highlight of the USDA257 genome is also the presence of many QS and QQ related genes (see Chapter 37). Similar to NGR234, the USDA257 genome encodes for two QS systems, most likely involved in the synthesis of *N*-AHL autoinducer-like molecules. The autoinducer synthase genes and their respective regulators were designated *traI*/*traR1; traR2* and *usdI*/*usdR* (Fig. 32.3). However, the functions of USDA257's *traR1* and *traR2* putative response regulators have not yet been experimentally confirmed. In addition and similar to NGR234, USDA257 carries a significant number of loci linked to modification or degradation of autoinducer molecules (Schuldes et al., 2012).

32.2.3 *Sinorhizobium fredii* HH103

Apart from the two above-described broad host isolates, the soybean-nodulating isolate HH103 has been the focus of many studies. The fast-growing rhizobial strain *S. fredii* HH103, which was originally isolated from Chinese soil from the Hubei Province in 1985, is able to form nodules on a limited number of legume cultivars (Dowdle and Bohlool, 1985). A more recent analysis suggested that about 15 legume genera including advanced soybean variants are susceptible to infection through HH103 and result in nitrogen-fixing nodules (Margaret et al., 2011). While HH103 is promiscuous, its host range clearly differs from the host ranges of NGR234 and USDA257 and is less wide. Competitive nodulation studies revealed that *Bradyrhizobium japonicum* strain USDA110 outcompetes HH103 in an acid soil, whereas in more alkaline soils the majority of the nodules are colonized by HH103 (Buendía-Clavería et al., 1994). The HH103 genome has been partially established recently (Weidner et al., 2012; Vinardell et al., 2015). Surprisingly, the 7.25 Mb genome of HH103 is spread over six replicons (pSfHH103*a*1/2–*e*) and a circular chromosome of 4.3 Mb. The six smaller circular plasmids range from 24 kb up to 2 Mbs in size (Margaret et al., 2011; Vinardell et al., 2015) (Fig. 32.2).

The partial HH103 genome shares a high degree of synteny with the NGR234 and USDA257 genomes. Similar to these two microbes, the symbiotic plasmid (pSfHH103*d*) of HH103 carries genes-encoding proteins relevant to nodulation and nitrogen fixation and additionally encodes a single T3SS (Weidner et al., 2012). The largest plasmid, pSfHH103*e*, carries genes involved in the production of surface polysaccharides such as exopolysaccharides (EPSs), lipopolysaccharides (LPSs), and capsular polysaccharides (KPSs), and the smaller plasmids pSfHH103*a*1/2 and pSfHH103*b* reveal the presence of numerous transposases (Margaret et al., 2011; Weidner et al., 2012; Vinardell et al., 2015).

Our first attempts to describe the secretion machinery composed of HH103 revealed the presence of around 137 secretory genes and proteins only spread on the chromosome, symbiotic plasmid, and the largest plasmid. Although the wealth of secretion-associated genes is very similar to NGR234, HH103 lacks the second complete copy of the T3SS. In contrast, HH103 carries almost twice as many

T4SS-related proteins (F-type) than recorded for NGR234. Similarities to T5SS and T6SS-associated proteins were not recorded (Table 32.2). Surprisingly, none of the identified secretion-related proteins were located on the four smaller plasmids pSfHH103*a*1/2, pSfHH103*b*, or pSfHH103*c*.

With respect to cell–cell communication, HH103 seems to be similarly equipped with QS and QQ-related genes as NGR234 and USDA257 (see Chapter 37). First alignment studies with HH103 and already published QS systems found among the Rhizobiaceae show that HH103 possesses also two systems. Clear homologs, which are to date annotated as hypothetical proteins in HH103, could be found to the QS *traI/traR* system originally described in *A. tumefaciens*. Similar to NGR234 and USDA257, this system is located on the symbiotic plasmid (pSfHH103*d*) of HH103 flanking the putative conjugal transfer operon (Fig. 32.3) and is probably responsible for the synthesis and recognition of *N*-AHLs. The second system with the proposed name *shhI/shhR* is located on the chromosome of HH103 and also shows an inverted order of synthase and regulator genes compared to *traI/traR*. Based on the similarity to the *ngrI/ngrR* and *usdI/usdR* system, *shhI* is most likely producing a coumestrol-like autoinducer.

To date, no experimental evidence exists that HH103 is able to exhibit QQ as a defense strategy in environments like the soil. Nevertheless, first comparative studies show that this rhizobial strain carries analogs of NGR234's QQ-related proteins, which are responsible for modification or degradation of AHLs.

32.3 MOLECULAR KEYS TO BROAD HOST RANGE IN *S. fredii* NGR234, USDA257, AND HH013

Broad host range is probably a result of many features that are encoded within the different rhizobial genomes (Table 32.1). Although the complete genome sequence of NGR234, USDA257, and HH103 has not revealed all of the mysteries of host specificity, probably many more pieces of the broad host range puzzle will fall into place once more "omic"-based studies are performed by fully exploiting the available genome sequences.

32.3.1 Protein Secretion as a Key to Host Range

One important observation is that correlations seem to exist between the host range of rhizobia and the number and type of specialized protein secretion systems they carry. Classic narrow host range rhizobia such as *S. meliloti* and *R. leguminosarum* that only nodulate a very restricted group of Middle Eastern and Northern European plants lack T3SSs and T4SSs, respectively (Galibert et al., 2001; Krehenbrink and Downie, 2008). NGR234, however, which has the greatest capacity to nodulate of all known rhizobia, carries almost twice as many, often duplicated, secretion systems then these narrow host model microbes. USDA257 and HH103 also both encode for more than 130 genes linked to the setup of secretory machines (Table 32.2). While USDA257 obviously lacks a functional T2SS it encodes a T6SS, which is absent in NGR234 and HH103. Specifically, the importance of the T3SS and the array of secreted nodulation outer proteins (Nops) have been elucidated in recent years in many studies for NGR234, USDA257, and HH103, clearly providing convincing evidence that a functional T3SS and secreted Nop effector proteins are keys to broad host range. Therefore, several mutational analyses were accomplished in NGR234, USDA257, and HH103 focusing on different components of the T3SS. The inactivation of selected T3SS-related genes in these three rhizobial strains abolished the secretion of various flavonoid-induced Nop effector proteins (e.g., NolX and NopL) and furthermore decreased their symbiotic capacity (de Lyra et al., 2006; Krishnan, 2002; Krishnan et al., 2003; López-Baena et al., 2008; Viprey et al., 1998; Zhang et al., 2011). Moreover, these studies suggested that Nops can act either as beneficial or detrimental symbiotic factors in a host-dependent manner (de Lyra et al., 2006).

Since only two of the *S. fredii* broad host range strains appear to encode for two copies of a T3SS, future work will have to elucidate the role of the second T3SS in these particular microbes. Furthermore, formal proof that any of the other diverse protein secretion systems identified in these microbes extending the host range of NGR234 has yet to be furnished.

32.3.2 NodD Proteins as First Modulators of Host Specificity

Rhizobial cells recognize secreted plant signals (flavonoids or isoflavonoids) by a sensor protein and LysR-type transcriptional activator usually encoded by *nodD* (Fisher and Long, 1993; see Chapter 51). The activated NodD protein binds to highly conserved DNA motifs of the so-called nodulation boxes (*nod boxes*), which are found in promoter regions of many nodulation loci. After binding, NodD regulates transcription of several nodulation genes (*nod/nol/noe*) (Gyorgypal et al., 1991; Schlaman et al., 1992). To recognize the different plant signals rhizobia have often multiple NodD homologs, which can vary in their preferences for flavonoids (see Chapter 50). Additionally, the symbiotic characteristics of NodD proteins can vary between different rhizobial species (Broughton et al., 2000). NGR234's NodD1 protein usually responds to a wide palette of inducing compounds excreted by the host plant. Transferring the *nodD1* gene of NGR234 into narrow host range strains such as *S. meliloti* and *R. leguminosarum* extended their nodulation capacity and thereby their host range. Nevertheless, NodD1 isolated

from these narrow host range isolates could not restore the ability of an NGR234-*nodD1* mutant to nodulate some of its original legume hosts (Relic et al., 1994; Spaink et al., 1987). In fact, these experiments show that some correlations can be made between the flavonoidic interaction with the different NodD proteins and the host specificity.

32.3.3 Nod Factors Are Keys to Broad Host Range

Binding of the NodD protein to *nod boxes* initiates the expression of nodulation genes, which are subsequently involved in the synthesis and secretion of Nod factors. These structures are oligomers of four or five 1,4-linked *N*-acetyl-glucosamine residues with different substitutions that are attached to the backbone (Spaink, 2000; see Chapter 51). The assemblage of the substitution and the backbone results in a highly specific Nod factor that is recognized by a particular legume host plant, allowing only certain rhizobia–plant associations to occur. Consequently, host specificity in these symbiotic interactions can be determined by the various Nod factors that are generated by different species of rhizobia (Downie, 1998).

The broad host range strain NGR234 secretes a large family of Nod factors that are 3-*O*, 4-*O*, or 6-*O* carbamoylated, *N*-methylated, and carrying a 2-*O*-methyl-fucose residue that may be either 3-*O* sulfated or 4-*O* acetylated. Currently, no other rhizobial isolate is known to synthesize such a wide range of lipochitooligosaccharides (Relic et al., 1993; Relic et al., 1994). Yet another piece of evidence suggests that Nod factors are keys to host range. Not only NGR234 treats the legume root with a large palette of Nod factors but also their concentration is much higher compared to Nod factors produced by very closely related rhizobia (Relic et al., 1994). Thus, it is reasonable to speculate that Nod factors and especially their numerous decorations are important keys to host range determination (Broughton et al., 2000; Deakin and Broughton, 2009; Perret et al., 2000). And although these factors are essential for nodulation, these signal molecules seem to be probably just one of several elements specifying host range.

32.3.4 NodO – a NodD Regulated Protein

One of the rhizobial nodulation proteins that are expressed under the control of the *nodD* gene product is NodO. This secreted protein contains a calcium-binding site and is proposed to be translocated by the T1SS (Sutton et al., 1994). Its role in symbiosis was reported in 1998, where a *Rhizobium* sp. BR816 *nodO* mutant was found to be impaired in its ability to nodulate a certain host strain (Vlassak et al., 1998). Furthermore, the *nodO* gene from *Rhizobium* sp. BR816 and also the *nodO* gene from *R. leguminosarum* bv. *viciae* could extend the host range of narrow strains such as *S. meliloti* (Economou et al., 1990). Additionally, in the absence of host-specific *nod* genes, NodO can compensate for the loss of the appropriate Nod factor. Although the role of NodO is still unclear, three functions could be assigned: NodO facilitates the uptake of the Nod factor, it can amplify the Nod factor; or it can bypass the host's Nod factor receptor (Walker and Downie, 2000).

Surprisingly, only very low sequence similarities to NodO could be found with the genomes of NGR234, USDA257, and HH103. Nevertheless, the previously mentioned results suggest that NodO plays an essential role in symbiosis in *R. leguminosarum* bv. *viciae* and few other rhizobial candidates (de Maagd et al., 1989).

32.3.5 Metabolic Capabilities

The diverse catabolic and metabolic functions encoded by NGR234, USDA257, and HH103 are perhaps another piece of the host range puzzle. Rhizobia have at least two lifestyles: one saprophytic and the other symbiotic and intracellular. A soil bacterium that is able to survive and grow under a wide range of nutritional conditions has more chances of surviving than strains that have very specific growth requirements (Oldroyd et al., 2011). More importantly perhaps, to be primed for the invasion of legumes rhizobia have to grow in the rhizosphere of approaching root systems. Bacteria that can metabolize virtually any carbon- and nitrogen-containing compound that emanates from plant roots will preferentially colonize them (Poole and Allaway, 2000; Sadowsky et al., 2013). This would also include the modification or perhaps degradation of the many flavonoid-signaling molecules released by plants as a primary defense barrier against microbial colonization. However, no data are available to support this hypothesis.

32.3.6 Surface Polysaccharides are Essential for Symbiosis

To establish a successful rhizobial–legume symbiosis, bacteria have to adapt to changing environmental conditions that occur in the proximity of plant roots. The bacterial surface is the first line of defense and in the plant–microbe interaction the first phase of attachment to root hairs. In response to the environment, rhizobia modify their outer cell surface composed of a number of different polysaccharides such as EPSs, LPSs, and KPSs (Fraysse et al., 2003; Skorupska et al., 2006). Although the exact molecular function of these surface polysaccharides remains unclear, their role in establishing a symbiosis with legumes has been reported. EPSs appear to prevent plant defense responses and thus are involved in early infection processes (Parniske et al., 1994; Staehelin et al., 2005; see Chapter 36). In contrast, LPSs play a role in the later stages of the nodulation processes (Carlson

et al., 2010). KPSs are tightly associated with the rhizobial outer membrane, are thus distinct from the loosely adhering EPS, and seem to promote the initiation and development of the infection thread (Le Quere et al., 2006). Rhizobial KPS are strain-specific antigens that are structurally analogous to the group II K-antigens of *E. coli* (Kannenberg et al., 1998).

Detailed genomic analyses proved that most genes linked to surface polysaccharide synthesis are located on the megaplasmid of NGR234. More than 25 genes stretching from *exoU* (NGR_b19500) to *exsI* (NGR_b01520) are involved in the synthesis of low-molecular-weight EPSs that are essential for nodule invasion on some plants (Staehelin et al., 2006). Furthermore, three clusters of genes (*rkp-1*, *rkp-2*, and *rkp-3*) are involved in the production of the K_R5 antigen in NGR234 (Becker et al., 2005). Chromosomally located *rkp-1* and *rkp-2* clusters are probably responsible for the production of a specific lipid carrier necessary for the synthesis of KPS and in the metabolism of nucleotide diphosphosugars, respectively (Schmeisser et al., 2009). In contrast, *rkp-3* is carried by pNGR234*b*.

32.3.7 Cell–Cell Communication Mechanisms as Novel Keys to Host Range

N-AHL-mediated signaling enables rhizobial strains to sense their local environment (rhizosphere) to subsequently coordinate the expression of certain genes. Such a synchronized gene expression is of great importance for bacterial symbionts as a successful infection strategy of eukaryotic hosts, as well as the ability to establish an effective symbiosis, requires apart from other signaling pathways a QS-dependent signaling (Bauer and Mathesius, 2004; LaSarre and Federle, 2013; Wisniewski-Dye and Downie, 2002). Most QS circuits found in plant-associated bacteria are similar in structure; however, the subordinated genes mediating physiological processes are diverse. The underlying QS signaling systems are often complex owing to the incorporation of multiple AHL synthase and response proteins and their organization in a regulatory hierarchy (Soto et al., 2006). Rhizobial QS regulatory systems that have a direct effect on symbiosis have already been described in *R. leguminosarum* bv. *viciae* (Cubo et al., 1992), *R. etli* (Daniels et al., 2002), and *S. meliloti* (Gurich and Gonzalez, 2009; see Chapter 37). The studies mainly working with mutations of single QS-related genes demonstrated the importance of QS for nodulation and nitrogen fixation. These studies could, in part, verify that QS systems regulate diverse genes that are of importance for symbiosis (Grote et al., 2014; Krysciak et al., 2014). Furthermore, it is also possible that the expression of rhizobial QS systems could be influenced by the host plants as these have the potential to detect AHLs as well as to generate mimics of such signaling molecules (Hirsch et al., 2003; Sanchez-Contreras et al., 2007).

The limited availability of nutrients and energy resources in such challenging environmental niches as the rhizosphere forces the competition in mixed populations (Soto et al., 2006). Since bacteria evolved the ability to communicate via QS systems, it is reasonable to speculate that these microbes evolved defense strategies to rival with each other and to disarm competitors by efficiently interfering with the key components of their QS systems (Dong et al., 2007; Gonzalez and Keshavan, 2006). Targets for such QQ processes can be either the autoinducer (AHL) synthase, the AHL signal molecule itself that can be degraded, or the cognate regulator that can be blocked by plant and/or bacterial mimics (Chajkowski and Jafra, 2009; Dessaux et al., 2011; LaSarre and Federle, 2013). Especially, the QQ strategy of AHL degradation by means of lactonases, amidases, or oxidoreductases has been found to play a significant role in obtaining a competitive advantage over other present microbes. Using this QQ strategy, plant-associated strains comprising AHLases or amidases are able to suppress other plant pathogens in their virulence activity, thereby protecting their host plant from colonization by these pathogens (Molina et al., 2003). Most surprisingly, studies carried out with transgenic plants expressing AHL-degrading proteins have been found to be resistant to QS-regulated infection by *E. carotovora* (Dong et al., 2000).

In addition to QS-mediated signaling that is important for the successful establishment of symbiosis, QQ processes may also play a key role in these rhizobia–legume associations. Therefore, the diversity of QS systems and also their availability and utilization in rhizobia might yet be another key to broad host range. Although no study has yet been published clearly demonstrating a link between host range and QQ, the ecological role of QQ proteins was already demonstrated in rhizosphere colonization studies (Krysciak et al., 2011).

Chapter 33

Motility and Chemotaxis in the Rhizobia

Dinah D. Tambalo and Christopher K. Yost

33.1 INTRODUCTION

It is generally believed that motility and chemotaxis are important in rhizobial ecology. This is based on the assumption that rhizobial cells would need to respond to specific compounds produced by the host plant, and be able to move toward the plant root system. In addition, there is a steep concentration gradient of nutrients in the soil, the highest abundance being in the rhizosphere; thus, the ability to move toward the rhizosphere would presumably be beneficial. Most of the genes involved in motility and chemotaxis in rhizobia have been studied in *Sinorhizobium meliloti*, and, within the last few years, additional information has been available in *Rhizobium etli*, *Rhizobium leguminosarum*, *Agrobacterium tumefaciens*, and *Bradyrhizobium japonicum*. With the increasing number of genome sequences available, it has also been possible to perform bioinformatic analysis to investigate the presence of motility-related genes in other rhizobial species.

33.2 THE ENTERIC MODEL SYSTEM OF CHEMOTAXIS AND MOTILITY

Most motile bacteria move through the use of flagella. Chemotaxis and flagellar motility have been studied in great detail in enteric bacteria, particularly *Escherichia coli* and *Salmonella* (recent reviews by Terashima et al., 2008; Wadhams and Armitage, 2004; Berg, 2003; Harshey, 2003; and Macnab, 2003). Thus, the enteric motility system will be used to describe, in brief, the flagellar structure and its movement. The flagellum consists of three substructures, namely: (i) the basal body that functions as a rotary motor; (ii) the filament serving as a helical propeller; and (iii) the hook that serves as a universal joint for the basal body and the filament (Terashima et al., 2008; Minamino and Namba, 2004; Berg, 2003). The basal body consists of a rod, a series of rings, the Mot proteins (stator), the switch complex, and a flagellum-specific export apparatus. The flagellar filament, on the other hand, is made up of flagellin subunits, and it extends many cell lengths from the cell surface (Minamino and Namba, 2004). Assembly of the flagellum and its movement require the synthesis of more than 50 gene products (Terashima et al., 2008).

E. coli and *Salmonella* typically exhibit five to eight peritrichous flagella randomly distributed around the cell (Harshey, 2003). Rotation of the flagella drives two types of movement: swimming and swarming motility. Swimming motility refers to the individual movement of bacteria within a liquid or semisolid environment while swarming motility corresponds to the coordinated movement of flagellated cells on top of a solid surface. Swimming motility is described in the next paragraph while rhizobial swarming will be discussed further in a different section.

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

In the enteric bacteria, counterclockwise rotation of the flagella forces the peritrichous flagella to coalesce into a bundle. The coordinated movement of the flagellar bundle propels the cell, resulting in "running" or smooth swimming. The clockwise rotation of some flagella or an individual flagellum disrupts the bundle, resulting in a "tumbling" motion, consequently causing the reorientation of the cell (Harshey, 2003). In the presence of an attractant gradient, the cell runs longer up the gradient. On the other hand, the presence of a repellent or decreasing concentrations of an attractant results in more tumbles.

Environmental stimuli are sensed by several cooperating chemotaxis mechanisms in the bacteria, including phosphotransferase chemotaxis (Neumann et al., 2012), energy taxis (Alexander, 2010; Schweinitzer and Josenhans, 2010), and the best understood mechanism involving transmembrane chemoreceptors (methyl-accepting chemotaxis proteins or MCPs). *E. coli* and *Salmonella* have five MCPs, four of which (Tar, Tsr, Trg, and Aer) are shared. Tap and Tcp chemoreceptors are specific for *E. coli* and *Salmonella*, respectively (Bren and Eisenbach, 2000). MCPs consist of periplasmic and cytoplasmic domains, with the former functioning as a ligand-binding site and the latter as a signaling domain (Hazelbauer, 1988). The cytoplasmic domain is flanked by methylation regions, and it also contains a binding site for the histidine autokinase CheA. Binding of CheA to the MCP is mediated by an adaptor protein, CheW. The binding of a repellent to the periplasmic domain of the MCP results in a conformational change that signals the phosphorylation of CheA. Phosphorylated CheA transfers the phosphate group to CheY, which becomes activated. CheY-P can then interact with the switch protein (FliM), causing a reversal in the direction of the flagellar motor rotation to a clockwise mode. The clockwise rotation disrupts the flagellar bundle resulting in a tumble and a change in the direction of movement. CheY-P spontaneously dephosphorylates but its inactivation is accelerated by the dephosphatase activity of CheZ. Inactivation of CheY results in the termination of the clockwise flagellar rotation. The other important Che proteins are CheR and CheB, which methylates and demethylates the MCPs, respectively. The methylation state of the MCPs influences their efficiency to stimulate CheA autophosphorylation. Resetting the receptors then allows bacteria to sense changes within a gradient (Belas et al., 2008; Wadhams and Armitage, 2004; Bourret and Stock, 2002; Bren and Eisenbach, 2000).

A number of the enteric motility and chemotaxis elements described above are conserved in rhizobia. However, there are also major differences, including flagellar filament structure, flagellar gene organization, number of flagellin genes, and chemotactic signaling. Some of these features have been described in reviews by Poole et al., 2010 and Yost and Hynes, 2000. In this chapter, recent studies on rhizobial chemotaxis and motility (e.g., swarming motility and gene regulation) are included. In addition, results from the analysis of additional rhizobial genome sequences are presented.

33.3 FLAGELLATION AND FLAGELLAR ROTATION IN RHIZOBIA

In Bergey's *Manual of Systematic Bacteriology* (Jordan, 1984), rhizobia are generally described as motile, with peritrichous flagella, except for *B. japonicum*, which is polarly flagellated. *Mesorhizobium* is motile by one or two subpolar flagella or it could also be peritrichously flagellated (Chen et al., 2005). *R. leguminosarum* VF39SM (Tambalo et al., 2010a) and *S. meliloti* (Götz et al., 1982) can have as many as 7 and 10 peritrichous flagella (Fig. 33.1a and c), respectively; and *R. leguminosarum* 3841 has 1–3 subpolar flagella (Fig. 33.1b). *A. tumefaciens*, on the other hand, has multiple flagella that are arranged circumthecally near one end of the cell (Chesnokova et al., 1997). The motility system of *B. japonicum* is quite different from other rhizobial species, having two flagellar systems consisting of a thick subpolar flagellum and a few thin peritrichous flagella at subpolar positions (Kanbe et al. 2007). The thick flagellum is semicoiled while the thin flagella appear in a tight-curly morphology (Kanbe et al., 2007). The presence of a dual flagellar system has been described previously in *Vibrio parahaemolyticus* (McCarter, 2004; Atsumi et al., 1992). However, the *B. japonicum* flagellar system differs from that of *V. parahaemolyticus* such that both thick and thin flagella are subpolar and unsheathed, as opposed to the polar positions of the sheathed flagella in *V. parahaemolyticus* (Kanbe et al., 2007; McCarter, 2004; Atsumi et al., 1992).

Rhizobial flagella from different species differ in terms of physical properties and appearance under an electron microscope. The plain filaments of *R. leguminosarum* (Tambalo et al., 2010a; Del Bel, 2004) appear smooth (Fig. 33.1d and e). Both thick and thin lateral flagella from *B. japonicum* also resemble plain flagellar filaments (Kanbe et al., 2007). In contrast, the complex filaments of *S. meliloti* (Fig. 33.1f) and *Agrobacterium* sp. strain H13-3 (previously called *Rhizobium lupini* H13-3) have a distinct ridging pattern (Trachtenberg and DeRosier, 1987; Trachtenberg et al., 1987; Krupski et al., 1985). The complex filaments synthesized by *S. meliloti* and *Agrobacterium* sp. strain H13-3 are also rigid (Scharf et al., 2001; Sourjik and Schmitt, 1998; Sourjik and Schmitt, 1996), a property that is thought to be favorable for motility in viscous environments such as in the soil biotope (Trachtenberg and Hammel, 1992). Both the plain flagella in *R. leguminosarum* and the thin filaments of *B. japonicum* rotate unidirectionally, which is similar to the observation for complex filaments (Trachtenberg and Hammel, 1992; Götz and Schmitt, 1987). The direction of cell movement is changed by modulating the speed of

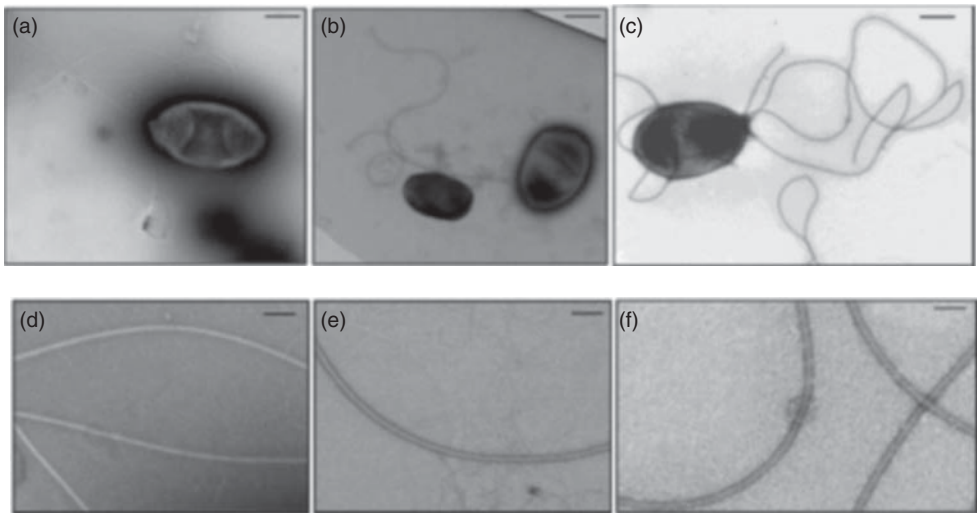

Figure 33.1 Electron micrographs of *R. leguminosarum* and *S. meliloti* 1021 flagellar filaments stained with 1% uranyl acetate. (a) VF39SM is peritrichously flagellated; (b) 3841 has a subpolar flagellum; and (c) *S. meliloti* 1021 is peritrichously flagellated. The flagellar filaments of (d) VF39SM and (e) 3841 appear to have a smooth surface and lack the ridging pattern observed on the surface of the complex flagella formed by (f) *S. meliloti* 1021. Bars: 500 nm for (a)–(c); 100 nm for (d)–(f). (Source: Tambalo et al., 2010a.)

flagellar rotation (Miller et al., 2007; Sourjik and Schmitt, 1996) so the organism turns rather than tumbles.

33.4 FLAGELLAR GENES AND THEIR GENETIC ORGANIZATION IN RHIZOBIA

The majority of the flagellar, motility, chemotaxis, and regulatory genes of *S. meliloti* (Sourjik et al., 1998), *A. tumefaciens* (Deakin et al., 1999), *M. loti* (Kaneko et al., 2000), and *R. leguminosarum* (Tambalo et al., 2010b) are located in a single region in their chromosomes. This type of genetic organization may facilitate coordinated expression of motility-related genes in the rhizobia. Analysis of the complete DNA sequences of the flagellar regulons revealed that the genes encoding nearly all of the proteins for the various rings, rod, hook, motor, and filament are present. In addition to the genes coding for the stator proteins (MotA and MotB), *motC*, *motD*, and *motE* were found in the genomes of these rhizobial species. MotC may stabilize the periplasmic domain of MotB; MotD appears to control the speed of flagellar rotation (Schmitt, 2002; Platzer et al., 1997); and MotE functions as a periplasmic chaperone for the proper folding and stability of MotC (Eggenhofer et al., 2006). The presence of the additional Mot proteins may be important in rhizobia since the flagellum functions by modulating its rotational speed rather than reversing the direction of its rotation. There are also two complete Che operons in *R. leguminosarum* and *R. etli* genomes (Miller et al., 2007). In *R. leguminosarum*, the first Che operon is located within the flagellar gene cluster, while the Che2 operon, although also found in the chromosome, is outside of the flagellar regulon. Both Che1 and Che2 operons encode the conserved set of CheAWYRB homologs that are also found in *E. coli* (Aizawa et al., 2000). *S. meliloti* also harbors two Che operons but only one has a complete set of CheAWYRB; the incomplete set of *che* genes is located on the megaplasmid pSymA and is next to genes putatively coding for pili. In the *R. leguminosarum* and *S. meliloti* genomes, there is no homolog to *cheZ*, which is consistent with previous observations that *cheZ* is found exclusively in the Betaproteobacteria and Gammaproteobacteria (Szurmant and Ordal, 2004). However, *S. meliloti* (Sourjik and Schmitt, 1998) and *R. leguminosarum* possess two or more genes coding for putative CheY proteins (Miller et al., 2007). The functions of the CheY proteins will be described later. In contrast to the rhizobial regulon described here, the *B. japonicum* genome has two sets of flagellar gene clusters and several small scattered regions with one or a few flagellar genes (Kanbe et al., 2007). The two large gene clusters contain duplicate flagellar genes, including flagellin genes that encode components of its thick and thin flagella.

33.5 CHARACTERIZATION OF RHIZOBIAL FLAGELLINS

Analysis of completely sequenced rhizobial genomes demonstrates the presence of at least two flagellin genes in each genome (Table 33.1). Among the sequenced rhizobia, *R. leguminosarum* has the largest number of predicted flagellin genes, with both biovars *viciae* (Young et al., 2006) and *trifolii* (Reeve et al., 2010) encoding seven flagellins.

Table 33.1 Number of flagellin genes and sizes of predicted proteins from sequenced rhizobia

Organisms	Number of Flagellin Genes in the Genome	Flagellin Genes	Length of Predicted Encoded Flagellins (Number of Amino Acids)
A. tumefaciens C58	4	*flaA, flaB, flaC, and flaD*	306–430
Agrobacterium sp. strain H13-3	3	*flaA, flaB, and flaD*	410–430
B. japonicum	7	*flaA, fliCI, fliCII, fliC1, fliC2, fliC3, and fliC4*	274–314 (FliA, FliCI, and FliCII) 757–763 (FliC1 to FliC4)
R. etli CFN42	6	*flaCch1, flaCch2, flaCch3, flaCch4, flaCch5, and flaCe*	301–342
R. leguminosarum bv. *viciae* strain VF39 and 3841	7	*flaA, flaB, flaC, flaD, flaE, flaF, and flaG*	301–337
R. leguminosarum bv. *trifolii* strains WSM1325 and WSM2304	7		301–332 (WSM1325) 301–389 (WSM2304)
S. meliloti 1021	4	*flaA, flaB, flaC, and flaD*	321–401
S. medicae WSM419	4	*flaA, flaB, flaC, and flaD*	321–395
*S. fredii U*SDA257	3	*flaC1, flaC2, and flaC3*	305–320
S. fredii NGR234	3	*flaA, flaB, and flaD*	305–320
M. loti MAFF303099	2	*flaA* (loci mlr2925 and mlr2927	328 and 356

In *R. leguminosarum* strains VF39SM and 3841, six flagellin genes (*flaABCDHG*) are found on the chromosome, with *flaA*, *flaB*, *flaC*, and *flaD* located within the flagellar regulon, *flaH* and *flaG* are in separate loci outside of the flagellar gene cluster; and *flaE* is plasmid-borne. In *S. meliloti*, the four flagellin genes are located in a tandem array in its 45-kb flagellar regulon (Sourjik et al., 1998). On the other hand, *flaA* and *flaB* (plus *flaC* in *A. tumefaciens*) are in tandem array but *flaD* is located on a distant portion of the flagellar regulons of *Agrobacterium* sp. strain H13-3 and *A. tumefaciens* (Scharf et al., 2001; Deakin et al., 1999).

The flagellins in *Rhizobium* (301–389 amino acids), *Sinorhizobium* (305–401 amino acids), *Agrobacterium* (306–430 amino acids), and *M. loti* (328 and 356 amino acids) are quite similar in terms of the length of the predicted protein sequences. For *B. japonicum*, FliCI (313 amino acids) and FliCII (314 amino acids) have sizes that are similar to those of the other rhizobia but the other flagellins (FliC1, FliC2, FliC3, and FliC4) are larger (757–763 amino acids). Sequence alignment of the amino acid sequences of the rhizobial flagellins revealed conserved residues at the amino- and carboxy-terminal ends. The terminal segments of flagellin proteins comprise the filament core and are essential for polymerization (Mimori-Kiyosue et al., 1997). Similar to the enteric system, the central region of the flagellins, which corresponds to the outer region of the filament, is considerably variable. In addition, the flagellin subunits cluster by genus: FlaA, FlaB, FlaC1/FlaC2, and FlaD for *S. meliloti* and *S. medicae*; FlaA/FlaCch1, FlaB/FlaCch2, FlaG/FlaC/FlaCchr3, FlaE/FlaCe, FlaH/FlaCch5 for *R. leguminosarum* and *R. etli*; FlaB and FlaC for *A. tumefaciens* C58; FlaA and FlaB for *Agrobacterium* sp. H13-3; mlr2925 and mlr2927 for *M. loti* MAFF303099; and FliC1 through FliC4 in *B. japonicum* (Fig. 33.2), suggesting that the flagellin genes did not undergo duplication or diversification until after the genera separated. Among the sequenced rhizobial species analyzed, *B. japonicum* encodes flagellins related to those of the other rhizobia only distantly.

Transcriptional studies and mutational analysis demonstrated that the rhizobial flagellar filaments are made up of more than one type of flagellin. This is contrary to the composition of the enteric flagellar filaments, which are composed of multiple copies of a single flagellin monomer, FliC (Macnab, 2003). In *S. meliloti* and *Agrobacterium* sp. strain H13-3, the flagellar filaments are assembled using four (FlaA, FlaB, FlaC, and FlaD) and three (FlaA, FlaB, and FlaD) flagellin subunits, respectively (Scharf et al., 2001). FlaA is the major flagellin subunit for both rhizobial species while FlaB, FlaC, and FlaD are secondary. Based on mutagenesis and electron microscopy imaging, FlaA and at least one of the secondary flagellins are required for the assembly of a functional flagellar filament (Scharf et al. 2001). Similarly, four flagellins (FlaA, FlaB, FlaC, and FlaD) contribute to the flagellar structure of *A. tumefaciens* (Deakin et al., 1999). Similar to *S. meliloti* and *Agrobacterium* sp. strain H13-3, mutation of *flaA* in *A. tumefaciens*

Figure 33.2 Phylogenetic tree of flagellins from *R. leguminosarum* VF39SM, *R. etli* CFN42, *S. meliloti* 1021, *S. medicae* WSM4189, *S. fredii* USDA257, *B. japonicum*, *M. loti* MAFF303099, *A. tumefaciens* C58, and *Agrobacterium* sp. H13-3.

C58 resulted in severely truncated and nonfunctional filaments. Thus, FlaA is the major flagellin, FlaB and FlaC are synthesized in lesser amounts, and FlaD is a minor component of the *A. tumefaciens* filament. In *R. leguminosarum*, three to six flagellins possibly make up its filament (Tambalo et al., 2010a). FlaA, FlaB, and FlaC are major components while FlaD and FlaG are minor components. Mutation of *flaA* in *R. leguminosarum* VF39SM results in a nonflagellated and nonmotile strain while mutation of *flaB* or *flaC* results in shorter flagellar filaments. For *B. japonicum*, four flagellins (FliC1, FliC2, FliC3, and FliC4) and two flagellins (FliCI and FliCII) possibly make

up the thick and thin flagella, respectively (Kanbe et al., 2007). Moreover, based on glycoprotein-specific staining, flagellins from *R. leguminosarum* (Tambalo et al., 2010a) and FlaA from *A. tumefaciens* (Deakin et al., 1999) are glycosylated. In the case of *R. leguminosarum*, the glycosylated flagellin(s) was(were) not identified because the subunits displayed similar migration distance on a protein gel. Sequence analysis of the seven flagellins showed the presence of glycosylation signals in each subunit. Analysis of the amino acid sequences of the other sequenced rhizobia in Table 33.1 showed putative glycosylation site(s) in at least one flagellin protein. Flagellar glycosylation has also been reported in a diverse number of bacterial species, and in some cases, it has been demonstrated to have a role in flagellar assembly (Logan, 2006). In *Azospirillum brasilense*, flagellin glycosylation is suggested to be involved in root adsorption (Moens et al., 1995), but there has been no direct evidence linking flagellin glycosylation with plant–microbe interactions. The biological role of flagellin glycosylation in the rhizosphere remains to be established.

33.6 CHEMOTAXIS

Rhizobia are chemotactic to a large number of diverse compounds as well as plant exudates (Kato and Arima, 2006; Yost and Hynes, 2000; Dharmatilake and Bauer, 1992; Barbour et al., 1991; Parke et al., 1985; Bowra and Dilworth, 1981). The exact nature of the receptors specific for these chemoattractants has not yet been determined. Nevertheless, the major elements of the chemotactic pathway in *E. coli* are present in the genomes of the rhizobial species that have been sequenced. Rhizobial species exhibit different numbers of chemotaxis operons and *mcp* genes (Table 33.2). There are two Che operons in the genome of *S. meliloti* but chemotaxis is controlled by a single operon (Schmitt, 2002). The second Che operon in *S. meliloti* is located on pSymA, and it is linked to genes involved in Type IV pilus biosynthesis, suggesting a role in twitching motility (Scharf and Schmitt, 2002). A Che operon similar to that of *S. meliloti* is conserved in *Agrobacterium* (Wright et al., 1998], *R. leguminosarum* (Che1 operon; Miller et al., 2007), corresponding to the group 1 Alphaproteobacterial Che operons described by Hauwaerts et al. (2002). *R. leguminosarum* also contains an additional complete Che operon (Che2 operon) corresponding to Che operon group 3. The *R. leguminosarum* Che1 operon is the major pathway that controls swimming bias and chemotaxis, and it is essential for competitive nodule formation. *B. japonicum* (Kaneko et al., 2002) and *R. etli* (Gonzalez et al., 2006) also have two Che operons while *M. loti* appears to have an incomplete set of *che* genes (Kaneko et al., 2000).

Bioinformatics analysis demonstrated that *S. meliloti* 1021 and *S. medicae* WSM419 have 9 *mcp* homologs each in their genomes while *M. loti* appears to have one plasmid-encoded *mcp* gene homolog. There are larger *mcp*-gene families in other rhizobia: up to 36 putative *mcp* genes in *B. japonicum* USDA110; 20 in *A. tumefaciens* C58; 27 in *R. leguminosarum*, and 28 in *R. etli* CFN42. The *mcpB* gene in *R. leguminosarum* may play a general role in chemotaxis since strains with a mutation in this receptor gene have a generalized lack of chemotactic ability. In addition, these mutants are affected in competitive nodulation. The ligand specificities encoded by the *mcp* genes in *R. leguminosarum* as well as in the other rhizobia remain to be elucidated. This could be a daunting task, since the ligands of these chemoreceptors could be unknown compounds in the rhizosphere or soil.

As mentioned earlier, there are two putative genes coding for CheY (CheY1 and CheY2) in *S. meliloti* but the CheZ protein is lacking. It is proposed that the absence of the phosphatase CheZ is compensated by CheY1 (Sourjik and Schmitt, 1998). CheY2 is the major response regulator that slows flagellar rotation upon phosphorylation by CheA (Schmitt, 2002; Sourjik and Schmitt, 1998). CheY2-P shuttles back the phosphoryl group to CheA, which then phosphorylates CheY1. Thus, CheY1 in association with CheA acts as a phosphate sink, thereby emulating the role of CheZ in the enteric bacteria (Schmitt, 2002; Sourjik and Schmitt, 1998). CheY1-P dephosphorylates spontaneously, but the rate may be too slow to provide sufficient free CheY1 (Schmitt, 2002). Very recently, Dogra et al. (2012) identified a new component (CheS) in *S. meliloti* that may play a role in accelerating CheY1-P dephosphorylation. CheS was demonstrated to bind to CheA, and phosphotransfer experiments demonstrated that CheS increases dephosphorylation

Table 33.2 Number of chemotaxis-like operons and chemoreceptors in sequenced rhizobial genomes

Organisms	Number of Chemotaxis-Like Operons	Number of Chemoreceptors (MCPs)
S. meliloti 1021	2 (1 complete set)	9
R. etli CFN42	2	28
R. leguminosarum	2	27
B. japonicum USDA110	2	36
A. tumefaciens C58	1	20
M. loti MAFF303099	1 (incomplete?)	1

of CheY1-P but not CheY2-P. Using surface plasmon resonance spectroscopy, it was further demonstrated that CheY1 binds more strongly (100-fold more) to CheA/CheS than to CheA alone. Thus, it was proposed that CheS facilitates signal termination by enhancing CheY1 and CheA interaction thereby promoting CheY1-P dephosphorylation (directly or indirectly), which results in a more efficient drainage of the phosphate sink. CheS is encoded by the major chemotaxis operon of *S. meliloti*, and CheS orthologs were also found in *S. medicae*, *A. tumefaciens*, and *R. leguminosarum* (Dogra et al., 2012).

33.7 REGULATION OF CHEMOTAXIS AND MOTILITY GENES

33.7.1 Flagellar Gene Expression in Free-Living Cells

While it is advantageous for bacteria to be able to move toward favorable environments and away from detrimental conditions, motility is energetically costly. The bacterial cell utilizes about 2% of its biosynthetic energy for the synthesis and function of the flagellum, thus flagellar gene expression is stringently regulated (Soutourina and Bertin, 2003). Similar to the enteric system, the flagellar genes of *S. meliloti* are regulated in a three-tiered hierarchy, and the genes are classified into three classes based on temporal order of expression (Fig. 33.3) (Rotter et al., 2006; Sourjik et al., 2000). The class IA genes are transcribed first and they encode VisN and VisR, which are LuxR-type proteins with characteristic DNA and ligand-binding domains. Individual mutations of *visN* and *visR* result in nonflagellated and nonmotile strains (Sourjik et al., 2000). It is believed that VisN and VisR may bind an unknown effector, and that they function as a heterodimer exerting control over the transcription of *rem* (class IB) (Rotter et al., 2006). Rem is an OmpR-like transcriptional activator that controls the expression of class II genes, which comprise basal body components (class IIA) and motility (class IIB) genes. A *rem*-mutant strain is nonflagellated and nonmotile. In *S. meliloti*, the proteins encoded by the class IIA genes *fliM* (switch protein/C-ring) and *orf38* (speculated to encode a structural component of the basal body) have been suggested to regulate the expression of the class III genes (flagellin and chemotaxis genes). Thus, similar to the enteric system, expression of the class III genes depends on the completion of the basal body structure and, possibly, flagellar export (Sourjik et al., 2000). The proteins encoded by class IIB genes (*motA*, *motB*, and *motC*) do not exert transcriptional control over the class III genes. In a different study, Hoang et al. (2008) reported that several motility genes in *S. meliloti*, including *flaF*, *flbT*, and *flaC*, are not regulated by Rem, although these genes are still controlled by VisN. In contrast to the regulation described for *S. meliloti*, the majority of the motility-related genes in *R. leguminosarum* are under VisN/R-Rem regulation (Fig. 33.3), but a subset of genes is independent of both VisN/R and Rem regulations (Tambalo et al., 2010b). The four flagellin genes (*flaA* through *flaD*), *motA*, *motB*, *che1* operon, and *mcpD*, are positively regulated by Rem through VisN/R. In strain VF39SM, the *flaE* gene that is plasmid-borne is repressed. Other chemotaxis and motility genes, which are found outside of the main motility gene cluster (*che2* operon, *flaH*, and *flaG*) or are plasmid-borne (*mcpC*), are not part of the VisN/R-Rem regulatory cascade, suggesting the presence of a secondary regulatory system in *R. leguminosarum*.

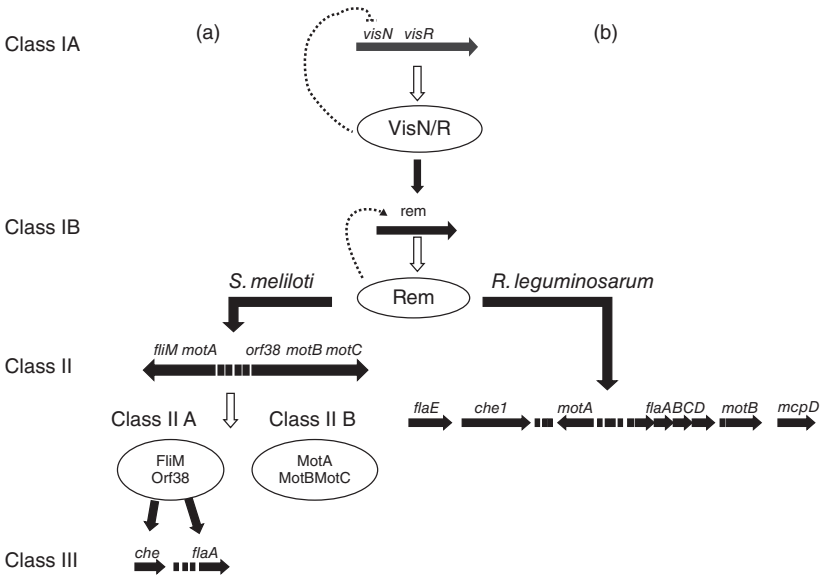

Figure 33.3 Regulation scheme of motility-related genes in (a) *S. meliloti* and (b) *R. leguminosarum*. In *S. meliloti*, the genes are classified into three classes, based on temporal level of expression. Genes are indicated as horizontal arrows and the corresponding gene products as ellipsoids. Translation to gene products is indicated by open vertical arrows. Black vertical arrows and bars indicate positive and negative regulation, respectively. Autoregulation of *visN* (in *R. leguminosarum*) and *rem* (in *S. meliloti*) is shown by dotted lines. This figure is modified from Tambalo et al. (2010b) and Rotter et al. (2006).

Real-time expression analysis showed that the expression of motility-related genes, including *flaF*, *flbT*, *cheY1*, *flaC*, *flgB*, *flgF*, and *motA*, in *S. meliloti* decreases as the cell density increases (Hoang et al., 2008). Correspondingly, electron microscopy imaging demonstrated that production of flagella is suppressed at high cell densities. Gene expression analysis further showed that the motility genes are controlled by the ExpR/Sin quorum sensing (QS) system through the VisN/VisR-Rem system. The Sin system is one of the two QS systems found in *S. meliloti* (see Chapter 37). ExpR, on the other hand, is a LuxR-type transcriptional regulator that activates exopolysaccharide (EPS) production in the presence of Sin-AHLs. Using an electrophoretic mobility shift assay, Bahlawane et al. (2008) demonstrated that AHL-bound ExpR binds to the promoter region of *visN* and inhibits its transcription. In addition, in the absence of ExpR, the expression of motility genes is lower at all growth phases. Complementation of an *expR* mutant strain with a constitutively expressed *visN* and *visR* restored the expression of motility-related genes to the wild-type levels at the early log phase of growth, suggesting that unbound ExpR and ExpR–AHL complex compete for the control of motility gene expression (Gurich and González, 2009). At low cell density, free ExpR probably activates *visN* and *visR*. As the cell population increases and the AHL concentration increases, the ExpR–AHL complex outcompetes the unbound ExpR. The ExpR–AHL complex then binds upstream of *visN* and *visR*, resulting in the repression of *visN* and *visR* expression.

