Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

CONTRIBUTORS

Vineeta Ahojja, M.D.

Chief Cardiology Fellow
Department of Cardiology
Wayne State University
Detroit, MI
USA

Vamadevan S. Ajay, M.P.H.

Research Fellow
Cardiovascular Health Research
Centre for Chronic Disease Control
New Delhi
India

Laurence Amar, M.D.

Faculté de Médecine René Descartes
Department of Vascular Medicine and
Hypertension
Université René Descartes
Hôpital Européen George Pompidou
Department of Vascular Medicine and
Hypertension
Assistance Publique des Hôpitaux
de Paris
Paris
France

**Lawrence J. Appel, M.D.,
M.P.H.**

Professor of Medicine
Welch Center for Prevention
Epidemiology and Clinical Research
Division of General Internal Medicine
The John Hopkins University School
of Medicine
Baltimore, MD
USA

Michel Azizi, M.D., Ph.D.

Faculté de Médecine René Descartes
Clinical Investigation Center
Université René Descartes
Hôpital Européen George Pompidou
Clinical Investigation Center
Assistance Publique des Hôpitaux
de Paris
Paris
France

George L. Bakris, M.D., F.A.C.P.

Professor and Section Director
Hypertension/Clinical Research Center
Department of Preventive Medicine
Rush Medical College
Rush University Medical Center
Chicago, IL
USA

Lydia A. Bazzano, M.D., Ph.D.

Assistant Professor
Epidemiology and Medicine
Tulane University School of Public
Health and Tropical Medicine
New Orleans, LA
USA

D. Gareth Beevers, M.D., F.R.C.P.

Professor of Medicine
University Department of Medicine
City Hospital
Birmingham
UK

**Lawrence J. Beilin, A.O., M.D.,
F.R.A.C.P.**

Professor
School of Medicine and Pharmacology
University of Western Australia
Perth, Western Australia
Australia

Andrew D. Blann, Ph.D.

Senior Lecturer
University Department of Medicine
University of Birmingham
Consultant Clinical Scientist
University Department of Medicine
City Hospital
Birmingham
UK

Matthew A. Boegehold, Ph.D.

Director
Center for Interdisciplinary Research in
Physiology and Pharmacology
Professor
Department of Physiology and
Pharmacology
West Virginia University
Morgantown, WV
USA

George W. Booz, Ph.D., F.A.H.A.

Assistant Professor
Department of Medicine and Medical
Physiology
The Texas A&M University System
Health Science Center College of
Medicine
Assistant Professor
Division of Pulmonary and Critical
Care Medicine
Scott & White Hospital and Clinic
Research Physiologist (WOC)
The Central Texas Veterans Health
Care System
Division of Molecular Cardiology
The Cardiovascular Research Institute
Temple, TX
USA

**Branko Braam, M.D., Ph.D.,
F.A.S.N.**

Associate Professor
Division of Nephrology and
Immunology, Faculty of Medicine
University of Alberta Hospital
Internist/Nephrologist
Division of Nephrology and
Immunology, Faculty of Medicine
University of Alberta Hospital
Adjunct Assistant Professor of Physiology
Department of Physiology
University of Alberta
Edmonton, Alberta
Canada

Elizabeth L. Brandon, Ph.D.

Postdoctoral Fellow
Physiology and Biophysics
University of Mississippi Medical Center
Jackson, MS
USA

Michael W. Brands, Ph.D.

Professor
Department of Physiology
Medical College of Georgia
Augusta, GA
USA

Mark Britton, M.D., Ph.D.

Physician and Research Scientist
Divisions of General Internal Medicine
and Translational Research and Clinical
Epidemiology
Department of Internal Medicine
Wayne State University
Detroit, MI
USA

Hans R. Brunner, M.D.

Professor Emeritus
Lausanne University
Lausanne
Switzerland
Medizinische Poliklinik
Universitaetsspital
Basel
Switzerland

Beverly Burke, B.Sc.

Clinical Pharmacology
William Harvey Research Institute
Barts and the London School of
Medicine and Dentistry
London
UK

Valerie Burke, M.D., F.R.A.C.P.

School of Medicine and Pharmacology
University of Western Australia
Perth, Western Australia
Australia

Francesco P. Cappuccio, M.D., M.Sc., F.R.C.P., F.F.P.H.

Cephalon Professor
Cardiovascular Medicine and
Epidemiology
Consultant Physician
Clinical Sciences Research Institute
Warwick Medical School
Coventry
UK

Robert M. Carey, M.D., M.A.C.P., F.A.H.A.

Harrison Distinguished Professor
of Medicine
Department of Medicine
University of Virginia School
of Medicine
Charlottesville, VA
USA

Barry L. Carter, Pharm.D., F.A.H.A., F.C.C.P.

Professor
Division of Clinical and Administrative
Pharmacy
College of Pharmacy
University of Iowa
Professor
Department of Family Medicine
Roy. J. and Lucille A. Carver College
of Medicine
Iowa City, IA
USA

Mark J. Caulfield, F.R.C.P.

Professor
Department of Clinical Pharmacology
William Harvey Research Institute
Barts and the London School of
Medicine and Dentistry
London
UK

Yuqing Chen, M.D.

Postdoctoral Researcher
Department of Medicine and
Pharmacology
University of California at San Diego
School of Medicine
La Jolla, CA
USA

Jay N. Cohn, M.D., F.A.A.C.

Professor of Medicine
Cardiovascular Division
Director
Rasmussen Center for Cardiovascular
Disease Prevention
University of Minnesota Medical Center
Minneapolis, MN
USA

John M. C. Connell, M.D., F.R.C.P., FMed.Sci., F.R.S.E.

Professor of Endocrinology
BHF Glasgow Cardiovascular Research
Centre, University of Glasgow
Consultant Endocrinologist
Western Infirmary
Glasgow
Scotland

Anthony Cox, B.Sc., MRPharmS, Clin Dip Pharm

Senior Pharmacovigilance Pharmacist
West Midlands Centre for Adverse Drug
Reaction Reporting
Sandwell and West Birmingham Hospitals
NHS Trust
Birmingham
UK

Madhusudan Das, Ph.D.

Visiting Scholar
Department of Medicine and
Pharmacology
University of California at San Diego
School of Medicine
La Jolla, CA
USA

Kevin P. Davy, Ph.D.

Associate Professor
Department of Human Nutrition, Foods
and Exercise
Director
Human Integrative Physiology Laboratory
Virginia Polytechnic Institute and State
University
Blacksburg, VA
USA

Cheryl R. Dennison, R.N., A.N.P., Ph.D.

Assistant Professor
School of Nursing
John Hopkins University
Baltimore, MD
USA

Shant Der Sarkissian, Ph.D.

Post Doctoral Research Associate
Department of Physiology and
Functional Genomics
University of Florida
Gainesville, FL
USA

Javier Díez, M.D., Ph.D.

Professor of Vascular Medicine
Department of Medicine
School of Medicine
University of Navarra
Head
Area of Molecular Cardiology
Department of Cardiology and
Cardiovascular Surgery
University Clinic of Navarra
Director
Division of Cardiovascular Sciences
Centre for Applied Medical Research
Pamplona
Spain

Peter A. Doris, Ph.D.

Associate Professor of Molecular
Medicine
Institute of Molecular Medicine
University of Texas Health Science
Center at Houston
Houston, TX
USA

Heather A. Drummond, Ph.D., F.A.H.A.

Assistant Professor
Physiology and Biophysics
University of Mississippi Medical Center
Jackson, MS
USA

Daniel A. Duprez, M.D., Ph.D., F.A.H.A., F.A.C.C., F.E.S.C.

Professor of Medicine
Cardiovascular Division
Medical School
University of Minnesota
Cardiologist
Cardiovascular Division
University Medical Center, Fairview
Director of Research
Rasmussen Center for Cardiovascular
Disease Prevention
Cardiovascular Division
Medical School
University of Minnesota
Minneapolis, MN
USA

Fernando Eljovich, M.D., F.A.H.A.

Director
Division of General Internal Medicine
Medical Director
Center for Diagnostic Medicine
Department of Medicine
Scott and White Clinic
Texas A and M University
Temple, TX
USA

Henry L. Elliott, M.D., F.R.C.P.

Senior Lecturer in Medicine and
Therapeutics
Division of Cardiovascular and Medical
Sciences
University of Glasgow
Consultant Physician
Medicine and Therapeutics
Western Infirmary
Glasgow, Scotland
UK

William J. Elliott, M.D., Ph.D.

Professor of Preventive Medicine,
Internal Medicine, and Pharmacology
Department of Preventive Medicine
RUSH Medical College of RUSH
University
Attending Physician
Preventive Medicine, Internal Medicine
RUSH University Medical Center
Chicago, IL
USA

David J. Eveson, M.D., M.R.C.P.

Stroke Association Fellow
Cardiovascular Sciences
University Hospitals of Leicester
Leicester
UK

**Gregory D. Fink, Ph.D.,
F.A.H.A.**

Professor
Department of Pharmacology and
Toxicology
Michigan State University
East Lansing, MI
USA

Nicola Fiotti, M.D.

Assistant Professor in Cardiovascular
Diseases
Clinical, Morphological, and
Technological Sciences
University of Trieste
Trieste
Italy

**John M. Flack, M.D., M.P.H.,
F.A.H.A.**

Professor and Interim Chairman and
and Chief
Division of Translational Research and
Clinical Epidemiology
Department of Internal Medicine
Wayne State University
Detroit, MI
USA

**Joseph T. Flynn, M.D., M.S.,
F.A.A.P.**

Professor of Clinical Pediatrics
Department of Pediatrics
Albert Einstein College of Medicine
Director
Pediatric Hypertension Program
Section of Pediatric Nephrology
Children's Hospital at Montefiore
Bronx, NY
USA

**Pierre Foëx, D.M., D.Phil,
F.R.C.A., F.Med.Sci.**

Professor
Nuffield Department of Anaesthetics
University of Oxford
Honorary Consultant
Nuffield Department of Anaesthetics
The John Radcliffe Hospital
Oxford
UK

**Lourdes A. Fortepiani, M.D.,
Ph.D.**

Research Assistant Professor
Department of Physiology
University of Mississippi Medical Center
Jackson, MS
USA

**Martin D. Fotherby, M.D.,
F.R.C.P.**

Senior Lecturer
Department of Cardiovascular Sciences
Consultant
Department of Stroke Medicine
University Hospitals of Leicester
Leicester
UK

Fetnat Fouad-Tarazi, M.D.

Division of Cardiology
Department of Medicine
The Cleveland Clinic Foundation
Cleveland, OH
USA

**Stanley S. Franklin, M.D.,
F.A.C.P., F.A.C.C.**

Clinical Professor of Medicine
Department of Medicine
Associate Medical Director
UCI Heart Disease Prevention Program
University of California, Irvine
Irvine, CA
USA

Ryan Friese, M.S.

Graduate Student
Department of Bioengineering
University of California, San Diego
La Jolla, CA
USA

**John W. Funder, A.O., M.D.,
Ph.D., F.R.A.C.P.**

Professor
Medicine
Monash University
Clayton, Victoria
Professorial Associate
University of Melbourne
Parkville, Victoria
Professor
Institute of Molecular Biosciences
University of Queensland
St. Lucia, Queensland
Senior Fellow
Prince Henry's Institute of Medical
Research
Clayton, Victoria
Australia

**James J. Galligan, Ph.D.,
F.A.H.A.**

Professor
Department of Pharmacology and
Toxicology
Michigan State University
East Lansing, MI
USA

Jeffrey L. Garvin, Ph.D.

Professor
Department of Physiology
Wayne State University
Senior Staff Investigator
Division of Hypertension and Vascular
Research
Henry Ford Hospital
Detroit, MI
USA

Christopher L. Gentile, M.S.

Research Associate
Department of Human Nutrition, Foods
and Exercise
Virginia Polytechnic Institute and State
University
Blacksburg, VA
USA

**Jacob George, M.B.Ch.B.,
M.R.C.P.**

Clinical Research Fellow
Department of Medicine and Therapeutics
School of Medicine
University of Dundee
Honorary Senior House Officer
Department of Medicine and Therapeutics
Ninewells Hospital and Medical School
Dundee, Scotland
UK

Lorenzo Ghiadoni, M.D.

Assistant Professor
Department of Internal Medicine
University of Pisa
Pisa
Italy

Carlo Giansante, M.D.

Associate Professor in Internal Medicine
Department of Clinical, Morphological,
and Technological Sciences
University of Trieste
Trieste
Italy

**Richard E. Gilbert, Ph.D.,
F.R.A.C.P., F.R.C.P.C.**

Professor
Department of Medicine
University of Toronto
Professor
Division of Endocrinology and Metabolism
St. Michael's Hospital
Toronto, Ontario
Canada
Professor
Department of Medicine
University of Melbourne
Melbourne, Victoria
Australia

Sabas I. Gomez, M.D.

Research Fellow
Department of Physiology and
Biomedical Engineering
Mayo Clinic
Rochester, MN
USA

Alan H. Gradman, M.D.

Professor
Department of Medicine
Temple University School of Medicine
Chief
Division of Cardiovascular Diseases
Western Pennsylvania Hospital
Pittsburgh, PA
USA

Joey P. Granger, Ph.D.

Department of Physiology and
Biophysics
University of Mississippi Medical
Center
Jackson, MS
USA

Guido Grassi, M.D.

Full Professor of Medicine
Clinica Medica
Università Milano-Bicocca
Monza
Full Professor of Medicine
Dipartimento di Medicina Clinica
Ospedale San Gerardo
Milan
Italy

**Philip Greenland, M.D.,
F.A.C.P., F.A.C.C., F.A.H.A.**

Harry W. Dingman Professor and
Chairman
Executive Associate Dean for Clinical
and Translational Research
Department of Preventive Medicine
Feinberg School of Medicine
Northwestern University
Chicago, IL
USA

Ehud Grossman, M.D.

Professor of Medicine
Sackler School of Medicine
Tel-Aviv University
Tel-Aviv
Head
Internal Medicine Department and
Hypertension Unit
The Chaim Sheba Medical Center
Tel-Hashomer
Israel

Johannie Gungadoo, B.Sc.

Department of Clinical Pharmacology
William Harvey Research Institute
Barts and the London School of
Medicine and Dentistry
London
UK

John A. Haas, B.S.

Associate in Research
Department of Physiology and
Biomedical Engineering
Mayo Clinic
Rochester, MN
USA

Peter Y. Hahn, M.D., F.C.C.P.,**D.A.B.S.M.**

Assistant Professor of Medicine
Division of Pulmonary and Critical
Care Medicine
Mayo Clinic College of Medicine
Rochester, MN
USA

John E. Hall, Ph.D.

Arthur C. Guyton Professor and Chair
Department of Physiology and
Biophysics
Associate Vice Chancellor for Research
University of Mississippi Medical Center
Jackson, MS
USA

Bruce A. Hamilton, Ph.D.

Associate Professor
Department of Medicine
Associate Adjunct Professor
Cellular and Molecular Medicine
University of California
San Diego School of Medicine
La Jolla, CA
USA

Joseph R. Haywood, Ph.D.

Professor and Chairperson
Pharmacology and Toxicology
Michigan State University
East Lansing, MI
USA

Jiang He, M.D., D.M.S., Ph.D.

Professor and Chair
Department of Epidemiology
Tulane University School of Public
Health and Tropical Medicine
Clinical Professor of Medicine
Department of Medicine
Tulane University School of Medicine
New Orleans, LA
USA

Marcela Herrera, M.S.

Research Associate
Division of Hypertension and Vascular
Research
Henry Ford Hospital
Detroit, MI
USA

Martha N. Hill, Ph.D., R.N.**F.A.A.N.**

Dean and Professor of Nursing
Office of the Dean
John Hopkins University
Baltimore, MD
USA

Radu Iliescu, M.D., Ph.D.

Instructor
Department of Physiology and
Biophysics
University of Mississippi Medical Center
Jackson, MS
USA

Chris Isles

Consultant Physician
Renal Unit
Dumfries and Galloway Royal Infirmary
Dumfries
UK

Joseph L. Izzo, Jr., M.D.,**F.A.C.P., F.A.H.A.**

Professor
Medicine; Pharmacology and Toxicology
SUNY-Buffalo School of Medicine and
Biomedical Sciences
Clinical Director
Medicine
Erie County Medical Center
Buffalo, NY
USA

Rumi Jaumdally

Haemostasis, Thrombosis and Vascular
Biology Unit
University Department of Medicine
City Hospital
Birmingham
UK

Daniel W. Jones, M.D.

Vice Chancellor for Health Affairs
Dean
School of Medicine
University of Mississippi Medical
Center
Jackson, MS
USA

**Patricia M. Kearney,
M.B.B.Ch.B.A.O., M.R.C.P.I.,
M.P.H.**

Honorary Lecturer
Epidemiology and Public Health
University College Cork
Cork
Ireland
Clinical Research Fellow
CTSU
University of Oxford
Oxford
UK

Hein A. Koomans, M.D., Ph.D.

Professor and Chairman
Department of Nephrology and
Hypertension
University Medical Center Utrecht
Internist/Nephrologist
Department of Nephrology and
Hypertension
University Medical Center Utrecht
Utrecht
The Netherlands

**Richard A. Krasuski, M.D.,
F.A.C.C.**

Associate Professor
Department of Medicine
Cleveland Clinic Lerner School
of Medicine
Director
Adult Congenital Heart Disease
Services
Cardiovascular Medicine
The Cleveland Clinic
Cleveland, OH
USA

**Henry Krum, Ph.D., F.R.A.C.P.,
F.C.S.A.N.Z.**

Professor
Epidemiology and Preventive Medicine
Monasu University
Alfred Hospital
Clinical Pharmacology
Director
NHMRC CCRE in Therapeutics
Monasu University
Melbourne, Victoria
Australia

Cheryl L. Laffer, M.D., Ph.D., F.A.H.A.

Department of Hypertension, Nephrology
Scott and White Clinic
Texas A and M University
Temple, TX
USA

Chim C. Lang, B.M.Sc., M.D., F.R.C.P.

Professor of Cardiology
Division of Medicine and Therapeutics
Ninewells Hospital and Medical
School
Honorary Consultant Cardiologist
Department of Cardiology
Tayside University Hospitals NHS Trust
Dundee
UK

Nigel J. Langford, M.D., M.R.C.P., M.R.Pharm.S.

Consultant Physician and Clinical
Pharmacologist
West Midlands Centre for Adverse Drug
Reaction Reporting
Sandwell and West Birmingham
Hospitals NHS Trust
Birmingham
UK

Debbie A. Lawlor, Ph.D., M.B., Ch.B.

Consultant Senior Lecturer in
Epidemiology
Department of Social Medicine
University of Bristol
Honorary Consultant in Public Health
North Bristol Acute Trust
Bristol
UK

Dexter L. Lee, Ph.D.

Assistant Professor
Department of Physiology and
Biophysics
Howard University
Washington, D.C.
USA

Bernard I. Lévy, M.D., Ph.D.

Professor
Department of Physiology
University Paris 7
Head
Department of Non-Invasive
Investigations
Hopital Lariboisière
Director
Centre for Cardiovascular Research
Inserm Unit 689
Paris
France

Daniel Link, B.S.

Research Specialist
Internal Medicine
University of Missouri
Columbia, MO
USA

Gregory Y. H. Lip, M.D., F.R.C.P. (London, Edinburgh, Glasgow), F.E.S.C., F.A.C.C.

Professor of Cardiovascular Medicine
Director, Haemostasis, Thrombosis and
Vascular Biology Unit
University Department of Medicine
City Hospital
Birmingham
UK

Graham W. Lipkin, M.D., F.R.C.P.

Honorary Senior Lecturer in Medicine
University of Birmingham
University Hospital Birmingham
Department of Nephrology
Birmingham, West Midlands
UK

Donald M. Lloyd-Jones, M.D., Sc.M., F.A.H.A.

Assistant Professor of Preventive
Medicine and of Medicine (Cardiology)
Feinberg School of Medicine
Northwestern University
Associate Physician
Cardiology
Northwestern Memorial Hospital
Chicago, IL
USA

Thomas E. Lohmeier, Ph.D.

Professor
Physiology and Biophysics
University of Mississippi Medical Center
Jackson, MS
USA

Brona V. Loughrey, B.Sc., M.B., B.Ch., M.R.C.P.

Specialist Registrar
Clinical Biochemistry
Royal Group of Hospitals
Belfast
UK

Thomas M. MacDonald

Professor of Clinical Pharmacology
Division of Medicine and Therapeutics
University of Dundee
Honorary Consultant Physician
Ninewells Hospital and Medical School
Dundee
UK

Robert J. MacFadyen, B.Sc., M.D., F.R.C.P.E., Ph.D.

Consultant Cardiologist and Senior
Lecturer in Medicine
University Department of Medicine and
Department of Cardiology
City Hospital
Birmingham
UK

Sushil K. Mahata, Ph.D.

Professor and VASDHS Principal
Investigator
Hypertension Research Unit
Department of Medicine
University of California, San Diego
School of Medicine
La Jolla, CA
USA

Giuseppe Mancia, M.D.

Full Professor of Medicine and
Chairman
Clinica Medica
Università Milano-Bicocca
Monza, Milan
Italy

Ana Carolina B. Marçano, Ph.D.

Clinical Pharmacology
William Harvey Research Institute
Barts and the London School of
Medicine and Dentistry
London
UK

Jennifer Martin, M.B.Ch.B., M.A., F.R.A.C.P., Ph.D.

Senior Lecturer
Department of Medicine
Melbourne University
Specialist Physician, Clinical
Pharmacologist
Department of Medicine
St. Vincent's Hospital
Melbourne, Victoria
Australia

John C. McGiff, M.D.

Professor and Chair
Department of Pharmacology
New York Medical College
Valhalla, NY
USA

Gordon T. McInnes

Professor of Clinical Pharmacology
Head
Section of Clinical Pharmacology
and Stroke
Medicine Division of Cardiovascular
and Medical Sciences
Gardiner Institute Western Infirmary
Glasgow
UK

Franz H. Messerli, M.D., F.A.C.C., F.A.C.P.

Director, Hypertension Program
Department of Cardiology
St. Lukes-Roosevelt Hospital
Columbia University College
of Physicians and Surgeons
New York, NY
USA

Steven M. Miller, B.Sc.(Hons.), M.B.Ch.B., M.R.C.P., Ph.D.

Clinical Lecturer in Medicine
Faculty of Medicine
University of Glasgow
Glasgow
Scotland

Paul Mitchell, M.B.B.S., M.D., Ph.D., F.R.C.Ophth., F.R.A.N.Z.C.O.

Professor
Department of Ophthalmology
University of Sydney
Sydney, NSW
Director
Ophthalmology
Westmead Hospital
Westmead, NSW
Australia

Jason Moore, Mb.Ch.B., M.R.C.P.

Honorary Lecturer in Medicine
University of Birmingham
Specialist Registrar in Nephrology
Department of Nephrology
University Hospital Birmingham
Birmingham, West Midlands
UK

Trevor A. Mori, Ph.D., C.P. Chem.

School of Medicine and Pharmacology
University of Western Australia
Perth, Western Australia
Australia

Marvin Moser

Clinical Professor of Medicine
Department of Medicine/Cardiology
Yale University School of Medicine
President
High Blood Pressure Foundation, Inc.
New Haven, CT
USA

Maryann N. Mugo, M.D.

Endocrinology Fellow
Department of Internal Medicine
Diabetes and Cardiovascular Disease
Research Center
Division of Endocrinology, Diabetes and
Metabolism
University of Missouri-Columbia
Harry S. Truman Memorial VA Medical
Center
Columbia, MO
USA

Patricia B. Munroe, Ph.D.

Department of Clinical Pharmacology
William Harvey Research Institute
Barts and the London School of
Medicine and Dentistry
London
UK

Nitish Naik, M.D., D.M.

Associate Professor
Department of Cardiology
Doctor
Department of Cardiology
All India Institute of Medical Sciences
New Delhi
India

Samar A. Nasser, P.A.-C., M.P.H.

Physician Assistant
Division of Translational Research and
Clinical Epidemiology
Department of Internal Medicine
Wayne State University
Detroit, MI
USA

Stephen J. Newhouse, M.Sc.

Department of Clinical Pharmacology
William Harvey Research Institute
Barts and the London School of
Medicine and Dentistry
London
UK

Leong L. Ng, M.D.

Pharmacology and Therapeutics Group
Department of Cardiovascular Sciences
Leicester Royal Infirmary
Leicester
UK

Carrie A. Northcott, Ph.D.

Post-Doctoral Fellow
Pharmacology and Toxicology
Michigan State University
East Lansing, MI
USA

Shannon M. O'Connor, B.S.

Research Assistant
Division of Translational Research and
Clinical Epidemiology
Department of Internal Medicine
Wayne State University
Detroit, MI
USA

Daniel T. O'Connor, M.D.

Professor
Department of Medicine and Pharmacology
University of California at San Diego
School of Medicine
La Jolla, CA
USA

Suzanne Oparil, M.D.

Professor of Medicine and Physiology
and Biophysics
Senior Scientist
Center for Aging
Director
Vascular Biology and Hypertension
Program of the Division of
Cardiovascular Disease
Department of Medicine
University of Alabama at Birmingham
Birmingham, AL
USA

Pablo A. Ortiz, Ph.D.

Senior Staff Investigator
Division of Hypertension and Vascular
Research
Henry Ford Hospital
Detroit, MI
USA

Gurusher S. Panjra, M.D.

Resident
Department of Medicine
Hypertension Program
St. Lukes-Roosevelt Hospital
Columbia University College
of Physicians and Surgeons
New York, NY
USA

Hari Krishnan Parthasarathy, M.B.B.S., M.D., M.R.C.P.

Specialist Registrar
Department of Medicine and Cardiology
Peterborough District Hospital
Peterborough, Cambridgeshire
UK

Ivan J. Perry, M.D., M.Sc., Ph.D., F.R.C.P., F.R.C.P.I., F.F.P.H.M.I., M.F.P.H.

Head of Department
Professor of Public Health
Epidemiology and Public Health
University College Cork
Cork
Ireland

Thomas G. Pickering, M.D., D. Phil.

Professor of Medicine
Director
Behavioral Cardiovascular Health and
Hypertension Program
Division of Cardiology
Columbia Presbyterian Medical Center
New York, NY
USA

Pierre-François Plouin, M.D.

Faculté de Médecine René Descartes
Department of Vascular Medicine and
Hypertension
Université René Descartes
Hôpital Européen Georges Pompidou
Department of Vascular Medicine and
Hypertension
Assistance Publique des Hôpitaux
de Paris
Paris
France

Dorairaj Prabhakaran, M.D., D.M.(Cardiology), M.Sc.

Additional Professor
Department of Cardiology
All India Institute of Medical Sciences
Doctor
Department of Cardiology
All India Institute of Medical Sciences
New Delhi
India

Ian B. Puddey, M.B.B.S., M.D., F.R.A.C.P.

Professor
Faculty of Medicine, Dentistry and
Health Services
University of Western Australia
Nedlands, Western Australia
Australia

John Quilley, Ph.D.

Associate Professor
Department of Pharmacology
New York Medical College
Valhalla, NY
USA

Mohan K. Raizada, Ph.D.

Professor
Department of Physiology and
Functional Genomics
University of Florida
Gainesville, FL
USA

Fangwen Rao, M.D.

Visiting Scholar
Department of Medicine
Center for Medical Genetics
University of California, San Diego
School of Medicine
La Jolla, CA
USA

Jane F. Reckelhoff

Professor
Department of Physiology and
Biophysics
University of Mississippi Medical Center
Jackson, MS
USA

**Kolli Srinath Reddy, M.D.,
D.M.**

President
Public Health Foundation of India
Professor
Department of Cardiology
All India Institute of Medical Sciences
Ansari Nagar, New Delhi
India

Damiano Rizzoni, M.D.

Associate Professor of Internal
Medicine
Department of Medical and Surgical
Sciences
University of Brescia
Brescia
Italy

**J. Ian S. Robertson, M.D.,
F.R.C.P., F.R.C.P., M.D.D. (Hons.),
M.A., M.B., B.S., F.A.H.A.,
C.Biol., F.I.Biol., F.R.S.**

Formerly Visiting Professor
Prince of Wales Hospital
Chinese University of Hong Kong
Hong Kong
China
Formerly Physician
Medical Research
Council Blood Pressure Unit
Western Infirmary

PREFACE

Why do we need another textbook of hypertension? Can a single textbook capture the explosion of knowledge in hypertension research and related areas such as vascular biology, genetics, physiology, molecular biology, nephrology, and cardiology? These are reasonable questions, especially when one considers the large number of hypertension textbooks and journals that are already available. Obviously, no single textbook or journal can adequately cover all of these advances. However, there have been few attempts to integrate the basic, clinic, and population science of hypertension research and treatment in a single textbook that can be used by scientists and practicing clinicians. Our goal for *Comprehensive Hypertension* was therefore to assemble the collective knowledge of leading hypertension experts into a comprehensive but readable synopsis of the field.

Comprehensive Hypertension is divided into four major sections: I. Epidemiology; II. Pathophysiology; III. Clinical Approaches; IV. Pharmacologic and Nonpharmacologic Interventions and Treatment Guidelines. Extensive color has been used throughout the book not just for the purpose of making the book attractive, but primarily to better illustrate key points in the figures. Each section is also color coded for quick reference. The section editors and contributors are internationally recognized experts who were selected to provide a comprehensive, but not encyclopedic, perspective of the science of hypertension and its everyday application to treatment of the patient.

The book is intended to be a useful reference for clinicians who provide care for hypertensive patients, for basic and clinical scientists who study the physiology of blood pressure regulation and the pathophysiology of hypertension, and for population scientists concerned with hypertension and related disorders. The book will also be a useful reference for other health care professionals.

In many ways, the field of hypertension research is a great success story. There is a wealth of new information on epidemiology, pathophysiology, and clinical trials. There are also many drugs available that can be used to effectively treat hypertension. However, over one *billion* people worldwide have higher than optimal blood pressure warranting some form of treatment. Hypertension continues to be the number one attributable risk factor for death throughout the world although lowering of blood pressure has been clearly shown to reduce stroke, myocardial infarction, heart failure, and kidney disease. Unfortunately, high blood pressure is often not treated as aggressively as many other conditions that have far less impact on human health. Only a small fraction (usually less than 30 percent) of hypertensive patients are adequately treated, even in countries where major professional and public education efforts have been made to convey the importance of effective treatment. This means that there is still much work to do, not only in understanding the etiology and pathophysiology of hypertension but also in communicating and implementing what we already know to more effective treatment of patients.

We hope that you find our attempts to synthesize this information in a readable but comprehensive textbook is useful, and we invite you to provide feedback on our efforts. We sincerely thank our section editors and contributing authors who have worked hard to make our job as senior editors much easier. We are also grateful to our colleagues at Elsevier, Natasha Andjelkovic (Executive Publisher), Ann Ruzicka Anderson (Senior Developmental Editor), and Bryan Hayward (Production Manager), for facilitating the transition from concept to reality through their editorial and production excellence.

Gregory Y. H. Lip, Birmingham, UK
John E. Hall, Jackson, Mississippi, USA

Table of Contents

SECTION 1 - EPIDEMIOLOGY

- *Blood pressure in Westernized populations
- *Low blood pressure populations, the impact of rural -urban migration
- *Regional differences in blood pressure in developed countries
- *Low blood pressure populations, the impact of rural -urban migration
- *Fetal influences on blood pressure: the Barker hypothesis
- *Blood pressure and the risks of cardiovascular disease and stroke

SECTION 2 - PATHOGENESIS OF HYPERTENSION - HEMODYNAMICS AND VASCULAR MECHANISMS

- *Haemodynamics of essential hypertension
- *Genetic models of hypertension
- *Experimental models of hypertension
- *Left ventricular physiology in hypertension
- *The arterial system in human hypertension
- *Resistance vessels in hypertension
- *Endothelial function
- *Vascular growth, angiogenesis and hypertension
- *Vascular smooth muscle
- *Cell membranes - vascular smooth muscle action transport - vascular smooth muscle regulation by calcium magnesium and potassium
- *Coagulation and platelet abnormalities
- *Cytokines and inflammation

SECTION 3 - PATHOGENESIS OF HYPERTENSION - RENAL AND NEUROHUMORAL MECHANISMS

- *Role of the kidney
- *Autonomic control and hemodynamics of hypertension, baroreceptor function and reflexes
- *Central nervous control of blood pressure
- *The Renin-Angiotensin System
- *Aldosterone and other adrenal steroids
- *The endothelins
- *Nitric oxide
- *Reactive oxygen species and oxidative stress
- *The natriuretic peptides
- *Other peptide and related systems
- *Other peptide and related systems
- *Eicosanoids
- *The kallikrein-kinin systems
- *Sex steroids - estrogens and testosterone

SECTION 4 - PATHOGENESIS OF HYPERTENSION - GENETICS AND LIFESTYLE

- *Genetic approaches to hypertension: relevance to human hypertension
- *Monogenic forms of human hypertension
- *Potential role of gene therapy in treating hypertension and cardiovascular disease
- *Lifestyle and blood pressure
- *Obesity
- *Dietary fats and blood pressure
- *Vegetarian diets, protein and fiber
- *Exercise
- *Electrolyte intake and human hypertension
- *Alcohol intake and blood pressure
- *Psychosocial stress and hypertension

SECTION 5 - TARGET ORGAN DAMAGE

- *The effects of hypertension on the structure of human resistance vessels
- *Pathogenesis of atheroma
- *The brain in hypertension
- *The kidney in hypertension
- *The heart in hypertension
- *The eye in hypertension
- *Aortic dissection

SECTION 6 - SPECIAL GROUPS

- *Hypertension in children
- *Hypertension in the elderly
- *Hypertension in pregnancy
- *Hypertension, Insulin resistance and diabetes
- *Hypertension in renal failure
- *Hypertension in ethnic subgroups
- *Renin subgroups in hypertension
- *Hyperadrenergic and 'labile' hypertension
- *Resistant hypertension
- *Perioperative hypertension, preparing the *Hypertensive patient for anesthesia and surgery
- *Hypertension in the setting of acute myocardial infarction and percutaneous interventions
- *Hypertension in patients with concomitant stroke
- *Hypertension in patients with concomitant cardiac disorders, eg. heart failure, atrial fibrillation, etc
- *Hypertensive urgencies and emergencies

SECTION 7 - SECONDARY HYPERTENSION

- *Renal and renovascular hypertension
- *Renin-secreting tumors
- *Primary aldosteronism and other forms of mineralocorticoid hypertension
- *Cushing's Syndrome and hypertension

- *Oral contraceptives, Hormone Replacement Therapy and hypertension
- *Drug-induced hypertension
- *Pheochromocytoma
- *Endocrine hypertension: Thyroid disease and acromegaly
- *Coarctation of the Aorta
- *Hypertension and central nervous system
- *Sleep apnea and hypertension

SECTION 8 - CLINICAL ASSESSMENT AND INVESTIGATIONS

- *Overview of assessment and investigation of the hypertensive patient
- *Blood pressure measurement
- *Clinical assessment and examination of the hypertensive patient
- *Ambulatory Blood Pressure Monitoring
- *ECGs, echocardiography, exercise testing, other cardiological investigations

SECTION 9 - DRUG TREATMENT

- *Diuretics
- *Beta-blockers
- *Calcium antagonists
- *ACE inhibitors
- *Angiotensin Receptor Blockers
- *Alpha-adrenoceptor antagonists
- *Vasodilators
- *Renin inhibitors and Neutral Endopeptidase *Inhibitors
- *Centrally acting drugs
- *Combination therapy in the treatment of hypertension
- *Interactions between antihypertensive drugs and other medications
- *Lipid-lowering therapy
- *Antithrombotic therapy
- *The target blood pressure when treating hypertension
- *Compliance, quality of life, cost-effectiveness

SECTION 10 - NON PHARMACOLOGICAL TREATMENT

- *Non-pharmacological management of hypertension
- *Multidisciplinary management of hypertension, role of the nurse

SECTION 11 - GUIDELINES

- *Guidelines for treating hypertension
- *Guidelines for treating hypertension - An overview, Europe and Australia
- *Guidelines for treating hypertension - An overview, D: Third World

Chapter

1

A Short History of the Study of Hypertension

D. Gareth Beevers and J. Ian S. Robertson

Key Findings

- This introductory chapter covers the history of research into hypertension. Particular attention is given to the measurement of blood pressure, the renin-angiotensin-aldosterone system, and drug trials for the treatment of hypertension.
- We discuss the principal achievements and certain methodological issues, as well as current gaps in our knowledge of the nature of hypertension and its treatment.
- We accept that there are many areas for debate and that some experts may not share our views on various aspects of the history of research into hypertension.

Awareness of the existence of hypertension—raised arterial pressure—as a physiologic or pathophysiologic entity has a long history, stretching back to antiquity. Appreciation of the causes, consequences, and benefits from correcting hypertension became progressively clearer, particularly in the second half of the 20th century, as the topic became the increasing focus of epidemiologic, physiologic, and clinical research. An extensive survey of the concepts and achievements in hypertension research in the 20th century was published in 2004; many of the chapters were written by persons who had participated.¹

This chapter will briefly outline that history, delineating the pathophysiologic, clinical, and therapeutic relevance of the topic. As far as possible, we propose to economize on references by quoting books and review articles to which the reader is directed for more detailed information.

EARLY HISTORY

Probably the first recorded observations on hypertension were made some 4000 years ago by the Chinese Yellow Emperor, Huang Ti,² who noted an association between kidney disease and heart disease, described aphasic apoplexy, and regarded an excessive dietary salt intake as hazardous.

If too much salt is used in food, the pulse hardens....

When the heart pulse beats vigorously and the strokes are markedly prolonged, the corresponding illness makes the tongue curl up and the patient unable to speak.

A relationship between the quality of the pulse and development of afflictions of the heart and brain was noted

by physicians of Thebes in ancient Egypt in the Ebers Papyrus of 1500 BCE, and later in India in the Caraka Samhita of around 150 BCE.^{3,4} The early Arabic texts of Masawah, and of the physician Abu Ali al-Hussain ibn Abdulla ibn Sina, usually known as Avicenna (980–1037 CE), also drew attention to abnormalities of the pulse in disease.⁵

CIRCULATION OF THE BLOOD

The significance of many early observations could not, however, be properly appreciated before William Harvey's description in 1628 of the circulation of the blood. In his great work *Exercitatio Anatomica du Motu Cordis et Sanguini in Animabilis*, he correctly set out the concept of blood flowing out from the heart via the arteries, through the periphery, and then returning by way of the veins. Harvey noted that blood went from the heart through the lungs and then back to the heart; however, he was not able to show how blood passed from the arterial to the venous system at the periphery, because no connections were visible to the naked eye. Nevertheless, Harvey rightly supposed that such links existed, but must be too minute to be seen. The Italian Malpighi did observe such capillary vessels, using a microscope, shortly after Harvey's death.^{6,7}

EARLY CLINICAL STUDIES: BRIGHT AND MAHOMED

During the 19th century, two physicians working at Guy's Hospital in London made crucial advances toward understanding clinical hypertension.^{8,9} In 1836 Richard Bright published an account of a hundred patients with overt renal disease, or proteinuria. Just over half of them had large hearts at *postmortem* examination. He proposed that this cardiac enlargement must be a consequence of an altered quality of the blood or of a raised circulatory pressure. Some 40 years later, Frederick Henry Horatio Akhbar Mahomed, a British physician whose grandfather had migrated from India,¹⁰ worked at the same hospital. Perhaps Mahomed's most important contribution was recognizing in 1874 patients with large-volume pulses who showed no evidence of kidney disease. Mahomed called this condition "chronic Bright's disease without albuminuria," which would now almost certainly be termed essential hypertension. Mahomed went on to note an association between raised arterial pressure and heart attack, stroke, epistaxis, gout, and excessive alcohol consumption, all aspects that remain of considerable epidemiologic interest. Yet another

of Mahomed's accomplishments was in improving the sphygmograph, an instrument for the clinical assessment of arterial pressure, as shall shortly be recounted.⁷

BLOOD PRESSURE MEASUREMENT

Crucial to the progress of physiologic and clinical studies on blood pressure was the availability of means for its measurement, and especially its noninvasive measurement. Such methods were developed progressively during the 18th, 19th, and 20th centuries.^{7,11}

The first direct measurement of arterial blood pressure was made in 1732 by the Anglican clergyman and distinguished scientist, Stephen Hales, who had a horse tied down to a gate, inserted a brass cannula into its crural artery, and observed that the blood rose up a glass tube to a height of 8 feet 3 inches.⁸

Poiseuille in 1783 adapted from Hales's intra-arterial tube a device that he called a hemodynamometer, comprising a U-shaped tube connected to a shorter tube; the latter could be introduced intra-arterially. The U-tube contained mercury that was separated from the blood by another liquid. By this means Poiseuille could observe arterial pulsation and quantify its pressure.

This approach was elaborated by Hérisson and Gernier, who, instead of inserting a needle or tube into a blood vessel, employed a tightly stretched rubber membrane over the artery. This so-called sphygmograph went on to be refined by Winternitz, Keith, and Ozanam. In 1847, Ludwig had a bird's feather mounted on a float on the mercury surface of the U-tube, and, with the aid of a rotating cylinder carrying smoked paper, was able to record the oscillation of the pulse.

Among several persons who elaborated and modified these procedures was Marey who, in 1860, devised a sphygmograph capable, noninvasively, of transmitting arterial pulsatile variations on to a writing cylinder. The sphygmograph was further improved by Mahomed, who went on to employ the apparatus clinically, and, among other observations, to detect an increase in arterial pressure in patients with scarlet fever and renal damage.

Further crucial advances toward the construction of genuinely robust and reliable devices for the clinical assessment of blood pressure were made by von Bash, Potain, and Mosso.

Then, in two articles published in 1896 and 1897, the Italian Scipione Riva-Rocci described his mercury sphygmomanometer and its method of use. This, with an inflatable cuff for arterial compression was, in essence, the principal apparatus subsequently employed for blood pressure measurement throughout the 20th century, and remains in use to this day. Most impressive are the detailed instructions provided by Riva-Rocci for the maintenance and calibration of the sphygmomanometer, and his emphasis that measurements must be made under favorable resting conditions for the patient. The American neurosurgeon, Harvey Cushing visited Riva-Rocci, and was sufficiently impressed as to order sphygmomanometers to be employed at Johns Hopkins Hospital in Baltimore for the routine measurement of blood pressure in his patients.

Initially only systolic pressure was measurable sphygmomanometrically, taking this as the height of the mercury column at the point of first appearance of the radial pulse distally when the cuff was deflated. Then, in 1905, the Russian army surgeon Nicolai Sergeivich Korotkoff described the results of auscultation over the brachial artery as the cuff on the upper arm was deflated.⁸ The pressure at which sounds first were heard has come to be called Korotkoff phase 1, the pressure at sudden muffling of sounds as phase 4, and the point of cessation of sounds as phase 5. Phases 1 and 5 are currently taken as indicating respectively systolic and diastolic arterial pressure, although at one time phase 4 was held by some to denote the diastolic reading.

Such auscultatory blood pressure measurements involved judgment by the observer, and hence could be biased, occasionally compromising epidemiologic studies. Reported values in millimeters of mercury consistently revealed a preference for numbers ending in zero or five. Several devices, including the London School of Hygiene Sphygmomanometer (the Rose Box) and the Hawkesley Random Zero Sphygmomanometer (the Garrow Muddler), were introduced in order to circumvent this problem. With the Rose Box, the observer noted the Korotkoff phases without having a simultaneous view of the mercury column. The Garrow Muddler was designed so that after the blood pressure reading had been obtained, the mercury column settled to a random number between zero and 60 mmHg. This number was then subtracted from the reading obtained by the clinician to obtain the true blood pressure.

The late 20th century saw the introduction of ambulatory blood-pressure monitoring over 24 hours. Such methods are of only minor inconvenience to the subject, who can continue with normal activities, and hence they provide a wealth of physiologic and pathophysiologic information. These approaches also amply confirmed the cautions of Stephen Hales and Riva-Rocci that extraneous stimuli and physical activity could greatly affect the arterial pressure. They also confirmed that a considerable number of patients who had been labeled as hypertensive did in fact have much lower or even normal blood pressures when away from the clinical setting.^{7,11}

By the beginning of the 21st century, the mercury sphygmomanometer was becoming progressively superseded by automatic and semiautomatic blood-pressure measuring systems based on oscillometry rather than the auscultatory principles of Korotkoff. These manometers have the advantage that they abolish one source of inaccuracy, namely observer error and bias. There is also increasing concern about the possible toxicity of organic mercury salts.

BLOOD PRESSURE IN POPULATIONS: THE PLATT-PICKERING DEBATE

The ready availability of the mercury sphygmomanometer permitted the survey of blood pressure values across populations, and engendered a crucial and lengthy debate between two prominent English physicians, Robert Platt and George Pickering, in the 1950s and 1960s.^{8,12,13}

Platt contended that essential hypertension is an inherited tendency to develop high blood pressure in mid-

life. In his view this was reflected in a discrete subgroup of subjects wherein hypertension caused serious morbidity. Such patients were, he thought, to be contrasted with another larger population in which the blood pressure rises little if at all with increasing years. Platt hence asserted that

the frequency distribution of blood pressure in middle age would show a bimodal peak with one peak at a so-called normal level of blood pressure and another peak representing the hypertensive members of the population.

Pickering's very different concept was that essential hypertension represents a quantitative deviation from the norm, a notion requiring that the distribution of blood pressures within populations be continuous, any differences being quantitative rather than qualitative. This idea was not original; Lord Dawson of Penn had stated in 1925 that "hyperpiesia [hypertension] is not a condition with a defined territory; it has no threshold."¹⁴ (Dawson was personal physician to King George V. Not all were impressed by Dawson's skill. A scurrilous jingle ran: "Lord Dawson of Penn has killed so many men; we all have to sing 'God save the King!' ") However, Pickering forcefully developed and promulgated the concept. Blood pressure values in individuals should, according to Pickering, be seen as determined by numerous genetic and environmental influences. Furthermore, adverse cardiovascular events were expected simply to be proportional to the height of the arterial pressure.

The immediate issues were eventually settled in Pickering's favor. Virtually all large population samples have demonstrated a continuous, roughly bell-shaped curve of the distribution of systolic and diastolic blood pressure, the curve being slightly skewed toward the upper end. Hence, it is now accepted that no clear-cut division, other than a quite arbitrary one, can be made between normal blood pressure and "hypertension."

It follows that the distribution of cardiovascular risk, although subject to a range of influences additional to the height of arterial pressure, is also continuous, there being no inferior point of cut-off at which risk ceases. At the highest blood pressure values, there are small numbers of persons at high risk. As lower, but still above-average blood pressures are considered, there is a much larger population in which, overall, the cardiovascular risks, although distinct, are more modest. Further, individuals whose pressures are average for their age are at greater cardiovascular danger than those with values below average. Thus, in general, hypertension is not a disease in the usual sense, but rather an indicator of cardiovascular hazard. These concepts, established only after extensive disputation and no little acrimony, are obviously central to the implementation of antihypertensive drug therapy and preventive medicine.

Geoffrey Rose developed from these ideas a "population strategy" for preventive therapy, whereby he proposed that a modest reduction in blood pressure and hence risk in the population as a whole (including persons whose pressures would be regarded as normal) might greatly

reduce the incidence of complications overall. By contrast, directing treatment preferentially toward those with distinctly high pressures would help only a minority.¹⁵ These concepts had wide appeal. However, other researchers questioned the scientific basis of Rose's notions, and were especially concerned that they were being promoted before being tested.¹⁶⁻¹⁸ Remarkably, Tunstall-Pedoe et al.¹⁹ found that between the mid-1980s and mid-1990s, blood pressure fell in 38 different populations, at all levels of readings. This could not, they reasoned, be a consequence of antihypertensive treatment, which would have shown a differential fall only at higher values; these observations remain unexplained.

THE COMPLICATIONS OF HYPERTENSION

The association between raised blood pressure and lesions of the heart, brain, and kidneys had been recognized in the 19th century, notably by Bright and by Mahomed.⁸⁻¹⁰ The various complications of hypertension were increasingly clarified in the 20th century, with arterial changes understood as fundamental to those adverse consequences.²⁰

Arterial changes

With hypertension, large- and medium-sized arteries (>1 mm in diameter) become thickened, rigid, dilated, and tortuous. Atheroma is prevalent. Smaller arteries evince thickening of the media, intimal expansion, and narrowing of the lumen. It is likely that the upward resetting of the pressure limits in autoregulation of blood flow via various organs that occurs in hypertension results at least in part from such structural changes in small arteries. In the late 20th century, arterial changes were particularly well studied in the brain, where the phenomenon appears to hold true, even though small cerebral arteries are poorly muscled (Figure 1-1).

Figure 1-1. Diagram showing the limits of autoregulation of cerebral blood flow (CBF) in a normal person (continuous line) and a patient with hypertension (dotted line). Cerebral blood flow is held constant over wide limits of systemic arterial pressure. If the systemic blood pressure exceeds the upper limit of autoregulation the brain will be overperfused and become edematous. If the pressure falls below the lower limit of autoregulation, cerebral ischemia, and possible infarction will result. (Redrawn from Kjeldsen SE, Julius S, Hedner T, Hansson L. Stroke is more common than myocardial infarction in hypertension: analysis based on 11 major randomized intervention trials. *Blood Press* 2001;10:190-92.)

Specific to small arteries in the brain are Charcot–Bouchard aneurysms, first described by Charcot and Bouchard in 1868,²¹ which were then long neglected and rediscovered by Russell in 1963.²² These small arteries are typically 0.2 to 1.0 mm in diameter and have attenuated walls; they predispose to intracerebral hemorrhage in hypertension.

The most severe arterial lesions resulting from hypertension occur during the malignant phase, and are the outcome of very high arterial pressure, especially when pressure has risen swiftly. The characteristic lesion of the malignant phase is fibrinoid necrosis or (“plasmatic vasculosis”) of small arteries and arterioles, which disrupt as a consequence of the very high blood pressure. An interesting inconsistency emerged in the late 20th century. Malignant-phase hypertension became rare in some countries, such as Australia and Sweden, while remaining common in Britain, notably in Glasgow and Birmingham.²³ This curiosity remains unexplained.

The heart

Patients with very severe hypertension can develop overt hypertensive heart failure without concomitant myocardial damage from coronary artery disease. In such instances, this is often associated with left ventricular diastolic, rather than systolic, dysfunction. While this complication is now becoming infrequent, it remains a problem, particularly in patients of African origin.²⁴

Coronary artery atheroma is one of the most common associations of hypertension that has been more thoroughly studied in recent years with greater attention given to mild blood pressure elevation and long-term cardiac functional impairment with left ventricular systolic dysfunction. In the lower ranges of hypertension, coronary arterial disease is usually more prevalent than stroke or cardiac failure. However, in recent trials,²⁵ strokes have outnumbered heart attacks, possibly because patients at particularly high risk participated in these studies.

The brain

Hypertension is a major cause of intracerebral hemorrhage, which accounts for 20% of all strokes. Many of these catastrophes occur at the site of Charcot–Bouchard microaneurysms of the small arteries deep within the brain.^{21,22}

Clinical stroke more often results from cerebral infarction, for which hypertension is again a predisposing factor. Atheromatous plaques can lead to progressive occlusion of arteries or can be a source of emboli that may be composed variously of atheromatous debris and cholesterol crystals, or mixtures of fibrin, leucocytes, and platelets.

A now very rare complication, acute hypertensive encephalopathy, in which headache, confusion, coma, and fits may occur, is almost always superimposed on malignant phase hypertension. Hypertensive encephalopathy is a consequence of the systemic arterial pressure exceeding the upper limit of cerebral autoregulation (Figure 1–1), with resulting overperfusion and cerebral edema. However, in recent years the ready availability of high-resolution computerized tomography and magnetic resonance

imaging has revealed brain infarctions in some patients who would have been thought in earlier times to have hypertensive encephalopathy.

The eye

Much interest in hypertension was focused on the eye because the fundus oculi can be inspected directly by means of the ophthalmoscope or retinal camera. The retinal arterial consequences of mild hypertension comprise thickening, irregularity, and tortuosity. Occasionally, emboli may be seen traversing the retinal circulation. Central or segmental retinal arterial or venous occlusions can accompany high blood pressure and may readily be diagnosed ophthalmoscopically.

The onset of the malignant phase can be recognized by the appearance of typically bilateral retinal exudates that may be circumscribed (“hard”) or fluffy (“cotton wool spots”) and hemorrhages. In the later stages, papilledema and retinal edema may also appear.

The retinal features of hypertension were classified in 1939 by Keith et al.²⁶ This system was for a time extensively applied, but is today probably obsolete, in part because it embraced the now discredited concept of arterial spasm. Furthermore, examination of these authors’ original data demonstrates that their grades III and IV patients had broadly the same adverse prognosis, which is quite different from patients with grades I and II retinopathy. The changes classified as grades I and II are as closely related to the patients’ age as to their blood pressure.^{27,28}

The kidney

The kidney typically sustains most consequences of the malignant phase, with extensive and progressive fibrinoid necrosis of afferent glomerular arterioles, glomerular infarction, and consequent renal impairment. Hence, in untreated malignant hypertension, provided the course is not terminated abruptly by a catastrophic stroke or cardiac failure, the patient will succumb to renal failure.

The decline of renal function with age is faster with raised arterial pressure, and end-stage renal failure attributable to hypertension became more prevalent in the last decades of the 20th century.^{29,30} Although some have questioned whether nonmalignant essential (nonrenal) hypertension is a major cause of renal failure,^{31,32} control of blood pressure has been demonstrated in multiple studies to attenuate progression of renal disease (see Chapter 49).

QUANTIFICATION OF RISK—SYSTOLIC AND DIASTOLIC PRESSURE AND COMPOUNDING RISK

It is remarkable that the harmful effects of hypertension were perceived by Bright and Mahomed,^{9,10} as well as by Huchard in 1889,³³ before accurate measurements of arterial pressure were achieved. Then, with the introduction of Riva-Rocci’s sphygmomanometer, initially only systolic pressure could be assessed. Even after Korotkoff had shown how diastolic might be measured, interest focused on the systolic pressure, and that predilection continued into the 1930s.

The quantitative relationship between arterial pressure and mortality from cardiovascular or renal disease was, from the 1930s onward, consistently shown in data from life insurance companies.³⁴ That correlation existed for both systolic and diastolic pressures with, for a given pressure level, men being more vulnerable than women.³⁵

For a time there was a change of emphasis, and diastolic pressure increasingly came to be regarded as pathogenically the more important, especially in the causation of malignant hypertension. The temporary trend for regarding diastolic pressure as being of greater influence was intriguingly shown in some of Pickering's writings. In the 1968 edition of *High Blood Pressure*, Pickering quoted, and considered at length, insurance company data showing the correlation of risk with both systolic and diastolic pressures.²⁷ Yet, in discussing the disproportionate elevation of systolic relative to diastolic pressure commonly found in elderly subjects, he stated:

One might suspect that such patients ... would be more prone to develop cardiovascular accidents ... but I know of no evidence bearing on the question.... [T]his form of hypertension will not be further considered in this book.

Subsequently, prospective epidemiologic studies, most notably the Framingham survey initiated in 1949,³⁵ clearly underlined once more the pathogenic importance of systolic, as well as of diastolic, pressure. Predominant (often termed "isolated") systolic hypertension clearly denoted hazard. In 2001, a more detailed paper from the Framingham Heart Study reported that after the age of ~40 years, systolic pressure and pulse pressure are more powerful predictions of cardiovascular risk than is diastolic.³⁶ Almost all long-term population studies now confirm that systolic blood pressure is more predictive than diastolic, although there remains some uncertainty about the prognostic role of diastolic blood pressure in young people who, by virtue of their age, are at low short-term risk.

Surveys such as that from Framingham further emphasized the compounding of cardiovascular and renal dangers of raised blood pressure by additional risk factors. These influences are now seen to include male gender, age, raised serum cholesterol and low density lipoprotein cholesterol, diabetes mellitus and impaired glucose tolerance, cigarette smoking, cold weather, and lower social class. The prevalence of complications is also modified by race/ethnicity and geographical location. More complex or controversial factors include body weight, serum uric acid, circulating levels of renin, angiotensin II and aldosterone, and the consumption of alcohol and salt.^{20,37-53}

More recently, Reaven has hypothesized that many of the common cardiovascular risk factors (notably, hypertension, diabetes and impaired glucose tolerance, obesity, and hyperlipidemia), may share a common etiology and outlook mediated by insulin resistance in the so-called "metabolic syndrome." These risk factors cluster and individuals with two or more have a greatly increased risk of cardiovascular disease.³⁵

SECONDARY HYPERTENSION

Secondary hypertension is defined as raised blood pressure resulting from a recognizable and often potentially correctable cause, and is thus to be distinguished from the much more prevalent primary ("essential") hypertension. In unselected populations of hypertensive subjects, no more than 1% to 5% of cases are secondary, although a much higher proportion of a given disease may be seen in centers having a particular interest in that condition.^{20,54-56}

The principal forms of secondary hypertension are listed in Box 1-1. They are evidently numerous and diverse. These various conditions were identified at irregular intervals throughout the 20th century and additions continue to be made.

Despite their comparative rarity, secondary forms of hypertension have attracted much interest. First, many such syndromes, particularly the rare monogenic forms of hypertension, are readily responsive to correction of the underlying cause. Second, a study of the mechanisms whereby the blood pressure is raised in these disorders facilitates insights into the pathophysiology of essential hypertension; this is a compelling impetus for the study of even very rare forms of secondary hypertension, many of which involve primary excess reabsorption of sodium by the renal tubules.

Box 1-1

Secondary Forms of Hypertension

Renal or renovascular diseases
 Unilateral
 Bilateral
 Angiotensinogen-producing tumor
 Mineralocorticoid-induced hypertension
 Aldosterone excess: Conn's syndrome and related disorders
 Carcinoma-secreting corticosterone or deoxycorticosterone
 Apparent idiopathic deoxycorticosterone excess
 11 β -OHS deficiency
 17 α -hydroxylase deficiency
 11 β -hydroxylase deficiency
 Pheochromocytoma and related disorders
 Intracranial tumor
 Guillain-Barré neuropathy
 Acromegaly
 Cushing's syndrome
 Thyroid disease
 Hypothyroidism
 Thyrotoxicosis
 Liddle's syndrome
 Gordon's syndrome
 Endothelin-secreting tumor
 Porphyria and hypertension
 Hormonal contraceptive use
 Drug-induced hypertension: various
 Coarctation of the aorta
 Pregnancy-induced hypertension

From Robertson JIS, ed. *Clinical Aspects of Secondary Hypertension*. Vol. 2, *Handbook of Hypertension*. Birkenhäger WH, Reid JL, eds., 1983;2.

Two interesting aspects of secondary hypertension were noted by Pickering in 1955.²⁷ The first of these was that virtually every such condition can enter the malignant phase, and that such transition was more likely with a rapid rise of blood pressure. The concept can now be broadened, because it is seen to apply not only to the malignant phase but also to all of the vascular complications of hypertension, including cardiac hypertrophy, with the proviso that with aortic coarctation the renal vasculature is protected. Such indiscriminate effects of high blood pressure are modified by concomitant pathophysiology in various syndromes. Thus, considerable evidence has suggested that elevation of angiotensin II can have especially adverse effects on the heart, arteries, and kidney.³⁷ A further proposal is that aldosterone can induce myocardial extracellular matrix and collagen deposition, although not all studies have supported the notion.^{39–43} An excess of circulating catecholamines, as with pheochromocytoma, can cause focal myocardial lesions. In Cushing's syndrome, increased cortisol may promote myocardial hypertrophy independently of blood pressure.

The second of Pickering's 1955 observations²⁷ was that blood pressure may remain raised in a proportion of cases of secondary hypertension even after the primary cause has been removed or corrected, although the pressure may be more readily controlled with drugs. Such persistent hypertension is probably largely a consequence of hypertension-induced changes, including structural thickening of the walls of resistance arteries, and especially to alterations of the arteries of the kidney. Renal functional impairment has been consistently noted as presaging a less satisfactory fall in blood pressure after correction of the causal abnormality.

PRIMARY ("ESSENTIAL") HYPERTENSION: SEARCH FOR A CAUSE

Appreciation of the remarkable array of disorders that can cause secondary hypertension provided ongoing stimuli and encouragement for investigating the pathogenesis of primary, or essential, hypertension. Insights gained therein should obviously facilitate appropriate preventive or therapeutic measures. Geoffrey Rose, however, pointed out that "ever popular terms like idiopathic and essential are actually nonsensical as all diseases must have a cause."⁵⁷

The mind and the sympathetic nervous system

This is an enormous field, which can be only briefly dealt with here. The topic was adumbrated some 2500 years ago by Hippocrates, who clearly perceived a link between mental and physical well-being.^{58–60} Almost certainly most laypersons would accept a connection between mental "stress" ("stress" being notoriously difficult to define) and raised blood pressure; by 1931 Hay had embraced the concept medically.³⁴

In the mid-19th century, Claude Bernard, Brown-Séquard, and Waller, among others, had shown that the sympathetic nervous system was regulated by centers in the brain, and that stimulation of the sympathetic nerves caused vaso-

constriction. Von Euler in 1946 established that the sympathetic neurotransmitter is noradrenaline (norepinephrine).

Experimental studies in animals by Hess in the 1930s and 1940s demonstrated how emotional and instinctive behavior could be reproduced by exciting discrete groups of neurons. Over the next two decades, Folkow and his colleagues, and subsequently Zanchetti and others, developed these ideas and established that the so-called "defense reaction" would neurogenically induce increases in heart rate and cardiac output; in blood flow through skeletal muscle, heart, and brain at the expense of flow via abdominal organs and skin; and often substantial rises in arterial blood pressure. Folkow went on to link these phenomena with the development of structural changes in resistance arteries, which then reinforced hypertension.

In the 1950s and 1960s, Brod and coworkers showed the pressor effect of forced mental arithmetic. Conversely, Timio and colleagues found that nuns living in seclusion had distinctly lower blood pressure than did control groups of women exposed to the stimuli of urban life but consuming a broadly similar diet.

In the later 20th century, Julius, Esler, and others proceeded to define a syndrome of borderline or mild established essential hypertension in young men and women with sympathetic nervous overactivity, including raised heart rate and cardiac output, with elevated plasma renin. All of these matters are discussed in detail in two recent reviews by Folkow⁶⁰ and by Esler.⁶¹

Adrenal medulla: Adrenaline (epinephrine)

The circulatory effects of intravenous administration of adrenaline (epinephrine) are tachycardia, an increase in systolic blood pressure, and a fall in diastolic blood pressure. These are not features of essential hypertension, leading Pickering to declare in 1955²⁷:

I have never had much doubt that adrenaline is not the agent concerned in producing essential hypertension, since its effects on the circulation are so different from the pattern found in essential hypertension.

However, ideas concerning the sympathetic nervous system mentioned above might link adrenaline with essential hypertension in a more subtle fashion. In 1976 the Glasgow group⁶² hypothesized that, because essential hypertension in its early stages can show features of sympathetic nervous system overactivity, the condition may be an exaggeration of the tendency for blood pressure to rise with age. Small increases in pressure resulting from such sympathetic overactivity could cause renal changes, which then maintain the rise in pressure and become the basis of further elevation. According to this group, with more marked hypertension later, the sympathetic element would diminish, but renal vascular resistance would rise.

These concepts were developed further by Brown and MacQuin in 1981,⁶³ who suggested that a primary abnormality in essential hypertension could be intermittent enhanced release of adrenaline from the adrenal medulla, perhaps as a feature of anxiety and the "defense reaction." Uptake of such episodically excessive circulating adrenaline

could then raise blood pressure by facilitating, via presynaptic beta-receptors, noradrenaline release. A substantial body of evidence, reviewed in detail by Nicholls and Richards,⁶⁴ has broadly supported these notions.

Adrenal cortex

The review by Nicholls and Richards⁶¹ further concluded that although adrenal cortical hormones might serve to support blood pressure elevation, current evidence is against their having an initiating role in essential hypertension. Certain aspects do, however, merit brief mention here.

Impaired activity of the enzyme 11 beta-hydroxysteroid dehydrogenase-2 (11 β -O β SDH-2) within the kidney limits the normal conversion of cortisol to cortisone, such that intrarenal cortisol gains access to renal mineralocorticoid receptors, and thereby induces mineralocorticoid hypertension. Stewart et al.⁶⁵ reported such a case in 1988. This is, of course, overt secondary hypertension. However, the possibility has been raised that milder degrees of such 11 β -O β SDH-2 deficiency within the kidney, or perhaps restricted to vascular smooth muscle, could be responsible for some cases of apparent essential hypertension. Alternatively, a placental deficiency of 11 β -O β SDH could expose the fetus to excessive cortisol, leading to low birth weight and later essential hypertension. These ideas remain to be further explored.

In the early 1960s evidence emerged of a sodium transport inhibitor capable of raising arterial pressure. Later reports indicated the existence of endogenous digitalis-like substances which could inhibit the sodium pump, Na-K-ATPase, and hence stimulate a rise in intracellular sodium and calcium leading to arteriolar constriction. Hamlyn et al.⁶⁶ subsequently found evidence that this was possibly a single steroid, ouabain or a closely related isomer, secreted by the adrenal cortex. The validity of these proposals has since, however, been widely questioned, although not refuted.

Aldosterone, the most powerful mineralocorticoid steroid secreted by the adrenal cortex, has interesting and important connotations in essential hypertension. As was

indicated in Box 1-1, aldosterone-secreting adenoma (Conn's syndrome) is one among many forms of secondary hypertension, wherein autonomous secretion of an excess of aldosterone by the tumor leads to raised arterial pressure with suppression of the renin-angiotensin system, which is normally a physiologic regulator of aldosterone secretion. Then, in the 1960s and 1970s, it became apparent that a number of hypertensive subjects who did not harbor an adrenocortical adenoma also showed raised aldosterone with low plasma renin levels. This condition was variously termed "idiopathic aldosterone excess," "nontumorous aldosteronism," or "pseudoprimary aldosteronism." In these cases, specific adrenocortical pathology was absent, although nodular changes, or widening, of the zona glomerulosa could sometimes be found, as in essential hypertension. Several groups in the 1970s went on to demonstrate that the aldosterone response to infused angiotensin II became enhanced in essential hypertension. As plasma renin tends to fall with advancing age in essential hypertension, it can readily be seen how such cases might be confused with genuine examples of an aldosterone-secreting tumor.

Indeed, in contrast to patients with aldosterone-secreting adenoma—where plasma angiotensin II and aldosterone are significantly correlated inversely (Figure 1-2A)—in subjects with "idiopathic" aldosterone excess, angiotensin II and aldosterone are positively correlated (Figure 1-2B). Therefore, in the latter aldosterone remains under the physiologic control of the renin-angiotensin system, and these are certainly not instances of "primary" aldosteronism.