Contrary to the growth-dependent expression of flagellar genes in *S. meliloti* described earlier, *R. leguminosarum* is continuously motile and flagellar genes are expressed at all growth phases (Tambalo et al., 2010b; Yost et al., 2004). This difference in temporal expression of flagellar genes in *S. meliloti* and *R. leguminosarum* suggests that although these nodule bacteria are closely related, they employ different strategies when confronted with unfavorable growth conditions such as poor growth conditions at the stationary phase. The downregulation of flagellar genes in *S. meliloti* leads to energy conservation while continued chemotaxis and motility under free-living conditions in *R. leguminosarum* may result in finding more nutrients and a more favorable environment (Tambalo et al. 2010b).

33.7.2 Flagellar Gene Expression in Bacteroids

Chemotaxis and motility are thought to be irrelevant for rhizobia once they have invaded a host plant and begun to differentiate into bacteroids. Using antiflagellin and anti-MCP antibodies, earlier studies demonstrated the absence of flagella and MCPs in bacteroids (Del Bel, 2004; Yost et al., 2004; Roest et al., 1995). Transcriptional experiments using gene fusions further demonstrated the repression of flagellin, chemotaxis, and motility genes in *R. leguminosarum* during symbiosis. Microarray experiments also showed that a flagellar gene in *M. loti* (Uchiumi et al., 2004) and 25 motility and chemotaxis genes in *S. meliloti* are downregulated in bacteroids. The signals and mechanisms for the repression of motility and chemotaxis are not established, but oxygen appears not to be the major signal, and known symbiotic regulators, such as FixL, FixK, and FnrN, may not be involved (Becker et al. 2004; Yost et al., 2004). The genes coding for the transcriptional activators VisN and Rem are also repressed during symbiosis in *R. leguminosarum*, suggesting that motility repression inside the nodules is possibly mediated by repression of VisN/R and Rem (Tambalo et al., 2010b).

33.7.3 Flagellar-mediated Swarming Motility

Swarming motility has only been described recently in the rhizobia. Swarming has been reported in *R. etli* CNPAF512 (Braeken et al., 2008; Daniels et al., 2006), *S. meliloti* (Nogales et al., 2010; Soto et al., 2002), *R. leguminosarum* bv. *viciae* (Tambalo et al., 2010c), *Agrobacterium vitis* (Sule et al., 2009), and more recently in *B. japonicum* (Covelli et al., 2013). In addition, initial characterization of *R. leguminosarum* isolates suggests that swarming could be widespread in *R. leguminosarum*; 11 out of 14 isolates tested demonstrated surface movement (Tambalo and Yost, unpublished). The specific composition of swarm media used to induce swarming differs; but they generally contain mineral salts and 0.1–1% of either of the following carbon sources: mannitol, arabinose, and glycerol. Surface movement was observed in *A. vitis* using a potato dextrose medium, which contains 1% dextrose (Sule et al., 2009). The concentration of the agar (and the type of agar in the case of *S. meliloti* QS77 (Soto et al., 2002)) appears to be critical for swarming. Surface movement was observed in agar concentrations ranging from 0.5% to 0.75%; a higher concentration (1.3%) results in swarming inhibition (Soto et al., 2002; Tambalo et al., 2010c).

33.7.4 Swarming Colony Morphology and Properties of Swarmer Cells

Rhizobial species exhibit different swarming patterns (Fig. 33.4). *R. etli* strains CFN42 (Fig. 33.4a) and CNPAF512, *S. meliloti* (Fig. 33.4b), *R. leguminosarum* 3841 (Fig. 33.4c), and *B. japonicum* (Covelli et al., 2012) swarm outwards from the point of inoculation forming short extrusions on the swarm edge. Swarming patterns in *R. leguminosarum* VF39SM (Fig. 33.4d) and *A. vitis* (Fig. 33.4e), on the other hand, appear more complex, with the formation of dendrite arms across the agar surface. In *R. leguminosarum*, the dendrite arms originate from the point of inoculation, then expand, and then branch further from the original dendrite arms. Furthermore, a cell density-dependent lag period (3–5 days) occurs before the initiation of swarming. This time frame is characterized by

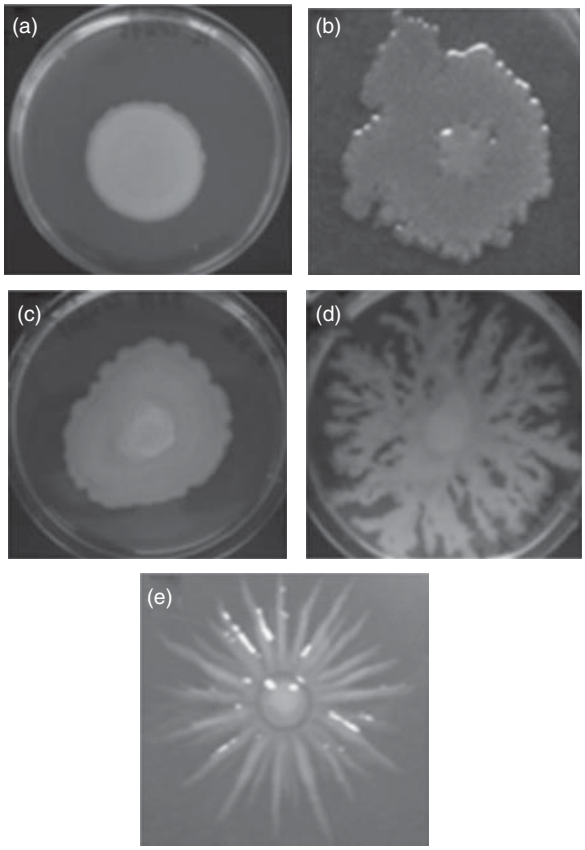

Figure 33.4 Pattern formation of rhizobial swarming colonies. (a) *R. etli* CFN42, (b) *S. meliloti* QS77 (Soto et al., 2002), (c and d) *R. leguminosarum* 3841 and VF39SM (Tambalo et al. 2010c), and (e) *A. vitis* F2/5 (Sule et al., 2009).

an increase in colony size, reflecting an increase in cell density. Thus, the lag period might be needed to reach a certain cell density to start swarming. Additionally, this phase may allow the metabolic and physiological changes associated with swarmer cells (Nogales et al., 2010; Overhage et al., 2008; Kim and Surette, 2004) and/or to build up extracellular swarm signals such as biosurfactants and extracellular slime (Verstraeten et al., 2008; Toguchi et al., 2000).

Swarming development in *S. meliloti* QS77 is accompanied by the accumulation of polysaccharides that are associated with a mucoid appearance (Soto et al., 2002). In addition, the swarming front is preceded by an extracellular slime (Tambalo et al., 2010c; Daniels et al., 2006), which may contain biosurfactants that facilitate surface movement (Verstraeten et al., 2008). Surfactants were detected in the matrix formed by *A. vitis*, but not in *R. leguminosarum*. Long-chain AHLs were also detected in the *R. etli* extracellular matrix, and these AHLs were demonstrated to have biosurfactant activity (Daniels et al., 2006). Swarming in *S. meliloti* 1021 requires the synthesis of siderophore rhizobactin 1021 (Nogales et al., 2010), which has surfactant properties and therefore probably acts as a wetting agent for surface translocation (Nogales et al., 2012). Differentiation into swarmer cells is also characterized by increased flagellation in *S. meliloti* (Soto et al., 2002), *R. leguminosarum* (Fig. 33.5a–e; Tambalo et al. 2010c), and *B. japonicum* Covelli et al., 2013). Increased flagellation in swarmer cells, relative to vegetative cells, may be necessary to overcome surface friction and/or higher viscosity created by the extracellular slime surrounding a swarming colony (Harshey, 2003). In contrast, *A. vitis* swarmer cells demonstrate similar flagellation pattern as vegetative cells, indicating that increased flagellation is not a requisite for *A. vitis* swarming (Sule et al., 2009). For *B. japonicum*, both subpolar and lateral flagella are synthesized by swarmer cells, with the latter type playing a major role in swarming. Swarmer cells were also observed to be twice as long as vegetative cells in *S. meliloti* (Soto et al., 2002) and *B. japonicum* (Covelli et al., 2013). It is believed that cell elongation results from the suppression of cell division in swarmer cells; but its role in swarming is not understood (Kearns, 2010). Another notable feature of *R. leguminosarum* swarmer cells is the formation of rafts, wherein adjacent cells are arranged parallel to their long axis (Fig. 33.5f). This rafting arrangement may promote rapid and coordinated movement of swarm cells on the agar surface (Daniels et al., 2004; Julkowska et al., 2004). *R. leguminosarum* swarmer cells were also found to be resistant to a number of different classes of antibiotics but the ecological role of antibiotic resistance in rhizobial swarmer cells remains to be elucidated.

33.7.5 Regulation of Swarming Motility

To date, little is known about the genetic control of rhizobial swarming motility. In *R. etli* CFNPAF512, swarming is regulated by the CinIR QS, which is activated in swarmer cells by its cognate AHL and other long-chain AHLs (Daniels et al., 2004). As mentioned earlier, apart from signaling function, the long-chain AHLs also act as biosurfactants. The major flagellin gene (*flaA*) and the genes coding for the transcriptional activators VisN and Rem are upregulated in *R. leguminosarum* swarmer cells, which is in agreement with increased flagellation. In *R. leguminosarum*, chemotaxis appears to be dispensable for swarming motility, which has also been reported in *Salmonella* (Mariconda et al., 2006). Mutation of the major chemotaxis operon (*che1*) and the secondary operon in *R. leguminosarum* did not significantly affect swarming motility (Tambalo, 2010). Apart from motility and QS-related genes, genes involved in polysaccharide synthesis or export and amino acid or polyamine metabolism may contribute to swarming. Individual mutations in these genes result in reduced or totally deficient swarming motility in *R. etli* CNPAF512 (Braeken et al., 2008). Furthermore, a recent transcriptomic profiling study in *S. meliloti* demonstrated that swarmer cells have different physiology compared with cells growing in liquid cultures (Nogales et al., 2010). Despite these studies,

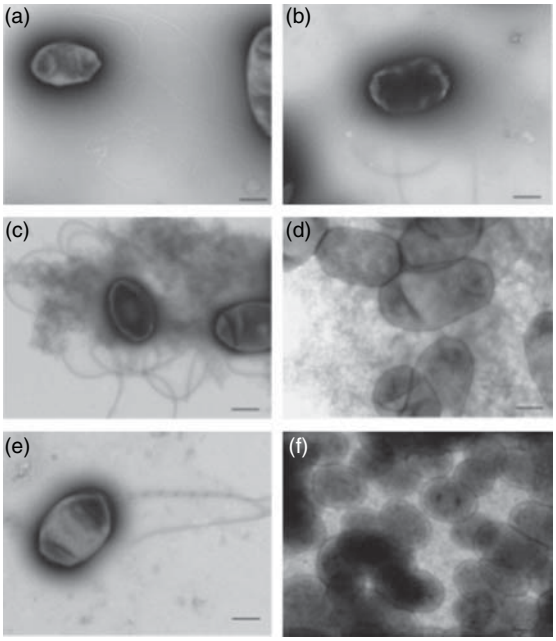

Figure 33.5 Transmission electron micrograph of *R. leguminosarum* VF39SM and 3841 vegetative and swarming cells. (a) VF39SM vegetative cells from a solid agar plate; (b) VF39SM vegetative cells taken from the center of a swarm plate; (c) VF39SM swarm cells taken from the edge of the swarm front; (d) 3841 vegetative cells from a solid agar plate; (e) 3841 swarm cells taken from the edge of the swarm front; (f) VF39SM cells taken from the edge of the swarm front. Adjacent cells are connected side by side forming rafts. Scale bar = 500 nm. (*Source*: Tambalo et al. 2010c.)

the signals and regulatory networks involved in rhizobial swarming remain poorly understood.

33.7.6 Flagellar-Independent Surface Motility in *S. meliloti*

Spreading or sliding motility has recently been reported in *S. meliloti* (Nogales et al., 2012). Sliding is a type of surface translocation that is brought by expansive forces in a growing culture in combination with special cell surface properties and surfactants that reduce friction between the cells and the substrate (Jarrell and McBride, 2008). Nogales et al. (2012) demonstrated that this type of translocation is flagellar independent; mutations in different *S. meliloti* strains that resulted in nonflagellated phenotypes did not affect surface spreading. In addition, sliding motility absolutely depends on the production of galactoglucan (EPS II) while overproduction of succinoglycan (EPS I) facilitates this movement (see also Chapter 36). It has been suggested that EPS II may serve as a hydrated milieu, providing sufficient moisture to facilitate spreading, or as a lubricant to reduce friction between cells and a semisolid surface. Twitching motility, which depends on a type IV pilus, has not been demonstrated in any rhizobia.

33.7.7 Role of Chemotaxis and Motility in Rhizobial Ecology

A number of studies have demonstrated an important role for motility and chemotaxis in the colonization of plant hosts by various rhizobial species. Although nonmotile or nonchemotactic rhizobial strains are still able to nodulate their host plants, they are usually less competitive than the wild-type strains (Yost et al., 1998; Malek, 1992; Bauer and Caetano-Anollés, 1990; Caetano-Anollés et al., 1988; Mellor et al., 1987; Soby and Bergman, 1983; Ames and Bergman, 1981). Individual mutations in the major chemotaxis gene cluster and a *mcp* gene in *R. leguminosarum* also resulted in altered competitiveness (Miller et al., 2007; Yost et al., 1998).

The role of swarming in rhizobial ecology is not yet established but this bacterial behavior may provide an ecological advantage in the rhizosphere, including colonization of plant hosts and protection from antimicrobials. During alfalfa rhizosphere colonization, *Pseudomonas fluorescens* F113 produces hyperflagellated phenotypic variants with enhanced swarming abilities, and these variants preferentially colonize distal parts of the roots (Sánchez-Contreras et al., 2002). Barak et al. (2009) also correlated swarming and alfalfa seedling colonization by identifying genes in *Salmonella enterica* that are required for swarming and colonization. In addition, alfalfa root exudates perpetuate *S. enterica* swarming. In *R. leguminosarum*, swarming motility can be enhanced or inhibited by seed exudates from Faba bean (*Vicia faba*) and lentil (*Lens culinaris*), respectively (Tambalo et al., 2014), which could affect bacterial colonization and plant host infection.

34.1 INTRODUCTION

34.1.1 Phosphotransferase Systems

Phosphotransferase systems (PTS) are widespread in the bacterial kingdom and a first description of the phosphorylation of a PTS enzyme in *E. coli* was published by Kundig et al. (1964). The best characterized systems are the so-called sugar PTS, which are facilitating the uptake and phosphorylation of incoming sugars in a wide range of Gram-negative and Gram-positive bacteria (for an extended review, see Deutscher et al., 2006). The sugar PTS is also the key player in the regulation of uptake and metabolism of different carbon sources, better known as carbon catabolite repression (CCR) in both model organisms *Escherichia coli* and *Bacillus subtilis* (Görke and Stülke, 2008). A paralogous system to the sugar PTS was first described in *E. coli* and named PTS^{Ntr} after its organization within the *rpoN* operon and a link to nitrogen metabolism (Powell et al., 1995). RpoN is the sigma factor governing the general expression of genes regulated by nitrogen availability in bacteria (see Chapters 10, 11). Both PTS consist of three core proteins that are subsequently phosphorylated in the presence of phosphoenol pyruvate (PEP). The first enzyme is called enzyme I (EI or EI^{Ntr} for PTS^{Ntr}) and rapidly autophosphorylates on a conserved histidine residue in the presence of PEP. This phosphate group is then transferred to another conserved histidine of a phosphocarrier protein (HPr or NPr for PTS^{Ntr}), which further donates the phosphate to a protein named enzyme II (EIIA or EIIA^{Ntr} for PTS^{Ntr}). In case of the sugar PTS, several EIIA proteins can be phosphorylated again on a conserved histidine. These EIIA proteins belong to EII membrane complexes of variable organization that share the ability to transport and subsequently

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

phosphorylate-specific sugars (Deutscher et al., 2006). The important difference of the PTS^{Ntr} is that EIIA^{Ntr} does not interact with any transport complexes of the PTS transporter family. PTS^{Ntr} is therefore thought to have only regulatory function (Pflüger-Grau and Görke, 2010). While sugar PTSs seem to have mainly evolved in Enterobacteriales, Vibrionales, and Firmicutes, the occurrence of PTS^{Ntr} in the absence of any sugar PTS might be a regular feature of Alphaproteobacteria and Betaproteobacteria, Chlamydiae, Planctomycetes, and Xanthomonadales (Cases et al., 2007).

34.1.2 Phenotypes of PTS^{Ntr} Mutants

Mutations of Pts^{Ntr} genes cause pleiotropic phenotypes in a wide range of bacteria (summarized by Pflüger-Grau and Görke, 2010). These phenotypes are described as nitrogen-related phenotypes (metabolism, fixation, and transport) observed in *Klebsiella pneumonia*, *Pseudomonas aeruginosa*, *Azotobacter vinelandii, Rhizobium etli*, and *R. leguminosarum* (Begley and Jacobson, 1994; Jin et al., 1994; Merrick and Coppard, 1989; Segura and Espin, 1998; Michiels et al., 1998; Prell et al., 2012), polyhydroxy alcanoate accumulation in *P. putida* and *A. vinelandii* (Noguez et al., 2008; Velazquez et al., 2007), carbon catabolite repression phenotypes in *P. putida* and *Sinorhizobium meliloti* (Cases et al., 1999; Pinedo et al., 2008), host interaction in *P. fluorescence* and *Legionella pneumophila* (Edelstein et al., 1999; Mavrodi et al., 2006), and regulation of K^+ transporters in *E. coli* and *R. leguminosarum* (Lee et al., 2007; Lüttmann et al., 2009; Prell et al., 2012). In many of these studies, EIIA^{Ntr} in its phosphorylated or nonphosphorylated form is thought to facilitate the regulatory effect in a direct or indirect way. Direct mechanistic evidence is only available for the regulation of K^+ transport in *E. coli* and *R. leguminosarum* (Lee et al., 2007; Lüttmann et al., 2009; Prell et al., 2012) and interaction with PhoR in *E. coli* (Lüttmann et al., 2012). Very recently, it has been shown that EIIAs phosphorylated via the PTS^{Ntr} might directly regulate the activity of central carbon metabolic enzymes such as pyruvate dehydrogenase and α-ketoglutarate dehydrogenase (Dozot et al., 2010; Pflüger-Grau et al., 2011).

However, while the sugar PTS is directly linked to sugar transport, the PTS^{Ntr} has only recently been linked to transport activities. The first report came from *Bradyrhizobium japonicum* where a PtsP (EI^{Ntr}) mutant was found to be unable to take up δ-aminolevulinic acid (ALA; King and O'Brian, 2001). ALA transport, which is facilitated via the oligopeptide transport system Opp, is abolished in a PtsP or LysC mutant of *B. japonicum* I110. LysC, which codes for an aspartokinase, is located upstream of PtsP in *B. japonicum.* PtsP and LysC interact with each other and ATP-dependent PtsP phosphorylation is reduced in the presence of LysC *in vitro* (King and O'Brian, 2001). The second example of a link of PTS^{Ntr} to transport is the direct regulation of K^+ transport activities by nonphosphorylated EIIA^{Ntr} in *E. coli* (Lee et al., 2007; Lüttmann et al., 2009) and in *R. leguminosarum* (Prell et al., 2012). In high K^+ medium, an *E. coli ptsN* (EIIA^{Ntr}) mutant has difficulties to grow because nonphosphorylated EIIA^{Ntr} inhibits the low-affinity K^+ transporter Trk via protein–protein interaction with TrkA (Lee et al., 2007), which leads to an accumulation of high intracellular K^+ levels. In contrast, in low K^+ medium, nonphosphorylated EIIA^{Ntr} stimulates the phosphorylation of the two-component system KdpDE, which leads to an increased transcription of the high-affinity K^+ transporter KdpFABC in *E. coli* (Lüttmann et al., 2009).

Here, we describe a link of the PTS^{Ntr} of *R. leguminosarum* to the ATP-dependent ABC transporter superfamily and the P-type ATPase K^+ transporter KdpABC.

34.2 RESULTS AND DISCUSSION

34.2.1 EI^{Ntr} Is Required for Full Activation of ABC Transport in *R. leguminosarum* 3841

While screening for Tn5 mutants of *R. leguminosarum* 3841 (Rlv3841) with altered surface phenotypes, a dry colony morphology on TY agar plates could be linked to a *ptsP* mutation (Prell et al., 2012). The mutant strain PtsP107 formed small, flat, and dry colonies in contrast to the large and mucous colonies formed by the wild-type Rlv3841.

We started to investigate a link between PTS^{Ntr} and ABC transport because of three reasons: (i) mutation of *ptsP* or *lysC* in *B. japonicum* I110 leads to the inactivation of Opp, an oligopeptide transporter of the ABC transporter superfamily (King and O'Brian, 2001); (ii) exopolysaccharide secretion, which makes *R. leguminosarum* strains extremely mucous, is known to involve ABC transporter components (Becker et al., 1995; Paulsen et al., 1997; Vanderlinde et al., 2010); and (iii) the two general amino acid ABC transport systems Aap and Bra are posttranscriptionally regulated by an unknown mechanism and upon an unknown signal in a glutamine oxoglutarate aminotransferase (GOGAT) mutant background in Rlv3841 (Mulley et al., 2011).

When the *ptsP* mutant PtsP107 was grown in AMS minimal medium with 10 mM glucose and NH_4Cl and transport rates of five different solutes, which are known to be exclusively taken up via at least seven ABC transport systems, were compared to transport levels of wild-type Rlv3841, a reduction of transport rates between 50% and 80% was observed (Fig. 34.1; Prell et al., 2012). In contrast, the uptake of succinate, which is facilitated via the proton-coupled DctA transport system, was unaffected. Consistent with this, PtsP107 grew very poorly on AMS glucose/glutamate plates because glutamate is taken up

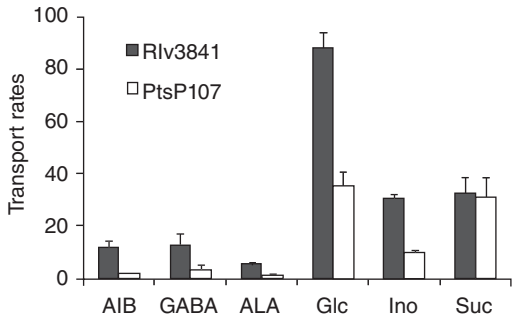

Figure 34.1 Transport rates of wild type Rlv3841 and its *ptsP*::Tn*5* mutant PtsP107. α-aminoisobutyric acid (AIB), γ-aminobytyric acid (GABA), δ-aminolevulinic acid (ALA), glucose (Glc), and inositol (Ino) are taken up via published ABC systems; succinate (Suc) is taken up via the proton coupled DctA transporter (for details see Prell et al., 2012). Rates are given in nanomole solute per min milligram per protein. (*Source*: Modified from Prell et al., 2012.)

via the ABC transport systems Aap and Bra in Rlv3841. These results suggested that PtsP is required for general ABC transport activation and posed the question whether the entire PTS^{Ntr} phosphorylation cascade is linked to that phenomenon.

34.2.2 Identification of Other PTS^{Ntr} Genes in the Rlv3841 Genome

The Rlv3841 genome contains at least 19 genes that encode proteins with homology to PTS components. One protein, LysC, should be added to this list, because it interacts with PtsP in *B. japonicum* I110 (King and O'Brian, 2001).

34.2.2.1 LysC. Upstream of PtsP (EI^{Ntr}, RL4283) orientated in the same direction, a *lysC* gene, was found (RL4284) in the Rlv3841 genome that very likely encodes an aspartokinase as demonstrated in *B. japonicum* (King and O'Brian, 2001). Mutation of the Rlv3841 *lysC* gene did not result in a surface phenotype identical to the *ptsP* mutation. When tested for amino acid transport, only a minor but significant reduction of transport rates could be measured in the *lysC* mutant RU4192, and bacterial two-hybrid experiments could not verify a protein–protein interaction between LysC and PtsP as shown in *B. japonicum* (Prell et al., 2012). In *B. japonicum* I110, a *lysC* or *ptsP* mutation has the same effect on Opp transport. Therefore, we concluded that there is no strong link between LysC and PtsP in *R. leguminosarum* in contrast to *B. japonicum*. Mutation of *lysC* in Rlv3841 also did not cause auxotrophy for the strain, which poses the question how *R. leguminosarum* generates lysine, threonine, and methionine, which require aspartyl β-phosphate as a precursor. Investigation of the Rlv3841 genome did not produce an obvious *lysC* homolog. However, the location of *lysC* upstream of *ptsP*, sometimes separated by one or few genes, seems to be a general feature of Alphaproteobacterial genomes with only very few exceptions (analysis of 197 genomes of the MicrobeOnline database; unpublished observation).

34.2.2.2 EIIA^{Ntr}. The next observation in Alphaproteobacterial genomes is that while *ptsN* coding for EIIA^{Ntr} is located downstream of *rpoN*, a *ptsO* gene coding for NPr is missing. NPr, the intermediate phosphocarrier protein of PTS^{Ntr}, is encoded within the *rpoN* operon of many other bacterial families. Surprisingly, *ptsN* (RL0425; PtsN1) has an additional copy within the Rlv3841 genome (pRL110376; PtsN2) located downstream of the K^+ transporter genes *kdpABCDE*. Mutation of *ptsN1* (RL0425) or *ptsN2* (pRL110376) alone did not result in a surface phenotype, but the double-mutant LMB272 (*ptsN1*::ΩSpec *ptsN2*::ΩTet) showed a dry surface phenotype on TY plates, although slightly less pronounced than that of PtsP107 (Prell et al., 2012). This surface phenotype of LMB272 was accompanied by a substantial reduction (~65%) of amino acid transport rates. The *ptsN1* single-mutant LMB271 also showed transport rates significantly reduced by ~40%, suggesting that PtsN1 is contributing stronger to the described phenotypes.

34.2.2.3 NPr. An obvious candidate for the intermediate phosphocarrier protein NPr was initially missing in the Rlv3841 genome. HPr and NPr share an amino acid identity of only 30% in *E. coli* K12. However, two HPr homologs were found on the Rlv3841 chromosome: RL0032 showed 37% and 33% identity to NPr and HPr from *E. coli* K12, while RL2903 had 28% and 31% identity, respectively. RL0032 is part of an operon that is also conserved in a majority of Alphaproteobacteria as mentioned by others before (Boel et al., 2003; Hu and Saier, 2002; Pinedo and Gage, 2009). This operon consists of genes encoding a two-component regulatory system: ChvIG, an HPr kinase/phosphatase (HprK with a conserved truncation; Boel et al., 2003), a single EIIA^{Man} protein lacking any membrane domains and an HPr homolog. This operon has attracted significant attention in the past. Mutation of *chvI* or *chvG* homologs has produced pleiotropic phenotypes in *Agrobacterium tumefaciens*, *Brucella abortus*, *Sinorhizobium meliloti*, and *Rhizobium leguminosarum* (Belanger et al., 2009; Charles and Nester, 1993; Sola-Landa et al., 1998; Vanderlinde and Yost, 2012). All the mentioned species require this system to successfully invade their respective hosts, and the growth phenotypes of *Sinorhizobium meliloti* and *Rhizobium leguminosarum chvIG* mutants are especially dramatic. In both species, *chvG* mutants are not able to grow in liquid broth or on full medium plates. Growth is limited to minimal medium plates with a reduced

selection of carbon and nitrogen sources (Belanger et al., 2009; Vanderlinde and Yost, 2012), and selection of those mutants has been challenging. Mutation of HprK, EIIA^{Man} (ManX), and HPr in *S. meliloti* 1021 are all linked to succinate-mediated catabolite repression (SMCR; Pinedo et al., 2008; Pinedo and Gage, 2009).

Mutation of RL0032 in Rlv3841 resulted in an identical surface and transport phenotype as mutation of *ptsP* (Untiet et al., 2013). This is a clear indication that RL0032 is indeed NPr the phosphocarrier protein of PTS^{Ntr} in *R. leguminosarum*, and that the general activation of ABC transport involves the whole PTS^{Ntr} phosphorylation cascade.

34.2.2.4 Nontransporting Dihydroxyacetone EII Complexes.

The second above-mentioned HPr homolog RL2903 is part of one of three dihydroxyacetone (DHA) PTS gene clusters (RL1749-52; RL2900-06; pRL120386-7), which make up the majority of PTS genes in Rlv3841. DHA PTS is responsible for DHA metabolism via PTS phosphorylation but not transport (Deutscher et al., 2006). According to Barabote and Saier (2005), these clusters might form a fully functional DHA PTS, which has never been reported to interact with sugar PTS or PTS^{Ntr}. We did not test Rlv3841 for growth on DHA, but mutation of RL2903 in Rlv3841 did not result in a surface phenotype or a reduction of ABC transport activity (Untiet et al., 2013).

Because of the conserved arrangement of (i) ***ptsP*** with *lysC*; (ii) ***npr*** with *chvIG*, *hprK*, and *manX*; and (iii) ***ptsN*** with *rpoN* but without *npr* (*ptsO* in *E. coli*), these genes probably express the typical PTS^{Ntr} of Alphaproteobacteria.

34.2.3 Phosphorylation of the PTS^{Ntr} Proteins

Because of the identical phenotypes of EI^{Ntr} (PtsP) and NPr mutants and the very similar phenotype of the EIIA^{Ntr} (PtsN1/2) double mutant in Rlv3841, we concluded that the regulating protein that activates ABC transport in a direct or indirect way must be phosphorylated EIIA^{Ntr} (Prell et al., 2012). Additionally, overexpression of PtsP in wild-type Rlv3841 increased amino acid transport rates, suggesting activation. Complementation of the respective mutants with PtsP, NPr, PtsN1, or PtsN2 on plasmids always fully restored the wild-type surface and transport phenotypes (Prell et al., 2012; Untiet et al., 2013). Complementation with nonphosphorylatable mutant versions of PtsP (PtsPH367A) and NPr (NPrH17A) on the low-copy number plasmid pRK415 did not change the surface phenotype nor activate ABC transport above the respective mutant levels (Untiet et al., 2013). This indicates that indeed phosphorylation of the PTS^{Ntr} proteins is required for ABC transport activation. However, overexpression of a nonphosphorylatable PtsN1 (PtsN1H66A) on the mid-copy number plasmid pBBRMCS5 in LMB272 (*ptsN1*::ΩSpec *ptsN2*::ΩTet) did complement both the surface and transport phenotype similar to the wild-type version (Prell et al., 2012). We concluded that PtsN1H66A must be a weak activator of ABC transport when overexpressed, and the experiment has to be repeated with low and single copy versions of PtsN1H66A.

We also purified EI^{Ntr} (PtsP) as a 6His-MBP (maltose-binding protein)-PtsP version and NPr as 6His-NPr from *E. coli* BL21 cells. We could show that 6His-MBP-PtsP readily autophosphorylates in the presence of ^{33}P-PEP but not in the presence of ^{33}P-ATP (Untiet et al., 2013). The phosphate on 6His-MBP-PtsP was then donated to 6His-NPr. The donation further to PtsN1, PtsN2, and possibly ManX (EIIA^{Man}) has still to be demonstrated. Phosphorylation of ManX and PtsN (EIIA^{Ntr}) by NPr was recently demonstrated for the protein homologs in *Brucella melitensis* (Dozot et al., 2010) and is therefore likely to also occur in Rlv3841. Indirect evidence for a possible phosphorylation of EIIA^{Man} by NPr (called HPr in that study) comes also from the work in *S. meliloti* where both proteins are linked to SMCR phenotypes (Pinedo et al., 2008).

34.2.4 Role of the EI^{Ntr} N-terminal GAF Domain

One unique characteristic that separates EI^{Ntr} from EI is an N-terminal extension of ~180aa harboring a GAF domain. GAF domains are well known in the NifA transcriptional regulator family, which is involved in sensing of the nitrogen status in nitrogen-fixing bacteria (Little and Dixon, 2003). GAF domains are ligand-binding domains and it is tempting to speculate that EI^{Ntr} GAF domain regulates phosphorylation of the PTS^{Ntr} cascade. However, a ligand binding to the EI^{Ntr} GAF domain still awaits its discovery.

Removing the GAF domain from the Rlv3841 EI^{Ntr} (PtsP) protein still allowed activation of ABC transport (Untiet et al., 2013). Consistent with this, the truncated PtsPΔGAF also still complemented the dry surface of the *ptsP* mutant PtsP107. This suggests that a ligand binding to GAF might be a negative regulator of PTS^{Ntr} phosphorylation.

34.2.5 A Second Level of Regulation of PTS^{Ntr}

In *Bacillus subtilis*, HprK is able to phosphorylate a conserved serine residue of HPr. This serine phosphorylation reduces the EI-mediated histidine phosphorylation of HPr and is a strong regulator of CCR (Görke and Stülke, 2008). HprK is absent in *E. coli* but present as a truncated protein in Alphaproteobacteria (Boel et al., 2003). In *Brucella melitensis*, it has been shown that HprK can phosphorylate NPr on the conserved serine residue. Prevention of that serine phosphorylation increases the levels of histidine phosphorylation

of NPr and therefore $EIIA^{Ntr}$ phosphorylation (Dozot et al., 2010). In *S. meliloti*, *hprK* mutation results in strong growth deficiencies, loss of SMCR, and loss of effective nodulation of alfalfa plants (Pinedo and Gage, 2009). Almost identical phenotypes were observed when an *npr* mutant (called *hpr* in that study) was complemented with an NPr variant, lacking the conserved serine residue. This indicates that the hprK mutant phenotypes are mediated via phosphorylation of NPr.

Complementation of an *npr* mutation in Rlv3841 with an NPr variant lacking the conserved serine residue also resulted in strong growth reduction of the strain similar to *S. meliloti*. Additionally, the strain turned very mucous (unpublished data). It is tempting to speculate that the very mucous phenotype results from increased ABC transport-dependent EPS secretion mediated via increased $EIIA^{Ntr}$ phosphorylation.

Altogether the presence of HprK and its ability to regulate NPr histidine phosphorylation in Alphaproteobacteria opens a new and exiting second level of $EIIA^{Ntr}$ (PtsN) and $EIIA^{Man}$ (ManX) regulation, which might involve direct interaction with carbon metabolic enzymes.

34.2.6 Regulation of the High-Affinity KdpABC Transporter

KdpABC is a P-type ATPase that is controlled transcriptionally by the two-component regulatory system KdpDE. In *E. coli*, nonphosphorylated $EIIA^{Ntr}$ (PtsN) stimulates the phosphorylation of KdpD, which in turn activates KdpE (Lüttmann et al., 2009). Phosphorylated KdpE increases transcription of *kdpFABC* mRNA and, therefore, KdpFABC activity. However, in *E. coli*, the main activator of KdpDE phosphorylation is the K^+ level of the medium. In contrast, *kdpABC* expression is under the strict control of PtsN in Rlv3841. A *kdpA* mutant (RU4393) abolishes growth in medium with K^+ levels below 100 µM (Prell et al., 2012). The *ptsN1/2* double-mutant LMB272 shows exactly the same phenotype, while wild-type Rlv3841 and the *ptsP* mutant PtsP107 grow down to K^+ levels of 1 µM. This indicates that PtsN is strictly required for *kdpABC* expression. Q-RT-PCR data support this hypothesis, showing that *kdpAB* expression is constitutively upregulated in PtsP107 compared to wild-type Rlv3841 (Prell et al., 2012) and downregulated in LMB272 (unpublished data). Constitutive upregulation in PtsP107 indicates that nonphosphorylated PtsN is the Kdp-activating variant identical to the situation in *E. coli*. However, a homolog of the low-affinity Trk K^+ transporter, which is inhibited by nonphosphorylated PtsN in *E. coli* (Lee et al., 2007), is absent in *R. leguminosarum*. Low-affinity K^+ transport is likely facilitated via the Kup systems in Rlv3841, which have so far not been implicated in PTS^{Ntr} regulation.

34.2.7 Inactivation of ABC Transport at Low K^+ Levels

The existing evidence that EII^{Ntr} (PtsN) is regulating several members of the ATP-dependent ABC transporter superfamily, and on the other hand, the essential P-type ATPase KdpABC suggests a general regulation of ATP-dependent transport activities (Prell et al., 2012). It also allows the prediction that under strong K^+ limitation, where *kdpABC* transcription is induced by nonphosphorylated PtsN, ABC transport, that requires phosphorylated PtsN should be limited. When tested, wild-type Rlv3841 transported amino acids under strong K^+ limitation (1 µM), where PtsN must be nonphosphorylated at rates comparable to the rates of the *ptsP* mutant PtsP107, where PtsN cannot become phosphorylated (Untiet et al., 2013). Consistent with that, Rlv3841 growth in glucose/glutamate medium at 1 µM K^+ levels was significantly slower than growth in glucose/ammonium medium, while growth rates at non-limiting conditions (1 mM K^+) are identical.

This is to our knowledge the first report where PTS^{Ntr} dictates the regulation of essential cellular functions, namely K^+ homeostasis and ABC transport activities at limiting K^+ medium levels (Untiet et al., 2013).

A model of PTS^{Ntr} regulation in Rlv3841 that summarizes our findings and proposed functions published by others is shown in Figure 34.2.

34.3 CONCLUSIONS

PTS are historically some of the most intensively studied regulatory systems in bacteria. Although sugar PTS are the best investigated, PTS^{Ntr} is probably the most widespread PTS among the different bacterial families. PTS^{Ntr} was initially thought to regulate aspects of nitrogen metabolism or probably mediate between carbon and nitrogen metabolism. In *E. coli*, nitrogen metabolic phenotypes disappeared when *ptsN* mutant strains with an intact *ilvGM* operon coding for acetohydroxy acid synthase II (AHAS II, an enzyme of the branched chain amino acid biosynthetic pathway) were analyzed (Reaves and Rabinowitz, 2011). AHAS I, encoded by *ilvBN*, is sensitive to increased K^+ levels in contrast to AHAS II, and the authors claim that the nitrogen-related *ptsN* mutant phenotypes are a result of increased intracellular K^+. However, nitrogen-related phenotypes in other proteobacteria could be a result of ABC transport inactivation.

The only verified mechanistic actions of the PTS^{Ntr} are inhibition/activation of K^+ transport (Lüttmann et al., 2009; Prell et al., 2012; Lee et al., 2007) and PhoR regulation (Lüttmann et al., 2012) mediated via nonphosphorylated $EIIA^{Ntr}$. Additionally, EIIAs might regulate the activity of central carbon metabolic enzymes (Dozot et al., 2010; Pflüger-Grau et al., 2011).

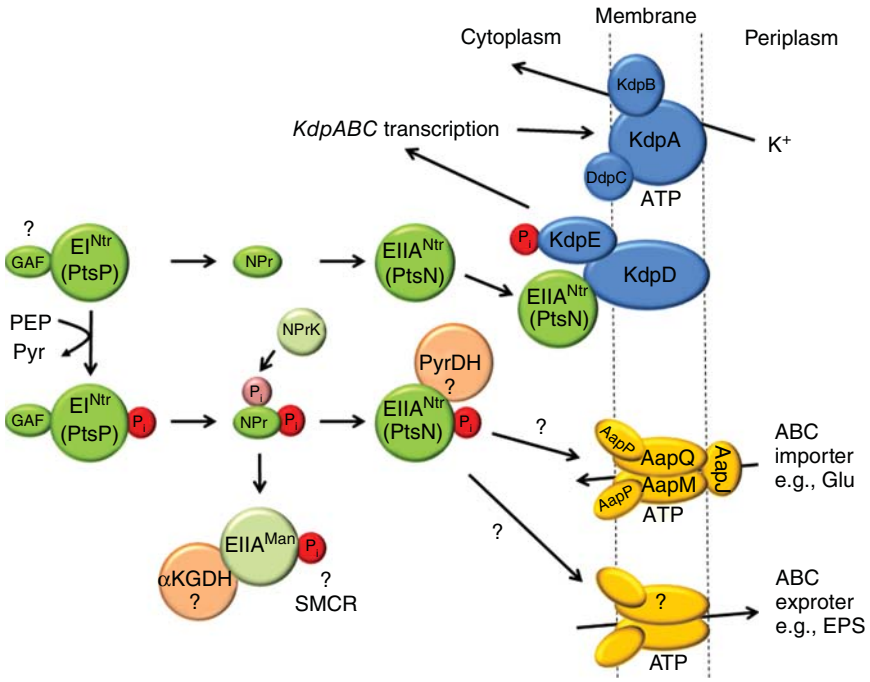

Figure 34.2 Model of PTS^{Ntr} regulation in *Rhizobium leguminosarum* with possible parallels to *Sinorhizobium meliloti*, *Brucella melitensis*, and *Pseudomonas putida*. Nonphosphorylated PTS^{Ntr} induces KdpABC by activation of KdpDE via protein–protein interaction (upper part) and phosphorylated PTS^{Ntr} activates ABC transport systems via an unknown mechanism (lower part). The regulating protein is in both cases EIIA^{Ntr}. Additionally, EIIA^{Man} regulates succinate-mediated catabolite repression (SMCR) in *S. meliloti* via an unknown mechanism. Possible cross-regulation of NPr histidine phosphorylation via regulatory serine phosphorylation by NprK (HprK) is indicated. Possible interaction with carbon metabolic enzymes such as pyruvate dehydrogenase (PyrDH in *P. putida*; Pflüger-Grau et al., 2011) and α-ketoglutarate dehydrogenase (αKGDH in *B. melitensis*; Dozot et al., 2010) are added. Question marks (?) indicate unknown ligands (EI^{Ntr} GAF), unknown mechanistic interactions (ABC transport regulation and SMCR), or not verified regulatory effects in Rlv3841 (metabolic enzymes and SMCR). (*Source*: Modified and extended from Prell et al., 2012.)

From our studies, it emerges that PTS^{Ntr} also regulates ABC transporter activities. Rhizobia are especially rich in ABC transport systems, probably as an adaptation to their oligotrophic lifestyle in soil and the rhizosphere (Mauchline et al., 2006). ABC transporter and P-type ATPases, such as KdpABC, are both primary transport systems with high affinities that use ATP hydrolysis to take up solutes against a gradient. We therefore speculate that PTS^{Ntr} might regulate ATP-dependent processes. This might also involve the balancing of carbon and nitrogen metabolism. Altogether we speculate that PTS^{Ntr} might in fact be a PTS^{ATP} or a PTS^{adenylate}.

GLOSSARY

CCR carbon catabolite repression

SMCR succinate-mediated catabolite repression

EI^{Ntr} enzyme 1 of PTS^{Ntr}, synonym PtsP, homolog of EI of sugar PTS

NPr phosphocarrier protein of PTS^{Ntr}, synonym PtsO, homolog of HPr of sugar PTS

EIIA^{Ntr} enzyme 2 of PTS^{Ntr}, synonym PtsN, homolog of EIIAs of sugar PTS

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

35.1 INTRODUCTION

Among the soil-dwelling actinobacteria, members of the genus *Frankia* are distinguished by their ability to form symbiotic nitrogen-fixing associations with a variety of woody dicotyledonous plants (termed actinorhizal plants) representing eight different plant families of angiosperms (Benson and Silvester, 1993; Schwencke and Carú, 2001; Perrine-Walker et al., 2011; Wall, 2000). *Frankia* exists either in a free-living state in the soil or in symbiosis with actinorhizal plants (Benson and Silvester, 1993; Chaia et al., 2010; Schwencke and Carú, 2001). Actinorhizal plants are ecologically important as pioneer community plants; distributed worldwide in a broad range of ecological conditions; and have economic significance in land reclamation, reforestation, soil stabilization, landscaping, and fuel. The symbiosis allows actinorhizal plants to colonize harsh environmental terrains.

Symbiotic interactions between *Frankia* and the host plant are not well understood at a molecular level. At the morphological level, the actinorhizal symbiosis has been well studied. Root nodule formation in actinorhizal plants occurs in several stages that require a series of interactions between the bacteria and host root cells (Perrine-walker et al., 2011; Obertello et al., 2003; Wall and Berry, 2008). To initiate the symbiosis, the bacteria must recognize its host plant, attach to the surface, and penetrate the root. *Frankia* infects host plants by two distinct routes: intracellular penetration of a plant epidermal cell at a bend in a deformed root hair and intercellular penetration *of* root epidermis cells and cortex cells. Following penetration, an infection thread is established that is composed of a mass of bacteria encapsulated by polysaccharide matrix produced by the host. As the infection progresses, limited cell divisions occur close to the infection site generating a prenodule. Some prenodule cells become infected by *Frankia* and differentiate to fix nitrogen (Laplaze et al., 2000). Concomitantly, cell divisions are induced in the pericycle in front of a xylem pole. These divisions give rise to a nodule lobe primordium. As the nodule lobe primordium grows, the nodule cortex becomes infected intracellularly by *Frankia* hyphae coming from the prenodule.

Host recognition by the microbe and the identification of the beneficial microbe partner by the host plant are central to the establishment of a solid mutualism. This interaction implies cell-to-cell communication mechanisms. Information on these initial stages of interaction between the actinorhizal host plant and their symbiont, *Frankia*, in the soil is lacking. Elucidation of the *Frankia* genomes (Normand et al., 2007; Sen et al., 2013; Ghodhbane-Gtari et al., 2013) has revealed the absence of the common *nod* genes found in the *Rhizobium*–legume symbiosis. This result suggests that the actinorhizal symbiosis uses novel signal compounds during the infection process. The signaling molecules of actinorhizal plants would be perceived by *Frankia* prior to infection and would alter their physiology. (Beauchemin et al., 2012) addressed this problem by analyzing the effects of host plant root exudates on *Frankia* physiology. *Frankia* sp. strain CcI3 and *Casuarina cunninghamiana* were selected as a model system because of several reasons including that the narrow-host-range symbiont *Frankia* sp. strain CcI3 genome was sequenced (Normand et al., 2007). As a follow-up, the effects of root exudates on other *Frankia* strains were also examined.

35.2 MATERIALS AND METHODS

Frankia cultures were grown and maintained as described previously (Beauchemin et al., 2012; Tisa et al., 1999). The following *Frankia* strains were used in this study: strains CcI3, ACN14a, QA3, CN3, EUN1f, and EAN1pec.

Plant growth conditions were as described previously (Beauchemin et al., 2012). Seeds from *C. cunninghamiana*, *Elaeagnus angustifolia, Alnus glutinosa*, *Myrica cerifera*, *Hippophae rhamnoides*, and *Betula pendula* were used in this study. Briefly, seeds were sterilized by hydrogen peroxide treatment and washed with sterile deionized water. The surface sterilized seeds were germinated in perlite at 28 °C with a 16 h light period and 8 h dark period. Figure 35.1 outlines the process for the production of plant root exudates. At 7–12 days after seed germination, five plant seedlings were aseptically transplanted from the perlite to an aluminum screen in a magenta box suspended over 50 ml of 1/4 Hoagland's modified basal salt solution (1/4 HS). The plants were incubated at 28 °C with a 16 h light period. For each magenta box, spent growth medium was replaced weekly with fresh sterile 1/4 HS medium. The spent plant growth medium (root exudates) was collected monthly and filter-sterilized.

The physiological effect of root exudates on *Frankia* cultures was determined as described previously (Beauchemin et al., 2012). Briefly, cultures exposed to root exudates were assayed by multiple methods. First, hyphal curling was observed under phase contrast microscopy. Second, cell surface changes were examined by FTIR spectroscopy (Furnholm et al., 2012) and by Congo red dye binding (Beauchemin et al., 2012; Etienne et al., 2002)

35.3 RESULTS AND DISCUSSION

35.3.1 Effect of Root Exudates on *Frankia* Growth

Aqueous root exudates were used in this study and represent the natural exudates of the plant root. Although

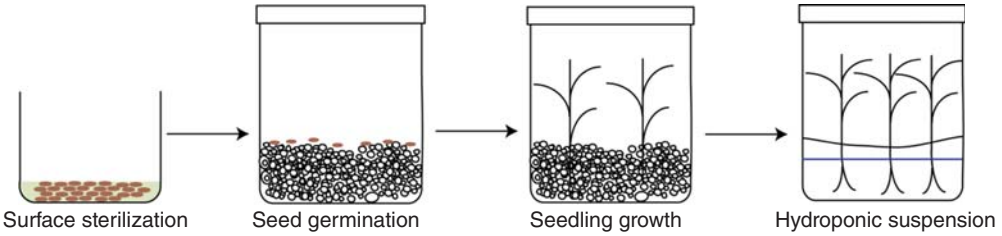

Figure 35.1 Diagram of workflow to grow aseptic seedlings for root exudates collection and nodulation studies.

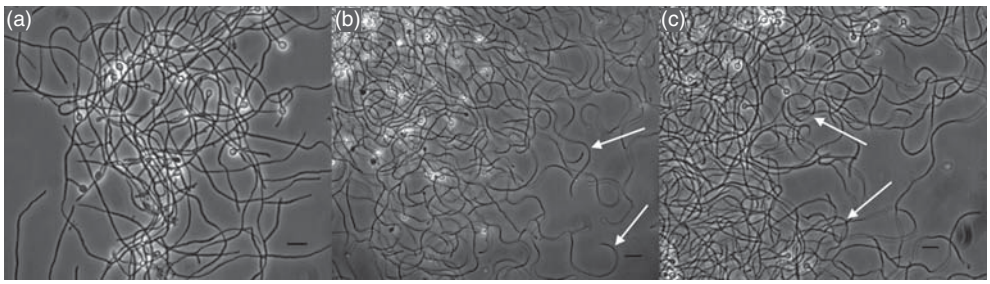

Figure 35.2 Hyphal curling response of *Frankia* CcI3 upon exposure to host root exudates. *Frankia* CcI3 cells incubated for 14 days in (a) 1/4 HS (N_2) medium (control), (b) soil-grown 2-month-old *C. cunninghamiana* root exudates, or (C) axenic 1-month-old *C. cunninghamiana* root exudates. Cultures were observed under phase contrast microscopy. Bar = 10 µm. Arrows point to regions showing curling effect. (From Beauchemin et al., 2012 with permission.)

flavonoid compounds have been identified in actinorhizal plants (Benoit and Berry, 1997; Popovici et al., 2010; see Chapter 50), we did not want to exclude any possible aqueous or organic plant signaling molecules. The exudates were collected over time from our magenta box system (Fig. 35.1). Root exudates from plants grown under both nitrogen-sufficient and nitrogen-deficient conditions were collected.

Root exudates alone were unable to support growth of *Frankia* sp. strain CcI3. In growth medium with root exudates in the absence of additional carbon sources, no growth yields were observed. In the presence of a carbon source, growth yield increased in response to root exudates and was more affected by dry weight changes than protein content. These results suggest that root exudates influence *Frankia* physiology by affecting other cellular components.

35.3.2 Root Exudates Caused Changes in *Frankia* Surface Properties and Hyphal Curling

The morphological effects of root exudates on *Frankia* physiology were examined. *Frankia* cultures exposed to root exudates showed a hyphal curling response (Fig. 35.2). The tips of the hyphae were curled or bent in response to the root exudates. Those cultures exposed to Hoagland's medium (control) did not exhibit this response.

The curling response was observed with root exudates from plants grown under both nitrogen-sufficient and nitrogen-deficient conditions. The age of the plants that root exudates were collected did not affect the curling response. The curling response was specific to the host plant root exudates, and *Frankia* sp. strain CcI3 cultures exposure to nonhost plant root exudates failed to respond.

Other surface properties were investigated. Congo red dye absorption was reduced for cultures exposed to host plant root exudates. Congo red dye binding has been aligned with changes in lipids and lipoproteins for mycobacteria (Cangelosi et al., 1999). These changes were confirmed by FTIR analysis. Exposure of *Frankia* cultures to plant host root exudates caused several changes in the spectral patterns that are indicative of alterations in fatty acids, fatty acids and proteins, and cell wall carbohydrates. In addition, the cells exposed to root exudates were more difficult to pellet than the control cells. Altogether, this observation and the Congo red and FTIR results indicate that the surface property changes occurred in response to the plant host nutrients and/or signaling molecules.

35.3.3 Root Exudates Exposure Caused Changes in Plant Infectivity

The effects of host plant root exudates on the *Frankia* surface property changes suggest major modifications in the bacterial exterior that could influence plant–microbe interaction.

Frankia cultures were pre-exposed to host plant exudates and tested for plant infectivity. Figure 35.3 shows the results of those experiments. Cultures pre-exposed to the root exudates produced root nodules 15 days after inoculation, while those untreated control cells initiated nodulation after 19.6 days.

35.3.4 Effects of Actinorhizal Root Exudates on Other *Frankia* Strains

Frankia sp. strain CcI3 is a narrow-host-range symbiont. We were interested in extending our study to other members of the *Frankia* including broad-host-range symbionts. The effects of several different root exudates were tested on

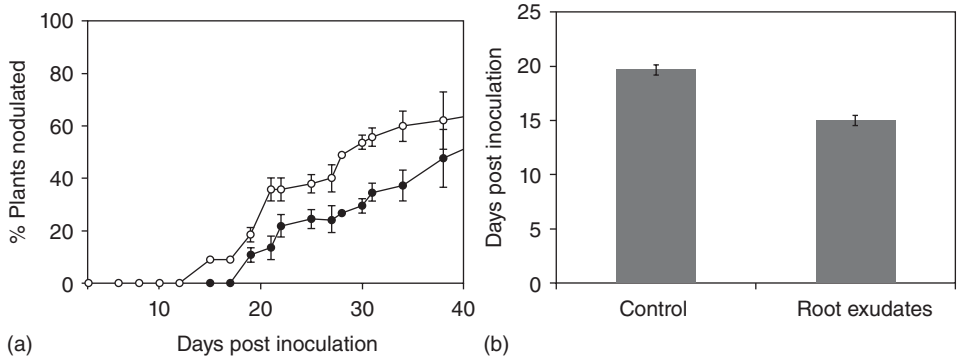

Figure 35.3 The effect of host root exudates pretreatment on plant nodulation frequency. Panel a shows a time course of plant nodulation. Prior to plant inoculation, *Frankia* CcI3 was pre-treated with *C. cunninghamiana* root exudates from nitrogen-deficient conditions (open circles) or 1/4 HS (N_2) medium (closed circles) for 6 days. The percentage of plants with nodules was determined as described in the "Methods" section. Data presented are the average percentage for three independent experiments. The average number of plants per condition in the three experiments was $n = 10$. Panel b shows the average number of days required to observe the first appearance of nodules on a plant in each treatment ($n = 3$). *Frankia* CcI3 was pretreated with *C. cunninghamiana* root exudates from nitrogen-deficient conditions or 1/4 HS (N_2) medium (Control) for 6 days. ANOVA analysis showed this to be a significant difference (p-value < 0.05). (From Beauchemin et al., 2012 with permission.)

Table 35.1 The effect of different plant root exudates on *Frankia* hyphal curling

Plant Root Exudates	*Frankia* sp. Strain CcI3	*Frankia* sp. Strain CN3	*Frankia* sp. Strain EUN1f	*Frankia alni* Strain ACN14a
Casuarina	+	–	–	–
Elaeagnus	–	–	+	+
Hippophae	–	–	+	–
Myrica	N.D.	–	–	+/–
Alnus	–	–	–	+
Betula	–	–	–	–
Hoagland Control	–	–	–	–

Symbols represent: +, hyphal curling; –, no curling, and +/–, an intermediate result.

Table 35.2 The effect of root exudates on the nodulation of actinorhizal plants

	Alnus Nodulation	
	1-Month Nodules per Plant	2-Month Nodules per Plant
ACN14a	4.0	7.6
ACN14a + *Alnus* root exudates	3.3	9.0
QA3	1.0	1.0
QA3 + *Alnus* root exudates	3.6	10.6
	Hippophae nodulation	
	1month	
EAN1pec	6.0	
EAN1pec + *Hippophae* root exudates	27.0	

The number of nodules per plant was counted after 1 month and 2 months.

Frankia strains for the hyphal curling response. Preliminary results are shown in Table 35.1. *Frankia* sp. strain CcI3 only responded to root exudates from *Casuarina. Frankia* sp. strain EUN1f responded toward root exudates from *Elaeagnus* and *Hippophae*, both host plant of this strain. *Frankia alni* strain ACN14a responded top *Alnus*, *Eleaegnus*, and *Myrica* root exudates, while the atypical *Frankia* sp. strain CN3 did not respond to any of the plant root exudates. The atypical *Frankia* strains are unable to reinfect their host plants and considered noninfective (Nod^-) and nonnitrogen-fixing (Fix^-) strains. These preliminary results indicate that the different host plants excrete a specific signal only perceived by their symbionts.

The effect of root exudates on plant infectivity was tested, and the preliminary results are presented in Table 35.2. The addition of *Alnus* root exudates increased the nodulation of *A. glutinosa* for both *Frankia* sp. strain QA3 and *Frankia alni* strain ACN14a. With the *Frankia* sp. strain EAN1pec, *Hippophae* root exudates increased the nodule formation of *H. rhamnoides.*

ACKNOWLEDGMENTS

This study was funded, in part, by USDA NIFA grant 2010-65108-20581, the New Hampshire Agricultural Experimental Station (NH585), and the Agence Nationale de la Recherche (grant ANR-08-JCJC-00700). FG-G was supported, in part, by a Postdoctoral Fellowship Program administered by the NH Agricultural Experimental Station at the University of New Hampshire.

Chapter 36

Exopolysaccharide Production in Rhizobia Is Regulated by Environmental Factors

Monika Janczarek
Department of Genetics and Microbiology, University of Marie Curie-Skłodowska, Lublin, Poland

INTRODUCTION

Rhizobia comprise a very diverse group of soil bacteria that induce the formation of new specialized organs on roots and stems of leguminous plants, called nodules, inside of which atmospheric nitrogen is reduced to ammonia. The establishment of symbiosis is a complex process involving exchange of many signals between the symbiotic partners, with plant flavonoids and rhizobial lipochitin oligosaccharides being the most important molecules (Downie, 2010; see Chapters 50, 51). In addition, acidic extracellular polysaccharides (EPS) play a significant role in the early stages of symbiotic interactions, especially when the host plants form indeterminate-type nodules (e.g., *Medicago*, *Vicia*, and *Trifolium* spp.) (Janczarek, 2011). The ability to produce EPS is a widespread feature among rhizobia. This polysaccharide is weakly associated with the bacterial surface and released in large amounts into the environment. Several different functions are ascribed to EPS, for example, protection against stress factors and antimicrobial compounds, nutrient gathering, and attachment to both abiotic surfaces and plant roots (Downie, 2010). Moreover, this polymer is essential for biofilm formation, constituting the major component of its matrix. EPS-deficient mutants of *Sinorhizobium meliloti* and *Rhizobium leguminosarum* elicit formation of nonnitrogen-fixing nodules on their host plants (Borthakur et al., 1988; Glucksmann et al., 1993a, b; Rolfe et al., 1996; van Workum et al., 1997; Cheng and Walker, 1998; Janczarek et al., 1999). Although EPS is essential for a great majority of rhizobia that establish symbioses with leguminous plants forming indeterminate-type nodules, there are known examples of symbioses demonstrating some differences. *Sinorhizobium fredii* HH103 does not require EPS and KPS for the establishment of effective symbiosis with *Glycyrrhiza uralensis*, the host plant forming indeterminate-type nodules (Margaret-Oliver et al., 2012). On the other hand, alterations in EPS can affect the symbiosis of *Bradyrhizobium japonicum* USDA 110 with soybean, which forms determinate-type nodules (Quelas et al., 2010).

The synthesis of rhizobial EPS is a complex process regulated at both transcriptional and posttranscriptional levels and influenced by several nutritional and stress factors.

This review describes the genetic control of EPS synthesis in rhizobia and regulation of this process by various environmental signals.

36.1 CHEMICAL STRUCTURES OF RHIZOBIAL EXOPOLYSACCHARIDES

EPS produced by rhizobia are species- or even strain-specific heteropolymers consisting of repeating units that contain common monosaccharides: D-glucose, D-mannose, D-galactose, L-rhamnose, D-galacturonic and D-glucuronic acids, and noncarbohydrate residues such as acetyl, pyruvyl, and succinyl groups. The uronic acids and negatively charged pyruvyl groups contribute to the acidic character

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

of this polysaccharide. Rhizobial EPS demonstrate high diversity in terms of the sugar composition, unit size, type of glycosidic linkages, and noncarbohydrate modifications. EPS are usually synthesized in two forms of different molecular masses, that is, high-molecular-weight (HMW) polymers of 10^6–10^7 Da and low-molecular-weight (LMW) forms consisting of monomers, dimers, and trimers of the repeating unit (González et al., 1998). The LMW EPS was found to be an active biological fraction required for successful infection of leguminous plants.

Fast-growing rhizobia (*Sinorhizobium* and *Rhizobium* species) produce EPS of lower diversity than those synthesized by slow-growing bacteria. A great majority of EPS of fast-growing rhizobia are composed of octasaccharide units, in which glucose is a dominant sugar component (Fig. 36.1). *S. meliloti* synthesizes two structurally distinct EPS: succinoglycan (EPS I) and galactoglucan (EPS II) produced under phosphate limitation (Her et al., 1990; Zhan et al., 1991; Reinhold et al., 1994). The repeating units of EPS I are composed of seven D-glucoses and one D-galactose joined by β-1,3, β-1,4, and β-1,6 glycosidic linkages, and substituted with acetyl, succinyl, and pyruvyl groups (Fig. 36.1a) (Reuber and Walker, 1993a,1993b; Reinhold et al., 1994; Zevenhuizen, 1997). In contrast, EPS II consists of disaccharide units that contain D-galactose and D-glucose joined by α-1,3 and β-1,3 linkages. All the galactosyl residues are substituted with 4,6-*O*-pyruvyl groups and most glucosyl residues are 6-*O*-acetylated (Fig. 36.1b) (Her et al., 1990; Reuber and Walker, 1993a,1993b; Zevenhuizen, 1997).

S. fredii NGR234 synthesizes EPS whose units contain D-glucose, D-galactose, and D-glucuronic acid in a molar ratio 4 : 2 : 2, modified with *O*-acetyl and pyruvyl groups (Fig. 36.1c) (Djordjevic et al., 1986).

The majority of strains belonging to three biovars of *R. leguminosarum* (*viciae, trifolii*, and *phaseoli*) secrete EPS containing identical octasaccharide units composed of D-glucose, D-glucuronic acid, and D-galactose residues in a molar ratio 5 : 2 : 1 (Fig. 36.1d) (Robertsen et al., 1981; McNeil et al., 1986; O'Neill et al., 1991; Philip-Hollingsworth et al., 1989; Orgambide et al., 1992; Lopez-Lara et al., 1993; Breedveld et al., 1993a, b). The backbone of the units contains two glucose and two glucuronic acid residues joined by α-1,4 and β-1,4 glycosidic linkages. However, several *R. leguminosarum* strains produce EPS whose units vary in the length of the side chain, patterns of noncarbohydrate modifications, and the type of linkages (McNeil et al., 1986; Canter Cremers et al., 1991). For example, the units of *R. leguminosarum* bv. *viciae* 248 EPS have an extra glucuronic acid residue in the side chain, whereas the subunits of the *R. leguminosarum* bv. *trifolii* 4S EPS do not contain terminal galactoses (Amemura et al., 1983; Canter Cremers et al., 1991). For more details, see (Ivashina and Ksenzenko, 2012). The units of *R. leguminosarum* EPS are usually substituted by two pyruvyl, one or two nonstoichiometric *O*-acetyl, and one nonstoichiometric 3-hydroxybutanoyl groups. However, the distribution pattern of *O*-acetyl and hydroxybutanoyl modifications is dependent on the culture medium and bacterial growth phase and may vary for some *R. leguminosarum* strains (McNeil et al., 1986; Canter Cremers et al., 1991).

Rhizobium tropici also produces EPS composed of octasaccharide units, which contain D-glucose and D-galactose residues in a molar ratio 6 : 2, substituted with *O*-acetyl and pyruvyl groups (Fig. 36.1e) (Gil-Serrano et al., 1990).

EPS produced by slow-growing bradyrhizobia show even higher diversity in comparison to those synthesized by fast-growing rhizobia, which mainly involves the sugar composition and size of the units. In addition, unit modification by *O*-methyl groups seems to be unique to this group of rhizobia. EPS of *Bradyrhizobium japonicum* USDA 110 displays the highest structural diversity, since it is composed of pentasaccharide units containing four different sugars: D-glucose, D-mannose, D-galacturonic acid, and D-galactose (a molar ratio 2 : 1 : 1 : 1) substituted with *O*-methyl and *O*-acetyl groups (Fig. 36.1f) (Minamisawa, 1989; Poveda et al., 1997). Moreover, the structure of NPS, the polysaccharide produced by *B. japonicum* cells inside root nodules, significantly differs from that of EPS synthesized by free-living bacteria (Fig. 36.1g) (An et al., 1995; Streeter et al., 1992). In contrast, *B. elkani* produces EPS composed of tetrasaccharide units that contain only two sugars, L-rhamnose and D-glucuronic acid, in a molar ratio 3 : 1 (Fig. 36.1h) (An et al., 1995). In addition, both EPS and NPS produced by *B. elkani* have an identical structure.

An interesting example of an exopolysaccharide whose structure essentially differs from that of all the above-described EPS is a polymer secreted by *Azorhizobium caulinodans* – the microsymbiont of *Sesbania rostrata*. It is a linear homopolysaccharide consisting of 4,6-*O*-pyruvyl-D-galactosyl residues linked with α-1,3 bonds (D'Haeze et al., 2004).

36.2 GENETIC CONTROL OF EPS SYNTHESIS

The biosynthesis of heteropolysaccharides in rhizobia is a multistep process, requiring the activity of many different enzymes involved in the synthesis of nucleotide sugar precursors and noncarbohydrate donors, assembly, and modification of repeating units, as well as polymerization and transport of EPS outside bacteria (Glucksmann et al., 1993a,1993b; Whitfield, 1995). EPS synthesis is carried out by a multienzymatic complex located in both bacterial inner (IM) and outer (OM) membranes. Polyprenyl lipid

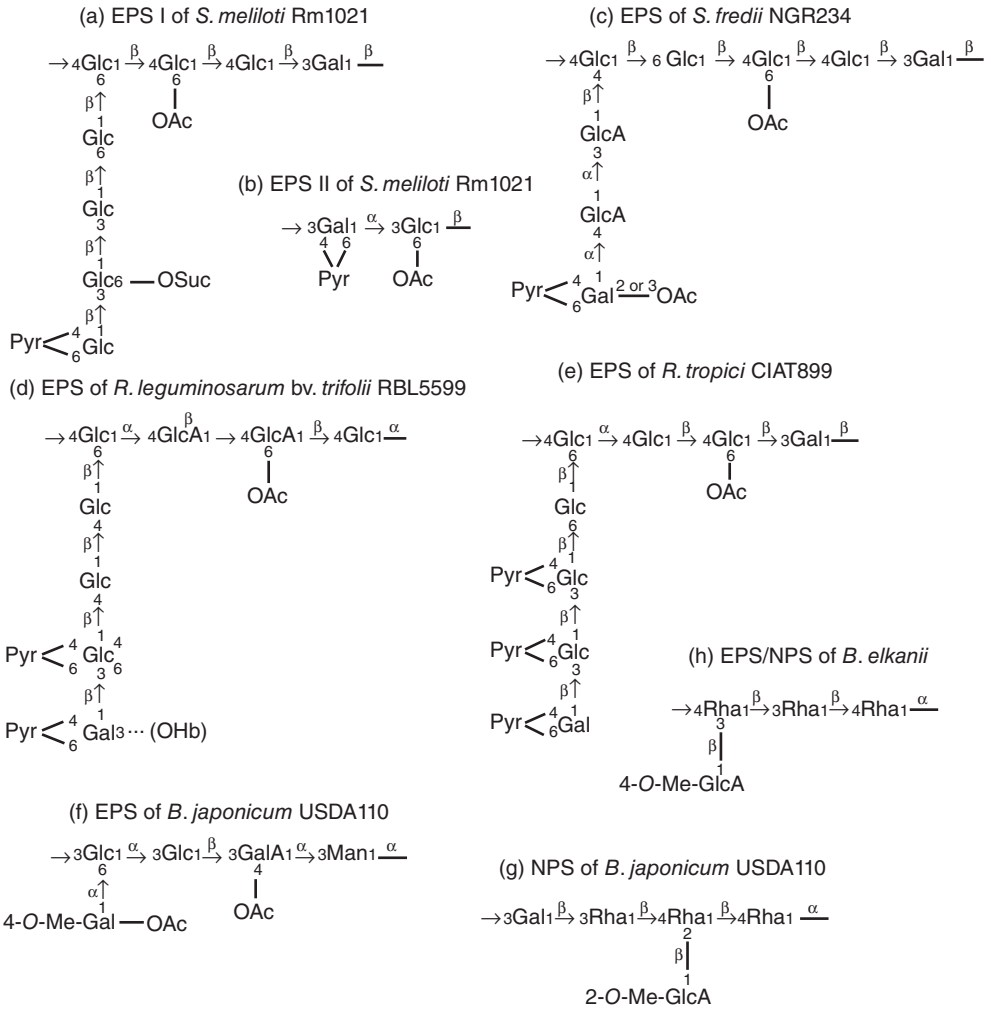

Figure 36.1 The chemical structures of EPS repeating units from different rhizobial species: (a) *S. meliloti* EPS I (Reinhold et al., 1994; Zevenhuizen, 1997; Reuber and Walker, 1993a,1993b); (b) *S. meliloti* EPS II (Zhan et al., 1991; Zevenhuizen, 1997; Her et al., 1990); (c) *S. fredii* NGR234 (Djordjevic et al., 1986); (d) *R. leguminosarum* bv. *trifolii* (Robertsen et al., 1981; O'Neill et al., 1991; Breedveld et al., 1993a); (e) *R. tropici* (Gil-Serrano et al., 1990); (f) *B. japonicum* (Minamisawa, 1989; Poveda et al., 1997); (g) NPS of *B. japonicum* (Streeter et al., 1992; An et al., 1995); (h) *B. elkanii* (An et al., 1995). Abbreviations: Glc, glucose; Gal, galactose; Man, mannose; Rha, rhamnose; GlcA, glucuronic acid; GalA, galacturonic acid; OAc, *O*-acetyl; Pyr, ketal pyruvate; Suc, succinyl; Me, methyl groups.

carriers anchored in the inner leaflet of the IM are acceptors to which nucleotide diphosphosugar precursors are sequentially bonded by specific glycosyltransferases. Then, assembled units are flipped across the IM to the periplasmic space by the Wzx-like translocase (Whitfield and Paiment, 2003; Liu et al., 1996). Polymerization of the units is most probably coupled with secretion of EPS outside bacteria. In this process, both the Wzy-like polymerase and the Wzc-like IM-periplasmic auxiliary protein are engaged (Paulsen et al., 1997; Whitfield and Paiment, 2003).

Genes involved in the synthesis of rhizobial EPS are usually grouped in large clusters located on chromosomes or megaplasmids (Fig. 36.2) (Kaneko et al., 2000; Finan et al., 2001; Kaneko et al., 2002; Young et al., 2006; González et al., 2006; Król et al., 2007; Reeve et al., 2010a, b). Such organization probably reflects coordinated and tightly regulated expression of EPS synthesis genes.

36.2.1 Genes Involved in the Synthesis of Succinoglycan and Galactoglucan in *S. meliloti*

So far, EPS synthesis and regulation of this process in rhizobia have been most extensively studied in *S. meliloti*. In this species, genes involved in succinoglycan synthesis are located on the pSymB megaplasmid in a large cluster

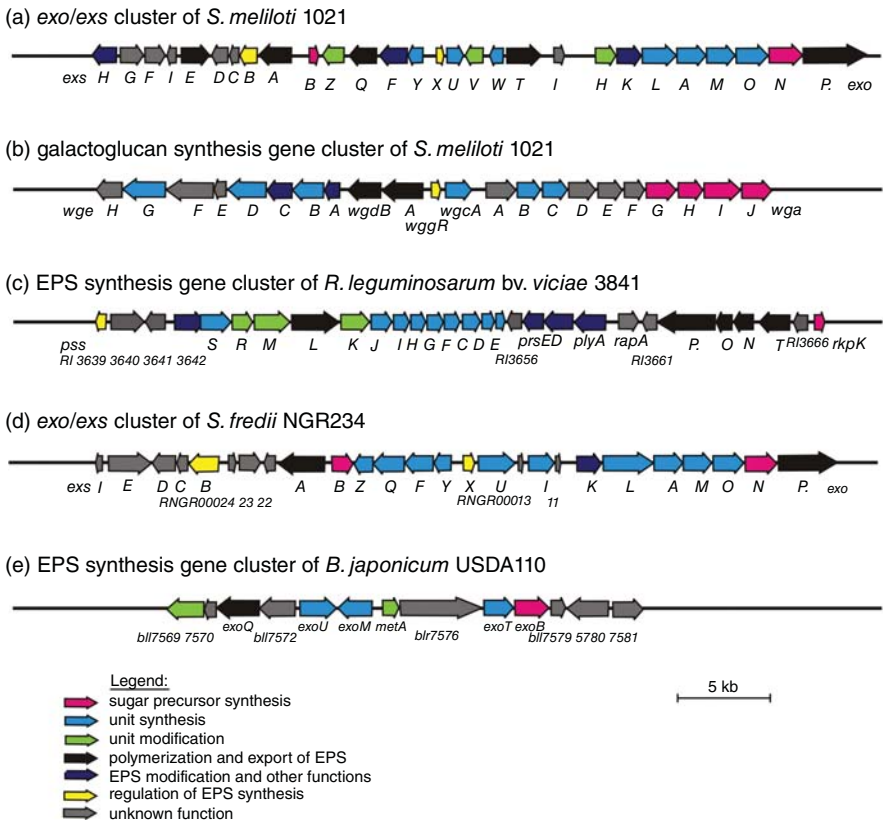

Figure 36.2 Genetic organization of the clusters involved in exopolysaccharide synthesis in several rhizobial species: (a) the *exo/exs* cluster of *S. meliloti* (Finan et al., 2001); (b) the galactoglucan synthesis gene cluster of *S. meliloti* (Finan et al., 2001); (c) *R. leguminosarum* bv. *viciae* 3841 cluster (Young et al., 2006); (d) *S. fredii* NGR234 cluster (Acc. no. AY316746); (e) *B. japonicum* USDA 110 cluster (Kaneko et al., 2002) (the figure is the modified figure from the reference (Janczarek, 2011)).

(~35 kb) containing 28 *exo/exs* genes (Fig. 36.2a) (Reuber and Walker, 1993b; Finan et al., 2001; Glucksmann et al., 1993a,1993b; Becker et al., 1993a,1993b,1993c). This cluster contains genes encoding enzymes responsible for the synthesis of nucleotide sugar precursors (*exoN* and *exoB*), unit assembly (*exoY*, *exoF*, *exoA*, *exoL*, *exoM*, *exoO*, *exoU*, and *exoW*) and modification (*exoH*, *exoV*, and *exoZ*), and polymerization and transport of EPS (*exoP*, *exoQ*, *exoT*, and *exsA*) (Glucksmann et al., 1993a,1993b; Becker et al., 1993a,1993b,1993c; Müller et al., 1993; Becker et al., 1995a,1995b). In addition, genes involved in regulation of EPS I (*exoR*, *exoS*, *exoD*, and *mucR*) and sugar precursor synthesis (*exoC*) are dispersed throughout the chromosome (Doherty et al., 1988; Uttaro et al., 1990; Reed et al., 1991b; Reed and Walker, 1991; Keller et al., 1995).

The assembly of octasaccharide units of EPS I is initiated by the addition of UDP-galactose to the lipid carrier located in the IM. In this step, two galactosyl-IP-transferase ExoY and auxiliary ExoF proteins are involved (Müller et al., 1993). The subsequent steps of unit assembly are carried out by glucosyltransferases encoded by *exoALMOUW* genes (Reuber and Walker, 1993a,1993b; Glucksmann et al., 1993b; Becker et al., 1993b,1993c). However, the enzyme responsible for the addition of the last sugar residue to the units has not yet been identified. *S. meliloti* strains carrying mutations in the *exoY*, *exoA*, *exoL*, and *exoM* genes do not produce EPS I and form nodules inefficient in nitrogen fixation (Glucksmann et al., 1993b; Müller et al., 1993; Becker et al., 1993b; Cheng and Walker, 1998).

Three enzymes are responsible for nonsugar modifications of EPS I: ExoV is required for the addition of pyruvyl; ExoZ modifies with acetyl; and ExoH provides succinyl groups to the units (Fig. 36.2a). The presence of succinyl groups in the EPS I is indispensable for the formation of the LMW fraction of this polysaccharide. The importance of this modification is confirmed by the phenotype of the *exoH* mutant, which produces exclusively HMW EPS I lacking succinyl groups and elicits ineffective nodules on alfalfa (Cheng and Walker, 1998). The *S. meliloti* strain carrying a mutation in *exoV* synthesizes only monomer units, indicating that this modification of the units is crucial for polymerization of succinoglycan (Reuber and Walker, 1993b; Becker et al., 1993c; York and Walker, 1998). In contrast, the *exoZ* mutant exhibits only a slightly diminished efficiency in infection thread formation and induces nitrogen-fixing nodules on its host plant (Reuber and Walker, 1993a; Buendia et al., 1991). Moreover, the presence of succinyl and acetyl substituents in EPS I affects the susceptibility of this polymer to cleavage by two glycanases (β-1,3-1,4-glucanase ExoK and succinoglycan depolymerase ExsH) (York and Walker, 1998).

Polymerization and secretion of EPS I are carried out by ExoP, ExoQ, and ExoT proteins (Fig. 36.2a) (Glucksmann et al., 1993a; Becker et al., 1993b). ExoP is an autophosphorylated tyrosine kinase. The N-terminal domain of this protein located mainly in the periplasmic space is crucial for EPS I polymerization, whereas the C-terminal domain, displaying ATPase activity, has a regulatory function (Becker et al., 1995b; Jofre and Becker, 2009). In addition, ExoQ is responsible for the production of HMW EPS I, whereas ExoT is indispensable for the synthesis of its LMW forms (trimers and tetramers). Also, the ExsA protein was found to be required for the export of HMW EPS I (Becker et al., 1995a).

The biosynthesis of EPS II is directed by genes grouped in a 27-kb cluster on the pSymB plasmid (Fig. 36.2b) (Becker et al., 1997; Moreira et al., 2000). In this cluster, 22 genes organized in five *wga*, *wgc*, *wggR*, *wgd*, and *wge* operons have been identified. The *wgaG*, *wgaH*, *wgaI*, and *wgaJ* genes are involved in the synthesis of deoxythymidine diphosphosugar precursors (dTDP-glucose and dTDP-rhamnose). The WgaB and WgeB proteins are putative β-glucosyltransferases, whereas the WgaC, WgcA, WgeD, and WgeG proteins are galactosyltransferases. Other genes of this cluster code for proteins potentially engaged in polymerization (*wgdA* and *wgdB*) and regulation of EPS II synthesis (*wggR*) (Becker et al., 1998; Moreira et al., 2000; Bahlawane et al., 2008).

36.2.2 Genes Involved in the Synthesis of EPS in *R. leguminosarum*

In the case of *R. leguminosarum*, the data concerning EPS synthesis are much more fragmentary. So far, precise functions in this process have been experimentally established only for a few proteins. The functions of other gene products have been predicted based on their sequence similarities to proteins deposited in databases. A majority of genes involved in the synthesis of EPS are grouped in a 35-kb chromosomal cluster, called Pss-I (Fig. 36.2c) (Young et al., 2006; Król et al., 2007). This region is highly conserved among all the hitherto sequenced genomes of *R. leguminosarum* and *R. etli* strains (González et al., 2006; Reeve et al., 2010a,2010b). Only some slight differences in nucleotide sequences and gene contents have been noticed between these strains (Ivashina and Ksenzenko, 2012). The Pss-I cluster encompasses genes required for the unit synthesis (*pssEDCFGHIJS*) and modification (*pssKMR*), polymerization, and export of EPS (*pssLTNOP*), as well as EPS processing (*pssW, plyA*, and *prsDE*). *exo5* (*rkpK*) is also located in the Pss-I cluster and together with the *exoB* gene, which is not linked to this region, is involved in the synthesis of nucleotide sugar precursors (UDP-glucuronic acid and UDP-galactose, respectively). The *exo5* gene encodes UDP-glucose dehydrogenase, which converts UDP-glucose to UDP-glucuronic acid. The mutant in this gene does not produce either extracellular or capsular polysaccharides and synthesizes lipopolysaccharide lacking galacturonic acid (Laus et al., 2004; Muszyński et al., 2011). UDP-galactose synthesized by ExoB (a UDP-glucose 4-epimerase) is a sugar precursor for the production of EPS and other galactose-containing polysaccharides (Canter Cremers et al., 1990). The *exoB* mutant produces EPS that does not contain terminal galactoses in its units, and this structural alteration strongly affects the ability of these bacteria to invade host plant roots (Sánchez-Andújar et al., 1997).

The assembly of EPS units is initiated by the PssA protein, which transfers glucose-1-phosphate from UDP-glucose to the lipid carrier. *pssA* encoding this enzyme is located on the chromosome at a long distance from the Pss-I cluster and is transcribed as a monocistronic mRNA (Borthakur et al., 1988; Ivashina et al., 1994; Janczarek et al., 1999). This gene is highly conserved in *R. leguminosarum* strains and the closely relatives *R. etli* and *R. gallicum* (Janczarek and Skorupska, 2003; Janczarek et al., 2009b). *pssA* mutants of *R. leguminosarum* do not produce EPS and induce nonnitrogen-fixing nodules on their host plants (clover, pea, and vetch) (Ivashina et al., 1994; Rolfe et al., 1996; van Workum et al., 1997; Janczarek et al., 1999).

The subsequent steps of the unit assembly are carried out by enzymes encoded by genes located in the Pss-I cluster (Fig. 36.2c). Among them, *pssD* and *pssE* genes encode glucuronosyl-β-1,4-glucosyltransferase, which catalyses the addition of the second sugar to glucose attached to the lipid carrier (Pollock et al., 1998). The *pssD* mutant displays a very similar phenotype to the *pssA* mutant; it does not produce EPS and elicits ineffective nodules on host roots. The third step of the unit synthesis is conducted by glucuronosyl-β-1,4-glucuronosyltransferase PssC (van Workum et al., 1997; Pollock et al., 1998). A mutation in *pssC* results in a twofold decrease in EPS synthesis and failed nodulation of vetch (Sadykov et al., 1998).

The *exo-344* (*pssJ*) gene encoding galactosyltransferase is most probably involved in the last step of the unit assembly. Breedveld et al. (1993a) described an *exo-344*::Tn*5* mutant of *R. leguminosarum*, which produced only heptasaccharide units lacking the terminal galactose.

Up to now, enzymes responsible for the remaining steps of the unit synthesis have not been characterized experimentally, although some Pss proteins encoded by the Pss-I cluster are most probably engaged in this process (Fig. 36.2c) (Sadykov et al., 1998; Król et al., 2007). Recently, Ivashina and Ksenzenko (2012) have proposed a model of the synthesis of the EPS units in *R. leguminosarum* based on sequence similarities of these proteins to enzymes available in databases and phenotypes of a few *pss* mutants. They postulate that the subsequent steps of the unit assembly are carried out by the PssS, PssF, PssI/PssG, and PssH/PssI

glycosyltransferases, respectively. Mutations introduced into the *pssFGHI* genes of *R. leguminosarum* bv. *viciae* VF39 only result in a decrease in EPS production, but they do not affect the structure of the synthesized polymer. Other genes of the Pss-I cluster, *pssR* encoding acetyltransfease, *pssM* encoding ketal pyruvate transferase, and *pssK* encoding for pyruvyltransferase, are involved in nonsugar modifications of the units. A mutation in *pssR* causes a significant reduction of acetyl groups in EPS, but this alteration in its composition has no effect on nodule development and nitrogen fixation (Ivashina and Ksenzenko, 2012). Moreover, two enzymes are responsible for unit pyruvylation; PssM is needed for the addition of the pyruvyl group to the subterminal glucose, whereas PssK is indispensable for pyruvylation of the terminal galactose. Bacteria carrying *pssM* mutation exhibit impaired differentiation into bacteroids and elicit nonnitrogen-fixing nodules on peas (Ivashina et al., 2010). A mutation in *pssK* exerts a stronger negative effect, since bacteria having a Tn*5* insertion in this gene do not produce EPS and are defective in nitrogen fixation (Ivashina and Ksenzenko, 2012). The above data indicate that this type of unit modification is essential for EPS polymerization in *R. leguminosarum*, as in the case of *S. meliloti* EPS I (Becker et al., 1993c; Glucksmann et al., 1993a).

Polymerization and export of EPS are carried out by a Wzx/Wzy-type secretion system consisting of proteins encoded by *pssL* and *pssTNOP* genes (Fig. 36.2c). The PssL protein displays significant similarity to Wzx-type flippases, which participate in the O-antigen translocation from the inner to the outer leaflet of the IM, whereas PssT is an integral IM protein showing similarity to Wzy-like proteins (Mazur et al., 2003; 2005). The PssP protein displays homology to *S. meliloti* ExoP and other membrane-periplasmic auxiliary proteins involved in polysaccharide synthesis (Mazur et al., 2002). A deletion of *pssP* abolishes EPS synthesis in *R. leguminosarum*, whereas a mutation in *pssT* results in overproduction of this polymer. PssN is a lipoprotein associated with the OM, which interacts with both the PssP copolymerase and the PssO protein located in the OM (Marczak et al., 2006; 2012). A *pssO* mutation abolishes EPS synthesis and negatively affects nitrogen fixation (Marczak et al., 2008).

The Pss-I cluster also contains genes involved in EPS processing (Fig. 36.2c). These include *prsDE* genes encoding components of the type I secretion system and *plyA* encoding glycosyl hydrolase (Finnie et al., 1997; 1998; Krehenbrink and Downie, 2008). The PlyA together with PlyB glycanase have the ability to cleave EPS and affect its processing (Zorreguieta et al., 2000). A *prsD* mutant synthesizes EPS of a higher degree of polymerization than the wild-type strain and induces formation of ineffective nodules on its host plant (Finnie et al., 1997).

36.2.3 Genes Involved in EPS Synthesis in Other Rhizobial Species

A region containing *exo* genes organized in several operons has been identified in the pNGR234b plasmid of *S. fredii* NGR234 (Fig. 36.2d) (Gray et al., 1990; Zhan et al., 1990). Large fragments of the *S. fredii exo* cluster are closely related or even identical to the *S. meliloti exo* region (these concern the *exoABYLMNPX* genes). The presence of these *exo* homologs in both the *S. fredii* NGR234 and *S. meliloti* genomes can be explained by very similar structures of EPS produced by these bacterial species. However, some differences in these clusters have been found (Zhan et al., 1990; Staehelin et al., 2006). These concern *exoV*, *exoW*, *exoT*, and *exoH* genes, which are absent in the *exo* cluster of *S. fredii* NGR234 (e.g., *exoH* is not located in the pNGR234b plasmid but in the genome) (Schmeisser et al., 2009). In *S. meliloti*, ExoH is needed for the addition of succinyl groups to the units of EPS I, whereas EPS of *S. fredii* NGR234 is not succinylated.

Similarly, a region involved in EPS synthesis has been identified in the genome of *B. japonicum* USDA 110 (Fig. 36.2e) (Becker et al., 1998; Kaneko et al., 2002). This cluster contains several genes organized in a few operons, among them genes encoding homologs of *S. meliloti* ExoB, glycosyltransferases, and ExoP. A mutant with a deletion of the genomic fragment encoding the C-terminal domain of ExoP, the entire ExoT, and the N-terminal domain of ExoB, produces only the LMW form of EPS lacking galactose and nodulates the host plant with a delay, inducing symptoms of plant defense reactions (Becker et al., 1998).

The data concerning EPS synthesis in moderately growing *Mesorhizobium* are also scarce. Recently, a region involved in the synthesis of this heteropolymer has been identified in the genome of *M. tianshanense* (Wang et al., 2008). In this cluster, *mtpABCD* and *mtpE* genes were found, which display significant similarity to the *R. leguminosarum pssTNOP* and *exo5* genes, respectively. Mutants in both *mtpABCD* and *mtpE* operons do not produce EPS and are defective in nodulation of their host plant (*Glycyrrhiza uralensis*) (Wang et al., 2008).

36.3 REGULATION OF EPS SYNTHESIS IN RHIZOBIA

EPS synthesis in rhizobia, a complex process regulated at different molecular levels, has been the most extensively studied in *S. meliloti* to date. Several environmental factors and stress conditions influence EPS production, affecting the amount and/or composition of the synthesized polymer (Zevenhuizen, 1997; Breedveld et al., 1993b; Quelas et al., 2006; Bardin and Finan, 1998; Mendrygal and González, 2000; Janczarek and Skorupska, 2009; 2011).

36.3.1 Regulation of EPS Synthesis in *S. meliloti*

36.3.1.1 Regulation of EPS I Synthesis. Depending on the culture conditions, *S. meliloti* produces two distinct EPS: succinoglycan and galactoglucan. To date, several genes involved in the regulation of the synthesis of these polymers have been identified on both the chromosome (*exoR*, *exoS*, *exoD, mucR*, *expR*, *syrM*, and *phoB*) and on the pSymB megaplasmid (*exoX*, *exsB*, and *wggR*). A great majority of these genes encode repressors, whereas the two *syrM* and *phoB* genes code for positive regulators of EPS I and EPS II synthesis, respectively (Reed et al., 1991a,1991b; Becker et al., 1995a; Keller et al., 1995; Rüberg et al., 1999; Mendrygal and González, 2000). A protein encoded by *mucR* is the main regulator of these biosynthetic pathways, acting as a positive regulator of EPS I synthesis and a negative regulator of EPS II synthesis (Rüberg et al., 1999; Bertram-Drogatz et al., 1998).

In general, regulation of succinoglycan production is almost always negative (Fig. 36.3). Up to now, six genes have been found to affect this process negatively. These include the *exoR*, *exoS*, *cbrA*, and *emmC* genes located on the chromosome and the *exoX* and *exsB* genes located in the *exo/exs* cluster. Mutations in both *exoS* and *exoR* genes result in a higher level of expression of several *exo* genes and increased production of EPS I in comparison to the wild-type strain (Doherty et al., 1988; Reed et al., 1991b). ExoS is a sensor protein of a two-component ExoS/ChvI regulatory system responsible for the recognition of environmental signals (Osterås et al., 1995). This protein with kinase activity is located in the IM and its sensor domain is directed to the periplasmic space. ExoS activates ChvI by phosphorylation, and this protein subsequently affects the transcription of several *exo* genes (Fig. 36.3). ExoR is located in the periplasmic space, where it interacts with the sensor domain of the ExoS protein and inhibits the ExoS/ChvI system signaling (Cheng and Walker, 1998; Wells et al., 2007; Chen et al., 2008). The ExoR protein negatively regulates the transcription of its own gene. In this regulation, the ExoS/ChvI system is also engaged, which positively affects *exoR* expression (Chen et al., 2008; Lu and Cheng, 2010). Phenotypic analyses of *exoS* and *chvI* mutants have indicated that this regulatory system is additionally required for growth on different carbon sources (Bélanger et al., 2009; Wang et al., 2010). Moreover, the *chvI* mutant exhibits hypermotility, lower tolerance to acidic conditions, and a lower level of poly-3-hydroxybutyrate synthesis than the wild-type strain. These data indicate that the ExoR, ExoS, and ChvI proteins form a regulatory system involved in several cell processes, including EPS I synthesis, nutrient utilization, and motility.

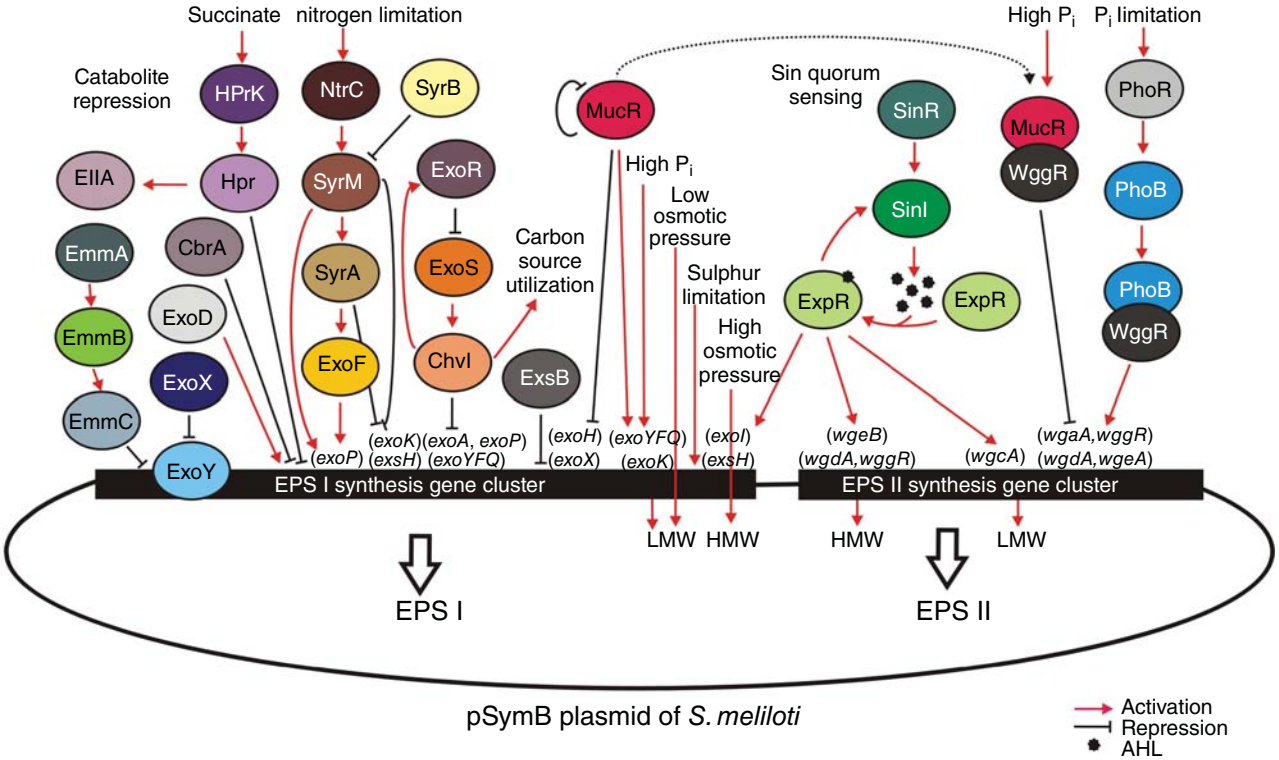

Figure 36.3 Regulation of EPS I and EPS II syntheses in *S. meliloti* (the figure is a modified version of the figure from the reference (Janczarek, 2011)).

exoX is another gene of the *exo/exs* cluster, which negatively regulates the synthesis of EPS I (Fig. 36.3). It has been found that the ratio of *exoX* to *exoY* copies is very important for the proper level of the synthesis of this polymer. ExoX is a small, inner membrane protein showing significant similarity to PsiA of *R. leguminosarum* bv. *phaseoli* and ExoX of *S. fredii* NGR234 (Borthakur et al., 1988; Gray et al., 1990). An *exoX* mutant overproduces EPS I, whereas a strain carrying multiple copies of this gene does not synthesize this polymer. It has been suggested that ExoX functions as a posttranscriptional inhibitor of the ExoY protein, since *exoX* does not affect the expression of *exo* genes (Müller et al., 1993; Reed et al., 1991a). The same localization of the ExoX and ExoY proteins makes their direct interaction possible.