Consequently, in 1979 researchers proposed that essential hypertension and so-called nontumorous or "idiopathic" hyperaldosteronism are a continuum of the same condition,^{67,68} and this has been repeatedly confirmed in statistical biochemical evaluations.^{69,70} Of course, many of these patients, like those with aldosterone-secreting tumors, respond well to potassium-conserving agents such as spironolactone or amiloride.

Despite repeated admonitions, several groups⁷¹⁻⁷⁴ continue to describe what is presumably essential hypertension

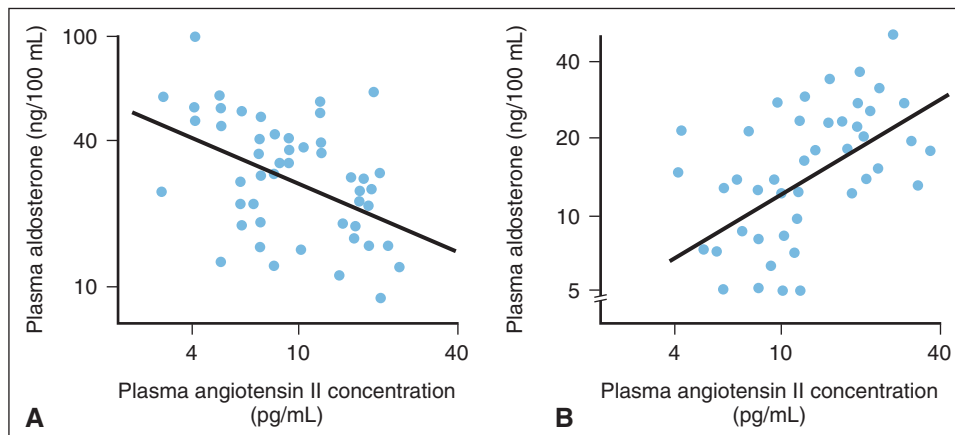

Figure 1-2. Relationship between concurrent basal early morning plasma concentrations of aldosterone and angiotensin II in untreated patients with (A) aldosterone-secreting adenoma ($r=-0.43$, $p<0.01$) and (B) idiopathic hyperaldosteronism ($r=0.46$, $p<0.01$). (Redrawn from Ferris JB, Brown JJ, Fraser R, Lever AF, Robertson JIS in Robertson JIS, ed. *Clinical Aspects of Secondary Hypertension*. Vol. 2, *Handbook of Hypertension*. Amsterdam: Elsevier, 1983:132-161.)

with modestly raised aldosterone, low renin levels, and raised aldosterone/renin ratios but no adrenal tumor, as “primary aldosteronism,” and some refer to an “epidemic” of the condition.^{75,76} Both tendencies have been roundly attacked by Norman Kaplan.⁷¹

The kidney and sodium intake

As may be evident from the previous discussion, from the very first glimpses of hypertension in the studies by Bright,⁹ the kidney was repeatedly suspected as having a central role in the pathogenesis of hypertension. Others whose work requires mention⁷⁷ in this historical account include Franz Volhard, who with Fahr in 1914, provided a detailed description of the renal pathology in Bright’s disease; Goldblatt and colleagues, who demonstrated in 1934 that sustained experimental hypertension could be produced by renal artery constriction; and Van Slyke, Homer Smith, and others, who refined the measurement of overall renal function. Then Borst in the Netherlands and Guyton in the United States provided evidence that body salt overload could be involved in raising arterial pressure.

These observations were reinforced by studies of secondary hypertension. Elevated blood pressure in end-stage renal failure was seen to be accompanied by sodium and water retention, and could be alleviated by removal of salt and water at dialysis.⁷⁸ With aldosterone-secreting adrenocortical adenoma and consequent aldosterone excess, body sodium content was shown to be increased and the extent of such increase to be closely correlated with hypertension severity. Treatment, either by administration of a potassium-conserving diuretic such as spironolactone or amiloride, or definitively by excision of the tumor, caused blood pressure to fall in proportion to the reduction of body sodium⁷⁹ (Figure 1–3).

It can readily be appreciated how these various observations could be linked with proposals made by the Glasgow group,⁶² Brown and MacQuin,⁶³ and Esler and colleagues,⁶¹ that renal lesions caused by sympathetic nervous system overdrive, possibly involving noradrenaline, adrenaline,

and the renin–angiotensin system, could lead to sustained and progressive blood pressure elevation, and hence be involved in the pathogenesis of essential hypertension. In 2002 Johnson et al.⁸⁰ elaborated the notion of subtle acquired renal injury as a mechanism of salt sensitivity in hypertension.

Findings pertinent to a different form of secondary hypertension resulting from unilateral renal artery stenosis in which stimulation of the renin–angiotensin system is fundamental to pathogenesis, demonstrated that this form is a syndrome characterized by depletion of body sodium content. Severity of such sodium depletion increases the higher the arterial pressure.⁸¹

In two large series of patients with untreated essential hypertension during the 1980s, subjects aged less than 40 years had body sodium content that was significantly subnormal, whereas patients aged over 50 had expanded body sodium (Figure 1–4). Independently of age, a significant positive correlation between body sodium content and the level of arterial pressure was reported. In accordance with the findings and concepts mentioned previously, researchers proposed that (1) many young patients with essential hypertension have sodium depletion, perhaps resulting from a natriuretic effect of hypertension caused by a mechanism independent of sodium retention; and (2) in older patients, body sodium content is expanded, possibly as a consequence of hypertension-induced renal changes and/or aldosterone excess.

Meanwhile, various trials had shown modest but distinct declines in blood pressure with dietary sodium restriction. It was emphasized that moderate sodium limitation lasting at least 1 month was most effective; short-term extreme salt deprivation, possibly in part by activating the renin–angiotensin system, could be less impressive. Moreover, the extent of such blood pressure reduction tended to be greater with age; dietary salt restriction was comparatively less effective in young hypertensive subjects. The results of five relevant meta-analyses^{84–88} are shown in Table 1–1. The analysis by He and MacGregor⁸⁸ is especially relevant, in that only

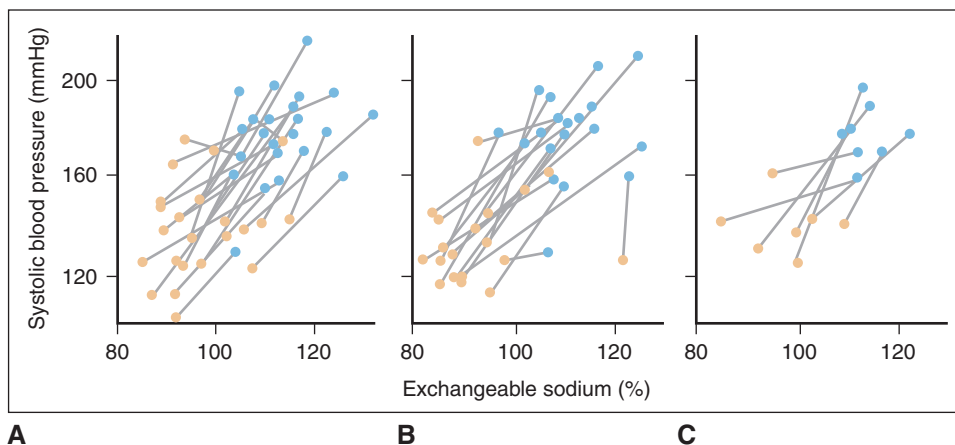

Figure 1–3. Patients with aldosterone-secreting adenoma. Systolic blood pressure related to total exchangeable sodium, expressed as percentage normal in relation to body surface area. (A) Before and after surgery. (B) Before and during spironolactone. (C) Before and during amiloride. (Redrawn from Robertson JIS, Secondary forms of hypertension in Birkenhäger WH, Robertson JIS, Zanchetti A, eds. *Hypertension in the twentieth century. Handbook of Hypertension*. 2004;22: pp. 298–335.)

Figure 1-4. Exchangeable sodium (NaE) expressed as percentage normal in terms of body surface area in men. Young hypertensive subjects (aged <35 years) show significantly subnormal body sodium content as compared with young normal subjects. Older hypertensive subjects (aged >50 years) have expanded body sodium. (Data from Johnson RJ, Herrera-Acosta J, Schreiner GF, et al. Subtle acquired renal injury as a mechanism of salt-sensitive hypertension. *N Engl J Med* 2002;346:913–23.)

studies of moderate salt restriction lasting for at least 1 month were included.

At this juncture, there are no obvious incompatibilities, but recommendations diverge markedly. One group (which includes one of us, DGB)⁵¹ recommends dietary salt restriction regardless of age as a routine part of antihypertensive therapy. Another (which includes JISR)⁵³ holds that this important issue contains many uncertainties that still require elucidation, and that the appropriateness of salt limitation in young hypertensive subjects is questionable.

Somewhat separate from these arguments is evidence^{51,52,88,89} that salt restriction might, *inter alia*, and independently of changes in blood pressure, protect against stroke and left ventricular hypertrophy. Others have conversely worried about the possible cardiovascular hazards of increases in circulating renin, aldosterone, noradrenaline, total cholesterol, and low-density lipoprotein accompanying sodium restriction, and consider that these matters should be subjected to clinical trials.⁸⁷ Interestingly, Kaplan and Opie, in a 2006 review entitled “Controversies in hypertension,”⁹¹ evidently discerned no such altercation, and endorsed general dietary salt restriction without reservation.

Urinary sodium and blood pressure

Urinary sodium excretion closely corresponds with the dietary sodium intake. Thus, the epidemiologic assessment of urinary sodium output has attracted much attention because it has been widely assumed that any observed correlation might indicate a causal connection between sodium ingestion and blood pressure. Amid a profusion of studies, two were large and of high methodologic quality.

In 1988 a Scottish report⁹² on 7354 men and women aged 40 to 59 years showed only a weak positive correlation between sodium excretion and blood pressure. The authors concluded that sodium had little or no evident independent role in determining blood pressure.

Also in 1988 the Intersalt Cooperative Research Group⁹³ reported on the relationship in 10,079 men and women aged 20 to 59 years and drawn from 52 centers worldwide. The initial analysis showed a positive association of sodium excretion with median blood pressure, and with the prevalence of (arbitrarily defined) hypertension when all 52 centers were included. However, when four distinctly disparate tribal populations with very low sodium values were excluded, the association disappeared. Meanwhile, in 15 of the individual centers there was a significant positive correlation between sodium excretion and systolic pressure, while a significant negative correlation was reported in two centers. There was also a close relationship between sodium excretion and the increase in blood pressure with age, an effect that persisted even after the four centers with very low salt intake were excluded.

In 1996 a reworking of the “Intersalt” data was published⁹⁴ with a more expansive correction for “regression dilution bias.” A stronger and significant correlation then emerged between urinary sodium and systolic blood pressure, albeit critics asserted that the reanalysis was inappropriate and invalid.⁹⁵

Whether a genuine correlation might be shown to exist between urinary sodium excretion (and by implication

MEAN REDUCTIONS (MMHG) IN BLOOD PRESSURE (SYSTOLIC/DIASTOLIC) IN FIVE META-ANALYSES OF DIETARY SALT RESTRICTION		
	Overall	
Grobbée and Hofman (81)	3.6/1.98	
	Hypertensive	Normotensive
Midgley et al. (82)	3.7/0.9	1.0/0.1
Graudal et al. (84)	3.9/1.9	1.2/0.26
Cutler et al. (83)	4.8/2.5	1.9/1.1
He and MacGregor (85)	4.2/2.4	1.6/0.6

Table 1-1. Mean Reductions (mmHg) in Blood Pressure (Systolic/Diastolic) in Five Meta-Analyses of Dietary Salt Restriction

dietary consumption) and blood pressure, it would not, however, permit the conclusion that excessive sodium intake was causal or even contributory. Given the evidence of subnormal body sodium content in young subjects with mild untreated hypertension, their increased sodium consumption could result from an increase in sodium appetite stimulated by that sodium shortfall, probably via angiotensin II.⁵³

Genetic aspects

Numerous studies from the 1930s to the present of parent–offspring relationships, natural versus adopted children, and identical and nonidentical twins, have provided evidence of distinct genetic influences on blood pressure in individuals.^{96,97} However, one consequence of the controversy between Pickering and Platt,^{8,12,13} and the eventual substantiation of Pickering’s assertion of the continuous distribution of blood pressure within populations was that blood pressure in individuals was seen as determined by numerous and diverse environmental and genetic influences. Enthusiasm for studies into genetic mechanisms causing raised blood pressure was dampened for several years.

Notwithstanding the smooth continuous but skewed distribution of blood pressures within a given population, there are inevitably a small number of subjects with secondary forms of hypertension concealed within the curve, in whom the causes of any blood pressure elevation are quite distinct. Further, Cusi and Bianchi⁹⁷ drew attention to the detailed mathematical analysis performed by McManus⁹⁸ on the systolic blood pressures reported in a survey by Bøe et al. in 1957⁹⁹ of 67,976 persons over the age of 14 in Bergen, Norway. Pickering had earlier¹⁰⁰ entered an important caveat concerning the systolic readings of Bøe et al. in that they showed marked digit preference—85% ended with 0 and 15% with 5. McManus found that despite the smooth distribution curve apparent on simple inspection of the data, a compound log-normal distribution provided a better and more significant fit than did a single log-normal curve. Although there was only one visible mode, the distribution was shown, in fact, to be compound and “biphasic,” as it contained individuals drawn from two separate populations. The appearance of a broadly symmetrical “normal” distribution does not, it was concluded, exclude the existence therein of different discrete distributions due to separate specific genetic (or other) effects. Thus, despite Pickering’s earlier concerns, searches for subgroups of essential hypertension with different heritable pathogenetic mechanisms were thereby encouraged.

An increasing resurgence of interest in these aspects occurred, especially during the last three decades of the 20th century. Bianchi and Barlassina,⁹⁶ in a major review of the profuse and complex evidence that had accumulated by 2004, concluded that it is unlikely that a single major gene influences essential hypertension. They predicted the imminent identification of a number of gene polymorphisms, each contributing 2% to 10% of genetic variation, depending on the population studied. Further, these authors asserted that gene interactions were likely to be useful targets of future research.

ALCOHOL AND HYPERTENSION

In the 19th century, Mahomed had suggested a link between alcohol excess and hypertension.¹⁰ In a study of French soldiers in 1918, Lian¹⁰¹ found a clear correlation between alcohol ingestion and the prevalence of hypertension. Such prevalence decreased throughout his classification of “les tres grands buveurs, les grands buveurs, les moyens buveurs, et les sobres.”

For a time interest in this relationship declined; Pickering made no mention of the topic in the 1955 and 1968 editions of his book.²⁷ However, numerous subsequent studies affirmed a likely pressor effect of alcohol ingestion.^{102–106} In the 1970s both the Framingham Study and the Copenhagen Heart Study demonstrated a clear relationship between alcohol intake and blood pressure. Even more convincing was the Kaiser Permanente Health Examination Survey of 1977, which confirmed the association in men, women, whites, blacks, and Chinese subjects, independently of educational status and body mass index.¹⁰⁴

The above results were tempered by repeated observations^{44,48} of the apparent protective effect against cardiovascular morbidity of a modest alcoholic intake. That beneficial effect disappeared with high levels of alcohol consumption, which were shown to increase the risk of stroke.⁴⁴ The benefit was initially thought to be a property of wine, and especially of red wine, but later studies showed an association with alcohol ingestion regardless of the type of beverage consumed. It has been argued that several meta-analyses of alcohol and cardiovascular disease could have been distorted by the reversion of some subjects to abstinence because of intercurrent illness.^{49,50}

BODY WEIGHT

Obesity was recognized by Hippocrates^{55,56} as being hazardous to health: “Persons who are naturally of a full habit die suddenly more frequently than those who are slender.”

The clinical and epidemiologic measurement of blood pressure in obese persons is particularly subject to error; thus, a suitably large sphygmomanometer cuff must be used on obese persons. Numerous studies¹⁰⁶ have nevertheless confirmed a relationship between body mass index and arterial pressure, and that blood pressure falls with weight reduction. Current estimates from population studies, including the Framingham survey,³⁵ suggest that excess weight gain may account for as much as 65% to 75% of the risk for essential hypertension.

Hypertension, abdominal obesity, insulin resistance, and dyslipidemia form a cluster that has become known as “the metabolic syndrome.” A combination of lifestyle modifications and aggressive antihypertensive drug therapy is recommended for treating patients with this syndrome.¹⁰⁷

OTHER INFLUENCES

A wide range of other factors may increase blood pressure, including cold weather and high ambient noise levels. Regular exercise, consumption of fresh fruits and vegetables,

and the intake of potassium and magnesium can lower blood pressure.^{108–110}

RENIN-ANGIOTENSIN SYSTEM

Perhaps the most important contribution to our understanding of the nature of hypertension has been the elucidation of the renin-angiotensin-aldosterone system. Several chapters in this volume are devoted to this system; to avoid repetition, its history is not covered in detail here. Honorable mention must, however, be given to Franz Gross, Jaques Genest, John Laragh, James O. Davis, and, of course, Jerome Conn. In addition, credit for the synthesis of drugs designed to block the system, initially with angiotensin-converting enzyme (ACE) inhibitors and later with angiotensin receptor blockers, must go to Miguel Ondetti, Bernard Rubin, David Cushman, and Pieter Timmermans. This list is, however, intrinsically unfair. Countless others have contributed just as much and many receive recognition elsewhere in this book.

Renin, a protein now recognized as an enzyme, was discovered as a pressor principle in renal extracts by Tigerstedt and Bergman in 1898.^{8,37–40,111,112} Elucidation of the complexities of this system comprised a major topic of biochemical, physiologic, and clinical research throughout the 20th century, with numerous and diverse implications for the pathogenesis of hypertension and its treatment.

For three decades after its discovery, renin was largely ignored. Then, in 1934, Goldblatt and colleagues demonstrated that it was possible to produce sustained experimental hypertension by applying constricting clamps to

the renal arteries. Surprisingly, although Goldblatt recognized that a humoral substance released from the kidney might be responsible, he did not at first consider renin as a contender. Others did, however, and in 1938 renin was once more extracted from kidneys and partially purified. Delineation of the detailed mode of involvement of renin in the pathogenesis of renovascular hypertension, which was at first thought likely to be simple, turned out to be remarkably intricate.¹¹³

Kohlstaedt et al. in 1938 and Munoz et al. in 1939 proposed that renin was an enzyme, which was confirmed in 1940 by Page et al. and Braun-Menendez et al. Renin acts on a circulating substrate, angiotensinogen, to form the vasoactive peptide angiotensin II. Details of this complex system as it is currently understood are shown in Figure 1–5. Angiotensinogen was identified chemically by Skeggs et al. in the late 1950s. The amino acid sequences of the bovine and equine octapeptides of angiotensin II were determined, respectively, by Elliott and Peart and by Skeggs et al. in 1956. Angiotensin II was synthesized in the same year.

Practicable assays for circulating renin were introduced in 1963 and 1964, and for angiotensin II in 1971; these were progressively refined in subsequent years. Numerous studies followed that established a wide range of actions attributed to angiotensin II: stimulation of aldosterone and vasopressin secretion, thirst, sodium appetite, a range of direct renal actions, and vagal inhibition (Figure 1–6).

A most important relationship with sodium balance was established in 1963, when it was shown that sodium restriction elevates, and sodium loading depresses, plasma renin.¹¹⁴ Bing and colleagues pioneered the study of renin in

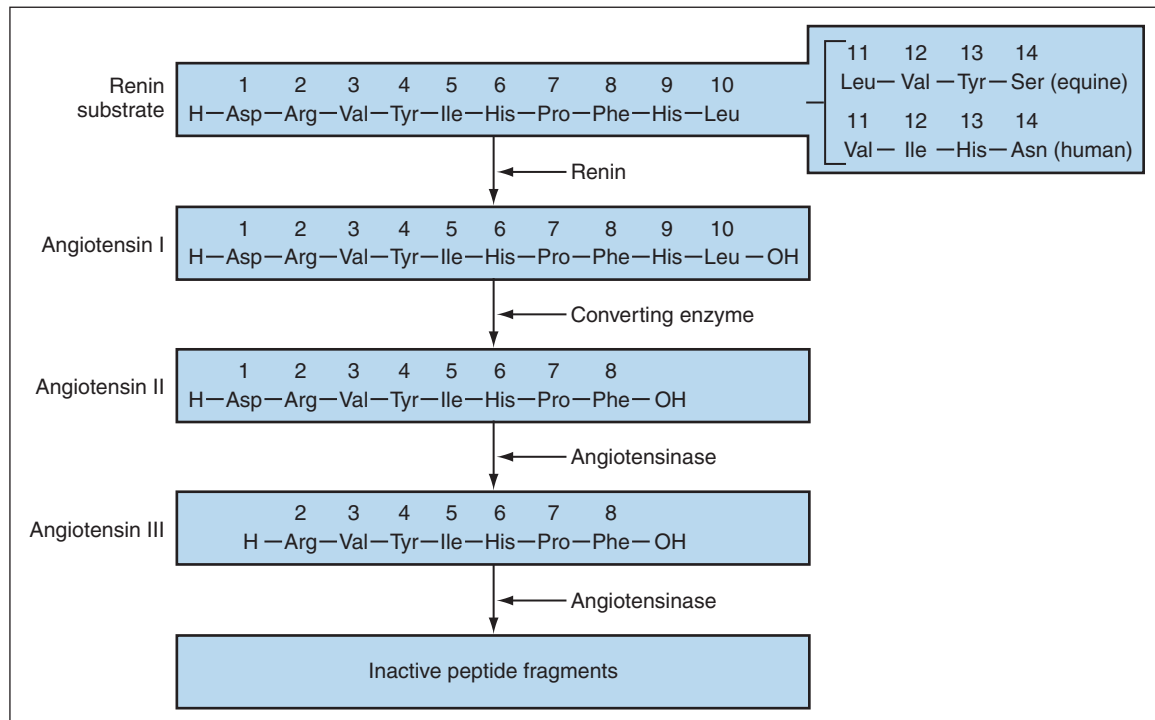

Figure 1–5. Outline of the biochemistry of the renin-angiotensin system. (Redrawn from Nicholls MG, Robertson JIS. The renin system and hypertension. In: Birkenhäger WH, Robertson JIS, Zanchetti A, eds. *Handbook of Hypertension* 2004;22:262–297.)

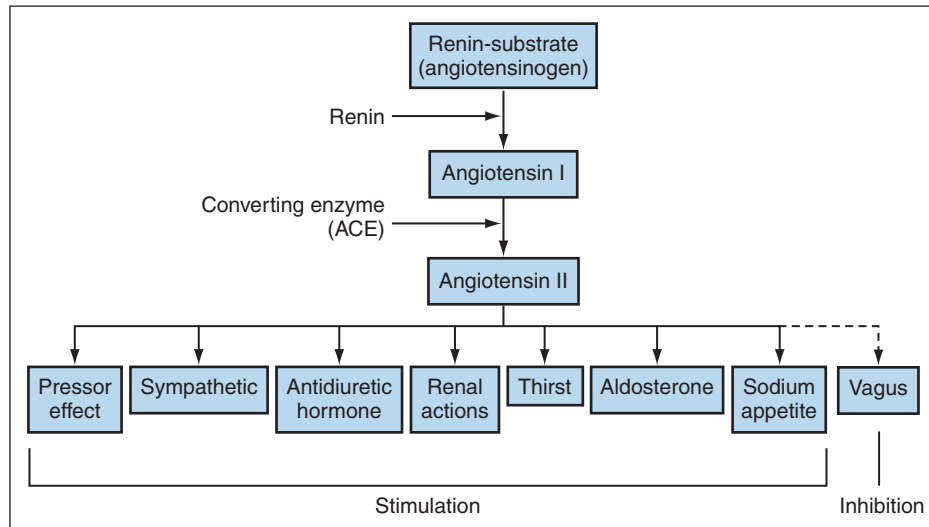

Figure 1-6. The renin–angiotensin system and its principal actions. (Redrawn from Nicholls MG, Robertson JIS. The renin system and hypertension. In: Birkenhäger WH, Robertson JIS, Zanchetti A, eds. *Handbook of Hypertension* 2004;22:262–297.)

extrarenal tissues, with their Danish laboratory reporting the presence of renin in the uterus and salivary glands as early as the 1960s. Renin is now recognized to be present in the brain, heart, blood vessels, adrenal cortex, testis, epididymis, ovary, amniotic fluid, pancreas, and the eye as well.

Two principal receptor subtypes for angiotensin II were identified, namely AT_1 and AT_2 . The AT_1 receptor mediates actions of angiotensin II that are indicated in Figure 1-6. Some established, probable, and possible cardiovascular functions of the AT_2 receptor are listed in Table 1-2. Receptor functions comprise an area of intense study in recent years to the present.

By the close of the 20th century, the renin–angiotensin system had been revealed to be widely involved in diverse physiologic processes and clinical disorders. Many of these as they concern humans are listed in Table 1-3.

In the late 20th century, a number of drugs were developed to interrupt the renin–angiotensin system at various sites (Figure 1-5). Thus far, two of the most clinically useful are the ACE inhibitors and the orally active antagonists of the AT_1 receptor. Several effective inhibitors of the enzyme renin were also produced. Initially, none of these possessed adequate oral bioavailability for clinical use, although some recent examples are more promising.^{115,116}

One of the least commendable aspects of the study of the renin–angiotensin system has been the reluctance or inability of some researchers to apply proper quantitative standards.¹¹⁰ Pickering expressed much concern about such deficiencies in 1963,¹¹⁷ at a time when the first reliable assays for renin were appearing:

Many workers do not even use a standard ... [but instead employ a] hillbilly method. You cannot compare results from day to day, from one laboratory to another, from country to country.

Even when an international reference preparation of renin was tested and made generally available in 1975,¹¹⁸ only a few researchers were able and willing to use it. In 1978 one of us (JISR) helped develop a quantitative approach

PHYSIOLOGICAL ROLES OF AT_2 RECEPTOR IN CARDIOVASCULAR SYSTEM

Action	Cell or tissue
Growth inhibition	VSMC Endothelial cell Cardiomyocyte Cardiac fibroblast Embryonic fibroblast
Proapoptosis	VSMC Endothelial cell Cardiomyocyte AT_1 receptor AT_2 receptor (Neuronal cell, R3T3 fibroblast)
Growth promotion	VSMC <i>in vivo</i> VSMC in culture Cardiac myocyte
Differentiation	VSMC (neuronal cell)
Decrease in cell matrix	Heart Coronary perivascular cells
Increase in cell matrix	VSMC Cardiac fibroblast Coronary perivascular cells
Decrease in blood pressure	In small arteries
Vasodilatation	Glomerular afferent arteriole
NO production	Kidney Coronary artery and microvessels Aorta
Improvement of cardiac function (LVEDV, LVESV, EF)	Heart
Decrease in chronotropic effect	Heart

From Nicholls MG, Robertson JIS. The renin system and hypertension. In: Birkenhäger WH, Robertson JIS, Zanchetti A, eds. *Handbook of Hypertension* 2004;22:262–297.
EF, ejection fraction; LVEDV, left ventricular end-diastolic volume; LVESV, left ventricular end-systolic volume; NO, nitric oxide; VSMC, vascular smooth muscle cells.

Table 1-2. Physiological Roles of AT_2 Receptor in Cardiovascular System

RENIN SYSTEM IN HEALTH AND DISEASE	
Stimulated	
<i>Certainly or probably involved physiologically, pathophysiologically and/or pathogenically</i>	
Normal pregnancy	Addison's disease and related disorders
Angiotensinogen-secreting tumor	Anorexia nervosa, bulimia nervosa, diuretic abuse, purgative abuse
Renovascular hypertension	Bartter's syndrome and related disorders
Malignant-phase hypertension (some cases)	Vascular and cardiac remodeling
Hemorrhage	Myocardial infarction
Acute circulatory renal failure	Cardiac failure
Multiple organ failure	Chronic renal failure with hypertension
Hepatic cirrhosis	Diabetes insipidus, especially nephrogenic forms
<i>Possibly involved pathophysiologically and/or pathogenically</i>	
Early polycystic kidney disease	Connective tissue diseases
Nephrotic syndrome	Raynaud's phenomenon
Aortic coarctation	Cancerous proliferation
Pheochromocytoma	
Suppressed	
Sodium and fluid excess	Essential hypertension (majority of cases)
Mineralocorticoid hypertension	Primary renin deficiency
Gordon's syndrome	Pregnancy hypertension (i.e., relative to normal pregnancy)
Liddle's syndrome	Syndrome of apparent mineralocorticoid excess

Table 1–3. Renin System in Health and Disease

combining angiotensin II assay with the establishment of relevant dose–response curves.¹¹⁹ Regrettably, only a few laboratories have since pursued such discipline.

The lack of proper quantification of the renin–angiotensin system continued into the early years of the 21st century, a lamentable deficiency. An analogy may be instructive: consider the difficulties in scientific intercourse if each center were to employ its own peculiar units of blood pressure measurement.

DEVELOPING DRUGS FOR BLOOD PRESSURE REDUCTION

Relationships between hypertension and cardiovascular and renal complications were already becoming clear in the early 20th century, but benefits of reducing blood pressure were by no means apparent. Indeed, it was widely believed that elevated arterial pressure served as a protective response to the narrowing of arterioles, and was necessary in order to maintain perfusion of vital organs. Thus, in 1931 Hay quoted (but did not endorse) the old saw:

The greatest danger to a man with a high blood pressure lies in its discovery, because then some fool is certain to try and reduce it.³⁴

The distinguished American cardiologist, Paul Dudley White, made the following comment:

Hypertension may be an important compensatory mechanism which should not be tampered with, even were it certain we could control it.¹²⁰

Despite such doubts, attempts at lowering high blood pressure were made, some of them by Hay.³⁴ In his text-

book on hypertension in 1926, Halls Dally listed a range of procedures¹²¹ directed to that end, almost certainly uniformly futile (Box 1–2).

Effective (but fearsome) antihypertensive measures were subsequently introduced.²⁶ In 1948, Kempner promulgated his rice and fruit diet, intolerably monotonous if continued for more than a few days, and which probably worked by means of extreme salt restriction. Also in the 1940s and

Box 1–2

Selected Antihypertensive Measures Recommended in 1926

Trunecek's solution (sodium chloride, sodium sulphate, sodium bicarbonate, and potassium sulphate)
 Total pancreas substance
 Calcium salts and atropine (Kylin)
 Five grains of blue pill and a saline draught
 Thymol oil (oil of thyme)
 Benzyl benzoate
 Fresh garlic
 Dilute hydrochloric acid
 Sodium bicarbonate, chloroform, gentia, or rhubarb
 Effervescent baths
 Douches
 Taking the waters at Harrogate, Cheltenham, or Leamington Spa

From Halls Dally JF. *High blood pressure: Its variation and control*. 2nd ed. London: Heinemann, 1926;134–147.

1950s dorsolumbar sympathectomy and extensive bilateral adrenalectomy were performed. These were formidable surgical procedures, with a high incidence of complications and usually unpleasant side effects, although they did reduce blood pressure.²⁷

An amusing contemptuous opinion concerning the discomforts of antihypertensive treatment around that time was expressed by S. Weiss of Boston¹²²:

Thus far, what has been done in an effort to reduce the blood pressure? Because of an ill-founded idea that protein was responsible for hypertension and kidney disease, the patient was denied meat and eggs and especially red meat.... His diet was rendered even more unpalatable by withdrawal of salt. Sympathy would doubtless have been extended to this half-starved fellow except that he probably was not able to eat anyway, his teeth having been extracted on the theory that focal infection had something to do with hypertension. Even before this he had sacrificed his tonsils and had his sinuses punctured because of the same theory. In case some food had been consumed, the slight residue was promptly washed out by numerous colonic irrigations.... Of course he was denied alcohol and tobacco as well as coffee and tea.... As a climax to the difficulties of this unfortunate person, he may now fall into the clutches of the neurosurgeon, who is prepared to separate him from his sympathetic nervous system.

Therapeutic expertise did, nevertheless, improve. The earliest effective antihypertensive drugs, the autonomic ganglion-blocking agents, hexamethonium and pempidine, followed logically from surgical sympathectomy, and were introduced in the late 1940s. In subsequent decades, more effective, better-tolerated, and longer-acting, orally effective agents were developed, including, successively, hydralazine, reserpine, thiazide diuretics, guanethidine, methyl dopa, beta-blockers, alpha-blockers, clonidine, minoxidil, calcium antagonists, ACE inhibitors, and angiotensin receptor blockers.^{123,124}

The more recently introduced drugs provide better blood pressure control. Although the issue is debated, this could be one, but almost certainly not the only, reason for their demonstrable superiority over earlier agents in limiting complications.^{23,125-131}

Today, a once-daily dose should produce, 24 hours after ingestion ("trough" drug level) a lowering of systolic pressure by ~10 mmHg and of diastolic pressure by ~8 mmHg. Larger reductions may be achieved with combinations of drugs. These drugs, incidentally, produce somewhat greater changes than have been reported with dietary salt restriction (Table 1-1).

DRUG TREATMENT TRIALS

Hypertension is accompanied by increased cardiovascular morbidity and mortality, but it does not necessarily follow that blood pressure reduction would correct such lesions. Fortunately, however, antihypertensive drugs were developed, and there are now many randomized trials investigating their usefulness.

With the introduction of effective antihypertensive drugs, it was soon determined that they could correct both malignant-phase hypertension (provided that serious renal impairment had not supervened) and overt hypertensive heart failure. Because the course of these conditions, if untreated, was almost invariably fatal, controlled trials were unnecessary, and would, indeed, have been unethical. The early drugs were fairly intolerable; therefore, their use could only be justifiable in patients at very high risk of death.

Demonstration of the ability of antihypertensive drug treatment to prevent complications where the condition had not progressed to the malignant phase or to cardiac failure required controlled trials. In 1964 Hamilton and colleagues^{132,133} reported a pioneering study in which initially uncomplicated patients were assigned to antihypertensive drug treatment or simply outpatient review. This trial demonstrated clear benefit from therapy, notably stroke prevention.

Numerous subsequent and larger trials were conducted, and these have been extensively reviewed.¹³⁴⁻¹³⁷ Strict rules were formulated for the conduct of such studies. These requirements included the allocation of patients at random to control or treatment groups; that the proposed conduct of the trial, especially the method of statistical analysis, be declared at the outset and not subsequently modified; that any additional therapeutic approaches such as dietary or other lifestyle changes should be identical in those allocated to active drug or control; and that the overall system of healthcare must be the same throughout the trial. Whether "open" studies (i.e., non-double-blind investigations) should be accepted without reservation was questioned. Remarkably, these precepts were repeatedly ignored or flouted, such that by the end of the 20th century the situation concerning the benefits of antihypertensive therapy remained depressingly obscure.

The U.S. Veterans Administration (VA) trial of 1967 and 1970^{138,139} was designed and initiated as a single study, but was subsequently halted in patients with severe hypertension, with the two resultant patient groups then being analyzed and reported on separately. It is hardly surprising that this behavior engendered much dispute and confusion, with arguments concerning whether it comprised one or two separate trials. As Hampton wrote in 1983,

The US Veterans' study broke almost every rule of trial design and analysis, and if it were offered to a medical journal today it would probably not be accepted for publication.¹³⁴

Two trials, the Hypertension Detection and Follow-up Program (HDFP)^{140,141} and the hypertensive group of those recruited to the Multiple Risk Factor Intervention Trial (MRFIT),¹⁴² were confounded by therapeutic interventions in the treatment group (dietary advice intended to lower body weight, serum cholesterol, and salt intake, plus anti-smoking counseling), which were additional to antihypertensive drugs. Obviously, the effects observed could have been the outcome of the hypertensive drugs, one of the other interventions, or some combination of them.^{143,144}

One much-quoted meta-analysis¹⁴⁵ (which, incidentally, accepted several "open" trials for inclusion) discarded the

MRFIT data, explicitly because of potential confounding.¹⁴⁶ Perversely and inexplicably, however, findings from the HDFP were included.

Further, in the HDFP the treatment group was offered a distinctly advantageous overall system of health care. Therefore, it was hardly surprising that mortality from a range of noncardiovascular diseases was lower in the special intervention than in the “control” group. Such benefit can hardly be attributed to the hypertension treatment. As Hampton wrote in 1983,

The HDFP study ought to be rejected because it was not a proper trial of the treatment of hypertension.... The HDFP seems to show that good care is better than bad care, but it tells us little about hypertension.¹³⁴

Another concern was the inconsistent attitude of trial analysts toward demonstrably unreliable diagnostic criteria for coronary artery disease. In the HDFP, only electrocardiographic data were considered reliable; reports of coronary events elicited by questionnaire or self-reporting were determined to be biased, and thus were initially rejected.¹⁴⁵ It was noted that

[t]he inclusion of “non-fatal myocardial infarctions” diagnosed by self-reporting or Rose questionnaire has inadvertently but seriously exaggerated the benefits of antihypertensive treatment in HDFP. The large benefits claimed for treatment in young subjects or in women are entirely due to this.¹⁴⁶

Yet subsequently, and despite clearly recognized flaws, some of the analysts returned, without explanation, to using data that they had themselves earlier condemned as unreliable.^{147,148}

Almost certainly the most perceptive and accurate meta-analysis to date was that published by Gueyffier et al. in 1996,¹⁴⁹ which excluded the HDFP, MRFIT, and the part of the VA study dealing with less severe hypertension. The authors found the most impressive treatment benefits in patients aged over 60: 46% reduction in congestive heart failure, 34% in stroke, 23% in cardiovascular mortality (all $p < 0.001$); 21% in major coronary events ($p < 0.01$); and 10% in all-cause mortality ($p < 0.05$). In marked hypertension (entry diastolic pressure at 100 to 130 mmHg), the only complication benefited was congestive cardiac failure, with an 89% reduction in risk ($p < 0.001$). In mild-to-moderate hypertension in younger patients, the only

significant benefit was a 49% reduction in stroke ($p < 0.001$); the lack of visible benefit concerning coronary events could not be attributed to lower morbidity, because such coronary events were more frequent than stroke in this age group. One of only two trials dealing with recurrent stroke found a significant reduction in the number of deaths with treatment ($p < 0.05$).

Sadly, Gueyffier and colleagues soon defected from the standards of that commendably rigorous meta-analysis of 1996. In 1997, Gueyffier, with a different mix of co-authors,¹⁵⁰ addressed the question of differential treatment benefit in men and women. Surprisingly, data from the HDFP, a study that Gueyffier et al. had rejected *in toto* just a year earlier because of its flawed design, were now accepted. Coronary events were computed as elicited by self-reporting, a process already shown to have seriously distorted and exaggerated the apparent benefits of drug treatment in the HDFP (“the large benefits claimed for treatment ... in women are entirely due to this”¹⁴⁷). Thus, the conclusions were guaranteed to be invalid from the outset.

The question of possible differential benefit among several types of antihypertensive agent remains unresolved. As mentioned above, the undoubted protective superiority shown in several studies by more modern drug classes could partly reside in their greater efficacy in lowering blood pressure.^{23,124–130} Two trials that addressed this issue^{150,151} reached conflicting conclusions. Both trials were, however, seriously confounded by substantial contamination of the treatment groups as initially defined during the course of the studies. The latter ALLHAT study¹⁵² has also been extensively criticized on various other methodologic grounds.^{153–155}

It should be apparent from the foregoing that overall the evaluation of antihypertensive treatment trials has been methodologically problematic. At present this deficiency is one of the more embarrassing aspects of research into hypertension. We can, and must, do better.

SUMMARY

This introductory chapter has chronicled progress in our appreciation and understanding of hypertension and its management up to the early 21st century. We hope that the chapter is a useful, if sometimes contentious, perspective on this exciting and therapeutically rewarding subject.

Chapter

2

Blood Pressure in Westernized and Isolated Populations

Lydia A. Bazzano, Jiang He, and Paul K. Whelton

Key Findings

- Cardiovascular disease accounts for 30.9% of global mortality and 10.3% of the global burden of disease.
- Hypertension is estimated to account for 4.4% of the total global burden of disease and contributes to 44% of all ischemic heart disease.
- Gender and race/ethnicity influence age-related changes in blood pressure.
- The distribution of hypertension in Westernized populations is influenced by a number of factors, including age, gender, and racial/ethnic composition of the population under study.
- The lowest prevalence of hypertension for both men and women was in Asia, other than China, and the Pacific Islands.
- Populations who do not demonstrate an age-related rise in blood pressure tend to live in primitive societies isolated from modern lifestyles and have a low salt intake, high level of physical activity, and an absence of obesity. Where there is migration to a more Westernized environment or where “modernization” is occurring *in situ*, blood pressure rises with age and hypertension begins to appear.

Despite recent advances in prevention and treatment, cardiovascular diseases (CVD) remain a major public health problem in both developed and developing countries. Once considered a disease of the industrialized world, it is now apparent that CVD is a public health menace worldwide. Currently CVD accounts for 30.9% of global mortality and 10.3% of the global burden of disease.¹ Worldwide, heart disease and stroke are responsible for nearly 17 million deaths each year, and at present, twice as many deaths from CVD now occur in developing countries compared to developed countries.² According to global burden of disease estimates, hypertension is one of the top 10 risk factors for disease worldwide.² Hypertension alone is estimated to account for 4.4% of the total global burden of disease and contributes to 44% of all ischemic heart disease.³

It has been recognized for some time that a direct positive relationship exists between blood pressure and CVD risk. This relationship has been observed in men and women of all ages, race/ethnic groups, and countries, regardless of other risk factors for CVD; it is strong, graded, and continuous across all levels of blood pressure.⁴ Because

hypertension is such a powerful and modifiable risk factor for the development of CVD, understanding the distribution and determinants of blood pressure in populations worldwide is of vital importance. Examining patterns of blood pressure distribution in Westernized or acculturated societies, those in isolated or unacculturated societies, and those in migrants from these societies can shed light on the role of environmental factors in the development of high blood pressures and hypertension.

BLOOD PRESSURE IN WESTERNIZED POPULATIONS

Relationship of blood pressure and age

Many studies in Westernized populations have found remarkably consistent results regarding the relationship of blood pressure to age. Nearly all have demonstrated that mean blood pressure rises with age in Westernized populations, and therefore, so does the incidence and prevalence of hypertension.⁵ However, depending on an individual's stage of life, gender, race, initial level of blood pressure and exposure to environmental factors, this general trend may vary a great deal.

Childhood and adolescence

The 1987 report of the Second Task Force on Blood Pressure Control in Children and its 1996 update compiled some of the best available data on the relationship of blood pressure and age in childhood and adolescence.^{6,7} Blood pressure measurements recorded on more than 70,000 children aged 1 to 20 who participated in nine cross-sectional surveys, were pooled to create normative blood pressure distribution curves by age. Blood pressure measurements were standardized and were obtained with the child in a seated position using a mercury sphygmomanometer or a Doppler instrument in infants. Among infants and children aged 3 to 12 years, the fourth Korotkoff sound was used to signify diastolic blood pressure, while in adolescents (13 to 18 years), both fourth and fifth Korotkoff sounds were used as markers of diastolic blood pressure. At birth, the average systolic and diastolic pressures were 70 mmHg and 50 mmHg, respectively. There is a rapid and pronounced rise in systolic blood pressure, so that by the end of the first year of life, systolic blood pressure averages 94 mmHg, while diastolic blood pressure rises only 2 mmHg over the same period. Thereafter, there is a tendency for blood pressure to rise with increasing age throughout the

remainder of childhood and adolescence. The slope for age-related change in blood pressure is much steeper for systolic (1 to 2 mmHg/year) than for diastolic (0.5 to 1 mmHg/year) blood pressure.

Evidence from the pooled data also reflects the influence of gender on blood pressure. From the age of 4 years onwards, the slope of the age-related change in blood pressure remains fairly constant for boys. For girls the pattern parallels that of boys until adolescence, when the slope for girls becomes considerably flatter than that of boys. Taken as a whole, the evidence suggests little difference in pattern of average blood pressure levels between genders until adolescence. During the teenage years, however, average blood pressure was consistently higher for boys compared to girls. As a consequence, by age 18, boys had average systolic and diastolic blood pressures that were almost 10 and 5 mmHg higher than the corresponding values for girls. There was no evidence for a systematic difference between the average levels of blood pressure in children of different race/ethnicities (white, black, and Mexican American). Data from the Bogalusa Heart Study and the Child and Adolescent Trial for Cardiovascular Health, however, indicate that mean blood pressure level is higher in black compared to white children and lower in Mexican-American compared to black and white children.^{8,9}

Adults and the elderly

There is a general tendency for both systolic and diastolic blood pressure to rise during adulthood.⁵ The age-related rate of increase is consistently greater for systolic than for diastolic blood pressure. Systolic blood pressure tends to rise until the eighth or ninth decade, whereas diastolic blood pressure tends to remain constant or decline after the fifth decade. As a consequence, pulse pressure increases progressively with aging. This is particularly true during the latter part of life.

The pattern of blood pressure change with age is modified to a certain extent by gender and race/ethnicity. In young adults, systolic and diastolic blood pressures tend to be higher in men than in women; however, the slope of age-related blood pressure increase is steeper for women than for men. As a result, by the seventh decade women tend to have levels of systolic blood pressure that equal or exceed those seen in men. Selective survivorship may explain part of this gender-related difference in blood pressure, as men with high blood pressure earlier on may be less likely to survive and contribute to average blood pressure later in life. Longitudinal analysis of the Framingham cohort and other data sets suggests, however, that selective survivorship only explains a portion of these age-related trends.¹⁰

Race and ethnicity also influence age-related change in blood pressure. This phenomenon has been well documented in the Third National Health and Nutrition Examination Survey (NHANES III) (Figure 2-1). In men and women, non-Hispanic blacks had the highest and non-Hispanic whites had the lowest average systolic blood pressure, although the differences among the three race/ethnicity groups were small. In women, non-Hispanic whites con-

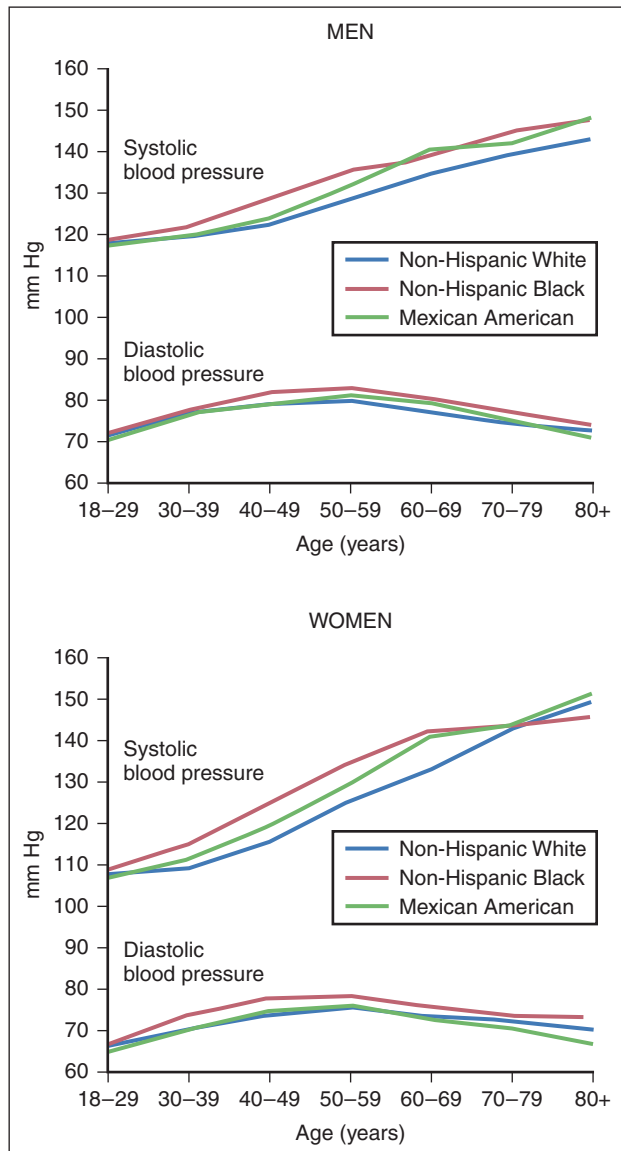

Figure 2-1. Mean systolic and diastolic blood pressures by age and race/ethnicity for men and women. U.S. population 18 years and older.

tinued to have the lowest average systolic blood pressure during the sixth decade. By the seventh decade, however, the three race/ethnicity groups had similar average systolic blood pressure levels. Non-Hispanic black women had a higher average diastolic blood pressure than non-Hispanic white or Mexican-American women. The same was true in men until the end of the fifth decade. Thereafter, diastolic blood pressures were similar in the three race/ethnicity groups.

CLASSIFICATION OF HYPERTENSION

The Sixth Report of the U.S. Joint National Committee for Detection, Evaluation, and Treatment of High Blood Pressure (JNCVI) was published in 1997 and recommended a classification of blood pressure that was adopted by the World Health Organization-International Society of

Hypertension.^{11,12} This classification scheme was updated in the Seventh Report (JNC VII), published in 2003 (Table 2–1).¹³ These criteria are for individuals who are not on antihypertensive medication and who are not acutely ill. The classification is based on the average of two or more blood pressure readings after an initial screening visit. When systolic blood pressure and diastolic blood pressure fall into different categories, the higher category should be selected to classify the individual's blood pressure.

According to JNC VII criteria, normal blood pressure is defined as a systolic blood pressure less than 120 mmHg and a diastolic blood pressure less than 80 mmHg. Those with a systolic blood pressure between 120 mm and 139 mmHg or diastolic blood pressure between 80 and 89 mmHg are designated as having prehypertension. Hypertension is characterized by a confirmed elevation of systolic (≥ 140 mmHg) or diastolic (≥ 90 mmHg) blood pressure. Hypertension is further characterized into two stages according to the patient's level of systolic and diastolic blood pressure. Stage 1 is the milder (systolic 140 to 159 mmHg and/or diastolic 90 to 99 mmHg) and most common form of hypertension. It accounts for approximately 80% of hypertension. Stage 2 hypertension includes those with systolic blood pressure of 160 mmHg or greater and/or diastolic blood pressure of 100 mmHg or greater. Isolated systolic hypertension is defined as systolic blood pressure of 140 mmHg or greater and diastolic blood pressure below 90 mmHg and staged appropriately.

DISTRIBUTION OF HYPERTENSION IN WESTERNIZED POPULATIONS

The distribution of hypertension in Westernized populations is influenced by a number of factors. The incidence and prevalence of hypertension varies by age, gender, and racial/ethnic composition of the population under study. Factors such as environmental exposures, including intake

of dietary sodium and potassium, body weight, alcohol consumption, and physical activity, also influence the incidence and prevalence of hypertension; however, those topics are beyond the scope of this chapter.

Age

As discussed previously, there is a large body of data available from Western populations that demonstrates rising mean blood pressure with increasing age. Consequently, the prevalence of hypertension increases with age. In NHANES III, the prevalence of hypertension increased with increasing age (Table 2–2). In the 18- to 24-year-old group, the overall prevalence of hypertension was only 2.6%. The prevalence of hypertension increased to 5.4% in 25- to 34-year-olds and 13.0% in 35- to 44-year-olds. The prevalence rates continued to rise with 27.6% of 45- to 54-year-olds affected and 43.7% of 55- to 64-year-olds. In 65- to 74-year-olds, the overall prevalence was 59.6% and in the 75-and-older age group, it was 70.3%. Several longitudinal cohort studies have also documented that incidence of hypertension increases with age.^{14–16}

Gender

Overall the prevalence and incidence of hypertension are slightly higher in men compared to women. In NHANES III, the age-adjusted prevalence of hypertension for all races/ethnicities was 23.5% in men and 23.3% in women. In whites the prevalence was 23.4% in men and 23.1% in women. In blacks the prevalence was slightly higher in women than in men, 28.2% and 27.9%, respectively. The relationship between gender and hypertension is modified by age. In young adults, the prevalence and incidence of hypertension are higher in men than in women. However, by their sixties, women tend to have levels of blood pressure that equal or exceed those seen in men. Consequently, the prevalence of hypertension is higher in women than in men late in life.

CLASSIFICATION OF BLOOD PRESSURE FOR ADULTS AGED 18 AND OLDER ACCORDING TO JNC VII ^a			
Category	Systolic Blood Pressure (mmHg)		Diastolic Blood Pressure (mmHg)
Normal ^b	<120	and	<80
Prehypertension	120–139	and	81–89
Hypertension ^c			
Stage 1	140–159	or	90–99
Stage 2	≥ 160	or	≥ 100

^aNot taking antihypertensive drugs and not acutely ill. When systolic and diastolic pressures fall into different categories, the higher category should be selected to classify the individual's blood pressure status. Isolated systolic hypertension is defined as systolic blood pressure of 140 mmHg or greater and diastolic blood pressure below 90 mmHg and staged appropriately.

^bNormal blood pressure with respect to cardiovascular disease risk is below 120/80 mmHg. However, unusually low readings should be evaluated for clinical significance.

^cBased on the average of two or more readings taken at each of two or more visits after an initial screening.

Table 2–2. Prevalence of Hypertension (%) in United States, 1989–1994

Race/Ethnicity

In NHANES III the prevalence of hypertension in different racial/ethnic groups was compared. It was found that in the 18- to 49-year-old group, non-Hispanic blacks had prevalence of hypertension of 15% in men and 8% in women, non-Hispanic whites had prevalence of hypertension of 11% in men and 4% in women, and Mexican Americans had the highest prevalence of hypertension in men of 20%, while in women it was only 3%.¹⁷ In the 50- to 69-year-old group, the prevalence was 45% in men and 43% in women among non-Hispanic blacks, 35% and 29% in men and women among non-Hispanic whites, and 37% in both men and in women among Mexican Americans, respectively. Overall the prevalence of hypertension is highest in male and female African Americans. The prevalence of hypertension is higher in white men than Mexican-American men, while the prevalence is higher in Mexican-American women than white women.

Several longitudinal cohort studies have also shown that African Americans have a higher incidence of hypertension than whites.^{14,15,18,19} In the Atherosclerosis Risk in Communities Study, the 6-year incidence of hypertension among 45- to 49-year-olds was 13.9% and 12.6% in white men and women, respectively, and 24.9% and 30.3% in African American men and women, respectively.¹⁷ The corresponding incidence of hypertension among participants aged 50 to 64 years was 18.0% and 17.0% in white men and women, respectively, and 28.3% and 29.9% in African-American men and women, respectively. Other longitudinal cohort studies indicated that the incidence of hypertension in African Americans was an average of two times higher than in whites.^{14,18,19}

Geographic region

According to a recent study of the global burden of hypertension, 26.4% of the world's adult population in 2000 had hypertension, and 29.2% were predicted to have hypertension by 2025.²⁰ Regions with the highest estimated prevalence of hypertension had roughly twice the rate of regions with the lowest estimated prevalence. In men, the highest estimated prevalence was in the

region of Latin America and the Caribbean, whereas for women, the highest estimated prevalence was in the former socialist economies. The lowest prevalence of hypertension for both men and women was in the region of Asia, other than China, and the Pacific Islands. Rates of hypertension by geographic region and gender are presented in Figure 2–2.

LIFETIME RISK OF HYPERTENSION IN WESTERNIZED POPULATIONS

Although the prevalence of hypertension is a useful indicator of burden of disease in the community, it does not tell us about the risk for developing hypertension in individuals. The individual risk for developing hypertension is best described by incidence or lifetime cumulative incidence statistics. Less information is available about lifetime cumulative incidence of hypertension because it requires follow-up of populations for a prolonged period of time.^{14–16,18,19}

The lifetime risk for developing hypertension was estimated among 1298 Framingham Heart Study participants aged 55 to 65 years and free of hypertension at baseline during the 1976–1998 period.²¹ For 55-year-old participants, the cumulative risk for developing hypertension was calculated through age 80 while for 65-year-old participants, the risk for developing hypertension was calculated through age 85 years. These follow-up time intervals (25 years for 55-year-olds and 20 years for 65-year-olds) correspond to the current mean residual life expectancies for white individuals at these two ages in the United States. The lifetime risks for developing hypertension were 90% in both 55- and 65-year-old participants (Figure 2–3). The lifetime probability of receiving antihypertensive medication was 60%.²¹

BLOOD PRESSURE IN ISOLATED POPULATIONS

In most Western populations, blood pressure levels rise with advancing age; however, the same is not true in many

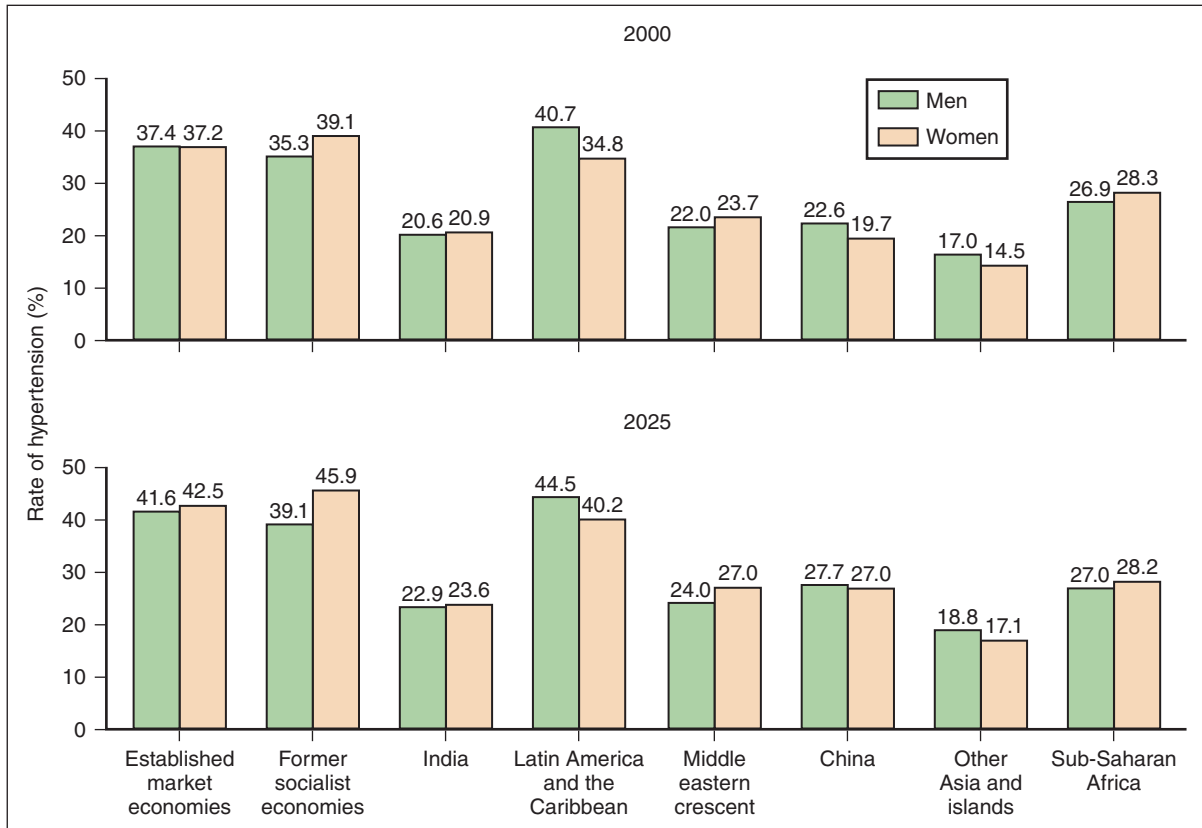

Figure 2-2. Frequency of hypertension in people aged 20 years and older by world region and gender in 2000 (upper) and 2025 (lower). (Redrawn from Kearney PM, Whelton M, Reynolds K, Muntner P, Whelton PK, He J. *Lancet* 2005; 365:217–23 with permission from Elsevier.)

isolated or unacculturated populations. Since 1929, when Donnison^{21,22} first described an isolated population in Kenya whose blood pressure did not rise with age, at least 30 similar reports have been published.²³ Other examples of such populations include Melanesians in New Guinea,^{24–27} South American Indians,^{25,28,29} Pacific Islanders,^{8,30–33} Navajo Indians,³⁴ a rural population in Delhi,³⁵ Kalahari

Bushmen,^{36,37} African Pygmies,³⁸ and the Yi farmers of southern China.³⁹ Most of these studies were conducted decades ago and methodology issues exist among them; however, more recent and rigorous studies, such as that among the Yi population,³⁹ have also shown that blood pressure remains low and does not rise in some isolated populations.

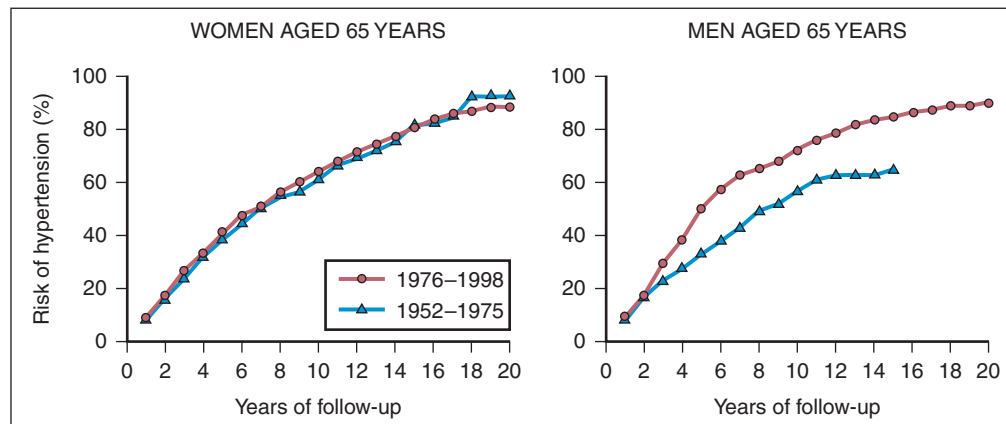

Figure 2-3. Residual lifetime risk of hypertension in women and men aged 65 years of the Framingham Heart Study. (Redrawn from Vasan RS, Beiser A, Seshadri S, Larson MG, Kannel WB, D'Agostino RB, et al. *JAMA* 2002;287:1003–10.)

Africa

Donnison²² in 1929 was the first to provide evidence suggesting that many Kenyan tribes had low blood pressures that rose little through adulthood.²² In an area around Lake Victoria in western Kenya, he surveyed the population and medical records of a large hospital located in the region. Among his findings, in surveying approximately 1000 individuals there were no cases of hypertension, and blood pressure levels were low, falling further with advancing age. A more recent study of approximately 2000 male subsistence farmers in Kenya, in an area adjacent to that studied by Donnison²² decades earlier, confirmed that systolic blood pressure showed no significant rise with age until participants passed 54 years of age and diastolic pressures showed a very small rise with age.⁴⁰ In this community, packaged or processed foods were not available, nor were electricity, water supply, or telephone communication, and transportation was primarily on foot within the local community. Most participants were subsistence farmers who engaged in heavy physical labor every day. Mean 24-hour urinary excretion of sodium in this population ranged from 53 to 93 mmol/day, while mean intake of sodium measured by dietary survey was just under 130 mmol/day (3 g/day).^{25,40} Of note, both systolic and diastolic blood pressure correlated positively with urinary sodium: potassium ratios in that study, suggesting that cation intake may play an important role in the differences in blood pressure among isolated populations and Westernized populations. A study among the Kung Bushmen living a nomadic, hunter-gatherer lifestyle in Botswana has also shown low blood pressures that increase little with age, and perhaps somewhat decrease with age.³⁷ In this population, dietary intake of sodium was approximately 86.9 mmol/day (2 g/day), while potassium intake approximated 204.6 mmol/day (8 g/day). Similarly, a study of Bushmen living in the Kalahari Desert, also hunter-gatherers, found an average systolic blood pressure of 100 mmHg, with diastolic pressure approximately 68 mmHg among men, with slightly higher values in women.³⁶ Again, blood pressure levels in both men and women did not show the age-related increases seen in Westernized populations. Among the Xhosa people of South Africa, blood pressure of those living a traditional lifestyle of subsistence farming in remote villages of the Transkei were low and rose little with advancing age.⁴¹

South and Central America

Studies examining the blood pressures of isolated populations in South and Central America have included the Cuna Indians, Yanomamo Indians, and Xingu Indians, among other populations.^{25,29,42,43} The Yanomamo and Xingu of the tropical rainforests near the equator have very recently been studied as part of an international cooperative study on blood pressures in diverse populations (Figure 2–4).²⁵ The Yanomamo Indians are perhaps one of the most unacculturated native tribes in South America and possibly in the world. They live in an area of about 200,000 km² located along the border of Brazil and Venezuela. The total population consists of approxi-

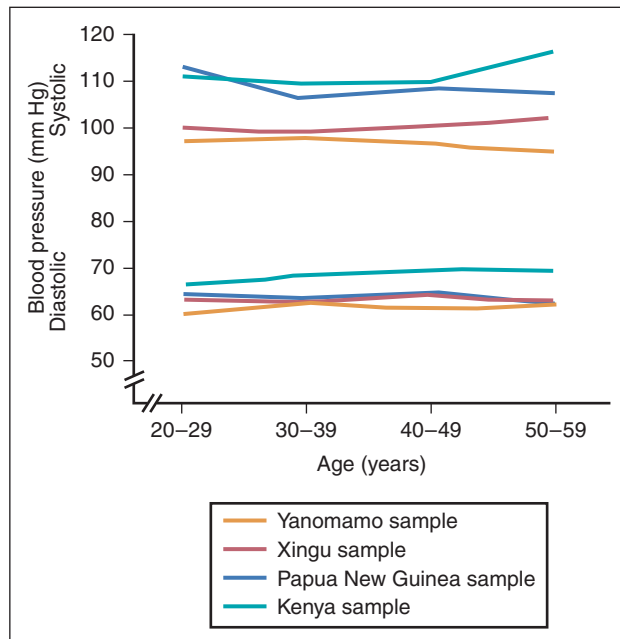

Figure 2–4. Blood pressure-age relationships among four isolated populations studied as part of the International Study of Salt Intake and Blood Pressure. (Redrawn from Carvalho JJ, Baruzzi RG, Howard PF, Poulter N, Alpers MP, Franco LJ, et al. *Hypertension* 1989;14:238–46.)

mately 18,000 individuals, scattered throughout the Amazon rainforest in 200 or so villages composed of 40 to 250 people each. By and large, the Yanomamo are seminomadic, slash-and-burn agriculturalists who live on a diet of locally produced crops and game, supplemented by wild fruits and insects. Dietary staples consist of cooked banana and manioc (cassava). In most villages there is little if any access to salt, refined sugar, alcohol, milk, or other dairy products. Similarly, the Xingu Indians occupy an area of 22,000 km² in the central region of Brazil. Although less isolated than the Yanomamo, the Xingu do not maintain regular contact with non-Indians. The diet of Xingu Indians is principally based on manioc (cassava) and fish. The consumption of meat from game animals is free in some tribes and restricted by taboos in others. The diet also includes, to a lesser extent, corn, sweet potatoes, cara, peanuts, bananas, and wild fruit. Salt and other foods sold in stores are not used regularly. Mean systolic blood pressures among the Yanomamo and Xingu Indians were 101 and 103 mmHg in men and 91 and 96 mmHg in women, respectively. Individuals studied in the Yanomamo villages consumed virtually no salt, while the Xingu Indians had a median intake of about one-third gram of salt daily. Among the Yanomamo Indians, urinary sodium excretion was 0.9 mmol/24 hours, while Xingu Indians had a urinary sodium excretion of 12.5 mmol/24 hours. Those in the sample from Papua New Guinea had a median consumption of 1.5 g of salt daily and the 24-hour urinary excretion of sodium was 37.5 mmol. This contrasts with the median consumption of more than 391.5 mmol/day (9 g/day) and 24-hour

urinary sodium excretion of 166 mmol in the rest of this study.²⁵

China

Blood pressure has been examined in several isolated populations of China. In 1937, Morse and Beh⁴⁴ reported that the blood pressure of aboriginal groups living in mountainous regions of Szechwan, Kweichow, and Yunnan was low, and rose little with advancing age. Cardiovascular diseases were extremely rare among these populations. More recently, the Yi people from the Szechwan Province have been studied extensively by He et al.^{39,45-47}

The Yi people are a minority population in China living in the Liangshan Yi Autonomous Prefecture in southern China, an area covering approximately 70,000 km². The Yi people live in remote mountain districts at 1,500 or more meters above sea level. Their main occupation is agriculture, and they are one of the most primitive societies in China. In the high-mountain regions, isolated from the outside world, the Yi farmers have preserved their own language and lifestyle. Their main crops are potatoes, oats, and buckwheat; they rarely eat meat, except during the Yi New Year in December. Owing to a shortage of water, Yi farmers rarely take a bath and almost never wash their hands, faces, and clothes. Before about 1950, it was extremely difficult for the high-mountain Yi farmers to obtain salt, and although salt is now more readily available, salt consumption has remained quite low. Mountainside Yi farmers have a lifestyle that is in many ways similar to that of the high-mountain Yi farmers, however, they are closer to a highway and have some contact with a more modern lifestyle. Their main staples are rice and corn, but also include potatoes, oats, buckwheat, and beans; they consume more meat and salt than high-mountain Yi farmers. Male Yi farmers, both high-mountain and mountainside residents, smoke home-grown tobacco and consume an average of 30 to 35 g of alcohol daily, corresponding to about three Western alcoholic drinks per day. He et al.⁴⁶ studied the blood pressures of 3419 high-mountain Yi farmers and 2936 mountainside Yi farmers, along with 517 Yi migrants who had moved to the county seat, and 1143 Han Chinese who resided in the county seat. They found a mean systolic blood pressure of 101.8 mmHg and 101.2 mmHg among high-mountain men and women, and 100.8 mmHg and 100.1 mmHg among mountainside men and women, respectively. The corresponding mean diastolic blood pressures were 63.0, 63.0, 62.2 and 62.5 mmHg, respectively. In terms of the age-blood pressure relationship, in all groups, blood pressure increased up to the second decade of life. Among men, no further significant increase was seen in systolic blood pressure for high-mountain and mountainside Yi men. Diastolic blood pressure did not increase much with age among high-mountain male farmers, while it increased late in life among the mountainside farmers. Among women, systolic blood pressure remained the same and did not increase with age for high-mountain farmers, but did increase in other groups. Diastolic blood pressure among women increased in all groups but with a very small slope among the high-mountain Yi.

Twenty-four-hour urinary excretions of sodium and potassium were markedly different among Yi mountain groups and Yi migrants to the county seat. For example, high-mountain and mountainside Yi farmers excreted an average of 73.9 and 117.9 mmol of sodium daily, and 58.6 and 48.5 mmol of potassium daily, respectively. Yi migrants excreted a mean of 159.4 mmol of sodium and only 28.3 mmol of potassium daily. Han residents of the county seat excreted 186.0 mmol of sodium and 29.0 mmol of potassium daily, on average, similar to the intakes of Yi migrants.⁴⁶

New Guinea and Pacific Islands

Studies among islanders in isolated populations such as New Guinea and certain Pacific Islands have also demonstrated a lack of age-related blood pressure rise. Sinnett and Whyte²⁷ studied approximately 1000 members of a New Guinean highland population. The participants were farmers and pig herders with an agriculture-based economy with very little Western influence. They also identified the lack of age-related blood pressure increase and noted that sodium intake was less than 43.5 mmol/day (1 g/day) among the islanders studied. Among the sample of islanders from Papua, New Guinea included in the Intersalt Study, median consumption of sodium was estimated at 65.3 mmol/day (1.5 g/day) and 24-hour excretion of sodium was 37.5 mmol.²⁵

Prior et al.⁴⁸ examined the populations of the Polynesian Islands of Raratonga and Pukapuka. Among Pukapuka Islanders, an age-related rise in blood pressure was seen only among women and was slight; however, among the Raratonga, blood pressures were higher and increased with age. Dietary surveys and urine analyses revealed a substantially greater mean salt intake among the Raratonga Islanders (mean 24-hour sodium excretion of 50 to 70 mmol in Pukapuka Islanders and 120 to 140 mmol/day in Raratonga Islanders).

Six Solomon Island populations were studied by Page et al.³³ All were rural populations living in villages without access to electricity; however, they varied widely in habitat, way of life, and degree of exposure to Western culture. Among the least acculturated populations, diastolic blood pressure fell with age in males, while among the more acculturated populations, there was no trend with age in males. Systolic pressures in males did not increase with age, whereas in females of the three most acculturated communities, systolic blood pressures did increase with age. In the three most acculturated societies, 24-hour sodium excretions ranged from 50 to 230 mmol, whereas among the least acculturated society, 24-hour urinary sodium excretion was under 20 mmol.

These comparisons of blood pressure in isolated populations suggest that sodium intake plays an important role in determining absolute levels of blood pressure and age-blood pressure relationships. More support for this observation has come from the examination of remote populations in the Intersalt Study.²⁵ The authors of that study concluded that a certain minimum intake of salt is required to produce a high frequency of hypertension in populations.

MIGRATION STUDIES

Populations that do not demonstrate an age-related rise in blood pressure tend to live in primitive societies isolated from modern lifestyles and have a low salt intake, high level of physical activity, and an absence of obesity. Many studies of those who migrate to a more Westernized environment or who are under modernization *in situ* have shown that blood pressure rises with age and hypertension begins to appear. This change in pattern of blood pressure with aging must be due to an alteration of environmental, rather than genetic influences. Such migrants, therefore, provide a unique population model in which to study the relationship between blood pressure and environmental factors.³⁹

In the Tokelau Island Migrant Study, the relationship between blood pressure and migration was studied in a cohort of 654 adult Tokelauans who either remained in their homeland or migrated to New Zealand.⁴⁹ Three surveys were conducted between 1968 and 1982. Results showed that both systolic and diastolic blood pressures of migrant men were higher compared with age-matched nonmigrants. In a longitudinal analysis of this cohort, it was noted that blood pressures tended to rise 1 mmHg/year faster among male migrants than among male nonmigrants, and about 0.4 mmHg/year faster among female migrants than among female nonmigrants.⁵⁰ Most of this rise in blood pressure could be attributed to weight gain. However, this study did not include a control group of New Zealand local residents.^{49,50}

The Yi migrant study is a more recent and significantly larger study of migration from an isolated population to a more Westernized population.³⁹ In the Yi migrant study, blood pressure was measured in 14,505 persons (8241 Yi farmers, 2575 urban Yi migrants, and 3689 Han urban residents) aged 15 to 89 years. Blood pressure was recorded as the mean of three seated measurements after a 10-minute rest period. At all ages, Yi migrant men had higher mean diastolic pressures than male Yi farmers, and had values similar to Han men. In women, mean systolic and diastolic pressures were lower in Yi farmers in the second half of life, while blood pressures were similar among Yi migrant women and Han women and higher than among Yi farmers. Definite hypertension, defined according to World Health Organization criteria as systolic pressure at least 160 mmHg and/or diastolic pressure at least 95 mmHg and/or use of antihypertensive medication, was extremely rare among Yi farmers (0.66% in men and 0.33% in women). The age-adjusted prevalence of hypertension in male Yi migrants was 4.25%, similar to the 4.91% seen in Han men. For women, age-adjusted prevalence of hypertension was lower among Yi migrants than in Han residents (2.40% and 4.76%, respectively) and much higher than that of Yi farmers. Differences in the prevalence of definite hypertension were especially marked in the oldest age groups. For example, among men aged 65 years and older, the prevalence of definite hypertension was 8.0 times higher in Yi migrants and 13.9 times higher in Han than in Yi farmers.

The contribution of urinary cations to change in blood pressure due to migration was also explored in this study of Yi farmers.⁴⁷ Blood pressure and overnight urinary electrolyte levels were measured on 3 consecutive days in 313 Yi farmers, 265 Yi migrants, and 253 urban Han residents, all male. Of the urinary electrolytes, a higher sodium:potassium ratio best explained the higher blood pressure in the migrants. Yi farmers had lower systolic (106.7 mmHg vs. 114.8 mmHg, respectively) and diastolic (66.2 mmHg vs. 71.3 mmHg, respectively) blood pressures than Yi migrants. However, even after adjustment for age, body mass index, alcohol intake, and urinary sodium, potassium, calcium, and magnesium excretion, Yi farmers continued to have lower average blood pressures than Yi migrants. In pooled analyses of all three groups, urinary sodium and calcium were positively related, and urinary potassium and magnesium were inversely related to blood pressure. These results suggest that migration is associated with a higher blood pressure that was partially but not entirely explained by higher levels of adiposity, alcohol, and sodium intake, and lower levels of potassium and magnesium intake.

Poulter et al.⁵¹ examined 325 members of the Luo tribe aged 15 to 34 years who had migrated to Nairobi and 267 controls living in 35 villages on the northern shores of Lake Victoria in western Kenya. They collected medical questionnaires, three 24-hour diet histories, height, weight, pulse, and blood pressure on migrants and controls. In addition, three 12-hour overnight urine samples were collected from all participants and analyzed for sodium, potassium, and creatinine concentrations.

They found that mean systolic blood pressure of migrants was significantly higher than that of controls, and the entire distribution of blood pressure was shifted to higher levels as compared with controls. Mean diastolic blood pressure differences also grew over time. They also concluded that blood pressure differences were not due to selective migration but more likely due to the contribution of dietary and urinary cations. Migrants' mean urinary sodium:potassium ratio was significantly higher than that of controls ($p < 0.001$), and weight and pulse rate were also higher among migrants. Their results are highly consistent with that of the Yi migrant study and strongly suggest that urinary sodium:potassium ratio and weight changes are important contributors to increased blood pressure among migrants from a low blood-pressure community, and therefore, may also be an important part of the initiation of essential hypertension.

CONCLUSIONS

High blood pressure is a major risk factor for cardiovascular disease worldwide. In Westernized populations, the pattern of blood pressure is such that most of the population is at increased risk for blood pressure-related cardiovascular diseases. In contrast, the pattern in many isolated populations is such that only a slight fraction of the population is at increased risk for blood pressure-related disease. In comparisons of Westernized populations

with those isolated populations that demonstrate little or no rise in blood pressure with age, one of the most salient and consistent differences between them is a very low mean sodium intake. Even within isolated populations, those with lower sodium intake and hence lower sodium:potassium excretion ratios in urinary testing, have lower blood pressures and less age-related increase in blood pressure.

Migration studies also lend support the primary role of environmental factors in the development of hypertension. Given that most of the major risk factors for hypertension are modifiable, and strong evidence that hypertension can be prevented altogether, the importance of primary prevention strategies in reducing the global burden of hypertension and cardiovascular diseases cannot be overstated.

Regional Differences in Blood Pressure in Developed Countries

Patricia M. Kearney and Ivan J. Perry

Key Findings

- Blood pressure increases with age across regions.
- In younger individuals high blood pressure is more prevalent in men, while in older populations more women than men have high blood pressure.
- The distribution of high blood pressure varies by ethnicity within regions.
- Hypertension is a major public health problem irrespective of age, race/ethnicity, or gender.
- In economically developed countries, the prevalence of hypertension ranges between approximately 20% and 50%, and overall approximately one-third of adults in developed countries are affected.
- The prevalence of hypertension is higher in Europe than in North America or Australia, but overall it is decreasing in most Western countries.
- Population-wide strategies are required for prevention, treatment, and control of hypertension.
- Formal population-level screening programs are required to increase the detection of hypertension.
- Awareness, treatment, and control are required at an individual level.
- Population-level interventions are also required.

Hypertension is an important public health challenge worldwide because of its high prevalence and the concomitant increase in risk of cardiovascular and renal disease.^{1,2} It has been identified as the leading global risk factor for mortality and has been ranked third as a cause of disability-adjusted life years.³ Hypertension is the most important modifiable risk factor for coronary heart disease, stroke, congestive heart failure, chronic renal failure, and peripheral vascular disease.⁴⁻⁹ Observational epidemiologic studies have demonstrated that elevated blood pressure is related to an increased risk of cardiovascular and renal disease.⁶⁻⁹ Also, randomized controlled trials have shown that antihypertensive drug treatment reduces the morbidity and mortality of cardiovascular and renal disease among patients with hypertension (Table 3-1).¹⁰⁻¹² The treatment of hypertension has improved dramatically over the past 30 years in many countries and this has contributed to the reduction in mortality due to coronary heart disease and stroke that has been observed in some developed countries.¹³ However, even in developed countries, most patients with hypertension do not have adequate treatment and control

of their blood pressure.^{14,15} Patterns of regional differences in hypertension prevalence may provide insight into the underlying determinants of blood pressure variation and facilitate improvements in hypertension treatment and control.

PREVALENCE OF HYPERTENSION IN DEVELOPED COUNTRIES

It has been estimated that more than one-quarter of the world adult population—totaling nearly 1 billion—had hypertension in 2000 and it is predicted that this proportion will have increased to 29%—1.56 billion—by 2025.¹⁶ In developed countries, the total number of people with hypertension in 2000 was estimated as 333 million, and it is predicted that this number will increase by 24% to 413 million by 2025.¹⁶ In economically developed countries, the prevalence of hypertension ranges between approximately 20% and 50%,¹⁷ and overall approximately one-third of the adult population in developed countries are affected (26.6% of men and 26.1% of women) (Table 3-2).

North America

According to data from the National Health and Nutrition Examination Survey (NHANES) III conducted in 1988–1992, as many as 42.3 million adult residents of the United States have hypertension, defined as having a systolic blood pressure ≥ 140 mmHg and/or a diastolic blood pressure ≥ 90 mmHg and/or taking antihypertensive medications. In addition, there are 7.7 million U.S. residents who have been told at least twice by a health professional that they have hypertension. Overall, there are about 50 million adult hypertensives in the United States.¹⁸ The most recent report of the Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure¹⁹ defined a new category, prehypertension (systolic blood pressure of 120 to 139 mmHg or a diastolic blood pressure of 80 to 89 mmHg), which identifies individuals at increased risk of cardiovascular disease. According to data from the NHANES 1999–2000, approximately 60% of American adults (67% of men and 50% of women) had prehypertension or hypertension and 27% had hypertension.²⁰ A similar prevalence of hypertension was reported in the Canadian Heart Health Survey, a cross-sectional population-based survey that collected data in each of the 10 Canadian provinces between 1986 and 1992.²¹ The study reported an overall prevalence of hypertension of 26% in men and 18% in women, which represents 4.1 million Canadian adults.

CHARACTERISTICS OF STUDIES							
Region	Country	Study Year	Age Range	Study Population	Device	Blood Pressure Methods	
						No. of Measures/No. of Visits	Preparation
North America	United States	1988–1994	≥18	National sample of 19,661	Standard mercury	6/2	5-minute rest
	Canada	1986–1992	18–74	National sample of 23,129	Standard mercury	4/2	5-minute rest
Europe	Spain	1990	35–64	National sample of 2,021	Random zero	3/1	—
	England	1998	≥20	National sample of 11,529	Electronic	3/1	5-minute rest
	Germany	1994–1995	25–74	Regional sample of 4,856	Random zero	3/1	30-minute rest
	Greece	1997	18–91	Regional sample of 665	Standard mercury	3/1	5-minute rest
Australia	Australia	1989	25–64	National sample of 19,315	Standard mercury	2/1	—
Japan	Japan	1980	30–74	National sample of 10,346	Standard mercury	1/1	—

Table 3–1. Characteristics of Studies

PREVALENCE OF HYPERTENSION							
Region	Country	Crude Prevalence of Hypertension			Age-Standardized Prevalence of Hypertension		
		Men (%)	Women (%)	Overall (%)	Men (%)	Women (%)	Overall (%)
North America	United States	23.5	23.3	23.4	21.0	19.7	20.3
	Canada	26.0	18.0	22.0	23.5	15.6	21.4
Europe	Spain	46.2	44.3	45.1	41.7	39.0	40.0
	England	43.4	35.0	38.8	34.7	25.7	29.6
	Germany	44.0	32.2	—	38.3	26.4	—
	Greece	30.2	27.1	28.4	18.5	15.9	16.9
Australia	Australia	31.9	20.7	—	30.8	20.1	—
Japan	Japan	50.1	43.3	—	42.7	35.0	38.3

Note: All studies defined hypertension as average BP of ≥140/90 mmHg and/or use of antihypertensive medication.

Table 3–2. Prevalence of Hypertension

Europe

Many studies have estimated the prevalence of hypertension in Western Europe although there are relatively few national studies. The reported prevalence tends to be higher than in equivalent studies in North America.²² The Spanish National Blood Pressure Study reported a prevalence of hypertension that increased with age and was higher in rural (49.4%) than in urban (43.2%) dwellers.²³ The study estimated that there were 6 million hypertensives aged 35 to 64 years in Spain.²³ The Health Survey for England 1998 was a cross-sectional, household-based nationwide survey of English adults aged 16 years or older.²⁴ According to the study, 41.5% of men and 33.3% of women had a systolic and/or diastolic blood pressure of ≥140/90 mmHg and/or were receiving antihypertensive therapy.

Australia

The prevalence of hypertension in the Australian general population was estimated as part of the National Heart Foundation's Risk Factor Prevalence Study, which was conducted from 1980 to 1989.²⁵ The survey was administered to a randomly selected sample as a multicenter cross-sectional survey in 1980, 1983, and 1989. The Australian Institute of Health and Welfare (AIHW) analyzed the data from the National Risk Factor Prevalence Study to obtain estimates of the prevalence of hypertension defined as systolic blood pressure ≥140 mmHg and/or diastolic blood pressure ≥90 mmHg and/or receiving treatment for high blood pressure. According to the AIHW analysis, the prevalence of hypertension in Australian adults aged 25 to 64 years was 31.9% in men and 20.7% in women.²⁶

HYPERTENSION AND AGE

There is a large body of data available from Western populations that demonstrates mean blood pressure rises with increasing age.^{2,27} While evidence from isolated “acculturated” societies suggests that such an increase in blood pressure is not a biological requirement,²⁸ in developed countries there is a general tendency for blood pressure to rise progressively with increasing age. As a consequence, there is a concomitant increase in the incidence and prevalence of hypertension with age. The age-related increase in blood pressure, however, varies considerably depending on the individual’s stage of life, gender, race/ethnicity, initial level of blood pressure, and exposure to environmental factors.

Childhood and adolescence

Information on the pattern of blood pressure in children and adolescents is provided by the report of the Second Task Force on Blood Pressure Control in Children.²⁹ This report was based on data from blood pressure measurements on over 70,000 children who participated in nine cross-sectional surveys conducted in the United States and the United Kingdom. At birth, average systolic and diastolic pressures were 70 mmHg and 50 mmHg, respectively. Shortly thereafter, there was a rise in systolic blood pressure, so that by the end of the first year of life it approximated 94 mmHg. Diastolic blood pressure rises by only 2 mmHg over the same time period. For the next 2 to 3 years, systolic and diastolic blood pressures remain stable. Thereafter, there is a tendency for blood pressure to rise with increasing age throughout the remainder of childhood and adolescence. The slope for age-related change in blood pressure is much steeper for systolic (1–2 mmHg/year) than for diastolic (0.5–1 mmHg/year) blood pressure.

The Task Force database provides information on an approximately equal numbers of boys and girls. There is little evidence of a difference in pattern of average blood pressure between the sexes until adolescence. During the teenage years, average blood pressure is consistently higher for boys than for girls. This is particularly true for systolic blood pressure. By age 18, boys have average systolic and diastolic blood pressures that are almost 10 mmHg and 5 mmHg higher, respectively, than the corresponding values for girls. There was no evidence for a systematic difference in average blood pressure between white, black, and Mexican American children in the Task Force database. However, data from the Bogalusa Heart Study and the Child and Adolescent Trial for Cardiovascular Health indicate that mean blood pressure level is higher in black compared to white children and lower in Mexican-American compared to black and white children.^{30,31}

Adults and the elderly

There is a general tendency for both systolic and diastolic blood pressure to rise during adult life.^{2,27} The age-related rate of rise is consistently higher for systolic than for diastolic blood pressure. Systolic blood pressure tends to rise until the eighth or ninth decade, whereas diastolic blood pressure tends to remain constant or decline after the fifth decade.

As a consequence, pulse pressure increases progressively with aging. This is particularly true during the latter part of life.

The pattern of blood pressure change with age is modified to a certain extent by gender and race/ethnicity. In young adults, systolic and diastolic blood pressures tend to be higher in men than in women. However, the age-related rise in blood pressure with age is steeper for women than for men. As a result, by the seventh decade women tend to have levels of systolic blood pressure that equal or exceed those seen in men. Selective survivorship may explain part of this gender-related difference in blood pressure as men with high blood pressure earlier on may be less likely to survive and contribute to average blood pressure later in life. Longitudinal analysis of the Framingham cohort and other data sets suggests, however, that selective survivorship only explains a portion of these age-related trends.³²

In NHANES III, the prevalence of hypertension increased with increasing age. In the 18 to 24 age group the overall prevalence of hypertension was only 2.6%. The prevalence of hypertension increased to 5.4% in 25- to 34-year-olds and 13.0% in 35- to 44-year-olds. The prevalence rates continued to rise with 27.6% of 45- to 54-year-olds affected and 43.7% of 55- to 64-year-olds. In 65- to 74-year-olds, the overall prevalence was 59.6% and in over 75-year-olds it was 70.3%. Similar increases in blood pressure with age have been demonstrated in a number of European studies.^{23,24,33–35} Across all of these age ranges the prevalence of hypertension is lower in North America than in Europe.²² However, there was evidence of heterogeneity in mean blood pressure among the European countries at different age groups.²² In the youngest age groups, Germany, England, and Finland reported the highest prevalence of hypertension, with a lower prevalence of hypertension in Italy and Spain. In the older age groups, Germany and Sweden had the highest levels of hypertension among the European countries while Italy had the lowest mean blood pressure measurements.

HYPERTENSION AND GENDER

Overall the prevalence and incidence of hypertension are slightly higher in men compared to women. In NHANES III, the age-adjusted prevalence of hypertension for all races/ethnicities was 23.5% in men and 23.3% in women. In whites the prevalence was 23.4% in men and 23.1% in women. In blacks the prevalence was slightly higher in women than in men, 28.2% and 27.9%, respectively. The relationship between gender and hypertension is modified by age. In young adults, the prevalence and incidence rates of hypertension are higher in men than in women. For example, in developed countries the overall prevalence of hypertension in young men (20–29 years) is over twice the prevalence in women (14.4% vs. 6.2%, respectively).¹⁶ The prevalence of hypertension remains higher in men than in women up until the sixth decade. However, by their 60s, women tend to have levels of blood pressure that equal or exceed those seen in men. Consequently, the prevalence of hypertension is higher in women than in men at older ages.

HYPERTENSION AND RACE/ETHNICITY

In a worldwide analysis of hypertension prevalence, the effect of race/ethnicity on the prevalence of hypertension differed by gender and by study country, so that overall no clear effect of race/ethnicity on the prevalence of hypertension emerged.¹⁷ In the United States, much interest has focused on the racial/ethnic differences in hypertension, although these differences are only half the size of the differences, for example, between the United States and Europe.²² In NHANES III, the prevalence of hypertension in different racial/ethnic groups was compared. In both men and women, non-Hispanic blacks had the highest and non-Hispanic whites had the lowest average systolic blood pressure until the end of the fifth decade. In the sixth and later decades, among men, Mexican Americans tended to have the highest average systolic blood pressure, although the differences among the three race/ethnicity groups were small. In women, non-Hispanic blacks continued to have the highest and non-Hispanic whites continued to have the lowest average systolic blood pressure during the sixth decade. By the seventh decade, however, the three race/ethnicity groups had similar average systolic blood pressure levels. Throughout adult life, men had a slightly higher average level of diastolic blood pressure than women did. Non-Hispanic black women had a higher average diastolic blood pressure than non-Hispanic white or Mexican American women. The same was true in men until the end of the fifth decade. Thereafter, diastolic blood pressures were similar in the three race/ethnicity groups. It was found that in the 18 to 49 age group, non-Hispanic blacks had prevalence of hypertension of 15% in men and 8% in women, non-Hispanic whites had prevalence of hypertension of 11% in men and 4% in women, Mexican Americans had the highest prevalence of hypertension in men of 20%, while in women it was only 3%.¹⁸ In the 50 to 69 age group, the prevalence was 45% in men and 43% in women among non-Hispanic blacks; 35% in men and 29% in women among non-Hispanic whites; and 37% in both men and in women among Mexican Americans, respectively. Overall the prevalence of hypertension was highest in male and female African Americans. The prevalence of hypertension was higher in white men than Mexican-American men, while the prevalence was higher in Mexican-American women than white women. Several longitudinal cohort studies have also shown that African Americans have a higher incidence of hypertension than whites.^{36–39}

In the Atherosclerosis Risk in Communities Study, the 6-year incidence of hypertension was 13.9% and 12.6% in white men and women, respectively, and 24.9% and 30.3% in African-American men and women, respectively, aged 45 to 49 years.³⁷ The corresponding incidence of hypertension among participants aged 50 to 64 years was 18.0% and 17.0% in white men and women, and 28.3% and 29.9% in African-American men and women, respectively. Other longitudinal cohort studies indicated that the incidence of hypertension in African Americans was an average of two times higher than in whites.^{36,38,39} The effect of race/ethnicity on the prevalence of hypertension was also assessed in the Health Surveys for England. Age-

adjusted mean blood pressure levels of older adults were highest among blacks. South Asian men had similar prevalence of hypertension as black men, while South Asian women had similar prevalence of hypertension to white women.

SECULAR TRENDS IN THE PREVALENCE OF HYPERTENSION

Repeated independent cross-sectional surveys in the same populations over time provide information about secular trends in blood pressure and hypertension (Table 3–3). However, attention must be paid to the comparability of the methods of sampling and blood pressure measurement, as well as the definition of hypertension between surveys. Few national data are available to examine the secular trend of hypertension in the general population. Generally speaking, the prevalence of hypertension has declined in most Western populations.¹⁶

The U.S. National Health and Nutritional Examination Surveys may provide the best data to examine the secular trends of hypertension although there was variation in sample size within each subgroup of the population, in the protocol for blood pressure measurement, and in the potential for measurement error.⁴⁰ Overall, hypertension prevalence in the United States has declined progressively since 1971, and the distributions of systolic and diastolic blood pressures have shifted downward during the approximately 30-year period between 1960–1962 and 1988–1991.⁴⁰ The decline in the prevalence of hypertension has been consistent across age, gender, and racial/ethnic groups. For example, the age-adjusted prevalence of hypertension defined as blood pressure $\geq 140/90$ mmHg and/or current use of anti-hypertensive medication peaked at 36.3% in 1971–1974 and declined to 20.4% in 1988–1991. Between 1976–1980 and 1988–1991, the prevalence of hypertension among black men aged 50 to 59 years remained relatively stable at 54.7% and 53.3%, respectively. The prevalence for black men aged 60 to 74 increased from 67.0% to 71.2%. In every other age-specific and ethnic group, hypertension prevalence between 1976–1980 and 1988–1991 declined markedly. The proportionate decrease was greatest among 18- to 29-year-olds and least among the 60 to 74 age group. Age-adjusted mean systolic blood pressure decreased from 131 mmHg in 1971–1974 to 119 mmHg in 1988–1991 in the U.S. general population.⁴⁰ Mean diastolic pressure decreased from 83 mmHg to 73 mmHg over the same time period. For black men and women, the decline in age-specific systolic blood pressure was greatest between 1971–1974 and 1976–1980; the decline in white men and women was greatest between 1976–1980 and 1988–1991 for most age groups. Age-adjusted diastolic pressure decreased in all subgroups between 1971–1974 and 1988–1991. Age-specific diastolic blood pressure also declined markedly and progressively between 1971–1974 and 1988–1991 for every group. However, while these analyses of data through 1991 have suggested that hypertension is declining, the most recent NHANES survey conducted in 1999–2000 reported a prevalence of hyper-

Table 3–3. Trends in Prevalence of Hypertension

tension of 28.7%, which was an increase of 3.7% from 1988–1991.⁴¹

The Health Survey for England was conducted in 1998 and updated the findings of a previous survey in 1992.²⁴ The prevalence of hypertension in those 16 years and older was similar in both surveys, 37% in 1998 and 38% in 1994.²⁴ The Monitoring Trends and Determinants in Cardiovascular Disease (MONICA) studies were conducted in a number of European countries over the 1980s and 1990s.^{42,43} Comparison of the results from the Belgian component of MONICA (1985–1992) with the earlier Belgian Inter-University Research on Nutrition and Health (BIRNH) project (1980–1984) demonstrated a significant decline in the prevalence of hypertension, from 41% and 30.5% to 26.7% and 20% in men and women, respectively.⁴⁴ As part of FINMONICA, four independent cross-sectional surveys were conducted in 1982, 1987, 1992, and 1997.³³ The prevalence of hypertension remained stable between 1982 and 1987. There was a significant downward trend in the prevalence of hypertension between 1987 and 1992. During 1992–1997, diastolic blood pressure remained unchanged but the mean systolic blood pressure decreased. In Germany, the MONICA Augsburg Project studied the prevalence of hypertension with three cross-sectional surveys in 1984–1985, 1989–1990, and 1994–1995.⁴⁵ In contrast with the

Belgian and Finnish studies, the age-standardized prevalence of hypertension increased slightly from the first to the third survey. In Greece, a 1997 survey⁴⁶ reported a prevalence of hypertension that was very similar to a much earlier study in Athens conducted between 1979 and 1983.⁴⁷ The prevalence of hypertension in the Australian general population was estimated as part of the National Heart Foundation’s Risk Factor Prevalence with surveys administered in 1980, 1983, and 1989.¹⁶ There was a significant reduction in the proportion of the survey participants who were classified as hypertensive during the 1980s.²⁵

AWARENESS, TREATMENT, AND CONTROL OF HYPERTENSION

In developed countries, there are relatively high levels of awareness and treatment with approximately one-half to two-thirds of hypertensives aware of their diagnosis and one-third to one-half receiving treatment. Treatment and control of hypertension in the community requires that elevated blood pressure be recognized and that individuals with hypertension receive adequate treatment. The degree of awareness, treatment, and control of hypertension varies considerably among countries (Table 3–4). In addition, hypertension control rates vary by age, gender,

AWARENESS, TREATMENT, AND CONTROL OF HYPERTENSION								
Region	Country	Study Year	Age Range	Gender	Hypertensives			Treated Hypertensives, Controlled (%)
					Aware (%)	Treated (%)	Controlled (%)

race/ethnicity, socioeconomic status, education, and quality of health care within countries.⁴⁸

Trends in level of awareness, treatment, and control

In the United States, there has been a trend towards greater awareness, treatment, and control of hypertension in the community.⁴¹ During the 12-year interval between NHANES II and III, the proportion of hypertensive patients who were aware of their condition increased from 51% to 73%.⁴¹ Increases in awareness were greater for whites than blacks during this time period. Awareness was higher for women than men among both blacks and whites. For example, 67% of black and white men with hypertension were aware of their diagnosis, while 79% and 82% of black and white women, respectively, were aware of their diagnosis at the time of NHANES III.

The increase in awareness of hypertension between 1976–1980 and 1988–1991 has been accompanied by an increase in the proportion of hypertensives receiving treatment with antihypertensive medications. Overall, the percentage of hypertensives receiving treatment increased from 31% in 1976–1980 to 55% in 1988–1991 in the U.S. population. The large difference in awareness of hypertension between men and women in NHANES III is mirrored by a 19% difference in treatment rates. Less than half of male hypertensives received treatment (46%),

while almost two-thirds of women were on treatment for their high blood pressure (65%). For both genders, the percentage of treatment increased by over 20% between 1976–1980 and 1988–1991, from 21% to 46% in men, and 43% to 65% in women. The percentages of treatment were virtually identical during NHANES III for black and white men at 46% and 47%, and both black and white women at 65%, respectively. The proportion of controlled hypertension increased nearly threefold at the 140/90 mmHg cut-point during the 12 years between NHANES II and III. The control rate of hypertension however remains low at 29%. Control rate is higher in women at 38% than in men at 22%. A greater percentage of whites achieved control than blacks, 31% and 26%, respectively. Control rates among treated hypertensives were higher in women than in men and in blacks than in whites. The overall percentage of treated hypertensives with controlled blood pressure increased from 32% in 1976–1980 to 55% in 1988–1991 in the U.S. general population. NHANES 1999–2000 reported no change in the awareness of hypertension, but a further increase of 6% in hypertension treatment and control.⁴⁰

Increasing levels of awareness, treatment, and control have also been reported in Europe. For example, the Health Survey for England reported increased hypertension awareness, treatment, and control from 46.0%, 31.6%, and 7.1% in 1994 to 52.2%, 38.0%, and 10.7% in 1998, respec-

tively.²⁴ Among individuals with hypertension, treatment rates were highest among black men and women. Among the treated hypertensives, levels of control did not differ among the three groups of older men but was lower in older South Asian women, compared with white women. In Germany, there was little improvement in the detection rate of hypertension over a 10-year period from 1984–1985 to 1994–1995.⁴⁵ Awareness of hypertension remained at approximately 50% in men and 60% in women. The proportion of individuals with hypertension who were receiving drug treatment increased by 7.9% in men and 4.1% in women.⁴⁵ Overall, levels of hypertension awareness, treatment, and control in Europe are much lower than in the United States, with levels in Canada lying approximately halfway between these extremes.¹⁵

PREVENTION

The U.S. National High Blood Pressure Education Program has recommended a combination of population-based and intensive targeted strategies for primary prevention of hypertension.⁴⁹ Interventions that have proved effective include weight loss, reduced intake of dietary sodium, moderate alcohol consumption, potassium supplementation, modification of eating habits, and increased physical activity.⁴⁹ These lifestyle changes also have positive effects on other cardiovascular risk factors such as obesity and type 2 diabetes. Secondary prevention efforts entail detection, treatment, and control of hypertension.

Although improvements have been made in the detection and treatment of hypertension in developed countries, rates remain far from adequate.^{15,17} Interventions to reduce the burden of cardiovascular disease have been successful in some developed regions including Europe, North America, Australia, and New Zealand.⁵⁰ These interventions have resulted in substantial reductions in age-adjusted cardiovascular mortality. Personal and nonpersonal health-service interventions have proved cost-effective at both regional and global levels.⁵¹ Although personal health-service strategies have greater potential to reduce the burden of disease, they are less cost-effective than population-wide ones.⁵¹ The availability of analyses of cost-effectiveness allows key decision makers to establish the most appropriate interventions with available resources.

SUMMARY

Hypertension is an important public health problem in developed countries. While the prevalence of hypertension

varies among the developed countries, there are some consistent findings. Hypertension prevalence increases with age and tends to be more common in men than in women. There is evidence of a small rural–urban gradient. Over the past decade the prevalence of hypertension has remained stable or decreased in developed countries. The distribution of hypertension within populations is influenced by a number of factors. The prevalence of hypertension varies by age, gender, and racial composition of the population under study. As well as internal factors, the prevalence of hypertension is also affected by environmental exposures, such as intake of dietary sodium and potassium, body weight, alcohol consumption, and physical activity. Any increase in the lifestyle factors of physical inactivity, overweight, high intake of dietary sodium, and low intake of dietary potassium are likely to be accompanied by a concomitant increase in blood pressure.

Awareness of hypertension has improved in the United States and other Western countries over the past decade, but remains inadequate, in particular as only a proportion of those who are aware of their diagnosis are treated, and an even smaller number of those receiving treatment are treated adequately.

An acknowledgment of the global nature of the problem of hypertension is required so that healthcare providers screen for and treat elevated blood pressure. The magnitude of the burden of hypertension, however, requires not only an increase in the awareness, treatment, and control of hypertension, but also concerted efforts targeting the primary prevention of hypertension. The lifetime risk of hypertension for white individuals in the United States has been estimated to be 90% in both 55- and 65-year-old participants.⁵² Improvements in the detection, treatment, and control of high blood pressure will not suffice to address a problem that affects a significant proportion of the population. A reduction in average blood pressure could be achieved by lifestyle modification of the general population, which would result in a reduced prevalence of hypertension.

Hypertension is a common public health problem throughout the developed world. It often goes undiagnosed and even when it is identified and treated, few hypertensives achieve adequate control of their blood pressure. The improvements in the awareness, treatment, and control of blood pressure in the United States provide hope that similar advances may be made elsewhere. However, given the high prevalence of hypertension in the community and the difficulties in achieving and maintaining the goals of therapy, lifestyle modification remains an attractive therapeutic option.

Chapter

4

Early-Life Influences
on Blood Pressure*Debbie A. Lawlor and George Davey Smith***Key Findings**

- Treated and well-controlled hypertensive adults still have a substantial excess mortality and reduced survival compared with normotensive adults. Therefore, identification of the means of preventing hypertension in earlier life is an important objective.
- Blood pressure “tracks” across the life course, such that those at the higher end of the blood pressure distribution in earlier life tend to be at the higher end of the distribution in later life.
- Children of lower socioeconomic status, those whose mothers experienced pregnancy-induced hypertension, whose mothers smoked throughout pregnancy, those with low birth weight, who have high-sodium diets in infancy, and who are obese in childhood or adolescence, tend to have higher blood pressure in adulthood.
- The mechanisms linking these early-life factors to later blood pressure, and the most appropriate means of preventing adult hypertension by intervening in early life, are currently unclear.
- Observational studies with repeat measurements of a range of socioeconomic, behavioral and biological factors assessed over the life course and the use of appropriate statistical methods are required to further understand the temporal relationships between risk factors and the mechanisms that link early-life exposures to future disease.
- There is a need for randomized trials with sufficient resources for long-term follow-up to assess the effects of interventions to reduce maternal smoking, increase breast feeding, reduce salt consumption in infancy, and prevent childhood obesity, on adult blood pressure and associated cardiovascular disease.

Blood pressure in middle-aged and older people is positively and linearly associated with coronary heart disease (CHD) and stroke risk.¹ While treating high blood pressure is beneficial in terms of reducing the occurrence of these outcomes,² treated and well-controlled hypertensive adults still have a substantial excess mortality and reduced survival compared with normotensives.³ Therefore, the identification of the means of preventing hypertension in earlier life is an important objective.

Blood pressure “tracks” across the life course, such that those at the higher end of the blood pressure distribution in earlier life tend to be at the higher end of the distribution in later life.⁴ These tracking correlations

increase with increasing age in childhood.⁵ The strong and increasing tracking correlations from mid-childhood onward suggest that being in the upper end of the blood pressure distribution in middle or older age is largely determined by the middle of one’s childhood years and certainly by the time of adolescence.

In this chapter we provide a summary of the current evidence concerning the early-life determinants of adult blood pressure, and discuss how current evidence ought to affect clinical or public health practice, in addition to discussing future research needs in this area. We begin by considering the association between childhood socioeconomic status (SES) and adult blood pressure since childhood SES may be an underlying determinant that acts through several of the other risk factors considered in the chapter. Other risk factors are presented in the chronological order in which they occur in an individual’s life course. Of note, many of these exposures act together, rather than in isolation, to have their effect.

EARLY-LIFE SOCIOECONOMIC POSITION

Adverse childhood socioeconomic status (SES) is associated with increased cardiovascular disease (CVD) risk in later life independently of adult SES.⁶ There is no strong evidence that childhood SES is associated with higher blood pressure also measured in childhood.^{7,8} However, childhood SES does appear to be associated with adult blood pressure, such that those from more adverse childhood SES have higher blood pressure in adulthood, independent of adult SES.^{9–11} Consistent with these findings, in the 1946 British birth cohort there was evidence of amplification of the effect of childhood SES on blood pressure, with the difference in blood pressure between manual and nonmanual childhood social class increasing by 1.0 mmHg per 10 years.¹¹

There could be several reasons for the increase in the magnitude of the effect of childhood SES on blood pressure over the life course. First, few studies conducted in childhood have adjusted for height, and height may mask any association in childhood, since taller children will tend to be from higher socioeconomic groups,^{12,13} but in childhood taller stature is associated with higher blood pressure.⁷ Second, there may be latent programming, with a range of adverse environmental exposures in fetal and early postnatal life that are related to socioeconomic disadvantage resulting in abnormal metabolic, structural, and hormonal development that does not manifest itself

as elevated blood pressure until later in life. Finally, childhood SES may influence later blood pressure, not through causing permanent damage in childhood or early adulthood, but by setting someone on a trajectory of risk exposures (e.g., poor diet, low levels of physical activity, smoking across the life course), which together result in high blood pressure in later life. In a recent prospective analysis of the Young Finns cohort study, we found that once height was taken into account, childhood SES was strongly associated with blood pressure in childhood (those from the most disadvantaged groups having higher blood pressure).¹⁴ As with other studies we found marked tracking of blood pressure and a strong association between childhood SES and blood pressure in early adulthood. Of note, we found that adjustment for childhood blood pressure resulted in marked attenuation of the association between childhood SES and adult blood pressure, suggesting that adverse childhood SES had a direct effect on blood pressure in childhood, which then tracked into adulthood.¹⁴

MATERNAL PREGNANCY CHARACTERISTICS

Maternal and pregnancy characteristics have most commonly been related to offspring blood pressure in childhood and adolescence, with very few studies relating these characteristics to adult blood pressure. However, the strong tracking coefficients of blood pressure from late childhood into adulthood (see above) mean that associations with blood pressure in late childhood and adolescence are likely to reflect similar associations into adulthood.

There is also a positive association between pregnancy-induced hypertension or maternal blood pressure measured during pregnancy and offspring blood pressure measured in childhood and adolescence.¹⁵ This may reflect intrauterine effects or the genetic transmission of blood pressure risk from parent to child. The fact that the maternal-offspring blood pressure association is similar to that of the paternal-offspring association suggests that intrauterine effects are unlikely to explain this association.¹⁶

The small number of studies that have assessed the association between maternal hemoglobin during pregnancy and offspring blood pressure in childhood and adolescence have found inconsistent results, with two studies finding inverse associations,^{17,18} one study finding no association,¹⁹ and one study finding a positive association.²⁰ Maternal smoking during pregnancy has been shown in three studies to be associated with increased offspring blood pressure in childhood and adolescence,^{21–23} but two other studies found no such association.^{17,20} In the largest study to date ($n=3864$), systolic blood pressure of children whose mothers had smoked throughout pregnancy was on average 0.92 mmHg greater than those whose mothers had never smoked, after adjustment for a range of maternal and infant characteristics, including SES and maternal body mass index (BMI) and gestational hypertension.²³ Blood pressure in children whose mothers

quit smoking early in pregnancy did not differ from those whose mothers had never smoked.

MATERNAL NUTRITION

The “fetal origins hypothesis” suggests that factors which impact on fetal growth have a long-term programming effect on future adult health. In early descriptions of the fetal origins or programming hypothesis, David Barker first suggested that maternal nutrition determined fetal nutrition which in turn impacted upon adult blood pressure and other CVD risk factors through abnormal development, *in utero*, of key systems that determined these CVD risk factors (the so-called Barker hypothesis).

However, it is now acknowledged that maternal nutrition does not equate to fetal nutrition.²⁴ The fetus of a poorly nourished mother can be well nourished, as nutrients are preferentially directed to the growing fetus. Conversely, a well-nourished mother may have a poorly nourished fetus because of defects in the fetal supply line from the placenta. Much of the direct evidence for an effect of maternal pregnancy diet and fetal nutrition on future blood pressure has come from animal studies, where experimental manipulation during pregnancy is possible.^{24–27} One of the great strengths of animal studies is the ability to be able to manipulate maternal nutrition separately from fetal supply line factors and vice versa.²⁴ In human studies it is impossible to do this. While animal studies have found a direct effect of maternal pregnancy dietary manipulation and reduced fetal supply on blood pressure and other CVD risk factors,^{24–27} the generalizability of their findings, as well as the extreme nature of some of the manipulations, such as ligation of umbilical vessels, makes interpreting these results with respect to humans problematic.²⁴

The effect of gross maternal pregnancy diet has been assessed in humans using two natural experiments, where pregnant women experienced extreme nutritional deprivation during the World War II.^{28–31} These found no effect of starvation during pregnancy on adult blood pressure in their offspring.^{28,31} However, this form of extreme starvation does not provide information on variations in maternal diet that occur in contemporary general populations and that might affect future blood pressure in offspring. Further, the offspring of women who actually gave birth to a viable offspring having gone through such extreme nutritional deprivation during pregnancy may be unique in many ways that make these findings difficult to generalize.

In well-characterized rat models, even mild restrictions in maternal protein during pregnancy have been found to be associated with increased blood pressure in offspring.^{26,27,32,33} These effects were similar for dietary manipulations at all stages of pregnancy.³² Results in humans have been mixed. Three historical cohorts found that blood pressure in adulthood was greater among those whose mothers had consumed diets characterized by high levels of animal protein and low levels of carbohydrates in late pregnancy (second half of pregnancy in one study)³⁴

and last trimester in two others^{35,36}), but there was no association between maternal diet at other times in pregnancy and offspring blood pressure.^{34–36}

In one prospective study there was no association between maternal intake of protein as reported at a mean of 30 weeks gestation and offspring blood pressure in adolescence, although maternal intake of fat was inversely associated with blood pressure in female offspring.³⁷ In a second prospective study neither maternal intake of protein assessed during the first trimester of pregnancy nor that assessed during the second trimester was associated with offspring blood pressure at a mean age of 6 months,³⁸ and a third study found no association between the ratio of protein to carbohydrate measured at 32 weeks gestation (nor any other micronutrient) and offspring blood pressure assessed at a mean of 7 years.³⁹ These inconsistencies may be explained by differences in study design, assessment of dietary intake in pregnancy and age at which blood pressure in the offspring is assessed. Ideally, randomized trials with long-term follow-up should be used to assess the effects of different maternal diets on future blood pressure risk, but such studies are expensive and difficult to conduct.

Observational epidemiologic studies have found that higher intakes of calcium during pregnancy, and by the children themselves in the early postnatal period, is related to lower blood pressure in offspring.^{40,41} Further, results from a randomized controlled trial conducted in Argentina found that mean systolic blood pressure at age 7 was lower in those whose mothers had been randomized to 2 g of calcium supplementation per day throughout pregnancy compared to those randomized to placebo, particularly if the child was overweight at age 7.⁴² Follow-up was complete for over 85% of both intervention and placebo group, and the mothers remained blind at the 7-year follow-up to which group they had been allocated. Replication of these findings in other populations would be useful.

BIRTH WEIGHT

By January 2005, nearly 100 studies assessing the association of birth weight with blood pressure had been published, and the finding in the majority of these studies of an inverse association has formed a central part of the “fetal origins of chronic disease” or “programming” hypothesis. In nearly all cases, this inverse association was strengthened on adjustment for concurrent body size. Four published systematic reviews of the association have all concluded that an inverse association is apparent, with a magnitude in the region of -1.5 to -2.0 mmHg/kg.^{43–46} However, the authors of these reviews and other investigators disagree in their conclusions concerning whether this association is causal, and if causal, whether it is of public health or clinical importance.

The consistency of findings in a range of different populations including children and adults, and populations from high-, middle-, and low-income countries,⁴⁵ suggest that the association is unlikely to be fully explained by

confounding factors, since the confounding structures will be different in these different populations. There is also evidence for specificity of the association with birth weight being associated with CVD and its risk factors but not with lung cancer, suggesting that SES and smoking are unlikely to explain the association.⁴⁷ Further, in studies where control for potential confounders has been possible, the inverse association between birth weight and blood pressure has been found to be independent of SES, maternal and participant smoking, maternal age, birth order, maternal blood pressure, and alcohol intake.^{48–51}

There has been considerable debate about the appropriateness or not of adjusting for contemporary size in studies assessing the association between birth weight and blood pressure in later life.^{52,53} In many studies the inverse association between birth weight and later blood pressure is strengthened or only becomes apparent upon adjustment for contemporary weight or BMI. One way to understand this effect of adjustment for contemporary size is to consider a population of adults, all of whom have the same weight or BMI at a particular age. It is differences in the growth trajectories from conception taken by individuals to reach this particular size that predict variations in blood pressure.¹⁶ Trajectories of below average growth *in utero* (representing poor fetal nutrition) and increased growth in childhood (related consumption of high-energy diets) appear to be particularly detrimental.^{45,54} However, in humans it is difficult to distinguish between intrauterine and postnatal effects and some have argued that nutrition in infancy is more important than fetal nutrition as a risk factor for high blood pressure and CVD.⁵⁵ Alternatively, the possible interaction between intrauterine and postnatal growth may be explained by developmental plasticity—the ability of environmental effects during sensitive developmental periods to affect the mature phenotype.^{56,57} The suggestion here is that, through a process of natural selection across generations, the intrauterine environment can “forecast” and prepare a developing human fetus for a postnatal environment of thrift. This preparation will have survival advantages in thrifty environments, but in contemporary Western environments of excessive nutrition the “setting” of metabolic and endocrine pathways for thrift may result in increased risk of hypertension, diabetes, and CVD since the “thrifty”-set metabolic pathways facilitate rapid/accelerated growth in an environment of plenty.⁵⁶

In a recent meta-analysis the magnitude of the effect of birth weight varied by study size, with a weaker association in the larger studies.⁴⁶ The authors concluded that publication bias had led to exaggerated conclusions about the effect of birth weight on blood pressure. However, this conclusion fails to recognize that in observational epidemiology, large studies often have lower-quality data. Two very large studies have demonstrated that blood pressure is poorly measured and that the true association of birth weight with blood pressure in these studies is consequently underestimated.^{58,59}

A number of investigators have questioned the public health importance of the association, pointing out that

even if one accepts an association of the magnitude of -1.5 mmHg/kg, this represents a change in blood pressure of less than 0.2 of a standard deviation for a very substantial (two standard deviations) change in birth weight.^{46,60} This weak association has been compared to the much stronger positive association between contemporary weight or BMI and blood pressure.⁶⁰ However, while contemporary size will have a direct effect on blood pressure, few investigators imagine that birth weight has a direct effect on blood pressure; rather it acts as a proxy indicator for other exposures, such as fetal nutrition and genetic factors, that may directly affect blood pressure. The associations of birth weight with blood pressure are likely therefore to underestimate the true strength of any association between the real exposure and blood pressure. It is noteworthy that the magnitudes of the associations between birth weight and CHD and stroke (two of the major consequences of high blood pressure) are strong and not dependent on BMI adjustment.⁴⁷

Possible mechanisms for the birth weight–blood pressure association

In terms of how the association between birth weight and adult blood pressure should impact on clinical and public health practice, we need to understand more about the underlying mechanisms. The “fetal origins hypothesis” (also known as the “developmental origins of adult disease and programming” hypothesis) suggests that poor intra-uterine nutrition leads not only to small birth size but also, depending on the timing (or critical period), it “programs” selective changes in body composition, cell size and number, hormonal axes, and metabolism that affect blood pressure and other CVD risk factors.⁶¹ Fetal growth is determined by both maternal and fetal nutrition and it is important to distinguish between the possible effects of maternal nutrition across her life course before pregnancy, maternal nutritional status and diet during pregnancy, and fetal nutrition (i.e., the net supply of metabolic substrate to the fetus) on both fetal growth and future offspring’s blood pressure.²⁴

In addition to roles for maternal nutrition, diet during pregnancy and the fetal nutrient supply line, it has been suggested that genetic factors might explain the association between birth weight and blood pressure. The same genetic factors may determine both fetal development, and hence birth weight and subsequent risk of insulin resistance and its associated risk factors including elevated blood pressure (the fetal insulin hypothesis).^{62,63} While the animal studies discussed above provide proof of principle that fetal programming not explained by genes exists, it is possible that genetic factors and fetal nutritional programming are both relevant to the association of low birth weight with elevated blood pressure in humans.

Examining the association of birth weight with blood pressure within twins has been proposed as a useful research method for distinguishing between fixed maternal factors, pregnancy-related factors, and genetic factors in the association between birth weight and adult disease. A logical progression in these studies is first to treat all of

the twins as individuals and simply assess the association between birth weight and blood pressure in the twin population (*between-twin* study). If an inverse association between birth weight and CVD is found between twins this suggests that twins *per se* do not differ from the general populations in which this association has been demonstrated. A *within-twin* pair analysis is then equivalent to matching on factors that are identical within twin pairs. If there is no association within monozygotic (MZ) pairs between birth weight and blood pressure (i.e., on average the smaller birth-weight MZ twin within any pair has similar blood pressure to the heavier twin), but an inverse association is seen in dizygotic (DZ) twins, then this suggests that factors which are identical between MZ twins (but not DZ twins) explain the association. Since MZ twins are genetically identical, fetal genes would be the most obvious explanation. However, approximately two-thirds of MZ twins share a placenta; therefore the lack of an association specifically within MZ twins may also be consistent with nongenetic placental factors.⁶⁴ If there is no association within both MZ and DZ (i.e., when the analysis is undertaken with matching on factors that are identical within either MZ or DZ twin pairs), but there is a between-pairs association, then the association between birth weight and disease would be most simply explained by fixed maternal factors that are identical for both twins in both MZ and DZ pairs. For twins, these factors would include maternal socioeconomic circumstances and environmental exposures in her early life, maternal birth characteristics and growth across her life, maternal age, diet, and smoking and other characteristics during pregnancy. If the within-twin pair associations for both MZ and DZ pairs are similar to the between-twin associations, then this suggests that fetal nutrition (which varies within both twin types) or any other factor that is not identical within twin pairs explains the association.

Studies have examined between- and within-twin pair associations of birth weight and blood pressure, and a recent systematic review and meta-analysis of these studies found a weaker association within-twin pairs than between-twin pairs, suggesting that factors shared by twins (fixed maternal factors from earlier in her life course and at the time of pregnancy) contribute to the association between birth weight and blood pressure in singletons.⁶⁵ However, comparisons of paired analyses in MZ and DZ pairs could not provide conclusive evidence for a role for genetic as opposed to shared environmental factors, because of small sample sizes and variations between studies in the methods used for determining zygosity.

Although the within- and between-twin study design looks very elegant, important differences exist between twins and singletons in their growth trajectories, with these differences appearing from very early in gestation, possibly being programmed at conception.^{66,67} Thus it is unclear whether one can generalize findings from twin studies to the majority of the population who are singletons. An extension of the within-twin analysis is a within-family or within-siblings analysis. While the complete control for genetic factors in such a study is not possible, they offer the advantage over twin studies of being more

generalizable. In a recent small (N=600 sibling pairs) within-siblings study, the results suggested that the inverse association between birth weight and blood pressure was not explained by fixed maternal factors such as SES, her nutritional status from conception to early adulthood, or maternal genetic factors.¹⁶ Since siblings (as opposed to twins) have experienced different pregnancies and share only 50% of their genes, maternal pregnancy characteristics and genetic factors might explain the association between birth weight and blood pressure. Indeed, in this study adjustment for paternal as well as maternal blood pressure reduced the strength of the association between birth weight and systolic blood pressure of the offspring in childhood, suggesting a potential role for genetic factors. The findings from this small study have now been replicated in a very large (N=103,548 sibling groups) study, providing strong evidence that the birthweight–blood pressure association is not explained by fixed maternal factors (Lawlor DA et al. paper submitted for publication June 2006).

INFANT FEEDING

Two meta-analyses of the association between breastfeeding and blood pressure in later life found very similar pooled estimates despite each including a number of different studies. The pooled estimates suggested an approximate difference in systolic blood pressure of 1 mmHg comparing those who were ever breastfed to those who were exclusively bottle fed.^{68,69} Whether this association is causal is difficult to determine since there was evidence of publication bias in both studies and other limitations of the individual studies, including measurement error in determining breastfeeding and confounding.

In one study, published since the most recent of these meta-analyses, parents of children aged 9 and 15 years at examination were asked about exclusive breastfeeding and there was a dose–response association, with greater duration of exclusive breastfeeding being associated with greater reductions in blood pressure.⁷⁰ This dose response provides some evidence of causality, but clear evidence for a causal effect requires evidence from randomized controlled trials. The clear benefits of breastfeeding make it impossible to randomize infants to different feeding regimens, but the long-term follow-up of the offspring of women who were randomized to different interventions to promote breastfeeding (if these were effective at increasing breastfeeding) might be one means of determining whether breastfeeding is causally related to blood pressure. The authors of a long-term follow-up of a randomized controlled trial of different feeding regimens in pre-term infants concluded that breast milk had a major beneficial effect on blood pressure and other CVD risk factors in adolescence. However, a recent detailed review of the role of infant feeding on CVD demonstrates that the majority of women randomized to pre-term formula actually also breastfed their children, and concludes that the results really show that individuals in that trial “who were given pre-term formula are more likely to display markers of cardiovascular disease risk.”⁷¹

DIETARY SODIUM INTAKE IN INFANCY AND CHILDHOOD

Among adults, salt intake reduction is associated with small reductions in blood pressure,^{72,73} although in childhood urinary sodium levels (a reflection of dietary intake and plasma clearance) do not appear to have a marked effect on blood pressure.^{74–78} However, there is evidence that infancy is a sensitive period with respect to the effect of sodium on future blood pressure. In a Dutch study in the early 1980s, infants were randomized to a low or a normal sodium diet for the first 6 months of life. The initial results of that study found that blood pressure in those allocated to the low-sodium diet was 2.1 mmHg lower at the end of the 6-month intervention period, but with further follow-up to 12 months there was no difference between the two groups.^{79,80} A 15-year follow-up of the participants found that mean systolic and diastolic blood pressure were markedly lower among the group originally randomized to the low-salt group compared to the high-salt group; mean difference in systolic blood pressure was 3.6 mmHg, and in diastolic blood pressure was 2.2 mmHg.⁸¹ This effect is considerably larger than any reported effects of salt reduction in adults. Interestingly, at the 15-year follow-up there was no difference in mean sodium intake in the two groups, suggesting that the effect was not due to dietary sodium in infancy influencing an individual’s taste for salt and later sodium intake. Because of the strong tracking correlations from age 15 onward, this effect of dietary sodium in infancy on blood pressure at age 15 would be likely to have a lasting effect on blood pressure into adulthood. These results should be treated with caution since there was considerable loss to follow-up, with only 35% of the original participants included. Further, their relevance to contemporary populations is unclear since infant formulas contain much less sodium now than they did in the early 1980s when this trial was conducted. To date no other published studies have assessed the effect of random allocation to different dietary sodium levels in infancy and later blood pressure. Since infant formulas in most Western countries now have sodium levels that are equivalent to physiological levels in breast milk, manipulating sodium intake in early infancy in a trial would not be ethical or feasible. However, it is likely that from weaning onward, infant diets will vary considerably in their sodium content, and a randomized controlled trial of the effects of different dietary intake of sodium from weaning age onward in infancy on future blood pressure would be valuable.

CHILDHOOD ADIPOSITY

There is a strong positive relationship between BMI and blood pressure at all stages of the life course.⁶⁰ Thus BMI measured in childhood is positively associated with blood pressure in childhood and this association remains throughout life. Since blood pressure tracks from childhood to adulthood, one would therefore expect an association between childhood BMI and adult blood pressure. Several

prospective studies have found that BMI or weight measured in childhood is positively associated with blood pressure measured in adulthood.⁶⁰ However, this association may not be independent of adult BMI.⁸² Increases in BMI during childhood or between childhood and adolescence are also associated with greater blood pressure in adulthood,^{83,84} and in a recent Australian study of children, those who changed from being overweight or obese at age 5 to normal weight at age 14 had similar mean blood pressure to those who were normal weight at both ages, whereas those who remained overweight or obese at both ages had higher mean blood pressure.⁸⁵

From a disease prevention perspective, preventing childhood obesity rather than trying to tackle established obesity in adulthood, may be most important since childhood obesity is strongly predictive of adult obesity,⁸⁶ and interventions to produce sustained weight loss once obesity is established in either childhood or adulthood are largely ineffective.⁸⁷

CHILDHOOD PHYSICAL ACTIVITY AND FITNESS

Physical activity in childhood could have a direct effect on blood pressure that tracks into adulthood and/or could be strongly correlated with activity levels in adulthood, which in turn are related to adult blood pressure. Increased levels of physical activity and physical fitness are associated with lower blood pressure in childhood.⁸⁸⁻⁹⁰ In the Harvard Alumni prospective cohort study, participation in vigorous activity while at college in adolescence and early adulthood was associated with a reduced risk of hypertension 16 to 50 years later.⁹¹ However, there was a stronger association between current (adult) activity and blood pressure than between activity levels in earlier life. A systematic review of intervention studies in adults with hypertension concluded that increasing levels of physical activity produced important reductions in blood pressure but only for the duration of regular activity.⁹² To our knowledge no intervention studies have examined the long-term effects of increased childhood activity on adult blood pressure.

THE ROLE OF EARLY-LIFE FACTORS IN EXPLAINING POPULATION-LEVEL DIFFERENCES IN MEAN BLOOD PRESSURE

Population variations in mean blood pressure, either between countries or over time, also suggest that early-life factors are important determinants of adult blood pressure. Geographic variations in adult blood pressure, which strongly correlate with variations in CVD rates, have been described for many years.⁹³ It has been assumed that geographic variations in blood pressure exist only in older adulthood and are not present in childhood.⁹⁴ However, there is increasing evidence of geographic variations in blood pressure in childhood, adolescence, and early adulthood that correlate strongly with mean blood pressure in adulthood.⁶⁰ Further, downward secular

trends in blood pressure, seen in most developed countries, have occurred in all age groups, with important declines in blood pressure levels among children for at least the past 50 years.⁹⁵⁻⁹⁸ These population findings suggest that the marked declines in blood pressure seen in recent decades are not primarily due to changes in adult risk factors or treatment of those with hypertension since these could not explain the similar declines in children and adolescents. They suggest that early-life factors are important in determining population levels of blood pressure and changes in blood pressure over time.

FUTURE RESEARCH NEEDS AND POLICY IMPLICATIONS

The greatest risk to public health of the associations described in this chapter is likely to be seen in developing countries where the effects of extreme poverty in early life and in earlier generations are increasingly combined with adverse Western diets and lifestyles in adulthood. Despite this risk, very little of the research in this area has been conducted in the developing world.

Work (from developed countries) suggesting that accelerated postnatal growth is detrimental to future high blood pressure and CVD health is a particularly important example of the need to extend this area of research into developing countries. Few would disagree with the suggestion that late weight catch-up in stunted infants or children resulting in the “stunted-(centrally) obese” adult is harmful to cardiovascular health. However, the short-term benefits of catch-up growth for small newborns, particularly in developed countries with continued exposures to infectious diseases and adverse environments, may outweigh any possible long-term detrimental effects.⁹⁹ A body of work is underway in this area in developing countries.^{100,101}

From a public health policy perspective, understanding the mechanisms and models that underlie the association between early-life risk factors and future blood pressure is important. Individual risk factors will interact with each other and with adult risk factors over the life course to determine future blood pressure. Understanding how different risk factors relate to each other, including temporal relationships, will require development and nurturing by funding agencies and the research community of prospective observational studies with repeat measurements of a range of socioeconomic, behavioral, and biological factors assessed from birth over the life course and across generations. Further, there is a need to develop appropriate statistical methods that model relationships between correlated and temporally related exposures as well as dealing with repeated measurements, hierarchical data, measurement error, and missing values.¹⁰² It is also important to establish randomized trials with sufficient resources for long-term follow-up to assess the effects of (1) interventions to reduce maternal smoking during pregnancy, (2) maternal dietary factors during pregnancy, (3) infant sodium intake, (4) increasing childhood physical activity, and (5) preventing childhood obesity on adult blood pressure and CVD.

SUMMARY

Children from lower-SES households, those whose mothers experience pregnancy-induced hypertension, whose mothers smoke throughout pregnancy, those with low birth weight, who have high-sodium diets in infancy, and who are obese in childhood or adolescence tend to have higher blood pressure in adulthood. However, the mechanisms linking these early-life factors to later blood pressure, and the most appropriate means of preventing adult hypertension by intervening in early life, are currently unclear. Some early-life factors that appear to influence blood

pressure—for example, mothers not smoking in pregnancy—have clear benefits irrespective of any possible effect on blood pressure, and should be promoted. However, more research is required to know what early-life interventions will have the greatest public health impact on reducing future hypertension and its associated diseases.

Blood Pressure and the Risks of Cardiovascular Disease and Stroke

Donald M. Lloyd-Jones and Philip Greenland

Key Findings

- Higher levels of blood pressure increase risk for all manifestations of cardiovascular disease (CVD) in a continuous and graded fashion, beginning at levels considered to be well within the “normal” range.
- The vast majority of hypertensive individuals have at least one other risk factor for CVD.
- Hypertension is associated with increased risk even in the absence of other risk factors, but risk increases dramatically when other risk factors are present.
- Elevated systolic blood pressure (SBP) is far more prevalent in the population than elevated diastolic blood pressure (DBP). SBP is at least as strong a risk factor as DBP, and often stronger, in predicting adverse CVD outcomes. SBP is also generally a stronger predictor of CVD events than pulse pressure (SBP minus DBP).
- The relative risks associated with hypertension are higher for heart failure and stroke, indicating a greater etiologic role for hypertension in these manifestations of CVD. Because rates of coronary heart disease (CHD) are substantially higher than rates of stroke and heart failure, hypertension has a greater population impact on CHD.
- Type of first CVD event occurring after hypertension onset varies according to age and sex.
- Younger men tend to experience CHD events first, whereas older men and women at all ages tend to experience stroke.
- Relative risks for CVD are at least as high for older as younger hypertensives, but absolute risks for CVD are substantially higher in older hypertensives, indicating their greater need for blood pressure treatment and control.
- Hypertension is more prevalent, and confers greater risks for CVD, in blacks compared with whites.