Similarly, *exsB* is involved in negative regulation of succinoglycan synthesis (Fig. 36.3) (Becker et al., 1995a). A mutant in this gene produces threefold more EPS I than the wild-type strain, whereas a strain carrying additional *exsB* copies synthesizes decreased amounts of the polysaccharide. Since the transcription of *exo* genes in this mutant does not differ in relation to the wild type (with the exception of *exoK*), it has been proposed that ExsB acts mainly at the posttranscriptional level (Becker et al., 1993b; Becker et al., 1995a).

Recently, a novel EmmA/EmmB/EmmC system has been identified in *S. meliloti*, which plays an important role in regulation of several cell processes including EPS I production, motility, and stress adaptation (Morris and González, 2009). This three-component system shows some functional similarity to the ExoR/ExoS/ChvI system described earlier. EmmA is a periplasmic protein, whereas EmmB and EmmC are sensor and response proteins, respectively. Mutations in the *emm* genes result in increased production of succinoglycan, decreased motility, and stress tolerance, and as a consequence, ineffective symbiosis with alfalfa. However, *exo* genes regulated by this system have not been established.

Also, *cbrA* coding for a stationary phase-induced sensor kinase negatively affects succinoglycan synthesis (Gibson et al., 2007). A mutant in this gene overproduces EPS I and demonstrates several cell envelope and symbiotic defects.

Among the regulators, MucR seems to be a main protein involved in positive regulation of succinoglycan synthesis, since the *mucR* mutant produces only residual amounts of the LMW form of this polysaccharide (Keller et al., 1995). MucR containing a C_2H_2 type zinc-finger motif binds to a palindromic sequence, called the MucR-box, in the *mucR* upstream region and negatively regulates the transcription of its own gene. Moreover, this protein binds to promoter regions of some *exo* genes and modulates their expression. It has been established that the MucR protein functions as the activator of expression of *exoK* and *exoYFQ* genes and the repressor decreasing *exoH* and *exoX* transcription (Bertram-Drogatz et al., 1997; 1998).

Likewise, *exoD* seems to be involved in positive regulation of EPS I synthesis, although its precise role in this process has not been established. A mutant in this gene produces diminished amounts of EPS I and is sensitive to alkaline conditions (Reed and Walker, 1991).

The synthesis of *S. meliloti* exopolysaccharides is affected by several nutritional and stress conditions. Limitations of nitrogen and sulfur and high concentrations of phosphate stimulate production of EPS I (Fig. 36.3) (Doherty et al., 1988). On the other hand, phosphate starvation induces EPS II synthesis, indicating that this nutrient is an important signal determining which of these biosynthetic pathways will be activated (Zhan et al., 1991; Rüberg et al., 1999; Mendrygal and González, 2000). Moreover, osmotic conditions affect EPS synthesis in *S. meliloti*. A low osmotic pressure results in production of LMW EPS I, whereas an increased osmotic pressure stimulates the synthesis of the HMW form of this polymer (Breedveld et al., 1990).

Additionally, nitrogen significantly affects the synthesis of succinoglycan, and the NtrC and SyrM proteins act as positive regulators of this process. Mutations in both *ntrC* and *syrM* genes result in a decrease of EPS I production under nitrogen starvation. NtrC is at the top of this regulatory cascade and induces *syrM* expression due to a deficiency of this nutrient (Dusha et al., 1999). Subsequently, SyrM activates the transcription of *syrA* and *exoP*, but represses the *exoK* and *exsH* genes. Similarly, the SyrA protein decreases the transcription of *exoK* and *exsH* genes, whereas it increases *exoF* expression (Dusha et al., 1999; Barnett et al., 1998). SyrM displays significant similarity to NodD regulators responsible for activation of the expression of nodulation genes (Barnett and Long, 1990). It has been confirmed that this protein not only influences EPS I synthesis but is also involved in determination of the ratio of its LMW to HMW forms. In addition, the SyrB protein encoded by a gene located on the pSymA plasmid negatively regulates *syrM* expression (Fig. 36.3) (Barnett and Long, 1997).

Moreover, a phosphotransferase system (PTS; see Chapter 34) involved in succinate-mediated catabolite repression in *S. meliloti* negatively influences EPS I production (Pinedo et al., 2008; Pinedo and Gage, 2009). A chromosomal cluster located downstream of the *exoS* contains *hprK*, *EIIA*, and *hpr* genes encoding components of the PTS system. Succinate is a preferred carbon source playing a special role in the metabolism of this bacterium. In the presence of succinate, the HPrK protein activates HPr and the phosphorylated form of this protein subsequently activates EIIA, leading to catabolite repression of regulated genes. Probably, the expression of some *exo/exs* genes is affected by the PTS system, since mutants in both *EIIA* and *hprK* genes produce significantly more EPS I than the wild-type strain (Pinedo et al., 2008; Pinedo and Gage, 2009).

36.3.1.2 Regulation of EPS II synthesis. Phosphate is the most essential environmental factor in stimulation of EPS II production. In contrast to succinoglycan, which is synthesized in the presence of high concentrations of phosphate (>10 mM), low concentrations of this nutrient usually found in soil (<10 μM), induce production of galactoglucan (Zhan et al., 1991; Mendrygal and González, 2000). This polymer most probably plays a dominant role in natural soil conditions and its LMW form is crucial for both root colonization and biofilm formation (Rinaudi and González, 2009).

Phosphate regulates many genes of *S. meliloti*, including those involved in EPS II synthesis (Rüberg et al., 1999; Krol and Becker, 2004). A two-component regulatory system consisting of the sensor protein PhoR and the response regulator PhoB is engaged in this regulation (Fig. 36.3). Under P_i limitation, the PhoR kinase activates PhoB, which binds to PHO-boxes located in the promoters of phosphate-regulated genes and induces their transcription (Yuan et al., 2006). It has been confirmed that several galactoglucan synthesis genes (*wgaA*, *wggR*, *wgdA*, and *wgeA*) belong to the Pho regulon and their expression significantly increases under P_i starvation (Krol and Becker, 2004).

In addition, two other regulatory proteins, WggR (ExpG) and MucR, participate in the regulation of EPS II synthesis (Becker et al., 1997; Bahlawane et al., 2008). Depending on the phosphate concentration, the WggR protein functions as an activator or a repressor of the expression of galactoglucan synthesis genes. Under P_i starvation, this protein binds to palindromic sequences in the promoter regions of the *wggR*, *wgdA*, *wgeA*, and *wgaA* genes and activates their transcription (Rüberg et al., 1999; Bahlawane et al., 2008). Under the same conditions, a mutation in *wggR* causes a decrease in EPS II production. In contrast, WggR together with MucR represses the expression of galactoglucan synthesis genes in the presence of high phosphate.

The transcription of the *wga*, *wge*, and *wgd* operons is directed by two distal and proximal promoters (Bahlawane et al., 2008). Motifs recognized by the MucR, WggR, and PhoB proteins have been identified upstream of the distal promoters of these genes. Under P_i starvation, the activated PhoB protein in cooperation with WggR binds to the promoter regions of the *wga*, *wgd*, and *wge* genes and induces their transcription. In contrast, under high-phosphate conditions, the transcription of these genes is strongly repressed by MucR, which binds to MucR-boxes located close to the binding sites of PhoB and WggR and inhibits their activity (Baumgarth et al., 2005; Bahlawane et al., 2008). These data indicate that the cooperative action of the WggR, PhoB, and MucR proteins ensures fine-tuning of the expression of the galactoglucan synthesis genes, which enables adaptation of *S. meliloti* to changing environmental conditions.

36.3.1.3 The Influence of Quorum Sensing on the Synthesis of S. meliloti Exopolysaccharides. In *S. meliloti*, a quorum-sensing system Sin regulates the expression of many genes, among them those involved in the synthesis of EPS I and EPS II, motility, chemotaxis, and nitrogen fixation (see Chapter 37). This system consists of a LuxR-type transcriptional regulator SinR and an autoinducer synthase SinI responsible for the synthesis of long-chain *N*-acyl homoserine lactones (AHL), which are released outside cells and whose concentration serves as a signal of bacterial population density (Marketon et al., 2003). The regulation of a majority of these genes requires the presence of an additional LuxR-type regulator ExpR (Hoang et al., 2004). The expression of *sinI* is regulated by the SinR and ExpR proteins (Fig. 36.3). SinR activates *sinI* transcription and, subsequently, SinI synthesizes AHL. In addition, the ExpR protein activated by AHL positively affects the transcription of *sinI*.

The *S. meliloti* wild-type strain produces large amounts of galactoglucan, which is responsible for the mucoid phenotype of colonies. In contrast, both *sinI* and *expR* mutants are defective in EPS II production and form dry colonies on agar plates, confirming the importance of the Sin system and the ExpR protein in the synthesis of this polymer (Hoang et al., 2004; McIntosh et al., 2008). It has been shown that the transcription of galactoglucan synthesis genes (particularly *wgcA*, *wgdA*, *wgeB*, and *wggR*) is highly induced by ExpR in the presence of AHL (Marketon et al., 2003; Pellock et al., 2002). Moreover, the expression of the *wge*, *wga*, and *wgd* operons is required for the synthesis of HMW EPS II, whereas *wgcA* expression is critical for the synthesis of its LMW form. Recently, it has been confirmed that the ExpR protein activated by AHL directly binds to promoter regions of the *sinI*, *wgaA*, and *wgeA* genes (McIntosh et al., 2008). Activation of transcription of these genes by ExpR is dependent on another regulator WggR. This protein most probably functions as a mediator in regulation of the galactoglucan synthesis genes under different conditions, which coordinates the action of the ExpR, PhoB, and MucR regulators (Bahlawane et al., 2008). The WggR protein is indispensable for induction of expression of EPS II synthesis genes by both PhoB under P_i limitation and ExpR when the MucR regulator is present. However, WggR is not required for ExpR functioning in the absence of MucR. At a low population density, MucR inhibits EPS II synthesis until the ExpR/Sin system abolishes this effect (Mueller and González, 2011). A very close location of the binding sites for the WggR, ExpR, PhoB, and MucR regulators in the promoters of the galactoglucan synthesis genes enables competition for these target sites and interactions between these proteins. The complex regulation of expression of these genes allows modulating the synthesis of this polysaccharide in response to changing environmental conditions (Bahlawane et al., 2008; McIntosh et al., 2008).

Recently, it has been confirmed that the ExpR/Sin system also affects EPS I synthesis (Glenn et al., 2007). The ExpR protein positively regulates the expression of some *exo/exs* genes (*exoI* and *exsH*). Sequences resembling binding sites for ExpR have been identified in promoters of these genes (McIntosh et al., 2008; Gurich and González, 2009).

36.3.2 Regulation of EPS Synthesis in *R. leguminosarum*

In contrast to *S. meliloti*, data concerning regulation of EPS synthesis in *R. leguminosarum* are scarce. So far, only a few genes involved in this process have been identified; these include *rosR*, *exoR*, *expR*, and *pssB* genes located on the chromosome, and *psiA* and *psrA* genes located on the symbiotic megaplasmid (pSym) (Fig. 36.4) (Borthakur and Johnston, 1987; Reeve et al., 1997; Janczarek et al., 1999, Janczarek and Skorupska, 2007; Edwards et al., 2009).

Among these genes, *rosR* plays the most significant role in this process (Janczarek and Skorupska, 2007). This gene is located at a long distance from both the Pss-I cluster and *pssA* gene and constitutes an individual open-reading frame. *rosR* is a conserved gene present in strains belonging to all *R. leguminosarum* biovars (Janczarek et al., 2009b). It shares high similarity with *rosR* of *R. etli* (Bittinger et al., 1997), *rosR* of *R. gallicum* (Janczarek et al., 2009b), *rosAR* of *A. radiobacter* (Hussain and Johnston, 1997), and *mucR* of *S. meliloti* (Keller et al., 1995). A mutation in *rosR* of *R. leguminosarum* bv. *trifolii* causes several phenotypic defects, indicating an essential role of this gene in EPS synthesis and symbiosis. The lack of a functional *rosR* gene leads to a threefold decrease in EPS production, changes in membrane and extracellular protein profiles, and higher sensitivity to some osmolytes and surface-active detergents (Janczarek et al., 2010). In addition, the *rosR* mutant displays essentially decreased motility, colonization of host plant roots, and symbiotic defects. On the other hand, multiple *rosR* copies significantly enhance EPS production, competitiveness, and efficiency of *R. leguminosarum* bv. *trifolii* strains in symbiosis with clover (Janczarek et al., 2009a).

The expression of *rosR* is a complex process regulated by some environmental factors. A strong distal promoter and two additional regulatory elements (an upstream promoter sequence and a TGN extended −10 motif) are responsible for the high level of transcription of this gene (Janczarek and Skorupska, 2009). In addition, several other regulatory motifs were identified in the *rosR* upstream region, among them a RosR-box, a LysR motif, PHO-boxes, and motifs resembling the *E. coli* cAMP-CRP-binding site (Janczarek and Skorupska, 2007; 2011). RosR is a 15.7 kDa protein having a C_2H_2-type zinc-finger motif, which binds to a 22-bp palindromic sequence, called the RosR-box, in the *rosR* promoter region and represses the transcription of its own gene (Janczarek and Skorupska, 2007). Moreover, the carbon source, phosphate, and plant flavonoids affect *rosR* expression. The transcription of this gene increases in the presence of clover root exudates and NodD activator as well as PhoB activator (Janczarek and Skorupska, 2011). In addition, *rosR* expression is significantly decreased in the presence of glucose, indicating that this gene is regulated by catabolic repression (Janczarek and Skorupska, 2009). In *R. leguminosarum*, EPS production is also affected by the type of the carbon source, phosphate, and plant flavonoids, suggesting that the level of EPS synthesis in the presence of these environmental factors is a result of the RosR action (Janczarek and Skorupska, 2004; 2009). Positive regulation of EPS synthesis by the RosR protein is most probably an effect of simultaneous activation of *pssA* transcription (Janczarek and Skorupska, 2007) and inhibition of expression of the *pssB* and *exoR* genes involved in negative regulation of this process (Fig. 36.4) (Janczarek M., unpublished data). In addition, phosphate, ammonium, and clover root exudates slightly affect the expression of *pssB*, *pssP*, *pssO*, and *pssA* genes (Janczarek and Skorupska, 2004; Wielbo et al., 2004).

A genome-wide genetic screening performed in *R. etli* has indicated that RosR is essential in regulation of transcription of many diverse genes, including those required for the synthesis and modification of surface polysaccharides (*pssK*, *exoB*, *prsD*, and *plyA*) (Bittinger and Handelsman, 2000).

In *R. leguminosarum*, EPS synthesis is also regulated by *exoR*, which shows significant similarity to the *S. meliloti exoR* (Fig. 36.4). The ExoR protein most probably functions as a negative regulator of this process, since the *exoR* mutant of *R. leguminosarum* bv. *viciae* produces significantly more EPS than the wild-type strain under nitrogen starvation (Reeve et al., 1997).

pssB also seems to affect EPS production, although the precise role of this gene in this process has not been established. The *pssB* mutant of *R. leguminosarum* bv. *trifolii* produces slightly more EPS than the wild-type strain and elicits ineffective nodules on clover (Janczarek and Skorupska, 2001). This gene encodes a protein belonging to the family of inositol monophosphate phosphatases, which are responsible for conversion of inositol monophosphate to inositol. Catabolism of this compound is very important for competition and survival of rhizobial strains in soil.

Two other genes, *psiA* and *psrA*, have been found exclusively on the pSym plasmids of strains belonging to *R. leguminosarum* bv. *phaseoli*, indicating that this regulatory mechanism is specific only for this biovar (Borthakur and Johnston, 1987; Mimmack et al., 1994). A mutation in *psiA* does not affect EPS synthesis, but additional copies of this gene result in inhibition of EPS production and abolish nodulation of *Phaseolus* plants (Latchford et al., 1991). The negative effect of multiple *psiA* copies is overcome in the presence of extra copies of the *psrA* or *pssA* genes, indicating that a balanced number of copies of these genes is

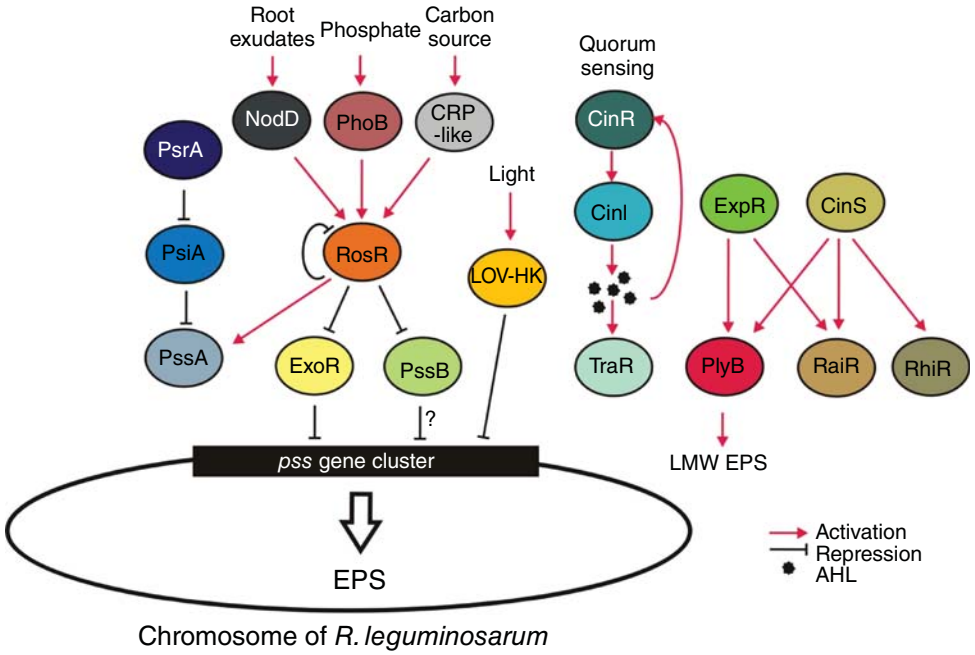

Figure 36.4 Regulation of EPS synthesis in *R. leguminosarum* (the figure is a modified version of the figure from the reference (Janczarek, 2011)).

required for a proper level of EPS synthesis. *psiA* codes for a small regulatory protein attached to the IM, which shows significant similarity to the *S. meliloti* ExoX. The same subcellular localization of PsiA as PssA suggests that this regulator most probably binds to this enzyme and inhibits its activity (Latchford et al., 1991). The transcription of *psiA* is repressed by the PsrA protein, which belongs to the family of transcriptional regulators containing a helix-turn-helix motif (Borthakur and Johnston, 1987; Mimmack et al., 1994). A *psrA* mutant produces less EPS than the wild type, whereas a strain carrying additional copies of this gene elicits nonnitrogen-fixing nodules on bean.

***36.3.2.1 Role of Quorum Sensing in the Synthesis of EPS in* R. leguminosarum.** In *R. leguminosarum* bv. *viciae*, four AHL-based quorum sensing systems have been identified (*cin*, *rhi*, *rai*, and *tra*) and shown to be involved in several cellular processes, among them are EPS production, plasmid transfer, and nodulation (Fig. 36.4) (Wisniewski-Dyé and Downie, 2002; see also Chapter 37). The *cin* system consisting of the CinR, CinI, and CinS proteins is at the top of this regulatory network and activates gene expression of the remaining quorum sensing systems. CinI is indispensable for AHL synthesis (*N*-(3-hydroxy-7-*cis*-tetradecenoyl)-L-homoserine lactone), whereas CinR induces *cinI* transcription in response to this signal. CinS is a small protein of an antirepressor function activating the transcription of regulatory genes *raiR* and *rhiR* of the *rai* and *rhi* systems and, additionally, the expression of *plyB* encoding an extracellular glycanase (Edwards et al., 2009; Frederix et al., 2011). This protein acts as an attenuator of the activity of the negative regulator PraR. Multiple *cinS* copies cause loss of colony mucoidy with colony aging, which is an effect of accumulation of the EPS-degrading PlyB enzyme.

Another regulatory protein ExpR also stimulates *raiR* and *plyB* expression, but this regulation does not require AHL (Edwards et al., 2009; Frederix et al., 2011). The ExpR protein of *R. leguminosarum* displays significant similarity to the *S. meliloti* ExpR. Nevertheless, several functional differences between these regulators have been observed. In contrast to the *S. meliloti expR* mutant, the *expR* mutant of *R. leguminosarum* forms colonies exhibiting morphology similar to that of the wild type. Moreover, the *R. leguminosarum* ExpR regulates a significantly lower number of genes than its homolog from *S. meliloti*, among them only *plyB* is associated with EPS production.

***36.3.2.2 The Influence of Light on EPS Synthesis in* R. leguminosarum.** Among the environmental factors, light is an essential signal that controls growth, development, and behavior of many different organisms (Purcell and Crosson, 2008). Light, oxygen, and voltage (LOV)-domain proteins are blue-light receptors found in higher plants, algae, fungi, and bacteria, which sense the wavelength and intensity of light and transduce this signal into various cellular pathways. Sequencing of bacterial genomes has shown that photoreceptor proteins are present not only in photosynthetic bacteria but also in heterotrophic bacteria such as *Brucella* and *Rhizobium*.

Recently, a *lov* gene encoding a sensor histidine kinase (LOV-HK) has been identified on the symbiotic megaplasmid pRL11 of *R. leguminosarum* bv. *viciae* 3841 (Bonomi et al., 2012). This protein contains the sensor LOV domain at the N-terminal end followed by an HK domain with histidine residue as a target site for autophosphorylation. Bonomi et al. (2012) have observed that light regulates EPS production, biofilm formation, flagella abundance, competitiveness, and nodulation in *R. leguminosarum* through this photoreceptor. Wild-type bacteria exposed to light show a substantial reduction in EPS production and biofilm formation, indicating that this signal negatively affects the synthesis of this polymer (Fig. 36.4). In contrast, the *lov* mutant shows no significant differences in the amounts of produced EPS and formed biofilm between light and dark conditions (Bonomi et al., 2012). But genes involved in EPS synthesis as targets for the LOV-HK protein have not been established so far. Light also affects competitiveness and nodulation in a *lov*-dependent manner, suggesting that this environmental signal is very important for adaptation of rhizobia to different ecological niches. However, genes encoding LOV-domain proteins are not common in rhizobial genomes, since only 5 among the 28 genomes sequenced to date harbor these genes (Krauss et al., 2009; Bonomi et al., 2012).

36.4 CONCLUSIONS

Exopolysaccharides secreted in large amounts to the environment by rhizobia are species-specific heteropolymers with several functions, including biofilm formation and protection against stress factors. Moreover, LMW EPS are biologically active forms essential for successful nodulation of leguminous plants (especially plants forming indeterminate-type nodules). So far, structures of EPS from several rhizobial species have been established. However, EPS synthesis and regulation of this process by environmental factors have been studied in detail only for one species – *S. meliloti*. These data indicate that EPS synthesis in this bacterium undergoes very complex regulation linked with other regulatory pathways such as quorum sensing and catabolite repression. In contrast, knowledge about proteins required for the synthesis of EPS as well as modulation of this process by different environmental factors in other rhizobial species is still scarce. Moreover, neither the precise function of LMW EPS nor plant receptors for this signal have been discovered so far.

Chapter 37

Regulation of Symbiotically Important Functions by Quorum Sensing in the *Sinorhizobium meliloti*–Alfalfa Interaction

Luciana V. Rinaudi-Marron and Juan E. González
Department of Molecular and Cell Biology, University of Texas at Dallas, Dallas, TX, USA

37.1 INTRODUCTION

The rhizosphere of plants, rich in root exudates, attracts a variety of microorganisms that play a significant role in plant health.

A major component of root exudates are phenolic compounds called flavonoids (Cesco et al., 2010), which are important determinants of host specificity in the rhizobia-legume symbiosis (Long, 1996; see Chapter 50). Flavonoids act as bacterial chemoattractants and stimulate the expression of nodulation genes, which will set off the initial steps required for the establishment of the symbiosis. Upon recognition of a compatible host, the bacterial NodD regulator is able to sense the presence of flavonoids and activate the biosynthesis and secretion of Nod factors (Schlaman et al., 1992). These oligomers of 1,4-linked *N*-acetyl-glucosamine trigger a series of morphological changes in the plant root that leads to the formation of nodules, specialized organs where nitrogen fixation occurs (see Chapter 51). As rhizobia gather around the roots, the production of exopolysaccharides (see Chapter 36) allows bacteria to colonize the plant surfaces and invade root hairs through a tubular structure called the infection thread (Gage et al., 1996; Cheng and Walker, 1998; Gage, 2002; Gage, 2004; see Chapters 41, 57, 59). When infection threads reach the meristem, bacteria are released into the cell cytoplasm surrounded by a plant-derived membrane. Inside the nodules, bacteria differentiate into their endosymbiotic form, bacteroids (see Chapter 31), and begin to convert atmospheric nitrogen into reduced forms of this element that the plant can incorporate into organic compounds.

In addition to flavonoids and Nod factors, quorum sensing plays a role as part of the signaling process that allows the establishment of the symbiosis. Quorum sensing is defined as a population density mechanism that enables bacteria to coordinately regulate gene expression and modify behaviors. In response to flavonoids, the rhizobial population density increases in the rhizosphere, and it is at this junction that quorum sensing becomes an important player in the symbiotic process. In this chapter, we review how quorum sensing regulates symbiotically relevant functions in the *S. meliloti*-alfalfa interaction.

37.2 QUORUM SENSING IN GRAM-NEGATIVE BACTERIA

The production of signaling molecules allows bacteria to assess the size of their population and to respond to these changes as a group instead of as individuals. When the accumulation of these diffusible molecules or autoinducers reaches a threshold level, they activate a transcriptional regulator that in turn modifies the expression of target genes.

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

The best characterized quorum-sensing mechanism in Gram-negative bacteria involves the production of *N*-acyl homoserine lactones (AHLs). These autoinducers are synthesized by AHL synthases belonging to the LuxI family from *S*-adenosyl methionine (SAM) and an acylated acyl carrier (Hanzelka and Greenberg, 1996; More et al., 1996; Val and Cronan, 1998; Parsek et al., 1999; Fuqua et al., 2001; Withers et al., 2001). All AHL molecules described so far share a homoserine lactone head group attached to a fatty acyl chain. The length of the acyl chain (which varies from 4 to 18 carbons), the presence of substitutions in the third-carbon position (which can be a hydrogen, hydroxyl, or oxo group), and the backbone saturation confer specificity to the quorum-sensing signals (Nealson et al., 1970; Pearson et al., 1995; Schripsema et al., 1996; Puskas et al., 1997; Marketon et al., 2002; Thiel et al., 2009). When a threshold of AHLs has accumulated, they bind to a receptor protein of the LuxR family (Fuqua et al., 1996). LuxR-type receptors are transcriptional regulators that have an amino-terminal AHL-binding domain and a carboxyl-terminal DNA-binding motif (Shadel et al., 1990; Slock et al., 1990; Choi and Greenberg, 1991; Hanzelka and Greenberg, 1995). The AHL-receptor complex binds to DNA promoter sequences called *lux* boxes (inverted repeated sequences located about −40 nucleotides from the transcriptional start site), and by doing so activates or represses the expression of quorum-sensing-regulated genes (Devine et al., 1989; Fuqua et al., 1994; Stevens et al., 1994; Stevens and Greenberg, 1997; Egland and Greenberg, 1999; Luo and Farrand, 1999; Stevens et al., 1999; Egland and Greenberg, 2000; Pompeani et al., 2008).

In rhizobia, quorum sensing has been shown to control exopolysaccharide production (Marketon et al., 2002; Pellock et al., 2002; Marketon et al., 2003; Teplitski et al., 2003; Gao et al., 2005; Glenn et al., 2007; Bahlawane et al., 2008b; McIntosh et al., 2008; see Chapter 36), biofilm formation (Wang et al., 2004; Edwards et al., 2009; Rinaudi and González, 2009), motility (Sourjik et al., 2000; Hoang et al., 2004; Daniels et al., 2006; Hoang et al., 2008; Gurich and González, 2009; Nogales et al., 2012; see Chapter 33), plasmid transfer (Marketon and González, 2002; Wilkinson et al., 2002; Danino et al., 2003; He et al., 2003; Tun-Garrido et al., 2003), nodulation and nitrogen fixation (Cubo et al., 1992; Rosemeyer et al., 1998; Rodelas et al., 1999; Daniels et al., 2002; Loh et al., 2002; Zheng et al., 2006), among other functions.

37.3 THE ExpR/Sin QUORUM-SENSING SYSTEM IN *Sinorhizobium meliloti*

The most extensively studied quorum-sensing system in *S. meliloti* is the ExpR/Sin system. The *sinI*/*sinR* locus was originally identified in the commonly used Rm1021 strain (Marketon and González, 2002). It is composed of the transcriptional regulator SinR and the autoinducer synthase SinI, responsible for the synthesis of several long-chain AHLs (C12-HL, oxo-C14-HL, C16:1-HL, oxo-C16:1-HL, and C18-HL) (Marketon et al., 2002). Plant inoculation assays showed that disruption of *sinI* or *sinR* leads to a decrease in the total number of nitrogen-fixing nodules in alfalfa, as well as a delay in the appearance of such nodules, suggesting that quorum sensing plays a role in the establishment of a successful symbiosis (Marketon et al., 2002).

Numerous cellular processes require the activation of another LuxR homolog, ExpR, by the *sin*-encoded AHLs in *S. meliloti*. Among the genes regulated by the ExpR/Sin quorum-sensing system are those involved in exopolysaccharide production (see Chapter 36), motility, chemotaxis (see Chapter 33), nitrogen fixation, metabolism, and metal transport (Pellock et al., 2002; Marketon et al., 2003; Teplitski et al., 2003; Hoang et al., 2004; Gao et al., 2005; Glenn et al., 2007; Hoang et al., 2008; Gurich and González, 2009; Mueller and González, 2011). Curiously, unlike most wild-type strains tested, the widely studied Rm1021 strain carries an insertional element (ISRm2011-1) within the coding region of *expR*, which makes it "insensitive" to AHLs because it lacks a complete quorum-sensing system (Pellock et al., 2002; Marketon et al., 2003).

37.3.1 Regulation of Exopolysaccharide Production by the ExpR/Sin Quorum-Sensing System

S. meliloti is capable of producing two exopolysaccharides involved in the plant nodule invasion process, succinoglycan, and EPS II (see Chapter 36).

Succinoglycan is a polymer of octasaccharide repeating subunits. Each subunit is composed of seven glucose molecules and one galactose residue joined by β-1,4, β-1,3, and β-1,6 glycosidic linkages and decorated by acetyl, succinyl, and pyruvyl groups (Aman et al., 1981; Reuber and Walker, 1993b; Reinhold et al., 1994). All the genes required for succinoglycan biosynthesis (*exo* genes) have been identified and are located on the pSymB megaplasmid of *S. meliloti* (Leigh et al., 1987; Glucksmann et al., 1993; Reuber and Walker, 1993a,1993b; see Chapter 36). This exopolysaccharide is produced in two distinct fractions: one of high molecular weight (HMW) and the other of low molecular weight (LMW). The symbiotically active form necessary for the establishment of the symbiosis with alfalfa is the LMW fraction of succinoglycan and consists of trimers of the octasaccharide (Battisti et al., 1992; González et al., 1998; Wang et al., 1999; see Chapter 36). Rm1021 *exo* mutants are symbiotically deficient, eliciting the formation of small nodules devoid of bacteria. Studies using

GFP-labeled *S. meliloti* revealed that strains impaired in the production of succinoglycan fail to initiate and elongate infection threads during the invasion of alfalfa roots (Leigh et al., 1985; Yang et al., 1992; Cheng and Walker, 1998; Pellock et al., 2000). A whole-genome expression profile of *S. meliloti* showed that the ExpR/Sin quorum-sensing system regulates genes involved in the production of succinoglycan and its LMW fraction (Hoang et al., 2004; Gurich and González, 2009). These results were confirmed by Glenn and coworkers, who observed a fivefold reduction in the production of succinoglycan in a strain deficient in the synthesis of AHLs. Interestingly, the expression of *exsH* and *exoK*, the endo-1,3-1,4-β-glycanases, necessary for the production of the symbiotically active LMW fraction of succinoglycan was also induced by the ExpR/Sin system (Glenn et al., 2007; Gurich and González, 2009). Disruption of *expR* and *sinI* also caused a delay in the appearance of the fluorescent halo surrounding succinoglycan-producing colonies, indicative of a reduction in the synthesis of the LMW fraction of the exopolysaccharide (Glenn et al., 2007).

In the absence of succinoglycan, EPS II can mediate the establishment of the symbiosis between *S. meliloti* and alfalfa (Zhan et al., 1989; see Chapter 36). EPS II is an exopolysaccharide of repeating dimer subunits made of an acetylated glucose and a pyruvylated galactose residue connected by α-1,3 and β-1,3 glycosidic bonds (Glazebrook and Walker, 1989; Her et al., 1990). Biosynthesis of EPS II is directed by the *exp* operon, also located on the pSymB plasmid (Glazebrook and Walker, 1989). As with succinoglycan, EPS II is produced in HMW and LMW forms. The LMW fraction, consisting of 15–20 disaccharide subunits of EPS II, is able to rescue nodule invasion in an exopolysaccharide-deficient strain (González et al., 1996). Production of EPS II and its symbiotically active LMW fraction requires the presence of an intact ExpR/Sin quorum-sensing system (Pellock et al., 2002; Marketon et al., 2003; see Chapter 36). Synthesis of EPS II is abolished in a *sinI* mutant, but this deficiency can be complemented by the addition of AHLs extracted from a *sinI*-proficient strain or by synthetic C16:1-HSL (Marketon et al., 2003). The mechanism by which the ExpR/Sin system induces the production of EPS II and the active LMW form of the exopolysaccharide was recently revealed by Mueller and González. The *exp* gene cluster is composed of the operons *expE*, *expA*, and *expD*, which are required for the structural biosynthesis of EPS II, as well as for the *expG-expC* operon, which encodes a transcriptional regulator and a glycosyl transferase, respectively (Glazebrook and Walker, 1989; Becker et al., 1997; Rüberg et al., 1999; Bahlawane et al., 2008a). In a quorum-sensing-proficient strain, the regulator MucR represses the synthesis of EPS II at low-population densities through direct interactions with the promoter regions of *expE*, *expA*, and *expD* (Rüberg et al., 1999; Bahlawane et al., 2008a). When quorum is reached, the ExpR-AHL complex activates the expression of the transcriptional regulator encoded by *expG*, which removes, at the transcriptional level, the MucR repression of EPS II production. Increased levels of expression of the *expC*-encoded glycosyl transferase cotranscribed with *expG*, along with maintained expression of the structural *exp* genes, results in the synthesis of the symbiotically active LMW form of EPS II (Mueller and González, 2011).

37.3.2 Regulation of Biofilm Formation by the ExpR/Sin Quorum-Sensing System

The ExpR/Sin system also controls biofilm formation in *S. meliloti*, mainly through the regulation of EPS II production (Rinaudi and González, 2009). Disruption of *sinI* or *expR* results in a dramatic reduction in biofilm formation. An identical phenotype was observed when EPS II synthesis was blocked by introducing a mutation in the *expA* gene. Moreover, only a quorum-sensing-proficient strain was able to develop highly structured and organized biofilms when evaluated by confocal laser scanning microscopy. Mutants unable to produce EPS II (*sinI*, *expR*, and *expA*) or the active LMW form of the exopolysaccharide (*mucR*) failed to aggregate and form biofilms. A reduction in the attachment to roots of the legume host was also correlated with the mutant's inability to produce EPS II. These results suggest that the quorum-sensing-regulated production of the symbiotically important form of EPS II not only mediates invasion of alfalfa but also contributes to the colonization of root surfaces (Rinaudi and González, 2009). Therefore, the ExpR/Sin quorum-sensing-mediated mechanism that regulates EPS II production in *S. meliloti* ensures that LMW EPS II is produced at the adequate population densities for root colonization and invasion of the host.

37.3.3 Regulation of Motility by the ExpR/Sin Quorum-Sensing System

The expression of many genes involved in the synthesis of flagella filaments (belonging to the *flb* and *fla* operons), the basal body and hook (*flgEKL* and *fliL* genes), as well as chemotaxis (*cheY1* gene) are dependent on the existence of a functional ExpR regulator, and downregulated in the presence of Sin-AHLs (Hoang et al., 2004; see Chapter 33). Previous studies have established that the LuxR-type transcriptional regulators VisN/R and the OmpR-like transcription factor Rem are activators of motility in *S. meliloti* (Sourjik et al., 2000; Rotter et al., 2006). The expression of *visN*, *visR*, and *rem* was downregulated, in a population density-dependent manner, in a *sinI* mutant compared to the quorum-sensing-proficient strain (Hoang et al., 2008). This suggests that when sufficient AHLs have accumulated, quorum sensing acts upstream of these

regulators and controls motility via the VisN/R-Rem regulatory pathway. Recent work showed that the ExpR-AHL complex regulates motility directly by binding to the promoter region of the VisN transcriptional regulator, resulting in the repression of flagella synthesis (Bahlawane et al., 2008b). It has been proposed that free ExpR and AHL-activated ExpR compete for control of motility genes (Gurich and González, 2009). At low-population densities, the basal levels of AHLs leave ExpR available to act as an activator of motility. As the concentration of AHLs increases, ExpR binds upstream of the *visN/R* operon and becomes a repressor, preventing the activation of motility and chemotaxis genes (see also Chapter 33).

A *sinI* mutant is highly motile and unable to repress the synthesis of flagella at high-population densities, which is detrimental to successful plant invasion (Hoang et al., 2008; Gurich and González, 2009). Blocking flagellar synthesis in a *sinI* strain (by disrupting the filament biosynthetic genes *flaA* and *flaB*) completely restored its competency for establishing symbiosis to wild-type levels. Blocking flagella rotation (not its synthesis) in the *sinI* mutant (*sinI motA*) was not able to restore the invasion efficiency in this strain (Gurich and González, 2009). These results taken together strongly suggest that the inability to shut down flagella in *S. meliloti* interferes with alfalfa plant invasion.

37.3.4 The ExpR/Sin Quorum-Sensing System Inside the Nodules

Genome-wide expression profile analyses revealed that the expression of all the ExpR/Sin quorum-sensing components (*sinR*, *sinI*, and *expR*), and quorum-sensing-regulated genes (such as those involved in EPS II synthesis) was strongly repressed in bacteroids and only detected in free-living cells (Gurich and González, 2009). The same studies also confirmed the activation of genes involved in nitrogen fixation and microoxic respiration in bacteroids compared to free-living cells, while metabolic, ribosomal, cell division, and translational genes were downregulated in the nodule (Gurich and González, 2009). Evidence suggests that the ExpR/Sin system plays a major role regulating the expression of genes necessary for bacterial survival in the soil, colonization of the host, and invasion of alfalfa roots, but it is inactivated once rhizobia enters the plant and the symbiosis has been established.

37.4 THE TRA QUORUM-SENSING SYSTEM IN *Sinorhizobium meliloti*

A second quorum-sensing system has been identified in *S. meliloti*. The Tra system, named for its homology to the equally named quorum-sensing system in *Agrobacterium tumefaciens* and *Rhizobium* strain NGR234, is located on the self-transmissible, nonsymbiotic pRme41a plasmid carried by *S. meliloti* Rm41 derivatives (Marketon and González, 2002).

This system is composed of three regulatory genes: *traI*, *traR*, and *traM* (Fig. 37.1). At low-population densities, TraM binds to and inactivates TraR, preventing it from inducing the *trb* operon until a high population is reached. At high-population densities, *traI*-encoded AHLs (3-oxo-C8-HSL, 3-OH-C8-HSL, and C8-HSL) accumulate to a level where they effectively bind to and activate the response regulator TraR. The TraR-AHL complex then upregulates the expression of the *trb* operon, which contains genes that encode for the formation of the mating pore and the conjugal tube, structural components necessary for the transfer of the plasmid (Marketon and González, 2002).

37.5 OTHER LuxR HOMOLOGS IN *S. meliloti*

The sequenced genome of *S. meliloti* Rm1021 reveals the presence of four additional LuxR homologs. As with the

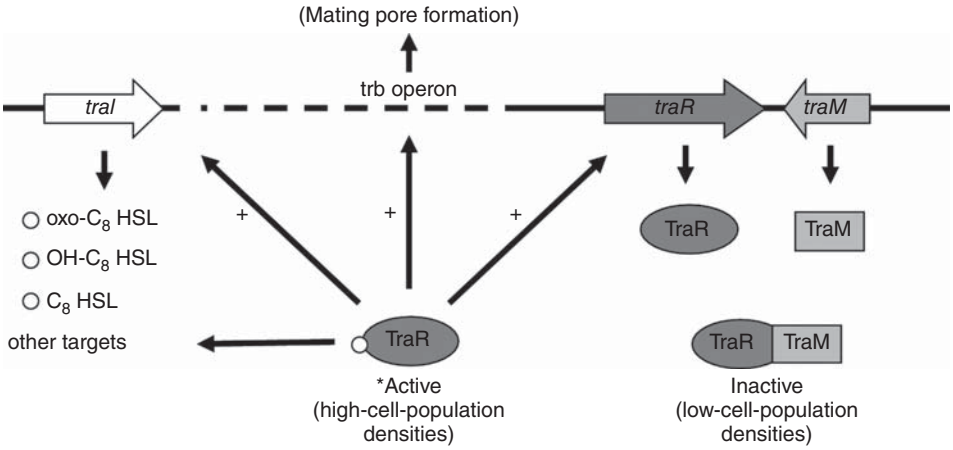

Figure 37.1 Tra quorum-sensing system in *S. meliloti*. This system controls conjugal plasmid transfer through the action of the *tra* genes, located in the pRme41a plasmid. TraI produces short-chain AHLs, and it is regulated by TraR. TraM is a repressor of TraR at low-population densities, which ensures that the Tra system is active only at the high-population densities, necessary for the conjugal transfer of pRme41a.

other two characterized LuxR-type regulators, SinR and ExpR, these LuxR homologs are located in the chromosome and are encoded by the SMc04032, SMc00878, SMc00877, and SMc00658 genes. However, none of them are directly associated with a known AHL synthase in *S. meliloti*, and therefore, they are considered orphan LuxR regulators (Galibert et al., 2001; Fuqua, 2006; Patankar and González, 2009b; Subramoni and Venturi, 2009).

Recent work has proposed a role for one of these orphan regulators (SMc04032), named NesR (Patankar and González, 2009a). Genome-wide expression analysis showed that NesR is involved in the active methyl cycle within the methionine biosynthetic pathway, responsible for the production of the important AHL precursor SAM. In the absence of an intact *nesR*, four genes were downregulated in the mutant when compared to the wild type. These encode for a methionine synthase (*metH*), a betaine methyltransferase (*bmt*), an *S*-adenosyl-L-methionine synthase (*metK*), and a methylene tetrahydrofolate reductase (*metF*). NesR does not seem to be associated with the production or regulation of the Sin-AHLs. The introduction of a mutation in the *nesR* gene does not cause a growth defect in the mutant; however, the absence of a functional copy of the regulator renders the strain less capable of tolerating hyperosmotic and detergent stresses. Although plant nodulation assays showed that the *nesR* mutant is as efficient as the wild type at establishing a successful symbiosis with alfalfa, co-inoculation assays revealed that the mutant was less competitive for nodulation than the wild-type strain of *S. meliloti*. Taken together, these results suggest NesR is a modulator of metabolic fitness, and it plays a role in *S. meliloti*'s stress adaptation and competition for plant nodulation (Patankar and González, 2009a).

Preliminary results indicate that SMc00878 controls the transcription of genes from the denitrification pathway in *S. meliloti* (A. Patankar and J.E. González, unpublished results), while the roles of SMc00877 and SMc00658 remain to be elucidated.

37.6 CONCLUSION

Plants live in close association with numerous microorganisms that inhabit the soil. Complex signaling mechanisms allow them to recruit beneficial microbes, which improve nutrient uptake, prevent colonization by pathogens, and modulate host defense responses (Berendsen et al., 2012). Among these beneficial microbes are rhizobia, nitrogen-fixing soil bacteria, able to establish a symbiosis with legume plants. Important signaling events are triggered in the rhizosphere by plant flavonoids, as well as bacterial Nod factors, exopolysaccharides, and quorum-sensing molecules.

The ExpR/Sin quorum-sensing system has been shown to regulate numerous symbiotically important functions in free-living *S. meliloti*. Such functions include the production of exopolysaccharides, biofilm formation, motility, and chemotaxis (Fig. 37.2). By being able to use AHLs to monitor the size of its population, *S. meliloti* allows the synthesis of flagella and the activation of motility at low-population densities, when cells are exploring new niches, searching for nutrients or trying to reach their host. As the population increases around the legume roots, motility is downregulated while the synthesis of the active LMW fractions of succinoglycan and EPS II is induced, events necessary for efficient plant invasion. Once invasion has occurred and the symbiosis has been established, all metabolic functions of

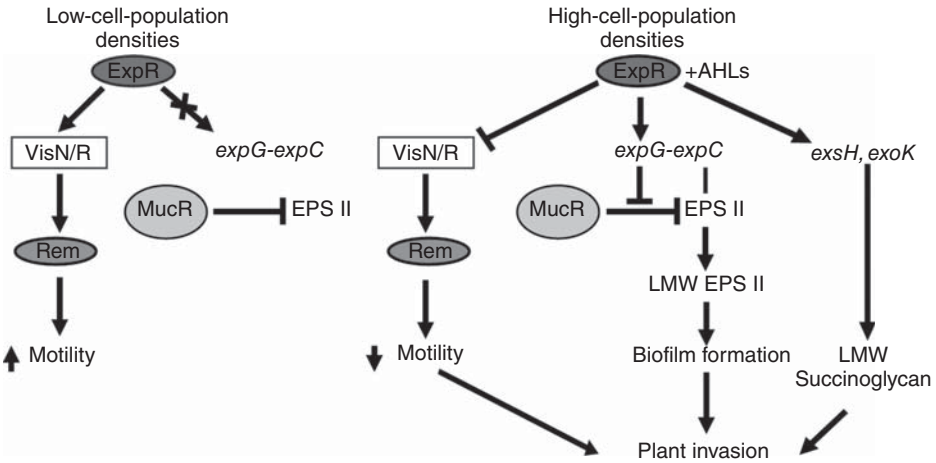

Figure 37.2 Quorum-sensing regulation of exopolysaccharide production, biofilm formation, and motility in *S. meliloti*. Low concentrations of AHLs, insufficient to activate ExpR, allow bacteria to be motile, a requirement for movement toward the legume host. At high-population densities, the ExpR-AHL complex blocks expression of *visN/R* while derepressing EPS II synthesis from MucR, leading to the production of the symbiotically active exopolysaccharides. Lack of flagella production and the presence of LMW succinoglycan and/or EPS II are necessary for the establishment of a successful symbiosis between *S. meliloti* and alfalfa plants.

the bacteroids are directed toward nitrogen fixation, while quorum sensing and quorum-sensing-regulated genes are repressed inside the nodule.

Little is known about the nonsymbiotic pRme41a plasmid present in *S. meliloti* Rm41, which carries the Tra quorum-sensing system (Marketon and González, 2002). *traI*-encoded AHLs, in conjunction with the regulator TraR, have been linked to the conjugal transfer of pRme41a (Marketon and González, 2002). It has been proposed that this plasmid also carries calystegin catabolic genes, a secondary metabolite found in the root exudates of some plants, and that the ability to utilize less-conventional substrates by strains such as Rm41 could provide them a selective advantage under natural conditions (Tepfer et al., 1988). The now available sequence of Rm41 and pRme41a could shed light on other potentially important functions harbored by this cryptic plasmid.

Finally, the genome of *S. meliloti* shows the presence of four orphan LuxR homologs: SMc04032 (NesR), SMc00658, SMc00877, and SMc00878 (Galibert et al., 2001). NesR was shown to affect stress adaptation and competition for nodulation (Patankar and González, 2009a), while the processes regulated by SMc00878 mostly fall within the denitrification pathway of *S. meliloti* (A. Patankar and J.E. González, unpublished results). The roles for SMc00658 and SMc00877, as well as the signal(s) responsible for activation of these orphan LuxR homologs remain to be identified.

The natural aggregation of *S. meliloti* that occurs in the plant host root milieu is the trigger that activates the bacterium's quorum-sensing system to coordinate a series of phenotypes essential for the successful invasion of alfalfa nodules. Once *S. meliloti* enters the nodule and directs its resources to the nitrogen-fixing process, quorum sensing and the genes regulated via its signaling system are no longer necessary, and they are inactivated by a mechanism still to be determined.

ACKNOWLEDGMENTS

We thank the members of our laboratory for critically reading the manuscript. We apologize to those whose contributions to the field we have not included in this review due to space limitations. Our work was supported by National Science Foundation grant MCB-9733532 and National Institutes of Health grant 1R01GM069925 to J.E.G.

Chapter 38

Lumichrome: A Bacterial Signal Molecule Influencing Plant Growth

Felix D. Dakora
Department of Chemistry, Tshwane University of Technology, Arcadia Campus, Pretoria, South Africa

38.1 INTRODUCTION

Both plants and bacteria use various mechanisms to overcome environmental limitations such as low nutrients. For example, plants secrete a mixture of molecules that promote nutrient mobilization for uptake by roots (Marschner, 1995; Dakora and Phillips, 2002). Many diazotrophs, including rhizobia, have been shown to use chemical molecules in their exudates to affect changes in plant development. For example, many bacterial species secrete specialized compounds such as siderophores to enhance Fe acquisition (Jurkevitch et al., 1986). Rhizobial bacteria are also known to release growth-promoting molecules (Fig. 38.1) such as gibberellins and cytokinins (Phillips and Torrey, 1970; 1972; Dart, 1974; Lynch and Clark, 1984) that promote bacterial cell growth and massively proliferate plant root hair production (Yanni et al., 2001) for increased water and nutrient uptake through an enhanced root absorptive capacity. In this study, the role of lumichrome as a signal molecule in plant development is assessed together with riboflavin and indole acetic acid (Fig. 38.1), two other bacterial metabolites that are important in rhizosphere functioning of symbiotic legumes.

38.2 COMPONENTS OF RHIZOBIAL EXUDATES AND THEIR EFFECTS ON PLANTS

In addition to bacterial hormones, a number of biologically active novel molecules have been purified and identified from rhizobial exudates that stimulate cell growth and nodule organogenesis (De Jong et al., 1993; Daychok et al., 2000). For example, lipochito-oligosaccharide molecules isolated from rhizobia (Fig. 38.1) have been reported to stimulate seed germination (Zhang and Smith, 2002) and seedling development in both monocots and dicots (Smith et al., 2002; see Chapter 107). In addition to *nod* gene induction, purified Nod factors have been found to morphogenically elicit nodule formation on host plants in the absence of rhizobial cells (Denarie et al., 1996). Applying 10^{-7} M or 10^{-9} M concentration of Nod factors to soybean plants increased root mass by 7–16% and root length by 34–44% (Smith et al., 2002; see Chapter 107). Similarly, spraying leaves of soybean, common bean, maize, rice, canola, apple, and grape plants with submicromolar concentrations [10^{-6}, 10^{-8}, or 10^{-10} M] of Nod factors increased photosynthetic rates by 10–20% (Smith et al., 2002) and resulted in a 40% increase in grain yield of a field-grown soybean crop (Smith et al., 2002; see Chapter 107). Furthermore, Nod factors have been found to induce the expression of genes involved in the phenylpropanoid pathway (Savoure et al., 1994; Spaink and Lugtenberg, 1994), with potential for increasing phytoalexin production, and hence greater protection of plants against pathogens (Dakora and Phillips, 1996). It has also been shown that, even at low concentrations [10^{-7} nM], Nod factors can promote AM colonization of both nodulating and nonnodulating plants (Xie et al., 1995), suggesting a role for this rhizobial metabolite in the establishment of mycorrhizal symbiosis (Parniske, 2008; see Chapter 108).

In addition to Nod factors, other metabolites have been identified in rhizobial exudates, and these include vitamins and amino acids. Although the presence of these compounds

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

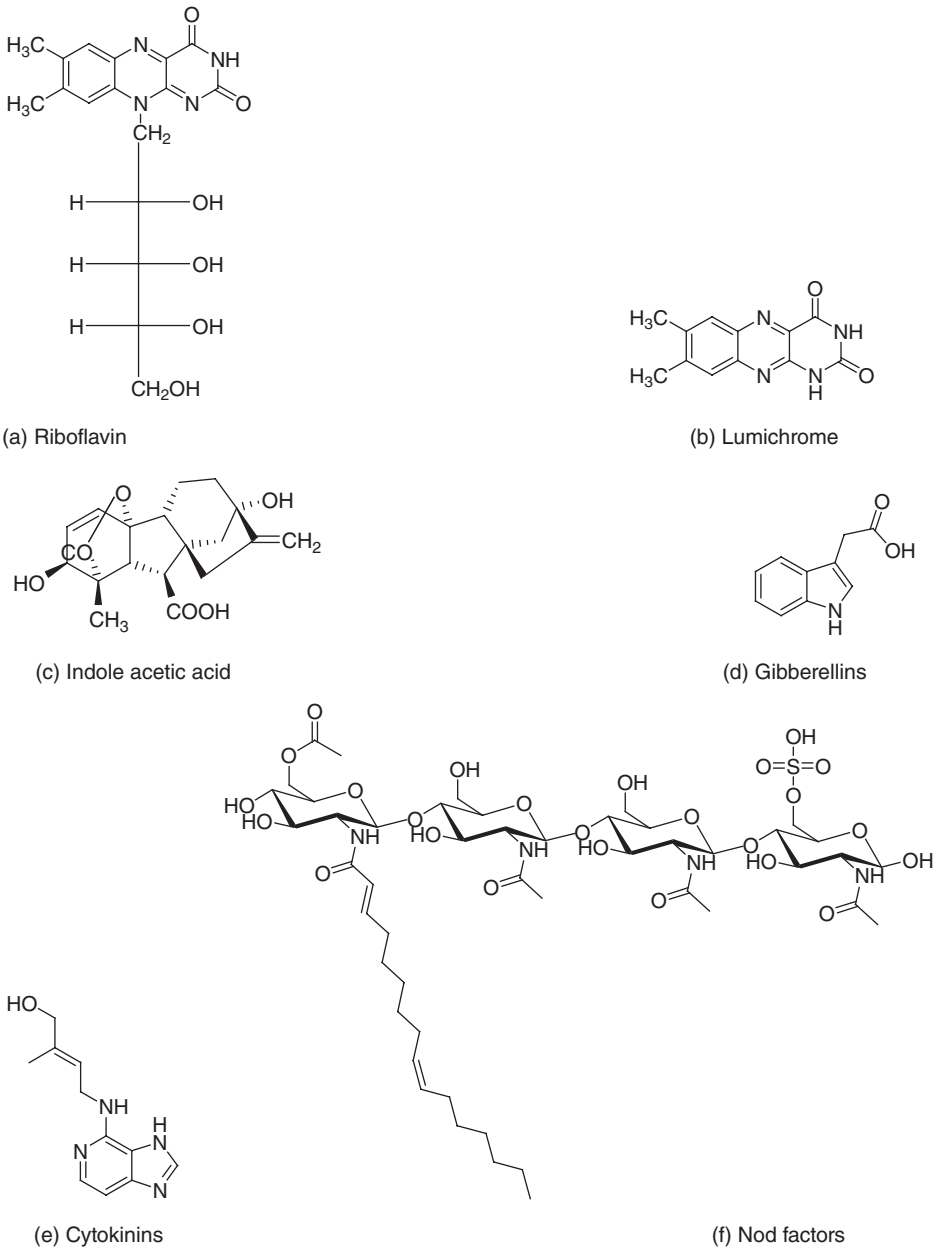

Figure 38.1 Structures of rhizobial molecules affecting plant function.

in bacterial cultures was reported a long time ago, it is only recently that their functional role in plant growth and metabolism has been documented. For example, the observed synthesis of the vitamins riboflavin and thiamine by root-nodule bacteria for cell growth occurred about 75 years ago (West and Wilson, 1938). Five years after that, riboflavin was isolated from field soil and was shown to be absorbed by plant roots and translocated to shoots (Carpenter, 1943). It was not until 35 years later that riboflavin was reported to stimulate plant growth (Rao, 1973). Since then, different vitamins such as thiamine, riboflavin, niacin, biotin, and pantothenic acid, as well as amino acids such as glutamate, lysine, arginine, tryptophan, and methionine have been isolated from culture filtrate of several bacteria species, including *Sinorhizobium meliloti*, *Rhizobium leguminosarum* bv. *viceae*, *Azospirillum brasilense*, *Azotobacter vinelandii*, and *Pseudomonas fluorescens*, (Rodelas et al., 1993; Sierra et al., 1999; Yang et al., 2002). Three other biologically active molecules that have been identified from rhizobial exudates and found to promote plant growth include lumichrome, riboflavin, and indole acetic acid (Phillips et al., 1999; Matiru and Dakora, 2005a,b; Kanu et al., 2007; Kanu and Dakora, 2009; see Fig. 38.1).

38.3 LUMICHROME: A RHIZOBIAL SIGNAL MOLECULE INVOLVED IN PLANT DEVELOPMENT

Lumichrome is a molecule commonly synthesized by both microbes and plants, and is also a known degradation product of the vitamin riboflavin (Phillips et al., 1999) (see Fig. 38.1). Because riboflavin is easily converted enzymatically or photochemically into lumichrome (Yagi, 1962; Yanagita and Foster, 1956), any discussion of lumichrome must include riboflavin. Applying purified lumichrome from *Sinorhizobium meliloti* exudate to roots of alfalfa seedlings increases root respiration by 11–30% and promotes plant growth by 8–18% (Phillips et al., 1999). The enhanced plant growth has been attributed to an increased net C assimilation, possibly via PEP carboxylase activity (Phillips et al., 1999).

Plants seem to show a mixed response to lumichrome application. While this molecule significantly increases root respiration in maize plants (Phillips et al., 1999; Matiru and Dakora, 2005a), it decreases root respiration in lupin and has no affect on cowpea, soybean, Bambara groundnut, pea, and sorghum (Matiru and Dakora, 2005a). Inoculating the roots of these monocots and dicots with infective rhizobial cells produces the same results as obtained with lumichrome application, in that maize shows significantly increased root respiration; lupin a decreased rate; and cowpea, soybean, Bambara groundnut, pea, and sorghum remain unaffected in their root respiration (Matiru and Dakora, 2005a). This clearly indicates that the observed changes in root respiration with bacterial inoculation are caused by the lumichrome molecule released by symbiotic rhizobia. Furthermore, both lumichrome and riboflavin have been implicated as quorum-sensing molecules in bacteria (Rajamani et al., 2008). The independent role of riboflavin as a signal molecule has also been underscored by the finding that *Sinorhizobium meliloti* strains carrying extra copies of the riboflavin biosynthesis gene *ribBA* release 15% more riboflavin than the wild type and were 55% more efficient in alfalfa root colonization for nodule formation (Yang et al., 2002).

Treating the roots of cowpea, Bambara groundnut, soybean, sorghum, and maize plants with 10 nM purified lumichrome and 10 ml of infective rhizobial cells [0.2 OD_{600}] for 44 h in growth chambers increases stomatal conductance and leaf transpiration rates in cowpea, but decreases both parameters in Bambara groundnut, soybean, and maize (Matiru and Dakora, 2005b). In the latter study, the effect of bacterial inoculation closely mirrored that of 10 nM lumichrome application, again indicating that rhizobial effects on these physiological changes (whether in nature or under experimental conditions) is most likely because of the lumichrome molecule released by symbiotic rhizobia in the rhizosphere. Thus, the finding that rhizobial inoculation in the field alleviates the effects of water stress in symbiotic legumes (Figueiredo et al., 1999) could be attributed to strain secretion of lumichrome that decreased stomatal conductance and reduced water loss.

The supply of 5 nM lumichrome to roots of cowpea and soybean seedlings also causes early initiation of trifoliate leaf development, expansion in unifoliate and trifoliate leaves, and increased stem elongation (Fig. 38.2), resulting in an increase in the total biomass of shoot and plant relative to control. Lumichrome [5 nM] also increases leaf area in maize and sorghum, and thus raises shoot and total biomass but has no effect on the leaf area of the other cereals. Root growth is also stimulated in sorghum and millet by the supply of 5 nM lumichrome. However, higher doses of lumichrome [50 nM] depresses development of unifoliate leaves in soybean, the second trifoliate leaf in cowpea (Fig. 38.2), and shoot biomass in soybean. The 50 nM concentration also consistently decreases root development in cowpea and millet, but has no effect on the other species. The data also show that the biological effect of lumichrome on plants is not age specific as growth of 11-day-old and 37-day-old sorghum; 23-day-old and 37-day-old soybean; 23-day-old and 37-day-old millet; and 11-day-old and 37-day-old cowpea are significantly increased by lumichrome supply at 5 nM concentration. Unlike the legumes, however, the supply of 5 nM lumichrome markedly increases [$P < 0.05$] root growth in cereals, especially sorghum and millet. These data further show that lumichrome is a rhizosphere signal molecule that affects seedling development in both monocots and dicots.

At the metabolic level, root application of lumichrome increases starch accumulation in roots of both *Lotus* and tomato, and the molecule has been suggested to be involved in carbon partitioning and the modulation of carbon fluxes in infected symbiotic plant cells (Gouws et al., 2012). This argument has been reinforced by the fact that *Lotus*-treated roots showed a reduction in organic acids and amino acids, all carbonaceous compounds. However, root treatment with lumichrome increases ethylene evolution rates in *Lotus*, but not in tomato (Gouws et al., 2012). Taken together, these findings show that bacteria are capable of producing various organic molecules that alter plant development. From the recent discoveries of active bacterial metabolites, it has become clear that apart from the classical phytohormones (e.g., auxins, cytokinins, gibberellins, and abscisic acid), additional signaling molecules exist that influence plant development. Although Phillips et al. (1999) attributed the enhanced plant growth from lumichrome application to an increased net C assimilation via PEP carboxylase activity, the dramatic expansion in unifoliate and trifoliate leaves and the increased stem elongation observed with lumichrome application to cowpea and soybean would seem to suggest that this molecule stimulates plant growth via cell division and cell expansion, as happens with classical phytohormones

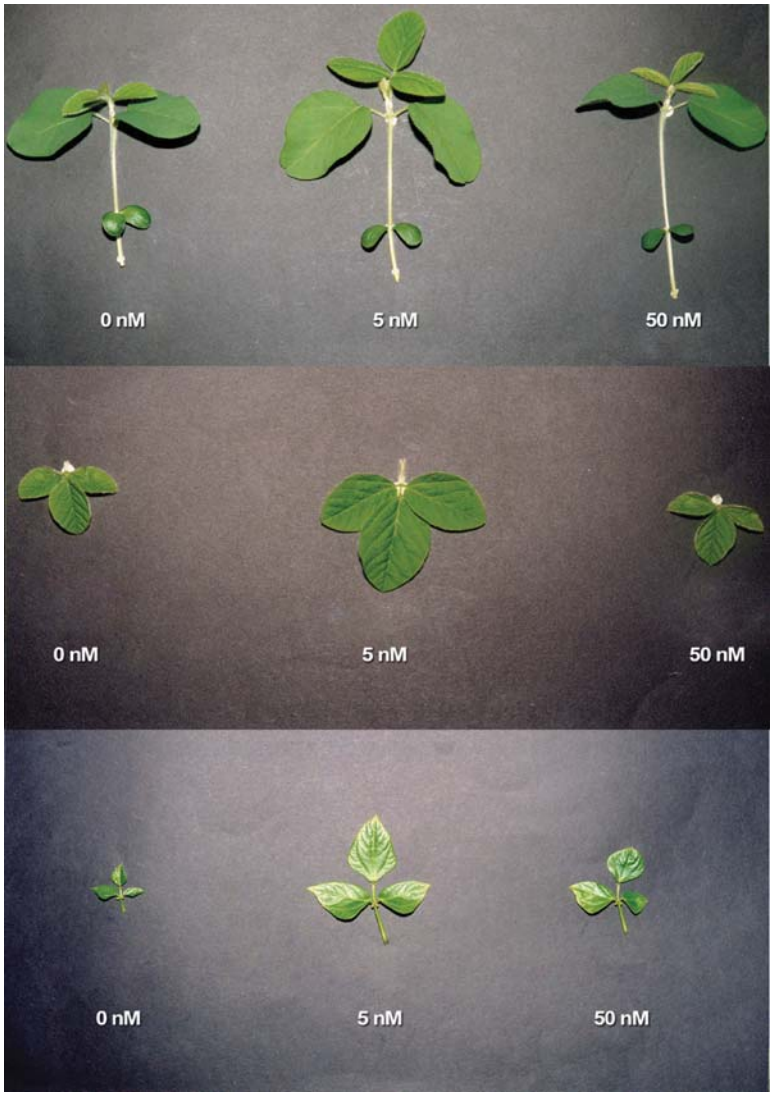

Figure 38.2 Lumichrome-induced changes in (a) stem elongation and trifoliate leaf development in soybean seedlings, (b) first trifoliate leaf initiation and expansion in soybean seedlings, and (c) first trifoliate leaf initiation and expansion in cowpea seedlings. (Letham et al., 1978; Ross et al., 2002; Campanoni et al., 2003; van der Graaff et al., 2003).

38.4 EFFECT OF LUMICHROME ON PLANT GROWTH AND PRODUCTIVITY

The increase in stem elongation, early initiation, and rapid expansion of trifoliate leaves observed with the application of 5 nM lumichrome to cowpea and soybean plants results in a twofold accumulation of dry matter in trifoliate leaves relative to the zero-lumichrome control (Matiru and Dakora, 2005b). In addition to legumes, lumichrome could also stimulate seedling development in cereal crops such as millet, sorghum, and maize. As a result, whole-plant dry matter yield of these cereal species receiving 5 nM lumichrome is greater compared to control (Matiru and Dakora, 2005b). At 5 nM lumichrome supply, root growth is much greater in the cereals (especially in millet and sorghum) than the legumes, suggesting that, in the former, lumichrome application alters assimilate partitioning in favor of root development. Gouws et al. (2012) also observed an increase in dry matter accumulation following lumichrome application to *Lotus* and tomato. The observed plant growth promotion by lumichrome in both monocots and dicots suggests that cereals could potentially benefit from lumichrome released by symbiotic rhizobia, in addition to N-fixed in cropping systems. Its growth-promoting effect on both monocots and dicots also suggests that lumichrome is capable of influencing plant rhizospheres in both natural and agricultural settings.

Foliar application of lumichrome at 10^{-6} M concentration significantly increases shoot and total dry matter yield of field-grown soybean plants (Khan et al., 2008). The increased accumulation of dry matter is partly due to a marked increase

in leaf area with lumichrome application (Khan et al., 2008). As found with cowpea and soybean (Matiru and Dakora, 2005a), the observed increase in plant growth and Fe uptake following sorghum inoculation with infective rhizobia (Matiru and Dakora, 2004) could be attributed to lumichrome secreted by the introduced bacterial cells.

38.5 EFFECT OF ENVIRONMENTAL FACTORS ON THE SYNTHESIS AND RELEASE OF LUMICHROME BY RHIZOBIA AND NODULE ENDOPHYTES

There are many factors affecting the production and release of metabolites by soil bacteria. For example, the synthesis and extracellular release of lumichrome, riboflavin, and indole acetic acid by rhizobia have been found to differ between and among species and strains (Kanu et al., 2007). In some studies, there is generally greater production of lumichrome, riboflavin, and indole acetic acid by N_2-fixing bacteria than those unable to nodulate *Psoralea pinnata* and sirato (Shokri and Emtiazi, 2010; Kanu and Dakora, 2012), a finding consistent with their role in symbiotic N_2 fixation (Phillips et al., 1999; Lambrecht et al., 2000; Matiru and Dakora, 2005a,b). For example, N_2-fixing strain TUT57pp produces 2.2-fold and 3.2-fold more indole acetic acid than the nonnodulating isolates TUT65prp and TUT33pap, respectively (Kanu and Dakora, 2012). Kanu and Dakora (2009) found that bacterial isolates from *Psoralea* nodules obtained from the Cape fynbos differ in their levels of secretion of lumichrome, riboflavin, and indole acetic acid, as well as in their exudation response to pH, salinity, and temperature. For example, while bacterial isolate AS2 from *Psoralea* nodules can produce greater amounts of lumichrome at both pH 5.1 and 8.1, strains RT1 and P1 secrete more lumichrome per cell at only pH 8.1. Strains AP1 and RP2 have also been found to produce more riboflavin at pH 8.1 than at pH 5.1; conversely strain RT1 produces greater amounts of riboflavin at pH 8.1 than at pH 5.1. Taken together, measured levels of lumichrome and riboflavin secreted by *Psoralea* bacterial isolates range from 0.1 to 15 nM (Kanu and Dakora, 2012).

Furthermore, two *P. repens* strains (RP1 and RP2] isolated from a very saline environment close to the Indian Ocean secrete large amounts of lumichrome and riboflavin at both low-salinity and high-salinity levels (Kanu and Dakora, 2009). Although the concentration of indole acetic acid produced by *Psoralea* isolates is greater at high acidity and high temperatures, with lumichrome the levels are much elevated at lower temperature (10 °C) than at high temperature (30 °C) (Kanu and Dakora, 2009). The greater lumichrome production at lower temperature is not surprising as Nod factors produced by *Bradyrhizobium aspalati* (now *Burkholderia tuberum*) isolated from *Aspalathus canosa* in the Cape fynbos have been found to be similar at 12 °C and 28 °C (Boone et al., 1999). This can be explained by the fact that legume nodulation in the Cape occurs with the winter rains when temperatures are around 10–15 °C. As found with salinity, plants and their associated microbial endophytes of the Cape fynbos seem metabolically adapted to the low winter temperatures.

Although we know the effect of N and P nutrition on Nod factor production in symbiotic rhizobia (McKay and Djordjevic, 1993; see Chapter 46), little information currently exists on the effects of these nutrients on the biosynthesis of other symbiotically important metabolites such as lumichrome, riboflavin, and indole acetic acid. A recent study has found marked variation in the secretion of lumichrome, riboflavin, and indole acetic acid by nodulating and nonnodulating bacteria isolated from *Psoralea* species (Shokri and Emtiazi, 2010; Kanu and Dakora, 2012). In another study (Kanu and Dakora, 2012), we have found much greater concentrations of lumichrome and riboflavin in exudates of five N_2-fixing and 11 nonnodulating bacterial strains grown at high P [5.7 mM] than at low P [1.4 mM]. The five N_2-fixing strains also differ in their levels of extracellular lumichrome secretion, with TUT23prt releasing the most lumichrome at both low P and high P, and TUT18pac the least.

Ammonium nutrition [28.1 mM or 112.0 mM NH_4^+] has no effect on the riboflavin synthesis and release (Kanu and Dakora, 2012), a finding consistent with the lack of response of Nod factor secretion to ammonium supply (McKay and Djordjevic, 1993).

However, lumichrome production is markedly affected by ammonium nutrition (Kanu and Dakora, 2012). Although some strains produce more or less lumichrome with ammonium supply, strains TUT23prt and TUT33pap can produce significant amount of lumichrome at both low and high ammonium concentrations (Kanu and Dakora, 2012). The level of lumichrome and riboflavin production by the test isolates from *Psoralea* species differs with nitrate nutrition. Feeding these strains with 59.3 mM nitrate results in significantly decreased concentration of lumichrome and riboflavin in cellular exudates, indicating an inhibitory effect of nitrate on the synthesis and release of the two metabolites. In fact, the levels of lumichrome in cell culture are decreased by high nitrate concentration for all the isolates. A similar decrease in Nod factor production has been observed by McKay and Djordjevic (1993), following nitrate supply to *Rhizobium leguminosarum* bv. *trifolii*. In the study by Kanu and Dakora (2012), it is interesting to note that the isolates, which showed the least production of riboflavin at high nitrate [e.g., TUT10pm and TUT13pac], are also among the least in lumichrome production at high nitrate. More importantly, however, the observed nitrate inhibition of lumichrome and riboflavin biosynthesis/release is in

addition to its known depressive effect on nodulation and N_2 fixation in symbiotic legumes (Streeter, 1988; Ayisi et al., 2000).

The observed variation in the secretion of lumichrome, riboflavin, and indole acetic acid by *Psoralea* root nodule isolates either exposed to different pH, salinity, and temperature regimes, or fed different levels of P, nitrate, and ammonium, suggests that genes encoding these metabolites are regulated differently by the imposed environmental factors (Kanu and Dakora, 2012). The data further suggest that natural changes in pH, salinity, and/or temperature in plant rhizospheres could potentially elevate the concentrations of lumichrome, riboflavin, and indole acetic acid in soils, with consequences for ecosystem functioning as both lumichrome and riboflavin have been reported to act as developmental signals that affect species in all three plant, animal, and microbial kingdoms.

38.6 ECOLOGICAL SIGNIFICANCE OF RHIZOBIAL EXUDATION OF LUMICHROME AND RIBOFLAVIN IN THE RHIZOSPHERE

In both natural and agricultural ecosystems, low or high production of lumichrome and riboflavin could have ecological consequences. For example, an increase in root respiration induced by lumichrome and riboflavin from root-colonizing rhizobia would lead to an elevated concentration of rhizosphere CO_2, which is needed for growth of rhizobial populations in soil (Lowe and Evans, 1962). Rhizobia and nodule endophytes isolated from eight *Psoralea* species (namely, *Psoralea pinnata*, *P. aphylla, P. aculeata*, *P. monophylla*, *P. repens, P. laxa*, *P. asarina*, and *P. restioides*) exhibit marked differences in the exudation of lumichrome, riboflavin, and indole acetic acid (Kanu and Dakora, 2009, 2012), three symbiotic signal molecules needed in bacteria–plant interactions (Phillips et al., 1999; Lambrecht et al., 2000; Matiru and Dakora, 2005a,b). Because the bacteria were isolated from different locations (e.g., Arabella Country Estate, Kleinmond, Betty's Bay, Rock Dam Valley, Kogelberg Nature Reserve, and Rooiles Nature Reserve) with differing soil conditions (e.g., wetland, upland), it is possible that their levels of metabolite secretion could be an adaptation to the local niche. As a result of their adaptation to the saline conditions of the beach, two *P. repens* strains isolated close to the ocean can secrete large amounts of lumichrome and riboflavin at both low and high salinities (Kanu and Dakora, 2009). Similarly, *Psoralea* isolates adapted to the acidic soils of the fynbos can produce greater amounts of indole acetic acid for symbiotic functioning even under very low pH conditions.

Furthermore, the increase in rhizosphere CO_2 concentration from lumichrome and riboflavin can stimulate growth of vesicular-arbuscular fungi (Becard and Piche, 1989; Becard et al., 1992) and increase the incidence of mycorrhizal symbiosis. These indirect benefits of lumichrome and riboflavin to legume symbioses via their effects on the plant are essential to enhance N and P nutrition. Also, the mere fact that most root-colonizing bacteria commonly produce and release lumichrome and riboflavin (Phillips et al., 1999), and some bacteria also produce eight times more extracellular riboflavin in exudates relative to internal cellular concentration suggesting that these molecules have evolved directly or indirectly as rhizosphere signals influencing outcomes of plant–bacterial interactions. The data further suggest that natural changes in pH, salinity, and/or temperature in plant rhizospheres could potentially elevate the concentrations of lumichrome, riboflavin, and indole acetic acid in soils, with consequences for ecosystem functioning as both lumichrome and riboflavin have been reported to act as developmental signals that affect species in all three plant, animal, and microbial kingdoms. The higher lumichrome production at lower temperature (10 °C) than at high temperature (30 °C) (Kanu and Dakora, 2009) has also ecological consequences for nodulation and N_2 fixation of *Psoralea* species in their Mediterranean fynbos habitat where winter rains support legume plant growth and symbiotic performance.

38.7 CONCLUSION

Bacterial exudation of the rhizosphere signals, lumichrome and riboflavin, can vary with rhizobial strain, soil temperature, and pH. Lumichrome taken up by plant roots and transported to the shoot probably elicits cell division, cell expansion, and cell extensibility, leading to an increased leaf expansion and stem elongation. A direct correlation exists between plant response to rhizobial inoculation and root application of lumichrome with respect to stomatal function. Both treatments consistently increase or decrease stomatal conductance and transpiration rates in responsive test species. Plant roots seem to be capable of collecting environmental signals from soil in the form of simple organic molecules released by microbes, and using them to adapt to their environment, for example, for drought tolerance when these molecules cause decreased stomatal conductance and consequently reduced water loss.

Chapter 39

Genes Involved in Desiccation Resistance of Rhizobia and Other Bacteria

Jodi L. Humann

39.1 INTRODUCTION

Rhizobia are Gram-negative, soil Alphaproteobacteria that are able to grow as free-living bacteria and can also form nitrogen-fixing, symbiotic relationships with legumes by inducing the formation of nodules on the roots of the plants. In these nodules, the bacteria convert dinitrogen gas from the atmosphere into ammonia, a form of nitrogen that can be used by the plant. To support this, the plant supplies the bacteria with carbon sources that are catabolized to provide the energy and reductant needed for nitrogen fixation (White et al., 2007). Formation of a nodule occurs after rhizobia in the soil infect the emerging root hairs of the plant. To survive when not in a symbiotic relationship, rhizobia must be able to cope with the conditions found in the soil or rhizosphere, including suboptimal pH and low water potential. Resistance to desiccation is not only an important phenotype for "wild" rhizobia living in the soil, but is also important in preparing rhizobia to be used as supplementary inocula in agricultural applications. Some rhizobia strains, such as *S. meliloti* Rm1021, are relatively desiccation resistant. After 2 months, 33% of Rm1021 cells were still viable after drying and subsequent rehydration (Humann et al., 2009). For other strains, such as *R. leguminosarum* 3841, only 37% of the cells are still viable after 16 h of drying (Gilbert et al., 2007). Figure 39.1 shows the differences in desiccation tolerance of four *S. meliloti* strains (J. L. Humann and M. L. Kahn, unpublished data). *S. meliloti* 2011 (Meade and Signer, 1977) and Rm104A14 (Somerville and Kahn, 1983) were much more desiccation resistant than Rm1021 (Meade et al., 1982) or its *expR*$^+$ derivative SM8530 (Pellock et al., 2002). Differences in desiccation tolerance among *B. japonicum* strains have also been observed (Osa-Afiana and Alexander, 1982b). Spore or cyst formation by rhizobia has not been observed (Jensen, 1961), suggesting that rhizobia have alternate adaptive mechanisms for surviving harsh environmental conditions. Vriezen et al. (2012; see Chapter 96) determined that during long periods of desiccation, a large portion of a *S. meliloti* 1021 cell population was viable but not culturable. The cells were intact, but did not form colonies when cultured. Desiccation research in rhizobia and other bacteria is starting to provide clues to the genes and pathways involved in desiccation resistance.

39.2 DESICCATION OF RHIZOBIA

Most of the early research on rhizobial desiccation resistance was physiologically based and was primarily directed at improving inocula and thus focused on what environmental factors and carrier materials could improve the survival of rhizobia prepared for agricultural applications (Bushby and Marshall, 1977; Chao and Alexander, 1982; Chao and Alexander, 1984; Kosanke et al., 1992; Osa-Afiana and

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

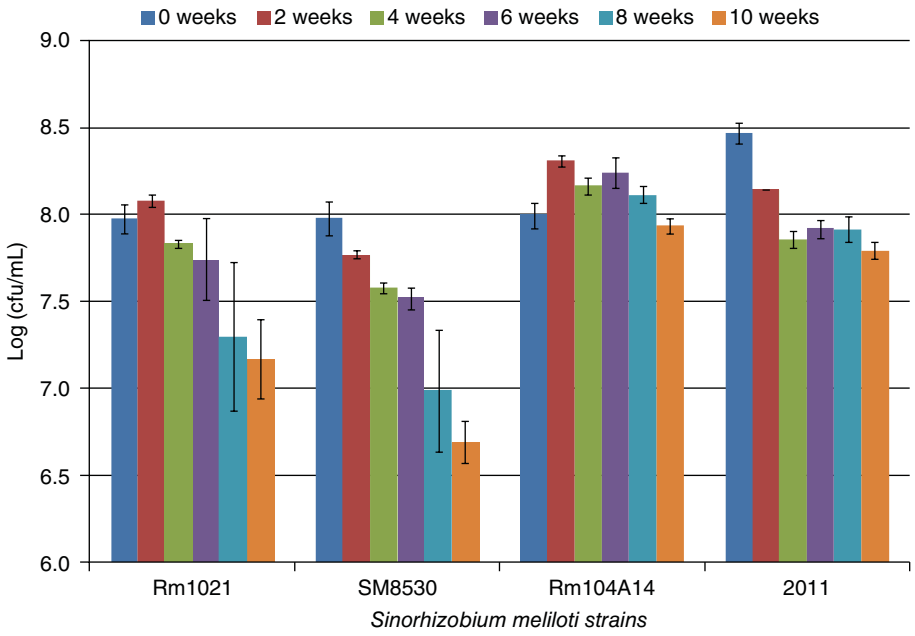

Figure 39.1 Survival of *Sinorhizobium meliloti* strains Rm1021, SM8530, Rm104a14, and 2011 to desiccation. The number of viable cells that survived desiccation was measured at 2 week intervals. Rm1021 and SM8530 had significant loss of viability, while Rm104a14 and 2011 showed less sensitivity to desiccation.

Alexander, 1982a; Vincent et al., 1962). Peat is the most common carrier for rhizobia inocula, but various materials have been used as carriers including coconut shells, charcoal, manure, and wheat straw (Chao and Alexander, 1984). Bushby and Marshall (1977) found that amending the soil with montmorillonite, maltose, sucrose, polyvinylpyrrolidone, or polyethylene glycol increased the survival rate of rhizobia under desiccating conditions. The effect of relative humidity on the desiccation tolerance of *Sinorhizobium meliloti* and *Bradyrhizobium japonicum* strains has been well documented (Mary et al., 1985; Mary et al., 1994). Although higher relative humidity is best for survival of rhizobia, if drying occurs at a slow pace the survival rate of rhizobia is higher than with rapid drying. Studies by Boumahdi et al. (1999; 2001) observed changes in cellular fatty acids during desiccation of *Sinorhizobium* and *Bradyrhizobium*. Short-chain fatty acids increased under reduced water activity and mild desiccation conditions. Vriezen et al. (2006) examined the effect of various physiological and physical conditions on the survival of *S. meliloti* during desiccation. They found that cells dried during the exponential growth phase had a lower survival rate than cells in a stationary growth phase at the time desiccation stress was initiated. Drying *S. meliloti* at temperatures above 37 °C also decreased the survival rate as did drying the cells on alfalfa seeds instead of on nitrocellulose or sand (Vriezen et al., 2006; Vriezen et al., 2012; see Chapter 96). Many factors affect the desiccation tolerance of rhizobia, and these factors make it difficult to replicate the natural desiccating conditions and the resulting bacterial response in the laboratory.

The goal of desiccation tolerance research is to determine how vegetative cells that are dried to a point where all biological processes have stopped survive extended periods of desiccation, and how the biological consequences of desiccation are resolved as the bacteria rehydrate. The desiccation process and response in prokaryotes has been reviewed in great detail (Billi and Potts, 2002; Potts, 1994; Potts, 2013). There are three stages of the desiccation process (Potts, 2013; Vriezen et al., 2007). Stage I is the drying of the cells, which results in the loss of water and the accumulation of salts and solutes and leads to osmotic and mechanical stress. Metabolic processes are also slowed and eventually stop due to lack of water. The lack of water may also contribute to increased DNA damage since the enzymes that would usually repair DNA and proteins are slowed or stopped. Stage II is the storage phase where the cells have lost all water and are just waiting to be rehydrated. Stage II is usually where the decline of cell viability occurs. The final step, stage III, is the rehydration of the cells. During this phase, bacterial metabolism is revived and enzymes repair the cell damage.

39.3 DESICCATION RESISTANCE GENES IN NONRHIZOBIA

Sensitivity to desiccation is a very common problem for bacteria, especially those that do not form spores. It is not clear whether similar or homologous mechanisms and genes are used to resist desiccation, but by examining all the available data common trends can be seen. DNA damage is an early effect of desiccation stress and two common types of DNA damage have been observed in desiccated bacterial cells: covalent modification and double-stranded breaks. After decades of desiccation, the DNA of the cyanobacteria *Nostoc commune* was covalently modified and formed

insoluble aggregates, but upon further examination the DNA was not degraded and did not exhibit signs of increased oxidative damage (Shirkey et al., 2003). Double-stranded DNA (dsDNA) breaks, which are very detrimental to the survival of bacteria, have been observed in desiccated cells of *Escherichia coli* (Asada et al., 1979), *Mycobacterium smegmatis* (Pitcher et al., 2007), and *Deinococcus radiodurans* (Dose et al., 1991; Mattimore and Battista, 1996).

The observation of DNA modification and damage in desiccated bacterial cells led to the identification of DNA repair genes that are involved in desiccation resistance from a variety of bacterial species. In *M. smegmatis*, deletion mutants lacking *ku* and *ligD*, the genes needed for bacterial nonhomologous end-joining DNA repair, exhibited increased sensitivity to desiccation (Pitcher et al., 2007). Desiccation-induced DNA damage has been studied in more detail in *D. radiodurans*, which is extremely resistant to ionizing radiation. The mechanisms needed for radioresistance and desiccation resistance somewhat overlap in this bacterium. Mattimore and Battista (1996) demonstrated that the longer wild-type *D. radiodurans* cells were dried, the more dsDNA breaks accumulated. A microarray study in *D. radiodurans* identified 32 upregulated genes that were induced in cultures recovering from desiccation or from ionizing radiation (Tanaka et al., 2004). Among these genes were common DNA repair genes such as *recA*, *ruvB*, *uvrA*, and *uvrB*. However, five other genes were the most highly expressed. Two of the genes (*ddrA* and *pprA*) encode DNA repair functions, *ddrB* encodes a single-stranded DNA-binding protein, and the remaining three genes (*ddrB*, *ddrC*, and *ddrD*) encode for proteins of unknown function (Harris et al., 2004; Narumi et al., 2004; Norais et al., 2009; Tanaka et al., 2004). RecA was also found to contribute to desiccation resistance in *Acinetobacter baumannii* (Aranda et al., 2011).

Regulatory and stress response genes, in addition to genes for biosynthesis of osmoprotectants and protein degradation, have also been implicated as having a role in desiccation resistance. Genes involved in stress response regulation (*sigB*) and protein degradation (*clpX* and *yjbH*) were found to have a role in desiccation resistance of *Staphylococcus aureus* (Chaibenjawong and Foster, 2011). In *Methylobacterium extorquens* AM1, PhyR is essential for plant surface colonization and is a response regulator that regulates several stress responses. A *phyR* deletion mutant was more sensitive to desiccation than the wild-type strain (Gourion et al., 2008). A transcriptomic analysis (LeBlanc et al., 2008) of desiccated *Rhodococcus jostii* RHA1 cells identified 406 genes that were upregulated during desiccating conditions (20% vs 100% RH). Among the mostly highly expressed transcripts were genes encoding stress response sigma factors (*sigF1*, *sigF2*), proteins that protect DNA during starvation (*dps1*, *dps2*) and two proteins in the ectoine biosynthesis pathway (*ectA*, *ectC*). Ectoine is a compound that helps bacteria survive osmotic stress by acting as an osmolyte. Trehalose production was linked to increased desiccation resistance in *E. coli* found in the soil (Zhang and Yan, 2012). Trehalose is an alpha-linked disaccharide that has a large capacity to retain water, which makes it a good compound to have around during desiccating conditions. In nonrhizobia, genes involved in DNA repair and protein degradation as well as genes that encode regulatory proteins and produce osmoprotectants have a role in desiccation resistance.

39.4 DESICCATION RESISTANCE GENES IN RHIZOBIA

Similar to other bacteria, the identified desiccation resistance genes in rhizobia also encode proteins involved in DNA repair, stress response, and osmoprotection. Studies have ranged from looking at the global response to desiccation via microarray experiments to looking at the effect of mutating specific genes on survival to dessication. A microarray study in *Bradyrhizobium japonicum* USDA 110 measured gene induction under desiccation stress (Cytryn et al., 2007). In *B. japonicum*, 225 genes were induced during all periods of desiccation, with an additional 446 genes induced during longer periods of desiccation. Genes that were induced during desiccation were diverse, but included genes involved in trehalose synthesis, EPS formation, sigma factors, oxidative and heat stress response systems, and DNA repair and modification.

One DNA repair system has been found to have a role in desiccation resistance of *S. meliloti*, and several others do not appear to affect viability. *S. meliloti* Rm1021 deletion mutants with lesions in the *uvrA*, *uvrB*, and *uvrC* genes were desiccation sensitive (Humann et al., 2009). These genes encode the nucleotide excision repair (NER) pathway, which targets lesions that distort the DNA helix, such as UV-induced cyclobutane pyrimidine dimers (CPDs) and 6,4-photoproducts, or bulky adducts caused by the reaction of DNA with various chemicals such as 4-NQO (Van Houten, 1990; Van Houten et al., 2005). While it has not been shown directly, it is reasonable to propose that *S. meliloti uvrA*, *uvrB*, and *uvrC* mutants cannot repair large, desiccation-induced DNA adducts and the accumulation of these is fatal. Although this desiccation-induced DNA damage is proposed to be recognized by the NER pathway, the exact nature of the DNA lesions is unknown. DNA from desiccated *S. meliloti* strains (wild-type and *uvr* mutants) was tested with CPD-specific antibodies (Gillette et al., 2001), and it was shown that these lesions were not present in the DNA of dried *S. meliloti* (J. L. Humann and M. L. Kahn, unpublished data). This is not surprising since CPDs and 6,4-photoproducts are typically generated by exposure of DNA to UV light, not desiccation. Deletion mutants

lacking *addAB*, *aidB*, *mutL*, *mutY*, *recA*, *ruvB*, *uvrD1*, or *uvrD2* were screened for desiccation sensitivity, and all the mutants had survival curves similar to that of the wild-type parent (J. L. Humann and M. L. Kahn, unpublished data). These data suggest that the *uvrABC* genes have a specific role in desiccation resistance, and that not all DNA repair mechanisms contribute to this type of cell durability.

Genes involved in cell membrane structure and exopolysaccharide (EPS) production have been identified as having a role in desiccation resistance in rhizobia. CtpA is a periplasmic protease that degrades misfolded periplasmic proteins, and a *ctpA* mutant in *Rhizobium leguminosarum* biovar *viciae* 3841 was 21 times more sensitive to desiccation than the wild type (Gilbert et al., 2007). The accumulation of defective proteins in the *R. leguminosarum ctpA* mutant cell envelope resulted in increased sensitivity to desiccation. Lipopolysaccharide (LPS) synthesis gene (*fabF1*, *fabF2*) mutants of *R. leguminosarum* biovar *viciae* 3841, which have modified very long-chain fatty acids, were impaired in the ability of the mutants to withstand desiccation (Vanderlinde et al., 2009). The EPS composition of the cell membranes also has an effect on desiccation resistance. In *Rhizobium sullae*, the production of high molecular weight EPS led to higher desiccation tolerance (Gharzouli et al., 2013). High molecular weight EPS compounds are very viscous and provide good osmoprotection. The importance of EPS was also observed in a desiccation-sensitive transposon mutant of *R. leguminosarum* biovar *viciae* 3841 (Vanderlinde et al., 2010). The transposon insertion was located in an ATP-binding protein that was part of an ATP-binding cassette transporter operon. The inactivation of the protein resulted in decreased EPS export and increased desiccation sensitivity.

In rhizobia, genes that encode stress response regulatory proteins have a role in desiccation resistance, but the exact role is harder to define. An *S. meliloti* Rm1021 transposon mutant with increased desiccation sensitivity had an insertion in the *relA* gene (Humann et al., 2009). RelA, a guanosine tetraphosphate synthetase and hydrolase, induces the stringent response during amino acid starvation (Wells and Long, 2002). In a *relA* mutant, the stringent response is not activated, and as a result the cell does not adjust to starvation quickly by downregulating protein synthesis and therefore depletes cellular metabolite pools more rapidly (Jensen and Pederson, 1990). In the case of desiccation, the lack of RelA activity appears to keep the cell from switching effectively to a "survival mode." A *relA* mutant of *Rhizobium etli* was also found to have decreased survival after heat shock, salt stress, or exposure to hydrogen peroxide (Braeken et al., 2008), further supporting the role of RelA in stress responses. A mutant in the *hpr* gene of *S. meliloti* also resulted in increased sensitivity to desiccation (Humann et al., 2009). HPr is a regulator of succinate-mediated catabolite repression (SCMR) in *S. meliloti* (Arango Pinedo et al., 2008). An *hpr* mutant in *S. meliloti* Rm1021 had altered carbon catabolism, lower survival in stationary phase, and early production of low molecular weight succinoglycan. Some or all of these physiological changes may contribute to decreased desiccation resistance. The homolog of *S. meliloti hpr* in *B. japonicum*, *ptsH*, is upregulated during desiccation, indicating that *hpr* may be involved in the drying stage of desiccation (Cytryn et al., 2007). Because these regulatory proteins affect so many different pathways, stress responses, and genes, it is hard to identify the exact role they play in desiccation resistance.

It is logical that stress response sigma factors would have a role in desiccation resistance. The *S. meliloti rpoE2* gene, which encodes a sigma factor that regulates extracytoplasmic function, is upregulated during salt stress, entry into stationary phase after carbon or nitrogen starvation, and heat shock (Sauviac et al., 2007; see Chapter 40). In addition, genes induced during desiccation in *B. japonicum* USDA 110 include an *rpoE* gene (Cytryn et al., 2007). The homolog of RpoE2 of *B. japonicum* USDA 110, *ecfG*, is also involved in heat shock and desiccation resistance during carbon starvation (Gourion et al., 2009). A *rpoE2* transposon mutant in *S. meliloti* Rm1021 was found to be sensitive to desiccation (Humann et al., 2009). The *M. extorquens* AM1 *phyR* gene described earlier is also involved in desiccation resistance of rhizobia. In *B. japonicum*, a *phyR* mutant had increased sensitivity to desiccation along with defects in nodulation and nitrogen fixation (Gourion et al., 2009). The *S. meliloti* Rm1021 *phyR* homolog is known as *rsiB1*. RsiB1 is an anti-anti-sigma factor that actually allows for the expression of *rpoE2* during stress conditions such as heat-shock and stationary phase (Bastiat et al., 2010; see Chapter 40). An *S. meliloti* Rm1021 *rsiB1* deletion mutant was more sensitive to desiccation than the wild type, indicating that the lack of *rpoE2* expression due to the *rsiB1* mutation is similar to having an *rpoE2* mutation (J. L. Humann and M. L. Kahn, unpublished data). The RpoE2 sigma factor has also been linked to trehalose accumulation, which has been implicated in desiccation resistance of rhizobia. An *otsA* (trehalose-6-phosphate synthase) and *treY* (maltooligosyltrehalose synthase) double mutant of *R. leguminosarum* bv. *trifolii*, which did not accumulate trehalose, exhibited increased sensitivity to drying (McIntyre et al., 2007). In *S. meliloti*, *otsA* expression is induced by the stress response sigma factor RpoE2 (Flechard et al., 2010). As a result, the desiccation-sensitive phenotype of the *S. meliloti rpoE2* mutant (Humann et al., 2009) may be related to a lack of trehalose synthesis and accumulation. As with the RelA and Hpr, the role that RpoE2 plays in desiccation resistance is potentially complicated because these proteins regulate various physiological processes that could act in desiccation resistance.