Arterial hypertension, or persistent, nonphysiologic elevation of systemic blood pressure, is a major risk factor for all forms of atherosclerotic and atherothrombotic cardiovascular disease (CVD). Moreover, it is now recognized that, beginning at levels well within the so-called “normal” range, higher levels of blood pressure (BP) generally increase risk in a continuous and graded fashion for multiple cardiovascular and noncardiovascular sequelae. Higher levels of BP are associated with increased risk for total mortality, CVD mortality, coronary heart disease (CHD) mortality, myocardial infarction (MI), heart failure (HF), left ventricular hypertrophy (LVH), atrial fibrilla-

tion, stroke, peripheral vascular disease, and renal failure. As discussed below, BP levels exert differential effects on risk for development of each of these endpoints. Individuals with hypertension are at risk for all manifestations of CVD, with concomitant risk factors influencing the manifestation as well. An understanding of the concept of “risk factors” and of epidemiologic measurements of association between a risk factor and disease will serve as an introduction to a detailed examination of BP as a risk factor for CVD and stroke.

The term *risk factor*, referring to an exposure that influences risk for development of disease, was coined in 1961 in a seminal paper from the Framingham Heart Study investigators.¹ Of note, that analysis was among the first to identify substantially elevated risks for CHD among men and women with elevated BP levels. An epidemiologic association between a proposed risk factor and a disease is likely to be causal if it fulfills the following criteria: (1) exposure to the proposed risk factor precedes the onset of disease, (2) there is a strong association (i.e., large relative risk) between exposure and disease incidence, (3) the association between exposure and disease is dose-dependent, (4) exposure is consistently predictive of disease in a variety of populations, (5) the association is independent of other risk factors, and (6) the association is biologically and pathogenically plausible, and is supported by animal experiments as well as clinical investigation.² Even more definitive support for an etiologic association between a proposed risk factor and disease can come from clinical intervention trials in which modification of the risk factor (by behavioral or therapeutic interventions) is associated with a decreased incidence of disease. Elevated BP clearly meets all of these criteria, and is accepted as an etiologic risk factor for CVD.

Absolute risk for disease associated with a given exposure is often expressed as the rate of development of new cases of disease per unit of time (or *incidence*) in exposed individuals. This proportion may be compared with the proportion among nonexposed subjects in a variety of ways. The *relative risk* of disease is the ratio of disease incidence among exposed compared with nonexposed individuals. As such, relative risk measures the strength of the association between exposure and disease, but it gives no indication of the absolute risk of disease. The *attributable risk* of a given exposure describes the proportion of the incidence of disease in a population that can be ascribed to the exposure, assuming that a causal relationship exists. The *population attributable risk* (PAR)

takes into account the proportion of individuals in the population who are exposed, as well as the relative risk for disease associated with exposure, to allow comparison of the impact of diverse risk factors on the burden of disease in a population. Therefore, attributable risk is a useful concept in determining the public health impact of a given risk factor and in selecting risk factors that should be targeted for prevention programs.³

CARDIOVASCULAR DISEASE RISK ACROSS THE SPECTRUM OF BLOOD PRESSURE

Individuals with hypertension, currently defined as untreated systolic BP ≥ 140 mmHg, or diastolic BP ≥ 90 mmHg, or receiving therapy for elevated BP, have a two- to three-fold increased risk for all CVD events combined, compared with nonhypertensive individuals. When CVD endpoints are considered individually, *relative* risks with hypertension are greatest for stroke and HF, and somewhat lower for CHD (Figure 5–1, bottom). Nonetheless, because CHD incidence is greater than incidence of stroke and HF, the *absolute* impact of hypertension on CHD is greater than for other manifestations of CVD, as demonstrated by the excess risks shown in Figure 5–1.

Although much of the focus on CVD risk has been on frank hypertension, it is clear that risks for CVD increase at higher BP levels, even within the so-called “normal” range. A recent epidemiologic pooling study of nearly 1 million men and women, which included data on more than 56,000 decedents, revealed that risks for CVD death

increase in a continuous fashion at levels starting as low as SBP of 115 mmHg and DBP of 75 mmHg, and possibly lower. For each 20-mmHg increment in SBP or each 10-mmHg increment in DBP, there was approximately a doubling of risk for stroke death and for ischemic heart disease death in both men and women.⁴

Other studies provide confirmation of these findings. Data from more than 347,000 middle-aged men (35 to 57 years old) screened for the Multiple Risk Factor Intervention Trial (MRFIT) provide precise estimates of incremental risks with higher BP levels. As shown in Figure 5–2 (bars), there is a continuous, graded effect of BP on the multivariable-adjusted relative risk for CHD mortality beginning at pressures well below 140 mmHg.⁵ Although *relative* risks are clearly highest for men with SBP ≥ 180 mmHg, these data help make an important point about BP levels in the population at which the majority of CVD events are occurring. In Figure 5–2, the numbers above each bar indicate the number of men in each stratum of SBP at baseline. Although the relative risks were highest for men with SBP ≥ 180 mmHg, the vast majority of men at baseline had an SBP ≤ 159 mmHg. Taking into account the number of men in each stratum and the expected rates of CHD death, there is a substantial number of excess CHD deaths occurring at lower BP levels (as shown by the line in Figure 5–2). Thus nearly two-thirds of excess CHD deaths occurred in men with baseline SBP between 130 and 159 mmHg, relatively “mild” levels of elevated BP.

Recent data from the Framingham Heart Study also indicate that the risk associated with BPs in the range of 130 to 139 mmHg systolic or 85 to 89 mmHg diastolic

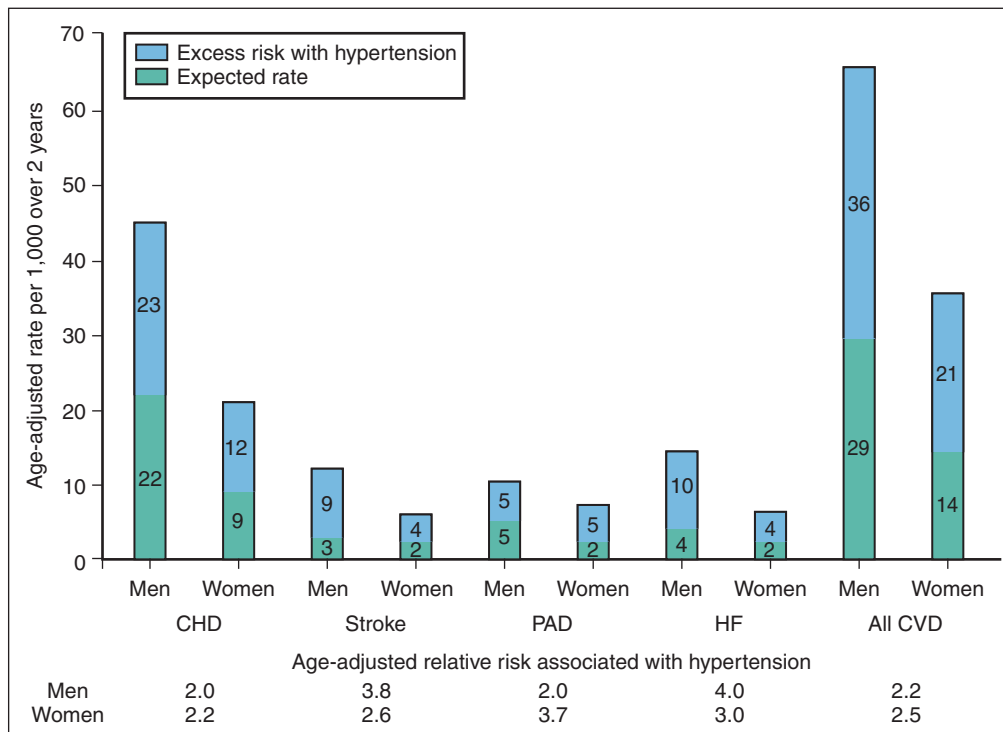

Figure 5–1. Age-adjusted relative risks and excess risks for selected manifestations of cardiovascular disease. Framingham Heart Study, 30-year follow-up. CHD, coronary heart disease; CVD, cardiovascular disease; HF, heart failure; PAD, peripheral arterial disease.

Figure 5–2. Multiple Risk Factor Intervention Trial screenees.⁵ CHD, coronary heart disease.

are substantial, despite the fact that these levels are not currently classified as hypertension. These “prehypertensive” levels of BP are associated with significantly elevated multivariable-adjusted relative risk for CVD of 2.5 in women and 1.6 in men.⁶ In the Physician’s Health Study, there was a nearly two-fold increased risk of stroke associated with borderline elevated SBP.⁷ Likewise, individuals with SBP between 120 and 139 mmHg or DBP between 80 and 89 mmHg have a high likelihood of progressing to frank hypertension over the next 4 years, especially if they are age 65 or older.⁸ For these reasons, JNC 7 (Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, Seventh Report) has reclassified the JNC 6 BP categories to place greater emphasis on prevention of hypertension. These previously “normal” and “high-normal” levels (i.e., SBP 120–139 or DBP 80–89) are now classified as “prehypertension.”⁹

Although clinical practice guidelines recommend treatment of hypertension in individual patients only when their *current* BP levels cross certain thresholds, there is evidence that *long-term* BP levels confer significant CVD risk over and above current levels. Vasan et al.¹⁰ observed that antecedent time-averaged BP predicted the incidence of CVD events even after adjustment for current BP and other traditional risk factors. Furthermore, antecedent BP (both recent and remote) predicted risk of CVD in both nonhypertensive and hypertensive individuals. Thus, delaying treatment of elevated BP until absolute risk or BP level crosses a threshold may not adequately reduce the risk of CVD events. These findings underscore the importance of preventing hypertension onset and of detecting and controlling elevated BP throughout the life span.¹⁰

For many CVD endpoints, there is effect modification by gender, with male hypertensives being at higher risk

for CVD events than female hypertensives; HF is a notable exception to this generalization. As discussed below, there is also substantial effect modification by age, with older hypertensives being at similar or higher relative risk but much greater absolute risk than younger ones.¹¹ Hypertension rarely occurs in isolation, and it confers increased risk for CVD across the spectrum of overall risk factor burden, with increasing importance in the setting of other risk factors.¹² As shown in Figure 5–3, absolute levels of CHD risk increase substantially with increasing risk factor burden, and risk is augmented still further by increases in BP levels from optimal to marked hypertension in both women (Figure 5–3, A) and men¹³ (Figure 5–3, B). Thus BP levels, and the risk they confer, must always be considered in the context of other risk factors and the patient’s global risk for CVD.

RISK FACTOR CLUSTERING

Hypertension occurs in isolation very infrequently. A recent assessment of 4962 middle-aged and older individuals from a community-based sample revealed that higher BP stages were associated with a higher mean number of other risk factors and higher rates of clinical CVD and/or target organ damage. Overall, among those with high-normal BP (SBP 130–139 or DBP 85–89 mmHg) or hypertension, only 2.4% had no other CVD risk factors, whereas 59.3% had at least one risk factor, and 38.2% had target organ damage, clinical CVD, or diabetes.¹⁴

The rising epidemic of obesity within Western societies has led to a greater understanding of the phenomenon of risk factor clustering, and of the pathophysiologic links between hypertension, other risk factors, and risk for CVD. The cluster of risk factors, including central obesity, atherogenic dyslipidemia (with low HDL cholesterol, high

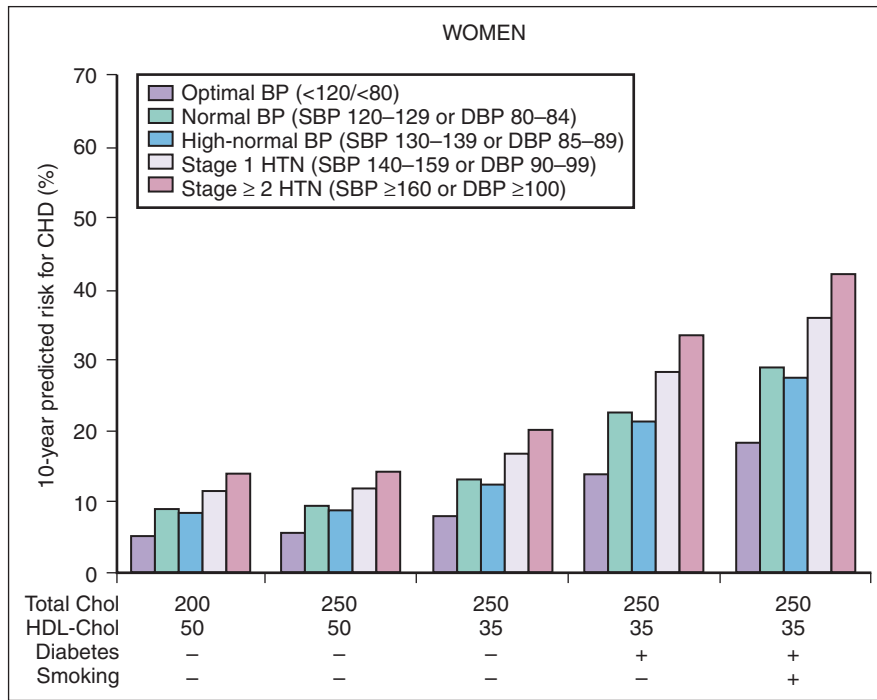

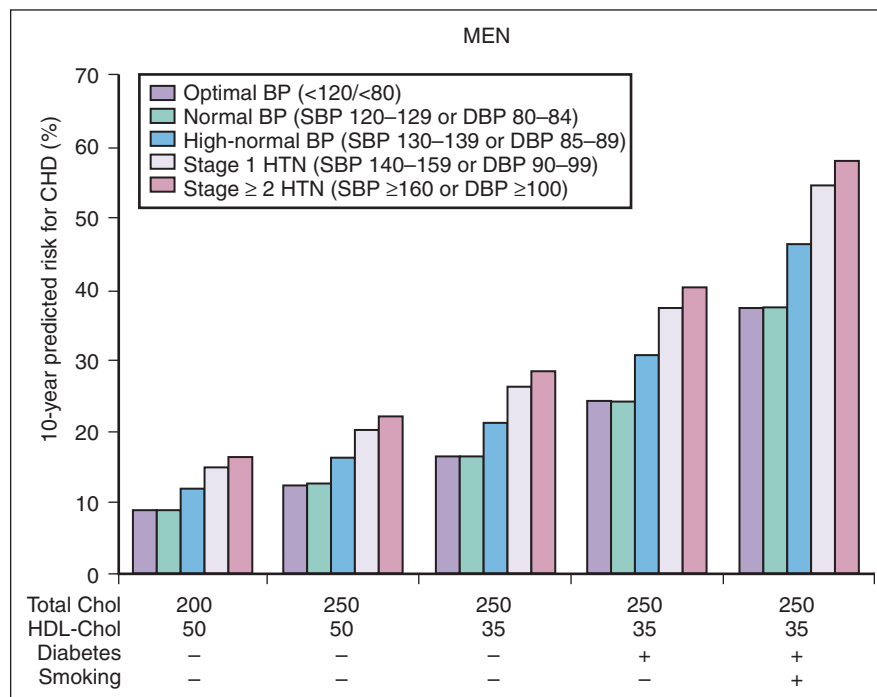

**A****B**

Figure 5-3. Predicted 10-year risk for coronary heart disease by level of major risk factors and JNC-VI blood pressure stage in women (A) and men (B). triglycerides, and small, dense LDL-cholesterol particles), impaired glucose metabolism, vascular inflammation, pro-atherogenic milieu, and elevated BP, has been termed the “metabolic syndrome.” Visceral adiposity and insulin resistance appear to play central roles in the development of metabolic syndrome, and elevated BP is a key diagnostic

feature.¹⁵ In some ethnicities, such as blacks, elevated BP is the most common criterion leading to diagnosis of the metabolic syndrome. Hypertension is associated with increased risk for CVD even in the absence of other risk factors, but risk increases dramatically when other risk factors are present, as shown in Figure 5-3.

SYSTOLIC BLOOD PRESSURE, DIASTOLIC BLOOD PRESSURE, PULSE PRESSURE, AND CARDIOVASCULAR DISEASE RISK

Early efforts at understanding risks associated with hypertension, and early clinical intervention trials, focused on DBP, since it was believed that DBP conferred the greater risk for events. Increases in SBP with age were thought to be adaptive, leading to the term “essential” hypertension. Studies of BP patterns with aging in the United States indicate that SBP rises linearly and monotonically with age after about age 30. DBP tends to rise gradually until about age 50, after which it plateaus for approximately 5 to 10 years, and then decreases to the end of the life span.^{16,17} These patterns of BP change are largely a function of vascular changes that occur as a result of aging and exposure to environmental and genetic factors that alter vascular function. Specifically, arteriosclerosis, loss of elasticity, and increasing vascular stiffness all contribute to increasing SBP and to decreasing DBP with age. The result of increasing SBP and decreasing DBP in middle-aged and older individuals is a steadily increasing pulse pressure, which is defined as the SBP minus the DBP.

A substantial body of epidemiologic and clinical evidence now indicates that SBP is at least as strong a risk factor as DBP, and often stronger, in prediction of adverse CVD outcomes.^{18–20} Kannel et al.²¹ were among the first to report on greater risks for CHD associated with SBP than DBP. They concluded that since “the net contribution [to risk] is greater for systolic than for diastolic pressure, the commonly held view concerning the innocuous nature of increased SBP in the elderly requires reevaluation.”²¹ Although these observations were first published in 1971, it was decades before this concept was widely appreciated and incorporated into clinical practice.

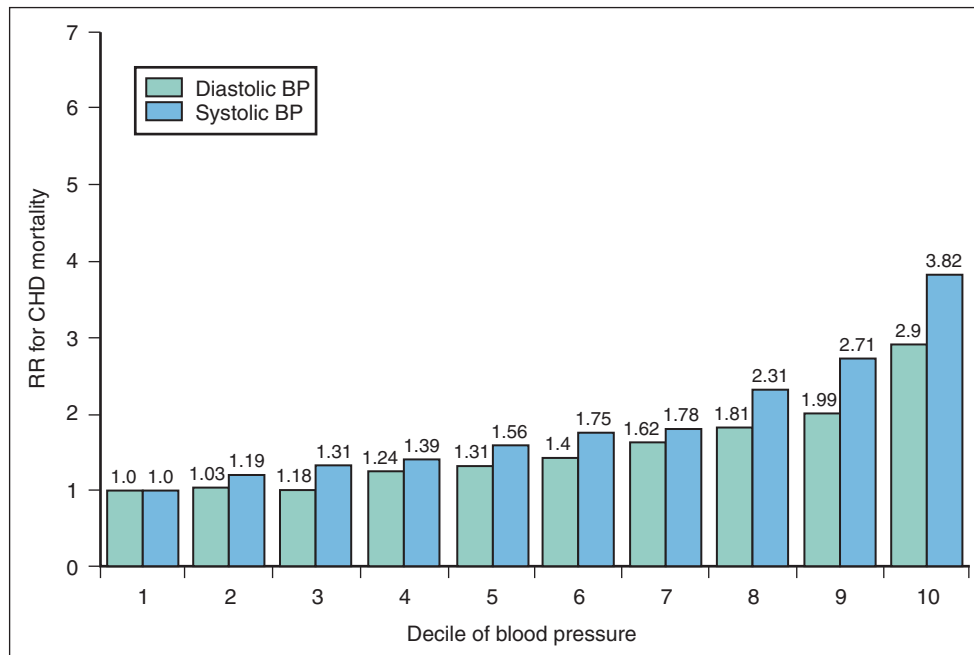

Risk for CVD (including CHD and stroke endpoints, separately or combined) is greater for SBP than DBP whether the two BP components are compared linearly,²⁰ by quintiles,¹⁹ by deciles (Figure 5–4),¹⁸ or by JNC stage.¹⁸ In addition, SBP predominates when SBP and DBP are considered jointly in multivariable models predicting CVD endpoints.²⁰ As shown in Figure 5–5, rates of CHD and stroke mortality increase dramatically with increasing SBP at any given level of DBP. However, for any given level of SBP, there is only a modest increase in stroke mortality with increasing DBP, and the trend is nonlinear at higher levels of SBP.¹⁸ In the Cardiovascular Health Study of older Americans, a one-standard-deviation increment in SBP was associated with higher adjusted risk for CHD and stroke than was a one-standard-deviation increment in DBP (or pulse pressure). In models with SBP and DBP together or SBP and pulse pressure together, SBP consistently dominated as the greater risk factor.²⁰ When men who were screened for inclusion in the Multiple Risk Factor Intervention Trial (MRFIT) were stratified into quintiles of SBP or DBP, risks for each SBP quintile were the same or higher than for the corresponding quintile of DBP.¹⁹ Similar findings were observed when MRFIT screenees were stratified into deciles of SBP and DBP; at every level, SBP was consistently associated with higher

risk for CHD or stroke mortality than the corresponding decile of DBP (Figure 5–4).¹⁸ Finally, when MRFIT screenees were stratified by JNC level of SBP and DBP, SBP level was associated with greater risk for CHD mortality than DBP level at each JNC BP stage.¹⁸

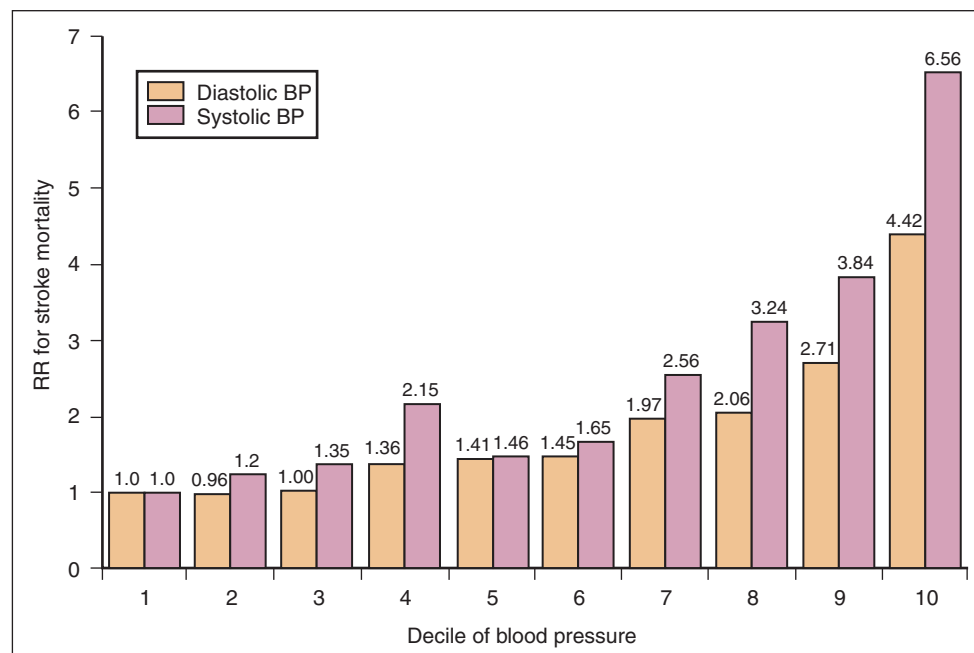

In fact, when DBP is considered in the context of the SBP level, an *inverse* association between DBP and CHD risk has been observed. Franklin et al.²² reported that, at any given level of SBP, the relative risks for CHD *decreased* with higher DBP. For example, at an SBP of 150 mmHg, the estimated hazard ratio for CHD was 1.8 at a DBP of 70 mmHg, whereas it was only 1.3 at a DBP of 95 mmHg. The higher the SBP level, the steeper was the decline in CHD risk with increasing DBP. These data provide some evidence for the importance of pulse pressure as a measure of risk, since higher risk was observed in this study when the pulse pressure widened.²² Pulse pressure will be discussed in greater detail later in this chapter.

Several other lines of evidence contribute to the realization that SBP is a more important predictor of risk in the population, and accounts for a far greater population attributable risk than does DBP. Overall in the U.S. population, elevation of SBP is far more prevalent than elevation of DBP.^{23,24} Indeed, isolated systolic hypertension is by far the most common form of hypertension.²⁴ In addition, SBP correctly classifies JNC stage far better than DBP, and SBP therefore determines need for treatment among high-normal and hypertensive subjects.^{23,24} Finally, large clinical trials^{25–27} have demonstrated substantial benefit with treatment of isolated systolic hypertension in patients aged ≥ 60 years. As a result of all of these observations, the Coordinating Committee of the National High Blood Pressure Education Program and the JNC 7 committee recommended that SBP become the major criterion for the diagnosis, staging, and management of hypertension in middle-aged and older patients, who represent the vast majority of hypertensives.^{9,28}

In recent years there has been intense interest in pulse pressure as a risk factor for CVD. However, investigators have struggled with how best to “anchor” the pulse pressure. For example, a patient with a BP of 110/60 has the same pulse pressure as a patient with a BP of 170/120 (pulse pressure = 50 mmHg for both), although the latter patient is clearly at higher risk for CVD. Various investigators have anchored the pulse pressure to the DBP, the mean arterial pressure, and the SBP. As discussed above, Franklin et al.²² observed that higher pulse pressure was associated with greater CHD risk among subjects with the same SBP. Chae et al.⁸ found that pulse pressure predicted incident HF in an elderly cohort, even after adjustment for mean arterial pressure, prevalent coronary heart disease, and other HF risk factors. In another study, SBP and pulse pressure conferred similar risk for HF.²⁹ However, many studies have found that SBP confers greater risk than pulse pressure,^{4,20,30} when SBP and pulse pressure are considered separately or as covariates in the same multivariable model. The aforementioned Prospective Studies Collaboration, which pooled data from 61 large epidemiologic studies and nearly 1 million men and women, found that the most informative measure of BP

A

B

Figure 5-4. Relative risks for mortality due to coronary heart disease (A) and stroke (B), according to decile of systolic and diastolic blood pressure in men aged 35 to 57 years. Impact of systolic and diastolic blood pressure on cardiovascular mortality. In: Laragh JH, Brenner BM, eds. *Hypertension: Pathophysiology, Diagnosis, and Management*. 2nd ed. New York: Raven Press, 1995:127.)

for prediction of CVD events was the mean of SBP and DBP, which predicted better than SBP or DBP alone, and much better than the pulse pressure.⁴ At present, JNC 7 recommends that clinical focus should remain on the SBP in determining need for therapy and achieving goal BP.⁹

BLOOD PRESSURE AND CORONARY HEART DISEASE

Elevated BP is one of the major risk factors contributing to the estimated 1.4 million CHD events that occur in the United States annually.³¹ As mentioned above, whereas

A

B

Figure 5-5. Death rates (per 10,000 P-Y) from coronary heart disease (A) and stroke (B) by systolic and diastolic blood pressure levels, considered jointly, in men aged 35 to 57 years. Multiple Risk Factor Intervention Trial screenees. DBP, diastolic blood pressure; P-Y, person-years; SBP, systolic blood pressure. (From Neaton JD, Kuller L, Stamler J, Wentworth DN. Impact of systolic and diastolic blood pressure on cardiovascular mortality. In: Laragh JH, Brenner BM, eds. *Hypertension: Pathophysiology, Diagnosis, and Management*. 2nd ed. New York: Raven Press, 1995:127.)

elevated BP is a major risk factor for CHD, it is a weaker risk factor for CHD, in terms of relative risks, than for stroke or HF. Nonetheless, because hypertension is the most prevalent CHD risk factor, and because the incidence of CHD is greater than the incidence of stroke or HF, the impact of elevated BP is greatest on CHD in the population.

Numerous studies have documented the graded and continuous risk for CHD endpoints associated with higher

BP levels. Risk for CHD mortality is not limited to subjects with frank hypertension, however. There is a linear, graded risk for CHD death that extends down even to optimal levels of BP. As shown in Table 5-1, in the Chicago Heart Association Detection Project in Industry, age-adjusted rates for CHD roughly doubled with each 20-mmHg increment in SBP or 10-mmHg in DBP.³² Similarly, the Prospective Studies Collaboration observed that, beginning at 115 mmHg, the risk for CHD death doubles for

RISKS FOR 25-YEAR CORONARY HEART DISEASE MORTALITY ASSOCIATED WITH SELECTED LEVELS OF BLOOD PRESSURE

Blood Pressure (mmHg)	Age-Adjusted Rate (per 10,000 person-years)	Multivariable-Adjusted Relative Risk (95% CI)
SBP <120 and DBP <80	5.3	1.39 (0.67–2.86)
SBP 120–129 or DBP 80–84	4.2	1.0 (ref)
SBP 130–139 or DBP 85–89	6.1	1.37 (0.81–2.30)

Table 5–1. Risks for 25-Year Coronary Heart Disease Mortality Associated with Selected Levels of Blood Pressure

each increase of 20 mmHg in the SBP; similarly, CHD death risk doubles for each increase of 10 mmHg in the DBP beginning at 75 mmHg.¹⁰ Furthermore, the presence of electrocardiographic left ventricular hypertrophy, an important consequence of hypertension, increased risk for CHD over and above elevated BP alone, indicating that duration and severity of hypertension are important determinants of risk, in addition to current BP levels. And, as shown in Figure 5–3, higher BP increases risk incrementally alone and in the presence of other established major CHD risk factors.

BLOOD PRESSURE AND STROKE

Hypertension is the chief factor contributing to the 700,000 strokes that occur each year in the United States. Hypertension is well established as the dominant risk factor for stroke, even when considered in the context of other known risk factors, such as cigarette smoking, atrial fibrillation, MI, and diabetes. Hypertension confers a threefold relative risk for stroke compared with levels <140/<90 mmHg, and approximately 80% of subjects have hypertension prior to the occurrence of a stroke. The attributable risk for stroke associated with hypertension varies between 33% and 53% in different age groups.³³ In adults at age 55 in the Framingham Heart Study, the lifetime risk for stroke was greater than one in six, but it was twice as high among those with hypertension compared with those who had BP of <120/<80 mmHg.³¹

Hypertension works synergistically with other risk factors to increase risk for stroke. For example, the effect of hypertension on risk for stroke is modified substantially by age. Data from 30-year follow-up of the Framingham cohort reveal that there is a linear increase in stroke rates with increasing level of BP, but absolute rates of stroke and transient ischemic attack (TIA) are substantially higher for subjects with hypertension in the age range of 65 to 94 years compared with 35 to 64 years.

As is true for CHD risk prediction, a risk prediction algorithm has been developed to estimate the absolute 10-year risk of an atherothrombotic brain infarct using standard CVD risk factors, plus the presence of atrial fibrillation, heart failure, and coronary disease.⁹ In these equations, hypertension represents the predominant risk

factor for stroke, but the risk in people with elevated BP varies over as much as a 10-fold range depending on the degree of exposure to the other risk factors.

Just as with CHD, risk for stroke is not limited to subjects with frank hypertension. There is a linear, graded risk for stroke that extends down even to optimal levels of BP. Beginning at 115 mmHg, the risk for stroke mortality doubles for each increase of 20 mmHg in the SBP; likewise, stroke mortality risk doubles for each increase of 10 mmHg in the DBP beginning at 75 mmHg.⁴ Thus at any given age, an individual with SBP of 135 mmHg is at approximately twice the risk, and one with SBP of 155 mmHg at four times the risk, as someone at the same age with an SBP of 115 mmHg.

BLOOD PRESSURE AND HEART FAILURE

With the aging of the population, the concomitant increase in the prevalence of hypertension, and improved survival after MI, HF has become an emerging public health concern. National surveillance data indicate that approximately 4.9 million Americans are living with congestive HF (CHF) currently, with 550,000 incident cases each year. Congestive HF is the leading cause of hospitalization for people aged ≥65 in the United States, with 970,000 hospital discharges in 2002, a major contributor to the estimated annual direct and indirect costs of \$28 billion in 2005.³¹

Study of the epidemiology of HF in representative or community-based populations has been problematic, in large part because of the difficulty of devising acceptable clinical and research criteria for the diagnosis of heart failure, which is a syndrome rather than a single clinical entity. However, several criteria^{34,35} now exist for diagnosing HF in clinical and epidemiologic research, which has assisted in understanding the risk factors for heart failure.

As with stroke, hypertension is also the dominant risk factor for HF. The overall remaining lifetime risk for HF is one in five for men and women aged ≥40, but at every age there is a stepwise increase in lifetime risk for CHF with increasing BP, with approximately a twofold gradient of risk in those with Stage 2 or treated hypertension compared with those with BP <140/<90 mmHg.³⁶ From 75%

to 91% of individuals who develop HF have antecedent hypertension.^{12,31} In one study, hypertension was associated with hazard ratios for the development of HF of approximately two for men and three for women over the ensuing 18 years.¹² As shown in Figure 5–6, the hazard ratios for HF associated with hypertension (two to three) were far lower than the hazard ratios for HF associated with MI, which were greater than six for both men and women. However, the population prevalence of hypertension was 60%, compared with approximately 6% for MI. Therefore, the PAR of HF, that is, the fraction of HF in this population that was due to hypertension, was 59% in women and 39% in men. The PARs for MI were 13% and 34% for women and men, respectively.¹²

RENAL DISEASE

Hypertension is also a major risk factor for the development of renal disease, and a major cause of the 80,000 deaths from end-stage renal disease that occurred in the United States in 2002.³ Of the estimated 100,000 cases of incident end-stage renal disease diagnosed in 2002,³¹ it was estimated that over 25% were due to hypertension, and more than 40% to diabetes.³⁷ However, these numbers may substantially underestimate the contribution of BP to the increasing incidence of renal disease, since the data collection form allows only listing of a single diagnostic cause, and hypertension is present in the vast majority of diabetics. Blacks have approximately four times the risk of whites of developing end-stage renal disease, in part due to their significantly higher prevalence of hypertension.³¹ In addition to its contribution to end-stage renal disease, elevated BP also occurs in and exacerbates milder forms of chronic kidney disease and worsens proteinuria.

COMPETING RISKS FOR DIFFERENT CARDIOVASCULAR DISEASE OUTCOMES IN HYPERTENSION

A recent analysis³⁸ of Framingham Heart Study participants who experienced new-onset hypertension has shed interesting light on the risks for CVD associated with hypertension. Hypertension confers risk for multiple types of CVD events, but there were no previous studies examining which CVD events occur as a first event after hypertension onset in a competing risks framework. Typically, epidemiologic studies follow participants for single outcomes, without considering the joint and competing risks for multiple outcomes. Examining these competing risks in hypertension may be important because the occurrence of one type of CVD event (e.g., stroke) may be associated with greater morbidity and mortality than another type of CVD (e.g., angina), and because the occurrence of one CVD event (e.g., MI) may markedly increase the risk for subsequent CVD events (HF, stroke). Focusing efforts on preventing the first event after hypertension onset could therefore have important implications on longevity and quality of life, and different strategies may be needed to prevent diverse outcomes.

In this study, 645 men and 702 women (mean age: 55±12 years in men, 59±12 years in women) who were free of CVD and had new-onset hypertension after 1977 were included. At all ages following the onset of hypertension, CVD was more likely to occur as a first event than non-CVD death. The 12-year competing cumulative incidence of any CVD endpoint as a first event in men was 24.7%, compared with 9.8% for noncardiovascular death (hazards ratio [HR]=2.53, 95% confidence interval [CI]=1.83–3.50); in women, the competing incidences were 16.0% versus 10.1%, respectively (HR=1.58, 95% CI=1.13–2.20). The contrast between risk for CVD and non-CVD death was most striking in men with hypertension onset at age <60 years; in this group, the 12-year risk of CVD was 19.9% compared with 3.5% for non-CVD death (HR=5.67, 95% CI=3.07–10.46). For both men and women, there was a dramatic rise in stroke and HF as first hard CVD events with hypertension onset at age ≥60 years, compared with <60 years. As shown in Figure 5–7, types of first hard CVD events differed by gender and age at hypertension onset: in men younger than 60, hard CHD events were the most common first events, whereas in older men and in women at all ages stroke was the most common first event.³⁸

These results may have important implications for primary prevention strategies. For example, in women and older men with new-onset hypertension, hypertensive-related CVD events (stroke, HF) predominate as first events. Thus clinicians and patients may want to focus their major efforts on achieving BP control, specifically aiming to lower the risk of stroke and HF in these subgroups, especially given the impressive reductions in stroke and HF documented in antihypertensive therapy trials. In younger men with new-onset hypertension, prevention might be tailored toward antihypertensive therapy plus use of lipid-lowering medications and aspirin, for which

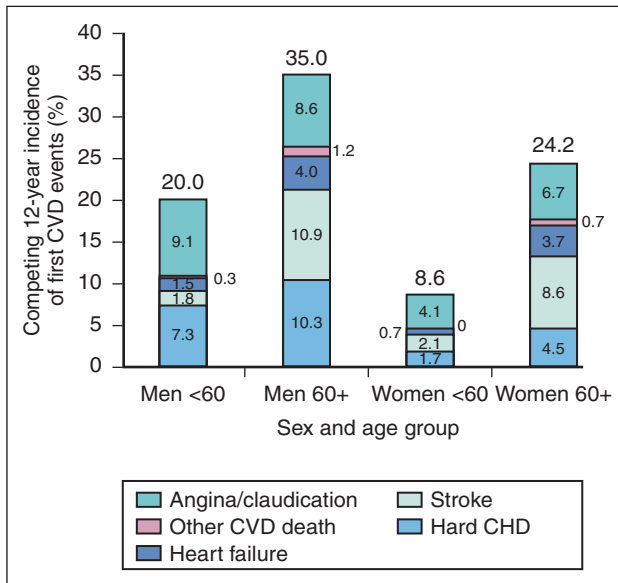

Figure 5–7. Competing 12-year incidence for different types of first cardiovascular disease events by age and sex among new-onset hypertensive men and women in the Framingham Heart Study.³⁸ CHD coronary heart disease; CVD, cardiovascular disease.

there are impressive data on preventing major nonfatal and fatal CHD events. Recent clinical trials support the approach of using these ancillary treatments to prevent CHD in hypertensive patients.^{39,40}

BLOOD PRESSURE IN THE ELDERLY AND MINORITY GROUPS

The elderly are among the fastest growing segments of the U.S. population,⁴¹ and they also have the greatest prevalence of hypertension.^{31,42} Hypertension occurs in the absence of other CVD risk factors only rarely in older persons,¹⁴ and it is often accompanied by a clustering of other risk factors. The prevalence of three or more coexisting risk factors is four times higher among hypertensive than among normotensive older individuals.⁴³

As discussed above, older hypertensive patients appear to be at risk for a somewhat different spectrum of first CVD events than younger patients. Among new-onset hypertensives aged <60, the most common first major CVD event after 12 years of follow-up was an MI or hospitalization for unstable angina. Conversely, in those with hypertension onset at age ≥ 60 years, the most common first major CVD event was a stroke, particularly among older women.³⁸ Whereas the risk for CHD increases steadily with increasing age, the risks for HF and atrial fibrillation increase more dramatically among older compared with younger hypertensives.^{35,44}

In a recent analysis of BP risks for CVD among adults across the age spectrum, relative risks for CVD associated with increasing BP stage did not decline with advancing age, and absolute risks increased markedly (Figure 5–8). Among participants aged ≥ 80 years, major cardiovascular

events occurred in 9.5% of the normal BP (referent) group, 19.8% of the prehypertension group (HR=1.9, 95% CI=0.9–3.9), 20.3% of the Stage 1 hypertension group (HR=1.8, 95% CI=0.8–3.7) and 24.7% of the Stage 2/treated hypertension group (HR=2.4, 95% CI=1.2–4.6).¹¹

Hypertension has a greater impact in some race/ethnic groups than in others. Hypertension is more prevalent in blacks than in whites.⁴² In addition, there is evidence to suggest that hypertension may confer differential risks for CVD, depending on race/ethnicity. For example, in a multivariable analysis from the Atherosclerosis Risk in Communities study, hypertension was a particularly strong risk factor for CHD among black women, with hazard ratios as follows: black women, 4.8 (95% CI=2.5–9.0), white women, 2.1 (CI=1.6–2.9), black men, 2.0 (CI=1.3–3.0), and white men, 1.6 (CI=1.3–1.9).⁴⁵ Further studies of the impact of BP on CVD across ethnic groups are needed.

SUMMARY AND PERSPECTIVES

In summary, elevated BP levels increase the risk for all manifestations of CVD, as well as total mortality and renal disease, in a continuous and graded fashion, beginning at levels at least as low as 115/75 mmHg. Increases in SBP with aging are the major cause of hypertension diagnosis in the population, and increases in SBP confer substantial risk for CVD events, regardless of age. Hypertension rarely occurs in isolation; rather, it is usually accompanied by other CVD risk factors that jointly and synergistically increase hypertension-related risks for CVD. Hypertension increases relative risks for stroke and heart failure most dramatically, but because CHD is more common, hypertension has its greatest impact in increasing the population risk for CHD. With the aging of the population and the worldwide obesity epidemic, the burden of hypertension and of its sequelae is likely to increase substantially. Greater efforts are therefore needed to prevent the development of hypertension, to control BP levels after the onset of hypertension, and to control associated risk factors in order to optimize CVD prevention across the population.

Future research should continue to define the risks associated with elevated BP, especially in minority groups and women. Epidemiologic data can continue to help us understand population trends in BP and suggest strategies for primordial prevention (prevention of risk factor development), and primary and secondary prevention of CVD once elevated BP is present. A better understanding is needed of the changes in arterial stiffness that are observed with aging, in order to determine whether there are lifestyle or other interventions that can prevent the age-related increases in SBP and pulse pressure. In addition, research into the links between elevated BP and other CVD risk factors may yield novel insights and new targets for therapy. Research into defining successful means for weight reduction and weight maintenance may provide the greatest public health benefit with regard to BP levels.

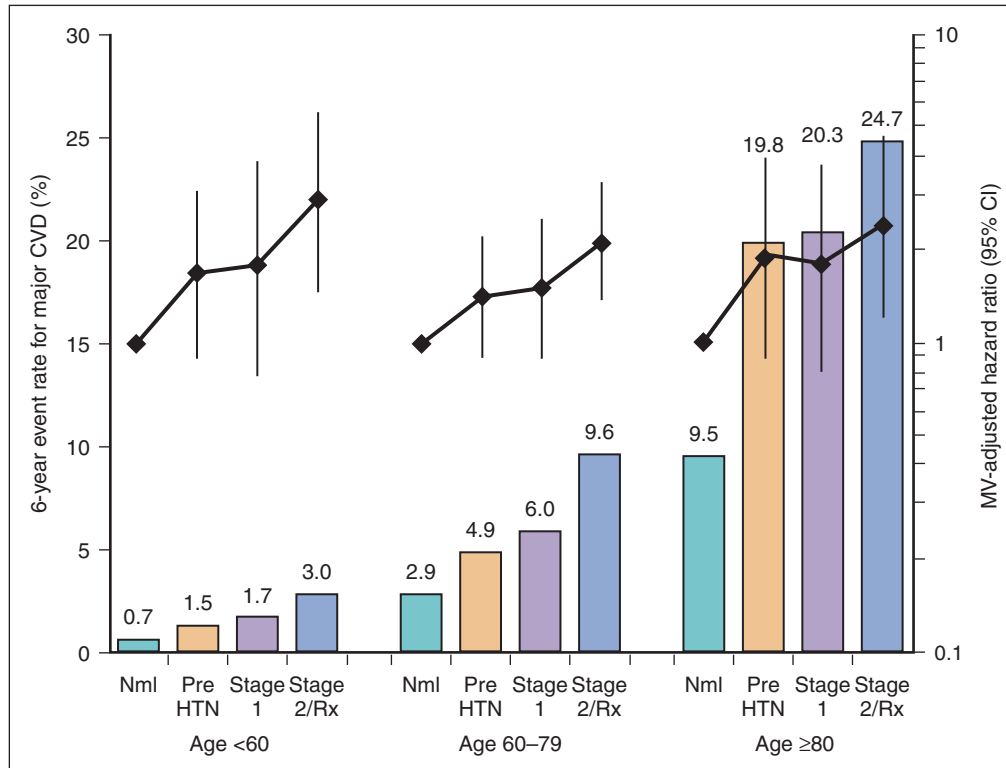

Figure 5-8. Six-year event rates (shown by the columns and on the left axis) and multivariable-adjusted relative risks with 95% confidence intervals (shown by the diamonds and lines and on the right axis) for major cardiovascular disease events by age group and blood pressure stage. Framingham Heart Study.¹¹ CVD, cardiovascular disease; HTN, hypertension; Nml, normal; MV, multivariable. Blood pressure is stratified as follows: normal (untreated systolic <120 and diastolic <80 mm Hg); prehypertension (untreated systolic 120–139 or diastolic 80–89 mm Hg); Stage 1 hypertension (untreated systolic 140–159 or diastolic 90–99 mm Hg); and Stage 2 (untreated systolic ≥160 or diastolic ≥100 mm Hg) or treated hypertension.

Lifestyle and Blood Pressure

*Lydia A. L. Bazzano and Jiang He***Key Findings**

- Among environmental risk factors, diet and nutrition play key roles, as well as physical inactivity, alcohol consumption, obesity, and stress, which clearly have an effect on blood pressure and the development of hypertension.
- Reduced dietary sodium intake lowers blood pressure in both normotensive and hypertensive individuals, reduces the incidence of hypertension, and may reduce the cardiovascular disease in overweight individuals.
- Potassium supplementation lowers blood pressure in both hypertensive and normotensive persons, although this may differ by level of dietary sodium intake.
- There is an inverse association between dietary protein intake and blood pressure. Increasing fiber intake has beneficial effects on blood pressure in both normotensive and hypertensive subjects, while supplementation of the diet with omega-3 polyunsaturated fatty acids reduces blood pressure.
- There is an inverse relationship between physical activity and blood pressure.
- A positive and independent association between alcohol consumption and elevated blood pressure is noted. Overweight and obesity also play an important role in the development of hypertension.
- Psychological and emotional stress may also contribute to the development of hypertension.

Hypertension is an important public health challenge worldwide. Its high prevalence and subsequent increased risk for developing cardiovascular diseases including heart attack, stroke, and chronic kidney disease have placed it as the leading risk factor for all-cause mortality, and a major cause of life-years adjusted disability.¹ A recent study on the global burden of hypertension found that 26.4% of the adult population in 2000 had hypertension and 29.2% were projected to have hypertension by the year 2025. This translates to approximately 972 million persons, with 333 million in economically developed countries and 639 million in economically developing countries who had hypertension in 2000. In 2025, 1.56 billion adults are expected to have hypertension.²

Hypertension is a complex disorder that is influenced by genetic and environmental factors as well as their interaction. Genetic factors may determine individuals' susceptibility to environmental risk factors and risk of developing hypertension. However, the environmental

factors must be present to trigger the pathogenesis of the disease in most persons with hypertension. Among environmental risk factors, diet and nutrition play key roles, with intakes of sodium, potassium, fats, fiber, and protein clearly having an effect on blood pressure and the development of hypertension. Physical inactivity, alcohol consumption, obesity, and stress also play important roles in the development of hypertension.

DIET AND BLOOD PRESSURE**Sodium intake**

Clinical trials have demonstrated that reduced dietary sodium intake lowers blood pressure in both normotensive and hypertensive individuals, reduces the incidence of hypertension, and may reduce the cardiovascular disease in overweight individuals.³⁻⁶ Evidence from the Trials of Hypertension Prevention, Phase II (TOHP II), showed that overweight participants with high normal blood pressures could reduce their blood pressures with sodium restriction and avoid the development of hypertension. In this trial, 2382 men and women (aged 30 to 54) with a diastolic blood pressure 83 to 89 and systolic blood pressure less than 140 who were 110% to 165% of ideal body weight were randomized to usual care, salt restriction, weight reduction, or both.⁴ Sodium restriction was associated with a 50- and 40-mEq decline in sodium intake at 6 and 36 months, respectively. Compared to usual care, systolic and diastolic blood pressure fell at 6 months by 2.9 and 1.6 mmHg with salt restriction. At 48 months, the relative risk of developing hypertension was 16% to 22% lower with lifestyle intervention than among those assigned to usual care.

The randomized controlled Trial of Nonpharmacologic Interventions in the Elderly (TONE) included a total of 975 men and women aged 60 to 80 years with systolic blood pressure less than 145 mmHg and diastolic blood pressure less than 85 mmHg while receiving treatment with a single antihypertensive medication. Of these participants, 585 obese participants were randomized to reduced sodium intake, weight loss, both, or usual care, and 390 nonobese participants were randomized to either reduced sodium intake or usual care groups. After 3 months of intervention, withdrawal of the single antihypertensive agent was attempted. As shown in Figure 6-1, participants who were assigned to reduce their sodium intake were significantly less likely to be diagnosed with high blood

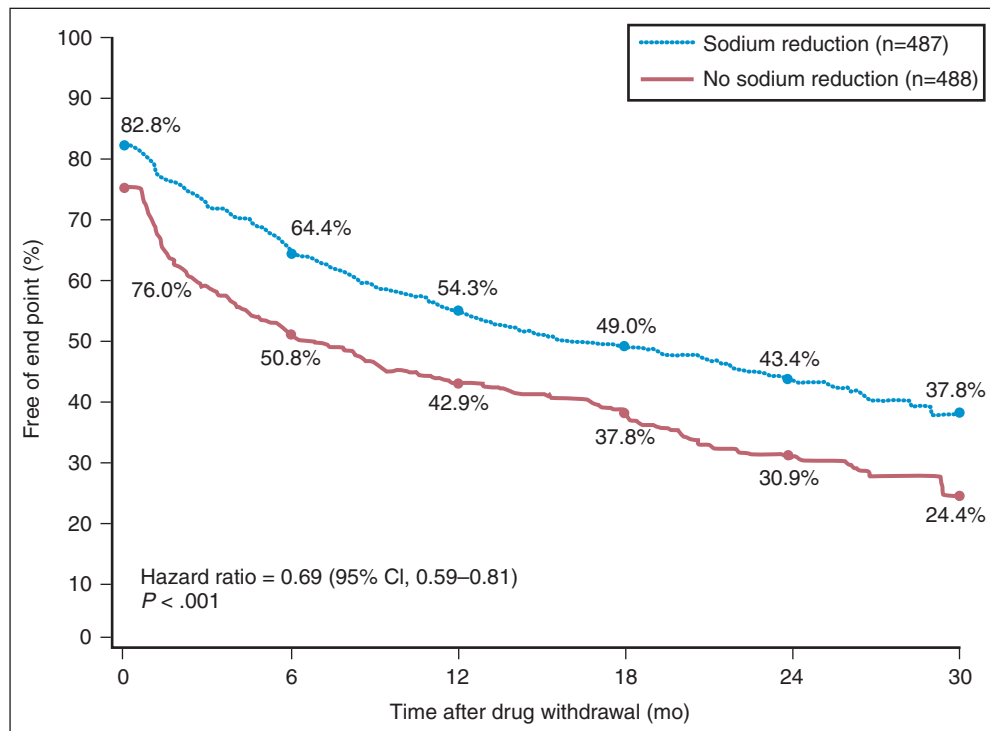

Figure 6–1. Percentages of the 487 participants who were, and the 488 who were not, assigned to the reduced sodium intake intervention who remained free of cardiovascular events and high blood pressure and did not have an antihypertensive agent prescribed during follow-up. (Adapted from Whelton PK, et al. *JAMA* 1998;279:839–46.)

pressure at a follow-up visit, be treated with an antihypertensive agent again, or have a cardiovascular event during the follow-up period as compared to those not assigned to reduce sodium intake (relative hazard ratio, 0.69; 95% confidence interval [CI]=0.59 to 0.81, $p<0.001$). Compared to the usual care group, the obese participants who were assigned to reduce sodium intake had a relative hazard of 0.60 (95% CI=0.45–0.80, $p<0.001$) for the combined endpoint.⁵

The Dietary Approaches to Stop Hypertension (DASH)-Sodium trial tested the blood pressure effects of three levels of sodium reduction in two diet groups.⁶ The three sodium levels were 143 mmol/d, reflecting typical U.S. consumption; 106 mmol/d, reflecting the upper limit of current U.S. recommendations; and 65 mmol/d, targeted at further reduction of blood pressure. In the control diet, which was designed to reflect a typical American diet, reducing sodium intake from the higher to the intermediate level significantly reduced systolic blood pressure by 2.1 mmHg, and reducing sodium intake from the intermediate to the lower level further decreased systolic blood pressure by 4.6 mmHg. In the DASH diet group, corresponding reductions in systolic blood pressure were 1.3 and 1.7 mmHg, respectively. The combination of DASH diet with lower sodium level reduced systolic blood pressure by 7.1 mmHg in nonhypertensive persons, and 11.5 mmHg in hypertensive persons.⁶

At least three meta-analyses of randomized controlled trials have also shown that sodium reduction decreases blood pressure and prevents hypertension.^{7–9} In all of these

studies, sodium reduction was associated with a significant reduction in systolic blood pressure among normotensive persons. Cutler et al.⁹ estimated that an average reduction of 77 mmol/day in dietary sodium intake resulted in a reduction of 2.8 mmHg in systolic blood pressure and 1.5 mmHg in diastolic blood pressure (Table 6–1).

While controversy remains as to whether reducing salt intake reduces the morbidity and mortality of cardiovascular diseases, some prospective cohort studies have suggested that a high sodium intake is associated with increased risk of cardiovascular disease. For example, in the National Health and Nutrition Examination Survey I Epidemiologic Follow-up Study (NHEFS), a 100-mmol higher level of sodium intake among obese persons was associated with a 32% increase in stroke incidence, 89% increase in stroke mortality, 44% increase in coronary heart disease mortality, 61% increase in cardiovascular disease mortality and a 39% increase in mortality from all causes.³

Potassium intake

Observational epidemiologic studies have identified an inverse association between dietary intake of potassium and blood pressure level within and across populations.¹⁰ The large-scale high-quality data from the International Study of Salt and Blood Pressure (INTERSALT), including more than 10,000 participants from 52 population samples in 32 countries worldwide, provide the most precise and accurate observational estimates of the effect of potassium on blood pressure.^{11,12} After adjustment for age, sex, body

SUMMARY OF REDUCTIONS IN BLOOD PRESSURE (MMHG) IN RESPONSE TO VARIOUS INTERVENTIONS BASED ON EVIDENCE FROM RECENT META-ANALYSES			
Intervention	Meta-Analysis	Change in Blood Pressure (95% Confidence Interval)	
		Systolic	Diastolic
Sodium reduction	Cutler et al., 1997 ⁹	-2.8 (-2.4 to -1.7)	-1.5 (-1.9 to -1.1)
Potassium supplementation	Whelton et al., 1997 ¹⁵	-3.1 (-4.3 to -1.9)	-1.9 (-3.4 to -0.5)
Fish oil supplementation	Geleijnse et al., 2002 ⁶⁸	-2.1 (-3.2 to -1.0)	-1.6 (-2.2 to -1.0)
Physical activity	Whelton et al., 2002 ⁸²	-3.8 (-4.9 to -2.7)	-2.6 (-3.4 to -1.8)
Alcohol reduction	Xin et al., 2001 ⁹¹	-3.3 (-4.1 to -2.5)	-2.0 (-2.6 to -1.5)
Weight loss	Neter et al., 2003 ⁹³	-4.4 (-5.9 to -2.9)	-3.6 (-4.9 to -2.3)

Table 6-1. Summary of Reductions in Blood Pressure (mmHg) in Response to Various Interventions Based on Evidence from Recent Meta-Analyses

mass index, alcohol consumption and urinary sodium excretion and correction for regression dilution bias, a 50-mmol per day increase in urinary potassium excretion was associated with a 3.36 mmHg lower systolic blood pressure and 1.87 mmHg lower diastolic blood pressure.

Diets low in potassium have also been implicated in the higher prevalence of hypertension in African Americans.^{13,14} Grim et al.¹³ studied blood pressure and electrolyte intake in a random sample of the African American and white populations of Evans County, Georgia. The prevalence of hypertension was higher in African Americans compared to their counterparts who were white. Sodium intake, assessed by collecting duplicate diets and 24-hour urine specimens, was similar in African Americans and whites. Potassium intake, on the other hand, was significantly lower in African Americans than in whites: 24 versus 40 mmol per day for men and 27 versus 36 mmol per day in women, respectively. Likewise in the Veterans Administration Cooperative Study on Antihypertensive Agents, 24-hour urinary excretion of sodium was similar in African American and white untreated hypertensives, but African Americans excreted 62% less potassium than their counterparts who were white, or 45 versus 73 mmol per day.¹⁴

Randomized controlled trials document that potassium supplementation lowers blood pressure in both hypertensive and normotensive persons.¹⁵ In a meta-analysis of 33 randomized controlled trials, potassium supplementation (median, 75 mmol/day) lowered systolic blood pressure by 3.1 mmHg (95% CI=-4.3 to -1.9) and diastolic blood pressure by 1.9 (95% CI=-3.9 to -0.5) (Figure 6-2) (Table 6-1). Conversely, a low dietary potassium intake has been associated with elevated blood pressure levels in randomized trials.^{16,17}

The effects of potassium supplementation may differ by level of dietary sodium intake. When diets concurrently include high sodium levels, the effects of an increase in potassium intake are enhanced,¹⁵ and may be blunted in those with a low baseline level of sodium intake. In their meta-analysis of randomized trials of potassium supplementation, Whelton et al.¹⁵ found a dose-response relationship between change in 24 hour urinary potassium and effect size in trials in which the participants were consuming a diet high in sodium ($p<0.001$).

Increased dietary potassium intake has also been associated with lower risk of stroke or cardiovascular diseases. Khaw and Barrett-Connor¹⁸ examined the relationship between potassium intake and stroke mortality among 859 male and female retirees in Southern California and identified a strong inverse association (relative risk [RR]=0.60, 95% CI=0.44-0.82).¹⁸ Likewise, Ascherio et al.¹⁹ identified an inverse association among the partici-

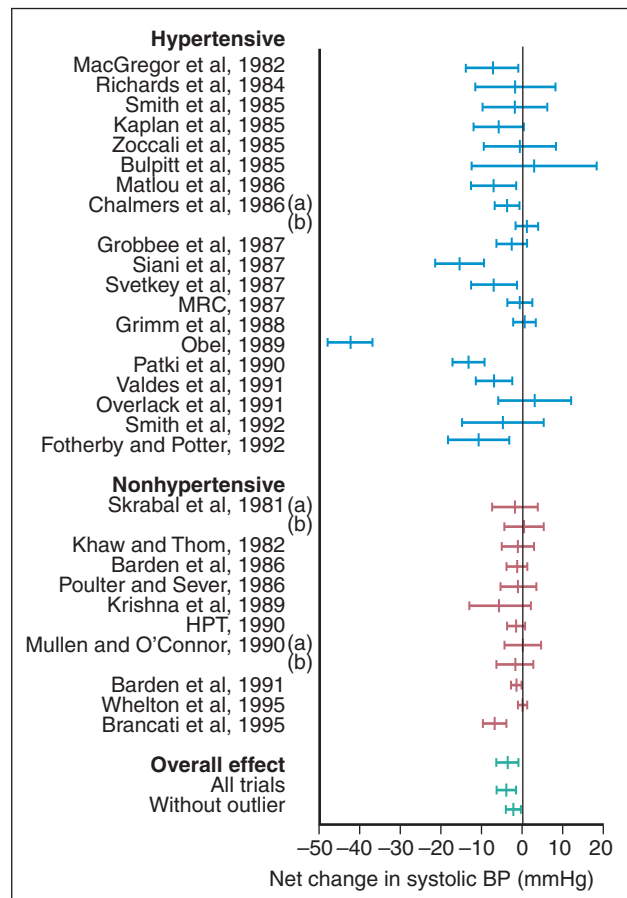

Figure 6-2. Average net change in systolic BP and corresponding 95% confidence interval after treatment with oral potassium supplementation in 32 randomized controlled trials. BP, blood pressure; MRC, Medical Research Council; HPT, Hypertension Prevention Trial. (Adapted from Whelton PK, et al. *JAMA* 1997;277:1624-32.)

pants in the Health Professionals' Follow-up Study. In the first National Health and Nutrition Examination Survey Epidemiologic Follow-up Study, Bazzano et al.²⁰ examined the relationship between dietary potassium intake and the risk of stroke in a representative sample of 9805 U.S. men and women. Over an average of 19 years of follow-up, participants consuming a low-potassium diet at baseline (<34.6 mmol potassium/24 hours) experienced a 28% higher hazard of stroke (RR=1.28, 95% CI=1.11–1.47, $p<0.001$) than other participants, after adjustment for established cardiovascular disease risk factors.

Fruits, vegetables and legumes are major sources of potassium in the diet. One cup of orange juice contains approximately 473 mg of potassium, one cup of cooked peas contains approximately 384 mg of potassium, and one medium-sized baked potato contains 926 mg of potassium.²¹ Dairy products, meats, and nuts are also important dietary sources of potassium. Suggested goal intakes for individuals in the United States are approximately 4.5 to 4.7 g per day or 115 to 120 mmol per day.

Dietary fat intake

A diet high in fat often includes energy in excess of that expended and so results in weight gain, which in turn can lead to increased blood pressure. When the relationship between total dietary fat intake and blood pressure has been investigated, after accounting for adiposity or change in body weight, conflicting results have been found. Total dietary fat intake has not been associated with blood pressure in cross-sectional epidemiologic studies^{22–25}; however, intake of dietary saturated fats was associated with hypertension in two Finnish studies^{22,23} and oleic acid was inversely correlated with blood pressure in two small clinical studies.^{26,27} Many other studies found no such association.^{25,26,28,29} Prospective studies have shown conflicting results. In the Nurses' Health Study, dietary fatty acids showed no association with the 4-year incidence of hypertension,³⁰ while analyses of the Multiple Risk Factor Intervention Trial (MRFIT) data showed positive associations between blood pressure and saturated fats and an inverse association with polyunsaturated fats.³¹ With a few exceptions,^{32–34} trials testing the effects of substituting carbohydrates or unsaturated fats for animal fat have not demonstrated significantly lower blood pressures.^{35–38} However, most of these trials were small and did not have the power to detect changes in blood pressure less than 3 to 5 mmHg.

Fat moderation has been one of the aspects of more complex interventions to prevent hypertension. For example, in the DASH study of dietary patterns, 459 adults with systolic blood pressures of less than 160 mmHg and diastolic blood pressures of 80 to 95 mmHg were fed a control diet that was low in fruits, vegetables, and dairy products, with a fat content typical of the average diet in the United States for 3 weeks, and then were randomly assigned to receive the control diet, a diet rich in fruits and vegetables, or a “combination” diet rich in fruits, vegetables, and low-fat dairy products and with reduced saturated (6% vs. 16% of energy) and total fat (27% vs. 37% of energy) for the next 8 weeks.³⁹ At baseline, the

mean (\pm standard deviation) systolic and diastolic blood pressures were 131.3 \pm 10.8 mmHg and 84.7 \pm 4.7 mmHg, respectively. The combination diet reduced systolic and diastolic blood pressure by 5.5 and 3.0 mmHg more, respectively, than the control diet ($p<0.001$ for each); and the fruits-and-vegetables diet reduced systolic blood pressure by 2.8 mmHg more ($p<0.001$) and diastolic blood pressure by 1.1 mmHg more than the control diet ($p=0.07$). Among the 133 subjects with hypertension, the combination diet reduced systolic and diastolic blood pressure by 11.4 and 5.5 mmHg more, respectively, than the control diet ($p<0.001$ for each); among the 326 subjects without hypertension, the corresponding reductions were 3.5 mmHg ($p<0.001$) and 2.1 mmHg ($p=0.003$).³⁹ While the possible effects of consuming a diet reduced in total and saturated fat on blood pressure cannot be distinguished from other components of the “combination” diet in this trial, it is likely from previous trials that those effects were small.

If present, the potential effects of polyunsaturated fatty acids (specifically, the n-6 variety) on blood pressure may be related to the modulation of prostaglandin synthesis. The deprivation of linoleic acid during a salt-loading study resulted in a significantly elevated blood pressure in the rat.⁴⁰ At the same time, total prostaglandin metabolites were reduced significantly. Cox et al.⁴¹ found that urinary excretion of prostaglandin E₂ was dependent on dietary intake of linoleic acid. Tobian et al.⁴² found that feeding high levels of linoleic acid to salt-sensitive Dahl rats on a high-salt diet reduced blood pressure and increased PGE₂ levels in the renal papilla, thereby facilitating the transport of sodium and increasing capacity for sodium excretion.^{43,44}

Dietary protein intake

Extensive evidence from observational studies supports an inverse association between dietary protein intake and blood pressure independent of body fat and body weight. These data have been reviewed several times over the past decade,^{45–49} and at least two meta-analyses of these data have been published.^{45,49} Recently two large observational studies have reported results on the relationship between dietary protein intake and blood pressure.^{31,50} The INTERSALT study analyzed data from 24-hour urinary samples of more than 10,000 participants for markers of protein intake. Inverse associations were significant ($p<0.001$) for two of three markers of protein intake and blood pressure with adjustment for 24-hour excretions of sodium, potassium, calcium, and magnesium; body mass index; and alcohol intake.⁵⁰ The International Study of Macronutrients and Blood Pressure (INTERMAP) analyzed data from 4680 men and women aged 40 to 59 from 17 population samples in China, Japan, the United Kingdom, and the United States. To assess diet, blood pressure, and other variables, participants were seen at four visits, four 24-hour dietary recalls were done, and two timed 24-hour urine specimens collected. A significant inverse relationship between vegetable protein and blood pressure was identified independent of body weight, but not animal or total protein and blood pressure.