Table 39.1 Genes that contribute to desiccation resistance in bacteria as determined by mutation or deletion

Cellular Process	Genus and Species	Gene Name or ID	Function	Reference
DNA repair	*Mycobacterium smegmatis*	*ku*	Nonhomologous end-joining repair	Pitcher et al. (2007)
	Mycobacterium smegmatis	*ligD*	Nonhomologous end-joining repair	Pitcher et al. (2007)

Osmoprotectant production	*Rhizobium leguminosarum*	*otsA*	Trehalose accumulation	McIntyre et al. (2007)
	Rhizobium leguminosarum	*treY*	Trehalose accumulation	McIntyre et al. (2007)

39.5 SUMMARY

Desiccation tolerance by bacteria is a multifaceted process that involves DNA repair, stress response induction, membrane structure, and the production of osmoprotectant compounds. Table 39.1 summarizes all the genes that have been confirmed by mutation or deletion to be involved in bacterial desiccation resistance. This table does not include the hundreds of genes that were upregulated or downregulated in microarray studies of desiccated bacterial cells. Desiccation tolerance and the cellular processes that are involved appear to have similarities among all bacteria. While desiccation-induced DNA damage has been extensively studied in *D. radiodurans* (Mattimore and Battista, 1996; Tanaka et al., 2004) and numerous DNA repair genes have been identified, there appears to be some differences in the DNA repair genes that are involved in desiccation. Although RecA is needed for desiccation resistance in *M. smegmatis* (Pitcher et al., 2007), a *recA* mutant in *S. meliloti* was not more sensitive to desiccation (J. L. Humann and M. L. Kahn, unpublished data). The question also remains about what type of desiccation-induced DNA damage the NER pathway repairs in *S. meliloti*. A role for the stress-response sigma factors and sigma factor regulators in desiccation resistance has been observed in rhizobia (see Chapter 40) as well as in *M. extorquens* (Gourion et al., 2008) and *S. aureus* (Chaibenjawong and Foster, 2011). However, since hundreds of genes can be regulated by a sigma factor, these mutations are not very specific in identifying specific processes that contribute to desiccation resistance. It is very clear that there is not just one operon or biological process that contributes to desiccation resistance, and instead a number of genes deal with different aspects of changes caused by the lack of water and ultimately of normal metabolic activity (see also Chapter 96).

The different levels of desiccation resistance within the same species of rhizobia or between different genera of rhizobia raise interesting questions about how the life history of these bacteria might differ. The differences are also important for the agricultural application of rhizobial inocula. If all rhizobia were highly tolerant to desiccation, their use as inocula for legume crops would be more cost effective and biologically effective. Are the differences due to expression levels of the genes identified in Table 39.1? Or is it because some rhizobia lack certain genes that are involved in desiccation resistance? Experiments looking for the presence and absence of genes or at differences in gene expression levels during desiccation challenges among the rhizobia might provide clues about how to engineer rhizobia to be more desiccation resistant and therefore more suitable for agricultural applications.

40.1 INTRODUCTION

Bacteria are exposed to constantly changing environmental conditions in nature, which can be stressful and limit their growth, or even lead to cell death. Bacteria have therefore evolved adaptation responses that make them able to cope with these fluctuations. Some of the responses function by eliminating the inducing stress and/or repairing the associated cell damages. In parallel to these stress-specific responses, a so-called general stress response is activated under many different stress or starvation conditions, resulting in a number of morphological, physiological, and metabolic changes that confer multiple stress resistance to the cells. Essential features of this response include cross-protection and prevention, since bacteria exposed to one particular stress become resistant not only to this inducing stress but also to other stresses that they have not experienced yet. The general stress response therefore appears as both short- and long-term adaptation responses, particularly in the absence of growth, a prevailing situation in nature where nutrients are often limiting (Hengge, 2011). Studies on model bacteria have revealed that the general stress response mainly relies on a global reorganization of gene expression, in which sigma factors play a central role. Sigma factors are dissociable subunits of the RNA polymerase that confer the specificity of gene promoter recognition. In bacteria growing actively without stress, the vegetative sigma factor is responsible for the transcription of housekeeping genes. Under stress conditions, various signals and mechanisms make new sigma factors available for interacting with the core RNA polymerase, thus allowing the holoenzyme to recognize new promoters and express new sets of genes (Sterberg et al., 2011). In *Bacillus subtilis* and other Gram-positive bacteria, the general stress response is controlled by σ^B (Hecker et al., 2007; Price, 2011), whereas in *Escherichia coli* and related γ-Proteobacteria, as well as several β- and δ-Proteobacteria, it is governed by σ^S (Battesti et al., 2011; Hengge, 2011). In all cases, activation of the sigma factors makes possible the expression of hundreds of new genes, some of which are involved in the acquisition of multiple stress resistance.

Rhizobia are soil bacteria that can enter a nitrogen-fixing symbiotic association with legume plants. In their natural environments, these bacteria are exposed to many stressful conditions that threaten their survival in the soil and, directly or indirectly, the efficiency of symbiotic nitrogen fixation. Among stresses that rhizobia can encounter in the soil are high and low temperatures, salinity, desiccation, low or high pH, as well as nutrient and oxygen deprivation (Zahran, 1999; van Veen et al., 1997). In plant tissues, bacteria are also exposed to oxidative and nitrosative stress conditions (Santos et al., 2001, Baudouin et al., 2006). A number of stress-specific responses have been described in rhizobia, leading to the identification of specific proteins and regulators involved in these responses (see for instance Meilhoc

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

et al., 2010; Jamet et al., 2005; Sagot et al., 2010; Minder et al., 2000). In contrast, until recently, much less was known about the general stress response and its regulation in these bacteria. Only a few of the known rhizobia (those belonging to the β-subclass of Proteobacteria) encode a σ^S homolog (Amadou et al., 2008), likely involved in the general stress response of these bacteria (although this has not been investigated so far). However, most of the known rhizobia are α-Proteobacteria (the so-called α-rhizobia), and none of the sequenced genomes of these bacteria encode a σ^S homolog. We review here the advances made in recent years in our understanding of the general stress response in α-rhizobia, its regulation, and its functions.

40.1.1 Evidence of the Existence of a General Stress Response in α-Rhizobia

Under laboratory conditions, the general stress response is activated when bacteria enter into the stationary phase. Thus, stationary-phase bacteria usually display a better resistance to multiple stresses as compared to exponentially growing bacteria. In *Rhizobium leguminosarum*, stationary-phase bacteria have been found to be more resistant than exponentially growing bacteria to heat, salt, oxidative, and acidic stresses (Thorne and Williams, 1997). Similarly, in *Sinorhizobium meliloti*, stationary phase bacteria have been found to be more resistant than exponentially growing bacteria to desiccation, oxidative, and heat stresses (Vriezen et al., 2006; see Chapter 96, Fléchard et al., 2009; Barra-Bily et al., 2010). In *Bradyrhizobium japonicum*, bacteria allowed to spend one night under carbon starvation have been found to be more heat resistant than bacteria challenged in the exponential phase of growth (Gourion et al., 2009). Taken together, these observations suggest that a general stress response of the same type as that described in other bacteria does indeed exist in certain rhizobia.

Another characteristic feature of the general stress response is its induction by diverse stress conditions. Pioneer studies aiming at the identification of genes upregulated under various conditions were first conducted on *S. meliloti* using reporter fusion libraries (Milcamps et al., 1998), but the most comprehensive studies have more recently been carried out using transcriptomic approaches. For instance, 60 *S. meliloti* genes have been found to be upregulated either after heat treatment or upon entry in stationary phase following carbon exhaustion from the culture medium (Sauviac et al., 2007). Expression of many of these genes has also been found to be induced under various other conditions, including microaerobiosis (Bobik et al., 2006; Becker et al., 2004), hyperosmotic conditions (Domínguez-Ferreras et al., 2006), and acidic pH (de Lucena et al., 2010), which suggests that they are part of the general stress response of this rhizobium species. Sauviac et al. (2007) noticed that one of these genes (*rpoE2*) encodes an extracytoplasmic function (ECF) sigma factor. RpoE2 turned out to be activated in these diverse conditions and to control the transcription of a large part of the "general stress response genes" identified (Sauviac et al., 2007). Interestingly, this sigma factor belongs to the ECF15 subgroup of ECF sigma factors (also called EcfG) specifically found in α-Proteobacteria where it is largely conserved, including in most α-rhizobia (Staroń et al., 2009). Subsequent studies conducted in some of these species (*Methylobacterium extorquens*, *Caulobacter crescentus*, *B. japonicum*, *Rhizobium etli*) have confirmed the involvement of EcfG sigma factors in the transcriptional control of large regulons in response to various external stresses (Alvarez-Martinez et al., 2007; Gourion et al., 2008; Gourion et al., 2009; Martínez-Salazar et al., 2009a; see Chapter 30 for a review see Francez-Charlot et al., 2011). In addition, in all these species, *ecfG* mutants have been found to be more sensitive than the wild-type strain to many stress conditions, including osmotic, oxidative, and thermic stresses (see later). Altogether, these observations indicate that EcfG sigma factors play the function of regulators of the general stress response and represent the long searched for functional analogs of the σ^S and σ^B described in model bacteria. In the following sections, we summarize the features of EcfG sigma factors, their regulation in response to stress, and the known functions of the response, with a special focus on α-rhizobia.

40.2 σ^{EcfG}, THE MAJOR REGULATOR OF THE GENERAL STRESS RESPONSE

40.2.1 The Basic σ^{EcfG} Transduction Cascade in α-Proteobacteria

A number of genetic, biochemical, and structural approaches have been conducted in various bacteria in order to decipher the signaling pathway of σ^{EcfG} activation in response to stress (Sauviac et al., 2007; Francez-Charlot et al., 2009; Gourion et al., 2009; Bastiat et al., 2010; Herrou et al., 2010; Lourenço et al., 2011; Kaczmarczyk et al., 2011; Herrou et al., 2012; Campagne et al., 2012; Sauviac and Bruand, submitted). The basic mechanism seems to be conserved in most α-Proteobacteria, with species-specific variations. It primarily involves three proteins: the sigma factor, an anti-sigma factor, and an anti-antisigma factor. All three components are almost always encoded by genes colocalized in the same genomic locus. The distribution and genomic organization of these genes in various α-rhizobia is shown in Figure 40.1.

The current model of σ^{EcfG} regulation is schematically depicted in Figure 40.2. In the absence of stress, the sigma factor is kept inactive by interaction with the anti-sigma

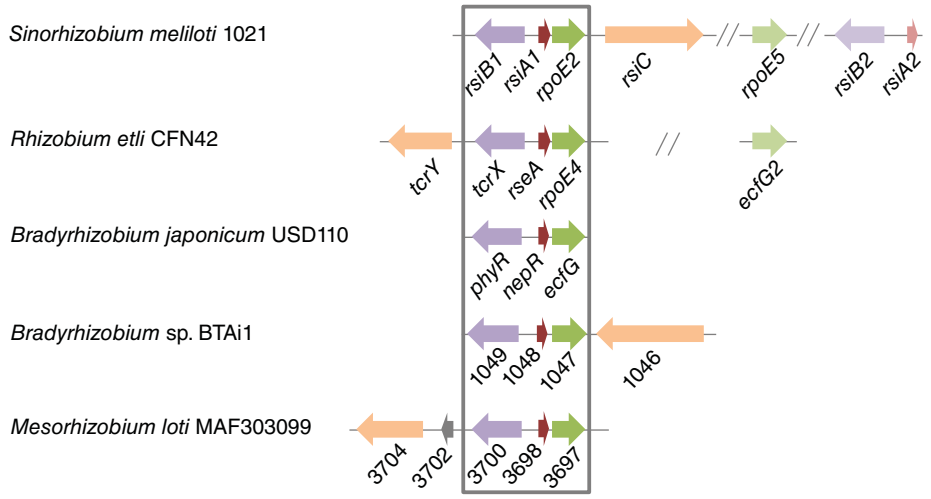

Figure 40.1 Genomic organization of genes known or supposed to be involved in the σ^{EcfG} transduction cascade in selected alpha-rhizobia. The conserved *ecfG* loci, encoding the main EcfG sigma factor (green), the anti-sigma (red), and the anti-antisigma (purple) are boxed in gray. Secondary genes encoding additional sigma, anti-sigma, or anti-antisigma factors are indicated when present, their genomic independency from the main locus being symbolized by //. Putative histidine kinases, when present in the vicinity of the conserved locus, are depicted in orange (note that only *S. meliloti* RsiC was shown to be involved in the control of the phosphorylation status of RsiB so far (Sauviac and Bruand, submitted)). A similar organization as in *S. meliloti* 1021 was found in other *S. meliloti* strains (AK83, 2011, BL225C, SM11, RM41, and GR4) and in *S. medicae* WSM419 and *S. fredii* (strains HH103, USDA277, and NGR234). A similar organization as in *R. etli* CFN42 was found in *R. etli* CIAT652, *R. tropici* CIAT899, *R. leguminosarum* bv. *viciae* 3841, and *R. leguminosarum* bv. *trifolii* (strains WSM1325 and WSM 2304), except that the latter three strains encode 0, 2, and 3 secondary *ecfG* genes, respectively. A similar organization as in *B. japonicum* USDA110 was found in *B. japonicum USDA6*. A similar organization as in *Bradyrhizobium* BTAi1 was found in *Bradyrhizobium* ORS278. A similar organization as in *M. loti* MAFF303099 was found in *M. ciceri* bv. biserrulae WSM1271, *M. australicum* WSM2073, and *M. opportunistum* WSM2075.

factor, called RsiA in *S. meliloti* or NepR in *B. japonicum* (see Chapter 30). This anti-sigma factor is a small (~60 amino acids) and seemingly soluble, cytoplasmic protein. Under stress conditions, a third protein, called RsiB or PhyR, respectively, becomes activated. RsiB/PhyR is an atypical response regulator of two-component regulatory systems, composed of two domains. The C-terminal domain carries a phosphor-receiver domain, with a conserved phosphorylatable aspartate residue, while the N-terminal domain shows homologies to ECF sigma factors. Upon stress exposure, the conserved aspartate residue of the receiver domain is phosphorylated, thus leading to a conformational change which releases the N-terminal domain. Because of its structural similarity with the sigma factor and its high affinity for the anti-sigma, this domain enters in competition for binding the anti-sigma, thereby releasing the sigma factor, which then becomes available for interacting with the core RNA polymerase and directing the transcription of its target genes. The sigma, anti-sigma, and anti-antisigma factor-encoding genes are all part of the σ^{EcfG} regulons, thus providing both positive- and negative-feedback regulatory loops to the system.

40.2.2 Signal Perception and Activation of the σ^{EcfG} Transduction Cascade

How PhyR/RsiB becomes phosphorylated under stress conditions is still not always completely clear. However, and not surprisingly, given the typical phosphor-receiver domain of the anti-antisigma, histidine kinases have been implicated in this reaction in *C. crescentus*, *Sphingomonas* sp. Fr1, and *S. meliloti* (Lourenço et al., 2011; Kaczmarczyk et al., 2011; Sauviac and Bruand, submitted). These proteins are encoded in the vicinity of their respective *ecfG* loci, but this organization is not always conserved, as seen, for example, in *B. japonicum* (see Fig. 40.1). These proteins are atypical in that they do not contain the usual domain of dimerization and histidine phosphotransfer found in classical histidine kinases, but instead harbor either a Pfam:HWE_HK or, less frequently, a Pfam:HisKA_2 domain (Staroń and Mascher, 2010). The proteins investigated so far were involved in controlling the phosphorylation status of RsiB/PhyR, through activation of their kinase activity and/or inhibition of their phosphatase activity in the presence of stress (Lourenço

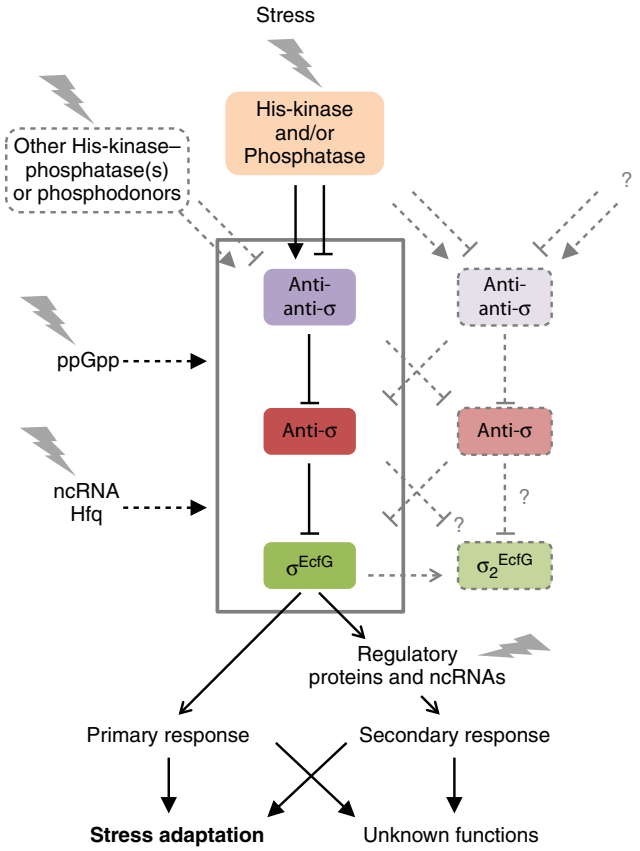

Figure 40.2 The σ^{EcfG} transduction cascade. The main conserved transduction cascade is boxed in gray, with the different proteins colored as their corresponding genes in Figure 40. 1. Arrows and T lines represent activations and inhibitions, respectively (open arrowheads: transcriptional activations, closed arrowheads: other types of activation). Possible variations of the cascade and other factors influencing the cascade are depicted as dotted arrows and proteins. Putative stress inputs are depicted as gray flashlights.

et al., 2011; Kaczmarczyk et al., 2011; Sauviac and Bruand, submitted). However, the nature of the inducing signals and how they are, directly or indirectly, perceived by these kinases/phosphatases, are still unknown. It is striking however that the N-terminal putative sensor domains of these proteins carry variable motifs, and that these proteins can be either cytoplasmic or membrane located, indicating that they can perceive various signals of diverse origins (Staroń and Mascher, 2010).

40.2.3 Variations Around the Basic Cascade

Variations to this basic model have been described in several bacteria (see Figs. 40.1 and 40.2). Additional (one or more) EcfG sigma factors often coexist in the same species, and are usually under the transcriptional control of the main EcfG sigma factor, although not encoded in a conserved genomic context (e.g., RpoE2 and RpoE5 in *S. meliloti*, or RpoE4 and EcfG2 in *R. etli*; Fig. 40.1). In *R. etli*, both sigma factors have been shown to be partially redundant for regulating the general stress response (Vercruysse et al., 2011). In *Sinorhizobium* species, two pairs of anti-sigma/anti-antisigma are encoded in the genome (RsiA1/B1 and RsiA2/B2), and in *S. meliloti*, are able to cross talk and cooperate to fully control sigma factor activity (Bastiat et al., 2010). In this case, however, expression of the second pair is not under the control of σ^{EcfG} and is therefore not sensitive to feedback regulatory control. In some species, additional histidine kinase/phosphatases of the same family and/or other phosphodonors have been proposed to cross talk under particular conditions for phosphorylating or dephosphorylating RsiB/PhyR, thus adding additional levels of control (Foreman et al., 2012; Sauviac and Bruand, submitted), although the biological significance of these findings remains to be established.

40.2.4 Other Factors Acting on the Transduction Cascade

Several reports suggest that still other factors are able to modulate the activity of this basic cascade (Fig. 40.2). In *R. etli*, expression of the RpoE4 regulon was shown to be downregulated in stationary phase in a *rsh* (*relA*) mutant, deficient in the synthesis of the alarmone (p)ppGpp (Vercruysse et al., 2011). Interestingly, this mutant is known to be more sensitive to heat, osmotic, and oxidative stress than the wild-type strain, and to be affected in stationary-phase survival (Braeken et al., 2008). This suggests that some of these phenotypes could result from a defect of the general stress response. In *E. coli* and other bacteria, (p)ppGpp is synthesized upon entry in stationary phase, and is known to increase the competitiveness of alternative sigma factors for binding the RNA polymerase, thereby increasing their contribution to gene expression in comparison with that of the vegetative sigma factor. In this manner, (p)ppGpp participates in the activation of alternative sigma factors in stationary phase, including the general stress response regulator σ^S and the ECF sigma factor σ^E (Sharma and Chatterji, 2010; Magnusson et al., 2005; Costanzo et al., 2008). The results obtained in *R. etli* therefore suggest that (p)ppGpp could be one of the factors contributing to the activation of the σ^{EcfG}-dependent general stress response in the stationary phase. In *S. meliloti*, however, no differential expression of the RpoE2 regulon was observed between wild-type and *relA* mutant bacteria upon entry in stationary phase (Krol and Becker, 2011), suggesting that the effect of (p)ppGpp on σ^{EcfG} activity is not universal. Alternatively, as *S. meliloti relA* mutants are known to accumulate suppressor mutations (Wells and Long, 2003), it cannot be ruled out

that the mutant strain used by Krol and Becker contains such a suppressor that restores normal RpoE2 activity.

In *S. meliloti*, the expression of *rpoE2* and some of its targets in the stationary phase was lowered in an *hfq* mutant. At the same time, the increase in stress resistance (heat, osmotic, and oxidative stresses) usually observed in stationary phase in the wild-type strain was impaired in the *hfq* mutant (Barra-Bily et al., 2010). These phenotypes could partly result from a deficiency of the general stress response. In *E. coli* and other bacteria, Hfq is an RNA chaperone involved in the activity of *trans*-acting noncoding small RNAs (sRNAs). sRNAs modulate gene expression through various mechanisms, including activation or inhibition of translation by Hfq-dependent base-pairing with RNA transcripts (Gottesman and Storz, 2011). In *E. coli*, σ^S translation is activated by several sRNAs with the help of Hfq (Repoila et al., 2003). On the other hand, the activity of σ^E is inhibited by two Hfq-dependent sRNAs whose expression is itself under σ^E control. This inhibition is indirect as the sRNAs inhibit the translation of outer membrane proteins whose presence in the periplasm triggers RpoE activation (Gogol et al., 2011). Thus, sRNAs, and by extension Hfq, can directly or indirectly affect the activity of sigma factors. In consequence, it is assumed that RpoE2 activity in *S. meliloti* is influenced directly or indirectly by one or more sRNAs. Interestingly, the RpoE2 regulon itself includes several sRNAs (see later), but their involvement in RpoE2 regulation has not been tested so far.

40.3 FUNCTIONS OF THE σ^{EcfG}-DEPENDENT GENERAL STRESS RESPONSE

40.3.1 The σ^{EcfG} Regulons

σ^{EcfG} regulons were determined in several α-Proteobacterial species, including three rhizobia: *S. meliloti*, *B. japonicum*, and *R. etli* (Sauviac et al., 2007; Gourion et al., 2009; Martínez-Salazar et al., 2009a; Schlüter et al., 2013). For this, microarrays or affymetrix chips were used to compare the transcriptomes of wild type and either *ecfG*-mutant or *ecfG*-overexpressor strains, grown under stress/starvation conditions or under exponential growth conditions. In *B. japonicum*, the PhyR regulon was also established by comparing the transcriptomes of wild-type and *phyR*-mutant strains, and has been found to be congruent with the σ^{EcfG} regulon, as expected since PhyR and σ^{EcfG} act in the same cascade (see earlier). These different analyses have led to the identification of ∼100–200 genes directly or indirectly regulated by the sigma factor. Interestingly, most genes were found to be induced by σ^{EcfG}, as expected from a transcriptional activator, whereas a few genes were found to be downregulated, suggesting either indirect σ^{EcfG} regulations or side effects of the *ecfG* mutations.

From all these studies, as well as from experimental mapping of transcription start sites, either for individual genes or at the genome scale using RNA sequencing approaches, it has been possible to identify a conserved motif in the upstream DNA regions of at least half of the σ^{EcfG}-dependent genes or operons: GGAAC-N(16-17)-CGTT, which presumably corresponds to the −35 and −10 regions recognized by σ^{EcfG}. Genes whose expression is regulated by σ^{EcfG} but do not carry such sequences in their promoter region are likely indirectly regulated by σ^{EcfG}. Conversely, a search for such a motif upstream from genes in whole sequenced genomes, or upstream transcription start sites in RNA-seq data has made the identification of additional putative σ^{EcfG} targets possible (Sallet et al., 2013; Schlüter et al., 2013). In all, ∼100–200 putative direct target promoters of σ^{EcfG} could be identified in each single genome, corresponding to at least 150–300 σ^{EcfG}-controlled genes, therefore confirming that these sigma factors are global regulators of gene expression, as expected for general stress regulators.

40.3.2 Indirect σ^{EcfG} Regulation

Another subset of σ^{EcfG} targets encodes putative regulators, which potentially make it possible to integrate additional signals and regulate additional sets of genes, thus forming a complex regulatory network. These regulators are likely responsible for the transcriptional control of some of the "indirect" σ^{EcfG} targets. Two kinds of regulators were identified: proteins and sRNAs. Regulatory proteins include sigma factors and one- or two-component transcriptional regulators. Of the sigma factors, one or several σ^{EcfG}-like factor(s) are often present. In *R. etli*, experimental evidence led to the suggestion that the two EcfG sigma factors control partly nonoverlapping sets of genes, but the genes preferentially regulated by either one of these sigma factors have not been identified (Vercruysse et al., 2011). Also, the transcription of one heat-shock sigma factor-encoding gene was found to be σ^{EcfG}-dependent (*rpoH2* in *S. meliloti* and *R. etli*), or suggested to be σ^{EcfG}-dependent, based on the stress inducibility and/or presence of upstream σ^{EcfG} binding sequences (see Sauviac et al., 2007 and references therein). How these rhizobial RpoH sigma factors are activated in response to stress is currently not known, and how their function differs from that of other RpoH sigma factor(s) present in these bacteria is presently unclear. Recent data have shown that *S. meliloti* RpoH2 does not play a significant regulatory role under heat shock conditions, but instead is active in stationary phase, and putative target genes have been identified (Barnett et al., 2012). Interestingly, some of the genes found to be upregulated upon RpoE2 overexpression are actually RpoH2 targets, which demonstrates that these sigma factors indeed act in a cascade (Schlüter et al., 2013).

Other σ^{EcfG}-dependent regulators include numerous members of two-component regulatory systems, the function of which is mostly unknown. In *S. meliloti*, two such systems appear under the control of RpoE2: SMa0113-SMa0114 and *exsF-exsG*. The former is involved in the regulation of succinate-mediated catabolite repression (Garcia et al., 2010), which could be consistent with a function of the σ^{EcfG}-dependent response during the transition from active growth to starvation conditions. The function of *exsF-exsG* is unknown, although its location in the middle of a cluster of *eps* genes may indicate a role in exopolysaccharide synthesis. Interestingly, both SMa0114- and *exsF*-encoded proteins belong to the same unusual family of histidine kinases as the kinases/phosphatases of the σ^{EcfG} transduction cascades (see earlier), pointing to an intriguing link between EcfG sigma factors and this protein family.

A number of sRNAs have been shown to be under direct control of RpoE2 in *S. meliloti* in two recent studies (Sallet et al., 2013; Schlüter et al., 2013). Additional sRNAs may also be indirectly controlled by σ^{EcfG}, such as the several *S. meliloti* sRNAs regulated by RpoH2 (Barnett et al., 2012; Schlüter et al., 2013). However, nothing is known to date about the possible targets and functions of these sRNAs in stress responses.

40.3.3 Phenotypic Analyses of Mutants in the σ^{EcfG} Cascade

Numerous phenotypic analyses have been conducted on mutants of the σ^{EcfG} transduction cascade in different α-Proteobacteria, leading to the definitive demonstration that these sigma factors are central regulators of the general stress response in these bacteria, playing a role analogous to that of σ^S and σ^B in *E. coli* and *B. subtilis*, respectively. Here, we mainly summarize the observations made in rhizobia.

40.3.3.1 Free-Living Phenotypes. Mutants of the sigma factor (*ecfG*) or the anti-antisigma (*phyR/rsiB/tcrX*) have been shown to display similar pleiotropic phenotypes in several rhizobia, that is an increased sensitivity to various stress conditions. In *R. etli*, the importance of the two EcfG-type sigma factors in stress resistance was highlighted by the fact that single *rpoE4* and *ecfG2* mutants are more sensitive than the wild-type strain to H_2O_2 or heat treatment, and that a double mutant is even more sensitive to these stresses (Vercruysse et al., 2011). Involvement of the secondary EcfG sigma factor RpoE5 in stress resistance of *S. meliloti* has not been tested so far.

It is noteworthy that, at least in *S. meliloti* and *B. japonicum*, stress sensitivity of *ecfG* mutants has been detected in bacteria from stationary-phase cultures, or those having spent one night under carbon starvation conditions, but not in exponentially growing bacteria (Barra-Bily et al., 2010; Fléchard et al., 2009; Gourion et al., 2009). This further supports the particular importance of the general stress response when bacteria are in stationary phase.

S. meliloti rpoE2 and *R. etli rpoE4*, *ecfG2*, and *tcrX* mutants have been found to be more sensitive to hydrogen peroxide than the isogenic wild-type strains (Martínez-Salazar et al., 2009a; Fléchard et al., 2009). In particular, *S. meliloti* has been shown to be more resistant to hydrogen peroxide in stationary phase than in exponential phase in an RpoE2-dependent manner. In both rhizobia, a catalase-encoding gene is controlled by the EcfG sigma factor. Thus, the *S. meliloti katC* gene is induced in stationary phase following exhaustion of either the carbon or nitrogen source, as well as in exponential phase following treatment with diverse stress agents (Jamet et al., 2003; Sauviac et al., 2007; Fléchard et al., 2009). Accordingly, the peroxydase activity of KatC was observed to increase in stationary phase (Jamet et al., 2003). Since a *katC* mutant has been found to phenocopy an *rpoE2* mutant, *katC* is supposed to be the gene responsible for RpoE2-dependent H_2O_2 resistance (Fléchard et al., 2009). One can assume that the CH00462 Mn-catalase controlled by RpoE4 plays a similar role in *R. etli*. Although catalases are probably the main actors of the EcfG-dependent H_2O_2 resistance, one cannot exclude the possibility that other genes are involved.

Among other σ^{EcfG}-dependent genes possibly involved in oxidative stress response are those that encode superoxide dismutases, such as the *sodC* genes in *S. meliloti* and *R. etli*. Although *R. etli rpoE4* and *tcrX* mutant cells are more sensitive to the superoxide generator methyl viologen than that of wild-type cells (Martínez-Salazar et al., 2009a), the *S. meliloti rpoE2* mutant was found to be as resistant as wild-type bacteria to external superoxide (Fléchard et al., 2009).

S. meliloti rpoE2 and *R. etli rpoE4*, *ecfG2*, and *tcrX* mutants have also been found to be more sensitive to osmotic stress than wild-type bacteria, as measured by sucrose and/or NaCl sensitivity, whereas *B. japonicum ecfG* and *phyR* mutants are not (Fléchard et al., 2010; Gourion et al., 2009). In *S. meliloti*, osmosensitivity of the *rpoE2* mutant could be associated with its deficiency in trehalose synthesis, a well-known osmoprotective compatible solute. The expression of genes involved in three different pathways of trehalose synthesis (*otsA*, *treS*, and *treY*), known to be required for osmoresistance (Domínguez-Ferreras et al., 2009), has been shown to be dependent on *rpoE2* in stationary phase and/or in exponential phase following a salt shock in *S. meliloti* (Fléchard et al., 2010). Similarly, in *B. japonicum*, expression of these genes, as well as the corresponding enzyme activities, increases *in vivo* in the presence of salt (Streeter and Gomez, 2006; Sugawara et al., 2010), and has been found to be dependent on σ^{EcfG} under carbon starvation conditions (Gourion et al., 2009).

Although trehalose synthesis genes obviously play a major role in σ^{EcfG}-associated osmoresistance, we cannot rule out the hypothesis that other genes are involved. Thus, *rpoH2*, which is often found among σ^{EcfG} targets, is involved in osmotic tolerance in *R. etli* and *Sinorhizobium* sp. BL3, suggesting that some RpoH2 targets are involved in osmotic resistance (Tittabutr et al., 2006; Martínez-Salazar et al., 2009b).

The *S. meliloti rpoE2* mutant was found to be more sensitive to heat stress than its wild-type counterpart (Barra-Bily et al., 2010). Although the heat-shock type sigma factor RpoH2 is under control of σ^{EcfG} in this rhizobium, an *rpoH2* mutant strain is not heat sensitive (Oke et al., 2001; Ono et al., 2001). This observation rules out the involvement of RpoH2 in σ^{EcfG}-dependent heat resistance. Also, an *rpoE2* mutant was isolated in a screening for desiccation-sensitive mutants of *S. meliloti* (Humann et al., 2009; see Chapter 39), and *B. japonicum ecfG* and *phyR* mutants were found to be more desiccation sensitive than the wild-type strain (Gourion et al., 2009). Interestingly, trehalose is not only an osmoprotective compound, but is also known to protect bacteria against desiccation and heat. Thus, mutants of *R. etli*, *R. leguminosarum* bv. *trifolii* and *B. japonicum* deficient in trehalose synthesis were found to be not only osmosensitive but also heat and/or desiccation sensitive (McIntyre et al., 2007; Sugawara et al., 2010; Reina-Bueno et al., 2012). Therefore, although the σ^{EcfG}-dependent genes responsible for desiccation and heat resistance have not formally been identified, one can reasonably suspect trehalose synthesis genes to be involved in these processes.

Although some σ^{EcfG}-dependent genes could be associated with some σ^{EcfG} mutant phenotypes, a surprisingly large number of σ^{EcfG} targets encode proteins or sRNAs of unknown function. Interestingly, some of these proteins are conserved in the σ^{EcfG} regulons of other α-Proteobacteria, and are even part of general stress regulons of phylogenetically distant bacteria. For instance, the *S. meliloti* SMc00371 and *R. etli* CH00268 open-reading frames encode proteins homologous to the *E. coli* YciF, a σ^{S}-dependent gene of unknown function (Hindupur et al., 2006). Altogether, these findings suggest a universal role of these proteins in general stress responses, although their function is still unknown.

40.3.3.2 Symbiotic Phenotypes. Mutants of *S. meliloti rpoE2*, *R. etli rpoE4*, and *R. leguminosarum* bv. *viciae rpoZ* are able to form nodules with normal fixation efficiency on *Medicago sativa/truncatula*, *Phaseolus vulgaris*, and *Pisum sativum*, respectively (Wexler et al., 2001; Sauviac et al., 2007; Martínez-Salazar et al., 2009a; Humann et al., 2009). An explanation for this lack of symbiotic phenotype could reside in the functional redundancy of rhizobial genomes. For instance, *S. meliloti* RpoE2 controls the transcription of *katC* and *rpoH2*, but two additional catalases (KatA and KatB) and one additional heat shock-type sigma factor (RpoH1) are encoded by the genome. If no clear symbiotic phenotype could be associated with single *katC* or *rpoH2* mutations, *katA katC*, *katA katB*, and *rpoH1 rpoH2* double mutants displayed dramatically altered symbiotic phenotypes (Sigaud et al., 1999; Oke et al., 2001; Ono et al., 2001; Jamet et al., 2003; Mitsui et al., 2004). This suggests that the lack of some gene expression in the *rpoE2* mutant background could be compensated for by functionally redundant genes. Similar hypotheses can be made for *R. etli* (Martínez-Salazar et al., 2009b). In any case, the lack of symbiotic deficiency of the *ecfG* mutants cannot be explained by sigma factor inactivity *in planta*, since σ^{EcfG} target genes were found to be expressed in nodules induced by wild-type *S. meliloti* and *R. etli*, either by transcriptomic analyses (Capela et al., 2006) or through the use of transcriptional *lacZ* or *gus* fusions (Oke et al., 2001; Jamet et al., 2003; Martínez-Salazar et al., 2009a). Interestingly, the two *S. meliloti* genes examined using fusions (*katC* and *rpoH2*) revealed expression in specific zones of the *Medicago sativa* nodules (the infection zone and the late senescence zone), as well as in infection threads. No such expression pattern was detectable using the *katC–lacZ* fusion in an *rpoE2* mutant background, confirming that RpoE2 is indeed active in nodules (unpublished data). Whether *in planta* RpoE2 activation is a reflection of the numerous stress conditions encountered by bacteria during root infection and nodule senescence, or simply results from the nongrowing, stationary phase-like state of nodule bacteria, is currently unknown.

In contrast, *B. japonicum phyR* and *ecfG* mutants exhibited marked symbiotic phenotypes on soybean (*Glycine max*; two different cultivars) and mung bean (*Vigna radiata*) (Gourion et al., 2009). In all cases, nodule formation and development were delayed, the number of bacteroids was reduced, and nitrogen fixation was lowered in comparison to wild-type bacteria, with consequent impact on the general state of the plant (small size, chlorotic leaves). The color and morphology of the nodules were variable, ranging from normal red nodules to aberrant white nodules with signs of necrosis, and sometimes emerging ectopic root-like structures. Although the origin of this particular phenotype is so far unknown, it has been proposed to result from an imbalanced hormonal control of root versus nodule development, as a consequence of the inefficient bacterial colonization of the nodule (Gourion et al., 2009). Nevertheless, the reason of this poor colonization is not known, although we can reasonably assume that it results from the inability of the rhizobial mutants to cope with the stressful nodule environment.

40.4 CONCLUSIONS AND FUTURE PROSPECTS

It is now clear that σ^{EcfG} sigma factors are the long searched for regulators of the general stress responses in α-Proteobacteria. Although the main transduction cascade leading to σ^{EcfG} activation in response to stress is largely conserved among these bacteria, a number of fundamental issues remain unexplored. Notably, the numerous different conditions capable of inducing these responses, ranging from nutrient/energetic stresses to physico/chemical injuries, suggest the existence of various stress-sensing systems. However, in a given species, only a limited number of kinases/phosphatases have been identified on top of the σ^{EcfG} signal transduction cascades. This suggests that either of the additional systems integrate the signals upstream from the kinases, or that so far unidentified additional levels of regulation of the response exist. Studies in other bacteria such as *E. coli* have demonstrated that the general stress response can be regulated at multiple levels, including expression (transcription, RNA turnover, and translation), stability, and activity of the σ^{S} sigma factor. The finding that σ^{EcfG} activity or expression could be affected by (p)ppGpp or sRNAs is the first indication that σ^{EcfG} must also be viewed as potentially regulated at various levels. Moreover, the genes controlled by σ^{EcfG} sigma factors indicate that the response is structured as a complex network, including numerous additional regulators, like one and two-component systems, other sigma factors, and sRNAs, which can all integrate additional signals and regulate separate subsets of genes. The relative importance of all of these secondary levels of gene regulation needs to be considered in the future, as it can make the extent and nature of the response variable depending on the inducing cue. Finally, even though it is believed that the main function of the general stress response is to provide cells with a better stress resistance, the function of most of the genes regulated during this response is still unknown. Thus, possible impacts of the response on other aspects of cell physiology, for instance metabolism or bacterial envelope structure, must be the object of future studies. Other functions of the response in rhizobia may include adaptation to the specific environments they live in, such as soil and plant tissues.

Physiology and Regulation of Nodulation

Chapter 41

The Root Hair: A Single Cell Model for Systems Biology

Marc Libault
Department of Microbiology and Plant Biology, University of Oklahoma, Norman, OK, USA

41.1 INTRODUCTION

As mentioned by Nelson et al. (2008), -omic studies performed on an entire tissue or organ composed of cells with different fates cannot provide a clear picture of the biological response of each cell type. This statement is especially true when referring to the initial steps of legume nodulation: the infection of the root hair cell, epidermal root cell type characterized by its polar elongation (Fig. 41.1), by nitrogen-fixing symbiotic bacteria. Applying a systems biology approach on a single differentiated cell type such as the root hair cell offers a unique opportunity to understand different aspects of plant cell biology. This chapter focuses on the strategies, challenges, and outcomes of a systems biology approach to study the response of the root hair cell, a model single cell type, to rhizobia inoculation.

41.2 THE ROOT HAIR SYMBIOTIC PATHWAY

Forward genetic approaches allowed the characterization of tens of legume genes controlling the infection process of the root hair cells. Mutants in these genes are defective in responding to the treatment of Nod factors, in root hair infection by rhizobia, and *a fortiori* in nodulation. Genetic analyses of these mutants led to the establishment of the symbiotic pathway (Fig. 41.2; see also Chapters 42, 43, 59, 110).

This pathway is initiated into the recognition of the nodulation factors (Nod factors), mixture of lipochito-oligosaccharides synthesized by the bacteria, by two-plant LysM receptor-like kinases. These receptors has been identified in *M. truncatula* (LysM receptor kinase 3 (LYK3) and Nod factor perception (NFP; see Chapter 51)) and in *L. japonicus* (Nod factor receptors 1 and 5 (NFR1, NFR5)). Thus, these receptors were identified based on the absence of root hair cell deformation and calcium spiking in response to rhizobia inoculation (Arrighi et al., 2006; Limpens et al., 2003; Madsen et al., 2003; Radutoiu et al., 2003). For a long time, the interaction between the receptor kinases and the Nod factors was assumed, but only recently it was demonstrated (Broghammer et al., 2012).

Although both NFR1 and NFR5 contribute to Nod factor response, only NFR1 seems to have a functional kinase domain involved, among others, into the phosphorylation of NFR5 (Madsen et al., 2011).

Recent studies in *Medicago* support the idea of the reorganization of the localization of plasma membrane proteins including LYK3. This conclusion was reached after the observation of the colocalization of LYK3 with flotillin-like 4 (FLOT4), a membrane raft-associated protein-regulating root hair cell infection by rhizobia (Haney et al., 2011) and the interaction between LYK3 and the symbiotic remorin 1 (SYMREM1), another membrane raft-associated protein-controlling rhizobial infection (Lefebvre et al., 2010). The role of membrane raft during nodulation is

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

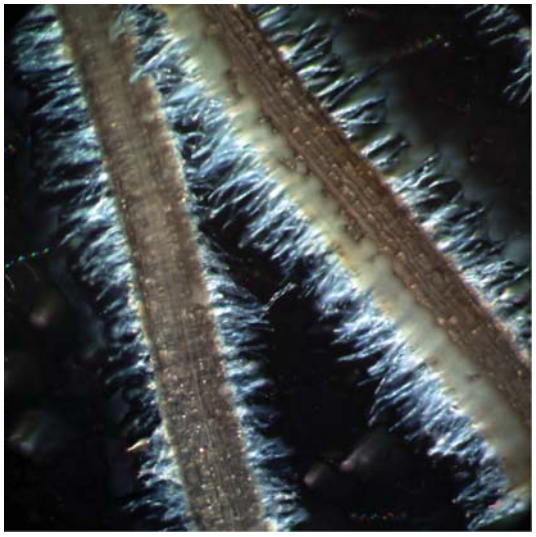

Figure 41.1 Root hair cells are single tubular root cells. Their distinctive lateral elongation increases the surface of exchange between the plant's root system and the soil. The main function of root hairs is to improve water and nutrient uptake by the roots. In legumes, they are the first site of infection by symbiotic nitrogen-fixing bacteria.

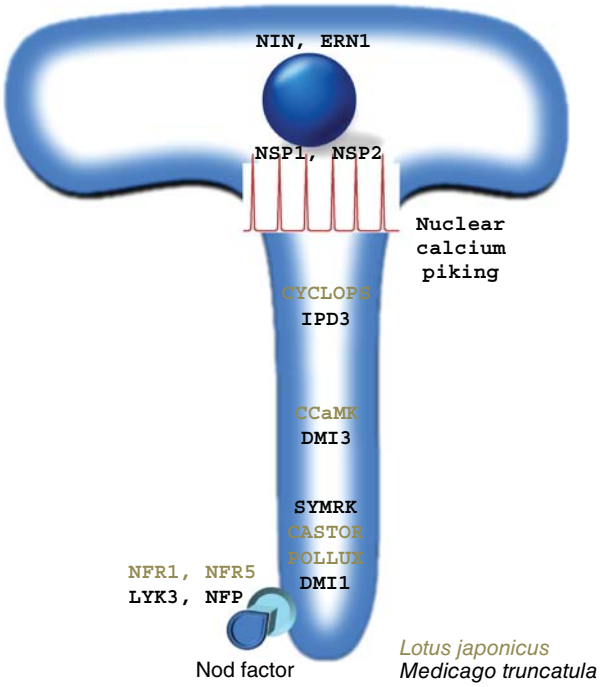

Figure 41.2 Signaling cascade activated in response to the recognition of the symbiotic nitrogen-fixing bacteria. This cascade is leading to the activation of a set of TFs (red circles), which is necessary to a successful infection of the root hair cells by the bacteria.

also supported by the essential function of FLOT2 during rhizobial infection of the root hair cells (Haney and Long, 2010).

Additional plasma membrane proteins are required to transduce the Nod factor signal in root hair cell. The *L. japonicus SYMbiosis Receptor-like Kinase* (*SYMRK*) and the *M. truncatula Does not Make Infections* (*DMI2*) genes act early in the signaling cascade, potentially directly under the control of the receptor lysine kinases (Endre et al., 2002; Stracke et al., 2002). The molecular function of these plasma membrane proteins is not currently characterized.

One well-characterized response of the root hair cells to Nod factor treatment or rhizobia inoculation is the oscillation of calcium concentration in the nucleoplasm and perinuclear cytoplasm (Capoen et al., 2011; see Chapters 54, 57). To capture these oscillations, researchers used fluorescent proteins or dyes sensitive to calcium concentrations such as the YC2.1 cameleon protein (Capoen et al., 2011) and the Oregon Green dextran (Imaizumi-Anraku et al., 2005).

By expressing the cameleon protein in roots, Kosuta et al. (2008) analyzed the amplitude and frequency of the oscillations of calcium of *M. truncatula* in response to *Sinorhizobium meliloti* and *Glomus intraradices* inoculations, the symbiotic bacterium, and fungus involved in nodulation and mycorrhization, respectively. Interestingly, Kosuta et al. (2008) observed different amplitudes and frequencies of calcium spikes depending on the nature of the microbes. This result was not confirmed by Sieberer et al. (2012; see Chapter 57). Nevertheless, it is unclear whether the frequency and the amplitude of the calcium oscillation is utilized by the plant cell to distinguish between rhizobia and mycorrhiza infection. If this is the case, it is attempting to hypothesize that the nature of the calcium oscillations would control the expression of a specific set of genes required for mycorrhization or nodulation, as previously reported by other groups using different systems (Song et al., 2012).

To date, the relationship existing between the recognition of the Nod factor by LysM receptor lysine kinases and their phosphorylation with the activation of calcium oscillations has not been revealed. One hypothesis would be the production of an isolated and related secondary messenger in response to the recognition of the Nod factor, such as the products of the degradation of phospholipids by the phospholipase C and phospholipase D (Charron et al., 2004; den Hartog et al., 2001; Engstrom et al., 2002; Pislariu and Dickstein, 2007). Another potential secondary messenger is mevalonate. Kevei et al. (2007) highlighted the interactions between *M. truncatula* DMI2 with 3-hydroxy-3-methylglutaryl CoA reductase 1 (HMGR1), a key enzyme in the biosynthesis of mevalonate, and controlling nodulation. However, the direct effect of these putative secondary messengers on calcium oscillation has not been demonstrated.

In *L. japonicus* and *M. truncatula*, calcium oscillations are under the control of the nuclear membrane cation

channels LjCASTOR, LjPOLLUX, and MtDMI1 (Ane et al., 2004; Capoen et al., 2011; Charpentier et al., 2008; Imaizumi-Anraku et al., 2005; Riely et al., 2007). To balance the influx and efflux of calcium in the nucleus, MCA8 encoding a calcium ATPase acts as a calcium pump responsible for the movement of calcium back to the nuclear membrane (Capoen et al., 2011). Calcium oscillations are perceived by the nuclear protein calcium- and calmodulin-dependent serine/threonine protein kinase (CCaMK in *L. japonicus*; DMI3 in *M. truncatula*) (Levy et al., 2004; Mitra et al., 2004). CCaMK has an integrative role in the Nod factor-associated signaling cascade since its only activation is sufficient to induce nodulation even in absence of rhizobia (Gleason et al., 2006; Tirichine et al., 2006; see Chapter 54). The binding of calcium ions to the calmodulin and EF-hand motifs of CCaMK protein induce the autophosphorylation of the kinase domain of the protein. The *L. japonicus* CYCLOPS and *M. truncatula* IPD3 proteins are phosphorylated by CCaMK (Horvath et al., 2011; Messinese et al., 2007; Ovchinnikova et al., 2011; Yano et al., 2008). The role of these nuclear calcium oscillations and the function CCaMK protein has not been resolved, but it is likely possible that they regulate the transcriptional activity of transcription factor acting downstream in the symbiotic pathway.

Transcription factors are master regulators of root hair cell response to rhizobia inoculation including the *Nodulation Signaling Pathway 1 and 2* (*NSP1* and *NSP2*) genes encoding GRAS transcription factors (Kalo et al., 2005; Smit et al., 2005). *In vivo* and *in vitro* experiments highlighted the direct interactions between NSP1 and NSP2 (Hirsch et al., 2009). In the same study, Hirsch et al. (2009) also demonstrated the binding of NSP1 to *cis*-elements located in the promoter region of the *Early Nodulin 11* (*ENOD11*) gene, which transcriptionally induced in response to rhizobia inoculation (Journet et al., 2001). Additional interactions between legume transcription factors and the promoter sequence of genes known to control nodulation has been reported. For example, using the yeast one-hybrid method, Andriankaja et al. (2007) demonstrated the binding of Ethylene Response Factor Required for Nodulation1 [ERN1], transcription factor acting early during the nodulation process (Middleton et al., 2007), with the *Medicago* ENOD11 promoter. More recently, Soyano et al. (2013) characterized the direct regulation of the expression of *L. japonicus NF-YA1* and *NF-YB1*, two activators of cortical cell division, by the NIN transcription factor encoding an RWP-RK transcription factor (Marsh et al., 2007).

The molecular mechanisms controlling the activity of these transcription factors in root hair cells are unknown. To date, the soybean orthologs of these transcription factors are upregulated in root hair cell in response to *B. japonicum* (Libault et al., 2010a).

41.3 SYSTEMS BIOLOGY APPROACH TO ELUCIDATE THE MOLECULAR RESPONSE OF ROOT HAIR CELLS IN RESPONSE TO RHIZOBIA

Our current knowledge of the genetic pathway controlling root hair cell response and infection by rhizobia is limited to several genes. There is no doubt that these genes are master regulators of the root hair cell infection based on the drastic defect in nodulation observed in related mutants. However, due to the complexity of the root hair response to rhizobia (i.e., recognition of the symbiont, deformation, and infection of the root hair cell), it is expected that a higher number of genes contribute to regulate the various aspects of the root hair cell response to rhizobia. These genes are not characterized, yet potentially due to functional redundancy between homologs or due to their subtle function in regulating legume root hair cell infection and nodulation. Reverse genetic and systems biology approaches represent a potential solution to identify these genes.

To specifically access a root hair cell before analyzing its biology and response to rhizobia in detail, researchers took advantage of the characteristic polar growth of the root hair cells (Fig. 41.1) to isolate them from the rest of the root system. The methodologies used to reach this goal vary according to the plants used and, more specifically, the nature of the root system. Nevertheless, these methods are based on the breaking of the thin root hair cells into liquid nitrogen followed by filtration steps to separate root hairs and the remaining root system. The methods currently used are as follows: (1) brushing of the root system in liquid nitrogen (Ramos and Bisseling, 2003); (2) gentle stirring of the root system in liquid nitrogen (Lauter et al., 1996). The first method is time consuming but more adequate to isolate root hair cell from fragile root system such as *M. truncatula*; whereas the second method allows a higher yield in root hair cells in a minimum time but is more destructive. As a consequence, contamination of the root hair cell preparation by fragmented roots is a major limitation. The filtration of the root hair cell preparation enhances the purity of the root hair cell preparations.

Among model legumes, root hair cells from *Medicago* and soybean have been isolated and used to analyze the response of the cell type to rhizobia inoculation. In *Medicago*, the transcriptomic response of the root hair cells to *S. meliloti* inoculation is currently being investigated [Dr. Jeremy Murray, John Innes Center, personal communication]. Since 2005, soybean has been extensively used to investigate root hair cell response to rhizobia inoculation owing to the ease to isolate gram quantities of root hair cells (i.e., as much as 1 g of root hair cells is isolated from 1000 seedlings). The application of various -omic methods

including transcriptomics (Libault et al., 2010a), proteomics (Brechenmacher et al., 2009; Brechenmacher et al., 2012), metabolomics (Brechenmacher et al., 2010), and phosphoproteomic analyses (Nguyen et al., 2012) on these soybean root hair cell preparations led to an impressive collection of data, clearly highlighting the complexity of the response of the root hair cells to rhizobia. These data were collected over time to monitor the dynamic changes of the root hair cell response to rhizobia at each stage of the infection process.

41.4 TRANSCRIPTOMIC APPROACH TO UNRAVEL THE COMPLEXITY OF THE ROOT HAIR CELL RESPONSE TO RHIZOBIA

To broadly analyze the transcriptional response of the root hair cells to rhizobia, both Affymetrix microarray and Illumina RNA-seq technologies were used. These technologies led to the identification of 1973 soybean genes differentially regulated in root hair cells in the few hours following *B. japonicum* inoculation (e.g., 12, 24, and 48 h after bacterial inoculation (Libault et al., 2010a)). Among these genes, the soybean gene orthologs to the receptor lysine kinase *NFR1* (*LYK3*), *NFR5* (*NFP*) were clearly upregulated in response to bacteria inoculation. In addition, among the 13 soybean genes orthologous to *M. truncatula* and *L. japonicus NSP1*, *NSP2*, *NIN*, and *ERN1*, five clearly show an induction of their expression in root hair in response to *B. japonicum* inoculation (Fig. 41.3).

Including these genes, a total of 233 genes were consistently regulated during soybean root hair infection. Looking at the identity of the 233 genes differentially expressed in soybean root hair cells, a significant percentage of them control cell wall biosynthesis and degradation (12 genes), the plant defense system (21 genes), and regulate transcriptional activity (19 genes; Fig. 41.4).

It is tempting to hypothesize that these 19 *B. japonicum*-inducible root hair transcription factor genes control the broad transcriptomic regulation of the root hair transcriptome in response to rhizobia. Ideally, the target genes of these transcription factors should be characterized specifically in root hair cells before and after the inoculation by rhizobia to enhance our knowledge of the symbiotic pathway. In addition, we cannot omit the fact that these transcription factors are responsible of the upregulation and then downregulation of the expression of defense-related genes as previously reported (Libault et al., 2010a). This is an essential aspect of legume nodulation because the finality of the nodulation is to allow the infection of plant cells by the symbiotic bacteria. The third category of genes strongly regulated upon *B. japonicum* inoculation is involved in

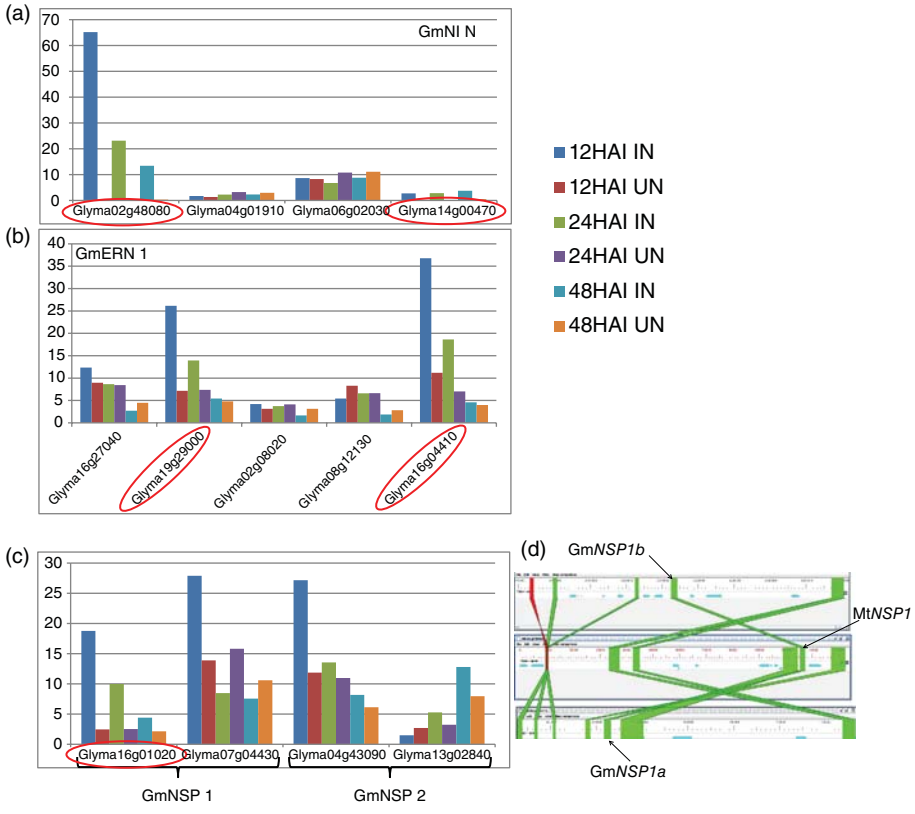

Figure 41.3 Relative expression levels of soybean genes orthologous to *Medicago* and lotus NIN (a), ERN1(b), *NSP1*, and *NSP2* (b) during the early stages of nodulation. Normalized gene expression (*y*-axis) was quantified using RNA-seq technology in root hair cells inoculated (IN) and mock-inoculated (UN) by *B. japonicum* and at three different times of the infection (i.e., 12, 24, and 48 h after inoculation (HAI)). Differentially expressed genes are highlighted in red. (d) Microsynteny relationships between MtNSP1 gene located on chromosome 8 and two soybean orthologs, GmNSP1a (Glyma16g01020) and 1b (Glyma07g04430), respectively. Synteny relationships between legume genes are highlighted in green and red blocks (the latter reflects inversions of the direction between orthologs).

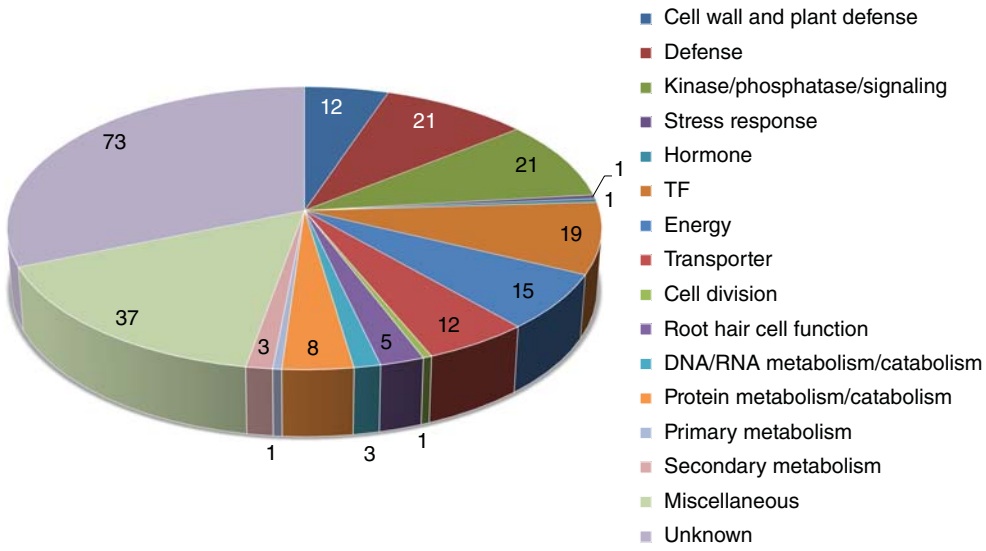

Figure 41.4 Distribution in functional categories of the soybean genes repetitively transcriptionally regulated 12, 24, and 48 h after *B. japonicum* inoculation (Libault et al., 2010a).

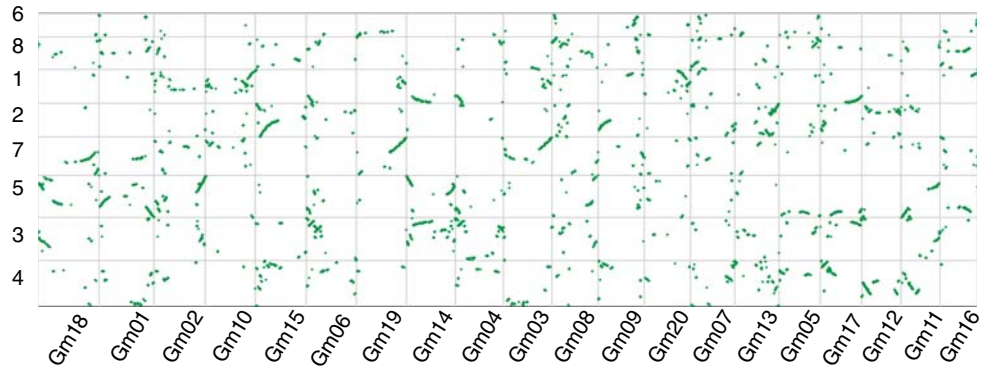

Figure 41.5 Macrosynteny relationships between the eight *Medicago* chromosomes (*y*-axis) and the 20 soybean chromosomes (*x*-axis). Each green dot on the graphic reveals synteny relationships between the two legumes. This figure was generated by the CoGe system (http://genomevolution.org/CoGe/).

cell wall biosynthesis and degradation. Many studies in *Arabidopsis* clearly connected changes in the composition of root hair cell wall with calcium oscillations and modifications in the extracellular pH and accumulation of reactive oxygen species as major regulators of root hair cell elongation (Monshausen et al., 2007; Monshausen et al., 2009; Monshausen et al., 2008). In legumes, the impact of reactive oxygen species on root hair cell elongation and deformation has been reported in response to the treatment of Nod factors or rhizobia inoculation (Cardenas et al., 2008; Lohar et al., 2007). Hence, it seems plausible that at least a subset of the genes and proteins controlling root hair cell elongation had been neofunctionalized to control root hair curling during the early stages of nodulation.

These 233 genes could be considered as valuable candidate for functional genomic studies based on their probable role during soybean root hair infection process. Using more stringent criteria, 41 soybean genes should receive careful attention from the legume community, considering the specific activation of their transcription only upon rhizobia inoculation (i.e., no transcripts were detected in various tissues, and, more interestingly, in mock-inoculated root hairs). Taking advantage of the strong synteny between the *Medicago* and soybean genome (Fig. 41.5) and the upcoming availability of the *Medicago* root hair transcriptome, our understanding of the common mechanisms of root hair cell infection by rhizobia between determinate and indeterminate nodulations will be revealed.

41.5 CHARACTERIZATION OF THE SOYBEAN ROOT HAIR PROTEOME, PHOSPHOPROTEOME, AND METABOLOME

To complement the root hair transcriptome and because the goal of the root hair systems biology approach is to provide an integrated and meaningful understanding of root hair cell infection by rhizobia, the root hair cell proteome has been characterized as well as its perturbation in response to rhizobia. The large quantities of soybean root hair cells are compatible with the sequencing of a large population of peptides, leading to an impressive collection of root hair cell proteins and the establishment of the first root hair proteome map. The soybean root hair protein map is the result of two complementary studies. The first study was published in 2009 combining 2D gel electrophoresis and 1D PAGE-liquid chromatography with multidimensional protein identification (MudPIT) technology (Brechenmacher et al., 2009). This study led to the identification of 1492 root hair cell proteins and clearly highlighted the complementarity of the different proteomic methods used to identify them. The functional categorization of these proteins clearly support the basic function of the root hair cell (i.e., many water and ion transporters and protein controlling root hair cell elongation had been identified). This first analysis was updated in 2012 using accurate mass and time (AMT) tag method (Brechenmacher et al., 2012). Owing to the higher sensitivity of the method used, the updated soybean root hair proteome map now encompasses 8262 proteins. As expected, the AMT approach identified 94% of the protein previously identified by 2D-gel SDS-PAGE and MudPIT approaches.

The differential abundance of root hair protein in response to rhizobia has been initiated using the soybean root hair as model. A total of 26 root hair proteins were differentially abundant in response to *B. japonicum* using a 2D SDS-PAGE approach (Wan et al., 2005). Among them, the abundance of a soybean phospholipase D significantly increases 6 h after *B. japonicum* inoculation. As mentioned earlier, this protein might play a critical role in the production of secondary messenger in the symbiotic pathway (den Hartog et al., 2001).

The functional characterization of the root hair cell proteins found in different abundance in response to *B. japonicum* is essential to a systems biology understanding of the infection of this single cell type.

To complement these investigations and based on the importance of posttranslational modification of proteins in the symbiotic pathway, the dynamic changes of the soybean root hair phosphoproteome in response to rhizobia have been investigated. To do so, Nguyen et al. (2012) digested root hair proteins inoculated and mock-inoculated with *B. japonicum* with trypsin; enriched their preparation in phosphopeptide using the nickel–nitriloacetic acid enrichment method; and then identified the phosphopeptides using reversed-phase liquid chromatography-tandem mass spectrometry. Not surprisingly, most of phosphorylation changes occurred within the first hours after inoculation. This very early response might be a reflection of the predominant role of the receptor kinases in the symbiotic pathway rapidly activated in response to rhizobia. Among the phosphoproteins identified, the phosphorylation level of 240 root hair cell proteins was significantly changed in response to *B. japonicum* inoculation including protein-controlling chromatin condensation, transcription, and translation. Combined with the transcriptomic study (Libault et al., 2010a), this result supports an early response of the root hair cell to rhizobia inoculation under the form of a massive posttranslational change of proteins (with a maximum at 3 h after inoculation), likely initiated by the receptor lysine kinases, and then a late response in the nuclei where nodulation-related transcription factors (e.g., NSP1, NSP2, and ERN1) will regulate the expression of hundreds of genes required to initiate the infection process with a maximum response between 12 and 48 h after inoculation.

To complement proteomic and phosphoproteomic studies, the root hair cell metabolome and its regulation in response to *B. japonicum* has been characterized. Among the 2610 root hair cell metabolites detected, 166 were found in different abundance in response to *B. japonicum* inoculation. Interestingly, flavonoids, plant metabolites activating the transcription of the Nod genes in bacteria, were found in higher abundance in inoculated root hair cell supporting the idea of a positive loop to enhance plant–bacteria interaction. Also, carbohydrates were also strongly accumulated in root hair cells in response to *B. japonicum* including trehalose. The use of *B. japonicum* mutants defective in trehalose biosynthesis supporting the root hair trehalose has a bacterial and not a plant origin. Because trehalose is an osmoprotectant, this accumulation of trehalose in infecting *B. japonicum* suggests the perception of an osmotic stress during the infection process by the bacteria.

41.6 UPCOMING CHALLENGES IN ROOT HAIR CELL SYSTEMS BIOLOGY

A systems biology analysis of root hair cell infection by rhizobia requires interdisciplinary studies. Hence, a major challenge in systems biology is the meaningful integration of various data sets (i.e., genomic, transcriptomic, proteomic, and metabolomic), leading to a deep understanding of the response of the root hair cell to rhizobia. The ease to isolate root hair cells and the development of methods to globally analyze their response to rhizobia inoculation are clear advantages to successfully apply a systems biology approach

because the data sets generated will not suffer from the multicellular complexity of plant organs and, as a consequence, will be unambiguous.

To enhance our understanding of the root hair cell infection, in addition to existing resources, additional aspect of root hair cell biology must be studies such as the compartmentalization of proteins and metabolites in root hair cell organelles (e.g., membrane rafts, liquid-ordered microdomains in cell membranes, are playing an important role during nodulation (Lefebvre et al., 2010)). A second field of investigation would be the characterization of the root hair epigenome and its regulation in response to rhizobia inoculation.

Ultimately, systems biology will unravel the positive and negative regulations of gene regulatory, proteomic, and metabolic pathways in root hair cells in response to rhizobia. Working at the level of one single cell type will help to generate and test computational model than to validate these networks. However, preliminary analyses clearly highlighted that gene expression and protein abundance are not tightly correlated even when working at the level of one single cell type such as the root hair cell (Libault et al., 2010b).

To analyze and integrate the various data sets, bioinformatic tools are needed. Many bioinformatics resources are currently available to visualize and to compare genomic, transcriptomic, proteomic, and metabolomics data sets such as the Legume Information System (http://www.comparative-legumes.org), Phytozome (http://www.phytozome.net/), SoyBASE (Grant et al., 2010), and SoyKB (Joshi et al., 2012). More recently, the iRootHair database has been created allowing researchers to access root hair resources even from nonlegume plants (Kwasniewski et al., 2013). Altogether, the use of these tools, the development of new computational resources, and the production of reliable data sets will help to unravel the root hair response to rhizobia inoculation.

42.1 INTRODUCTION

Two root nodule symbioses are known between nitrogen-fixing soil bacteria and higher plants: legumes (as well as the nonlegume *Parasponia*) associated with Rhizobia and plants collectively designated actinorhizal that interact with *Frankia*. In both cases, the microsymbionts induce the formation of special organs on the roots of their host plants, named root nodules able to fix nitrogen. Legume and actinorhizal nodules differ in their ontogeny and structure (Franche et al., 1998; Wall, 2000, Pawlowski, 2009; Santi et al., 2013). Both legumes and actinorhizal plants belong to the Rosid I clade, thus suggesting that they share a predisposition for symbiosis (Soltis et al., 1995; Doyle, 1998,

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

2011; Bell et al., 2010). Several independent evolutionary origins have been postulated for rhizobial symbioses (Doyle, 2011) and three to four for actinorhizal symbioses (Swensen, 1996). The molecular bases of this predisposition are not yet known.

Molecular approaches have progressed for actinorhizal species during last decades mainly for the temperate species, *Alnus glutinosa* and *Datisca glomerata*, and the tropical trees of the Casuarinaceae family (Obertello et al., 2003; Laplaze et al., 2008; Bogusz and Franche, 2012, Svistoonoff et al., 2014). For the latter, transgenic plants have been obtained (Franche et al., 1998), and recent work shows the successful application of a RNA silencing system (RNAi) using hairy root in *Casuarina glauca* and in *Datisca glomerata* (Gherbi et al., 2008; Markmann et al., 2008). Thus, actinorhizal symbioses emerged recently as simple and original systems of root nodule initiation, and they offer the opportunity to explore developmental strategies significantly different from legumes to form nitrogen-fixing nodules.

One of the key goals for understanding actinorhizal root nodule symbiosis is the identification of the network of plant and bacterial determinants whose gene products interact to initiate root nodule formation and to support the nitrogen-fixation process. Recent years have witnessed intense growth of different genomic approaches (ESTs, microarray, and deep sequencing) for high-throughput analyses of genes and their transcripts. This was recently applied to different actinorhizal systems, and we review here the current state of knowledge on the genomics of the actinorhizal symbiotic interaction.

42.1.1 Actinorhizal Species

Actinorhizal plants represent about 200 species encompassing 25 genera in eight different angiosperm families, in three different orders (Huss-Danell, 1997): the Betulaceae, Casuarinaceae, and Myricaceae of the order Fagales; the Rosaceae, Rhamnaceae, and Elaeagnaceae of the order Rosales; and the Coriariaceae and Datiscaceae of the order Cucurbitales (Vessey et al., 2004). In some families all members are nodulated (Coriariaceae, Elaeagnaceae, Datiscaceae, and Casuarinaceae), whereas in others, only a portion of the genera are nodulated (Betulaceae, Myricaceae, Rhamnaceae, and the Rosaceae). They are widely distributed, found on all continents except in Antartica, are perennial dicotyledonous angiosperms, and are, with the exception of the genera *Datica*, woody trees or shrubs. Examples of well-known genera include *Alnus* (alder), *Elaeagnus* (autumn olive), *Hippophae* (sea buckthorn), and *Casuarina* (she oak). Most actinorhizal plants are capable of high rates of nitrogen fixation comparable to those found in legumes (Torrey, 1976). Ecologically, actinorhizal plants are usually pioneers on nitrogen-poor soils, and are frequently found in relatively harsh sites, including glacial till, new volcanic soil, sand dunes, clear cuts, and desert and chaparral (Schwencke and Caru, 2001). As a consequence, these plants play an essential role in land stabilization and soil reclamation (Sprent and Parsons, 2000). Actinorhizal plants have been used in erosion control, soil reclamation, agroforestry, and dune stabilization, as well as in fuel production. The properties of actinorhizal plants as pioneer species are linked mainly with the ability of their root to develop original organs, the nodules, containing the symbiotic N-fixing bacteria, in response to low nitrogen conditions.

42.1.2 The Actinomycete *Frankia*

The microsymbiont *Frankia* is a filamentous Gram-positive actinomycete and is characterized by a slow growth rate and high G + C DNA content (Simonet et al., 1990; Benson and Silvester, 1993). In pure culture, *Frankia* presents three major structures: vegetative hyphae (multiplication form), vesicles that are the site of nitrogen fixation, and sporangia (dissemination form). No *Frankia* strain specific to a single host plant species has been described to date (Pawlowski and Sprent, 2008). Nevertheless, host specificity is present at different levels and a broad correspondence can be defined between the phylogenies of *Frankia* strains and actinorhizal plants (see Chapter 24, this book).

Due to the lack of genetic tools (Mullin and Dobritsa, 1996), most aspects of *Frankia* biology, particularly symbiosis, are still unknown (Perrine-Walker et al., 2011). Several trials of genetic transformation, mutagenesis, and functional complementation failed to provide conclusive results. The recent sequencing of different *Frankia* genomes (Normand et al., 2007a,b; Persson et al., 2011) should bring new information. This is detailed in Chapter 24.

42.1.3 Development of Actinorhizal Nodules

Actinorhizal nodule development only occurs under conditions of nitrogen deprivation, and it is assumed that plant root emit signals of still unknown nature that are perceived by *Frankia*. Signal exchange between *Frankia* and the host plant has been investigated by several laboratories (Prin and Rougier, 1987; van Ghelue et al., 1997; Ceremonie et al., 1999). Root flavonoids are prime candidates for plant signaling molecules, since they govern plant–microorganism cross talk in the rhizosphere and regulate the expression of *nod* genes in *Rhizobium*, prompting thus synthesis of the rhizobial signal molecule, the so-called nodulation (Nod) factors (Abdel-Lateif et al., 2012; Chapters 50, 51).

On the bacterial side, a partial purification of a root hair deforming factor from the supernatant of *Frankia alni* cultures was achieved using root hair deformation assay on *Alnus*. This *Frankia* root hair deforming factor was

found to be of different nature than Nod factors (Ceremonie et al., 1999). Complete genome sequencing of *Frankia* strains infective on Alnus (ACN14) and Casuarina (CcI3) confirmed so far the absence of the canonical Rhizobia *nodABC* genes (Normand et al., 2007a; Hocher et al., 2012) in these strains. However, the recent sequencing of the strain *Candidatus Frankia datiscae* could bring new insights into the nature of the *Frankia* molecule signal (Persson et al., 2011). Several approaches are presently underway to isolate and characterize further the root hair deforming factor.

Depending on the host plant, two modes of infection of actinorhizal plants by *Frankia* have been described: intercellular root invasion and intracellular root hair infection (Berry and Sunnel, 1990; Duhoux et al., 1996; Wall and Berry, 2008). Intracellular infection (e.g., of *Casuarina, Alnus,* and *Myrica*) starts with root hair curling induced by an unknown *Frankia* signal. *Frankia* penetrates the curled root hairs and infection proceeds intracellularly in the root cortex (Lalonde and Knowles, 1975; Berg, 1990). At the same time, limited cell divisions occur in the cortex, leading to the formation of a small external protuberance called the prenodule (Berry and Sunnel, 1990). Most of prenodule cells are infected with *Frankia*. But, while cortical cell divisions lead to the formation of a nodule primordium in legumes, actinorhizal prenodules do not evolve in nodules. The function of the *C. glauca* prenodule is not yet fully understood, but studies of the expression of symbiosis-related genes (*cg12*, *cghb*, see above for details) coupled to cellular modification (cell wall lignification) indicated that the prenodule displays the same characteristics as the nodules and can be considered as a very simple symbiotic organ (Laplaze et al., 2008; see also Chapter 55).

The prenodule could thus be a parallel symbiotic organ on its own or the remaining form of a common nodule ancestor for legumes and actinorhizal plants (Gualtieri and Bisseling, 2000; Laplaze et al., 2008).

Concomitant with prenodule development, cell divisions are induced in pericycle cells opposite to a protoxylem pole, giving rise to an actinorhizal lobe primordium. Concerning the intercellular root invasion pathway (e.g., *Discaria*, *Ceanothus*, *Elaeagnus*, and *Hypophae*), *Frankia* hyphae penetrate between two adjacent rhizoderm cells and progress apoplastically through cortical cells within an electron-dense matrix secreted into the intercellular spaces (Miller and Baker, 1985; Racette and Torrey, 1989; Liu and Berry, 1991; Valverde and Wall, 1999). Unlike the intracellular mode of infection, no prenodule is formed in the root cortex. Once the nodule primordium has developed from the pericycle, intracellular penetration by *Frankia* and the formation of infection threads is initiated acropetally in developing cortical cells of the nodule lobe primordium, following a pattern similar to that described in plant species invaded through root hairs (see also Chapter 55).

The mature actinorhizal nodule consists of multiple lobes, each of which is a modified lateral root. In each lobe there is a central vascular bundle, and *Frankia* is restricted to the cortical cells. Four zones were characterized in actinorhizal nodules: the meristem zone (I) at the apex of nodule, this zone is responsible for indeterminate growth of nodule and always free from *Frankia;* the infection zone (II) is adjacent to the apical meristem, the hyphae infect some of the new cells derived from meristem activity that subsequently enlarge; and the fixation zone (III) is composed of infected and uninfected cells. Within this zone, infected host cells are hypertrophied. *Frankia* hyphae and vesicles are present, *Frankia nif* genes, coding for the nitrogenase complex, are expressed (Pawlowski et al., 1995), and the nitrogenase protein is detected (Huss-Dannell and Bergman, 1990). Therefore, in this zone, active nitrogen fixation takes place and the uninfected cells are smaller than infected cells; the senescence zone (IV) in older nodule lobes where host cytoplasm and endophyte degeneration is observed (Newcomb and Wood, 1987), *nifH* expression is switched off, and nitrogenase activity is lost in legume and actinorhizal nodules (Vikman et al., 1990; Swaraj et al., 1993).

42.1.4 Molecular Events Associated with Nodulation in Actinorhizal Species

During differentiation of the symbiotic actinorhizal root nodule, a set of genes – called actinorhizal nodulin genes – is activated in the developing nodules (Mullin and Dobritsa, 1996, Pawlowski et al., 1997). Similar to legumes, two major types of actinorhizal nodulin genes have been defined by their pattern of expression and function. Early nodulin genes are expressed before the beginning of nitrogen fixation; they are thought to be involved in plant infection or in nodule organogenesis, whereas late nodulin genes comprise sequences involved in different metabolic activities necessary for the functioning of the nodule (Obertello et al., 2003). Many nodule-specific or nodule-enhanced expressed genes have been detected in several actinorhizal plants including *Alnus*, *Datisca*, *Elaeagnus*, and *Casuarina* and were reviewed by several authors (Pawlowski and Bisseling, 1996; Wall, 2000; Hocher et al., 2006; Laplaze et al., 2008, Chapter 43, this book).

42.1.5 Genomic Resources for Actinorhizal Plant Species

Our group in collaboration with P. Normand's group has developed the first genomic platform to identify plant genes involved in the symbiotic process between *Frankia* and actinorhizal species (Hocher et al., 2006, 2011a). Starting from cDNA libraries obtained from noninoculated roots (controls), inoculated roots (2, 4, and 7 days post-inoculation

(dpi)) and nodules (3 weeks post-inoculation), two sets of ESTs were sequenced for *Casuarina glauca* and *Alnus glutinosa*. For both species, the ESTs database contains a total of about 35 000 valid ESTs. Each set of ESTs sequence data was processed and annotated using a multimodule custom pipeline as described in Hocher et al., (2006, 2011a,b) to generate a set of nonredundant gene sequences. The clustering resulted in about 15 000 unigenes for *A. glutinosa* and for *C. glauca.* To analyze transcriptional changes occurring during symbiosis in *A. glutinosa* and *C. glauca*, a 15K Agilent custom oligonucleotide chip was designed for each species. Two biological conditions were compared for both plants: noninoculated roots and 3-week-old nodules and resulted in the identification of sets of differentially expressed genes for *C. glauca* and *A. glutinosa* (Hocher et al., 2011a).

42.1.6 Genetic Program Recruited During Symbiosis of Actinorhizal Species

The global analysis of our data revealed that 11 to 14% of the 15 000 unigenes were regulated or specifically induced during nodule development for *A. glutinosa* and *C. glauca*, respectively. A majority of them are linked to transport, metabolism, protein synthesis machinery, cell wall, defense, and response to stress indicating that nodulation is associated with a high metabolic activity. This situation was found to be very close to that described in different transcriptomic studies performed in model legumes (Asamizu et al., 2000; Journet et al., 2002; Colebatch et al., 2004; El Yahyaoui et al., 2004; Maunoury et al., 2010; see also Chapter 41). For the first time, a similar global behavior was found during nodulation of two actinorhizal species and this behavior was found very similar to what is described for legumes, thus suggesting similar genetic programs for root nodule symbioses.

Furthermore, among the regulated genes, all the different nodulins already described in *A. glutinosa* and/or *C. glauca* (Goetting-Minesky and Mullin, 1994; Ribeiro et al., 1995, 1996; Guan et al., 1996a,b, 1997; van Ghelue et al., 1996; Pawlowski et al., 1997, 2003; Jeong et al., 2004; Svistoonoff et al., 2003) were identified in both species with a similar regulation pattern (Hocher et al., 2011a).

42.1.7 Role of Flavonoids in Actinorhizal Symbiosis

If several studies have reported the implication of flavonoids during actinorhizal plants–*Frankia* interaction, direct evidence of flavonoids as early signals between plant and *Frankia* is still lacking (Perrine-Walker et al., 2011; Abdel-Lateif et al., 2012). *Casuarina glauca* transcriptome analysis brought new insights into a putative role of flavonoids during actinorhizal symbiosis. Eight genes implicated in a flavonoid biosynthetic pathway were identified and a kinetic study of their expression during a nodulation time-course revealed a higher accumulation of isoflavone reductase transcripts as soon as 12 h after inoculation of the plant by the bacteria (Hocher et al., 2006; Auguy et al., 2011). These data suggest that flavonoids could act as plant signals in actinorhizal symbioses and might influence the symbiotic specificity in actinorhizal symbioses (Hocher et al., 2011b). However, direct evidence of their involvement is still lacking. We thus used RNA interference to silence chalcone synthase, the enzyme involved in the first committed step of the flavonoid biosynthetic pathway, in *Casuarina glauca*. Plants impaired in flavonoid biosynthesis were generated and used to study flavonoid accumulation and further nodulation. Knockdown of chalcone synthase expression reduced the level of specific flavonoids and resulted in severely reduced nodulation. Nodule formation was thus rescued by supplementing the RNAi plants with naringenin, an upstream intermediate in flavonoid biosynthesis. For the first time, a direct evidence of an essential role for flavonoids during the early stages of actinorhizal nodulation was demonstrated (Abdel-Lateif et al., 2013).

42.1.8 An Actinorhizal Signaling Pathway

In legumes, recent work using model species as *Medicago truncatula* and *Lotus japonicus* elucidated the role of many genes essential for the different nodulation steps (Oldroyd et al., 2009; Oldroyd, 2013). A very important discovery was that a genetic overlap exists between legumes root nodule symbiosis and the more ancient arbuscular mycorrhizal symbiosis referred to as the "SYM" signaling pathway (also known as the CSSP; Capoen et al., 2009; Markmann and Parniske, 2009; see Chapters 54, 55, 108, 110). Very little is known about symbiotic determinants of actinorhizal plants (see Chapter 43). Apart from the recent demonstration of the role of *SymRK* and *CCamK* in different actinorhizal species (Gherbi et al., 2008; Markmann et al., 2008; Svistoonoff et al., 2013; Chapter 43, this book), exploration of genomic data developed using *A. glutinosa* and *C. glauca* allows to identify orthologs of most of legume genes covering all members of the symbiosis pathway from the signal perception to the nodulation process *via* the bacterial and fungal common part (Hocher et al., 2011a). Six of them (*Lys6*, *CCaMK*, *Hap2-1*, *HMG*, *Cyp2*, and *Cyp4*) were identified in both species. More interestingly, expression analysis of these genes revealed that transcript accumulation in nodules *versus* uninfected roots was not only comparable between the two actinorhizal species but also similar to those found in legumes (Hocher et al., 2011a). These results support thus, for the first time, a role for these genes in the

actinorhizal–*Frankia* symbiosis and suggest a conserved signaling pathway for endosymbiosis. Moreover, the overlapping of legume and actinorhizal root nodule symbioses reinforces the hypothesis of a common genetic ancestor of the nodulating clade with a genetic predisposition for nodulation (Soltis et al., 1995; Doyle, 2011).

42.1.9 A Conserved Genetic Program Among Endosymbioses

Some features of root nodule endosymbiosis could have been recruited from the more ancient arbuscular mycorrhiza (AM), which is formed by the majority of land plants with fungi belonging to the phylum Glomeromycota (Kistner and Parniske, 2002; Oldroyd et al., 2011). This led to the hypothesis that pre-existing AM genes were recruited during the evolution of root nodule symbiosis (Parniske, 2008).

Concerning actinorhizal species, information about arbuscular mycorrhizae is still very sparse (Tromas et al., 2012; Diagne et al., 2013). In order to identify the *C. glauca* genes regulated by AM symbiosis, the *Casuarina* 15K chip was hybridized with cDNA from two biological conditions: noninoculated roots and roots that are 45 days after inoculation by the fungus *Rhizophagus irregularis*. Global analysis resulted in the identification of a set of differentially expressed genes in *C. glauca* AM roots (Tromas et al., 2012). Comparative transcriptomics was thus used to identify genes induced during AM in several plant species, including the legume species *Medicago truncatul*a, rice and the actinorhizal tropical tree *C. glauca*. This analysis revealed a group of 84 genes induced during AM in these three distant species. Interestingly, these genes correspond mainly to proteases, cytochrome P450 family, and transporters, and more probably represent core functions needed for AM symbiosis.

Moreover, a group of genes commonly induced during AM, rhizobial, and actinorhizal nodulations was also identified by comparing the genes upregulated in AM and actinorhizal symbioses in *C. glauca* to those upregulated in both nodules and AM recently identified in the model legume *M. truncatula.* Twenty-four *C. glauca* genes induced in AM roots and nodules (MycUp/NodUp) presented significant sequence homology with *M. truncatula* MycUp/NodUp genes. Once again, genes encoding proteases formed the largest cluster (10/24), suggesting that proteases play a significant common role in the three endosymbioses. Gene encoding transporters represented the second largest group. These genes might represent part of the heart of endosymbioses, conserved between the ancestral AM symbiosis and the more recent legume rhizobial and actinorhizal symbioses. This list represents genes probably linked to processes such as nutrient exchange, infection, and intracellular accommodation of the microsymbiont, and reflects the molecular tinkering that took place during evolution of nodulation using parts of ancestral AM mechanisms. Further functional characterization of these genes is now needed to understand their precise role in the three different endosymbioses and to explain how they were recruited during the evolution of RNS.

42.2 CONCLUSION AND FUTURE DIRECTIONS

In conclusion, the recent development of genomic resources for actinorhizal plant species and *Frankia* represent a major step that allowed to progress in the identification of key symbiosis determinants. The identification of a "core" symbiotic program essential for root nodulation and endomycorrhization in legumes and actinorhizal species provide important information on a likely recycling of ancient AM genes for new function related to nitrogen fixation in these species. However, further functional studies are now needed to understand their precise role in the different endosymbioses.

The recent development of high-throughput sequencing technologies (i.e., RNA-Seq), offers new perspectives for large-scale transcriptomic analyses. Two RNA-Seq projects are actually developed in our group on the *C. glauca–Frankia* symbiotic system. The first project is funded by ANR (France), and RNA-Seq is used to identify very early induced genes linked to the symbiotic process. The second project is funded by DOE-JGI (USA) and is developed in collaboration with the Common Microbiology Lab (IRD, Dakar – Sénégal). All plants of Casuarinaceae are known to be salt tolerant and our aim is to understand mechanisms linked to salt tolerance by identifying genes linked to salt tolerance in *C. glauca*. This project is linked to revegetation projects developed notably in Senegal. Another important perspective is to make all actinorhizal plants and *Frankia* genomics data available through a WEB platform with the aim to integrate and distribute knowledge related to actinorhizal symbioses worldwide.

On a longer term, the basic knowledge obtained on legume–*Rhizobium* and actinorhizal symbioses may help define strategies to expand the capacity of nodulation to nonnodulating crop plants (Beatty and Good, 2011; see Chapter 108).

43.1 INTRODUCTION

To cope with nitrogen deficiency, some plants evolved the capacity to form nitrogen-fixing root nodules in association with soil bacteria. This ability is restricted to two groups of plants: legumes and *Parasponia* (Cannabaceae) that interact with Gram-negative Proteobacteria collectively called rhizobia, and actinorhizal plants, a group of 220 species of Fagales, Cucurbitales, or Rosales, that interact with Gram-positive actinomycetes of the genus *Frankia* (Vessey et al., 2005). All these plants are phylogenetically related and clustered together in the Fabid clade, which also contains numerous nonnodulating taxons. However, nodulation is not an ancestral trait, it probably appeared independently 12–16 times during the evolution of Fabids (Doyle, 2011). Fabids appear to have evolved a predisposition to develop nitrogen-fixing nodules, which is not found in any other group of plants. The genetic basis of this predisposition is not well understood.

Molecular mechanisms leading to nodulation are particularly well studied in model legumes where key signaling molecules and major molecular determinants involved in nodule formation have been discovered. One of the most studied features is the Nod signaling pathway, which is activated by the specific recognition of bacterial Nod factors by plant LYSM receptor-like kinases (see Chapter 51). At least seven genes involved in the Nod pathway are also essential to establish arbuscular mycorrhizae, suggesting that legume nodulation recruited parts of the ancient "myc" program used by most plants to interact with arbuscular mycorrhizal fungi (Oldroyd, 2013). Genes of the common nod/myc pathway are also needed to form root nodules in *Parasponia* and actinorhizal plants (Op den Camp et al., 2011; Gherbi et al., 2008; Markmann et al., 2008; see also Chapter 42). However, the recent discovery of a *Bradyrhizobium* strain that does not rely on Nod factors to interact with its legume host (Giraud et al., 2007; see Chapter 28) unveiled an unexpected diversity of mechanisms used by plants to interact with nitrogen-fixing bacteria even within the legume family. Exploration of the molecular basis of nodule formation is therefore needed in different branches of nodulators to identify universal mechanisms and the genetic basis of the predisposition for nodulation found only in Fabids. This review deals with *Discaria trinervis*, an actinorhizal shrub native in northern Patagonia and its interaction with *Frankia*, which we began to compare at the molecular level with other nodulating plants.

43.1.1 *D. trinervis*: Classification, Distribution, and Symbiotic Specificity

D. trinervis (Fig. 43.1a), recently renamed *Ochetophila trinervis* (Medan et al., 2009) belongs to the family Rhamnaceae, which is included in the Rosales order. *D. trinervis* is mainly found on poor land gravel soils in xeric forests and steppe sites, often close to rivers or lakes (Fig. 43.1b) and is always nodulated and mycorrhized (Chaia et al., 2006a). Two other species, *Discaria chacaye* and *Discaria articulata*, grow in the same region and the three species coexist in

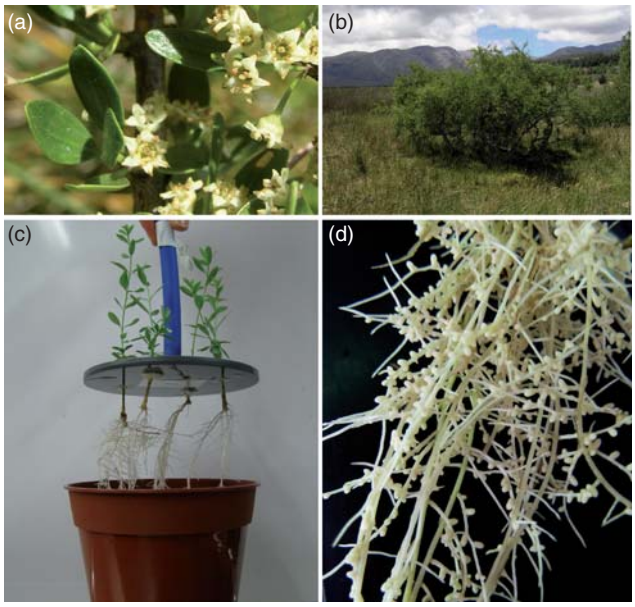

Figure 43.1 *Discaria trinervis* in its natural habitat, the northwest of Patagonia (a–b) and in hydroponic culture in laboratory conditions (c–d).