Inverse associations were also found in analyses of the MRFIT cohort.³¹

In the most recent review of this literature, 26 cross-sectional analyses were identified from 18 different studies, with 16 of these identifying an inverse relationship between protein or a marker of its intake and blood pressure or hypertension.⁴⁸ In the same review, five longitudinal studies were identified, which have reported on dietary protein intake and blood pressure or incidence of hypertension. Of those, three reports found no association, two found an inverse association, and one found an inverse association between vegetable protein and both systolic and diastolic blood pressure, and a direct association between animal protein and change in systolic blood pressure.⁵¹

Trials of protein supplementation or substitution of protein for carbohydrate or fat in the diet have produced inconsistent results. Early studies investigated responses to low- and high-protein diets with added beef or soy protein and addition of one egg per day to the diet.⁵²⁻⁵⁴ These studies did not find a significant association between intervention diets and blood pressure during the study period. More recently, trials of soybean protein supplementation have demonstrated lower blood pressures in the intervention group participants.^{47,55,56} He et al.⁵⁷ collected data from 302 participants, aged 35 to 64 years, with an initial untreated systolic blood pressure of 130 to 159 mmHg, diastolic blood pressure of 80 to 99 mmHg, or both. Study participants were randomized to receive 40 g of isolated soybean protein supplement per day or a complex carbohydrate control for 12 weeks, and blood pressures were obtained at baseline, and at 6 and 12 weeks. Body weight was maintained in both groups without significant change. Compared to the control group, the net changes in systolic and diastolic blood pressure were -4.31 mmHg (95% CI= -2.11 – -6.51 mmHg, $p<0.001$) and -2.76 mmHg (95% CI= -1.35 – -4.16 mmHg, $p<0.001$), respectively after 12 weeks (Figure 6-3). In addition, increased protein intake has been a feature of more complex interventions such as the combination (fruit, vegetable, and low-fat dairy) diet in the DASH trial. In that combination diet, 17.9% of energy was derived from protein versus 13.8% of energy in the control diet.³⁹

The mechanism by which dietary protein influences blood pressure is largely unknown. However, dietary protein intake could influence blood pressure through the actions of its many constituent amino acids. For instance, both tyrosine and tryptophan lower blood pressure when injected intraperitoneally in animal models.^{58,59} Arginine is a metabolic precursor of nitric oxide, and the amino acid cysteine influences nitric oxide metabolism,⁵⁰ while tyrosine and phenylalanine affect the synthesis of catecholamines in the central nervous system.⁶⁰

Dietary fiber intake

Observational and experimental studies have demonstrated that increasing fiber intake has beneficial effects on blood pressure in both normotensive and hypertensive subjects.^{46,61} Clinical trials have shown wide variation in blood pressure responses to dietary fiber supplementen-

Figure 6-3. Mean differences in systolic (*top*) and diastolic (*bottom*) blood pressures and 95% confidence intervals among trial participants randomized to receive soybean protein supplementation or complex carbohydrate. (Adapted from He J, et al. *Ann Intern Med* 2005;143:1-9.)

tation.⁴⁶ For example, a recent randomized, placebo-controlled trial of fiber supplementation involved 110 trial participants aged 30 to 65 years who had untreated, but higher-than-optimal blood pressure or stage 1 hypertension who were randomly assigned to receive 8 g/day of water-soluble fiber from oat bran or a control intervention. An average of the nine measurements was used to determine mean blood pressure at the baseline and termination visits. The net changes in systolic blood pressure were -1.8 mmHg (95% CI= -4.3 to 0.8) following 12 weeks, -2.2 mmHg (95% CI= -5.3 to 1.0) following 6 weeks, and -2.0 mmHg (95% CI= -4.4 to 0.3) for an average of the 6- and 12-week visits. The corresponding net changes in diastolic blood pressure were -1.2 mmHg (95% CI= -3.0 to 0.5) following 12 weeks, -0.8 mmHg (95% CI= -3.1 to 1.4) following 6 weeks, and -1.0 mmHg (95% CI= -2.6 to 0.5) for an average of the 6- and 12-week visits.⁶¹

Given the many clinical trials of dietary fiber and blood pressure which may have lacked power to detect small but meaningful blood pressure effects, a meta-analysis of

randomized placebo-controlled trials of the effects of fiber supplementation on blood pressure was conducted by Whelton et al.⁶² They identified 25 randomized controlled trials, and abstracted data on study design, sample size, participant and intervention characteristics, duration of follow-up, and change in mean blood pressure. Fiber supplementation (average dose of 10.7 g/d) was associated with a significant -1.65 mmHg (95% CI= -2.70 to -0.61) change in diastolic and a non-significant -1.15 mmHg (95% CI= -2.68 to 0.39) change in systolic blood pressure. A significant reduction in both systolic and diastolic blood pressure was observed in trials conducted among participants with hypertension: -5.95 mmHg (95% CI= -9.50 — 2.40) and -4.20 mmHg (95% CI= -6.55 — 1.85), respectively. Similarly, trials with a duration of intervention at least 8 weeks long also showed significant reductions in both systolic and diastolic blood pressures, -3.12 mmHg (95% CI= -5.68 — 0.56) and -2.57 mmHg (95% CI= -4.01 — 1.14), respectively.⁶² Fiber supplementation was also a part of the DASH study interventions. Both the fruit and vegetable and the combination diets included 31 g of fiber daily versus the control diet which included 9 g of fiber daily.³⁹

Moreover, dietary fiber intake may also favorably influence other cardiovascular risk factors resulting in lower risk of coronary heart disease. For example, in the large NHEFS cohort, a higher intake of dietary fiber appeared to be associated with a reduced risk of coronary heart disease.²⁰ Beneficial effects of fiber were related to water-soluble types of fiber more so than insoluble fiber in that study.

The potential effect of dietary fiber intake on blood pressure may have several mechanisms, given that dietary fiber has multifaceted effects on both digestion and absorption of nutrients. Soluble fiber increases insulin sensitivity in both diabetics and normal subjects.⁶²⁻⁶⁴ Insulin resistance and its concomitant compensatory hyperinsulinemia have been suggested to play a role in the etiology and pathogenesis of hypertension,⁶⁵ although this concept has been controversial. A diet supplemented with fiber may also form a component of weight-loss strategies, and reducing body weight is another mechanism by which a dietary fiber may aid in the prevention of hypertension.^{66,67}

Fish and fish oil

Several lines of evidence suggest that supplementation of the diet with omega-3 polyunsaturated fatty acids, commonly referred to as fish oils, reduces blood pressure by altering prostaglandin synthesis. However, many of the clinical trials of fish oil supplementation have been of insufficient size to detect relevant blood pressure changes. At least three meta-analyses of clinical trials of fish oil supplementation and blood pressure have been conducted.⁶⁸⁻⁷⁰ All three of these found significant antihypertensive effects of fish oil. The most recent, conducted in 2002, analyzed 36 trials of fish oil supplementation and found that intake of fish oil (median dose 3.7 g/day) reduced systolic blood pressure by 2.1 mmHg (95% CI= -1.0 — 3.2 , $p<0.01$) and diastolic blood pressure by 1.6 mmHg (95% CI= -1.0 — 2.2 , $p<0.01$). Restricting their

analysis to double-blind trials demonstrated blood pressure reductions of 1.7 mmHg (95% CI= -0.3 — 3.1) systolic and 1.5 mmHg (95% CI= -0.6 — 2.3) diastolic.⁶⁸ These estimates correspond well with those of the meta-analysis conducted by Appel et al.⁶⁹ Weighted pooled estimates of 11 clinical trials of fish oil supplementation and blood pressure in normotensive individuals yielded systolic blood pressure reductions of 1.0 mmHg (95% CI= -2.0 — 0.0) and diastolic reductions of 0.5 mmHg (95% CI= -1.2 — 0.2). In six trials of hypertensives, weighted pooled estimates of systolic and diastolic blood pressure changes were -5.5 mmHg (95% CI= -8.1 — 2.9) and -3.5 mmHg (95% CI= -5.0 — 2.1), respectively.⁶⁹

Dietary pattern

People manipulate their diets by choosing foods rather than nutrients. Consequently, studies of food intake and blood pressure have become as important as those of nutrient intake. Epidemiologic studies have suggested that a dietary pattern that includes abundant fruits, vegetables, and low-fat dairy products may lower blood pressure.

Several observational studies of fruit and vegetable intake have shown an association with lower blood pressures.⁷¹⁻⁷⁴ For example, in a cross-sectional study conducted among 4393 Spanish men and women, blood pressure was inversely associated with fruit and vegetable consumption as measured by food frequency questionnaire.⁷¹ Among 1710 men enrolled in the Chicago Western Electric cohort and followed for 7 years, average systolic blood pressure/diastolic blood pressure increase was 1.9/0.3 mmHg per year. The systolic blood pressure of men who consumed 14 to 42 cups of vegetables a month (0.5 to 1.5 cups/day) versus less than 14 cups a month (<0.5 cups/day) was estimated to rise 2.8 mmHg less in 7 years ($p<0.01$). The systolic blood pressure of men who consumed 14 to 42 cups of fruit a month versus less than 14 cups a month was estimated to increase 2.2 mmHg less in 7 years ($p<0.05$).⁷² A study in children of the Framingham Children's study suggests similar effects of consuming a diet high in fruits and vegetables.⁷³ Fruits and vegetables are major sources of potassium and fiber in the diet of most peoples worldwide.

Low-fat dairy products may also play a role in the prevention of hypertension and the lowering of blood pressure. Most dairy products provide significant amounts of calcium and protein, both of which likely contribute to blood pressure lowering effects. Several meta-analyses of the association between calcium intake and blood pressure have substantiated a small blood pressure-lowering effect of calcium supplementation.⁷⁵⁻⁷⁸

The DASH clinical trial demonstrated that manipulation of dietary pattern with increased consumption of fruits, vegetables, and low-fat dairy products while maintaining constant energy consumption, lowers blood pressure and may prevent the onset of hypertension.³⁹ The combination diet significantly lowered blood pressure in all major subgroups including men, women, African Americans, non-African Americans, hypertensives, and normotensives. The effect of the DASH combination diet in hypertensive individuals is similar in magnitude to drug monotherapy

for hypertension, and from a public health perspective, wide adoption of the DASH dietary pattern may shift the population blood pressure distribution downward, thereby reducing the risk of blood pressure–related cardiovascular diseases.

PHYSICAL ACTIVITY AND BLOOD PRESSURE

Observational epidemiologic studies have demonstrated a consistent inverse relationship between physical activity and blood pressure independent of body weight and adiposity. In a Japanese cohort of 6017 men aged 35 to 60 years, a walk of 21 minutes or more compared with 10 minutes or less was associated with a 29% lower risk of hypertension (p for trend=0.02).⁷⁹ In the Atherosclerosis Risk in Communities Study cohort, white men who performed the most leisure activity (primarily walking and cycling) had 34% lower odds of developing hypertension over 6 years compared with those who were least active (odds ratio=0.66, 95% CI=0.47–0.94, p for trend=0.01).⁸⁰ In that study, leisure physical activity was not associated with the incidence of hypertension in white women or African Americans.

Evidence from randomized controlled trials also supports the role of physical activity in lowering blood pressure. At least two meta-analyses of randomized trials of aerobic exercise effects on blood pressure have been conducted to date.^{81,82} Kelley conducted a meta-analysis among women aged 18 years and older, including 10 randomized trials with 732 participants. Overall, a significant reduction in systolic, by –2 mmHg (95% CI=–3 to –1 mmHg) and diastolic, by –1 mmHg (95% CI=–2 to –1 mmHg), blood pressure was observed in these women.⁸¹ In the meta-analysis by Whelton et al.,⁸² 54 randomized controlled trials with 2419 men and women participants were included in the analysis (Figure 6–4) (Table 6–1). Pooled estimates showed that aerobic exercise was associated with a significant reduction in mean systolic and diastolic blood pressure: –3.84 mmHg (95% CI=–4.97––2.72) and –2.58 mmHg (95% CI=–3.35––1.81), respectively.⁸²

Some of the mechanisms by which physical activity reduces blood pressure may be independent of body weight. For instance, aerobic exercise improves insulin sensitivity and lowers insulin levels, which have been implicated in the pathogenesis of hypertension.⁸³ Physical activity may also lower blood pressure by causing weight loss.⁸⁴ Therefore, promoting physical activity could have substantial public health benefits as a means to reduce blood pressure.

ALCOHOL CONSUMPTION AND BLOOD PRESSURE

Moderation of alcohol intake is an important part of efforts to prevent hypertension and decrease blood pressure. Observational epidemiologic studies have demonstrated a positive and independent association between alcohol consumption and elevated blood pressure.^{85–87} Several clinical trials of the effects of alcohol

reduction on blood pressure have been conducted.^{88–91} However, most of these studies have had small sample sizes and have reported inconsistent findings. One trial of 641 U.S. military veterans also failed to show a decrease in blood pressure with alcohol reduction.⁹⁰ In that study, veterans with an average intake of three or more drinks per day and with diastolic blood pressures between 0 and 99 mmHg were randomly assigned to either a cognitive-behavioral alcohol reduction program or observation for 15 to 24 months. The intervention group reduced alcohol intake by an average of 1.3 drinks per day compared with the control group; however, this net reduction was less than the anticipated minimum of two drinks per day. The intervention group had a 1.2/0.7 mmHg greater reduction in blood pressure than the control group (p =0.17 for systolic and p =0.18 for diastolic) for the 6-month primary endpoint. One explanation for the lack of significant reduction in blood pressure in this study is the relatively small change in alcohol intake of these veterans.

Because of the large number of studies with small sample sizes, and the importance of even small reductions in blood pressure, meta-analysis of these randomized controlled trials has been conducted by Xin et al.⁹¹ Fifteen randomized controlled trials with a total of 2234 participants were included. Overall, alcohol reduction was associated with a significant reduction in mean systolic and diastolic blood pressures of –3.31 (95% CI=–4.10––2.52) and –2.04 mmHg (–2.58––1.49), respectively (Figure 6–5) (Table 6–1). A dose–response relationship was seen between the mean percentage of alcohol reduction and mean blood pressure reduction in this study.

BODY WEIGHT AND BLOOD PRESSURE

Overweight and obesity play important roles in the development of hypertension. Several studies support the role of weight loss in the prevention and treatment of hypertension. The TONE trial was designed to determine whether weight loss or dietary sodium reduction would produce satisfactory blood pressure control after withdrawal of antihypertensive drug therapy, using a factorial design.⁵ The average reduction in weight for obese participants assigned to weight loss was approximately 3.5 to 4.5 kg, versus an average of 0.9-kg reduction for those not assigned to the weight-loss arm. At the trial endpoint, 39% of those randomized to weight loss remained off antihypertensive medication with a blood pressure of less than 150/90 mmHg and without a blood pressure–related complication, compared with 26% of those not assigned to weight loss 30 months after the attempted withdrawal of antihypertensive drug therapy.

He et al.⁹² examined the relationship between long-term weight loss and hypertension by studying 181 men and women who participated in the TOHP, phase I (TOHP I). At baseline in 1987–1988, participants were aged 30 to 54 years and had diastolic blood pressure of 80 to 89 mmHg and systolic blood pressure of less than 160 mmHg. They were randomly assigned to one of two 18-month lifestyle modification interventions (aimed at either weight loss or dietary sodium reduction) or to a

Figure 6-4. Average net change in systolic blood pressure and corresponding 95% confidence intervals related to aerobic exercise intervention in 53 randomized controlled trials. (Adapted from Whelton SP, et al. *Ann Intern Med* 2002;136:493–503.)

usual care group. Post-trial follow-up was conducted in 1994 and 1995. Blood pressure was measured by blinded observers with a random-zero sphygmomanometer, and incident hypertension was defined as a systolic blood pressure of at least 160 mmHg or a diastolic blood pressure of at least 90 mmHg, or treatment with an antihypertensive medication. After 7 years of follow-up, the incidence of hypertension was 18.9% in the weight-loss group and 40.5% in its control group. In logistic regression analysis adjusted for baseline age, gender, race,

physical activity, alcohol consumption, education, body weight, systolic blood pressure, and urinary sodium excretion, the odds of hypertension was reduced by 77% (odds ratio 0.23, 95% CI=0.07–0.76, $p=0.02$) in the weight-loss group compared with their control groups. Similar significant reductions in blood pressure and hypertension were found in the TOHP, phase II.⁸⁴

Evidence from a meta-analysis of randomized controlled trials of the influence of weight reduction on blood pressure also supports weight loss as an important inter-

vention for the prevention and treatment of hypertension.⁹³ Twenty-five randomized controlled trials published between 1966 and 2002 with a total of 4874 participants were included. Authors found that a net weight reduction of 5.1 kg (95% CI=-6.03—4.25) by means of energy restriction increased physical activity or both reduced systolic blood pressure by 4.4 mmHg (95% CI=-5.93—2.95) and diastolic blood pressure by -3.57 mmHg (95% CI=-4.88—2.25) (Figure 6-6) (Table 6-1).

STRESS AND BLOOD PRESSURE

Psychological and emotional stress may also contribute to the development of hypertension and incremental increases in blood pressure via the body's sympathetic nervous system.⁹⁴ Trials of relaxation techniques ranging from transcendental meditation to biofeedback have shown small but potentially important improvements in blood pressure with use of these noninvasive methods.⁹⁵⁻⁹⁷ Unfortunately, several of these trials have methodologic weaknesses that may have affected their results.⁹⁷

In one well-conducted randomized trial, Schneider et al.⁹⁸ tested the short-term efficacy of two stress-reduction

techniques in the treatment of mild hypertension in older African Americans. A total of 127 individuals aged 55 to 85 years with prehypertension or stage I hypertension were randomized to a 3-month transcendental meditation (TM) or progressive muscle relaxation (PMR) or educational control (EC) program, which included information on lifestyle factors, and were followed in a primary care, inner-city health center. Of these, 16 did not complete follow-up blood pressure measurements. Both active intervention groups showed significant reductions in systolic and diastolic blood pressures compared with the EC group. Compared with the EC group, the TM group showed a reduction of 10.7 mmHg in systolic ($p=0.0002$) and 6.4 mmHg diastolic ($p=0.00005$) blood pressure. Compared with the EC group, the PMR group showed adjusted reductions of 4.7 mmHg in systolic ($p=0.054$) and 3.3 mmHg in diastolic ($p=0.02$) blood pressures. The reductions in the TM group were significantly greater than in the progressive muscle relaxation group for both systolic blood pressure ($p=0.02$) and diastolic blood pressure ($p=0.03$).⁹⁸ The findings of this study and others suggest that psychosocial interventions in hypertensive and prehypertensive individuals warrant more investigation.

SUMMARY

In 2000, nearly 927 million people worldwide were affected by high blood pressure. The need for lifestyle interventions in the prevention and treatment of hypertension is increasingly a priority. Since the majority of cardiovascular events occur in individuals with high normal or mildly elevated blood pressure, public health strategies to shift population blood pressure to a lower level is of utmost importance in order to reduce the burden of cardiovascular disease. Even small reductions in blood pressure, if applied to an entire population, could have an

enormous beneficial effect on cardiovascular events. The effects of changes in dietary patterns, including reduced consumption of sodium, increased intake of potassium, and certain foods, and increasing physical activity, moderation of alcohol intake and weight loss have been documented in well conducted randomized clinical trials.⁹⁹ On the other hand, the effects of dietary fat, fiber, protein, fish oil, and psychosocial stress need to be further examined. Evidence suggests that even small changes in blood pressure due to lifestyle change of the population would result in significantly lower rates of hypertension and cardiovascular diseases worldwide.

Dietary Fats and Blood Pressure

Trevor A. Mori, Valerie Burke, and Lawrence J. Beilin

Key Findings

- Population studies provide support for a protective effect of omega-3 (ω 3) fatty acids against atherosclerotic heart disease and sudden death. Evidence suggests that ω 3 fatty acids also provide protection against stroke, particularly ischemic stroke.
- Omega-3 fatty acids have multiple effects leading to improvements in blood pressure, cardiac function, arterial compliance, vascular function, and lipid metabolism, as well as reduced cytokine formation, and antiplatelet and anti-inflammatory effects.
- In humans, the two principal ω 3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), have differential effects on blood pressure, vascular reactivity, heart rate, and serum lipids.
- In population studies, lower blood pressure is associated with higher polyunsaturated fat intake and higher blood pressure with higher saturated fat intake, but population studies cannot define effects of specific nutrients and may be confounded by lifestyle factors.
- There have been no consistent effects of omega-6, monounsaturated, or saturated fats on blood pressure, but some studies suggest that monounsaturated fat may lower blood pressure, particularly in hypertension and diabetes.
- Complex dietary changes such as those eaten by many vegetarians are associated with lower blood pressures and less obesity and reduce blood pressure in randomized controlled trials. Such diets are characterized by increased fruit and vegetables and nuts, relatively high levels of low-fat dairy products, and hence poly- and monounsaturates and lower levels of saturated fats than in a typical Western diet.
- The Dietary Approaches to Stop Hypertension trials showed that the blood pressure-lowering effect of increased fruit and vegetables could be retained in the presence of lean meat, poultry, and fish, and enhanced by reduction in saturated fats and increased polyunsaturates or monounsaturates from low-fat dairy products.
- These complex dietary patterns probably lower blood pressure through effects of multiple nutrients and micronutrients, including effects of dietary fiber, potassium, magnesium, antioxidants, and effects of fats on endothelial and vascular function.

This chapter reviews evidence for effects of different types and quantities of dietary fats on blood pressure. As more recent evidence is available concerning specific effects of omega-3 (ω 3) polyunsaturates, they are

considered in more detail in relation to their overall effects on cardiovascular disease. The focus is primarily on human studies, although animal data are considered where they are concordant with clinical data and throw additional light on mechanisms.

OMEGA-3 POLYUNSATURATED FATTY ACIDS

There is considerable evidence from clinical, experimental, and epidemiologic studies that the ω 3 fatty acids, derived from fish and fish oils, are protective against atherosclerotic heart disease and sudden coronary death.¹⁻² Omega-3 fatty acids have multiple biological effects leading to improvements in blood pressure³⁻⁶ and cardiac function,⁷ arterial compliance,^{8,9} endothelial function and vascular reactivity,^{10,11} lipid metabolism,^{12,13} reduced neutrophil/monocyte cytokine formation,¹⁴ and antiplatelet¹⁵ and anti-inflammatory effects.¹⁶ Recent evidence has demonstrated that in humans, eicosapentaenoic acid (EPA) (20:5 ω 3) and docosahexaenoic acid (DHA) (22:6 ω 3), the two main ω 3 fatty acids, have differential effects on lipids,¹⁷⁻¹⁹ blood pressure,²⁰ heart rate,²⁰ and vascular reactivity.¹⁰

Observational studies

Bang and Dyerberg²¹ first showed a low incidence of coronary deaths in Greenland Eskimos consuming a high-fat diet rich in ω 3 fatty acids derived from seal and whale blubber, compared with Danes who ate a typical Western diet.²¹ These observations recognized that EPA²² and DHA²³ accounted for prolonged bleeding time, decreased platelet adhesiveness, and low plasma triglycerides in these individuals.

Numerous prospective population studies have confirmed a relationship between increased fish consumption and lower rates of coronary mortality and/or sudden death. The Zutphen study showed that men eating as little as one fish meal a week had more than a 50% lower coronary death rate than those who never or rarely ate fish.²⁴ A follow-up study by the same authors demonstrated that a small consumption of fish protected against coronary heart disease mortality in an elderly population.²⁵ Similarly, the Cardiovascular Health Study reported an inverse association between fish consumption and fatal ischemic heart disease in an elderly population (>65 years).^{26,27} Interestingly, the association held for tuna, broiled or baked fish, but not fried fish or fish sandwiches.²⁷ In the same cohort, consumption of fish such as tuna, broiled or baked fish,

but not fried fish, was also associated with a reduced incidence of congestive heart failure.²⁸ An inverse association between fish consumption and coronary heart disease mortality was also shown in a study from Sweden²⁹ and in two studies from Finland in patients with established coronary artery disease.^{30,31}

Data from the Multiple Risk Factor Intervention Trial (MRFIT) showed that when men comprising the control group were divided into quintiles according to their mean ω 3 fatty acid intake, there were significant inverse correlations between ingestion of fish oils and coronary heart disease, all cardiovascular diseases, and all-cause mortality, with the highest quintile having a 40% to 50% lower mortality rate.³² The Chicago Western Electric study in middle-aged men showed that those who ate >35 g of fish daily had a 38% reduced risk of death from coronary heart disease at the 30-year follow-up, with a dose-dependent effect of increasing fish consumption.³³ In addition, the U.S. Physicians' Health Study reported that consumption of more than one fish meal per week conferred a 52% risk-adjusted reduction in sudden cardiac death compared with men that consumed fish less than monthly.³⁴ The study, however, did not show a significant association between fish consumption and overall cardiovascular endpoints.³⁵ In a follow-up of the same cohort, prospective, nested, case-control analysis among men followed for up to 17 years, showed that baseline blood levels of ω 3 fatty acids were inversely related to the risk of sudden death.³⁶ Men in the third and fourth quartile had an adjusted relative risk of 0.28 and 0.19, respectively, relative to those in the lowest quartile.

Hu et al.³⁷ have shown in the Nurses' Health Study that higher consumption of fish and ω 3 fatty acids was also associated with a lower risk of coronary heart disease in women. Women consuming two to four fish meals per week had an adjusted relative risk of 0.69 compared with those who ate less than one fish meal per month. In a subanalysis of diabetic women from the same cohort, two to four fish meals per week was associated with an adjusted relative risk of 0.64 for coronary heart disease and 0.67 for total mortality compared with those who ate less than one fish meal per month.³⁸

In a case-control study of patients with primary cardiac arrest, Siscovick et al.³⁹ reported that eating the equivalent of one fatty fish meal per week in the month prior to the event was equivalent to a 50% reduction in risk of a primary event. Burchfiel et al.⁴⁰ showed in the Honolulu Heart Program that consumption of fish at least twice a week was associated with a 65% risk reduction in Japanese-American men who were heavy smokers.

Recent findings have shown that fish consumption was also associated with a reduction in the incidence of atrial fibrillation in an elderly population⁴¹ and in patients undergoing coronary bypass surgery.⁴²

Not all studies have shown associations between fish consumption and cardiovascular events,⁴³ possibly due to the uncertainty of estimation of usual dietary fish consumption, failure to distinguish fatty- from low-fat fish, and the complex correlation between diet and other lifestyle factors. In a systematic review, Marckmann et

al.⁴⁴ suggested that the discrepancy between studies may also relate to differences in the study populations, with only high-risk individuals benefiting from increasing their fish consumption. The authors proposed that a 40- to 60-g/day fish intake would confer a 50% reduction in death from coronary heart disease in high-risk populations. These findings have been supported in similar meta-analyses.⁴⁵⁻⁴⁷

The strongest evidence for a protective effect of ω 3 fatty acids is from two randomized controlled trials in patients who had previous heart attacks. In the Diet and Reinfarction Trial, men who had recovered from a myocardial infarction were randomized to either a "usual care" group or they were advised to increase their ω 3 fatty acid intake by eating two to three servings of fatty fish weekly.⁴⁸ Those men who increased dietary fish consumption and/or took fish oil supplements had a 29% reduction over 2 years in sudden cardiac death. The GISSI Prevenzione study⁴⁹ involved patients who had survived a myocardial infarction within the previous 3 months. These patients were randomized in a factorial, open-label, controlled design to either fish oil (1 g daily), vitamin E (300 mg daily), both interventions, or no treatment. After 3.5 years, fish oil supplementation was associated with a 30% reduction in cardiac mortality, a 20% reduction in total mortality and a 45% decrease in sudden death, whereas vitamin E had no significant effect. The combination of fish oil with vitamin E did not increase the benefit compared with fish oil alone. In a subsequent report, the authors demonstrated that a significant reduction in sudden death was apparent 4 months after commencing the program.⁵⁰

There is less evidence for benefits of fish on blood pressure from population studies, although this may be in part due to methodologic issues. However, a cross-sectional comparison of Bantu fisherfolk with non-fish-eating Bantu farmers showed that the former had a much lower increase in blood pressure with ageing.⁵¹ Paradoxically, the high incidence of hypertension in Japan occurs despite high fish intake, although this may be due to very high salt consumption.

An inverse association between increasing intakes of ω 3 fatty acids and risk of stroke has been shown in the Nurses' Health Study,⁵² in men participating in the Health Professional Follow-up Study,⁵³ and in the Cardiovascular Health Study.⁵⁴ In all reports, the effect was observed for ischemic but not hemorrhagic stroke.

Clinical trials

Randomized controlled trials of fish oils or dietary fish consumption provide unequivocal evidence for a blood pressure-lowering effect of ω 3 fatty acids. Meta-analyses have shown such an effect in hypertensives.³⁻⁵ In a meta-analysis of 31 placebo-controlled trials of effects of fish oils on blood pressure, Morris et al.⁴ found an overall reduction of -3.0/-1.5 mmHg with a significant dose-response effect estimated at -0.66/-0.35 mmHg/g ω 3 fatty acid. The hypotensive effect was strongest in hypertensive (treated and untreated) subjects (-3.4/-2.0 mmHg). Appel et al.³ estimated that blood pressure fell 1.0/0.5 mmHg in normotensives (11 trials)

and 5.5/3.5 mmHg in untreated hypertensives (6 trials) with an average intake of more than 3 g/day of ω 3 fatty acids. More recently, Geleijnse et al.,⁵ in a meta-analysis of 36 trials, showed that ω 3 fatty acids reduced blood pressure by $-2.1/-1.6$ mmHg. Blood pressure-lowering effects tended to be greater in older (>45 years) ($-3.5/-2.4$) and hypertensive ($>140/90$ mmHg) ($-4.0/-2.5$) individuals.

The study by Bonaa et al.⁵⁵ is most conclusive in terms of clinical trials. This population-based study involved untreated mildly hypertensive subjects randomized to 6 g/day of 85% EPA and DHA or 6 g/day corn oil for 10 weeks. Relative to the corn oil group, the group treated with fish oil had a $-6.4/-2.8$ mmHg decrease in blood pressure. In addition, blood pressure reductions were inversely related to baseline plasma phospholipid ω 3 fatty acids. Other placebo-controlled studies have demonstrated significant benefits of dietary ω 3 fatty acids on blood pressure in hypertensives.⁵⁶⁻⁶⁰ Prisco et al.⁶¹ showed that 24-hour ambulatory blood pressure was reduced by 5 to 6 mmHg after taking 3.44 g/day of ω 3 fatty acids for 2 months, in mild essential hypertensive, normolipidemic men. Toft et al.⁶² also confirmed that in essential hypertensives blood pressures fell by 3.8/2.0 mmHg more than controls after 16 weeks of 4 g/day of fish oil containing 85% EPA plus DHA.

The blood pressure-lowering effects of ω 3 fatty acids are potentiated by sodium restriction⁶³ and concomitant usage of antihypertensive drugs. In this regard, fish oils amplified the hypotensive action of the β -adrenergic receptor blocker propranolol in mild-to-moderate hypertensives,⁶⁴ but there was no additional benefit in hypertensives on ACE inhibition.⁶⁵ However, fish oils may be a useful adjunct to antihypertensive therapy with β -blockers or diuretics.⁶⁶ Others have shown that ω 3 fatty acids reduced blood pressure by 3.1/1.8 mmHg in treated hypertensives who were taking β -blockers alone, diuretics alone, or a combination of the two.⁶⁶

Vandongen et al.⁶⁷ compared the effects of 12 weeks of fish meals or fish oil supplements providing 2.2 to 6.3 g/day (mean intake 3.65 g/day) of ω 3 fatty acids in the setting of a high- or low-fat diet in 120 men with high-normal blood pressure. Although individual subgroups showed no significant falls in blood pressure, in all the groups combined there was a significant inverse correlation between the falls in systolic and diastolic blood pressure and heart rate, and increases in ω 3 and decreases in ω 6 fatty acids in platelet phospholipids.

Studies from our Unit examined whether dietary ω 3 fatty acids in the form of dietary fish had independent and additive effects to weight control on blood pressure.⁶⁸ In a factorial design study, 63 overweight, treated hypertensives were randomized to weight loss alone by calorie restriction, a daily fish meal (approximately 3.65 g/day ω 3 fatty acids), the two combined, or a control diet, for 4 months. The final 4 weeks involved weight stabilization for the weight control groups whose weight fell an average 5.6 kg. Twenty-four-hour ambulatory blood pressures showed significant independent and additive effects of dietary fish and weight loss. Relative to controls, daytime

blood pressures fell by 6.0/3.0 mmHg in the fish group, 5.5/2.2 in the weight loss group, and 13.0/9.3 with the combination (Figure 7-1). Fish consumption was also associated with significant reductions in heart rate by three to four beats per minute, suggesting an autonomic/cardiac component to the blood pressure reduction.

The antihypertensive effect of eicosapentaenoic acid versus docosahexaenoic acid

There is evidence that DHA and EPA have differential effects on lipid metabolism^{17-19,69} and platelet aggregation.⁷⁰ Blood pressure control is also differentially affected by EPA and DHA. In humans, Mori et al.²⁰ showed that DHA, but not EPA, significantly reduced 24-hour ($-5.8/-3.3$ mmHg) and daytime (awake) ($-3.5/-2.0$ mmHg) blood pressure, relative to the placebo in overweight, mildly hypercholesterolemic subjects (Figure 7-2). Patients were given 4 g daily of highly purified EPA, DHA, or olive oil (placebo) capsules, while continuing their usual diets for 6 weeks. These effects were

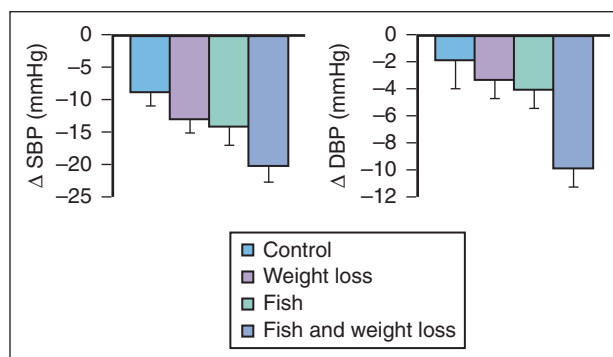

Figure 7-1. Changes from baseline to post-intervention in 24-hour ambulatory SBPs and DBPs during awake hours in the control, weight loss, fish, and combined weight loss and fish groups. Data are shown as mean plus standard error of the mean. DBP, diastolic blood pressure; SBP, systolic blood pressure.

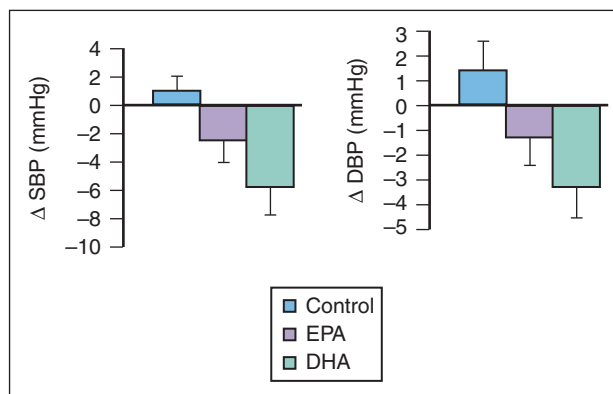

Figure 7-2. Changes from baseline to post-intervention in 24-hour ambulatory systolic and diastolic blood pressures in the control (olive oil), EPA, and DHA groups. Data are shown as mean plus standard error of the mean. DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid.

accompanied by significant improvements in endothelial and smooth muscle function in the forearm microcirculation with DHA but not EPA, as well as reduced vasoconstrictor responses.¹⁰ The study also showed that DHA, but not EPA, significantly reduced 24-hour, awake and asleep heart rate by 3.5, 3.7, and 2.8 bpm, respectively.²⁰ In contrast, Woodman et al.¹⁸ showed that neither EPA nor DHA given as 4-g doses daily for 6 weeks, decreased blood pressure in treated hypertensive, type 2 diabetic patients. Possible explanations for the lack of an antihypertensive effect may have been related to concomitant use of other pharmacologic agents, presence of glycemia, and increased blood pressure variability in these diabetic patients.

Mechanisms for antihypertensive effects of omega-3 fatty acids

Vascular function and the role of nitric oxide

Benefits on blood pressure following dietary ω 3 fatty acids are likely to be due to changes in vascular, cardiac, and/or autonomic function. Fish oil supplementation in hypertensive rats increased endothelial relaxation in aortic rings exposed to acetylcholine⁷¹ and decreased pressor reactivity of perfused mesenteric resistance vessels.⁷² Yin et al.⁷¹ showed that increased endothelial relaxant effects were due at least in part to suppression of thromboxane A₂ (TXA₂) or cyclic endoperoxides, with the additional effect of enhanced endothelial nitric oxide (NO) synthesis. Studies in humans have shown that fish oils reduced forearm vascular reactivity to angiotensin II and noradrenaline.^{73–75} The blunting effect of fish oils on noradrenaline and angiotensin II responses in human forearm resistance arteries were antagonized by oral administration of indomethacin, suggesting that ω 3 fatty acids, at least in part, modify cyclooxygenase-derived prostanoids.⁷⁶ Indomethacin *per se*, at the dose given, did not affect responses to the two agonists.

Fish oils had a minimal effect on acetylcholine-induced vasodilation or reactive hyperemia in forearms of healthy subjects.⁷⁶ However, ω 3 fatty acids restored impaired responses to endothelium-dependent vasodilators in patients with coronary artery disease,^{77,78} as well as in animal models, including the SHR,⁷¹ the glucocorticoid-induced hypertensive rat,⁷⁹ and the hypercholesterolemic and atherosclerotic pig,⁸⁰ all characterized by endothelial damage. Vasodilatory responses to acetylcholine in hypercholesterolemic subjects were also enhanced by dietary fish oil in the absence of changes in total cholesterol.⁸¹

Individuals with type 2 diabetes who received ω 3 fatty acids supplements have improved forearm vasodilator responses to acetylcholine, but not to glyceryl trinitrate, suggesting that fish oils may protect against vasospasm and thrombosis by enhancing NO release and suppressing thromboxane.⁸² Additional evidence that ω 3 fatty acids affect production or release of NO, was from studies demonstrating enhanced responses to endothelium-dependent vasodilators such as bradykinin, serotonin, ADP, and thrombin, in rings of coronary arteries taken from pigs fed cod-liver oil.⁸³ In addition, EPA potentiated

in vitro NO release evoked by IL-1 β in vascular smooth muscle cells⁸⁴ and in endothelial cells in response to ADP and bradykinin.⁸⁵

Omega-3 fatty acids may also improve endothelial function in systemic large arteries in humans. Goodfellow et al.⁸⁶ showed a significant improvement in flow-mediated dilatation of the brachial artery following 4 months with 4 g daily of ω 3 fatty acids, in subjects with hyperlipidemia. The improvement was confined to endothelial-dependent responses.

Studies in rats have shown differential effects of EPA and DHA on vascular function.^{87,88} Engler et al.⁸⁸ reported that in aortic rings EPA and DHA induced endothelium-dependent and independent vasodilation, respectively. McLennan et al.⁸⁷ demonstrated that DHA was also more effective than EPA at inhibiting thromboxane-like vasoconstrictor responses in the aortas from spontaneously hypertensive rats (SHR). They suggested that DHA prevented thromboxane-induced contraction and perhaps restored the vasoconstrictor/vasodilator balance following impairment of the normal NO-related processes. Whether DHA inhibits thromboxane synthetase or thromboxane A₂/prostaglandin H₂ receptor function remains uncertain.

Indirect evidence for a beneficial effect of DHA but not EPA on endothelial function in humans was obtained by measuring serum and urinary nitrate output.⁸⁹ However, these results are only suggestive of increased NO production in endothelial cells, since nitrates are also derived from other sources. Mori et al.¹⁰ reported that DHA, but not EPA, improved vasodilator responses to endogenous and exogenous NO donors and attenuated vasoconstrictor response to noradrenaline in the forearm microcirculation of overweight subjects with hyperlipidemia. The mechanisms were predominantly endothelium independent, based on enhanced vasodilatory responses following co-infusion of acetylcholine with L-NMMA and infusion of nitroprusside, both of which are endothelium independent. However, the data do not preclude an endothelial component in the dilatory responses associated with DHA. These findings were associated with a reduction in blood pressure in these patients following supplementation with DHA, but not EPA.²⁰ Yin et al.⁷¹ previously showed an endothelial-independent vasodilatory effect of ω 3 fatty acids in perfused mesenteric resistance vessels from SHR.

The favorable effects of DHA on vasoreactivity¹⁰ may be attributable to direct and indirect effects of DHA on the arterial wall. DHA incorporation into endothelial membranes could increase membrane fluidity, calcium influx, and endogenous synthesis and release of NO. Additional mechanisms may include direct effects of DHA on receptor-stimulated NO release, enhanced release of vasodilator prostanoids, and/or endothelial-derived hyperpolarizing factor, consistent with experimental evidence.⁷⁹ Enhanced vasodilator response to sodium nitroprusside may be due increased biotransformation to NO or increased reactivity of smooth muscle cells to vasorelaxation as a result of decreased calcium influx.⁹⁰ Increased release of cyclooxygenase-derived vasodilatory metabolites may have accounted for the decreased vaso-

constrictor response to noradrenaline following DHA.¹⁰ Vasodilator effects of DHA could also be related to increased basal production of NO in smooth muscle cells as a consequence of decreased release of platelet-derived growth factor (PDGF),⁹¹ since induction of NOS in vascular smooth muscle cells is inhibited by PDGF.⁹²

Vascular compliance

Blood pressure is strongly influenced by arterial compliance, which in turn is influenced by endothelial function. In this regard, McVeigh et al.⁸ showed that compliance in the large arteries and more peripheral vasculature, as measured by pulse-contour analysis, improved significantly after 6 weeks of fish oil compared with olive oil, in type 2 diabetic individuals. There were no changes in mean arterial blood pressure, cardiac output, stroke volume, or systemic vascular resistance. In patients with dyslipidemia, EPA and DHA supplementation improved arterial compliance by 35% and 27%, respectively.⁹ There was no significant difference in the effect between EPA and DHA.

Vasodilator and vasoconstrictor prostanoids

The antihypertensive effect of ω 3 fatty acids may also relate to modulation of vasodilator and vasoconstrictor prostanoids. Omega-3 fatty acids suppress production of thromboxane B₂ (TXB₂), a metabolite of the vasoconstrictor and potent aggregator TXA₂.⁹³ Diets rich in ω 3 fatty acids decreased TXA₂ with concomitant increased TXA₃, the analogous but significantly less biologically active EPA-derived metabolite, in patients with atherosclerosis.⁹⁴ An increase in prostaglandin I₃ (prostacyclin, PGI₃), derived from EPA and equipotent in the vasodilatory and antiaggregatory activities to the arachidonic acid-derived prostaglandin I₂ (PGI₂), without a fall in PGI₂, was reported following ω 3 fatty acids.^{94,95} It was suggested that a significant increase in total prostacyclin (PGI₂ and PGI₃) formation, together with reduced total thromboxane (TXA₂ and TXA₃), may explain altered endothelial and vascular responses following dietary ω 3 fatty acids.

Plasma noradrenaline and adenosine triphosphate levels

Hashimoto et al.⁹⁶ showed that rats fed DHA intragastrically had reduced plasma noradrenaline levels and increased adenylyl purines such as adenosine triphosphate (ATP), released both spontaneously and in response to noradrenaline from segments of caudal artery. Furthermore, plasma adenylyl purines were significantly inversely associated with blood pressure. This finding is noteworthy, in view of the fact that ATP causes vasodilation by stimulating the release of NO from endothelial cells, by a direct action on vascular smooth muscle cells and by hyperpolarizing smooth muscle cells. The authors suggested that DHA-accelerated ATP release from vascular endothelial cells, in conjunction with reduced plasma noradrenaline, may have been responsible for the fall in blood pressure associated with ω 3 fatty acids.⁹⁶

Membrane function/membrane fluidity

Incorporation of ω 3 fatty acids into plasma and cellular membranes likely alters the physicochemical structure of the membrane leading to changes in fluidity, flexibility, permeability, and function of the membrane and membrane-bound proteins. It is plausible this may affect enzyme activity, receptor affinity, and transport capacity of the cell, including synthesis and/or release of NO. Hashimoto et al.⁹⁷ showed that DHA had a greater effect than EPA in increasing membrane fluidity of endothelial cells cultured from rat thoracic aortas, a finding that may have significance in view of the greater effect of DHA compared to EPA on maintaining vascular function and reducing blood pressure in humans.^{10,20}

Cardiac function

A reduction in heart rate in animals^{98,99} and humans^{18,20,67,68,100,101} following dietary ω 3 fatty acids suggests a significant cardiac component associated with the antihypertensive effects. This is possibly mediated by effects on autonomic nerve function or β -adrenoreceptor activity. In a recent meta-analysis of 30 studies, ω 3 fatty acids were shown to reduce heart rate overall by -1.6 bpm, with greater reductions in trials with baseline heart rate >69 bpm (-2.5 bpm) and in trials of >12 weeks duration (-2.5 bpm).¹⁰²

Data from human studies also strongly suggest that ω 3 fatty acids increase heart rate variability in patients at high risk of sudden cardiac death and in healthy individuals,^{103,104} supporting an antiarrhythmic effect of ω 3 fatty acids.

In humans, Mori et al.²⁰ reported that heart rate was reduced by DHA, but not EPA. The authors showed that in overweight, mildly hyperlipidemic, but otherwise healthy men given 4 g daily of EPA, DHA, or olive oil for 6 weeks, 24-hour, awake, and asleep heart rate fell -3.5 , -3.7 , and -2.8 bpm, respectively, following DHA. Interestingly, EPA resulted in a small, but nonsignificant rise in heart rate. In a follow-up trial of similar design in type 2 diabetic individuals, the same authors confirmed that DHA, but not EPA, significantly reduced clinic standing and supine heart rates (-5.8 and -3.9 bpm, respectively) compared with the placebo.¹⁸ Differential effects of EPA and DHA on heart rate were supported by the findings of Grimsgaard et al.¹⁰⁰

Omega-3 fatty acids are incorporated into myocardial cells altering electrophysiologic function in a manner that reduces the vulnerability to ventricular fibrillation.⁷ The antiarrhythmic effects of ω 3 fatty acids are most likely related to their ability to inhibit the fast, voltage-dependent sodium current and the L-type calcium currents.⁷ Evidence of potassium channel modulation has also been provided.⁷ Moreover, the free fatty acids and not phospholipid-bound fatty acids conferred the inhibitory effect.⁷ McLennan et al.⁸⁷ also showed that DHA, but not EPA, prevented ischemia-induced cardiac arrhythmias in hooded Wistar rats fed purified oils, confirming differential effects demonstrated in humans.^{18,20,100}

SATURATED, MONOUNSATURATED, AND OMEGA-6 POLYUNSATURATED FATTY ACIDS

Possible mechanisms

There are plausible mechanisms that link the type or amount of dietary fats and blood pressure. These include effects on prostaglandin synthesis,¹⁰⁵ endothelial function,¹⁰⁶ vascular reactivity,^{107,108} changes in lipid composition of cell membranes, resulting in modification of transport processes,¹⁰⁹ and insulin resistance, which is increased by saturated fatty acids.¹¹⁰ Antioxidants present in dietary fats, such as polyphenols in olive oil,¹¹¹ could also influence blood pressure.

While some studies suggest that saturated, monounsaturated, or ω 6 fatty acids affect blood pressure, evidence is inconsistent and, overall, reviewers consider that these dietary fats do not have a modifying role.^{112,113} Because interest has moved from a focus on individual nutrients to the benefits of a prudent diet, as used in the Dietary Approaches to Stop Hypertension (DASH) trials,¹¹⁴ there have been few relevant clinical trials since these reviews.

Observational studies

In cross-sectional studies, lower blood pressure has been associated with polyunsaturated fat or polyunsaturated/saturated (P/S) fat ratio, and higher blood pressure with saturated fats.^{115–117} However, other studies have reported contradictory findings^{118,119}; more recently, the large National Health and Nutritional Examination Survey III in the United States found that higher intake of monounsaturated and polyunsaturated fats was associated with higher blood pressure.¹²⁰ In a study of 1000 Australian schoolchildren at ages 9 and 12, no relation was found between dietary fat type or quantity and blood pressure.^{121,122}

Cross-sectional studies that have examined fatty acids in adipose tissue, red cells, or plasma also show no consistent effect of saturated or ω 6 PUFA or P/S ratio on blood pressure.^{117,123,124}

In large prospective studies, no association between the incidence of hypertension and intake of saturated, polyunsaturated, or monounsaturated fats has been found.^{118,119,125}

Population studies cannot recognize effects of specific nutrients, while dietary patterns may be confounded by other lifestyle factors such as obesity and physical activity. Smoking and alcohol consumption, both of which are associated with higher intake of fat and lower consumption of fruits and vegetables,^{126,127} can affect interpretation. Inaccuracies in recording food intake also influence results.¹²⁸ While measurement of tissue fatty acids avoids errors in dietary data, levels are affected by metabolic processes and by lifestyle, particularly alcohol consumption¹²⁹ and smoking.¹³⁰

Clinical studies

Many early studies that investigated associations between dietary fats and blood pressure had design flaws. These

included uncontrolled interventions, multiple changes in nutrients, failure to allow for familiarization in measurement of blood pressure, and failure to control for lifestyle factors.^{112,131}

Saturated and omega-6 fatty acids

Randomized controlled trials in normotensive individuals have shown no consistent effects on blood pressure with dietary modifications to change the intake of saturated fat, polyunsaturated fat, or the P/S ratio.^{132–134} Changes in the P/S ratio achieved by using supplements combined with a standard low-fat diet, rather than changes in foods, also showed no effect on blood pressure.¹³⁵ Linoleic acid supplements have produced no change¹³⁶ or reduction in blood pressure.¹³⁷

Studies in hypertensives have also shown no consistent effects of saturated fat, ω 6 polyunsaturated fat, or P/S ratio on blood pressure. This applies to both the use of modified diets¹³⁸ and dietary supplements.^{139,140}

Monounsaturated fatty acids

In most studies, no effect of monounsaturated fatty acids on blood pressure in normotensives has been seen, using either dietary change^{141,142} or fatty acid supplements.¹⁴³ However, in a randomized controlled trial in normotensive young men, systolic and diastolic blood pressure fell relative to controls during 4-week periods of a diet rich in monounsaturated fat.¹⁴⁴ The authors suggested that effects may be mediated by improvements in glucose homeostasis.

In a small study of hypertensive women that compared oleic acid-rich safflower oil and olive oil as sources of monounsaturated fats,¹⁴⁵ systolic and diastolic blood pressures were lower with the olive oil diet. In patients treated with antihypertensive drugs, a diet rich in monounsaturated fat from extra-virgin olive oil was associated with lower blood pressure and a greater reduction in the dose of drugs needed to control hypertension than a similar diet based on sunflower oil.¹¹¹ The authors suggested that the improvements were related to antioxidant polyphenols present in the olive oil rather than to differences in fatty acid composition of the two diets.

Although diets high in monounsaturated fats have been reported to improve glycemic control, lipid profile, and blood pressure in type 2 diabetes, their use is controversial.¹⁴⁶ In a controlled trial in type 2 diabetics, replacement of 20% of energy from carbohydrates with 20% of energy from monounsaturated fat, providing a total of 50% energy from fat, was associated with lower blood pressure.¹⁴⁷ This observation does not distinguish between the effects of lower carbohydrates and higher monounsaturated fats. However, blood pressure in diabetics also fell with a diet containing 30% energy from fat, of which 10% was monounsaturated, relative to an isoenergetic diet in which polyunsaturates replaced the monounsaturates.¹⁴⁸

In studies that report lower blood pressure associated with olive oil as a source of monounsaturated fat, it is not clear whether any effects relate to the type of fat, dietary patterns, or to other components of olive oil, such as

antioxidants. Responses may differ in patients with type 2 diabetes mellitus.

Trans fatty acids

Trans fatty acids, formed in the process of hardening polyunsaturated fats in the manufacture of margarines and shortening, contribute 2% to 4% of energy in a typical diet in the United States.¹⁴⁹ These fatty acids have properties intermediate between cis unsaturated and saturated fatty acids and can increase blood cholesterol.¹⁵⁰

Trans fatty acids have not been shown to affect blood pressure. In normotensive men and women, blood pressure did not differ significantly between diets containing 8% to 10% of energy as oleic acid, trans fatty acids, or saturated fatty acids.^{151,152} Substitution of 20% of energy from fat with soybean oil, semiliquid margarine, soft margarine, partially hydrogenated soybean oil, solid margarine, or butter showed no effect on blood pressure in a small crossover trial that may have included treated hypertensives.¹⁵³

The way in which fats are cooked is another relatively unexplored issue, with one study reporting an association between the risk of hypertension and the intake of excess polar compounds in cooking oil and the use of sunflower oil.¹⁵⁴

In summary, except for ω 3 fatty acids, there is no consistent evidence for specific effects of the type or amount of dietary fat on blood pressure in humans, independent of other dietary components and lifestyle factors. Complex dietary changes, which include modification of dietary fats, patterned on lacto-ovo-vegetarian diets^{155,156} and those as used in the DASH trials,¹¹⁴ offer an effective and palatable approach to prevention and treatment of hypertension.

DIETARY FATS AS PART OF COMPLEX DIETARY CHANGES

Whereas there is clear-cut evidence concerning blood pressure-lowering effects of ω 3 fatty acids of marine origin, data on effects on blood pressure of saturated, monounsaturated, or shorter chain polyunsaturated fats or on the ratio of polyunsaturated to saturated fats are more difficult to interpret. As outlined above cross-sectional and prospective population data show inconsistent associations between these fats and blood pressure levels or the prevalence of hypertension. In a study of dietary and lifestyle factors on the prevalence of hypertension across five Westernized countries, only fish fatty acids contributed to the attributable risk.¹⁵⁷ On the other hand, the Chicago Western Electric study of 8-year blood pressure changes in middle-aged men showed an independent association between the Keys dietary lipid score and systolic blood pressure, while vegetable protein, vitamin C and beta carotene, were inversely related.¹⁵⁸ With recent attention on the health benefits of a “Mediterranean”-type diet, it is interesting that in a large study from Greece adherence to such a diet was inversely associated with blood pressure, with intake of olive oil, fruit, and vegetables all having statistically significant effects.¹⁵⁹

However, reports on populations in which differences in dietary fats are part of more complex dietary changes have been more consistent in terms of associations with blood pressure. Since the early twentieth century, there have been reports showing that strict lacto-ovo-vegetarians or vegans had lower blood pressures and less hypertension than meat eaters.^{160–163} By comparing Seventh Day Adventist vegetarians with another religious group, meat-eating Mormons, Rouse et al.¹⁶⁴ were able to show that these effects were most likely due to diet rather than other lifestyle factors. As vegetarian populations tended to eat less saturated fats and more polyunsaturates, this led to suggestions that a high P/S ratio diet might predispose to lower blood pressures.¹⁶⁵ However, diets of vegetarians and vegans are characterized by a wide variety of nutrients and whole-food differences compared with regular meat eaters as well as lower BMI and several other lifestyle differences that could influence blood pressure. Although differences in BMI are attributed by some to the blood pressure differences between vegetarians and meat eaters,¹⁶⁶ this is not the entire explanation.¹⁶⁴ Factor analysis of dietary patterns related to blood pressure differences between Seventh Day Adventist vegetarians and Mormon meat eaters in Western Australia suggested that combinations of changes in polyunsaturated, fiber, and vitamin C might be responsible.¹⁶⁷

Several more recent cross-sectional population studies suggest that combinations of nutrients including fruit, vegetables, and low-fat dairy products contribute to lower blood pressures.^{168,169} A recently published but “historical” prospective analysis on 1710 men in the Chicago Western Electric Study from 1958 to 1966 also supported the concept that diets high in fruit and vegetables and lower in meats other than fish reduced the risk of developing hypertension.¹⁷⁰

Randomized controlled trials of dietary interventions have thrown more light on the issue and can be divided into two broad categories. The first refers to trials that have restricted dietary changes to fats alone, without substantially altering intake of other nutrients or micronutrients. Such trials are difficult to conduct without altering total caloric intake, which can itself affect blood pressure. Studies of this nature have already been described in this review, and have generally been negative with regard to effects of saturated and ω 6 polyunsaturates on blood pressure. The secondary category of dietary trials also attempts to increase the ratio of polyunsaturated to saturated fats, but in the process affects intake of all major food groups, usually increasing consumption of fruit, nuts, vegetables, and fish, while reducing consumption of high-fat dairy products, meat, and poultry. This results not only in changes in dietary fats, but also in the type and amount of protein and carbohydrates, and in a range of micronutrients including antioxidant vitamins and other antioxidants, fiber, and fiber types. Furthermore, such diets are usually characterized by an increase in lower glycemic index foods, in minerals such as potassium and magnesium, and sometimes a reduction in sodium intake.

There is good evidence from randomized controlled trials that such complex dietary changes reduce blood pressure and some evidence that dietary fat patterns contribute to these changes. Randomized controlled trials of lacto-ovo-vegetarian diets and in regular meat eaters showed falls in blood pressure in both normotensives¹⁵⁵ and untreated hypertensives.¹⁵⁶ These trials involved an increase in P/S ratio from around 0.3 to 1.0, along with other nutrient changes. Iacono et al.¹⁷¹ and Puska et al.¹⁷² conducted dietary trials increasing P/S ratio in hypercholesterolemic subjects and consistently showed falls in blood pressure. They concluded that changes in the amount and type of fat were responsible; however, their interventions also involved complex dietary changes characterized by an increased consumption of fruit, vegetables, and low-fat dairy products at the expense of high-fat dairy and meat products. Following a series of studies that focused on individual nutrient changes in fats, fiber, or protein type, it was concluded that lower blood pressures induced by vegetarian diets were probably due to a combination of complex dietary changes rather than any specific dietary component.¹⁷³ A small study of the effects of a “prudent” diet in normotensives¹⁷⁴ also showed that it was not necessary to exclude meat from dietary patterns similar to those eaten by vegetarians to achieve blood pressure reduction.

It was on the basis of these various strands of evidence pointing to effects of complex dietary patterns and with the clear-cut blood pressure lowering effects of vegetarian diets, the DASH trial¹¹⁴ was designed to determine whether diets more acceptable to the general population would lower blood pressure in subjects with high normal blood pressure or mild hypertension. This landmark trial included three arms, a control group who continued the normal Western diet, a group who substantially increased fruit and vegetable consumption, and a third group who ate the “DASH combination diet,” which also decreased saturated fat intake and increased consumption of low-fat dairy products.¹¹⁴ There was a progressively greater blood pressure reduction across the three groups with a significantly greater effect of the combination diet. Although the DASH trial provides the best evidence for a role of dietary fats on blood pressure as part of a more complex dietary change, it is not as conclusive as the authors suggested, as the group who changed their fat intake also altered their intake of meat products and increased fish intake and consumption of low-fat dairy products containing other nutrients and minerals. Moreover, although there were no significant weight changes during the 8-week study, there was a reduction in estimated calorie intake with the complex DASH diet that might have contributed to blood pressure reduction.

Subsequent studies on effects of DASH-type diets on blood pressure, such as the DASH salt study,¹⁷⁵ have all included the whole dietary package and are thereby unable to throw further light on the contribution of fats *per se* to changes in blood pressure.¹⁷⁶ Moreover, in the PREMIER study, the DASH combination-diet regimen

achieved no additional blood pressure reduction over and above standard measures for weight control, increased physical activity and modest sodium and alcohol restriction.¹⁷⁶ The original DASH study was a “proof of principle” trial in which the meals were all provided at communal canteens where the volunteers were strictly supervised. Interestingly, the “acceptability” of and adherence to the full recommendations of the DASH diet as regards increased fruit and vegetable consumption in noninstitutionalized individuals were not borne out in the more relaxed environment of the PREMIER study nor in an Australian study in which sodium restriction but not the DASH package lowered blood pressure.¹⁷⁷

Further evidence of the contribution of monounsaturated fats comes from a study in which the complete carbohydrate-rich DASH diet was compared with two arms, one of which was enriched with protein and the other with predominantly unsaturated fats at the expense of carbohydrates in a 6-week cross-over design.¹⁷⁸ Compared with the carbohydrate-rich diet, the unsaturated fat diet further decreased blood pressure by 1.3 mmHg overall and by 2.9 mmHg in hypertensives. Unfortunately, there was no standard Western diet control group.

CONCLUSIONS

There is sound evidence for blood pressure lowering—effects of ω 3 fatty acids of marine origin taken in either the form of fish oil supplements or regular intake of fish to provide 3 to 4 g of ω 3 fatty acids daily. Lesser amounts of ω 3 fatty acids have an antiarrhythmic effect in subjects at a high risk of heart disease. Clinical trials suggest that omega-3 fatty acids reduce the risk of coronary heart deaths in patients with prior heart disease, while population studies suggest that higher fish consumption protects against ischemic heart disease and ischemic stroke in the general population. Omega-6 polyunsaturates and monounsaturates when substituted for saturated fatty acids may have some blood pressure-lowering effect if they are part of complex dietary changes that include substantial increases in consumption of fruit, nuts, and vegetables and low-fat dairy products. These effects can be enhanced by moderation of salt intake.

From the clinical and public health viewpoint of optimum diets for preventing and managing hypertension, it is probably not critical whether increases in P/S ratio effectively lower blood pressure, as the improvements in lipid profile resulting from these changes in dietary fats are sufficient justification as measures to reduce long-term cardiovascular risk. More important from the blood pressure viewpoint is the type and amount of ω 3 fatty acids and the effects of various types of fats on cardiac rhythm stability, atherosclerosis, thrombosis, endothelial function, satiety, total caloric intake, and palatability. For example, high saturated fat consumption as part of high-calorie diets also contributes to increasing rates of obesity and will have an importance influence on blood pressure through this mechanism.

Chapter

8

Effects of Dietary Patterns

*Lawrence J. Appel***Key Findings**

- Of the environmental factors that influence blood pressure (i.e., diet, sedentary lifestyle, toxins, and psychosocial factors), dietary factors have a major, and likely predominant, role in determining blood pressure.
- Dietary modifications that lower blood pressure are a reduced sodium intake, increased potassium intake, weight loss (among those who are overweight or obese), and moderation of alcohol consumption (among those who drink).
- Certain dietary patterns (vegetarian, Dietary Approaches to Stop Hypertension [DASH]-style, and Mediterranean diets) are also associated with reduced blood pressure.
- Evidence from clinical trials has often documented subadditive effects among established risk factors, that is, the combined effect of two or more blood pressure-reducing components is less than the sum of blood pressure reductions from each component alone.

Elevated blood pressure results from environmental factors, genetic factors, and interactions among these factors. Of the environmental factors that influence blood pressure (i.e., diet, sedentary lifestyle, toxins, and psychosocial factors), dietary factors have a major, and likely predominant, role in blood pressure homeostasis. A substantial body of evidence strongly supports the concept that multiple aspects of diet affect blood pressure. Dietary modifications that lower blood pressure are reduced sodium intake, increased potassium intake, weight loss (among those who are overweight or obese), and moderation of alcohol consumption (among those who drink).¹ A very high intake of n-3 polyunsaturated fatty acids from pill supplements (commonly termed “fish oil”) also lowers blood pressure but at doses that are commonly associated with side effects.

Certain dietary patterns (vegetarian, Dietary Approaches to Stop Hypertension [DASH]-style, and Mediterranean diets) are also associated with reduced blood pressure. The blood pressure lowering effects of these dietary patterns reflects the cumulative effects of their constituent nutrients that include the well-established factors that affect blood pressure (e.g., potassium) and perhaps other factors (e.g., fiber, meat) whose effect on blood pressure is uncertain. To a limited extent, available research has explored whether the blood pressure effects of individual nutrients are additive, synergistic, or subadditive. Evidence from clinical trials has often documented subadditive effects among estab-

lished risk factors, that is, the combined effect of two or more blood pressure-reducing components is less than the sum of blood pressure reductions from each component alone.²⁻⁴ Nonetheless, the cumulative effects, even if subadditive, can be substantial and have major public health benefits.

The primary objective of this chapter is to review the effects of selected dietary patterns (vegetarian, DASH-style, and Mediterranean diets) on blood pressure. In addition to lowering blood pressure, these dietary patterns have also been associated with a reduced risk of cardiovascular disease, particularly coronary heart disease. In this chapter, I also review the effects of dietary carbohydrate and protein on blood pressure. See Chapter 7 for a review of the effects of fat on blood pressure.

VEGETARIAN DIETS

Vegetarian diets have long been associated with reduced blood pressure.⁵ In non-Western societies that consume a largely plant-based diet, hypertension is rare, while migration from these often rural societies to more urban societies is associated with a rise in blood pressure and increased prevalence of hypertension.^{6,7} In industrialized countries, where hypertension is commonplace, individuals who consume a vegetarian diet have substantially lower blood pressure than nonvegetarians. Some of the lowest blood pressures observed in industrialized countries have been documented in strict vegetarians living in Massachusetts. Vegetarians also experience a lower, age-related rise in blood pressure^{8,9} (Figure 8-1). Importantly, observational studies from Europe and the United States have consistently documented that vegetarian diets are associated with a reduced risk of coronary heart disease.¹⁰

Aspects of a vegetarian lifestyle that might affect blood pressure include nondietary factors (e.g., physical activity), well-established dietary risk factors for elevated blood pressure (e.g., sodium, potassium, weight, alcohol), and other aspects of a vegetarian diet (e.g., high fiber, no meat). As discussed in the next section, observational studies have to a very limited extent controlled for the well-established determinants of blood pressure.

Weight certainly accounts for part of the blood pressure-lowering effect of a vegetarian lifestyle. On average, vegetarians weigh considerably less than nonvegetarians. However, in analyses that adjust for or stratify by weight, an effect of vegetarian diets on blood pressure often persists.^{8,11} Fewer studies have determined whether reduced sodium

Figure 8-1. Blood pressure by age in a strict vegetarian population in Boston and in nonvegetarian populations in East Boston and Framingham, Massachusetts. (Adapted from Sacks FM, Kass EH. *Am J Clin Nutr* 1988;48(Suppl 3):795-800.)

and/or increased potassium are responsible for the blood pressure-lowering effects of vegetarian diets. Although data are limited, vegetarians tend to consume more potassium than nonvegetarians. The high intake of potassium, a nutrient that lowers blood pressure,¹² likely results from consumption of fruits and vegetables. Available evidence indicates that the salt intake of vegetarians is similar to and potentially exceeds that of nonvegetarians; such findings suggest that the blood pressure-lowering effects of a vegetarian diet can be further improved by reducing salt intake. In a matched-pairs analysis of vegetarians and nonvegetarians, Armstrong et al.¹³ documented that vegetarians had higher urinary potassium excretion (62.9 mmol/day) than the nonvegetarians (54.8 mmol/day), while the urinary excretion of sodium was nonsignificantly higher in the vegetarians (mean of 169.7 vs. 61.2 mmol/day). Such data are consistent with evidence that an increased intake of fruits and vegetables^{14,15} lowers blood pressure. It is doubtful that physical activity accounts for the lower blood pressure of vegetarians. Armstrong et al.⁸ noted that vegetarians and nonvegetarians had similar levels of self-reported, leisure-time physical activity and had similar occupations.

Two trials, one in nonhypertensives¹⁶ and another in hypertensives,¹⁷ have documented that adoption of a vegetarian diet can reduce blood pressure. Other trials have explored the relationship between animal products and specific nutrients (e.g., saturated fat) on blood pressure.⁹ In a trial of nonhypertensive individuals,¹⁶ consumption of a vegetarian diet, similar in nutrient composition to a ovolactovegetarian diet, led to significant reductions in systolic blood pressure (5-6 mmHg) and diastolic blood pressure (2-3 mmHg), compared to a nonvegetarian diet. In the trial of hypertensives,¹⁷ an ovolactovegetarian diet compared to a nonvegetarian diet reduced systolic blood pressure by 5 mmHg but not diastolic blood pressure; sodium and potassium intakes appeared similar in the vegetarian and nonvegetarian diets. Still, neither trial tightly controlled these aspects of the diets. In a series of small trials, exchanging meat and eggs for vegetable products and reducing saturated fat had no significant impact on blood pressure.^{9,18}

In summary, both observational studies and clinical trials indicate that adoption of a vegetarian diet can lower blood pressure. It is likely that the effects on blood pressure result from several factors. While vegetarians tend to weigh less than nonvegetarians and tend to consume more potassium, other aspects of vegetarian diet, yet to be elucidated, also contribute to the blood pressure-lowering effects of these diets.

MEDITERRANEAN-STYLE DIETS

In view of the heterogeneous cultures and agricultural patterns of the Mediterranean region, the "Mediterranean" diet is not a single diet. Rather, this term applies to dietary patterns that emphasize fruits, vegetables, bread, cereals, potatoes, beans, nuts, and seeds; that include olive oil, dairy products, fish, poultry, wine, and eggs; and that are reduced in red meat.¹⁹ As such, these diets tend to be low in saturated fat and high in monounsaturated fat, fiber, and folic acid.²⁰ Although detailed information on the nutrient composition of Mediterranean diets is sparse, such diets are presumably rich in other nutrients, such as potassium. Despite the difficulties of characterizing a Mediterranean-style diet, interest in such diets is considerable because of their apparent health benefits, particularly a reduced risk of coronary heart disease. Recent observational studies have documented that the reduced risk of coronary heart disease from a Mediterranean-style diet extends to the general population,²¹ those with prior coronary heart disease,²² and older-aged adults.²³

In addition to reducing the risk of coronary heart disease, Mediterranean-style diets appear to reduce blood pressure. Early evidence came from the landmark Seven Countries Study. Specifically, in parts of Greece where traditional diets are eaten, the prevalence of hypertension was half that of Western Europe and the United States.²⁴ Subsequently, a cross-sectional study of 1154 Greek women and 1128 Greek men free of cardiovascular disease documented that consumption of a Mediterranean-style diet was associated with a 26% reduced prevalence of hypertension, even after controlling for potential confounders.²⁵

In a recent observational study, the Greek European Investigation into Cancer and Nutrition (EPIC) study, greater adherence to a Mediterranean diet was associated with lower blood pressure.²⁶ In this study, higher blood pressure was associated with a lower intake of olive oil, fruit, and vegetables, and a higher intake of meat, meat products, and cereals. The authors speculate that the high salt intake of cereals accounted for the direct association of cereal intake with blood pressure.

Few trials have tested the effects of Mediterranean-style diets on blood pressure. In one small-scale study that enrolled nonhypertensive adults residing in southern Italy, replacement of their usual diet with a diet increased in saturated fats and reduced in monounsaturated fat and carbohydrate led to an increase in blood pressure.²⁷ A modified Mediterranean-style diet with increased α -linolenic acid had no effect on blood pressure in the Lyon Diet Heart Study.^{28,29}

THE DASH-STYLE DIETARY PATTERNS

In the early 1990s, when the DASH research effort was initiated, the well-established, dietary determinants of blood pressure were weight, salt, and alcohol. However, several lines of evidence suggested that other dietary factors likely influence blood pressure. As discussed previously, vegetarian diets were associated with lower blood pressure in both observational studies and clinical trials. In other observational studies, an increased intake of potassium, calcium, magnesium, fiber, and protein were each associated with lower blood pressure. Still, in clinical trials in which these nutrients were tested separately, reductions in blood pressure were typically small and/or inconsistent.

In this setting, the original DASH trial tested whether modification of whole dietary patterns might affect blood pressure.³⁰ The DASH trial tested two hypotheses: (1) that increased intake of fruits and vegetables lowers blood pressure, and (2) that an overall healthy dietary pattern (initially known as the “combination” diet, now called the “DASH” diet) lowers blood pressure. The DASH trial was the first of a series of three large, controlled feeding studies testing the effects of dietary patterns on blood pressure. Subsequently, the DASH-Sodium trial⁴ tested the main and interactive effects of sodium reduction and dietary patterns, while the OmniHeart trial³¹ determined whether partial substitution of carbohydrate with protein or monounsaturated fat could further lower blood pressure.

In contrast to previous diet–blood pressure trials, which often were supplement trials or behavioral intervention studies, the DASH trial was a feeding study, in which participants received all of their food for 11 weeks. After a 3-week run-in on a control diet that is typical of what many Americans eat, participants were randomized to eat for 8 weeks one of the following three diets: (1) continuation of the control diet, (2) a “fruits and vegetables” diet, or (3) the DASH diet. The DASH diet emphasized fruits, vegetables, and low-fat dairy products; included whole grains, poultry, fish and nuts; and was reduced in fats, red meat, sweets, and sugar-containing beverages (Table 8–1). This diet was rich in potassium, magnesium,

calcium, and fiber, and was reduced in total fat, saturated fat, and cholesterol; it was also somewhat increased in protein, because previous observational studies had noted an inverse association of protein intake with blood pressure.^{32,33} The control diet had a nutrient composition that was typical of that consumed by many Americans at the time the trial was designed. Its potassium, magnesium, and calcium levels were comparatively low, while its macronutrient profile and fiber content corresponded to average U.S. consumption. The fruits and vegetables diet was rich in potassium, magnesium, and fiber, but otherwise similar to the control diet, that is, the macronutrient profile of the fruits and vegetables diet and the control diet were similar.

All three diets contained similar amounts of sodium (approximately 3000 mg/day). Energy intake was adjusted to maintain body weight. Permissible alcohol intake during the trial was no more than two drinks per day. In this fashion, the study directly controlled the major, established dietary determinants of blood pressure (salt, weight, and alcohol).

DASH participants were 459 adults with prehypertension or stage 1 hypertension, that is, a systolic blood pressure of less than 160 mmHg and diastolic blood pressure of 80 to 95 mmHg (not on medication). The mean age was 45 years, average blood pressure was 131/85 mmHg, and 29% had stage 1 hypertension (systolic blood pressure 140–159 mmHg and/or diastolic blood pressure 90–95 mmHg). By design, African Americans comprised 60% of the population.

Among all participants, the DASH diet significantly lowered mean systolic blood pressure by 5.5 mmHg and mean diastolic blood pressure by 3.0 mmHg. The fruits and vegetables diet also significantly reduced blood pressure but to a lesser extent, about 50% of the effect of the DASH diet. Such findings are consistent with other studies, which indicate that increased fruit and vegetable intake can lower blood pressure.^{14,15} The effect of the DASH diet was relatively rapid; the full effect was apparent at 2 weeks and was sustained until the end of feeding 6 weeks later (see Figure 8–2). In subgroup analyses, the DASH diet significantly lowered blood pressure in all major subgroups (blacks, nonblacks, men, women, hypertensives, and nonhypertensives). However, the effects of the DASH diet in black participants (6.9/3.7 mmHg) were significantly greater than corresponding effects in nonblack participants (3.3/2.4 mmHg). The effects in hypertensive individuals (11.6/5.3 mmHg) were particularly striking and were significantly greater than the effects in nonhypertensive (3.5/2.2 mmHg) individuals.³⁴

Results from the DASH trial have led some individuals to question the importance of established dietary risk factors for elevated blood pressure. To this end, the subsequent DASH-Sodium trial provided convincing empirical support for recommendations to simultaneously implement sodium reduction with the DASH diet. The DASH-Sodium trial tested the effects of sodium reduction and the DASH diet, alone and combined, on blood pressure. While sodium reduction alone and the DASH diet alone each lowered blood pressure, the combination of sodium reduction with the DASH diet led to the largest blood

pressure reductions.⁴ Overall, adoption of the DASH diet should supplement, rather than supplant, established lifestyle changes to reduce blood pressure.

The DASH diet, as well as the diets studied in OmniHeart trial (discussed later), are safe and broadly applicable to the general population. However, because of their relatively high potassium, phosphorus, and protein content, these diets are not recommended in persons with stage 3 or 4 chronic kidney disease, that is, an estimated glomerular filtration rate of less than 60 mL/min/1.73 m².³⁵

Speculation about the effective (and ineffective) components of the DASH diet has been considerable. The diet that emphasized fruits and vegetables resulted in blood pressure reductions that were approximately half of the total effect of the DASH diet. Fruits and vegetables are rich in potassium, magnesium, fiber, and many other nutrients. Of these nutrients, potassium is best established as a means to lower blood pressure, particularly in persons with low intake, in persons with hypertension, and in blacks.³⁶

Aside from testing fruits and vegetables, the DASH trial was not designed to identify the specific nutrients and foods responsible for the observed reductions in blood pressure. Compared to the fruits and vegetables diet, the combination diet had more vegetables, low-fat dairy products, fish, calcium, protein, and complex carbohydrate, and was lower in saturated fat, monounsaturated fat, total fat, cholesterol, and red meat. Hence, inferences about the effects of specific nutrients and foods are largely speculative, and rely more on the interpretation of data from other studies than on results of the DASH trial itself.

While the blood pressure reductions from the DASH diet are impressive, it is plausible that this carbohydrate-rich dietary pattern can be improved by replacing some carbohydrate with either protein or monounsaturated fat. With this objective, the OmniHeart trial compared the effects of three healthy dietary patterns—a diet rich in carbohydrate (similar to the DASH diet), a second rich in protein (about half from plant sources), and a third diet

Figure 8–2. Blood pressure by week during the Dietary Approaches to Stop Hypertension feeding study in three diets (control diet, “fruits and vegetables diet,” and “DASH diet”). (Adapted from Appel LJ, Moore TJ, Obarzanek E, Vollmer WM, Svetkey LP, Sacks FM, et al. *N Engl J Med* 1997;336(16):1117–24. Copyright 1997 Massachusetts Medical Society.)

rich in unsaturated fat (predominantly monounsaturated fat)³¹ (Table 8–2). All three diets were reduced in saturated fat, cholesterol, and sodium, and rich in fruit, vegetables, fiber, potassium, and other minerals at recommended levels. As displayed in Figure 8–3, *A* and *B*, each diet lowered systolic blood pressure. Furthermore, substituting some of the carbohydrate (approximately 10% of total kilocalories) with either protein (about half from plant sources) or with unsaturated fat (mostly monounsaturated fat) further lowered blood pressure.

Results from the DASH, DASH-Sodium, and OmniHeart trials have important clinical and public health implications. The effect of DASH-style diets in hypertensives is similar in magnitude to drug monotherapy for hypertension. Hence, these dietary patterns should be an effective initial treatment for hypertension before prescription of drug therapy. Although none of the trials enrolled medication-treated hypertensives, DASH-style diets, similar to other effective lifestyle changes, should also be an effective adjuvant therapy.

From a public health perspective, DASH-style diets may be an effective means to prevent hypertension. In addition, adoption of a DASH-style diet could shift the population blood pressure distribution downward, thereby reducing the risk of blood pressure–related cardiovascular disease. It has been estimated that a population-wide reduction in blood pressure of the magnitude observed in

the DASH trial could reduce stroke incidence by 27% and coronary heart disease by 15%. In addition to reducing blood pressure, the DASH-style diets are nutrient-rich and meet each of the major nutrient recommendations established by the Institute of Medicine.^{37,38}

DASH-Sodium and OmniHeart were controlled feeding studies. To determine the feasibility and effects of the DASH diet in the context of established lifestyle recommendations, the PREMIER trial tested the effects of two multifactorial interventions in comparison to an advice-only control group. One lifestyle intervention attempted to reduce weight, lower sodium intake, and increase physical activity. One of the interventions also included the DASH diet. Those assigned to the latter group increased their intake of fruits, vegetables, and dairy products but, in the contrast to the DASH feeding studies, did not achieve the nutrient and food group targets of the DASH diet. Still, the best blood pressure control was consistently observed in the group that also received the DASH diet.^{39,40}

CARBOHYDRATE

A complex body of evidence suggests that both type and amount of carbohydrate affect blood pressure.⁴¹ Worldwide, there are many societies that eat carbohydrate-rich, low-fat diets that have low blood pressure levels compared to Western populations.⁴² Still, data from observational

^aBy design, the following nutrient targets were similar in each diet: cholesterol <150 mg/day, fiber ≥30 mg/day, sodium 2300 mg (100 mmol)/day, potassium 4700 mg (120 mmol)/day, magnesium 500 mg/day, and calcium 1200 mg/day.

^bNutrient targets in the DASH diet were identical to those in the CARB diet, except that in DASH, the proportion of kilocalories from protein was 18% and from carbohydrate was 55%. Bolded italic text highlights major differences between diets.

^cThe glycemic index of the three diets was moderate and similar (68 in CARB, 71 in PROT, and 75 in UNSAT).

^dThe average daily intake of soy protein was 0.5 g in CARB, 7.3 g in PROT, and 0.5 g in UNSAT.

CARB, similar to the DASH diet; DASH, Dietary Approaches to Stop Hypertension; PROT, rich in protein, about half from plant sources; UNSAT, rich in monounsaturated fat.

Table 8–2. Nutrient Targets and Average Daily Servings of Foods by Diet at 2100 kcal in OmniHeart Trial

studies that specifically examined the effect of carbohydrate intake on blood pressure have been inconsistent (direct in one study,³² no association in another,⁴³ and inverse association in another⁴⁴). In early trials, typically small, increasing carbohydrates by reducing total fat generally did not reduce blood pressure.⁴⁵ In contrast, the recently completed OmniHeart feeding study documented that in the setting of a healthy diet similar to the DASH diet, partial substitution of carbohydrate with either protein (about half from plant sources) or monounsaturated fat

A

B

Figure 8–3. Effects of three healthy dietary patterns tested in the OmniHeart feeding study on systolic blood pressure in all participants (A) and in hypertensive participants (B). CARB, similar to the DASH diet; PROT, rich in protein, about half from plant sources; UNSAT, rich in monounsaturated fat. (Adapted from Appel LJ, Brands MW, Daniels SR, Karanja N, Elmer PJ, Sacks FM, et al. *Hypertension* 2006;47(2):296–308.)

lowers blood pressure; importantly, the type of carbohydrate in each diet, as indicated by the total dietary glycemic index, was moderate and virtually identical in each diet.³¹

Some trials have tested the effects of acute sugar consumption on blood pressure. In several^{46,47} but not all studies,⁴⁸ consumption of sugars increased blood pressure. Consistent with these studies are results from a weight-loss trial in which a low glycemic index–diet reduced blood pressure to a greater extent than a standard high glycemic index.⁴⁹ Potential mechanisms for a direct effect on blood pressure include interactions with salt intake, promotion of salt retention,^{46,50} and increased catecholamine production or release with stimulation of the sympathetic nervous system.^{51–54} Overall, additional research is warranted prior to making specific recommendations about the amount and type of carbohydrates as a means to lower blood pressure.

PROTEIN

A paradigm shift has occurred regarding the effects of dietary protein intake on blood pressure. The prevailing belief regarding protein's effect on blood pressure has been that there is either no association⁵⁵ or a direct association.^{8,42,56} As highlighted below, the best available

evidence is that increased protein intake, particularly from plant sources, can lower blood pressure.

As reviewed by Obarzanek et al.⁵⁷ and subsequently by He and Whelton,⁵⁸ an extensive, and generally consistent, body of evidence from observational studies has documented significant inverse associations between protein intake and blood pressure. Observational studies also suggest that an increased protein intake, especially protein from plant sources, might prevent cardiovascular disease.^{59,60} Among the earliest findings were observations from the 1970s and 1980s in Asian countries, especially Japan and China, in which there was an inverse association between protein intake and rates of hypertension and stroke.^{61,62} Subsequently a large number of observational studies reproduced this relationship. Recently two major observational studies, the International Study on Macronutrients and Blood Pressure (INTERMAP) and the Chicago Western Electric Study, documented significant inverse relationships between protein intake and blood pressure.^{44,63} In these studies, protein from plant sources was associated with lower blood pressure, while protein from animal sources had no effect.

Some trials have also examined the effects of increased protein intake on blood pressure. Most of these trials tested soy-based interventions on blood pressure. In some but not all of these trials, soy supplementation replacing carbohydrates reduced blood pressure.^{64,65} One of the most persuasive studies is a recent large trial conducted in China which documented that increased protein intake from soy supplements, replacing carbohydrates, lowered blood pressure.⁶⁶ In the recently completed OmniHeart study, partial substitution of carbohydrates with protein (about half from plant sources) lowered blood pressure.³¹

Several mechanisms by which protein might lower blood pressure have been proposed. One potential set of mechanisms focuses on the biological effects of constituent amino acids. Synthesis of catecholamines in the central nervous system is affected by the intake of tyrosine and phenylalanine.⁶⁷ Tyrosine⁶⁸ and tryptophan⁶⁹ lower blood pressure when injected intraperitoneally into animals. Histidine (a precursor for the synthesis of histamine) contributes to regulation of sympathetic nervous system⁷⁰ and dilation of peripheral vessels.⁷¹ Arginine is the metabolic precursor of nitric oxide, a powerful vasodilator

EFFECTS OF DIETARY FACTORS AND DIETARY PATTERNS ON BLOOD PRESSURE: SUMMARY OF THE EVIDENCE

DASH, Dietary Approaches to Stop Hypertension.		

Table 8-3. Effects of Dietary Factors and Dietary Patterns on Blood Pressure: Summary of the Evidence

that acts on the endothelium.⁷² According to Moncada and Higgs,⁷² increased ingestion of arginine may reverse vascular reactivity changes and reduce intimal thickness in atherosclerosis, reduce the excessive proliferation of smooth muscle cells in hypertension, and lower blood pressure. Taurine may reduce blood pressure by natriuretic and diuretic effects in the kidney or inhibitory effects on the renin angiotensin system.⁷³ Alternatively or concomitantly, biologically active peptides (e.g., peptides with angiotensin-converting enzyme inhibitor activity) may lower blood pressure.⁷⁴

In aggregate, data from clinical trials, in conjunction with evidence from animal studies and observational studies, support the hypothesis that substitution of carbohydrates with increased intake of protein, particularly from plants, can lower blood pressure. However, it remains uncertain whether the effects result from increased protein or reduced carbohydrate.

SUMMARY

A substantial body of evidence strongly supports the concept that multiple dietary factors affect blood pressure

(Table 8–3). Dietary modifications that effectively lower blood pressure are weight loss, reduced salt intake, increased potassium intake, and moderation of alcohol consumption (among those who drink). Available evidence is sufficiently strong to conclude that certain dietary patterns—specifically, DASH-style diets, vegetarian diets, and perhaps Mediterranean-style diets—also lower blood pressure. Substitution of carbohydrate with protein from plant sources or monounsaturated fat also reduces blood pressure. Other dietary factors may affect blood pressure, but the effects are small and/or the evidence is uncertain.

DASH-style diets, vegetarian diets, and Mediterranean-style diets, while distinctive, share several common features. Each is rich in fruits, vegetables, and other plant products such as nuts and seeds, and each is reduced in saturated fat and meats. Each diet has several variants, thereby enhancing their generalizability and appeal. Efforts to enhance the adoption of these dietary patterns are warranted in view of their beneficial effects on blood pressure and cardiovascular disease.

Renovascular Hypertension: Pathophysiology and Evaluation of Renal Function

Sabas I. Gomez, John A. Haas, and J. Carlos Romero

Definition

Renovascular hypertension (RVH) is the elevation of blood pressure (BP) that follows the incomplete occlusion of one or both renal arteries.

In humans, the partial occlusion of one renal artery is produced by fibromuscular dysplasia or atherosclerosis.

In animals, RVH is induced by constricting the renal artery with a clamp or with a stent that induces intimal arterial hyperplasia.

Key Findings

- Experimental reduction of renal perfusion pressure (RPP) leads to an initial increase in plasma renin activity (PRA) that correlates with both the degree of the stenosis and the increase in blood pressure. In a later phase, plasma renin activity is “normalized” at the same time that there is a progressive elevation of oxidative stress, which from that point on correlates with the increase of BP.
- The increase in BP tends to restore renal blood flow (RBF) in the stenotic kidney and it increases RPP in the contralateral kidney, producing a compensatory natriuresis. This equilibrium could persist for years when the stenosis is mild.
- In cases with severe stenosis, the increase in BP needed to restore RBF is so large that it is followed by cardiac insufficiency and volume depletion (through natriuresis in the contralateral kidney), which lead to renal failure.
- Unilateral constriction of a renal artery produces a decrease in renal volume on the stenotic side, while it increases the volume of the contralateral kidney. In the stenotic kidney, the degree of the stenosis correlates with a fall in RBF, glomerular filtration rate (GFR), tubular sodium load, and sodium excretion. In the contralateral kidney, there is a marked opposite directional change in all of these parameters.
- This sequence of events is reproduced by the intravenous infusion of small subpressor doses of angiotensin II (Ang II), which stimulates the production of oxidative stress and chronically increases BP in the same fashion as that seen in RVH.
- Slow pressor responses are greatly facilitated by sodium overload. Sodium depletion abolishes slow pressor responses along with the “side effects” of angiotensin such as cardiac hypertrophy, inflammation, or stimulation of oxidative stress.
- All changes in renal hemodynamics and renal tubular function can be estimated with three-dimensional computerized tomography that has high temporal resolution.

Clinical Implications

- Accurate determinations of changes in renal hemodynamic and tubular function in both the stenotic and contralateral kidneys plus the level of oxygen consumption with BOLD-MRI will allow the clinician to evaluate renal function more accurately as well as better determine the efficacy of revascularization on medical treatment.

In 1937, Goldblatt et al.^{1,2} demonstrated that in the dog, constriction of one renal artery (two-kidney, one-clip Goldblatt hypertension, or 2KD-1CGH) without disturbing the contralateral kidney is followed by a significant increase in mean arterial pressure (MAP). However, the mechanisms responsible for hypertension in this model are still debatable.^{3–5} These problems, along with the lack of knowledge about the specific changes induced in the stenotic kidney by arterial constriction, as well as in the contralateral kidney by the development of hyperplasia, has made it difficult to assess renal function, and thereby to predict the clinical outcomes of surgical interventions or medical treatments that are directed to correct the stenosis^{6–8} or to reduce hypertension by medical treatment.

This chapter examines new developments in the pathogenesis of renovascular hypertension that have been obtained by the application of novel x-ray and magnetic resonance imaging (MRI) techniques.

EFFECTS OF RENAL ARTERIAL CONSTRICTION ON RENAL HEMODYNAMICS AND SODIUM EXCRETION

In the stenotic kidney, the acute decrease of renal perfusion pressure (RPP) below the range of autoregulation (<75 mmHg), is accompanied by a proportional and transient decrease in renal blood flow (RBF) and glomerular filtration rate (GFR),^{9,10} and by a very prominent fall in tubular fluid dynamics (TFD) and urinary sodium excretion.^{11,12} These changes are followed by a significant increase in the renal content of renin¹³ and plasma renin activity (PRA).^{3,10,14,15} These elevations of PRA are most likely responsible for the immediate increase in sodium retention and in MAP (about 20 to 40 mmHg, depending

on the severity of the stenosis), which reaches a plateau and stabilizes within the following 2 weeks.^{10,15} In fact, during the acute phase of hypertension, PRA correlates with the increase in MAP,^{10,16} while the administration of angiotensin II (Ang II) converting enzyme or Ang II receptor antagonists produces a rapid (<1 hour) normalization of MAP.^{17–19} This increase of MAP does not affect RBF or GFR in the contralateral kidney because of a vasoconstrictor response due to renal autoregulation.^{11,12} Pressure natriuresis in the contralateral kidney is significantly increased; however, it is blunted by the antinatriuretic effect of high levels of circulating Ang II.^{4,20} Under these conditions, a rather unstable equilibrium is reached where the hypertension and antinatriuresis due to activation of the renin-angiotensin system (RAS) improves perfusion of the stenotic kidney without imposing a significant functional load on the contralateral kidney.¹⁰ This marks the transition to stable chronic phase (Figure 9–1, A), which equilibrium can be broken by changes in the degree of stenosis and/or in fluid volumes. For example, in well-controlled studies, Ferrario et al.²¹ and Leenen and de Jong²² showed that in animals with mild renal stenosis, RBF was restored with moderate elevations of systemic blood pressure (BP), while the animals with severe renal artery stenosis required very high levels of BP. This increase of BP overwhelms the antinatriuretic effects of Ang II, producing a marked increase in sodium excretion in the contralateral kidney. This response could lead to volume depletion and a significant fall in MAP, which stimulates more release of renin inducing an even more pronounced vasoconstriction. All of these changes could easily precipitate renal failure (Figure 9–1, B). Wilson et al.²³ were the first to characterize this vicious circle in rabbits, which was later on studied in more detail by Möhring et al.²⁴ in rats, while Barraclough²⁵ showed that this outcome could occur in humans. This response,

similar to that occurring in the chronic phase of 2KD-1CGH, represents a compromise between the level of increase in BP (which is needed to restore the function in the stenotic kidney) and the ability of the contralateral kidney to maintain fluid volume in spite of pressure-induced natriuresis.^{5,10,26} Such equilibrium is an important feature because the tendency toward volume depletion will render hypertension almost entirely dependent on the levels of plasma renin. In these circumstances, high BP can be normalized by blocking Ang II.

On the contrary, excessive sodium retention or an amount of sodium retention inappropriate to the existing levels of Ang II will render hypertension very dependent on volume or oxidative stress and endothelin,²⁷ while blockade of the RAS will have a smaller effect^{17,19} on both oxidative stress and endothelin, and on MAP. This assumption is well illustrated by a study we conducted to assess the role of Ang II and sodium intake in rabbits having severe and moderate 2KD-1CGH.²⁸ In these animals, severe hypertension (BP increased from control levels of 80±3 mmHg to 117±3 mmHg) occurred with high levels of plasma renin activity (21.6 ng/mL/h). This was accompanied by high levels of plasma creatinine and ECFV depletion (as measured with inulin). Correction of volume depletion with a high-sodium diet for 10 days decreased PRA, while BP fell from 117±3 to 98±2.5 mmHg and also improved plasma creatinine. The same effect was obtained after intravenous administration of 1000 ng/kg/min of saralasin (a peptide analog that blocks Ang II). In contrast, moderate 2KD-1CGH, which elicited a BP level of 97±2 mmHg, was not altered by a high-sodium diet, volume expansion, or angiotensin antagonist (Figure 9–2). In this study, there was no attempt to define the effects of volume depletion. However, in pilot studies, volume depletion with diuretics failed to increase BP in moderately hypertensive rabbits, in spite of a very signifi-

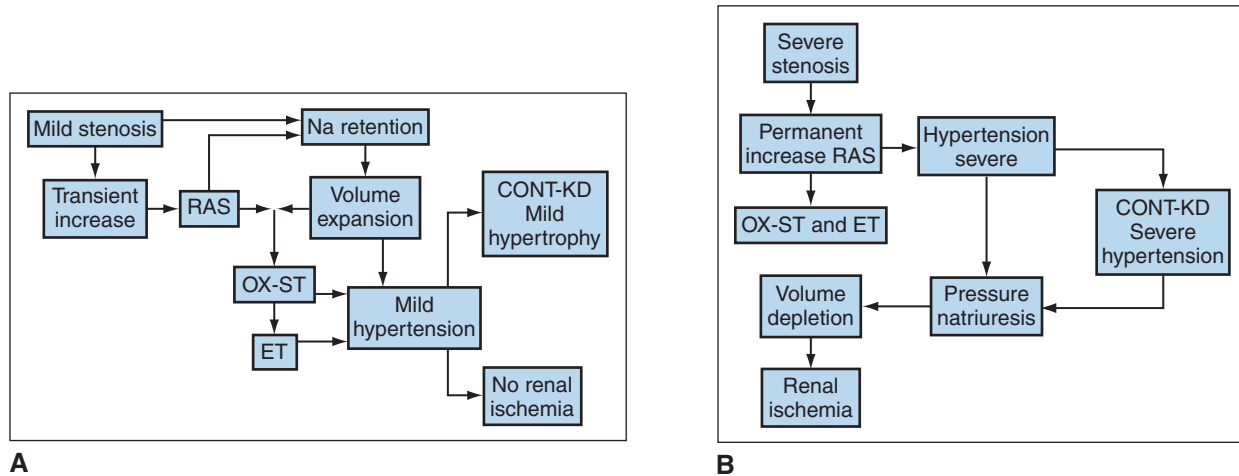

Figure 9–1. Effects of mild (A) and severe (B) stenosis during the development of unilateral renovascular hypertension. In mild stenosis, the increase in systemic blood pressure is sufficient to restore renal circulation in the stenotic kidney, but is not enough to provoke in the contralateral kidney pressure natriuresis, thus reaching an equilibrium. This is in contrast with the effect of severe stenosis (B), which needs a very significant elevation of blood pressure to restore the perfusion of the stenotic kidney. This induces pressure natriuresis, which is followed by volume depletion that aggravates renal ischemia; the most likely outcome of this latter decompensation is renal insufficiency. CONT-KD, contralateral kidney; ET, endothelin; OX-ST, oxidative stress; RAS, renal artery stenosis.

Figure 9-2. Effect of intravenous infusion of angiotensin II^{1,8} (ang ant) on normotensive rabbits and after the development of renovascular hypertension during normal and high salt intake. Vertical bars represent mean plus standard error.

cant increase in PRA. These may be due to the fact that the increase in PRA, produced by diuretics, is secondary to volume depletion, whereas in the development of severe RVH, the increase in PRA occurs first and volume depletion is secondary to hypertension (pressure natriuresis). Discussion about the possibility of activating a secondary hypertensive mechanism has relied upon the assumption that the level of Ang II is inappropriate with the existing fluid volumes or vice versa.²⁷ However, the significance of circulating levels of Ang II remains ill defined. Nishiyama et al.²⁹ and van Kats et al.³⁰ have shown that the infusion of minute amounts of Ang II is rapidly accumulated in the kidney yielding cortical and medullary levels that were 20 and 19 times higher, respectively, than the concentration in plasma.²⁹ These results raise a question on the extent to which the inverse correlation that exists between circulating plasma Ang II and extracellular fluid volumes may be less significant than the relationship between the intrarenal concentration of Ang II (in renal interstitium) versus renal interstitial pressure. As pointed out in an extensive review on this subject, the interstitial pressure of the kidney is highly positively correlated with changes in extracellular fluid volumes.²⁷

Finally, it should be emphasized that high levels of circulating Ang II do not necessarily stimulate oxidative stress, as occurs in severe sodium restriction. In order for Ang II to stimulate oxidative stress, the levels should be inappropriately high with respect to fluid volumes. Under these conditions, there is a reduction of nitric oxide (NO) and a production of significant levels of peroxynitrites and isoprostanes (ISOP).²⁷ These changes appear to favor an increase in the synthesis of endothelin which could be stimulated by Ang II or by some components of oxidative stress.^{31,32} In this manner, the decrease in the concen-

tration of the vasodilator NO with a concomitant elevation of ISOP and endothelin will significantly enhance the vasoconstrictor effect of Ang II, which explains the slow pressor response, or they may sustain hypertension *per se* without a prominent participation of Ang II.²⁷

There are some additional aspects with respect to the equilibrium among Ang II, sodium balance, oxidative stress, and endothelin that deserve comment. In the majority of cases, the functional equilibrium between the stenotic kidney and the contralateral kidney is achieved and can last for years, during which the effects of high BP on the contralateral kidney are characterized by development of progressive arterial hyperplasia, glomerular obsolescence, renal hyperplasia, and nephrosclerosis.³³ Meanwhile, the stenotic kidney undergoes vascular and tubular atrophy and mitotic hyperplastic transformation with different degrees of inflammation.^{26,34} All these anatomic alterations in both kidneys are assumed to be accompanied by specific changes in tissue perfusion index (TPI=milliliters of blood per gram of tissue), RBF distribution, and TFF in superficial and deep nephrons. In the past, these changes have only been partially assessed by micropuncture studies in superficial nephrons.^{26,35,36} We intend in this overview to examine the results of recent studies performed with the use of novel noninvasive computerized tomography with high temporal resolution. This technique has allowed evaluation of the specific hemodynamic and tubular functional changes that coexist with defined renal anatomic alterations in each kidney. Renal ischemia is measured indirectly by estimating with MRI the renal levels of deoxyhemoglobin (dHb), and allows a significant advance in diagnosis of the stenosis, and more accurate predictability of successful stenosis repair or revascularization.

ROLE OF RENIN-ANGIOTENSIN SYSTEM

Earlier studies reported that the inhibition of Ang II formation with converting enzyme inhibitor (CEI) produced a significant decrease of MAP only when administered in the early phase of 2KD-1CGH (within the first 2 weeks).^{4,17-19} However, no immediate effects on BP (1 to 2 hours) were noticed when these maneuvers were performed in the chronic phase (more than 4 weeks) of hypertension.^{19,26} These results were interpreted as indicating that the early phase of 2KD-1CGH was “renin dependent,” while another mechanism was responsible for the maintenance of hypertension in the chronic phase.²⁶ At that time, some investigators thought that in the chronic phase of hypertension, the increase in total peripheral resistance was due to arteriolar hyperplasia. However, this assumption was not supported by experimental evidence showing that chronic hypertension was completely reversed by removing the renal arterial constriction or by removal of the clipped kidney.^{23,37} Furthermore, Miller et al.³⁸ showed that the chronic phase of 2KD-1CGH was blunted if the formation of Ang II was inhibited prior to the constriction of the renal artery with CEI. These observations in animals have correlative observations in humans.³⁹⁻⁴¹ In general, the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 6) explicitly recognizes the potential for BP reduction to slow the progression of renal disease in essential hypertension. Nonetheless, the major stumbling block in RVH (as opposed to essential hypertension) is that the reduction of systemic pressure can aggravate the underperfusion of the stenotic kidney,⁴² particularly when the therapy is supplemented by diuretics.^{42,43} However, reduction of BP is very beneficial in the contralateral kidney.⁴³⁻⁴⁵ In one of these studies, the administration of Ang II converting enzyme produced a shrinking of the stenotic kidney with fibrosis and marked atrophy (called medical nephrectomy) while the structure and function of the contralateral kidney were preserved.⁴⁶ The damage in the stenotic kidney was not attributed to the effect of BP reductions because it was not seen during administration of minoxidil; however, the beneficial effects of BP reduction in the contralateral kidney were more evident with CEI than with minoxidil.⁴⁶ The lack of information about oxidative stress and endothelin and the relative effects on these processes produced by CEI or minoxidil make interpretation of the results difficult. In general, all other studies show that there is great variability of antihypertensive treatments to restore BP or renal function.⁴²

THE SO-CALLED SLOW PRESSOR RESPONSES TO ANGIOTENSIN II

The reasons for the variable efficacy of CEI and Ang II antagonist to lower BP during the chronic phase of Goldblatt hypertension are consistent with the fact that the levels of PRA are within the range found in normotensive animals.^{10,15,19,47,48} The occasional hypotensive response to CEI has been explained by assuming that the

blockade of ACE (which is also a kininase II) produces simultaneously an accumulation of (unmetabolized) bradykinin. However, experimental data have failed to support this assumption.⁴⁹

Another possibility to explain how normal levels of Ang II maintain high levels of BP in 2KD-1CGH is that Ang II activates an independent vasoconstrictor mechanism that initially potentiates its pressor effect and that later on may act, to a certain extent, independent of Ang II. In fact, it has been shown that the intravenous infusion of a small (subpressor) concentration of Ang II, one not sufficient to acutely produce any significant increase in BP, induces very sustained hypertension when given for several days.^{20,50} This response should be distinguished from the “fast pressor responses,” which are characterized by a rapid elevation of BP (reaching a maximal response in 1 to 2 minutes) that follows the infusion of large doses (60 to 800 ng/mL/kg) of Ang II.⁵¹ In contrast, the “slow or indirect pressor effect” developed progressively and may reach a maximum following 7 to 10 days of intravenous infusion.^{4,20,52,53} In a study conducted by Brown et al.,⁵³ it was shown that the infusion of 10 ng/kg/min of Ang II to normotensive rats increases BP by 40 mmHg, reaching a plateau on the 7th day of infusion. These levels of BP could only be reached in normotensive rats by the rapid infusions of 270 ng/kg/min of Ang II, in which case the circulating levels of Ang II measured 1 minute after was approximately 2220 pg/mL of Ang II. In contrast, the rats with a chronic infusion of Ang II, having a similar level of hypertension, exhibited circulating levels of Ang II (230 pg/mL) that were slightly elevated with respect to those recorded in normotensive untreated rats (150 pg/mL). Blockade of Ang II with Ang II receptor antagonist produced, in the group chronically infused with Ang II, a reversal of hypertension in the following 7 hours. These studies have been confirmed and extended by Hu et al.⁵⁴ who showed that slow responses can be induced not only by Ang II (3 ng/kg/min), but also by very minute amounts (0.3 ng/kg/min) of recombinant renin.⁵⁴ Under these conditions, the levels of circulating Ang II (6±2 ng/mL) do not differ from those measured during the control period (5±2 ng/mL)⁵⁴ (Figure 9-3). Because of the time required for the development of the slow responses, it is tempting to postulate that this phenomenon occurs after the initial phase (1 week) in the development of RVH, and that the chronic phase is better characterized by the increase in oxidative stress and endothelin.

SODIUM BALANCE

Brunner et al.⁵⁵ have shown that the physiologic levels of PRA correlate inversely with the amount of sodium intake in normotensive or hypertensive patients. This relationship indicates that for any given level of sodium intake, the existing levels of Ang II and NO are within the range needed to maintain sodium balance and normal arterial pressure. Reciprocally, one can also say that any plasma level of PRA that is within the normal range can induce hypertension if it is inappropriately high with respect to fluid volume. These characteristics have been eloquently

Figure 9-3. Plasma angiotensin II (vertical axis) level during renin (orange bars) or angiotensin (green bars) infusions of 3 ng of angiotensin per minute. * $p < 0.05$ versus control period. C, control days; E, experimental days; R, recovery days.

exposed by the studies of DeClue et al.,⁵⁶ who showed that if circulating levels of Ang II are clamped by a continuous infusion of Ang II at the rate of 5 ng/kg/min, then the level of BP is determined by the amount of sodium intake (Figure 9-4). Moreover, under similar conditions where circulating levels of Ang II have been clamped (5 ng/kg/min), and the intake of sodium chloride has been set at 500 mEq/day, administration of a diuretic (furosemide) tends to normalize BP by reducing fluid volumes (to levels that are presumably appropriate to the concentration of Ang II). Krieger and Cowley⁵⁷ lend support to the previous finding by showing that Ang II-induced hypertension can be prevented if volume expansion is prevented by controlling sodium intake.

The concept of excessive levels of Ang II with respect to the level of sodium intake was first introduced by Hollenberg et al.,⁵⁸ showing that some hypertensive individuals are incapable of lowering the level of renin activity during volume and expansion. They call this group “non-modulators,” and the alteration was corrected by the administration of CEIs because it brought the levels of Ang II to a level appropriate to the existing fluid volume. There is also evidence that the chronic phase of moderate RVH exhibits many of the characteristics of the slow pressor responses to Ang II. For example, during the first month of the development of hypertension, there is a significant correlation between the elevation of systemic plasma renin activity and the absolute increase in MAP from control levels. As mentioned previously, during this phase renin plays a predominant role in sustaining hypertension. In contrast, after 2 months of the development of hypertension, the levels of plasma renin activity are nearly normal and exhibit a very poor correlation with BP. In contrast, the circulating level of isoprostane, which as mentioned previously is a marker of oxidative stress, exhibits a poor correlation during the first month of the development of hypertension. However, after 2 months the level of circulating isoprostane is proportional and correlates with increases in BP. Interestingly, all the studies mentioned thus far indicate that the elements which participate in chronic phase of renovascular hypertension

may not be different than those participating in essential hypertension. In both forms of hypertension, the kidney plays an important role⁵⁹—it evolves with normal levels of plasma renin or angiotensin, there is a secondary activation of oxidative stress, and both are characterized by an isolated increase in total peripheral resistance. These similarities have been emphasized by Hall.⁶⁰

OXIDATIVE STRESS

Two of the major components of oxidative stress are superoxide and hydrogen peroxide (H_2O_2). Superoxide and H_2O_2 can be generated in many vascular cells, and are derived from NADPH oxidase, cyclooxygenase, lipoxygenase, heme oxygenases, peroxidases, and hemoproteins such as heme and hematin.²⁷ The mechanism(s) by which Ang II causes production of superoxide has not been entirely elucidated. However, Mollnau et al.⁶¹ found that chronic (7 days) Ang II infusion increased expression of nox 1, gp91(phox), and p22(phox) subunits of NADPH oxidase via a protein kinase C mechanism.²⁷ This Ang II-mediated increase in the production of superoxide then sets into motion a series of events that play important roles in hypertension.

Under normal conditions (Figure 9-5, left), the superoxide that is produced in the cell combines with superoxide dismutase (SOD), which converts it to H_2O_2 . H_2O_2 is further metabolized to H_2O by the action of catalase and glutathione peroxidase, but under pathologic conditions (Figure 9-5, right) when an oxidative environment is present in cells, H_2O_2 can be a source of hydroxyl radicals.²⁷ Also, under oxidative conditions, tetrahydrobiopterin (BH_4), a cofactor required for the NO synthase (NOS) activity, can

Figure 9-4. Percent changes in mean arterial pressure induced by progressive elevation of sodium intake (horizontal axis) in normal dogs and dogs receiving a continuous intravenous infusion of angiotensin. Ang II, angiotensin II; MAP, mean arterial pressure.

Figure 9-5. Normal physiology (*left*). Angiotensin II (Ang II) has been shown to upregulate synthesis of NAD(P)H oxidase subunits to produce superoxide (O₂⁻). Under normal conditions, superoxide will be converted by superoxide dismutase (SOD) to hydrogen peroxide (H₂O₂). Hydrogen peroxide is converted to water via the actions of catalase. In the presence of tetrahydrobiopterin (BH₄), nitric oxide synthase (NOS) produces nitric oxide (NO) from L-arginine (L-Arg). Pathophysiology (*right*). Under oxidative conditions, BH₄ is converted to dihydrobiopterin (BH₂), and NOS produces superoxide (O₂⁻). A combination of O₂⁻ and NO is peroxynitrite (ONOO⁻). Peroxynitrite produces vasoconstriction by converting arachidonic acid (aa) to F₂-isoprostanes and by increasing thromboxane A₂ (TxA₂). Peroxynitrite also causes vasoconstriction by inhibiting prostacyclin (PGI₂) synthase and thereby decreasing vasodilator prostacyclin (PGI₂).

be oxidized to dihydrobiopterin (BH₂). In this case, NOS will produce superoxide rather than NO,⁶²⁻⁶⁴ making this another mechanism by which ROS can be produced and NO concentrations can be reduced.

RECENT ADVANCES IN THREE-DIMENSIONAL COMPUTERIZED TOMOGRAPHY WITH TEMPORAL RESOLUTION IN MEASURING CHANGES IN INTRARENAL DISTRIBUTION OF BLOOD FLOW AND TUBULAR DYNAMICS

Romero and Lerman⁶⁵ surveyed the major advances made in the exploration of renal function since the development of static and dynamic computerized tomography (CT). One of the most important steps toward the estimation of organ blood flow was made by a team of investigators at the Mayo Clinic who developed the first three-dimensional (3D) computerized tomography scanner with high temporal resolution.⁶⁶ This instrument was successfully used to measure changes in intrarenal distribution of blood flow, and the accuracy of these determinations was better than with any other method, including inert gases, thermodynamics, microspheres, and so on.^{67,68}

The theoretical basis to study renal function from image reconstruction was published in 1986.⁶⁹ Furthermore, 3D tomography with temporal resolution is an excellent methodology to study changes in total RBF, medullary and cortical blood flow, and renal volume.⁷⁰ Jaschke et al.⁷¹ were the first to indicate the convenience of electron-beam CT to study the distribution of blood flow. Electron-beam CT measures functional changes in both kidneys during the development of RVH. Excellent correlations were found between RBF measured with electromagnetic flow probes and electron-beam CT and between GFR measured with inulin and electron-beam CT (Figure 9-6).

Electron-beam CT scanning during the renal passage of contrast media, which behaves like inulin (filtered in the glomeruli and not reabsorbed by the renal tubules), yields a profile of density changes in proximal tubules, descending and ascending segments of the loop of Henle, distal nephrons, and collecting ducts, which reflects tubular reabsorption in these segments (Figure 9-7). This concept was confirmed by measuring changes in contrast medium concentration along the renal tubules induced by furosemide.⁷² This diuretic reduces sodium chloride reabsorption in the thick ascending loop of Henle. Consequently, electron-beam CT estimations showed a decrease in tubular fluid transit time and a concomitant enhancement of tubular fluid concentration from the proximal to the loop of Henle, while both transit times in distal tubules and collecting ducts were shortened along with a fall in tubular fluid concentrations.

CHANGES IN RENAL HEMODYNAMICS IN STENOTIC AND CONTRALATERAL KIDNEYS IN RENOVASCULAR HYPERTENSIVE PIGS

Results of studies conducted before and after the development of hypertension due to unilateral renal arterial constriction in swine are illustrated in Figure 9-8. It can be seen that during the control period when the MAP in the aorta was 105±3 mmHg, the right and the left kidney exhibited a volume of 75±3 and 78±3 cm³, respectively. Under these conditions the blood flow to each of these kidneys was 323±5 mL/min and 340±6 mL/min, respectively. Tissue perfusion, the amount of blood perfusing each gram of tissue, was 4.31±0.3 for the right kidney and 4.37±.4 mL/cm³ for the left kidney. After 1 month of renal arterial constriction, when MAP was 145±5 mmHg, there was a significant reduction in volume in the stenotic kidney to 68±3 cm³, whereas the contralateral kidney volume increased by 66% to 125±5 cm³. These changes were accompanied by an 18% reduction in blood flow to 276±7 mL/min in the stenotic kidney, whereas in the contralateral kidney renal blood flow was increased by 78% to 576 mL/min. It should be noted that in spite of this opposite directional change in both kidneys, the amount of kidney blood flow per gram of tissue remained relatively constant. Flow per gram of kidney weight decreased only by 0.06% (to 4.07±0.3 mL/cm³) in the stenotic kidney, while the same flow increase by only 0.07% in the contralateral kidney to 4.61 cm³. These

Figure 9-6. Correlation between measurement of glomerular filtration rate performed with inulin (horizontal axis) or with electron beam computerized tomography (vertical axis). GFR, glomerular filtration rate; EBCT, electron beam computerized tomography.

results could be interpreted as indicating that renal parenchyma adjusts itself to the amount of blood that is received. Furthermore, histologic analysis also suggests that in the stenotic kidney, the reduction of renal parenchyma is mainly due to a replacement of interstitial fibrosis along with degenerative changes in renal tubules. Renal fibrosis is also present in the contralateral kidney, but the increase in volume is mainly accounted for by an increase in renal tubular volume and vascular hypertrophy.

Highly relevant to hemodynamic changes in the stenotic and contralateral kidney described above is the fact that in the stenotic kidney RBF, GFR, and distal delivery of tubular fluid correlated with the severity of the stenosis. This strongly suggests that the major determinant of the decrements in hemodynamic and renal tubular parameters as well as tissue damage was dependent on the fall of renal perfusion pressure distal to the clip. In the contralateral kidney, the increments in blood flow, GFR, and distal delivery of tubules as well as tissue volume did not correlate well with an increase in perfusion pressure, perhaps due to the tendency of the kidney to autoregulate blood flow when renal perfusion pressure is increased.

RENAL OXYGEN CONSUMPTION, TUBULAR REABSORPTION, AND RENAL ISCHEMIA

Renal oxygen consumption has been conventionally divided into (1) a small, but constant, basal oxygen uptake, and (2) a variable functional oxygen uptake. More precisely, the basal oxygen consumption is the oxygen

uptake that occurs in the nonfiltering kidney without tubular reabsorption. The functional oxygen consumption is the total oxygen uptake needed to reabsorb sodium. The existence of these two components, basal and functional oxygen consumption, was demonstrated by Lassen et al.⁷³ in 1961. These investigators decreased renal perfusion pressure from 100 mmHg to 50 mmHg. Under these conditions, the glomerular capillary hydrostatic pressure decreased from 60 to 30 mmHg, below the glomerular capillary colloidal osmotic pressure. In the absence of GFR, oxygen consumption, which is determined by the very basal metabolic needs of the renal tissue, was calculated to be 1 $\mu\text{mol/g/min}$ of O_2 .⁷³ This consumption is comparable to that observed in other epithelial secretory tissue, such as the submaxillary gland, parotid gland, and pancreas in resting conditions.⁷³ Interestingly, as renal perfusion pressure was increased above 50 mmHg, renal oxygen consumption increased proportionally, exhibiting a high correlation with both glomerular filtration rate (tubular sodium load) and sodium reabsorption (Figure 9-9). Under these conditions, the renal oxygen consumption increased to 6 $\mu\text{mol/g/min}$. These observations led to the notion that suprabasal oxygen consumption is determined by the amount of sodium being reabsorbed in the renal tubules.

Figure 9-7. Changes in x-ray density (CT numbers) in the cortex, outer medulla, and inner medulla during the passage of x-ray contrast media that behaves like inulin. The time at which the peaks of density were detected in the renal cortex (proximal and distal tubules) in the outer medulla (descending and ascending loop of Henle) and in the inner medulla (tip of the loop of Henle and collecting duct) are represented in the horizontal axis. CT, computerized tomography.

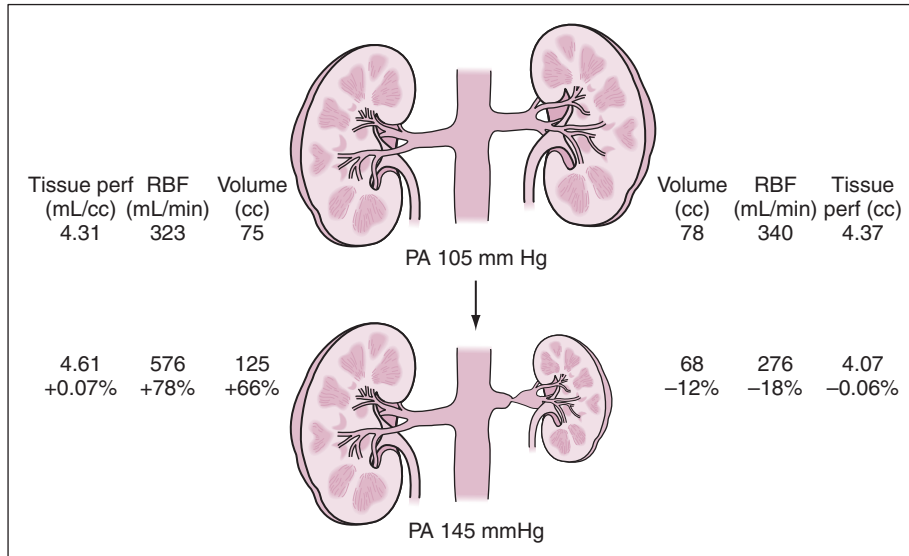

Figure 9-8. Changes in tissue perfusion, renal blood flow, renal volume, and arterial pressure induced by stenosis of renal artery. PA, arterial pressure; RBF, renal blood flow; Tissue perf, tissue perfusion; Vol, renal volume.

Figure 9-9. Correlations between total renal oxygen uptake with the values of glomerular filtration rate (*left*) and the rate of sodium tubular reabsorption (*right*).

Such observations raised the question of whether all renal tubular segments have the same energy requirement and thus equivalent oxygen consumption. In this regard, early studies indicated that energy requirement is a major characteristic of distal tubules because mannitol infusions, which inhibit proximal sodium reabsorption, do not alter oxygen consumption.⁷⁴ In contrast, saline infusions, which tend to decrease significantly proximal sodium reabsorption and at the same stimulate distal tubular reabsorption, significantly increase oxygen consumption.⁷⁴⁻⁷⁶ Furthermore, these observations agree with the finding that the enzymes responsible for gluconeogenesis, such as glucose 6-phosphatase, fructose-1, 6-diphosphatase, and phosphoenolpyruvate carboxykinase, are limited to the proximal tubules.⁷⁷ Gluconeogenesis is an energy-requiring process that by its very nature does not proceed in the same cell in which glycolysis provides energy. Oxidative metabolism, chiefly of fat, is therefore the major source of energy in

the proximal tubular cells of a cortex.⁷⁵ On the other hand, the enzymes that participate in glycolysis—hexokinase, phosphofructokinase, and pyruvate kinase—predominate in distal segments of the nephron, such as medullary ascending limb, cortical thick limb, distal convoluted tubules, and the entire collecting duct.⁷⁷

In agreement with all these observations, it was also found that the concentration of Na-K-ATPase is five to eight times higher in the distal than in the proximal tubules.⁷⁸ This enzyme is mainly responsible for metabolic active transport of sodium from the tubular lumen to the renal interstitium. Na-K-ATPase is inhibited by ouabain, ethacrynic acid, and furosemide. In a study performed in anesthetized dogs where mannitol was given first to inhibit proximal tubular sodium reabsorption (mannitol diuresis), ouabain reduced sodium potassium ATPase activity in the kidney by 75%. Under these conditions, sodium reabsorption was decreased by 40% and renal

oxygen consumption by 45%. Contrasting with these findings was the observation that the administration of acetazolamide, an inhibitor of carbonic anhydrase (which accounts for most of the sodium reabsorption in the proximal tubules), reduced total Na reabsorption to a level further down than that induced by ouabain without decreasing oxygen consumption.⁷⁹

It should be emphasized here that for years it was assumed that the kidney was supplied with more than enough oxygen to perform its work because, under conditions where the renal artery contains 8.8 $\mu\text{mol/mL}$ of oxygen, the vein shows a concentration of 7.3 $\mu\text{mol/mL}$. Thus the renal artery–venous difference of O_2 concentration is very small, averaging 1.4 $\mu\text{mol/mL}$.⁷⁷ However, when one considers that the kidney blood supply is 20% of total cardiac output per minute, it becomes apparent that the whole organ has a high oxygen consumption.⁷⁷ This is particularly true for the outer medulla where oxygen consumption represents 79% of the total supply. For comparative purposes, it should be stated that the outer medulla consumes 79% of its oxygen supply, while the heart consumes 65%⁷⁷ (Table 9–1).

When considering the blood and oxygen supplied to the cortex and the medulla, there are additional characteristics that are determined by the special anatomic arrangement of the intrarenal vasculature. For example, small intrarenal arteries run in parallel to small intrarenal veins. This allows the rapid transfer of oxygen from the artery to the vein, decreasing hemoglobin saturation before blood reaches the peripheral vasculature. This transfer of oxygen is particularly prominent in the renal medulla where oxygen passes from the descending to the ascending vasa recta. This accounts for the small arterial venous differences of oxygen in the kidney and also for the observation that oxygen concentration in the vein is higher than in peripheral capillaries. This characteristic places the outer medulla in a relatively vulnerable situation because of the high oxygen consumption associated with a relatively low oxygen supply. Oxygen delivered to the outer medulla is 7.6 mL/min/100 g of tissue, where oxygen consumption is 6 mL/min/100g of tissue (Table 9–1). This explains the selective injury produced in thick ascending limb segments under conditions of renal ischemia produced by controlled

hemorrhage, or after prolonged renal vasoconstriction, because it is induced by blockade of prostaglandin synthesis in dogs submitted to sodium depletion and simultaneously the administration of contrast x-ray medium.^{80,81}

In agreement with all these data are preliminary studies indicating that, in the stenotic kidney, the decrease of renal blood flow, GFR, and tubular sodium load is proportional to the degree of renal stenosis. In these studies, the amount of fluid reaching the distal tubules, as well as tubular concentration of solutes, falls in proportion to the decrease in RBF and GFR. Consequently, in these kidneys, there is a proportional decrease in oxygen consumption. Under these conditions, the amount of oxygen consumption, which is inhibited by the administration of furosemide (an inhibitor of the Na-2Cl-K co-transporter), is also proportionally decreased. From all of these observations, we have hypothesized that the fall in the so-called furosemide-induced suppression of oxygen consumption (FISOC) can be used as an index of distal tubular sodium reabsorption, and will correlate with the ability of the kidney to recover after recirculation is reestablished by surgical interventions or by percutaneous transluminal renal artery angioplasty (PTRAA).

In the contralateral kidney, the opposite is likely to be observed. A significant increase of O_2 consumption can be predicted on the basis of a 66% increase in total renal volume (renal hypertrophy), a 78% elevation of RBF, and 60% increase in GFR observed in previous studies. These changes are also attended by proportional elevations of distal tubular fluid flow and Na reabsorption. FISOC should be increased. However, these changes in the contralateral kidney, which reflect a compensatory reaction to minimize the decreased function of the stenotic kidney, create vulnerability to decrements in RPP. Since the ability of the contralateral kidney to autoregulate is significantly decreased, the minimum perfusion pressure needed to maintain RBF, GFR, and Na excretion in the contralateral kidney is not known. Hence, a fall in MAP that follows the PTRAA could precipitate renal insufficiency, if recirculation of the stenotic kidney is not sufficient to restore renal function and compromises renal circulation and everyday function in the contralateral kidney.

RATIO OF OXYGEN CONSUMPTION TO OXYGEN DELIVERY IN OUTER MEDULLA OF KIDNEY AND OTHER ORGANS				
Region or Organ	O_2 Delivery	Rate of Blood Flow (mL/min/100 g)	O_2 Consumption	O_2 Consumption/ O_2 Delivery (%)
Hepatoportal	11.6	58	2.20	18
Kidney	84.0	420	6.80	8
Outer medulla	7.6	190	6.00	79
Brain	10.8	54	3.70	34

Table 9–1. Ratio of Oxygen Consumption to Oxygen Delivery in Outer Medulla of Kidney and Other Organs

SUMMARY

Renovascular hypertension is a form of secondary hypertension, that is, an underlying disease is leading to the cause of elevated BP. The renal vascular (renovascular) alteration is a narrowing of the artery(s) to one or both kidneys. This reduction of blood flow leads to the affected kidney or kidneys to mistakenly respond as if the BP is low. The primary mechanistic response to this stimulus is to secrete hormones that increase peripheral vascular

resistance by inducing vasoconstriction and, secondarily, to signal the body to retain salt and water, which causes an increase in BP. The ensuing cascade of events involves many pathogenic mechanisms, including the renin-angiotensin system and oxidative stress, and varies depending on the presence of a functioning contralateral kidney. We have developed 3D imaging techniques of the kidney that allow for quantification and assessment of kidney function, thus making early detection and evaluation of the disease possible.

Chapter
10

Left Ventricular Physiology and Pathophysiology in Hypertension

George W. Booz

Key Findings

- The left ventricle in hypertension undergoes remodeling that eventually proves detrimental to heart function.
- Specific events include cardiac muscle hypertrophy, interstitial fibrosis, and increased mass with or without increased wall thickness.
- A common feature of the left ventricular (LV) remodeling is impaired relaxation (diastolic dysfunction), often accompanied by impaired contractility.
- Increased LV mass is an important risk factor for cardiovascular disease, including ventricular arrhythmias and heart failure.

Clinical Implications

- Atrial fibrillation and stroke, secondary to left arterial enlargement, may occur with LV hypertrophy.
- Compromised oxygen delivery makes the hypertrophied myocardium susceptible to ischemic damage, and patients with LV hypertrophy are more likely to exhibit renal damage.

In hypertension, the left ventricle undergoes hypertrophy as a compensatory mechanism to reduce wall stress and maintain pump function in the face of the increased afterload. The introduction of echocardiography as a diagnostic tool, however, has established that the increased left ventricular (LV) mass observed in hypertension cannot be construed simply as a compensatory process, but represents an important, independent predictor of morbidity and mortality.^{1,2} In fact, LV hypertrophy, which is generally defined based on LV mass normalized to body size (LV mass index), represents a stronger risk factor than blood pressure for adverse cardiovascular events. At which point increased LV mass ceases to be compensatory and becomes deleterious in hypertension is not known, but the concept of inappropriate LV mass or excess mass beyond that predicted based on gender, body height, and hemodynamic burden has been introduced to better address this issue.³⁻⁷ Inappropriate LV mass not only predicts cardiovascular risk independent of other risk factors, such as age and blood pressure (as does conventionally defined LV mass), but also in the presence or absence of echocardiographic LV hypertrophy. The idea of inappropriate LV mass also underscores a major difference between the appropriate (physiologic) LV hypertrophy produced by exercise and that observed with

hypertension. Additionally, unlike what occurs with exercise, hypertension induces changes in both the contractile and supportive compartments of the heart that are maladaptive and eventually prove detrimental to normal pump function.⁸

ANATOMY AND BIOCHEMISTRY

An increase in cardiac workload brought on by conditions that cause volume or pressure overload results in an increase in LV mass as a primary adaptive mechanism. Pure pressure overload is thought to induce a concentric pattern of left ventricle hypertrophy due to the replication of sarcomeres in parallel.^{9,10} In this form of hypertrophy, the increase in LV mass is accompanied by a thickening of the septal and posterior walls (the ratio of LV wall thickness to cavity diameter increases), as a compensatory mechanism to maintain normal wall stress. With volume overload, in contrast, individual muscle fibers elongate due to the addition of sarcomeres in series. Consequently, LV mass increases, but relative wall thickness remains normal, resulting in LV dilation and an eccentric pattern of hypertrophy. Echocardiography reveals, however, that the overall geometric response of the heart to arterial hypertension can follow any one of four patterns (Figure 10-1), with approximately half of all patients exhibiting a normal LV geometry (Table 10-1).¹¹⁻¹³ These different patterns of adaptation are not simply attributable to differences in severity or duration of hypertension, but are thought to reflect the variable impact of preload on the left ventricle due to changes in blood volume and/or venous compliance, as well as LV dilation due to the growing inadequacy of (concentric) hypertrophy to compensate for increased afterload. Additionally, genetic factors and an association of obesity with eccentric hypertrophy influence the geometric pattern. A normal LV mass with increased relative wall thickness (concentric remodeling) is proposed to be a consequence of volume underload from pressure natriuresis “canceling out” the effect of pressure overload, which does not occur with concentric hypertrophy.^{12,13} At the other extreme, concomitant pressure and volume overload is thought to result in a pattern of eccentric hypertrophy. Indices of systemic hemodynamics and cardiac performance in hypertensive patients are consistent with this interpretation (Table 10-1). Additionally, stroke volume is positively related to the LV minor/major hemiaxis ratio at end-diastole. At the lower extreme, with the most elliptic cavities, are patients

Figure 10–1. Left ventricular geometric patterns in hypertensive patients. Echocardiography shows that the left ventricle can adapt any one of four geometric patterns in response to hypertension, reflecting the relative contributions of pressure and volume overloads. LVM, left ventricular mass index; RWT, relative wall thickness; RV, right ventricle; LV, left ventricle; LVH, left ventricular hypertrophy; d, left ventricular chamber diameter; e, left ventricular wall thickness. (Values are from Ganau A, Devereux RB, Roman MJ, de Simone G, Pickering TG, Saba PS, et al. *J Am Coll Cardiol* 1992;19:1550–8.)

HEMODYNAMICS AND CARDIAC PERFORMANCE ASSOCIATED WITH VARIOUS LEFT VENTRICLE GEOMETRIC PATTERNS IN HYPERTENSION				
	Normal Left Ventricle	Concentric Remodeling	Concentric Hypertrophy	Eccentric Hypertrophy
Prevalence	52%	13%	8%	27%

Table 10–1. Hemodynamics and Cardiac Performance Associated with Various Left Ventricle Geometric Patterns in Hypertension

with concentric remodeling. At the upper end, with the most spherical cavities, are patients with eccentric hypertrophy.

LV hypertrophy associated with arterial hypertension represents primarily an increase in the size of individual muscle fibers, accompanied by interstitial and perivascular fibrosis due to an accumulation of fibrillar collagen.^{10,14} These changes result from both mechanical forces acting on the heart, as well as pressure-overload activation of the sympathetic and renin-angiotensin system (Figure 10–2).^{14,15} Additionally, both pressure and volume overload induce expression of a number of growth and fibrotic factors by cardiac fibroblasts and myocytes, including angiotensin II, IL-6 family cytokines, endothelin-1, insulin-like growth factor I, and TGF- β .^{16,17} Hypertrophy at the level of the cardiac myocyte represents an increase in protein content, but is distinguishable from physiologic hypertrophy because of an accompanying gene expression profile that is presumably maladaptive. Specifically, expression of genes associated with embryonic development (e.g., those for β -myosin heavy chain, skeletal α -actin, as well as atrial and brain natriuretic peptides) is increased, and expression of some adult cardiac muscle genes, (e.g., α -myosin heavy-chain and sarcoplasmic reticulum Ca²⁺-ATPase) is decreased.¹⁸ The hypertrophied heart charac-

teristically exhibits decreased β -adrenergic responsiveness. In part, this is due to increased myocardial levels of β -ARK1, a kinase responsible for homologous desensitization of β -adrenergic receptors. Alterations in metabolism occur as well in the hypertrophied myocardium. These include reduced fatty acid oxidation, increased glucose uptake, and glycolysis, and less coupling of glycolysis to the tricarboxylic acid cycle.^{19,20} The myocardial fibrosis seen in hypertension results from increased collagen type I and III synthesis by fibroblasts, but there are also changes in the ratio and cross linking of the collagen types.^{14,21} Changes in the activity of enzymes that degrade collagen, matrix metalloproteinases (MMPs), occur in a temporal fashion: initially activity is increased, followed by a chronic phase of normal activity, which gives way to increased activity and collagen degradation that contributes to chamber dilation.^{22,23} During the compensatory phase of LV hypertrophy, the increase in extracellular collagen contributes to myocardial stiffness, abnormalities of cardiac function, and the increased frequency of ventricular arrhythmias commonly observed in hypertensive patients.²¹ Additionally, by constraining vasodilation of intramyocardial coronary arteries, perivascular fibrosis has a part in the decreased coronary reserve frequently seen in hypertension.²⁴

GENETICS

Early observations that the magnitude of LV hypertrophy varies considerably among individuals with the same levels of blood pressure, and may even be absent, suggested that genetics plays a role in hypertension-related LV hypertrophy. Support for this has been provided by analyses of epidemiologic studies that attempted to parse the impact of independent determinants of LV hypertrophy, such as age, gender, blood pressure, and body mass index (BMI), from a contribution of heredity. One of the first such analyses, of the largely Caucasian population-based Framingham Heart Study, suggested indeed that heredity has a greater impact on LV mass than systolic blood pressure.²⁴ Combined large-population studies have provided estimates for heritability of LV mass that fall within a range of 0.2 to 0.8.^{25–30} This broad range likely reflects not only a contribution of shared genes and familial environment, but also ethnic differences among genes responsible for LV hypertrophy and remodeling.

An increased risk of concentric remodeling and concentric, but not eccentric, LV hypertrophy was found among siblings of affected subjects in echocardiographic sub-studies of the population-based MONICA Augsburg surveys.³¹ After adjusting for age, blood pressure, and BMI, the risk elevation related to a familial disposition of LV hypertrophy was 1.4 to 1.7. Several analyses involving juvenile twins reached the conclusion that inherited factors strongly influence interindividual variability of LV mass.^{32–34} Additionally, after adjusting for other confounders, black identical twins exhibited a higher intraclass correlation coefficient for LV mass than black fraternal twins. A similar finding was reached in a recent population-based study of healthy adult twins, suggesting that LV phenotype has a significant genetic determination that may be independent of age or environment.³⁰

The issue of ethnic or racial differences in LV mass among hypertensive adults is one of particular relevance for black hypertensive Americans, who experience substantially higher rates of stroke, coronary heart disease, and heart failure than white Americans.^{35,36} A higher prevalence of increased LV mass was observed in young black adults compared with their white counterparts in a cohort of the prospective Coronary Artery Disease Risk Development in Young Adults (CARDIA) Study³⁷ and in a longitudinal study of children.³⁸ In an analysis of the Hypertension Genetic Epidemiology Network (HyperGEN) Study, substantial differences were noted in prevalence and magnitude of cardiac structure changes between blacks and whites undergoing treatment for hypertension.³⁶ Blacks had increased LV mass and relative wall thickness in multivariable models that adjusted for important confounders.