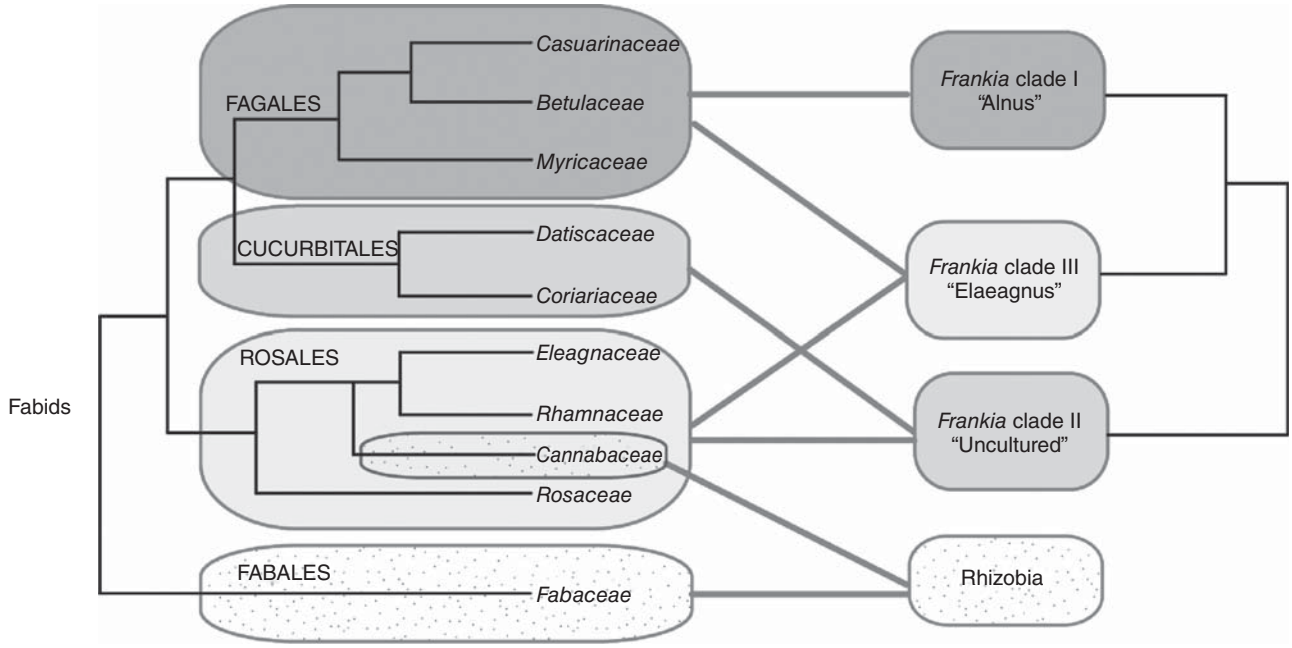

Figure 43.2 Phylogenetic relationships between plant families containing species able to form root nodules and the corresponding symbionts. Gray lines represent compatible interactions leading to nodulation.

some areas (Chaia et al., 2006b). Similar to all actinorhizal plants, *D. trinervis* shows symbiotic specificity, being nodulated by *Frankia* isolates from a particular set of actinorhizal plants belonging to Elaeagnaceae–Rhamnaceae clade, but not by *Frankia* from Myricaceae, Betulaceae, Casuarinaceae, Rosaceae, Coriariaceae, and Datiscaceae (Wall, 2000). *Frankia* isolates from Rhamnaceae and Eleagnacea belong to the same cluster (=clade III; Fig. 43.2), which appears to have the greatest metabolic versatility and are generally considered to be broad host-range symbionts with bigger genomes compared to *Frankia* from other clusters (Normand et al., 2007; see Chapter 24). Cross-inoculation experiments show that *Frankia* obtained from one *Discaria* species is able to nodulate all other *Discaria* with different levels of efficiency, suggesting that the recognition between *Frankia* and *Discaria* spp. would be mediated by a finely tuned signaling mechanism (Chaia et al., 2006b; Chaia, 1998).

43.1.2 Infection Establishment and Regulation

Frankia strains infect their hosts by two mechanisms: root hair infection as in *Myrica*, *Comptonia*, *Alnus*, and *Casuarina* or intercellular penetration as in *Elaeagnus, Hippophae, Ceanothus*, *Cercocarpus*, *and Discaria* (Wall, 2000). The initial steps of root hair infection are similar to what occurs in model legumes and have been extensively studied (Wall and Berry, 2008; Svistoonoff et al., 2010a). Much less is known about intercellular infection that takes place in about 35% of legume genera and 75% of actinorhizal genera (Sprent, 2007; Wall, 2000).

In *D. trinervis*, *Frankia* filaments in contact with the root surface adhere to the epidermis and enter the root by penetrating between epidermal cells and then between outer cortical cells (Fig. 43.3a). Root hairs are not involved in the initiation of nodulation and do not show any morphological response during these early interactions with the bacteria; they remain undeformed throughout the process of nodulation (Fig. 43.3a). Nevertheless, epidermal cells sense the presence of the invading bacteria and secrete locally an electron-dense material into the intercellular spaces through which *Frankia* filaments progress (Valverde and Wall, 1999b). Bacterial infection triggers cell divisions in the pericycle and the formation of a nodule primordium giving rise to a nodule lobe (Fig. 43.3a). Nodule lobes are structurally similar to a lateral root, with a central vascular bundle and an indeterminate apical meristem (Fig. 43.3a). *Frankia* filaments progress intercellularly until they reach the nodule cortex where they become intracellular as they infect cortical cells (Fig. 43.3a). No infection threads or transcellular infection could be detected, each infection takes place from the intercellular space (Valverde and Wall, 1999a). Mature nodules consist of several lobes with dichotomous ramifications and have an indeterminate growth (Fig. 43.3c).

Nodulation of *D. trinervis* is autoregulated (Valverde and Wall, 1999b; Valverde et al., 2000). Regulation by nitrogen (Valverde et al., 2000), phosphorous (Valverde

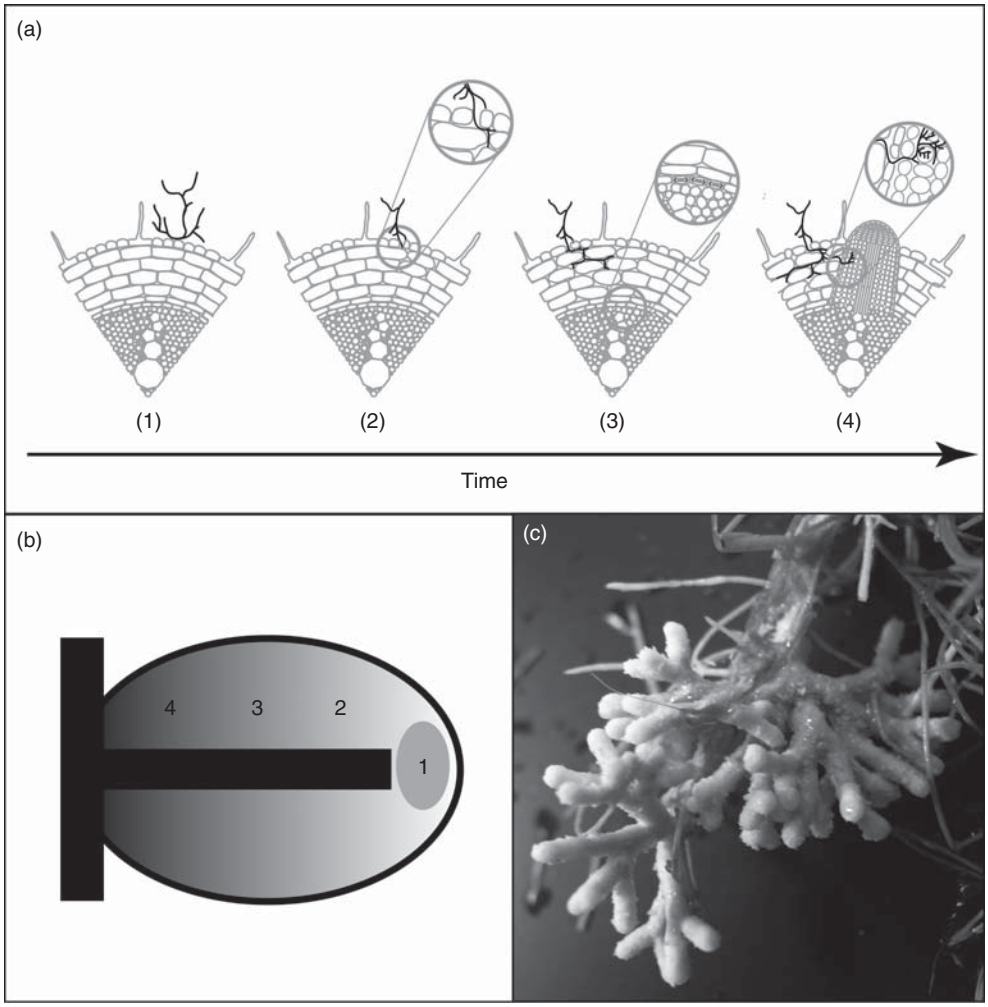

Figure 43.3 (a) Formation of actinorhizal nodules in *D. trinervis*. *Frankia* attaches to the root epidermis (1) and penetrates between epidermal cells without triggering any root hair deformation (2). Filaments progress in the intercellular space (2) triggering cell division in the pericycle (3) to form a nodule primordium (4). *Frankia* becomes intracellular in cortical nodule cells which are infected by filaments from the intercellular space. (b) In mature nodules, four zones are observed: the meristematic zone of the nodule that is always free of *Frankia* (1), the infection zone (2) containing newly formed cortical cells that are progressively infected and become hypertrophied, the fixation zone (3) where *Frankia* nitrogen-fixing vesicles are present, and a senescence zone (4) where Frankia and plant cells degenerate. The nodule presents a root-like structure with a central vasculature. (c) A mature nodule consisting of several branched lobes.

et al., 2002), and ethylene (Valverde and Wall, 2005) has been described and shows similar characteristics to what is observed in legumes and other actinorhizal plants, regardless of the infection pathway. *D. trinervis* autoregulation shows a particularity concerning mature nodules and control of new infections, compared to root hair-infected nodulated plants as *Alnus acuminata* (Chaia et al., 2006a,b). If mature nodules in *D. trinervis* stop to fix nitrogen for any reason, new infections by *Frankia* are not allowed in the growing younger parts of the root as it occurs in root hair-infected nodulated plants as *A. acuminata* (new infections can occur in this case). It is hypothesized that *Frankia* remaining intracellularly in the root cortex of *D. trinervis* sustain the feedback inhibition of new infections in the growing root. If more nitrogen fixation is needed because of the growth demand of the plant, new symbiotic tissue is developed by enlargement and further development of already existing mature nodules instead of generating new infections and development of new nodules – as it happens in intracellular root hair-infected plants (Chaia et al., 2006a,b). This mechanism found in laboratory experiments (Chaia et al., 2006a,b) appears to be corroborated by seasonal variations of field nodules of *D. trinervis* growing in the wild in Patagonia (Chaia, 1993).

Intercellular infection with similar characteristics to the one described in *D. trinervis* is a common feature of all

actinorhizal Rosales (Wall, 2000) and was recently described in mutants of *Lotus japonicus*, which can be nodulated by rhizobia unable to synthesize Nod factors, suggesting that intercellular infection is an ancestral process that is still present in some lineages (Madsen et al., 2010).

43.1.3 Establishment of Molecular Tools for *D. trinervis*

In laboratory conditions, *D. trinervis* plants grow vigorously and nodulate well in hydroponics (Fig. 43.1c and d). This is an advantageous system to study the symbiotic interaction because roots can be easily inoculated, observed, or extracted with minimal perturbation. Such roots are also clean, white, and poorly lignified; as a consequence, simple protocols for nucleic acid extraction including commercial kits originally developed for model plants such as *Arabidopsis thaliana* or *M. truncatula* can be directly applied to *D. trinervis*.

An essential tool to perform molecular analyses is the possibility to perform genetic transformation. Stable genetic transformation performed using *Agrobacterium tumefaciens* is available for two Casuarinaceae species (Svistoonoff et al., 2010a) and several nonactinorhizal Rosales (Gambino and Gribaudo, 2012). However, establishing an efficient genetic transformation procedure based on *A. tumefaciens* is often difficult since it requires both an efficient gene transfer protocol and the development of an *in vitro* regeneration method. An alternative method is based on *Agrobacterium rhizogenes*. Similar to *A. tumefaciens*, this bacterium is able to transfer genes of interest into the genome of the infected host plant, but in addition its T-DNA fragment carries genes driving auxin and cytokinin biosyntheses. This modified hormonal balance stimulates the formation of roots at the wounding site. Composite plants consisting of a nontransgenic aerial part and transgenic roots can thus be easily obtained in few weeks without any *in vitro* regeneration step (Benabdoun et al., 2011). To set up this genetic transformation system in *D. trinervis*, we first analyzed its susceptibility to two strains of *A. rhizogenes*: A4RS and ARqua1 carrying a plasmid with a 35S::GFP fusion to detect transgenic roots. The classic *in vitro* inoculation was compared to an *ex vitro* method reported to be successful in several plant species (Collier et al., 2005). The *ex vitro* method using Arqua1 was the best compromise to obtain good cotransformation efficiency (up to 80%) while minimizing the impact on root system architecture, which is very strong with the aggressive A4RS strain. The symbiosis was found to be fully functional in composite plants as revealed by nodulation tests, histological observations, and acetylene reduction assays. Cotransformed roots were specifically and efficiently nodulated with *Frankia*, and the resulting nodules were indistinguishable from nontransgenic nodules in terms of developmental timing, anatomy, nitrogen fixation, and feedback control by nitrogen (Imanishi et al., 2011).

43.1.4 *D. trinervis* Infection: Conserved and Divergent Molecular Mechanisms Compared to *C. glauca*

Over the past years, considerable amount of information has been produced on molecular mechanisms that determine nodule formation in *Casuarina glauca* (Svistoonoff et al., 2010a; Peret et al., 2009). We were particularly interested in the early steps of the interaction when bacterial recognition and accommodation take place. In contrast to *D. trinervis*, *Frankia* infects *C. glauca* via root hairs. As in model legumes, *Frankia* induces root hair deformation and penetrates a deformed root hair encapsulated by a cell wall deposit. Cell divisions are triggered in the cortex and give rise to a swollen structure, the prenodule, which becomes infected by *Frankia*. Similar to *D. trinervis*, cell divisions are induced in the pericycle and give rise a nodule primordium. Cortical nodule cells become invaded by *Frankia*. Infection in prenodules and nodules is mediated by infection threads, that is, lines of transcellular encapsulated hyphae (Peret et al., 2009). Several genes expressed specifically during the infection of *C. glauca* by *Frankia* were characterized, and their promoters were found to retain their specific activation pattern in model legumes indicating a strong conservation of molecular mechanisms involved in root hair infection between legumes and actinorhizal plants (Perrine-Walker et al., 2011). Three of these genes whose expression is strongly related to plant cell infection by *Frankia* were analyzed in the context of *D. trinervis* intercellular infection: *MtEnod11*, *Cg12*, and *CgAux1*.

MtEnod11 is a gene from *M. truncatula* coding for a proline-rich cell wall protein widely used as an early infection-related molecular marker for associations involving rhizobia, arbuscular mycorrhizal fungi, and even nematodes (Boisson-Dernier et al., 2005). Pro*MtEnod11* is strongly activated in *M. truncatula* and *C. glauca* during *Frankia* infection in infected root hairs, prenodules, and nodules, particularly in the infection zone (Svistoonoff et al., 2010b). *Cg12*, a gene from *C. glauca*, encodes a subtilisin-like serine protease expressed specifically in response to *Frankia* inoculation in infected root hairs, infected cells in prenodules, and mature nodules (Laplaze et al., 2000; Svistoonoff et al., 2003). In *D. trinervis*, Pro*MtEnod11* and Pro*Cg12* were found to be specifically activated in response to *Frankia* inoculation (Imanishi et al., 2011). Strong activation was detected in cells containing *Frankia* intracellularly in nodules as it is the case in *C. glauca* (Svistoonoff et al., 2003; Svistoonoff et al., 2010b) or *M. truncatula* (Svistoonoff et al., 2004; Boisson-Dernier et al., 2005) and also in some epidermal and cortical cells 3–7 days after *Frankia* inoculation. At this early stage, *Frankia* has not yet become intracellular; *Frankia* filaments are present exclusively in intercellular spaces and are progressing toward the future nodule primordia (Valverde and

Wall, 1999a). These results were later confirmed with the promoter of *Dt12*, the putative ortholog of *Cg12* in *D. trinervis*. The fact that these cells strongly activate Pro*Cg12* and Pro*MtEnod11* suggest the presence of at least a partial overlapping developmental program related to bacterial accommodation inside the root, which does not require the presence of intracellular bacteria.

CgAux1 encodes an auxin-influx carrier from *C. glauca*. Similar to Pro*Cg12* and Pro*Mtenod11*, Pro*CgAux1* is activated in *C. glauca* in *Frankia*-infected cells including root hairs, and also in root vasculature and root tips (Péret et al., 2007; Péret et al., 2008). In contrast to Pro*Cg12* and Pro*MtEnod11*, Pro*CgAux1* retains its nonsymbiotic activation pattern in *D. trinervis* but not its infection-related activation: expression was found in root tips and vasculature and nodules behaved as normal roots showing Pro*Aux1* activation only in the vasculature and meristem. As for *Cg12*, we confirmed these results with *DtAux1*, the putative ortholog of Cg*Aux1* in *D. trinervis* (Imanishi et al., 2014). These results point to a different auxin distribution in *D. trinervis* compared to *C. glauca*. Auxin distribution and fluxes were recently analyzed in *C. glauca* using antibodies against two auxins (PAA and IAA) and the auxin-efflux carrier PIN1 (Perrine-Walker et al., 2010). We performed similar experiments in *D. trinervis*. In *C. glauca*, auxins are concentrated in infected cells. The distribution of *CgAux1* in infected cells and PIN1 in noninfected cells surrounding infected cells is coherent with an accumulation of auxin in infected cells. Interestingly, in *D. trinervis*, PIN1 labeling was found in infected cells that are also labeled by anti-PAA and anti-IAA antibodies, again pointing to differences in auxin fluxes and roles between the two symbiotic systems (Imanishi et al., 2014).

43.1.5 An Universal Role of CCamK Activation in Nodule Organogenesis

In legumes, the *CCamK* gene encodes a calcium and calmodulin-dependent kinase, which plays an essential role in nodulation and mycorrhization (Oldroyd, 2013; see Chapter 54). Autoactive versions of CCAMK induce the formation of spontaneous nodules in model legumes (Gleason et al., 2006; Tirichine et al., 2006) and also in *Parasponia* (Op den Camp et al., 2011). We recently characterized the ortholog of *CCAMK* in *C. glauca*, *CgCCAMK*. We showed that *CgCCAMK* is essential for actinorhizal nodulation and mycorrhization in *C. glauca* and is able to fully complement the *M. truncatula* dmi3 mutant. A construct with a deleted version of *CgCCamK* lacking the autoinhibitory domain was introduced in *C. glauca*. Similar to legumes, this autoactive CgCCAMK lead to the formation of small spontaneous nodules in *C. glauca* without the presence of *Frankia*. The same construct was introduced in *D. trinervis* and in contrast to *C. glauca* nodules were numerous and bigger, almost identical to normal nodules except that they did not contain any *Frankia* (Svistoonoff et al., 2013). These results demonstrate that the activation of CCAMK is an universal mechanism, sufficient to activate the organogenesis program leading to nodule formation in all nodulating species, regardless of the symbionts or the infection mode.

43.1.6 Identification of Signaling Molecules and Their Receptors

As it was stated earlier, the interaction between *D. trinervis* and *Frankia* involves recognition between the symbiotic partners (Wall, 2000). Recognition should be a consequence of signal–receptor recognition events. Since there is no early plant response such as root hair deformation that can be used to bioassay early signaling between *Frankia* and *D. trinervis* roots, a different physiological approach measuring nodulation kinetics (Gabbarini and Wall, 2008) was used to characterize a diffusible factor of *Frankia* origin from strain BCU110501, isolated from *D. trinervis* (Chaia, 1998). This factor is relatively small (<12 kDa), it is synthesized by dense bacterial cultures, is negatively charged at pH 7.0, and is sensitive to protease treatments (Gabbarini and Wall, 2011a,b). Moreover, this diffusible *Frankia* factor appears to be related to the root hair deforming activity of *Frankia* BCU110501 on *A. acuminata* root hairs (Gabbarini and Wall, 2011a,b), suggesting a partial recognition plant response. It is worth noting that the barrier of symbiotic recognition between *Frankia* and either *D. trinervis* or *A. acuminata* could not be bypassed or physiologically complemented by just diffusible signals of plant or bacterial origin (Gabbarini and Wall, 2011a,b). To further characterize these signaling molecules, we plan to develop bioassays based on the specific activation of Pro*Dt12* at early stages of the interaction with *Frankia*.

In legumes, nod factors are perceived by receptor-like kinases containing LysM motifs encoded by genes *NFR5* and *NFR1* in *L. japonicus* (Oldroyd, 2013). We recently identified a putative ortholog of *NFR5* in *D. trinervis* (=*DtNFR5*) and will perform a functional analysis of this gene using an RNAi approach.

43.2 CONCLUSION

The development of molecular tools in *D. trinervis* has opened new possibilities to study the genetic mechanisms of intercellular root invasion and single cell infection. The study of genes previously characterized in other actinorhizal species such as *C. glauca* or in model legumes will provide useful information to understand this poorly known infection mechanism and allow the identification of universal mechanisms used by all plants able to form nitrogen-fixing nodules. *D. trinervis* is a Rosale, an order containing

numerous species unable to nodulate (most Rosaceae) and the only nonlegume able to form nodules with rhizobia (=*Parasponia*). Comparative studies at the molecular level between nodulating and nonnodulating Rosales should bring important cues about the evolution of nodulation.

44.1 INTRODUCTION

In nature, many legumes develop nodules on their roots in which rhizobia fix atmospheric nitrogen into ammonia by means of the enzyme nitrogenase. In return, the rhizobia obtain photoassimilates from the host that had been fixed within plant leaves, demonstrating that light quantity is critical for the effectiveness of this symbiosis. However, light quality also has a tremendous influence on the success of the legume–rhizobial symbiosis. In this chapter, we review the literature on the effects of light quality on the establishment of the legume–rhizobial symbiosis and describe our own work to update our current knowledge concerning nodule development and light.

44.2 RESULTS AND DISCUSSION

Numerous reports exist in the literature about sufficient light quantity being critical for effective root nodule formation (Fred and Wilson, 1934; Fred et al., 1938). In addition, adding glucose and sucrose to the nutrient medium when light was limiting enhanced root nodule formation in some legumes (Van Schreven, 1959). These observations support the idea that the accumulation of photoassimilates provides energy and compounds important not only for root nodule formation but also for nodule function to maintain a successful mutualism between the two symbiotic partners.

If we consider the fact that chlorophyll absorbs both red (R; 600–700 nm) and blue light (400–500 nm), we can conclude that the difference in light quality (wavelength) also affects the photosynthetic activity leading to the establishment of the symbiosis. The fact that the effects of light quality on symbiosis are independent of photosynthetic activity has been reported by a number of investigators. Lie (1964) studied the effects of short-time irradiation of R or far-red (FR) light at the end of the photoperiod of the light cycle of the day (end-of-day; EOD) on pea and kidney bean root nodule formation, and reported that root nodule formation following irradiation with FR light was suppressed compared to R light treatment (Lie, 1964). This phenomenon – that root nodule formation is suppressed by irradiating FR light at the EOD – was reported not only for pea (Lie, 1969) but also for broad beans (Lie, 1971), soybean (Kasperbauer et al., 1984; Hunt et al., 1987), and southern pea (cowpea) (Kasperbauer and Hunt, 1994). In contrast, Balatti and Montaldi (1986) showed that the number and biomass of soybean root nodules

Biological Nitrogen Fixation, Volume 1, First Edition. Edited by Frans J. de Bruijn.

20 days after inoculation with *Bradyrhizobium japonicum* were significantly increased following FR irradiation in EOD compared to R irradiation. The reasons for these contradictory results are unclear, but may depend on light quantity or the exact timing of the irradiation. Nevertheless, root nodule formation was restored by the irradiation of R after FR treatment in EOD (FR + R) and repressed once again following a light treatment of FR + R + FR in EOD. Because these results illustrate the classic photoreversibility of FR with R, the involvement of phytochrome in root nodule formation was strongly indicated (Lie, 1964; Hunt et al., 1987; Kasperbauer and Hunt, 1994).

That phytochrome participates in the perception of the R/FR ratio and the shade avoidance syndrome (SAS) is well known. Plants have photoreceptors that sense the presence of their neighbors by monitoring the ratio of R, mainly absorbed by chlorophyll, to FR light, which is not. A low R/FR ratio indicates the presence of neighbors that may be competitors for photosynthetically active radiation (PAR), thereby initiating the SAS, such that plant crowding causes plants to grow taller or to bend to the light to avoid being shaded (Smith and Whitelam, 1997; Neff et al., 2000; Franklin, 2008; Franklin and Quail, 2010). However, these low R/FR light conditions are suboptimal for root nodule formation. Kasperbauer and Hunt (1994) investigated the effect of the difference of R/FR ratio on southern pea root nodule formation by covering the surface of the pots with either gray-white or brick-red soil. Because the spectral distribution of light reflected from different soils is not the same, the R/FR ratio radiated to each pot through its covering differed. The final results showed that the number of root nodules 18 days after inoculation was higher when plants were grown under high R/FR (gray-white soil) than under low R/FR (brick-red) conditions (Kasperbauer and Hunt, 1994). In another experiment, this time in the field where multiple plants were planted together, the R/FR light ratios that these plants perceived depended not only on the degree of shading but also on row orientation because chlorophyll absorbs R light more efficiently than FR light. Root nodule formation for soybean and southern peas planted in either a north–south (low R/FR) or east–west (high R/FR) orientation was investigated. For both species, plants positioned in an east–west row orientation produced more nodules than those orientated north–south. In other words, plants grown under high R/FR ratios produced more nodules (Hunt et al., 1990; Kasperbauer and Hunt, 1994). However, the photosynthetic photon flux density (PPFD) for plants exposed to high R/FR conditions was higher than that for low R/FR exposure in both sets of experiments. Therefore, these investigators did not eliminate the possibility that root nodule number was affected by photosynthetic activity and the greater allocation of photoassimilates. Based on these results, we reasoned that root nodule formation was linked to the perception of the R/FR ratio and used *Lotus japonicus* (Suzuki et al., 2011; Shigeyama et al., 2012) to test this hypothesis.

To verify that root nodule formation is under the control of the perception of the R/FR ratio, we examined nodule formation in *L. japonicus* MG20 wild-type and *phyB* mutant plants grown under different R/FR light conditions. In our study, the PPFD of the R light-emitting diode (LED) remained constant to eliminate differences in the amount of photosynthate produced under low R/FR and high R/FR treatments. Signaling via phyB, the major red light photoreceptor used during seedling development, regulates responses to photoperiodism, end-of-day FR, and R/FR ratios in white light-grown plants (Neff et al., 2000; Franklin et al., 2003). From our experiments, we determined that the shoot and root fresh weights of *phyB* mutants were significantly reduced compared to those of MG20 plants grown under white light conditions. In addition, the number of root nodules of the *phyB* mutants was lowered compared to that of MG20 plants. To better understand the effect of the R/FR ratio on plant growth, we measured the fresh weights of the aerial plant parts, root length, and root nodule number under different R/FR light conditions. We found no statistically significant difference for either root length or shoot fresh weight for *L. japonicus phyB* mutants or MG20 plants, respectively, when the plants were grown under high R/FR and low R/FR light conditions. However, very few nodules developed on the *phyB* mutant roots under different R/FR light conditions. In addition, although nodules developed on MG20 plants grown in high R/FR light, very few nodules were detected on the roots of the low R/FR-grown plants.

Sucrose, a highly soluble disaccharide that provides energy sources for plant cells (Huber, 1989), is synthesized from the primary products of photosynthesis. To investigate whether a difference in photosynthetic activity was present while PPFD is constant, the sucrose content of the roots was measured after the plants were grown under different R/FR light conditions. We found that the sucrose content of roots in low R/FR-grown plants increased compared to the high R/FR-grown plants, suggesting FR light irradiation may be responsible for the increase in sucrose content. Nevertheless, the fact that root nodule number was reduced in the low R/FR-grown plants in spite of the higher sucrose content strongly suggests that phyB sensing of the R/FR ratio has a significant influence on nodulation. However, we cannot completely eliminate the possibility that photosynthetic products contribute to root nodule formation when the plants are grown under different R/FR light conditions.

Because the number of root nodules for both low R/FR-grown MG20 plants and white light-grown *phyB* mutants decreased, we hypothesized that phyB-mediated signaling in plants controlled by root nodule formation. Robson et al. (2010) suggested that phyA and JA signaling cooperate to regulate the balance between shade avoidance responses in FR-enriched light and defense responses

to mechanical damage or herbivores. In low R/FR light, phyB signaling suppressed both JA-mediated gene expression and JA-dependent defenses against insect herbivory (Moreno et al., 2009). By contrast, other reports indicate that antagonistic interactions between JA-mediated defense signaling and chromophore-mediated light signaling exist. For example, mutations in either *HY1* or *HY2*, which encode a phytochromobilin synthase, enhanced JA production and sensitivity (Zhai et al., 2007). For root nodule formation, JA has been reported to be a negative regulator. In *L. japonicus*, shoot-applied methyl jasmonate (MeJA) strongly suppressed the early stages of nodulation, including infection thread formation and *NIN* expression, and also inhibited lateral root formation (Nakagawa and Kawaguchi, 2006). In *Medicago truncatula*, JA also suppressed root nodule development, at an even lower concentration (Sun et al., 2006). Thus, we predicted that JA production and/or sensitivity would be enhanced in low R/FR-grown MG20 plants and white light-grown *phyB* mutants. We analyzed the expression of JA-responsive genes (*PDF1.2*, *JAR1*, and *MYC2*) in *L. japonicus* grown under different R/FR light conditions. The expression of *PDF1.2*, *JAR1*, and *MYC2* genes decreased in low R/FR-grown MG20 plants compared with plants grown under high R/FR light conditions. Moreover, their expression levels declined in *phyB* mutants under white light conditions in contrast to MG20 plants. These results strongly suggested that JA production and/or sensitivity decreased in low R/FR-grown MG20 plants and white light-grown *phyB* mutants, which was contrary to our expectations. To check whether JA concentration correlated with the expression of JA-responsive genes, we measured the endogenous concentrations of JA and JA-Ile in roots grown under white light condition. We found no significant difference in endogenous JA concentration between MG20 wild-type plants and *phyB* mutant plants. However, the endogenous concentration of JA-Ile significantly decreased in roots of *phyB* mutants. JA-Ile, the isoleucine conjugate of JA, is a biologically active hormonal signal (Staswick and Tiryaki, 2004) and is generated by a JAR1-encoding JA-amino acid synthetase. The *JAR1* gene product is involved in pathogen defense, sensitivity to ozone, and wound responses (Guranowski et al., 2007; Staswick, 2008; Koo et al., 2009). Our results might be explained by the fact that the conversion of JA to JA-Ile was suppressed due to decreased *JAR1* expression in the *phyB* mutants grown under white light conditions, which would give rise to a reduced concentration of JA-Ile in the *phyB* mutants. Thus, we concluded that root nodule formation was suppressed because the JA-Ile concentration was low in plants grown under low R/FR light conditions.

To examine the effect of JA directly on root nodule formation under different R/FR light conditions, JA was added to the plant growth medium. Both shoot and root growth of MG20 plants were decreased as the concentration of JA increased. Although the root nodule number per plant was reduced after adding a high concentration (10 μM) of JA, nodule number per plant for plants grown in low (0.1 μM) JA significantly increased when compared to control plants that received no exogenous JA. Furthermore, nodule number per root length increased for plants treated with 0.1, 1, and 10 μM JA over the untreated controls. Our results differed from those reported for *M. truncatula* (Sun et al., 2006), in that in our study, we found that *L. japonicus* nodule number was increased at low concentrations of JA.

If reduced nodule formation in low R/FR-grown MG20 plants and white light-grown *phyB* mutants is due to a low concentration of endogenous JA-Ile, we predicted that nodule formation would be enhanced by JA application. To test this possibility, the effect of JA treatment on root nodule development was analyzed. We found that the number of root nodules and nodule primordia in 0.1 μM JA-treated plants was slightly increased compared to untreated plants. We also examined the expression of JA-responsive genes and the *NIN* gene in 0.1 μM JA-treated or untreated plants. *NIN* is required for infection thread formation and nodule primordium initiation in *L. japonicus* (Schauser et al., 1999). The expression of *NIN* gene was significantly increased in 0.1 μM JA-treated plants. Although JA addition did not affect the total root length, the number of infection threads per root length was significantly increased in MG20 plants compared to the untreated plants. These results strongly suggest that low concentrations of JA function as a positive regulator for root nodule formation in *L. japonicus*.

In addition, we analyzed the effect of JA treatment on root nodule formation in *phyB* mutants. Following 0.1 μM JA treatment of *phyB* mutants, shoot length was unaffected and root length was decreased compared to the untreated plants. However, the number of root nodules per plant significantly increased compared to the number in the untreated plants. Moreover, nodule number per root length significantly increased in response to 0.1 and 1 μM JA treatments. Based on the responses of JA treatments to shoot length, total root length and root nodule number, the sensitivity of MG20 plants and *phyB* mutants to JA is not likely to be significantly different. To summarize, the cause of reduced root nodule formation in low R/FR-grown MG20 plants and white light-grown *phyB* mutants is due to the inhibition of JA-Ile production.

The literature also reports about the effects of R/FR ratios on the interaction between plants and microbes. For example, low R/FR ratio reduced *Arabidopsis* resistance to *Botrytis cinerea* (Cerrudo et al., 2012),‘ and fluorescent illumination with a high R/FR ratio improved the resistance of cucumber seedlings to powdery mildew (*Sphaerotheca cucurbitae*) (Shibuya et al., 2011). Moreover, in the case of the interaction between plants and pests, wild tobacco and *Arabidopsis* grown under high R/FR conditions were less susceptible to feeding damage by insect herbivory compared to low R/FR-grown plants (Izaguirre et al., 2006; Moreno

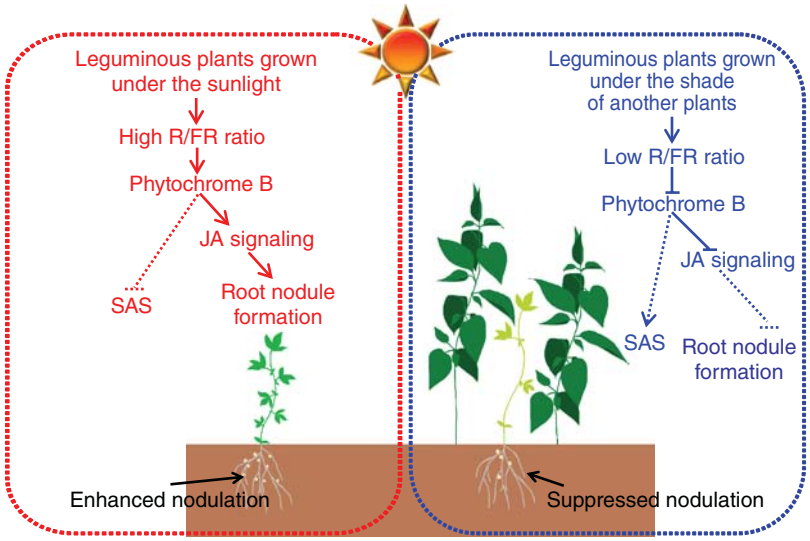

Figure 44.1 Model representing the proposed mechanism of JA and phyB signaling for shade perception and root nodule formation. In high R/FR light, phyB suppresses SAS and enhances root nodule formation through an increased concentration of JA-Ile. In low R/FR light, SAS is restored by the inactivation of phyB, and root nodule formation is suppressed due to a reduced concentration of JA-Ile. Small letters and dotted lines mean inactivation and suppression, respectively.

et al., 2009). JA signaling is involved in these plant defense mechanisms. Plants grown under high R/FR light produced more JA and protected themselves from pathogens, whereas plants grown under low R/FR light were more susceptible to infection or feeding damage by pathogens and predators due to the reduced production of or decreased sensitivity to JA (Cerrudo et al., 2012; Moreno et al., 2009; Ballaré, 2011). In root nodule symbiosis, the rhizobial infection process is enhanced by this mechanism.

For plants, photosynthesis is the most important biochemical reaction for survival. Plants grow taller or bend to light, but at the same time they assume the risk that they are more likely to be invaded by pathogens. In low R/FR light, phyB is inactivated by photoconverting the active Pfr form into Pr, and as a result, phytochrome-interacting factor 4 (PIF4) and 5 (PIF5) accumulate, leading to the synthesis of auxin (IAA) and bioactive gibberellins (Ballaré, 2011), phytohormones required for plant growth. However, the synthesis of phytohormones is incompatible with the production of JA, making it very difficult for plants to maintain active growth and high-level defense responses at the same time. Legumes show the same energy constraints by limiting the initiation of energy-costly nodules under low R/FR conditions. However, by obtaining sufficient nitrogen through the establishment of a symbiosis with rhizobia for maintaining effective growth, legumes may ultimately be better able to balance growth and defense than nonlegumes.

A model representing the proposed mechanism of JA and phyB signaling for shade perception and root nodule formation is depicted in Figure 44.1.

In high R/FR light conditions, phyB suppresses SAS and enhances root nodule formation through an increased concentration of JA-Ile. In contrast, in low R/FR light conditions, SAS is restored by the inactivation of phyB and root nodule formation is suppressed due to the reduced concentration of JA-Ile. Our data show that root nodule formation involves the perception of the R/FR light ratio and requires signaling through phyB and JA. Although root nodule development is initiated in the soil under low light, the R/FR light conditions in soil are suboptimal for sustaining root nodule function. Thus, host legumes shaded by other plants initiate a shade avoidance response and modify their growth to obtain sufficient light for maximizing photosynthesis. Nevertheless, under such low R/FR light conditions, the host plants suppress root nodule development to conserve energy. We conclude that this SAS for root nodule formation is required for *L. japonicus* nodule development. In conclusion, sensing both light quality and quantity is essential for establishing and maintaining a successful nitrogen-fixation symbiosis. How common this interaction is among the symbiotic Fabaceae is not known at this time.

Out of Water of a New Model Legume: The Nod-independent *Aeschynomene evenia*

Jean-François Arrighi and Fabienne Cartieaux
IRD, Laboratoire des Symbioses Tropicales et Méditerranéennes (LSTM), UMR IRD/SupAgro/INRA/UM2/CIRAD, F-34398 Montpellier, France

45.1 INTRODUCTION

The pantropical genus *Aeschynomene* belongs to the *Dalbergieae* tribe, an important group within the papilionoid legumes that is represented by peanut (*Arachis hypogaea*), the second most important crop legume. They share with arachid and other legumes of both the Dalbergioid and Genistoid clades to be infected by rhizobial strains in an intercellular manner to produce fully infected nitrogen-fixing nodules.

The initial interest of studying *Aeschynomene* relies on the fact that 22 semi-aquatic species have the capacity to form nitrogen-fixing nodules on both roots and stems. This unusual behavior among legumes is only shared with a few species of the genera *Sesbania*, *Neptunia*, and *Discolobium* (Boivin et al., 1997). In addition, some *Bradyrhizobia* isolated from *Aeschynomene* stem nodules exhibit the property uncommon among rhizobia of developing a photosynthetic system (Evans et al., 1990; Giraud and Fleischman, 2004; see Chapter 28). It has been shown that the photosynthetic activity of *Bradyrhizobium* plays a key role during stem nodulation by directly furnishing energy to the bacterium that can be used for biological nitrogen fixation (Giraud et al., 2000; see Chapter 28).

More recently, some photosynthetic *Bradyrhizobium* strains have been shown to be unique because they lack the canonical *nodABC* genes required for the synthesis of Nod factors (NF), whereas they maintain the ability to elicit efficient nodules (Giraud et al., 2007). This revealed the existence of a Nod-independent symbiotic process. To identify the plant determinants of this new and original symbiotic process, *Aeschynomene evenia* was recently proposed as a new legume model. In this review, we discuss the interests of studying this species, its characteristics, and the development of functional tools for its analysis.

45.1.1 Interests of *A. evenia* as a New Model Legume

Studies of *Rhizobium*–legume symbiosis have mainly been conducted on the symbiotic models: *Lotus japonicus–Mesorhizobium loti*, *Medicago truncatula–Sinorhizobium meliloti*, and *Glycine max–Bradyrhizobium japonicum*. They have led to a better understanding of the molecular mechanisms of this interaction with the identification of numerous components of the symbiotic pathways (reviewed in Oldroyd et al., 2011 and Oldroyd, 2013). In these systems, the early steps of the symbiosis are well conserved: this involves the perception by the plant of bacterial signal molecules called Nod factors that trigger two coordinated programs, bacterial infection through transcelullarly progressing infection threads and distant nodule organogenesis (see Chapter 51). However, these model legumes belong to the Phaseolid and Galegoid clades, and they are far from representing the diversity of the symbiotic mechanisms used by legumes to interact with rhizobium (Sprent, 2007; Sprent and James, 2008) (Fig. 45.1). Indeed, legumes of the more basal Genistoid and Dalbergioid clades, which represent

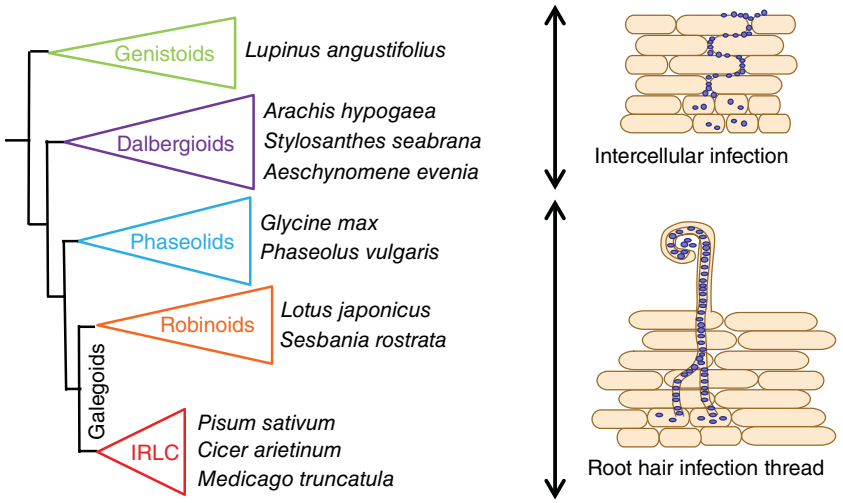

Figure 45.1 Evolution of the symbiotic infection process within the Papilionoid lineage. On the left, tree representation of the phylogeny of the Papilionoids with triangles representing the major clades. Some notable species are indicated for each clade. On the right, infection processes encountered in the different clades: the intercellular infection mode with progression of the rhizobia between root cells and the intracellular infection mode mediated by the development of an infection thread. (*Source*: Figure adapted from Bertioli et al. (2009) and Held et al. (2010).)

about 25% of the legume species, display another mode of infection where the entry of bacteria occurs intercellularly between epidermal cells. In addition to the absence of infection thread formation, there is no distant induction of a primordium. Instead, the nodule originates from successive divisions of only one or few infected cortical cells. This has been well described for *Arachis hypogaea* and *Lupinus albus*, two major legumes crops, as well as *Aeschynomene* spp. (Chandler, 1978; Chandler et al., 1982; Gonzales-Sama et al., 2004; Bonaldi et al., 2011).

Most surprisingly, in some *Aeschynomene* spp., a Nod-independent symbiotic process has been described where the symbionts, that is, photosynthetic *Bradyrhizobium* strains, are able to efficiently form nodules in the absence of NF synthesis (Giraud et al., 2007). A similar Nod-independent infection process has been observed in some double mutants of *L. japonicus*, although at a very low frequency (Madsen et al., 2010). In this genetic experimental system, single-cell infections were observed, without the formation of infection threads, independently of plant NF receptors and bacterial NF. This infection process was suggested to correspond to the ancestral state of the rhizobial infection, which could have been maintained during evolution in some legumes such as *Aeschynomene* spp. The absence of the requirement of NF to trigger symbiosis has been identified to date only in some *Aeschynomene* species, and the *Bradyrhizobium* strains that can use a Nod-independent infection strategy form a distinct lineage within the *Bradyrhizobium* phylogeny (Miché et al., 2010). The specificity between Nod-independent *Aeschynomene* and some *Bradyrhizobium* suggested to Okubo et al. (2012) that this symbiotic interaction could correspond in fact to an evolved state.

Deciphering the molecular mechanisms of the Nod-independent symbiosis will shed light on the evolutionary history of the *Aeschynomene–Bradyrhizobium* system. This would also serve to better understand the molecular basis of intercellular bacterial invasion and nodule organogenesis, particularly in Dalbergioid legumes, for which our knowledge remains limited due to the absence of appropriate genetic tools.

For these purposes, we explored the diversity of the Nod-independent *Aeschynomene* species. We selected *A. evenia* as it was closely related to the widespread but polyploid *A. indica* – used as host plant to study the symbiotic photosynthetic *Bradyrhizobium* – and it satisfied the required features for genetic and molecular approaches (Fig. 45.2) (Arrighi et al., 2012; Okubo et al., 2012; Bonaldi et al., 2010b). The *A. evenia* cultivar line IRFL 6945 displays a small and diploid genome (460 Mb, $2n = 20$) that is comparable to the two model legumes *M. truncatula* and *L. japonicus* (520 and 470 Mb, respectively). The species is autogamous, and an artificial hybridization method was successfully set up to perform directed crosses. *A. evenia* is easily cultured both *in vitro* and in pots. Efficient germination and small-sized plantlets facilitate their manipulation in laboratory conditions. A short generation time that can be accomplished in 10 weeks and the profuse seed production (thousands seeds over a plant lifetime) are other advantageous characteristics to obtain abundant material. Moreover, it is a short-lived perennial and rooting of cuttings is easily performed, which allows maintaining plants of interest. With genetic, symbiotic, and transformative properties that are discussed hereafter, this makes *A. evenia* a genetically tractable species to decipher the Nod-independent process.

45.1.2 Genotype Diversity

A. evenia is primarily American with a distribution from the southern United States to Argentina, but accessions are also found in regions of Africa. To investigate the intraspecific diversity, a set of 27 accessions representing almost all the

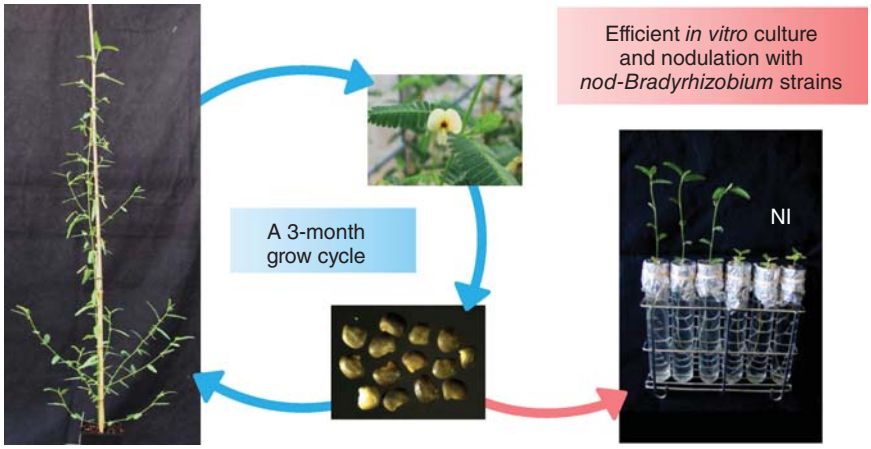

Figure 45.2 *Aeschynomene evenia* development and culture. (a) The plant presents a 3-month seed-to-seed cycle in greenhouse culture. (b) *In vitro* culture of inoculated plants (on the left) and not inoculated plants (NI) (on the right) with *Bradyrhizobium* strains. (*Source*: Adapted from Arrighi et al. (2012).)

accessions available in germplasm banks, and originating from regions of the world where this species naturally grows, was used. We conducted a polyphasic analysis by combining phenotypic, genotypic, molecular, and cross-compatibility approaches. It evidenced an important intraspecific differentiation with the accessions of the two described botanical types *evenia* and *serrulata*, forming sister taxa in the molecular phylogenies and showing a high genetic divergence. Such ongoing speciation process was also observed for other legume species such as *Arachis hypogaea* (Ferguson *et al*., 2004) and *Medicago truncatula* (Ellwood et al., 2006). This led us to propose a revision of the taxonomic classification of *A. evenia* (Arrighi et al., 2013).