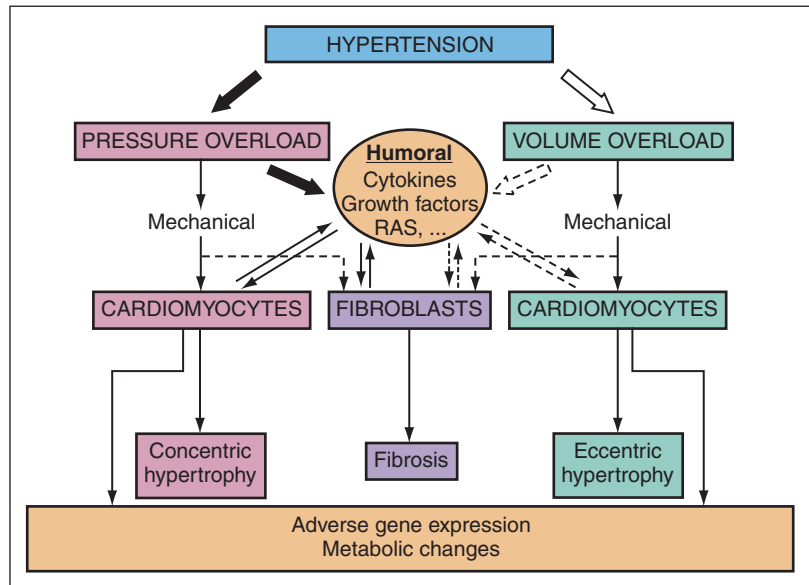

Figure 10–2. Hypertension-induced remodeling of the left ventricle reflects the dual contribution of mechanical and humoral stimuli resulting from both pressure overload (predominately) and volume overload. A greater contribution of humoral stimuli (endocrine, paracrine, and autocrine) occurs with pressure overload. These stimuli act on both fibroblasts to increase perivascular and interstitial fibrosis, and on cardiomyocytes to induce pathologic hypertrophy, which entails adverse changes in gene expression and metabolism. Both cardiomyocytes and fibroblasts produce cytokines and growth factors, which can amplify left ventricular remodeling in an autocrine/paracrine manner.

Adjusted LV internal dimension was smaller in blacks than whites, consistent with the predominant pattern of concentric LV hypertrophy in hypertension.

Which genes influence susceptibility of the left ventricle to hypertrophy in hypertension is not known to any great degree. The focus to date has been on genes of hormonal systems, such as the renin-angiotensin-aldosterone system, activated in hypertension and implicated in LV hypertrophy. Likely due to a number of factors, including small sample size, absence of Hardy-Weinberg equilibrium, genotyping errors, and differences in population background, many of these studies have produced contradictory results. A prime example is studies involving an insertion/deletion (I/D) polymorphism of a 287-bp Alu element in intron 16 of the ACE gene. This polymorphism seemed a good candidate to influence LV hypertrophy, since the DD genotype is linked to enhanced ACE activity. In this case, meta-analysis of contradictory case-control studies showed LV hypertrophy overall was not associated with the D allele; however, in untreated patients, the DD genotype exhibited a higher risk of cardiac hypertrophy compared to the II genotype, suggesting that the D allele may worsen LV hypertrophy if hypertension is not controlled.³⁹ Carriers of the Glu27 allele of the β_2 adrenergic receptor,⁴⁰ and noncarriers of the 192 base pair allele of a cytosine-adenosine repeat in the IGF-I promoter⁴¹ were reported to be at higher risk for developing cardiac hypertrophy. A +9/-9 exon 1 polymorphism of the B_2 bradykinin receptor⁴² and single nucleotide polymorphisms (SNPs) in the angiotensinogen, apolipoprotein B, angiotensin II type 1 receptor (AT₁), and α_2 -adrenoreceptor genes, have all

been shown to impact on the magnitude of regression of LV hypertrophy during antihypertensive treatment.^{43,44} The G1675A polymorphism associated with reduced expression of the angiotensin-II type 2 receptor (AT₂),⁴⁵ and the –344C/T promoter polymorphism of the aldosterone synthase gene, associated with increased plasma aldosterone levels, have also been linked to LV hypertrophy.⁴⁶

PHYSIOLOGY AND PATHOPHYSIOLOGY

Increased systolic blood pressure associated with increased peripheral resistance and arterial stiffening is an important determinant of LV hypertrophy. Blood pressure, however, is also affected by cardiac performance, and mathematical modeling based on clinical data suggests that the heart makes a substantial contribution to increased blood pressure in hypertension. One such analysis showed that the contribution of cardiac pump function to blood pressure in hypertensive patients is a function of the remodeling process, with estimates of 21%, 65%, and 108% for concentric remodeling, concentric hypertrophy, and eccentric hypertrophy, respectively.⁴⁷ For hypertensive patients with a normal geometry of the left ventricle, the estimated contribution was 55%.

A number of associations between target organ damage and LV remodeling have been described in hypertension. Patients with LV hypertrophy are more likely to exhibit kidney damage, carotid plugging, or increased carotid intima-media thickness.⁴⁸ The risk of target organ damage can be further stratified by LV geometric pattern, the risk being highest with concentric and intermediate with eccentric hypertrophy.^{2,49–51} Cardiac hypertrophy *per se* does not explain this relationship, as concentric remodeling of the left ventricle, that is, increased wall thickness with normal LV mass, represents an independent predictor of increased cardiovascular risk in hypertensive patients as well.¹³ The higher levels of blood pressure and neurohormonal activation seen with concentric hypertrophy (predominant pressure overload) likely explain the greater risk of target organ damage, since each of these parameters impacts on cardiac, vascular, and renal remodeling. LV concentric hypertrophy is associated with especially high arterial pressure, and patients with this pattern of remodeling have the most advanced retinopathy on fundoscopic examination, and the most severe abnormalities in arterial structure and function, including greater arterial hypertrophy, arterial stiffness, and increased total peripheral resistance.^{52,53} In mild to moderate hypertension, abnormalities in carotid arterial structures are most severe with concentric remodeling or hypertrophy. Perhaps not surprisingly, concentric geometry is more likely to be associated with cerebrovascular events. Concentric LV hypertrophy is also associated with the greatest renal dysfunction, and is likely to potentiate the decline in glomerular filtration rate with aging.⁵⁴ On the other hand, while lower systemic arterial stiffness is associated with eccentric hypertrophy, so also is aortic root dilation, and those individuals may be at higher risk of an adverse event.⁵⁵

Left arterial (LA) enlargement, symptomatic of hypertensive heart disease, commonly occurs in hypertensive

patients with LV hypertrophy, and represents a risk factor for arterial fibrillation and stroke.⁵⁶ Left arterial enlargement occurs in response to stiffening of the ventricle and increased LV end-diastolic pressure, but may also be secondary to changes in systolic LV function. When observed in patients with normal systolic function by echocardiography, LA enlargement is generally interpreted as an early sign of reduced diastolic LV function. In middle-aged and older hypertensive patients with LV hypertrophy, LA enlargement was found to be especially prevalent among patients who were obese, older, female, or had eccentric LV geometry.⁵⁷ The degree of LV hypertrophy did not impact on the occurrence of LA enlargement, nor did the presence of atrial fibrillation or mitral regurgitation.

PATHOPHYSIOLOGY

Arterial hypertension is commonly accompanied by impaired LV systolic performance as assessed by mid-wall fractional shortening using echocardiography.⁵⁸ Measuring midwall shortening kinetics identifies patients with systolic dysfunction despite normal LV chamber performance and has independent prognostic value. Among asymptomatic normotensive or hypertensive adults, lower midwall shortening is associated with less favorable indices of arterial structure and function, and hemodynamics.⁵⁸ Depressed myocardial contractility has been observed in young patients (~33 years old) with borderline to mild hypertension, exhibiting concentric LV remodeling, and thus represents an early consequence of increased blood pressure independent of an increase in LV mass.⁵⁹ In older individuals (~66 years old) with Stage I to II hypertension, LV systolic performance was shown to worsen as LV mass and relative wall thickness increased either separately or together, when assessed as either endocardial or midwall shortening.⁶⁰ The prevalence of depressed endocardial fractional shortening was highest among individuals with eccentric hypertrophy, while impaired midwall shortening predominated among those with concentric remodeling or hypertrophy. However, in a large population with untreated hypertension, LV hypertrophy was found to be a determinant of impaired mid-wall systolic function independent of concomitant changes in chamber geometry.⁶¹

A moderate impairment in diastolic function as evidenced by a slight increase in atrial filling peak velocity has been noted to accompany LV geometric remodeling in the early stages of hypertension.⁶² Others have noted that a relatively modest prolongation of isovolumic relaxation time (IVRT) may occur in hypertension before any systolic dysfunction, even when contractility is monitored at the level of the midwall.⁶³ The less severely abnormal relaxation is independent of geometry or load and could be due to metabolic abnormalities. Overall, when measured as midwall shortening, the progression in the impairment of systolic function parallels those in diastolic function,⁶⁴ likely because factors thought to contribute to abnormal diastolic filling, such as impaired calcium handling, increased interstitial fibrosis, and subendocardial ischemia, might also impact on systolic function. In otherwise healthy,

unmedicated patients with moderate hypertension and normal conventional measures of systolic function, subnormal midwall shortening was highly correlated with abnormal diastolic function, identified by late (A) LV inflow velocity greater than early (E) velocity and longer IVRT.⁶⁵ The latter parameter differs among individuals grouped according to LV geometry, primarily due to a positive correlation with LV mass. A subsequent report showed that depressed LV midwall performance and impaired diastolic filling (prolonged IVRT and abnormal E/A ratio) were interrelated independent of covariates, yet also related to LV mass independently of one another.⁶⁶

Among moderate hypertensive patients with LV hypertrophy, *inappropriate* LV mass was independently associated with higher prevalence of systolic and diastolic abnormalities.^{4,5} The percentage of patients with systolic myocardial dysfunction was 43% and 79% for those with eccentric and concentric LV hypertrophy, respectively. Notably, the prevalence of prolonged IRVT was high (65% to 77%) among all patients with LV hypertrophy, regardless of classification as appropriate or inappropriate. This finding is consistent with diastolic dysfunction preceding abnormal systolic function in hypertension. Among patients with mild hypertension and LV hypertrophy, inappropriate LV mass was associated with concentric LV geometry and reduced midwall systolic mechanics.⁶⁷ Among patients with moderate to severe hypertension, inappropriately high LV mass was associated with lower systolic function (ejection fraction, midwall shortening, and circumferential end-systolic stress) and diastolic function (prolonged IVRT and lower mitral E/A ratio), independent of LV hypertrophy, concentric geometry, and other covariates.⁴

In hypertensive patients without LV hypertrophy, myocardial oxygen consumption per unit weight is increased. LV hypertrophy is accompanied by a normalization of oxygen consumption, but the ratio between cardiac work and oxygen utilization or myocardial efficiency is reduced. Possible explanations include a greater oxygen demand of a more active interstitial compartment in LV hypertrophy, as well as alterations in substrate utilization and mechanics of hypertrophied muscle fibers. However, not all studies have observed reduced myocardial efficiency with left ventricular hypertrophy, possibly because of differences in the geometric pattern of LV hypertrophy in the populations. Myocardial efficiency was found to be more reduced in hypertrophied hearts that exhibited a concentric compared to eccentric pattern.⁶⁸ Myocardial perfusion reserve and hyperemic myocardial blood flow are also reduced in the hypertrophied left ventricle; however, in this case, an impact of LV geometric pattern has not been consistently observed.^{68,69} Impaired myocardial blood flow is thought to be due for the most part to reduced intramyocardial coronary density because of increased interstitial fibrosis. Compromised oxygen delivery makes the hypertrophied myocardium more susceptible to ischemic damage, particularly during exercise.

While studies have shown that the reversal of LV hypertrophy with antihypertensive treatment is associated with a reduced risk for subsequent cardiovascular disease,

few have addressed the prognostic impact of geometric structure during treatment. Perhaps not unexpectedly, the persistence of concentric hypertrophy during hypertensive treatment is associated with lower systolic performance, as well as greater cardiovascular morbidity and mortality.⁷⁰ However, the incidence of cardiovascular events is greater in patients presenting as well with LV concentric remodeling during treatment, that is, normal LV mass but increased wall thickness. The close association between concentric geometry (both concentric hypertrophy and remodeling) and cardiovascular events is likely explained by a number of factors, including more severe abnormalities in diastolic filling, lower myocardial contractility, and a higher risk of arrhythmias, as well as more pronounced vascular remodeling.

CLINICAL IMPLICATIONS AND PERSPECTIVES

Echocardiographic determination of LV hypertrophy in patients with hypertension is a strong independent predictor of cardiovascular morbidity and mortality, with those exhibiting concentric LV hypertrophy having the greatest risk.^{2,49-51} This geometric pattern of hypertrophy is associated with especially high arterial pressure and dramatic alterations in arterial structure, which affects the coronary arteries as well and may lead to myocardial infarction. Partly as a consequence of postinfarction remodeling, the left ventricle begins to adapt an eccentric geometry. Thus in arterial hypertension, the common clinical course for LV remodeling is thought to be concentric LV remodeling, concentric LV hypertrophy, followed by eccentric LV hypertrophy due to postinfarction remodeling (as well as growing wall stress, and fluid retention). Consistent with this scenario, cardiovascular disease, including coronary artery disease, is more common among patients with eccentric LV geometry than those with more concentric LV geometry.⁷¹

Most patients with LV hypertrophy are asymptomatic, but angina, dyspnea, syncope, and sudden death do occur. Both the electrocardiogram and echocardiogram are commonly used to diagnose LV hypertrophy. The former is useful as an initial screen to detect LA or LV hypertrophy, arterial fibrillation, ventricular arrhythmias, and myocardial ischemia. An echocardiogram provides information on chamber dimensions and wall thickness of the left atrium and left ventricle, wall motion abnormalities, and LV performance (ejection fraction). Echocardiographic determination of the concentric phenotype during treatment may also prove to have utility for assessing treatment effectiveness.

While hypertrophy is generally considered to be a compensatory response of the left ventricle to arterial hypertension, the hypertrophied LV hypertrophy eventually undergoes decompensation and transition to a dilated cardiomyopathy and heart failure (Figure 10-3). At that stage, the heart is unable to pump sufficient blood to meet the metabolic demands of organs and tissues, and as LV end-diastolic and LA pressures increase, pulmonary venous congestion and pulmonary congestion ensue.

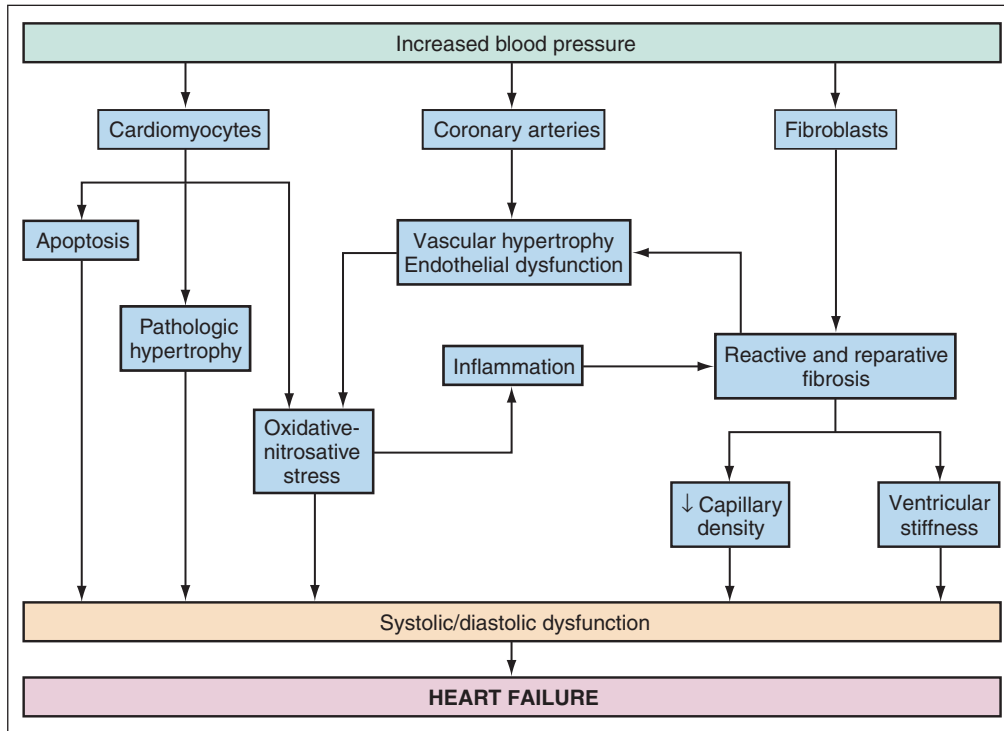

Figure 10-3. Systolic and/or diastolic dysfunction in hypertension results from the impact of increased blood pressure on cardiomyocytes, coronary arteries, and cardiac fibroblasts. Reduced oxygen delivery to cardiomyocytes due to impaired vessel function and decreased capillary density may result from increased fibrosis, which also contributes to increased ventricular stiffness. Compromised oxygen delivery, along with endothelial dysfunction and the altered expression and cellular localization of nitric oxide synthase isoforms by cardiomyocytes, may result in oxidative-nitrosative stress. In turn, oxidative-nitrosative stress may impair cardiomyocyte contractility and relaxation, contribute to cardiomyocyte apoptosis, and create an inflammatory state that further stimulates reactive fibrosis. Pathologic hypertrophy of cardiomyocytes has also been proposed to be associated with activation of G-protein coupled signaling events linked to apoptosis.

Heart failure is a leading cause of death in the developed world, and while life expectancy has been increased through drug development, a diagnosis of heart failure generally proves fatal.⁷² Concentric or eccentric hypertrophy both may progress to heart failure. Although there is evidence that cardiac myocyte cell death is one contributing factor, the specific mechanisms responsible for transition of hypertrophy into heart failure are still unknown. Oxidative-nitrosative stress and/or NO-redox disequilibrium are likely contributing factors as well.^{73,74} In approximately half of the cases, heart failure is associated with reduced contractility (systolic heart failure). Heart failure resulting from hypertension may also be associated with normal LV function, that is, ejection fraction (diastolic heart failure). Compared to patients with systolic heart failure, patients with heart failure and preserved ejection fraction are generally older, female, and have a history of hypertension.^{72,75} The etiology of heart failure with preserved ejection fraction, the contribution of systolic-ventricular and arterial stiffening, and its optimal treatment are questions currently being investigated.^{72,75,76}

SUMMARY

Hypertension exerts profound effects on LV geometry and structure that involve contractile and noncontractile

compartments, which can prove detrimental to normal pump function of the heart. The LV geometric remodeling often seen in hypertension represents an important independent predictor of morbidity and mortality, with a concentric pattern of hypertrophy presenting the highest risk. A common feature of LV remodeling in hypertension is impaired relaxation (diastolic dysfunction) due to interstitial fibrosis, abnormal Ca^{2+} homeostasis, modifications of myofilament Ca^{2+} sensitivity, and possible increased stiffness within the sarcomere. The degree of diastolic dysfunction progresses with the severity of hypertension, and is often accompanied by impaired contractility. Aging also has a greater negative impact on diastolic function than systolic function, which may explain the high incidence of diastolic heart failure with preserved systolic function in the elderly. Increased myocardial fibrosis is thought to contribute to the effect of aging on diastolic function. The effect of aging on other components of diastolic function needs to be explored, as well as the impact of gender on aging-associated LV remodeling, given the greater incidence of diastolic heart failure with preserved systolic function among women. In light of recent evidence in rats, linking reactive fibrosis and diastolic dysfunction associated with hypertension to macrophage accumulation,⁷⁷ a future avenue to explore is the role of inflammation in diastolic dysfunction and the impact that aging has on the

inflammatory process. The question of whether oxidative-nitrosative stress in the myocardium as a putative causative factor in precipitating the inflammatory response could serve as a therapeutic target to ameliorate myocardial fibrosis and diastolic dysfunction in hypertensive hearts will need to be answered.⁷⁸

In hypertension, the left ventricle commonly undergoes hypertrophy to compensate for the increased afterload, but if hypertension is poorly controlled or untreated, the left ventricle decompensates and heart failure follows. The events responsible for the transition of hypertrophy to heart failure are not well understood, although a loss of cardiac muscle seems to be involved. The role that increased extracellular matrix degradation plays, due to

enhanced activity of MMPs, has not been well explored. Finally, regression of LV hypertrophy is associated with a lower overall risk of cardiovascular disease. Weight loss, exercise, salt restriction, and lowering blood pressure with most antihypertensive agents produce regression. Another strategy might be to exploit intrinsic regulators of cardiac hypertrophy that have been identified in the past few years, including the antihypertrophic NO-cGMP system. Given the report that persistence of concentric hypertrophy during hypertensive treatment is associated with greater cardiovascular morbidity and mortality, developing strategies that aggressively target the concentric phenotype warrants special attention.

Hemodynamics of Hypertension

Joseph L. Izzo, Jr.

Key Findings

- In hypertension at any age, increased or inappropriately high sympathetic nervous system (SNS) activity causes or exacerbates a fundamental hemodynamic imbalance that includes both inappropriately high cardiac output and inappropriately high systemic vascular resistance (SVR).
- Hypertensive individuals appear to make a transition from a high-output, low-resistance state to a low-output, high-resistance state as they age. It is not clear that such a transition occurs in most individuals with hypertension or if this transition is part of the usual aging process.
- Arterial pressure and cardiac output must vary to meet different physiologic, thermoregulatory, and metabolic demands and hemodynamic responses to physiologic and metabolic stimuli vary within and across individuals. Under stimulated conditions, either flow or resistance may change based on the nature of the stimulus and the underlying disease state.
- The generation of systolic pressure is far more complex in its physiology than the generation of diastolic blood pressure (BP) and systolic BP contains information about both nonpulsatile and pulsatile flow.
- An in-depth analysis of a systolic pulse contour yields the concept of “ventricular–vascular interactions” during systole. During early systole, the interaction of the left ventricle and the aorta generate a forward pressure wave and an initial systolic peak pressure (usually called P1). In late systole, the interaction of the forward pressure wave and flow discontinuities in the peripheral arterial tree generate reflected pressure waves that often augment P1 (forming P2). The observed systolic pulse contour is the sum of these “ventricular–vascular interactions.”
- Increased pulse pressure (PP) (generally P1) is sometimes due to an isolated increase in stroke volume (severe anemia, hyperdynamic hypertension, aortic insufficiency, thyrotoxicosis, vitamin deficiency, or arteriovenous shunting, renal failure) but the etiology of wide PP or isolated systolic hypertension is predominantly due to increased central arterial stiffness.
- Stiffening of the aorta and carotid arteries has another important homeostatic consequence: increased blood pressure variability. With collagen deposition and calcification, baroreflex mechanoreceptors are restrained in their ability to stretch, thus reducing the effect of an important negative feedback loop controlling SNS outflow.
- At all points along the arterial tree, forward- and backward-traveling waves summate to create the unique morphology of the pressure wave at a particular point. Central and peripheral pressure waveforms differ because of the relative timing differences of the incident and reflected waves at the two sites.

- As pressure waves travel downstream, the forward pressure wave is amplified due to increased impedance in arteries of decreasing caliber, causing PP amplification. The wall composition also changes with arterial size; in the thoracic aorta, there is a predominance of elastin over collagen, but in the peripheral conduit arteries, there is more collagen than elastin. Importantly, not all segments of the arterial tree become stiffer with aging or disease.
- Cardiac and vascular target organ damage is a predictable interrelated consequence of the systolic hypertension with direct implications for cardiovascular symptoms and pathology. Increased central systolic BP increases cardiac afterload and leads to left ventricular hypertrophy. Increased central arterial stiffness and cardiac afterload cause decreased exercise tolerance, diastolic dysfunction, and eventually, heart failure. Ischemic heart disease is exacerbated as well due to reduced diastolic pressure and reduced coronary filling, especially in response to systemic vasodilation.

By its very name, *hypertension* is essentially a hemodynamic syndrome. This statement does not contradict the observations that hypertension is associated with a diverse series of metabolic, functional, and structural abnormalities. Rather, it stipulates that hypertension is not a lesser byproduct of a broader “metabolic syndrome.” While central obesity appears to contribute in parallel to metabolic abnormalities (e.g., insulin resistance) and increased systolic and diastolic blood pressure, the syndrome of hypertension in the population over age 50 is also directly related to increased stiffness of the aorta and central arteries, with accompanying increases in systolic blood pressure, decreases in diastolic blood pressure, and widening of pulse pressure. There is little to suggest that “essential” hypertension has a primary genetic basis; rather it is best characterized as an acquired, age-related syndrome that occurs primarily in highly industrialized societies. Remarkably, the pathogenesis of systolic hypertension is still poorly understood, probably owing in large measure to its complexity. Current research has begun to focus on arterial wall pathophysiology, but other mechanisms, especially inappropriately high activity of the sympathetic nervous system (SNS), appear to play a causal or permissive role in all forms of hypertension. The syndrome of hypertension is thus a highly heterogeneous condition best described by its intrinsic hemodynamic abnormalities.

BASIC HEMODYNAMICS

Ohm's Law and circulation

The classical approach to the hemodynamics of hypertension applies the same principles that govern an electrical circuit (Ohm's Law). In this steady-state model:

$$\text{Mean arterial pressure (voltage)} = \text{Cardiac output (current)} \times \text{Systemic vascular resistance (impedance)}$$

In extending this simplified model to the investigation of human hemodynamics, mean arterial pressure (MAP) has been historically determined from peripheral sphygmomanometry using the following formula:

$$\text{MAP} = \text{diastolic blood pressure} + 1/3 \text{ pulse pressure}$$

This approximation of mean pressure holds for heart rates above 55 to 60; if bradycardia is present, MAP is somewhat overestimated. A more accurate approximation of MAP can also be obtained by oscillometric blood pressure (BP) methods that identify MAP as the pressure at which the maximum oscillatory amplitude of the pulse occurs. Systemic resistance is mathematically more closely related to diastolic pressure or MAP than to systolic pressure.

Pressure-volume homeostasis

There is a certain degree of BP homeostasis that can be explained as counter-regulation of cardiac output and systemic vascular resistance (SVR); if one increases, the other tends to fall. Yet the primary physiologic mechanisms that defend arterial pressure itself (SNS, renin-angiotensin system, renal salt-water handling) do not correspond directly to any flow-resistance model. BP regulation is better explained by the concept of pressure-volume homeostasis. Foremost in BP counter-regulation is the SNS, which responds instantaneously and chronically to both pressure and volume signals.^{1,2} Circulatory SNS homeostasis involves two major inhibitory baroreflexes that control SNS outflow: the aorto-carotid baroreflex that responds to changes in arterial pressure or "afterload," and the cardiopulmonary baroreflex that responds to changes in cardiac filling or "preload." Under usual physiologic circumstances, both of these reflexes work in tandem to prevent hypoperfusion and hypotension. If there is a sudden fall in arterial pressure, aorto-carotid mechanoreceptors are "unloaded" and afferent signals are sent to the brainstem instantly to stimulate SNS outflow to the heart and vasculature.³ If blood volume and cardiac preload are suddenly reduced, cardiac mechanoreceptors are unloaded and SNS activation proceeds via the same brainstem centers affected by aorto-carotid baroreflex unloading.³⁻⁵ Conversely, salt loading or extracellular volume expansion suppresses SNS activity. During upright postural adaptation, the degree of SNS stimulation correlates strongly with the degree of reduction in cardiac stroke volume caused by gravitational blood pooling.⁶ In contrast, acute increases in central blood volume lead to withdrawal of SNS activity, with ensuing renal vasodilation, enhanced natriuresis, and dilation of systemic arteries and veins, independent of aorto-carotid baroreflex function.⁷ Thus the cardiopulmonary

baroreflex system can override a normal aorto-carotid system, especially during postural adaptation or other conditions that affect central blood volume.⁶⁻¹⁰

SNS overactivity in hypertension

In hypertension at any age, there is increased or inappropriately high SNS activity,¹¹⁻¹⁵ which causes or exacerbates a fundamental hemodynamic imbalance that includes *both* inappropriately high cardiac output and inappropriately high SVR. High cardiac sympathetic drive has been demonstrated via pharmacologic blockade of beta-receptors,^{16,17} and by radiotracer methods that reveal high cardiac norepinephrine turnover.¹⁸ High peripheral vascular sympathetic tone and increased alpha-adrenergic receptor dependency¹⁹ occur in association with altered fatty acid metabolism in vascular smooth muscle cells, creating a potential link to obesity-related hypertension.²⁰ Increased plasma catecholamines^{11,12,15} have been repeatedly demonstrated in hypertensive individuals, both young and old. The etiology of the high SNS activity in hypertension is undoubtedly complex, but SNS overactivity is associated with obesity,²¹ aging,^{11,12} and higher BP in general.^{11,12,15} In chronic hypertension, baroreflexes cannot fully compensate for inappropriate SNS activity and cannot restore elevated BP back to normotensive levels due to the phenomena of resetting and blunting. Aorto-carotid baroreflexes quickly *reset* at any pressure level so that acute increases or decreases in BP affect SNS activity equally in normotensive people and those with early hypertension. The only change is in the set-point of the response. With chronic hypertension, however, aorto-carotid baroreflexes also become *blunted*, in that an acute increase in blood pressure causes less SNS suppression.²² Abnormal cardiopulmonary baroreflex activity in hypertension²³ also contributes to abnormal pressure-volume homeostasis. For example, the high muscle SNS nerve traffic in hypertensives cannot be suppressed to a normal degree during salt loading.¹³

Pressure-flow imbalances in aging and hypertension

Steady-state hemodynamic studies have yielded a view that hypertension is caused by an isolated increase in SVR. Yet in most people with diastolic or systolic hypertension, it can be argued that cardiac output is also inappropriately high.^{19,24-28} Arterial pressure is more tightly regulated than cardiac output but neither is a highly regulated physiologic variable and wide intra-individual variations in BP and blood flow are necessary to meet diverse physiologic demands. In the population at large, cardiac output at rest varies by at least threefold,^{6,24} creating a very broad overlap between normal and hypertensive individuals in cardiac output or SVR. With or without hypertension, aging has a marked effect on systemic hemodynamics. Early in life, heart rate and cardiac output are relatively high, while later in life, heart rate and cardiac output decrease.^{11,12,15} In cross-sectional studies, SVR increases at least until middle age,¹² while pulse pressure continues to increase with advancing age²⁹ due to continuous increases in central arterial stiffness.

Thus the BP configuration in later years is usually isolated systolic hypertension.^{30,31}

There are certain recurring hemodynamic patterns that have been described in the population. At one extreme is “hyperdynamic,” or high-output hypertension,^{32,33} which occurs in younger individuals with early or “borderline” hypertension, and is associated with normal or low SVR.¹⁵ At the other extreme, older individuals, especially those with long-standing high blood pressure, typically manifest high SVR and normal-to-low cardiac output.^{11,12} Hypertensive individuals thus appear to make a transition from a high-output, low-resistance state to a low-output, high-resistance state as they age.³⁴ Yet it is not clear that such a transition occurs in most individuals with hypertension or if this transition is part of the usual aging process. One prospective 20-year follow-up study documents within-individual transitions from high cardiac output to high SVR but the study group only included those with hyperdynamic hypertension,³⁵ not the larger group who manifest isolated systolic hypertension as the only sign of the condition. In the Framingham study, systolic hypertension usually precedes diastolic hypertension.³⁶ Thus the best available information suggests that the vast majority of older hypertensives never manifest either diastolic hypertension or a hyperdynamic phase of the disorder, despite the fact that inappropriately high cardiac output at any age exacerbates hypertension.³⁷ It is also likely that the apparent age-related transition from high flow to high resistance is due to the peculiar form of selection bias intrinsic to cross-sectional studies.

In longstanding hypertension, structural cardiac and vascular maladaptations further sustain the high blood pressure. The degree of left ventricular hypertrophy (LVH) is closely related to the individual’s chronic systolic blood pressure.³⁸ Some studies suggest that LVH may be at least partially a result of chronically high SNS activity.³⁹ Over time, arteriolar smooth-muscle hypertrophy^{40,41} also appears to sustain the inappropriately high SVR. Fortunately, these chronic structural changes are at least partially reversible because adequate long-term treatment of hypertension favorably affects both LVH⁴² and vascular smooth-muscle hypertrophy⁴¹ and reduces overall cardiovascular risk.⁴²

Hemodynamic stress response patterns

Arterial pressure and cardiac output must vary to meet various physiologic, thermoregulatory, and metabolic demands, and hemodynamic responses to physiologic and metabolic stimuli vary within and across individuals. Under stimulated conditions, either flow or resistance may change based on the nature of the stimulus and the underlying disease state. During physiologic extremes such as bicycle exercise, the cardiac output of conditioned individuals can increase by over four-fold.²⁴ Even during relatively mild stresses such as the assumption of the upright posture, gravitational pooling and diminished venous return cause a decrease in upright cardiac output by about 20% compared to the supine posture.^{6,43} Mental and physical stress can be used as laboratory probes to

partially differentiate hypertensives from normotensives; hypertensives tend to respond to mental or physical stress with a combined pattern of increased cardiac output and peripheral vasoconstriction, whereas normotensives tend to respond with increased cardiac output alone.^{26,44} Psychosocial-physiologic differences in stress responses can also be demonstrated; the presence of a personality profile characterized by suppressed anger or hostility defines a subpopulation of individuals that responds with vasoconstriction after mental stress rather than increased cardiac output.⁴⁵ A variety of subacute or chronic environmental adaptations also affect resting cardiac output and SVR. In the northern latitudes, for example, resting supine cardiac output is about 15% lower in the winter than the summer in normal and borderline hypertensive individuals.⁴³

There is an important conservation mechanism that further modifies flow-resistance relationships and permits selective flow redistribution. Flow distribution across organ beds is made possible by selective vasoconstriction, which allows diverse physiologic adaptations with the least possible increase in cardiac work. Under usual resting or lightly stimulated conditions, about 40% of cardiac output goes to skeletal muscle, while about 20% to 25% each goes to the brain and kidneys. In response to various physiologic stimuli, both total cardiac output and the fractional flow sent to each major organ bed can vary widely. Modulation in organ perfusion is dependent on a variety of systemic and local vasoregulatory mechanisms, including regional SNS activity and the influences of circulating hormones such as vasopressin.⁴⁶

Limitations of steady-state hemodynamic model

As can be gleaned from the foregoing discussion, there are major limitations to the use of steady-state hemodynamic formulas to describe chronic hypertension. In the past, it was assumed that the syndrome of hypertension could be described adequately by the concept of increased SVR (i.e., diastolic hypertension) with normal cardiac output but this is a gross oversimplification of the problem. The simplified steady-state model is still useful as a teaching aid but it does not fully explain critical features of pulsatile flow or hypertensive target organ damage. First, the components of Ohm’s Law do not correspond to the physiologic control mechanisms: there are no constant flow or resistance sensors in the body, and circulatory systems are pulsatile, not constant-flow systems. Second, the physiologic variation in SVR is extremely wide within and between individuals, with extremely broad overlap between normal and hypertensive individuals.^{11,24,47,48} Third, it is now clear that the consequences of hypertension are much more closely related to systolic blood pressure, which is only partially dependent on systemic resistance.^{49,50} Finally, hemodynamic profiling has not proved to be a useful guide to therapy in chronic hypertension; antihypertensive drugs, which exert complex actions on the neuroendocrine and hemodynamic mechanisms, often lead to parallel reductions in cardiac output and systemic resistance.

There are also practical problems that plague the measurement of flow and resistance in humans. Invasive studies are neither practical nor definitive, and the wide physiologic variability of flow and resistance in everyday life makes threshold values essentially meaningless. Noninvasive studies of systemic hemodynamics are also technically difficult to reproduce. Doppler flow studies are difficult because of the peculiar geometry of the aortic root. The integral of a peripheral pulse contour could be used to estimate stroke volume were it not for the presence of reflected waves and other peripheral pulse transmission phenomena. Echocardiographic (ECG) determination is subject to substantial variations in results because of differences in ventricular geometry, and is relatively costly. Nuclear studies are expensive, cumbersome, and time consuming, and cannot detect acute hemodynamic changes. Impedance cardiography using ECG-gated variation in thoracic impedance can be used to derive stroke volume. While within-subject changes are relatively reliable using this technique, interindividual comparisons require a population-based algorithm that can be influenced by variable thoracic-abdominal anatomic configurations and altered conductivity within the thorax.

PULSATILE HEMODYNAMICS

The National Heart, Lung, and Blood Institute has redefined the approach to hypertension by focusing on systolic rather than diastolic pressure as the principal clinical endpoint for diagnosis and monitoring of hypertension, ending the twentieth-century view that hypertension is simply an elevation of diastolic BP.⁴⁹ The Joint National Committee in its seventh report has reiterated this position⁵¹ and professional organizations worldwide have subsequently concurred. Systolic pressure is very highly correlated with pulse pressure (PP = systolic – diastolic pressure), and both are independent cardiovascular disease risk predictors.⁵² Systolic pressure is preferred over PP as a clinical management variable, however, because it is almost identical to PP in its predictive value in epidemiologic studies. Systolic BP has been the principal dependent variable in successful clinical trials,⁵³ is easier to understand, and is more accurately determined.⁴⁹ Detection methods have also changed; oscillometric methods are becoming more widely used. They are reasonably reliable for the detection of mean and systolic pressures but depend on proprietary algorithms that differ among manufacturers,⁵⁴ and are intrinsically not as accurate in estimating diastolic BP or PP.⁵⁵

Pulse as biological signal

The generation of systolic pressure is far more complex in its physiology than the generation of diastolic BP and systolic BP contains information about both nonpulsatile and pulsatile flow. Teleologically, it can be argued that systolic pressure and PP are more physiologically relevant to short-term and long-term BP control because normal cardiovascular homeostasis requires cyclical stretch to generate feedback signals. It is attractive to speculate that the cardiac stretch and peripheral pulse volume are the

primary biological signals sensed by cardiac and arterial smooth-muscle mechanoreceptors. Cellular stretch, further modified by other deformation signals in some cells (e.g., endothelium) alter cell function via changes in ion transport, cell metabolism, and production of autacoids and vasoactive substances, all of which can affect local and regional blood flow.⁵⁶ At the same time, afferent fibers from specialized mechanoreceptors communicate with the central nervous system to regulate systemic flow. This integrated model provides the necessary information for systemic and regional cardiovascular homeostasis.

Ventricular–vascular interactions and pulse contours

An in-depth analysis of a systolic pulse contour yields the concept of “ventricular–vascular interactions” during systole (Figure 11–1). During early systole, the interaction of the left ventricle and the aorta generate a forward pressure wave and an initial systolic peak pressure (usually called P1). In late systole, the interaction of the forward pressure wave and flow discontinuities in the peripheral arterial tree generate reflected pressure waves that often augment P1 (forming P2). The observed systolic pulse contour is the sum of these “ventricular–vascular interactions” (Figure 11–2). Hypertension can be subdivided into its hemodynamic components using these concepts (Figure 11–2). In this model, increased systemic resistance causes increases in both systolic BP and diastolic BP, whereas increased systolic BP can result from increased cardiac stroke volume or increased aortic impedance (due to decreased aortic diameter or increased aortic stiffness). Increased aortic stiffness also leads to a decrease in diastolic BP through alteration in capacitance and reduced diastolic “runoff” (Figure 11–3).

Systolic hypertension: Aortic abnormalities

Large arteries serve two major interrelated functions: transfer of blood to peripheral organs (the conduit or

Figure 11–1. Anatomy of a central pulse wave. Several different physical forces determine the morphology of a pulse contour, which is the result of a series of ventricular–vascular interactions. Early systolic interactions of the ventricle and the aorta determine the height of the forward pressure wave (P1). Later in systole, a primary reflected wave returns to the aortic root where it summates with the decaying forward wave (P2), augmenting central systolic pressure, especially in older individuals with hypertension.

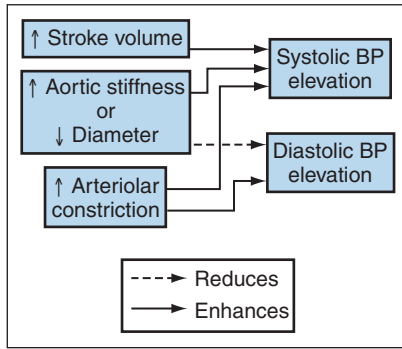

Figure 11–2. Pathogenesis of systolic and diastolic hypertension. Diastolic BP elevation occurs principally as a result of systemic vasoconstriction. Systolic BP elevation is the result of increased diastolic BP as well as increased cardiac stroke volume, increased aortic stiffness, or decreased aortic diameter. Central pulse pressure is also affected by the timing and magnitude of reflected pressure waves, whereas peripheral pulse pressure is predominantly determined by the forward pressure wave (see text). BP, blood pressure.

transmission function) and partial damping of cardiac pulsation (the compliance or capacitance function). Circulatory pulsation is reflected clinically by the amplitude of the PP, which is determined by the underlying series of

ventricular–vascular interactions. Increased PP (generally P1) is sometimes due to an isolated increase in stroke volume (severe anemia, hyperdynamic hypertension, aortic insufficiency, thyrotoxicosis, vitamin deficiency, or arteriovenous shunting, renal failure⁵⁷), but the etiology of wide PP or isolated systolic hypertension (ISH) is predominantly due to increased central arterial stiffness.⁴⁹ Whether or not the diastolic (or mean) pressure is elevated depends on the concomitant degree of elevation of systemic resistance (Figure 11–1). In normal young people, the elastic recoil function of the proximal aorta serves to dampen the impact of pulsatile flow (i.e., it narrows the PP) by retaining a fraction of each cardiac stroke volume in the central arteries during systole and then delivering this retained volume to the distal circulation during diastole (Figure 11–3).⁵⁸ Because the normal aorta functions as a capacitance chamber (Windkessel model) and a passive third pumping chamber, pulsatile flow is damped and PP is relatively narrow. When central arteries are intrinsically smaller, or if they stiffen with aging and hypertension, the capacitance and damping functions of the aorta are diminished and more of each individual stroke volume is forced through the resistance arterioles during systole. The amplitude of the forward pressure wave (and PP) increases, and the systolic peak itself becomes sharper,⁵⁹ independent of any changes in cardiac output or systemic resistance. With aging, because of the reduction in the elastic recoil function of the aorta, the fraction of each stroke volume retained in the aorta during systole is decreased. Consequently, there is a

Figure 11–3. Capacitance function of the aorta and pathogenesis of wide pulse pressure. In individuals with elastic central arteries (usually younger people, *left panel*), the aorta is distended by each cardiac stroke volume, with the retained remnant of each stroke volume delivered by aortic elastic recoil to the periphery during diastole. This phenomenon represents normal capacitance or damping of cardiac pulsation. As vessels stiffen (usually older people, *right panel*), the fraction of stroke volume delivered during systole increases and the pressure and flow during diastole decrease. The hallmark of central arterial stiffness (reduced capacitance and damping) is thus a widened PP. PP, pulse pressure. (Adapted from Izzo JL Jr, *J Am Geriatr Soc* 1982;30:352–9: Blackwell Scientific.)

corresponding reduction in diastolic flow and BP and a net widening of PP. Degenerative stiffening of the aorta and central arteries is sometimes called *arteriosclerosis* to differentiate it from *atherosclerosis*, the occlusive result of endovascular inflammatory disease, lipid oxidation, and plaque formation. At a cellular level, arteriosclerosis is the result of age and hypertension-related adaptations in the tunica media, including the breakdown of the elastin network, increased collagen deposition, and vascular smooth-muscle hypertrophy.^{60–63}

It has been taught that an age-related increase in aortic diameter is a major contributing factor to increased impedance and wide PP.⁶⁴ This line of reasoning, however, runs counter to the basic principles of arterial biomechanics and to the observed trends in large observational studies. The input impedance of an artery is *directly* proportional to the root of its “effective stiffness” (wall elasticity-thickness product) and *inversely* proportional to the root of the fifth power of its diameter. With aging and hypertension, wall thickness and intrinsic wall stiffness do increase but these changes are accompanied by age-related increases in aortic diameter.⁶⁵ It seems most plausible that the age-related increase in diameter serve to counteract (rather than cause) the age-related increases in effective arterial stiffness and the wide PP. In smaller individuals, including women, isolated systolic hypertension begins with a smaller aortic diameter and normal aortic wall properties. Mitchell et al.⁶⁶ have reported an inverse relationship between aortic diameter and systolic BP in middle-aged individuals with systolic hypertension (with or without diastolic hypertension). An inverse relationship between aortic size and systolic blood pressure (or PP) was also observed in recent studies, such as the Framingham Heart study and the LIFE study.^{31,65,67,68}

The idea that wide PP hypertension is not simply “burned-out” diastolic hypertension is also supported by the Framingham and NHANES databases to the effect that the onset of hypertension in middle-aged individuals begins with elevated systolic pressure (and normal diastolic pressure).^{31,69} The most rational interpretation of current data is that individuals with smaller aortas have an intrinsic tendency toward wide PP as a result of increased aortic impedance. Age-related dilatation of the aorta also occurs but does not fully compensate for the increased systolic BP load. Aging and hypertension-related increases in aortic wall thickness and changes in intrinsic wall composition are maladaptive compensations for increased aortic diameter (and load) that exacerbates the wide PP.

Stiffening of the aorta and carotid arteries has another important homeostatic consequence: increased blood pressure variability. With collagen deposition and calcification, baroreflex mechanoreceptors are restrained in their ability to stretch, thus reducing the effect of an important negative feedback loop controlling SNS outflow.²² In response to an increase in cardiac output, the absence of the aortocarotid baroreflex allows maintenance of a higher heart rate and vascular resistance than would normally occur, thus leading to a prolonged increase in systolic pressure after stimulation. Conversely, vasodila-

tion after exercise or a large meal is met with a lessened counter-regulatory SNS-mediated vasoconstriction, and pressure remains low for a longer period of time.^{70–72}

Pulse wave reflection and augmentation

Late systolic ventricular–vascular interactions involve the impact of reflected pressure waves, which arise at points of “impedance mismatch” (where the flow and pressure waves are not perfectly matched). Common reflection sites are branch points, constrictions, areas of turbulence, or areas of change in wall stiffness. Reflected waves can be characterized by two basic properties: timing and amplitude. Timing is a function of pulse wave velocity (PWV), which is directly dependent on arterial stiffness and the distance to the reflecting site and inversely dependent on arterial diameter. The amplitude of the reflected wave is dependent on the reflection coefficient generated in the distal circulation and is usually characterized as the augmentation pressure (increment over the incident wave caused by the reflected wave) or augmentation index (AI), the fraction of total PP attributable to the reflected wave) (Figure 11–2), usually corrected for height⁷³ or gender⁷⁴ and heart rate.⁷⁵

At all points along the arterial tree, forward- and backward-traveling waves summate to create the unique morphology of the pressure wave at a particular point. Central and peripheral pressure waveforms differ because of the relative timing differences of the incident and reflected waves at the two sites. Since these pattern differences are somewhat predictable, the central waveform theoretically can be recreated from the corresponding peripheral waveform using a generalized transfer function. Yet there remains considerable debate about the reliability of this approach.^{55,74,76–82} Overall, even if the nuances of the central waveform are lost in the application of a fixed transfer function, central systolic pressure can be reasonably estimated from the radial pressure waveform.^{55,78} In contrast, central PP cannot be as easily estimated because of intrinsic inaccuracies in the measurement of peripheral diastolic pressure.⁵⁵

There is a popular misconception that AI is primarily a measure of arterial stiffness. Instead, the principal determinant of AI is the reflection coefficient, which is strongly influenced by peripheral vasomotor tone. AI correlates strongly with DBP, MAP, and SVR.^{83,84} The peripheral circulatory contribution to AI has been demonstrated by the instantaneous increases in AI that occur during acute infusion of vasoconstrictors such as norepinephrine,^{85,86} angiotensin II,^{86,87} or endothelin.⁸⁸ Conversely, nitrovasodilators immediately diminish AI.^{89–92} In experiments in which AI and PWV have been measured simultaneously, acute changes in AI are far greater than the corresponding changes in PWV. There is a small effect of age or arterial stiffness on AI, but overall AI is only weakly related to arterial stiffness.

Pulse pressure amplification and microcirculation

As pressure waves travel downstream, the forward pressure wave is amplified due to increased impedance in arteries

of decreasing caliber, causing *pulse pressure amplification*.⁹³ Wall composition also changes with arterial size; in the thoracic aorta, there is a predominance of elastin over collagen, but in the peripheral conduit arteries, there is more collagen than elastin. Importantly, not all segments of the arterial tree become stiffer with aging or disease. In hypertensives⁹⁴ and diabetics,⁹⁵ the brachial arteries demonstrate normal or increased age-related compliance, at least in part due to their relatively larger diameters compared to normal individuals. It seems likely that this enhanced compliance serves as an important offload mechanism that transfers the capacitance function a little further downstream.

In normal young people, brachial systolic pressure is often 10 to 20 mm Hg higher than aortic root systolic pressure, but with very wide interindividual variation. It has been said that there is a diminution of pulse pressure amplification (PPA) with aging,⁶² but this statement is based on the comparison of peak pressures at the radial artery, which is almost exclusively related to the amplitude of the forward wave (P1) compared to the sum P1 and the reflected wave at the aortic root.⁶² Newer studies are beginning to compare central and peripheral P1 values to learn more about the properties of large arteries independent of wave reflection.⁹⁶ The practical importance of variability in PPA is that brachial cuff blood pressures do not provide uniformly accurate information about central or distal systolic pressure or PP. Thus, in order to obtain more relevant information about a given patient, it will be necessary to use measures other than a standard blood pressure cuff applied to the arm.

Hypertensive target-organ damage

Thus, it can be seen that cardiac and vascular target organ damage are predictable interrelated consequences of the systolic hypertension with direct implications for cardiovascular symptoms and pathology. Increased central systolic BP increases cardiac afterload and leads to left ventricular hypertrophy.⁹⁷ Increased central arterial stiffness and cardiac afterload (Figure 11–4) cause decreased exercise tolerance,^{98,99} diastolic dysfunction, and eventually, heart failure.^{98,100–102} Ischemic heart disease is exacerbated as well due to reduced diastolic pressure and reduced coronary filling,¹⁰³ especially in response to systemic vasodilation.^{104,105}

It is highly likely that PP markedly affects normal microcirculatory function and structure and that wide PP contributes to organ dysfunction. For example, glomerular filtration rate (GFR) is PP-dependent,¹⁰⁶ and therefore PP must affect salt and water excretion. Renal pulsation itself is probably critical to the maintenance of normal excretory function because kidneys with reduced pulsatility (e.g., a rejecting or ischemic renal allograft or the Page model of perinephritic scarring) have reduced GFR^{107,108} with hypertension. In individuals with “prehypertensive” blood pressures, higher PP is associated with higher cardiac output and reduced capillary density.¹⁰⁹ This phenomenon of “microcirculatory rarefaction” has been reported in individuals with insulin resistance^{110,111} and salt-sensitive hypertension,¹¹² and is histologically similar to focal renal

Figure 11–4. Central pulse contours and cardiac workload in aging and hypertension. Cardiac workload (the integral of the central pulse contour during systole) can be decomposed into relative contributions of diastolic pressure (A), the early systolic interaction of ventricular emptying with aortic impedance (B), and the late systolic interaction of ventricular emptying with the distal circulation and reflected waves (C). With advancing age, central PP (systolic – diastolic) widens. In this example, MAP and early systolic load (B) remain constant, diastolic pressure load (A) decreases, and late-systolic load (C) markedly increases. The net result for the older individual is central ISH and increased cardiac load due to the need for left ventricle to sustain contraction until late systole to counteract the effects of increased wave reflection. This pattern leads to concentric left ventricular hypertrophy and is associated with peripheral target-organ damage. ISH, isolated systolic hypertension; MAP, mean arterial pressure; PP, pulse pressure.

glomerulosclerosis, the hallmark lesion of progressive renal failure. To complete the cycle, PP has been found to correlate with the degree of albuminuria,¹¹³ and central arterial stiffness correlates inversely with GFR.^{114–117} Systolic hypertension or wide PP is the principal etiologic finding in ischemic stroke⁵² and the PWV is directly related to the severity of carotid plaques.¹¹⁸ It is also likely that the cerebral microcirculation in hypertension is affected similarly to the kidneys, because systolic hypertension and wide PP are associated with leukoariosis, lacunar infarcts, and dementia,¹¹⁹ which appear to be close correlates of glomerular capillary hypertension, focal glomerulosclerosis, and chronic kidney disease, respectively.

Vascular smooth muscle hypertrophy is also likely to be a primary response to increased PP. In hypertension, there is increased arteriolar wall thickness relative to the luminal diameter of resistance arterioles,^{41,120} a phenomenon that serves to sustain systemic resistance (and therefore systolic BP) at an inappropriate level. Additional stiffening of the aorta further elevates systolic pressure BP, thus creating a “vicious cycle,” where increased PP leads to further increases in PP. Fortunately, there is some reversibility of this structural abnormality because arteriolar hypertrophy is partially reversible with vasodilator drugs such as angiotensin-converting enzyme

inhibitors. In contrast, beta-blocker drugs, which do not tend to reduce PP, do not reduce the increased arteriolar wall-to-lumen ratio found in essential hypertension.⁴¹

SUMMARY

Hypertension is a hemodynamic syndrome first described as an anomaly of increased resistance to steady-state flow. Although this “classical” approach retains some utility as a teaching model and for classifying pharmacologic responses, a pulsatile model is necessary to explain important features of the pathogenesis and natural history of hypertension. Age-related changes in pulsatile hemo-

dynamics, exacerbated by the presence of hypertension, form the basis for a series of interdependent functional and structural changes that also have metabolic implications. The pathogenesis of hypertension and its consequences are not linearly related but rather form a “vicious cycle” that, in effect, leads to premature cardiovascular aging. Central arterial stiffness and wave reflections modify the systolic pulse contour and lead to specific patterns of target organ damage that extend simultaneously from the heart to microcirculations. These continuously evolving interactive pathophysiologic changes in hypertension are thus both causes and effects of this ubiquitous hemodynamic syndrome.

The Arterial System in Human Hypertension

Daniel A. Duprez and Jay N. Cohn

Key Findings

- Structural and functional properties of the arterial wall are altered in hypertension even at the early stages of the disease.
- Arterial stiffness is the most important cause of increasing systolic and pulse pressure, and of increasing pulse pressure with aging.
- Morbidity and mortality associated with hypertension are primarily related to arterial damage and may affect one or several organs.

Clinical Implications

- Considering the potential implications of arterial assessment in the prevention of cardiovascular disease, evaluation of the arterial effects of antihypertensive treatment is recommended.

The principal function of the arterial system is to deliver an adequate supply of blood to tissues and organs. In performing this primary conduit function, the arteries transform the pulsatile flow generated by ventricular contraction into a continuous flow of blood in the periphery. This latter cushioning function is dependent on the mechanical properties of the arterial walls.

Blood pressure (BP) is a powerful cardiovascular (CV) risk factor that acts on the arterial wall and is responsible in part for various CV events, such as cerebrovascular accidents and ischemic heart disease.¹ In clinical practice, two specific and arbitrary points of the BP curve, peak systolic BP (SBP) and end-diastolic BP (DBP), are used to define the CV risk factor. Because the goal of drug treatment of hypertension is to prevent CV complications, it appears likely that the totality of the BP curve, not simply two specific and arbitrary points, should be considered to act mechanically on the arterial wall and therefore should be used to propose an adequate definition of high BP (Figure 12–1).

PHYSIOLOGIC ROLE OF ARTERIES

Traditionally the BP curve has been considered to contain a steady component, mean BP, and a pulsatile component, the pulse pressure. Hemodynamic research has shifted away from a steady-flow approach toward a pulsatile flow approach because the former is less predictive in relation to cardiovascular morbidity and mortality.^{2,3} The growing

importance of pulsatile pressure indices paralleled the notion that not only increases in systemic vascular resistance but also increases in arterial stiffness are important in the pathophysiology of hypertension.⁴

A current approach consists of considering the BP curve as the summation of a steady component, mean arterial blood pressure (MAP), and a pulsatile component, pulse pressure (PP). MAP, the product of cardiac output multiplied by total peripheral resistance, is the pressure for the steady flow of blood and oxygen to peripheral tissues and organs. The pulsatile component, PP, is the consequence of intermittent ventricular ejection from the heart. PP is influenced by several cardiac and vascular factors, but it is the role of large conduit arteries, mainly the aorta, to minimize pulsatility. In addition to the pattern of left ventricular ejection, the determinants of PP (and SBP) are the cushioning capacity of arteries and the timing and intensity of wave reflections. The former is influenced by arterial stiffness, usually expressed in the quantitative terms of compliance and distensibility. The latter result from the summation of a forward wave coming from the heart and propagating at a given speed (pulse wave velocity, or PWV) toward the origin of resistance vessels and a backward wave returning toward the heart from particular sites characterized by specific reflection indices.^{5,6} Information about the interaction between the left ventricle and the physical properties of the arterial circulation can be derived by the descriptive and quantitative analysis of the arterial pressure pulse waveform.^{7,8}

Ejection of blood into the aorta generates a pressure wave that is propagated to other arteries throughout the body. As in elastic conduits, this forward-traveling pressure wave may be reflected at all points of structural and/or functional discontinuity of the arterial tree. From these different points of discontinuity, mainly located in the distal arteries at the branching origins of arterioles, a reflected wave is generated that travels backward toward the ascending aorta. Thus incident and reflected pressure waves are in constant interaction along the arterial circuit and are summed up into the actual pressure wave. The final amplitude and shape of the measured aortic BP wave are determined by the phase relationship (timing) between the two component waves. The timing of incident and reflected pressure waves depends on pulse wave velocity, the traveling distance of pressure waves, and the duration of ventricular ejection. In young subjects, under physiological conditions, the backward pressure wave returns from the distal arterial compartment during diastole,

Figure 12-1. In clinical practice two specific and arbitrary points of the blood pressure curve, peak SBP and end DBP, are used to define normotension and hypertension. Several parameters are derived from the blood pressure curve to provide information about the arterial system. This figure illustrates some examples: SRI is derived from the ratio of the second over the first peak of the systolic part of the radial artery wave form (P_2/P_1). C_1 (large artery elasticity index (LAEI)) and C_2 (small artery elasticity index) are derived from diastolic pulse contour analysis of the radial artery waveform. Augmentation pressure is the difference between the second and the first peak of the systolic part of the radial artery waveform ($P_2 - P_1$). The augmentation index is the ratio $P_2 - \text{DBP} / P_1 - \text{DBP}$. DBP, diastolic blood pressure; SBP, systolic blood pressure; SRI, systolic reflective index. (From Duprez DA, Kaiser DR, Whitwam W, et al. *Am J Hypertens* 2004;17:647–653 with permission from *The American Journal of Hypertension Ltd.*)

making PP higher in peripheral than in central arteries. This physiological phenomenon, called PP amplification, is influenced by pulse wave velocity. With heightened PWV, the reflecting sites of the distal compartment appear “closer” to the ascending aorta, and the reflected waves occur earlier, being more closely in phase with incident waves in this region. Such an earlier return of wave reflections means that the reflected wave affects the central arteries during systole and not during diastole. This disturbed signal results in an augmentation of aortic and ventricular pressures during systole and reduces aortic pressure during diastole. Hence, altered mechanical properties of the aortic wall influence the level of aortic SBP (which is increased) and DBP (which is decreased) as a consequence of early wave reflections. Finally, all these findings taken together indicate that a disturbed pressure signal arising from the distal arteries through disturbed wave reflections may alter the heart-vessel coupling and lead to increased CV risk. Evidence for this pathophysiologic mechanism arises from studies of pulsatile arterial hemodynamics, as highlighted recently by the role of pulse wave velocity and wave reflections as independent factors in CV risk in hypertension and various CV diseases.^{9–11}

Wave reflections alter the ventricular-vascular coupling not only through increased arterial stiffness and changed timing, but also through modifications in their amplitude. Such possibilities depend on the reflectance properties

of the arterial tree, which arise from the distal part of the arterial tree. They are influenced by the geometry, number, structure, and function of smaller muscular arteries and arterioles. Thus acute and active arterial and arteriolar constriction results in earlier aortic wave reflections at the aortic level and hence increased PP. It appears that elastic arteries buffer the pulsations, muscular arteries actively alter propagation velocity, and arterioles serve as major reflection sites. Each of these alterations (or their combination) enables cross-talk between the proximal and distal compartments of the arterial tree, which leads to the predominant or selective increases of SBP and PP observed in aged and/or hypertensive populations at high CV risk.^{12,13} In the presence of decreased ventricular ejection, these frequency-dependent factors disturb the heart-vessel coupling, increase the load of the heart, and favor cardiac hypertrophy, coronary ischemia, and ultimately CV death.¹⁴

The interest in the arterial cushioning function of pulsatile flow has given us a myriad of indices generated by various noninvasive measurement techniques, which only indirectly measure the desired arterial stiffness characteristics. Given their complexity in describing the structure and function of these indirect approaches, simplified mathematical models have been developed.^{15,16} However, it is important to recognize that different parts of the arterial system have different functions. The

proximal large arteries buffer the pulsations; the more distal or muscular arteries alter propagation velocities and vascular impedance, and serve as major reflection sites. Each of these alterations or their combination enables a cross-talk between the proximal and distal compartments of the arterial tree.

PHYSIOLOGIC EFFECTS OF VASCULAR WALL ALTERATIONS

All arteries exhibit compliance characteristics that can be defined as the increase in caliber for a given rise in pressure (dV/dP , where dV is the change in artery volume over a linear length and dP is the rise in pressure during the cardiac cycle). Only the smaller arteries and arterioles provide major resistance to flow, which is exquisitely sensitive to changes in the caliber of these microvessels. The role of compliance in the conduit arteries is a critical determinant of their storage capacity during systole. Much of the stroke volume delivered by the ventricle is accommodated in the pressure-dependent increase in arterial caliber, and this volume is released during diastole to help maintain diastolic pressure. When compliance of these conduit arteries is reduced, the result is less storage of stroke volume and/or a greater increase in systolic pressure to distend the noncompliant arterial bed. Increased workload on the left ventricle and a decrease in

aortic diastolic pressure are the hemodynamic accompaniments of reduced large artery compliance, which will lead to an increase in systolic blood pressure as it is observed in systolic hypertension and in diabetes.^{17,18}

Compliance of the more distal arterial system at sites of tapering and at branch points serves to cushion the arterial pulse wave during its transmission through the arterial bed. The less the cushioning effect the greater the magnitude and frequency of oscillations or reflections that appear to have their origin at these sites in the vascular bed. The pressure response to these oscillations results from a complex interaction of the storage volume of these cushioning vessels, compliance of the more proximal arterial system, and pulse wave velocity that influences the rate at which these reflections are transmitted back to the root of the aorta. Compliance of the arterioles also will influence pulsatile vascular resistance. To the extent that pulsatile pressure is transmitted to the arterioles, the caliber of these vessels, and thus the resistance, will vary throughout the cardiac cycle, depending on the compliance of these vessels. Another possible effect of compliance alteration is its influence on shear force at the arterial wall. Such alterations in shear force may contribute to endothelial damage and to the atherosclerotic process in the conduit arteries.^{18,20}

Arterial stiffness is determined by its visco-elastic properties, which are in turn dependent on the structure (or composition) and function of the vessel wall.²¹ Alterations in the extracellular matrix of the media and adventitia have long been implicated in the pathogenesis of age- and blood pressure-related increase in arterial stiffness. There is now good evidence that acute and low-grade chronic inflammation is associated with stiffening of the large arteries²² (Figure 12–2). This is likely to promote atheroma formation and increase cardiovascular risk. The exact mechanisms responsible for arterial stiffening remain to be elucidated but are likely to reflect both functional and structural changes in the vessel wall. It is possible that inflammation may be involved in the initiation as well as development of hypertension, with the exertion of proinflammatory actions through several mediators,

including adhesion molecules, chemokines, growth factors, heat shock proteins, endothelin-1, and angiotensin.^{23,24} Indeed, even a persistent low-grade inflammatory state could result in a high but within “normal range” concentrations of inflammatory cytokines. Moreover, low-grade inflammation has been associated with endothelial damage and dysfunction and consequently will lead to impaired vasodilation and hypertension.

CONTROL OF ARTERIAL TONE

An increase in arterial tone has traditionally been viewed as the hallmark for elevated blood pressure. Although some have suggested that an increase in cardiac output with normal vascular resistance is the initial hemodynamic abnormality in patients with hypertension,²⁵ the chronic hypertensive state usually is associated with an increase in total systemic vascular resistance. This increase in resistance is generally attributed to an increase in vascular tone.²⁶ The mechanism for this increase is, however, cryptic. The role of the sympathetic nervous system, the renin-angiotensin system, electrolyte changes, alterations in release of endothelial relaxing factor, increased release of endothelial constricting factors, and other factors that mediate tissue blood flow autoregulation have all been implicated in the process.¹ Neural and hormonal influences that alter tone of the arteriole, and thus the calculated systemic vascular resistance, also play a role in the larger conduit arteries. An increase in smooth muscle tone in the muscular arteries that represent most of the conduit vessels will alter the pressure-to-volume relationship in these vessels and result in a decrease in arterial compliance or elasticity.²⁷

The problem of identifying an abnormality in arterial tone related to some neural or hormonal effect is compounded by the fact that during daily life, arterial tone and blood pressure changes are continuously induced by alterations in neurohormonal activity. During exercise, emotional or temperature stress, and even during periods of standing, these systems may be activated and an alteration in regional or systemic vascular tone may result. Therefore, the dilemma in identifying individuals with elevated blood pressure from the normal fluctuations of blood pressure in normotensive individuals is intensified. Attempts to define the hypertensive state by the degree of blood pressure elevation or the sustained nature of this elevation during 24-hour monitoring often serves as the only distinguishing feature between the normotensive individual with fluctuations in arterial tone and the hypertensive who is thought to be at risk for cardiovascular events.

CONTROL OF ARTERIAL STRUCTURE

Although hypertension was traditionally viewed as a disease of increased arterial tone, the vascular structural abnormality in hypertensive disease has become the focus of more recent investigation. Those same neural and hormonal influences that alter arterial tone appear also to induce changes in arterial structure. Thus the blood

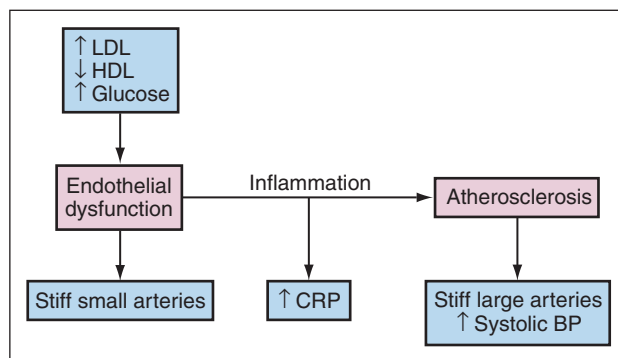

Figure 12–2. Role of vascular inflammation on large and small arteries stiffness in the pathogenesis of arterial hypertension. BP, blood pressure; CRP, C-reactive protein. (From Duprez DA, Somasundaram PE, Sigurdsson G, et al. *J Hum Hypertens* 2005;19:515–9.)

pressure increase and the hormones that produce arterial constriction both tend to stimulate arterial growth, whereas blood pressure reduction and hormones that induce vasodilation tend to induce growth regression. Growth of both vascular smooth muscle cells and connective tissue may be induced by hemodynamic and hormonal influences.

Vascular remodeling (Figure 12–3) is considered an adaptive response to elevation of arterial pressure to normalize the wall tension. In essential hypertension, large artery remodeling is characterized by an increase in media thickness–lumen diameter ratio and cross-sectional area. This augmentation of media mass, or hypertrophic remodeling, is explained by changes in size or number of vascular smooth muscle cells and matrix collagen deposition.²⁸ In resistance arteries (diameter $\leq 300 \mu\text{m}$), essential hypertension is associated with a reduced lumen and increased media thickness–lumen ratio but without cross-sectional area increase, producing a type of remodeling designated as inward eutrophic remodeling.²⁹ To explain this different response between large and small arteries, it is suggested that small arteries are not submitted to an augmented wall stress because they are initially constricted.³⁰ This remodeling of the vascular structure is dependent not only on blood pressure but also on blood flow and hormonal environment, in which the renin-angiotensin-aldosterone system plays a crucial role.

Arterial injury is considered as the starting point for what is called arterial remodeling.³¹ Once the endothelium has been injured, an immunologic cascade sets in. Cell surface molecules that mediate interaction of leukocytes and endothelium such as vascular and intercellular cell adhesion molecule 1 (VCAM-1 and ICAM-1) get upregulated.³² Inflammatory cells are therefore directed to the site of injury by chemoattractant factors such as monocyte chemoattracting protein 1 (MCP-1). Secretion of chemokines and cytokines by endothelial and lymphoid

cells upholds the process of inflammation. Macrophage-colony stimulating factor (M-CSF) effects an upregulation of the scavenger receptors on the activated macrophages and by this stimulates the uptake of oxidized lipoproteins and the formation of foam cells. Growth factors like platelet-derived growth factor (PDGF) expressed by endothelial cells induce a migration of smooth muscle cells into the intima of the atheromatous lesion, which is subjected to intracellular matrix degradation mainly evoked by metalloproteinases (MMPs).³³ The growth of an atherosclerotic plaque is compensated by caliber expansion of the whole vessel, while keeping the lumen size steady, the so-called positive remodeling. As soon as the plaque exceeds a certain dimension, the lumen gets affected, leading to arterial stenosis, the so-called negative remodeling. Minor decreases in the lumen of small arteries and arterioles will significantly increase resistance. Accordingly, these segments of the arterial tree are known as resistance arteries, and they may play an important role in the development of hypertension and may also contribute to its complications.³⁴ The vascular changes in resistance arteries that result in decreased lumen size in hypertension may be structural, mechanical, or functional. Extracellular matrix remodeling is very important in the process of vascular remodeling. With chronic vasoconstriction, the small arteries may become embedded in the remodeled extracellular matrix and may not return to their vasodilated state.³⁵

The arterial structural changes that accompany hypertension may serve as a distinguishing feature between the normotensive individual with fluctuating blood pressure and vascular resistance and the truly hypertensive individual at risk for vascular events. Furthermore, this abnormality of structure may exist even in the absence of an elevated blood pressure and thus may identify individuals in the normotensive range who are at risk for cardiovascular events. Preliminary studies have suggested that a reduction in small artery compliance can be detected in subjects with a parental history of hypertension even before their pressure is significantly elevated.³⁶ No other simple technique, except the crude measurement of so-called risk factors, is able to identify this at-risk population.

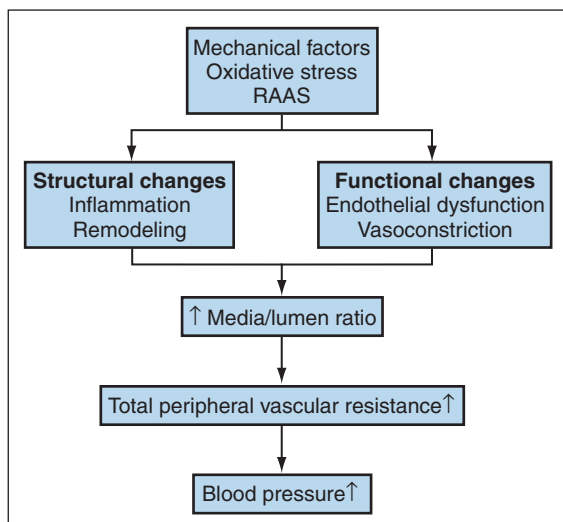

Figure 12–3. The effect of structural and functional changes of the arterial system in the pathogenesis of arterial hypertension. RAAS, renin-angiotensin-aldosterone system.

SEQUENTIAL CHANGES IN HYPERTENSION

Abnormalities of the arterial vasculature that precede cardiovascular morbid events are likely to occur in a temporal sequence (Figure 12–4). The initial abnormalities appear to be functional, in large part related to endothelial dysfunction associated with decreased bioavailability of NO.³⁷ A decrease in constitutive release of NO, which maintains low small artery tone, may be the initial abnormality, but it is soon accompanied by a decrease in stimulated release of endothelial vasodilators, as manifested by a reduction in flow-mediated dilation of conduit arteries.^{38,39} These functional abnormalities of the vasculature should precede and are mechanistic precursors of the structural alterations that are responsible for thickening of the conduit artery wall,⁴⁰ increases in pulse

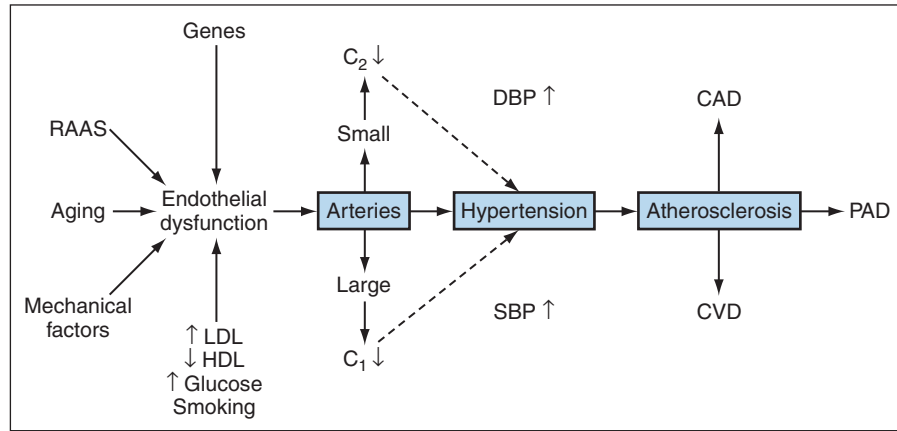

Figure 12-4. Temporal sequence of arterial changes in arterial hypertension. The functional defect starts predominantly in the small arteries as endothelial dysfunction. Structural dysfunction occurs later and affects large and small arteries leading to the reduction of small (C_2) and large arterial elasticity (C_1). This will lead to increase of diastolic and systolic blood pressure. Further damage of the arterial system in arterial hypertension leads then to atherothrombotic complications, such as acute myocardial infarction, stroke, and PAD. CAD, coronary artery disease; CVD, cardiovascular disease; DBP, diastolic blood pressure; PAD, peripheral arterial disease; SBP, systolic blood pressure; RAAS, renin-angiotensin-aldosterone system.

pressure,⁴¹ and atherosclerotic plaque development.⁴² These structural changes may also result in additional functional abnormalities. But cross-sectional studies suggest that this sequence of vascular manifestations of vascular disease is not always detectable.

Functional and structural changes in the artery wall precede and accompany atherosclerosis and its obstructive and thrombotic events. These changes should alter the volume increment that occurs in the arterial bed during the systolic pressure increase with each cardiac cycle. A variety of techniques developed in recent years provide quantitation of these pathophysiologic changes in the arterial wall (Figure 12-5). Because aging produces changes similar to those observed in atherosclerosis, all methods for evaluation must be corrected for age and, perhaps, gender.⁴³ Thus to serve as a useful surrogate for disease progression, the method must provide insight into disease presence independent of age. Furthermore, if arterial wall compliance, elasticity, or stiffness is to serve as a valuable surrogate for efficacy of therapy, it should be tracked with disease progression and regression.

An understanding of the sequential changes that occur in the arterial system is crucial in order to appreciate the temporal influence on the occurrence of cardiovascular disease and its response to treatment. Diagnostic procedures are currently designed to assess the extent and severity of vascular disease after the development of symptoms or when morbid events occur. The diagnostic challenge must be to detect abnormal structure and function in the vascular system before the development of symptoms or signs of cardiovascular disease.¹³ By providing a direct assessment of abnormal structure or tone in the arterial vasculature, alterations in arterial compliance may improve risk stratification and identify individuals with early vascular damage who are predisposed to future vascular events.⁴⁴

EFFECTS OF AGING

Available evidence suggests that the incidence of systolic hypertension is increasing in individuals over 50 years of age. The reasons for this evolution are quite simple⁴⁵ (Figure 12-6). First, prolongation of the duration of life is responsible for an increased number of older individuals with increased systolic blood pressure (SBP). Second, the goal for treatment of systolic-diastolic hypertension in middle-aged subjects has been based on the reduction of diastolic blood pressure (DBP). Because it is much easier

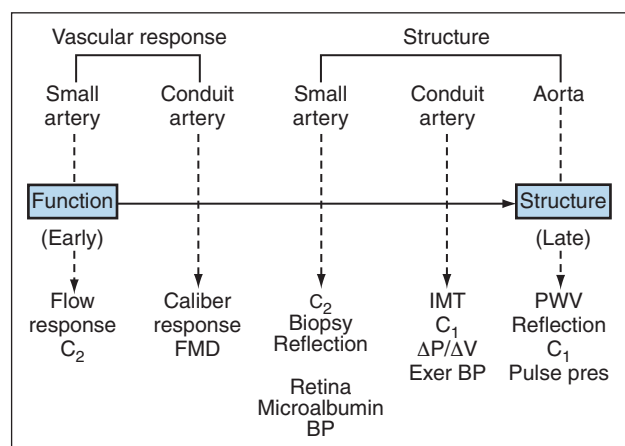

Figure 12-5. Methods to study the sequential changes of the arterial system in arterial hypertension. $\Delta P/\Delta V$, pressure/volume relationship of a single artery; C_1 , large artery elasticity index; C_2 , small artery elasticity index; exer BP, blood pressure rise in response to a standardized exercise test; flow response, response to acetylcholine; FMD, flow-mediated vasodilation; IMT, intima-medial thickness of carotid artery; reflection, augmentation index; retina, retinal vasculature; pulse pres, auscultatory pulse pressure; PWV, pulse wave velocity.

to control DBP (<90 mmHg) than SBP (<140 mmHg), and because, with age, DBP tends spontaneously to be reduced and SBP to be enhanced, this situation contributes *per se* to increase the incidence of systolic hypertension in the elderly. All these findings are important to consider, as the pathophysiologic mechanisms of systolic hypertension involve not only altered vascular resistance, the classical hallmark of high blood pressure (BP), but also changes of stiffness and wave reflections, which refer to conduit arteries, mainly the aorta and its principal branches.

Adaptations in the arterial vasculature play a critical role in influencing cardiovascular hemodynamics with advancing age.⁴⁶ The generalized structural and functional changes in the arterial circulation contribute to alterations in regional blood flow, progression of atherogenesis, and the microvascular abnormalities that occur during senescence.⁴⁷ In large arteries, aging results in progressive deposition of calcium salts, fraying and fragmentation of

elastin, and an increase in the number and cross-linking of collagen fibers that alter the compliance characteristics of the vessel wall.⁴⁸ A rigid aorta is less able to buffer the pulsatile output from the heart; it contributes to an increase in systolic blood pressure and left ventricular afterload and a decrease in diastolic blood pressure and impaired coronary perfusion. Recent evidence suggests that an increase in pulse pressure is accompanied by progressive vessel wall damage and atherogenesis, and is associated with an increase in cardiac morbidity and mortality rates.⁴⁹

While it is generally accepted that the structural and functional changes associated with aging impair compliance of the arterial circulation, these studies have been confined to the large conduit arteries and have emphasized that changes in pulsatile arterial function do not progress in a uniform or consistent manner in all arteries.⁵⁰ Prior studies that used pulse wave velocity to estimate the stiffness of arterial segments have indicated that the aorta stiffens progressively at an accelerated rate compared with other arterial segments. Echo-tracking technology has revealed that age-related changes in pulsatile function are nonhomogeneous within localized arterial segments of elastic and muscular arteries and that the compliance characteristics of the radial artery may paradoxically increase with age.⁵¹ In contrast to the marked heterogeneity in the physical characteristics of localized arterial segments with aging, consistent and predictable changes occur in the arterial pulse contour regardless of the site of measurement. These changes reflect alterations in total arterial compliance and can be quantified with the pulse contour analysis technique, which provides an assessment not only of the physiologic behavior of the large conduit arteries that serve a capacitance function, but also of the smaller arteries that represent the predominant site of reflected waves or oscillations in the arterial bed.⁴³

THERAPEUTIC RESPONSE IN HYPERTENSION

The goal of therapeutic interventions to lower blood pressure is the reduction of the risk of cardiovascular events. Because these events are directly related to structural abnormalities in arterial circulation, it is intuitive that an effective therapy should slow or reverse these abnormal structural changes. Efforts have also been made to identify a favorable effect of drug therapy on arterial compliance measurements. These have been studied by both pulse contour analysis and by ultrasound estimates of arterial wall thickness and distensibility. Preliminary studies have shown favorable effects of a number of drug interventions on these arterial characteristics.⁵² Of course, any antihypertensive agent would be expected to reduce arterial stiffness because BP reduction *per se* unloads the stiff components of the arterial wall such as collagen. However, it seems likely that pharmacologic treatment can improve arterial stiffness beyond BP reduction.⁵³

Pharmacologic trials often focus on large proximal elastic arteries (such as the aorta and the common carotid artery) because they represent the largest contribution to

systemic compliance and therefore have the most impact on left ventricular load. Although muscular arteries, like the brachial, radial, and femoral arteries, contribute only modestly to total compliance, they are of interest to determine the contribution of smooth muscle relaxation to the increase in arterial compliance. Improving compliance of distal muscular arteries reduces the contribution of wave reflections to left ventricular afterload, but also is a marker for improved endothelial function that should favorably affect the long-term structural abnormalities in the large and small arteries. Reducing mechanical stress, either steady or pulsatile, at the site of proximal elastic or distal muscular arteries, is also a desirable goal of drug treatment.

In most pharmacologic studies, the elastic properties of large arteries have been assessed noninvasively. Direct techniques include measurements of carotid-femoral pulse wave velocity (PWV), an index of aortic stiffness, and or measurements of cross-sectional distensibility and compliance (carotid, femoral, and radial arteries). Indirect techniques are frequently based on models of local (brachial) or systemic circulations.⁵⁴ Small artery behavior is best assessed by pulse contour analysis. Late systolic pressure augmentation of a reflected wave can be detected in radial artery waveform recordings. More reliably, the diastolic decay of the radial pulse wave can be subjected to computer analysis that utilizes a modified Windkessel model to calculate both large and small artery compliance that quantitates the functional and structural status of both vascular segments.^{7,10,12,16,44}

Whether classes of antihypertensive agents vary in their efficacy to affect arterial structure and thus influence arterial compliance via a pressure-independent mechanism is controversial and remains to be evaluated in large-scale trials or in meta-analysis of smaller studies. Most published studies have included small groups of patients (<20 patients/group), and are thus underpowered to conclude a lack of efficacy of one drug versus another. Moreover, several studies are short-term studies in which the effect of antihypertensive on the arterial system was studied during a period of 4 weeks or less. Long-term studies are much more important to know the effect of the antihypertensive agent on the vascular tree beyond blood pressure lowering.^{55,56}

Despite these limitations, it is thus far generally accepted that angiotensin-converting enzyme inhibitors, angiotensin-II receptor blockers, aldosterone antagonists, calcium antagonists (especially dihydropyridines), and nitrates share a similar ability to decrease arterial stiffness in hypertensive patients in long-term studies. The effect on large artery stiffness is dependent to a considerable extent on reducing blood pressure, whereas the effect on small artery stiffness is predominantly influenced by improved endothelial function. It is also well accepted that the nonselective β blocker propranolol and the selective β_1 blocker atenolol are less efficacious during long-term treatment than β blockers with vasodilating properties.⁵⁷ Nonspecific vasodilators have only a moderate effect to decrease arterial stiffness, while diuretics have nearly no effect or a minor effect in reducing arterial stiffness.

Table 12–1 summarizes the effects of antihypertensive drugs on arterial stiffness.

The early *in vivo* diagnosis and follow-up of subclinical progression of arteriosclerosis is important for the evaluation of efficient preventive and therapeutic interventions. The carotid artery intima media thickness (IMT) is a reliable surrogate marker of arteriosclerosis and could be easily investigated with high resolution B-mode sonography. Due to its good reproducibility, the IMT measurement is optimal for tracking the progression or regression of atherosclerotic disease. The increase of IMT is influenced by numerous vascular risk factors (age, smoking, hypertension, dyslipidemia) and positively associated with the incidence of vascular events in the arterial vasculature (stroke, myocardial infarct). Studies of antihypertensive medication have confirmed that lowering blood pressure significantly reduces the progression of IMT. It is likely but not documented that reduced progression of IMT is accompanied by a decrease of future vascular events.^{58,59}

The hope for the future is that a practical noninvasive screening technique will be used to assess the function and structure of the arterial wall in subjects with hypertension or even subjects at risk to develop hypertension. The effect of antihypertensive therapy on the functional and structural vessel wall abnormality can then be monitored during therapeutic intervention. Thus a drug regimen that did not favorably affect the arterial structure or function in a given patient could be replaced by another drug regimen that might be more effective. The correction of the arterial wall abnormality could then serve as a guide to therapeutic efficacy rather than the absolute level of blood pressure, which now serves as the surrogate marker. How the blood pressure changes and the arterial wall changes might relate needs to be intensively studied. Furthermore, it would be necessary to confirm that a favorable effect on the arterial wall is associated with a reduction of morbid events. It is therefore now important to assess the efficacy of any new antihypertensive strategy with regard to not only its ability to reduce blood pressure, but also its impact on structural and functional alterations in large and small arteries.⁶⁰

CONCLUSIONS

Recognition that the artery wall is an important target of the disease we aim to treat has stressed the need for monitoring techniques to identify effective treatments in trials and to track individual patients for the natural history of their disease and the efficacy of interventions. Although data using existing technologies are still limited in scope and follow-up, pulse wave analysis is particularly attractive because of its simplicity and apparent sensitivity. Pulse wave velocity also is relatively simple, but its confinement to the aorta and large conduit arteries limits its application to identifying structural changes in the large arteries. Reproducibility and freedom from extraneous

influences are critical to the application of methods for monitoring. Blood pressure measurement itself is neither reliably reproducible nor free from extraneous influences. Nonetheless, BP has served in population studies as a guide to cardiovascular risk. Its use in individuals, however, usually is buttressed by repeated measurements, either in the office or at home, by exclusion of outlying measurements, and by awareness of environmental conditions at the time of measurement. Assessment of the mechanical properties of the small and large arteries has the potential to be far more sensitive and specific for detecting CV disease and the response to drug therapy than the BP alone.⁴⁴

Chapter
13Resistance Vessels
in Hypertension

Michel E. Safar and Bernard I. Lévy

Key Findings

- The blood pressure curve involves two different components: a steady component corresponding to mean arterial pressure and to continuous flow within small resistance arteries, and a pulsatile component corresponding to pulsatile pressure and flow within large arteries.
- The two hemodynamic components are in constant interaction not only through neurohumoral pathways but also through the transit of wave reflections.
- Survival in subjects with hypertension requires adaptive mechanisms, including the structure and function of resistance vessels, that affect the entire cardiovascular system.
- A clear knowledge of the continuous cross-talk observed between the different components of the vascular tree is needed to understand cardiovascular risk.

The aorta takes origin from the left ventricle and almost immediately curves, in a three-dimensional way, giving off branches to the heart, head, and upper and lower limbs (macrocirculation). Beyond the early branches, the total cross-sectional area of the arterial tree begins to expand dramatically. Whereas the total cross-section increases, the average diameter is reduced, reflecting the increased number of bifurcations toward arterioles (microcirculation).^{1,2} Along the arterial and arteriolar tree, the forces governing flow are dependent on the pressure generated by the heart. This quantity, which is the difference between the actual pressure and its hydrostatic component, is commonly referred to as “blood pressure” (BP).¹ It is the gradient of pressure, which drives the flow. The distribution of this pressure gradient through the circulation, which is largely dissipated in forcing the blood through the microcirculation, is the origin of vascular resistance. The behavior of vascular resistance in the presence of high BP is the subject of this chapter, taking into account, that within the arterial tree, the heart is an intermittent, but not a steady, pump. Increased vascular resistance is considered a hallmark of hypertension.

HEMODYNAMICS, HISTOPATHOLOGY,
AND BIOCHEMISTRY

BP profile along the arterial tree

At the end of ventricular ejection, the pressure in the aorta falls much more slowly than in the left ventricle because

the large central arteries, and particularly the aorta, are elastic and thus act as a reservoir during systole, storing some of the ejected blood, which is then forced out into the peripheral vessels during diastole (Windkessel effect). Then the pressure pulse generated by ventricular contraction travels along the aorta as a *wave* (Figure 13–1, A). It is possible to calculate its velocity (pulse wave velocity [PWV]) from the delay between two waves located at two different sites, if the distance between measuring sites is known (Figure 13–2). Furthermore, when simultaneous BP measurements are made at different points all along the aorta, it appears that the pressure wave changes shape as it travels down the aorta. Whereas the systolic blood pressure (SBP) actually increases with distance from the heart, the *mean* level of the arterial pressure (MAP) falls slightly (about 4 mmHg) during the same course along the length of the aorta (Figure 13–1, A). Thus the amplitude of the pressure oscillation between systole and diastole (the pulse pressure [PP]) nearly doubles (Figure 13–1). The process of PP amplification continues in the branches of the aorta out to the level of about the third generation of branches. Thereafter both PP and MAP decrease rapidly to the levels found in the microcirculation where a quasi steady flow is observed. Thus whereas the macrocirculation is characterized by pulsatile flow as well as by the propagation of a pressure wave, PWV and PP amplification, the microcirculation is influenced by steady flow, and hence follows Poiseuille’s law. Under this condition, the pressure gradient becomes proportional to the velocity and viscosity of blood, to the length of the arteriolar tree, and mostly is inversely proportional to the fourth power of vascular diameter.

Several animal studies have examined the hydrostatic pressure profile along the macro and microcirculation, that is, between the heart and capillaries.^{1–3} The general consensus is that the BP decrease occurs predominantly in precapillary vessels ranging from 10 to 300 μm . Conversely, a very high vascular resistance (which represents the mechanical forces that are opposed to blood flow) builds up abruptly from larger to smaller arteries, over a transitional short length of the path between arteries and veins, thus causing a dramatic decrease in MAP. At the same time, the PP amplitude decreases, resulting in almost completely steady flow through resistance vessels. A further contribution to opposition to flow derives also from the reflection of arterial pulsations that cannot enter the high resistance vessels and are summated with pressure waves approaching the area of high resistance^{1,2} (Figure 13–1, B and C). This area of reflection, which is directly related to the number

Figure 13–1. Pressure wave along the arterial tree. **A**, Forward pressure wave is propagated from the heart toward the microvascular network at a given pulse wave velocity; pulse pressure is higher in peripheral than in central arteries due to a higher SBP and a slightly lower DBP. **B**, Pressure wave is reflected and the principal reflection sites are located in the microvascular network. **C**, Backward pressure wave returns toward the heart at the same PWV as the pressure wave. The arterial BP curve is in fact the summation of the incident and reflected pressure waves at each point of the arterial (aortic) tree. BP, blood pressure; DBP, diastolic blood pressure; PWV, pulse wave velocity; SBP, systolic blood pressure.

and geometric properties of arteriolar bifurcations,¹ will be analyzed in detail at the end of this chapter.

Histomorphometric characteristics of the arterial wall

The basic architecture of arterial and arteriolar vessels is usually described in terms of cross-sectional arrangement of vascular smooth muscle (VSM) cells and extracellular matrix (ECM). The former predominates in arterioles (microcirculation) and the latter in large arteries (macro-circulation).⁴ Large arteries are mainly constituted, within the media, of lamellae of elastic material with intervening layers of VSM cells, collagen fibers, and ground substance. In the proximal aorta, elastin is the dominant component, while in the distal aorta the collagen to elastin ratio is reversed, and in peripheral arteries, collagen predominates. Thereafter, VSM cells become the quasi-exclusive material of the vascular wall. This description is consistent with the chemical properties and gene expression of elastin, collagen, and VSM cells along the aorta and its branches.⁵

The protein product of the elastin gene is synthesized by VSM cells and secreted as a monomer, tropoelastin.^{2–4} After post-translational modification, tropoelastin is cross-linked and organized into elastin polymers that form concentric rings of elastic fenestrated lamellae around the arterial lumen. Elastin-deficient mice die from an occlusive fibrocellular pathology caused by subendothelial proliferation and accumulation of VSM cells in early neonatal life.⁶ Thus elastin is a crucial signaling molecule that directly controls VSM cell biology and stabilizes arterial structure and resting vessel diameter. On the other hand, vascular collagen is determined at a very young developmental stage, and thereafter remains quite stable due to a very low turnover. Nevertheless, the proportion of collagen types I and III has a differential mechanical impact on stiffness of the vessel wall.⁷ Furthermore, neurohumoral factors, particularly those related to angiotensin II and aldosterone, modulate collagen accumulation.⁸ Finally,

collagen is also subjected to important chemical modifications, such as breakdown, cross-linking or glycation, resulting in marked changes in stiffness along the vessel wall.³

ECM is responsible for the passive mechanical properties of the arteries, in particular of the aorta and its main branches.^{1,2} In a cylindrical vessel, when the transmural pressure rises, a curvilinear pressure-diameter curve ensues, mainly due to the recruitment of elastin at low pressure and of collagen fibers at high pressure.^{1,2} Nevertheless, several other molecules, through their role in cell–cell and cell–matrix attachments, may contribute to the three-dimensional repartition of mechanical forces within the arterial wall.³ As an example, in rat proximal elastic arteries, the main VSM cell type consists of desmin-negative cells with high levels of connexins C_{x43} . In small- to medium-sized muscular arteries, the main VSM cell type is desmin-positive with low levels of C_{x43} .⁹ Interestingly, in mice lacking desmin, isobaric carotid stiffness is increased.¹⁰

VSM cells do not represent a homogenous population. For the same genomic background, there are different mixtures of phenotypes, involving not only contractile and secretory properties but also proliferative and apoptotic behavior.^{3,11} The distribution of each of these phenotypes is mainly influenced by age, location within the vascular tree, and presence of underlying pathologic factors. Contractile properties, which are mainly expressed in arterioles, are responsible for the active mechanical properties of small and large vessels.^{1–3} Changes in VSM tone may occur either directly or through signals arising from endothelial cells. Endothelium is a source of substances, particularly nitric oxide (NO), and of signal transduction mechanisms¹² that necessarily influence the biophysical properties of vessels.^{1–3} Many of these signals are influenced by blood flow through the mechanism of endothelium-dependent dilatation, which is not restricted to vessels of particular size (muscular or musculoelastic). In contrast, the role of mediators arising from endothelium predominates in muscular distal arteries.^{12,13} The wall–lumen ratio of such vessels is influenced by the local differential effects of NO and other vasodilating (bradykinin, prostaglandins) or vasoconstrictive (norepinephrine, angiotensin, endothelin) agents. Whether such arteriolar changes may modify the pattern of wave reflections issued from distal VSM cells is the subject of recent research.³

VASCULAR DEVELOPMENT AND GENETICS

The pulsatile component of BP represents a direct continuation of the heart beat and originates at the proximal part of the thoracic aorta. This is necessarily the module of hemodynamic forces that predominates during the early phase of vascular development, and must be rapidly brought under control at birth for cardiovascular (CV) survival. In contrast to PP, the optimal MAP may be achieved only from the distal part of the arterial tree, where the microvascular network develops and Poiseuille's law is applicable.

Figure 13–2. PWV measurement between the common carotid artery and the origin of common femoral artery (end of the aorta): the time delay (ΔT) between the noninvasive BP recordings is measured using a foot-to-foot method; the PWV is obtained from the distance (L) between the two recordings and ΔT . BP, blood pressure; PWV, pulse wave velocity.

Accordingly, the steady phenomenon of MAP occurs at a later phase of CV development.

As shown from the previous hemodynamic descriptions, the BP curve results from the interaction between two different components: a steady one, corresponding to MAP, and a pulsatile one corresponding to PP (Figure 13–3). Studies of rats and knockout mice indicate that the genetics of each of these two components may be analyzed separately.^{10,14} Genome-wide linkage analysis has shown the importance of identifying genetic factors in subjects with high PP independently of MAP.¹⁵ Thus for genetic studies, an evaluation of the totality of the BP curve, mainly of the aortic curve, is necessary for an adequate description of the main phenotypes of hypertension. From this viewpoint, an important finding in subjects with hypertension results from studies of the ACE I/D gene polymorphism. (Other genetic findings are developed in other chapters of this book.) Staessen et al.¹⁶ were the first to show that the DD genotype was significantly associated with hypertension, but mostly with isolated systolic hypertension in the elderly. In this population, the DD genotype is associated not only with increased PP but also with increased arterial stiffness and accelerated increase of PP with age.^{16,17} Furthermore, more recent research suggests that the combination of two or three specific gene polymorphisms (ACE, aldosterone synthase and alpha-adducin gene polymorphisms) affect SBP, PP, and vessel wall properties more profoundly than a single genotype.¹⁶

Whatever the gene polymorphisms may be, blood vessel development is primarily issued from the *in situ* differentiation of endothelial cells from the mesoderm and their coalescence into primary vessels.^{13,18} Subsequent remodeling of the primary vascular plexus into a more mature vascular system occurs through a process known as angiogenesis. This involves sprouting, splitting, and remodeling of

Figure 13–3. Aortic BP in younger and older subjects for the same MAP (i.e., the same cross-sectional area under the curve). The shapes of the aortic blood BP curves differ markedly in younger and older subjects. The latter has a higher SBP and lower DBP due to increased arterial stiffness and early wave reflections. These early wave reflections cause a supplementary increase of SBP during systole, called the augmentation index, and mainly observed in older subjects. Another index of wave reflection may be calculated in diastole (called here, distal or oscillatory compliance). BP, blood pressure; DBP, diastolic blood pressure; MAP, mean arterial pressure; SBP, systolic blood pressure.

capillaries, which leads to reorganization of the primary vessels into large and small vessels, and hence dominantly contributes to the progressive increase of vascular resistance, and thereby MAP. Hormonal factors such as angiotensin II participate in this process.^{13,18} Nevertheless, a major point is that vessels adapt to flow in order to optimize the shear stress to which they are subjected. Flow not only shapes the global patterning of the arterial tree, but also regulates the activation of several biochemical markers such as ephrin B2 and neuropilin.¹⁸

For the understanding of resistance vessels development, it is worth noting that Poiseuille's law recognizes arteriolar length and the fourth power of vascular radius as the most important geometric factors determining the resistance of microvascular network. Thus the resistance of a tree-like branched network can be described by relatively simple extensions of Poiseuille's classic equation.¹⁸ Nevertheless, the number of blood vessels coupled in parallel is also an important factor to consider. Computer simulations have shown that elimination of a number of small arterioles from a vascular bed (rarefaction) causes an increase in total resistance.¹⁹ In the particular case of arcade-like networks, the situation is quite difficult to define, as they contain arteriolar branches that are coupled both in series and in parallel. In these networks, resistance is determined by the combined contribution of the length and diameter of individual arterioles, their branching angles, the location of their branching points, and the number of branches.¹⁸ Thus in order to identify vascular resistance, it is important to define not only the absolute number of blood vessels, but also the nature of the changes in the

network. Interestingly, this network may serve as sites of wave reflections (see above). A model developed by Green¹⁹ has demonstrated that removal of arteriolar segments causes an increase in resistance, and that the extent of the increase is sufficient to explain the enhanced vascular resistance observed in several experimental models of hypertension based on microvascular rarefaction.

PATHOPHYSIOLOGY: RESISTANCE VESSELS AND THE MICROCIRCULATION IN HYPERTENSION

The function of microcirculation is to optimize nutrient and oxygen supply within the tissues in response to variations of demand, and to minimize large fluctuations of hydrostatic pressure in the capillaries causing disturbances in capillary exchange.^{13,18} In hypertension, the main question is to determine under which conditions a large drop in hydrostatic pressure may be achieved from the larger to the smaller arteries without any deleterious effect on tissue blood flow causing organ damage.¹⁸

Location and main characteristics of peripheral vascular resistances in chronic hypertension

As mentioned previously, the pressure drop along the vascular bed occurs predominantly in precapillary vessels ranging from 10 to 300 μm in diameter.^{1-3,18} Studies of skeletal muscle in spontaneously hypertensive rats (SHR) have concluded that pressure is elevated approximately proportionally throughout the precapillary vasculature.^{1-3,18} DeLano et al.²⁰ found that if the measured pressures are normalized by the systemic MAP, pressures are virtually identical in normotensive rats and SHR at all the locations studied. These results suggest that because the major pressure drop occurs in the smallest arteries and arterioles, these vessels represent the principal site of the increased vascular resistance in hypertension. The most striking evidence results from the marked increase of resistance that occurs when the vasculature is maximally relaxed.²¹ From Poiseuille's law, it appears that altered minimum vascular resistance could be the result of a diminution of the lumen diameter of individual vessels, of vessels being longer, or of their rarefaction (a decreased number of vessels connected in parallel).^{13,18} Thus it seems likely that, in hypertension, the structure and function of microcirculation may be altered in different ways, and does not involve necessarily a vessel diameter narrowing. A first possibility is that the mechanisms regulating vasomotor tone may be abnormal, leading to enhanced vasoconstriction, reduced vasodilating responses, and/or altered autoregulation.^{13,18} Another possibility is the presence of anatomic alterations of the structure of individual precapillary resistance vessels, such as increases in their wall-to-lumen ratios^{20,21} or reduction of the density (rarefaction) of arterioles or capillaries within a given vascular bed.^{13,18} It seems likely that the relative contribution of these factors may differ in various vascular beds and may vary according to hypertension models.

Hypertensive changes in vasomotor tone and autoregulation

The most obvious mechanism increasing resistance to blood flow in arterioles is vasoconstriction. Only small changes in lumen size are required to make large adjustments in flow and pressure. Vasomotor tone in resistance arteries is controlled by local or metabolic regulation and by the sympathetic nervous system.^{13,18} In addition, paracrine substances, mostly released by the endothelial cells, play a key role in the control of local vasomotor tone. Endothelin and prostaglandin H₂/thromboxane A² are important vasoactive candidates to consider in the mechanisms of hypertension.^{13,18}

The tone of the microcirculation and, consequently, the levels of tissue perfusion are tightly coupled to the status of tissue oxygen consumption. When oxygen requirements are increased, blood inflow increases accordingly.² The ability of a vascular bed to constrict and dilate in order to maintain flow during changes of perfusion pressure, independently of any systemic neurohumoral regulation, is termed "autoregulation." In coronary circulation, autoregulation is most effective between pressures of 60 and 160 mmHg.²² Importantly, chronic hypertension shifts the range of pressures over which autoregulation occurs in the myocardium, so that flow will begin to decline at greater pressure. A similar hemodynamic mechanism has been observed within renal and cerebral circulations.^{1-3,20} The nature of the signaling molecules that participate in the local autoregulation process remains poorly understood. In experimental hypertension, vasoconstriction seems to be particularly enhanced at the initial stages when arterial pressure increases rapidly, producing a rapid increase in myogenic tone.²³ On the other hand, a loss of vasodilating properties, particularly of endothelial origin, has been also reported in other animal models.^{13,18,24}

Structural factors of increased vascular resistance: Increased wall-lumen ratio and/or microcirculation rarefaction

Hypertrophy of the vascular wall, resulting in decreased lumen size, and medial hypertrophy, resulting in heightened vasodilated vascular resistance, are concepts that received considerable attention in models of secondary hypertension.^{18,21,24} Increases in the media-lumen ratio of small arteries have been widely documented in several forms of experimental secondary hypertension.^{18,21} These changes are consistent with the view that vessels maintain constant wall stress in the face of changing pressure. Resistance arteries at the beginning of the resistance section of the vascular bed ($\pm 300 \mu\text{m}$) exhibit only weak myogenic responses and remodel with a combination of lumen reduction and wall hypertrophy. Small resistance arteries (50 to 10 μm), where most hemodynamic resistance is located, are protected against increased circumferential wall stress and do not hypertrophy during chronic hypertension. Thus it is not clear whether arterioles undergo increases in wall-lumen ratio in primary hypertension. SHR arterioles have not been reported to show consistently either reduced luminal diameter or wall thickening

(reviewed by Struijker-Boudier et al.²⁵). In hypertensive humans, reduced arteriolar lumen diameters are difficult to demonstrate,^{21,25} since only *in vitro* determinations are available and three-dimensional measurements cannot be easily done. Thus in hypertensive humans, the expression “altered structure of the arterial wall,” is often somewhat ambiguous. A narrowed lumen with resulting increased media–lumen ratio can occur without any change in the amount of material in the vessel wall.²¹ Conversely, an increased media–lumen ratio may not cause a narrowed lumen, and an increased amount of wall material (demonstrated by an increase of the wall cross-sectional area) is not necessarily accompanied by a smaller lumen or elevated media–lumen ratio.^{13,18} Finally, in hypertensive humans, the structural changes and impaired vasodilator capacity resulting from the increased wall–lumen ratio contribute to CV complications.^{18,21,26} Nevertheless, these changes are not always directly related to BP level. They cannot represent the exclusive mechanism responsible for high MAP in subjects with essential hypertension.

Independently of changes in wall–lumen ratio, Hutchins et al.²⁷ first described up to 50% rarefaction of the microvasculature in the cremaster muscles of SHR, and Prewitt et al.²⁸ subsequently found rarefaction of capillaries and arterioles in SHR gracilis muscle. There is now much evidence that the development of hypertension is accompanied by a diminished density of arterioles and capillaries in skeletal muscle in both animal models and human hypertension.^{29–31} Rarefaction^{13,18} can be either functional, resulting from vasoconstriction strong enough to close the vascular lumen and prevent the perfusion of a capillary bed, or structural, in which case the vessels are absent or their density is decreased in perfused tissues. Because functional rarefaction of the capillary beds in skeletal muscles of normotensive animals has been described in the past,^{13,18} only arteriolar and capillary structural rarefaction may greatly contribute to the basic mechanisms of hypertension. Previously, we discussed to what extent the structural rarefaction of the microvascular network may contribute to the increase in vascular resistance and MAP. It is possible that this process may result from the net effect of combined growth and apoptosis.^{3,11,18,25} Furthermore, the rarefaction process may predominate in specialized organs or tissues, such as the kidney.^{13,18} Numerous experimental studies and significant statistical associations between reduced nephron numbers and high BP strongly suggest the latter possibility.³

CLINICAL IMPLICATIONS AND PERSPECTIVES: CROSS-TALK BETWEEN HEART AND RESISTANCE VESSELS

Studies in hypertension have constantly shown consistent links between cardiac function and resistance vessels, as well as the role of small vessels in end-organ damage. These links are traditionally described as exclusively due to specific neurohumoral or cellular mechanisms. However, sophisticated mechanical factors may also participate in this cross-talk.^{2,3}

Ejection of blood into the aorta generates a BP wave that is propagated to other arteries throughout the body. As in elastic conduits, this forward traveling pressure wave is reflected at all points of structural and/or functional discontinuity of the arterial tree, that is, mainly at the origin of resistance arteries (Figure 13–1, B). Thus a reflected wave is generated that travels backward toward the ascending aorta (Figure 13–1, C). Incident and reflected pressure waves are in constant interaction along the arterial circuit and are summed up into the actual pressure wave. The final amplitude and shape of the measured aortic BP wave are determined by the phase relationship (timing) between the two components of these waves. In younger subjects, under physiologic conditions with elastic arteries, the backward pressure wave returns from the distal arterioles during diastole, making PP higher in peripheral than in central arteries and boosting coronary perfusion.^{2,3} In older subjects with rigid arteries and hence heightened PWV, the reflecting sites corresponding to arteriolar branching appear “closer” to the ascending aorta and the reflected waves occur earlier (Figure 13–3), being more closely in phase with incident waves in this region. Such an earlier return of wave reflections results in an augmentation of aortic and ventricular pressures during systole and reduces aortic pressure during diastole, favoring myocardial ischemia (Figure 13–3). Hence, altered mechanical properties of the aortic wall influence the level of aortic SBP (which is increased) and DBP (which is decreased). Finally, a disturbed pressure signal arising from arterioles modifies wave reflections, worsens the heart–vessel coupling and favors CV complications. Evidence for this pathophysiologic process has been highlighted by the role of PWV and wave reflections as independent CV risk factors in subjects with hypertension and other CV diseases.^{32–35}

Importantly, wave reflections alter the ventricular–vascular coupling not only through increased arterial stiffness and change in timing but also through modifications in their amplitude. This process depends on reflectance properties of the vascular bed, which mainly arise from microvascular network. Every change in the local properties of an artery may be the site of partial reflection of the pressure wave, in the same way that any discontinuity in a stretched string is a source of reflection. These reflections are influenced by the geometry, number, structure, and function of smaller muscular arteries and arterioles, and finally microvascular rarefaction. Taylor³⁶ previously reported that an increase of the arterial cross-sectional area at peripheral bifurcations causes a delay of wave reflections with subsequent selective decreases of SBP and PP through changes in the peripheral reflection pattern. In subjects with hypertension, an opposite pattern has been described, resulting from hypertrophy and/or remodeling of arteriolar vessels.³ Furthermore, age influences greatly all these modifications and tends to increase SBP and PP more rapidly in the central than in the distal arteries, causing a reduction of SBP and PP amplification. This reduction also constitutes an independent predictor of CV mortality in hypertensive subjects.³⁷

SUMMARY

In summary, the present description has shown that, within the vascular tree, elastic arteries buffer the pulsations, muscular arteries actively alter propagation velocity, and arterioles serve not only as resistance vessels but also as major reflection sites. Within the CV system, all these alterations (or their combination) enable a continuous cross-talk between the heart and the microvascular network.^{2,3} Disturbance of these frequency-dependent alterations favors a predominant increase of SBP and PP, as observed in aged and/or hypertensive populations with high CV risk. This process contributes to increasing the heart's load

and favors cardiac hypertrophy and coronary ischemia, finally causing CV death. The consequences of these findings on the clinical aspects of systolic or systolic-diastolic hypertension and on the strategy for CV diseases remain to be taken into consideration in the future.

ACKNOWLEDGMENTS

This study was performed with the help of INSERM and GPH-CV (Groupe de Pharmacologie et d'Hémodynamique Cardiovasculaire), Paris. We thank Anne Safar, MD, for helpful and stimulating discussions.

The Endothelium in Hypertension: Assessment and Clinical Aspects of Micro- and Macrovascular Function

Andrew D. Blann

Definition

- Endothelial function refers to the ability of the endothelium to adequately perform its physiological roles, such as in the regulation of blood pressure and in hemostasis.

Key Findings

- Endothelial function can be objectively quantified.
- Endothelial function is involved in the pathogenesis of cardiovascular disease. Diverse pathological processes that damage the endothelium therefore precipitate its dysfunction.

Clinical Implications

- Hypertension and thrombosis, and therefore increased risk of adverse cardiovascular events such as myocardial infarction, stroke and heart failure, result from endothelial dysfunction.

The endothelium is important in several physiological and pathological processes, with direct involvement in regulation of local blood flow (via vessel tone), regulation of vessel permeability, regulation of the clotting cascade (via expression of anticoagulant and procoagulant factors), and regulation of leukocyte and fluid movements into the media and therefore the tissues.^{1,2} Thus, if the maintenance of endothelial function is important in minimizing or slowing the development and progression of heart disease and atherosclerosis it follows that the converse is also true (i.e., that loss of vascular integrity is associated with an increased risk of developing, for example, left ventricular hypertrophy and atherothrombotic disease). Indeed, Virchow introduced the concept that loss of endothelial integrity is a part of the pathogenesis of thrombosis over 150 years ago.

In the present day, this concept is supported by the fact that endothelial function is impaired in all of the classical (e.g., diabetes mellitus, hypertension, smoking, hypercholesterolemia) and several emerging cardiovascular risk factors (Table 14–1). Given the role of the endothelium in regulating the coagulation cascade, the link between endothelial dysfunction and disease development may be an alteration in the balance of procoagulant and anticoagu-

lant factors, resulting in abnormal coagulability and the consequences of inappropriate thrombogenesis such as myocardial infarction, congestive heart failure, and stroke.^{3–5}

ASSESSING ENDOTHELIAL FUNCTION AND DYSFUNCTION

Before describing endothelium damage/dysfunction, we first briefly revisit vascular physiology. The vascular endothelium comprises a vast number of flattened orthogonal cells that line the entire vascular tree. Broadly speaking, the endothelium impacts onto cardiovascular disease in (at least) two independent but potentially overlapping areas: thrombosis/hemostasis and the regulation of blood pressure. In the former, the endothelium expresses/secretes/releases both procoagulants (e.g., von Willebrand factor, tissue factor, factor V) and anticoagulants (e.g., thrombomodulin, heparin, prostacyclin). Vascular tone and blood pressure are regulated by the balance between vasodilators (e.g., nitric oxide, NO) and vasoconstrictors (e.g., endothelin). It is clear, therefore, that disruption of vascular physiology can have a fundamental influence on both thrombosis and hypertension.^{6,7}

Thus, given the central role of the endothelium in preventing the development and progression of atherothrombotic disease it is clearly desirable to be able to assess the endothelium in terms of its structural and functional integrity. Plasma proteins have long been used as assessors in these terms. Some of these assessor molecules can be relatively easily measured in the laboratory, although not all (e.g., tissue factor) are specific for the endothelium and others (e.g., NO) are virtually impossible to measure simply and directly. Of those that have potential as markers of endothelial function, increased levels of plasma von Willebrand factor (vWf) have long been taken to imply an insult to the endothelium⁸ and are present in all risk factors for atherosclerosis as well as in frank vascular disease. Increased levels also predict adverse cardiovascular outcome. Increased levels of other plasma markers (tissue plasminogen activator, soluble E selectin, and soluble thrombomodulin) have also been described as reflecting endothelial perturbation.^{2,9}

Recently, a more physiological view of the assessment of large vessel endothelial function has been developed [i.e., flow-mediated dilatation (FMD)].^{10,11} This uses a cuff

to occlude the brachial artery, followed by assessment of blood flow distal to the occlusion (using high-frequency ultrasound) following reversal of the occlusion. The release of the cuff causes endothelial-dependent vasodilatation, which is thought to be mediated via shear stress causing release of NO from endothelial cells. The change in diameter of the brachial artery is therefore a measure of the endothelium-dependent vasodilatation. The endothelium-independent response can be assessed by the use of sublingual nitrate medications that act directly on the smooth muscle cells.

Laser Doppler with iontophoresis is a relatively novel method of assessing *microvascular* endothelial function in an area of skin. Iontophoresis uses a small electric current to deliver vasoactive substances such as acetylcholine or sodium nitroprusside through the skin. Acetylcholine stimulates the endothelial cells to produce NO, and therefore measures the endothelial-dependent response. Sodium nitroprusside is a NO donor that directly stimulates the smooth muscle of the skin arterioles and thus bypasses the endothelial cell.^{12,13}

Probably the strongest evidence of *severe* damage to the vasculature by a factor or factors known or unknown is the appearance of circulating endothelial cells (CECs) in the plasma.^{14–16} These cells can be identified in the blood using immunomagnetic separation and by flow cytometry, and represent either damaged endothelial cells that have broken off the vessel wall and are thus circulating, or progenitor cells migrating from the bone marrow to repair a site of endothelial damage. The debate regarding their purpose or significance continues, but in either case CECs appear to be markers of severe endothelial damage. Clinically, they are associated with the presence of, and prognosis following, myocardial infarction—with elevated numbers of CECs at 48 hours post myocardial infarction predicting major adverse cardiac events at 30 days and 1 year.^{15,16} Thus,

technically CECs are not so much a direct marker of endothelial function as a marker of the degree of damage done to this tissue, and as such are a tool of vascular biologists. These aspects are summarized in Box 14–1.

ENDOTHELIAL FUNCTION IN HYPERTENSION AND CARDIOVASCULAR DISEASE

Endothelial dysfunction/damage is present in all classical cardiovascular risk factors and in clear disease (Table 14–1, which also highlights some possible mechanisms). Evidence of this has been provided from changes in vascular function defined by altered release of specific molecules (e.g., vWf, tissue plasminogen activator) into the blood, and altered reactivity of large vessels (e.g., the brachial artery) to changes in blood flow (i.e., FMD)(Box 14–1). Indeed, the literature is dominated by these two methods. As endothelial damage is associated with increased plasma vWf, and as endothelial dysfunction is associated with impaired (i.e., reduced) FMD, in theory the two ought to correlate inversely if they are themselves related. This has been demonstrated in a study largely of patients with hypertension but often with other risk factors¹⁷ (Figure 14–1). Thus, patients with the highest vWf also generally have the most adverse (i.e., lowest) FMD. Similarly, those with good FMD have low vWf. However, this study is unusual in that almost all workers chose one of these two approaches.

As yet, microvascular function—as assessed, for example, by laser Doppler iontophoresis—is a relatively new technique that has made relatively little impact on cardiovascular pathophysiology.^{12,13} However, relevant studies

Box 14–1

Assessment of Endothelial Function and Integrity

- Changes (almost always an increase) in specific plasma proteins such as von Willebrand factor, soluble E selectin, and soluble thrombomodulin.
- Changes (generally an impairment) in response to altered blood flow in large vessels such as the brachial artery (i.e., flow-mediated dilatation, FMD). This may be due to impaired release of nitric oxide by a damaged endothelium.
- Changes (generally an impairment) in response to pharmacological stimulation (e.g., microelectrically driven transdermal acetylcholine) in small blood vessels such as those of the forearm (i.e., laser-Doppler iontophoresis).
- Increased numbers of circulating endothelial cells in the plasma are likely to reflect direct damage to the mural endothelium.

MAJOR PATHOLOGICAL MECHANISMS LEADING TO VASCULAR DYSFUNCTION

Risk Factor	Possible Mechanism Primary
Hypercholesterolemia	Cytotoxic oxidized LDL
Smoking	Carbon monoxide, hypoxia
Diabetes	Hyperglycemia
Hypertension ^a	Hydrostatic pressure
Hyperhomocysteinemia	Unclear: homocysteine itself (?)
Inflammation	Excessive cytokine stimulation
Secondary	
Obesity	Unclear/compound
Physical inactivity	Unclear/poor overall cardiovascular health
Renal disease	Uremia
Liver disease	Hyperbilirubinemia
Insufficient antioxidants	Poor diet deficient in vitamins, etc.
<p>a. Hypertension may be a primary or secondary pathological process because it can be a cause or consequence of endothelial dysfunction (see text for discussion). Although male sex and increasing age are often cited as risk factors for atherosclerosis, these can hardly be described as major pathological mechanisms and are certainly not treatable.</p>	

Table 14–1. Major Pathological Mechanisms Leading to Vascular Dysfunction

Figure 14–1. Correlation between von Willebrand factor and FMD. The correlation line between FMD and von Willebrand factor is shown, with 95% confidence intervals [FMD = flow-mediated dilatation; vWf = von Willebrand factor]. Correlation between FMD and vWf: $r=-0.517$, $p<0.001$. (Redrawn from Felmeden DC, Blann AD, Spencer CGC, et al. A comparison of flow mediated dilatation and von Willebrand factor as markers of endothelial cell function in health and in hypertension: Relationship to cardiovascular risk and the effects of treatment. *Blood Coag Fibrinolysis* 2003;14:425–31, with permission.)

are emerging. For example, advanced age is associated with endothelial dysfunction, and reduced arterial elasticity parallels changes in impaired endothelium-dependent vasodilation. It appears that reduced arterial elasticity may be used as a noninvasive measure for the determination of endothelial function.¹⁸ Farkas et al.¹⁹ used similar technology to demonstrate impaired microvascular responses in essential hypertension compared to normotensives, although notably the plasma marker vWf was no different. Weight reduction and exercise are effective in improving body mass index in the obese, but also in improving macrovascular function (brachial artery FMD).²⁰ However, this program did not improve microvascular reactivity as evaluated by laser-Doppler perfusion imaging after iontophoresis with acetylcholine, or as evaluated by levels of plasma marker vWf. One hesitates to jump to the conclusion that large-vessel reactivity is more sensitive than small-vessel reactivity or plasma markers, as these may reflect different aspects of endothelial pathophysiology.

The most recent marker of vascular damage, CECs, has also (as yet) made little impact in hypertension. The potential mechanisms of endothelial cell detachment from the vessels are multiple and not exclusive. Different experimental models have documented that denudation of the vessels can be triggered by mechanical injury, defective adhesive properties of the endothelial cells, protease- or cytokine-mediated detachment, or the activation of an apoptotic program. Therefore, if increased numbers of CECs do indeed reflect a damaged endothelium such levels should correlate with other assessment methods (e.g., plasma markers and with FMD). Indeed, Rajagopalan et al.²¹ found an inverse correlation between CECs and FMD. Kas-Deelen et al.²² found that CECs strongly ($p<0.001$) correlated

with vWf but not with soluble E selectin, whereas Makin et al.²³ also correlated CECs with vWf and plasma tissue factor. Because vWf is essentially the gold standard plasma marker for endothelial damage,^{8,9} this is strong evidence that CECs also reflect severe vascular disturbance. Moving to hypertension, correlations between pulmonary artery blood pressure and CEC number have been reported.^{24,25} This relationship may be due to the high blood pressure damaging and thus converting mural endothelial cells into CECs. Notably, it is established that the plasma marker of endothelial damage (vWf) is raised in hypertension.^{26–28}

If endothelial damage/dysfunction is present, can it be reversed by intervention? Many antihypertensive drugs are known to prevent or reduce progression of arterio-occlusive disease, and many also reduce major cardiovascular endpoints, but often the mechanisms behind this cardiovascular protection remain elusive.

ANTIHYPERTENSIVE THERAPY AND THE ENDOTHELIUM

Evidence of endothelial perturbation in hypertension include increased release of vWf^{17,26–28} and impaired FMD.^{17,29} Furthermore, both of these markers predict adverse cardiovascular outcome,^{30–32} and (as mentioned) they have an inverse relationship¹⁷ (Figure 14–1). Clinically, there is of course considerable evidence that successful treatment of hypertension by virtually all classes of drugs lowers cardiovascular risk,^{33–39} and it is attractive to presume that this benefit is the direct consequence of lower blood pressure—although other mechanisms cannot be ruled out. Thus, these large epidemiological studies are generally unable to answer more complex questions of the mechanism of this benefit at the level of the molecule and/or cell.

With regard to studies on antihypertensive therapy and the endothelium, most are relatively small and of short duration. In addition, adequate blood pressure control with monotherapy is difficult, and in many instances two or more drugs are needed. Many existing studies cannot dissect out the effects of individual drugs or the associated nonpharmacological methods (e.g., salt restriction, weight loss, and so on), which is part of modern holistic hypertension management.

Calcium channel blockers (CCBs)

In general, although CCBs tend to improve endothelial function^{40–47} the mechanism of this is debatable. One route may be by improving blood pressure: another effect could be due to direct action on the endothelial cells (for example, in acting on cell membrane calcium channels to reduce the influx of calcium into cells).^{48,49} By decreasing calcium flux into smooth muscle cells, CCBs enhance the vasodilatation produced by NO.⁵⁰ It has been suggested that these drugs may restore NO availability through an antioxidant mechanism, and that they may enhance NO action through inhibition of superoxide-induced NO decomposition in the vessel wall.^{51–53}

Alternatively, CCBs may also act by reducing the production of endothelins.⁵⁴ The potentiation by ET-1 of vasoconstriction produced by other agonists such as nor-

adrenaline and serotonin is also inhibited by CCBs.⁵⁵ Nifedipine has been shown to improve endothelial function in patients with hypercholesterolemia independently of the effect on blood pressure.⁵⁶ CCBs may not all be the same. For example, Ding et al.⁵⁷ reported that nifedipine and diltiazem (but not verapamil) up-regulated endothelial nitric oxide synthase (NOS) expression, implying that the dihydropyridine and benzothiazepine classes (but not the phenylalkylamine class of drugs) are better for improving the endothelial function.

ACE inhibitors (ACEIs)

Large clinical trials such as the HOPE and PROGRESS studies^{33,34} (using ramipril and perindopril) have suggested that ACEIs have a role over and above their antihypertensive effect in reducing vascular complications. They may improve blood pressure and endothelial function via different mechanisms beyond inhibiting the renin-angiotensin system alone. One such mechanism is to reduce the inactivation of bradykinin, causing an augmentation of NO release.⁵⁸ Another is stabilizing the beta 2-receptor, reducing oxidative stress and tissue ET-1 levels,⁵⁹ and preventing the formation of angiotensin II (which can cause endothelial dysfunction by inhibiting NOS activity). Another mechanism induces oxidative stress and increases the levels of NO.^{60–62} Numerous other trials of ACEIs have been shown to improve endothelial function.^{63–70} For example, the TREND study (Trial on Reversing Endothelial Dysfunction)⁶⁸ looked at endothelial function in normotensive patients with coronary artery disease and found that quinapril significantly improved coronary artery diameter in response to acetylcholine after 6 months of treatment.

Angiotensin II receptor blockers (ARBs)

ARBs are a relatively new class of drugs, and although losartan has been shown to be more effective than atenolol in reducing vascular endpoints⁷¹ data on their role in improving endothelial function is limited. In studies comparing losartan⁷² or irbesartan⁷³ with beta blockers, the ARBs have been shown to have a beneficial effect on endothelial function and to be superior to the beta blockers in this effect (although one study found them equally effective).⁷⁴ However, a small study by Li Saw Hee et al.⁶⁷ did not show any changes in plasma endothelial marker vWf after 8 weeks of therapy with losartan.

Alpha and beta blockers

The available data do not appear to support the hypothesis that endothelial function is tremendously improved by these agents. In experimental animal models, carvedilol (but not propranolol) appears to protect against endothelial damage,⁷⁵ but studies in human hypertensives on the effects of beta blockers on endothelial function have given varying results. Seljeflot et al.⁷⁶ showed that treatment

with atenolol and doxazosin causes a decrease in levels of vWf, but these tended to correlate with the blood pressure reduction and could be just a reflection of the lowered blood pressure. Indirect measurements of endothelial function, such as with gluteal skin biopsy or forearm blood flow, do not show any improvement when using atenolol.^{72,73} One study using nevigolol⁷⁷ did show an improvement in the forearm blood flow after treatment. Thus, beta blockers may improve endothelial function solely by their blood-pressure-lowering properties and whether or not they have any additional influence(s) on the endothelium remains uncertain. The same may be true with alpha blockers, and for both classes the improvement with treatment appears to correlate with the amount of blood pressure reduction.

CONCLUSIONS AND PERSPECTIVES

Numerous large international trials have clearly shown that the successful treatment of hypertension brings cardiovascular benefit. However, although eminent opinion states that the endothelium is important in this risk factor linking the two may not be straightforward and debate continues.^{50,78–83} Endothelial dysfunction has been identified in patients with virtually every known cardiovascular risk factor, and its presence predicts future adverse events. It is clear that most workers favor vWf as a plasma marker of damage to the endothelium,^{26–28,76} although others have used endothelin-1 and soluble E selectin.^{28,84,85}

Treatment of hypertension generally results in an improvement in endothelial function that accompanies the reduced cardiovascular risk. Although there are considerable data on the genetics of hypertension,^{86–88} unlike the risk of left ventricular hypertrophy (and on ACE polymorphisms, for example) there are as yet no well-recognized genetic polymorphisms influencing the endothelium that are likely to impact clinical medicine directly. These topics are dealt with extensively in other chapters of this book.

Current clinical resources do not allow for routine measurement of endothelial function in individual patients, except in research settings. In addition, markers of endothelial function have been used to predict increased cardiovascular risk in populations but not in individuals. To be useful in predicting an individual's specific cardiovascular risk, a test must have an acceptable positive and negative predictive value, and this is emphatically not the case for the current measures of endothelial function available. In addition, many of these tests are time consuming and operator dependent, which reduces the likelihood of them becoming useful clinical tests. However, in a research setting these tests are often extremely useful parameters that provide information on the effectiveness of a drug or an intervention in reducing cardiovascular risk in a population.

Chapter
15Vascular Remodeling and
Rarefaction in Hypertension

Matthew A. Boegehold

Definitions

In established hypertension, structural changes within the resistance vasculature involve vascular wall remodeling to produce smaller passive diameters and/or the regression and loss of small arterioles from the network (“structural rarefaction”).

A structural reduction in passive vessel diameters can occur through inward vascular wall growth (“hypertrophic inward remodeling”) or rearrangement of existing wall elements without wall growth (“eutrophic inward remodeling”).

Key Findings

- Vascular wall remodeling can be triggered by a pressure-dependent increase in circumferential wall stress and/or the local actions of various growth factors. Ongoing investigations are continuing to provide important details on the intracellular signaling pathways through which this remodeling occurs.
- The structural rarefaction of arterioles can be triggered by a prolonged cessation of luminal flow that accompanies intense vasoconstriction, or by a reduction in the local concentrations of angiotensin II and/or other endogenous trophic factors.
- In addition to contributing to increased total peripheral resistance (and therefore elevated arterial pressure), the functional consequences of vascular wall remodeling include a reduced capacity for maximal dilation and altered responsiveness to vasoactive stimuli, whereas those for arteriolar and capillary rarefaction include increased heterogeneity in local blood flow and alterations in transcapillary exchange—including a reduced efficiency for tissue oxygen delivery.

Clinical Implications

- Because structural changes in the resistance vasculature may contribute importantly to some types of end-organ damage in hypertensive individuals, antihypertensive therapy is becoming increasingly more focused on reversing these changes.

When fully established, most forms of primary and secondary hypertension are characterized by a normal cardiac output and elevated total peripheral resistance (TPR). Because the chronic elevation in arterial pressure is usually attributable to increased TPR, a long-standing goal of hypertension research has been to define the mechanisms that underlie the development and maintenance of this increased resistance. From a physiologic standpoint, it is equally important to understand the effect of a sustained increase

in vascular resistance on local blood flow and its regulation in various organs, and the effect of any attendant flow abnormalities on organ function and the progression of end-organ damage. This information is critical for the development of more effective clinical strategies to treat hypertension and its consequences. Some of this information has been obtained from studies on human subjects, but because detailed investigation of the resistance vasculature and its function often requires invasive procedures more of this information has been obtained from various animal models of hypertension. The rat is the most common species used for this purpose. Investigators have developed a variety of rat models that exhibit hypertension of genetic origin—such as the spontaneously hypertensive rat (SHR)—or hypertension that has been experimentally induced, such as the two-kidney one-clip rat. Although there may be some differences between humans and other mammals in the regulatory mechanisms that influence blood pressure and blood flow, there are also many similarities that justify the use of these animal models.¹

As discussed in earlier chapters, the primary resistance vessels in most organs and tissues include the arterioles as well as the small feed arteries located immediately upstream from the microcirculation. These feed arteries, which typically range between 100 and 350 μm in luminal diameter, are often referred to as “resistance arteries.” The actual distribution of total vascular resistance between the resistance arteries and the true arterioles can vary depending on the vascular bed. Although *in vivo* microvascular pressure measurements generally indicate that the arterioles control most of the resistance, there are some organs (such as the brain) in which as much as 50% of total vascular resistance is attributable to the resistance arteries.²

Structural changes have been found throughout the resistance vasculature of hypertensive individuals, and these changes can contribute importantly to the maintenance of increased TPR. In early studies, these structural changes were inferred from findings that hemodynamic resistance in the absence of vascular tone (“passive resistance”) is elevated in hypertensive patients and animals.³ From direct observations of the vasculature, we now know that these changes include (1) alterations in vessel wall structure that lead to reduced luminal diameters and increased responsiveness to vasoconstrictors and (2) a loss of arterioles and capillaries from microvascular networks, which can also have profound effects on the exchange of water and solutes between the vascular compartment and surrounding tissues. Recent studies have provided detailed information

on the cellular and molecular mechanisms that underlie these structural changes, and continuing efforts to further clarify these pathways represent an important focus of current hypertension research.

There is also mounting evidence to indicate that changes in vascular wall structure and network architecture not only contribute to the development and maintenance of high blood pressure but may play a major role in the development of some types of end-organ damage that occur in hypertensive individuals. Because end-organ damage is the ultimate cause of the morbidity and mortality associated with hypertension, the prevention or reversal of these structural changes has become an important goal in the therapeutic management of hypertension.

ANATOMY AND BIOCHEMISTRY

Direct observations of the vasculature in different forms of hypertension have revealed that the increased vascular resistance of most organs is ultimately due to a reduction in the inner diameter of resistance vessels and/or a reduction in the number of these vessels being perfused in parallel. This latter phenomenon is commonly referred to as “microvascular rarefaction.” These abnormalities are often localized to specific regions of the resistance vessel network, although the relative importance of reduced diameters versus rarefaction to the overall resistance increase can vary from one organ to another, and can also change within any particular organ as hypertension develops.¹

Reduced inner diameters through vessel wall remodeling

In hypertension, the inner diameter of resistance vessels may be functionally reduced through sustained vasoconstriction^{4,5} and/or structurally reduced through anatomic remodeling of the vessel wall.⁶ Because the resistance of each vessel is inversely related to the fourth power of its radius, a relatively small decrease in radius can produce a large increase in resistance to flow. Studies in which different stages of hypertension have been compared indicate that functional and structural reductions in diameter are not always independent of each other, but are often linked in a temporal sense. In early (developing) hypertension, inner diameters are reduced primarily through an active increase in resting vascular tone. The mechanisms by which tone could be increased in relation to microvascular rarefaction are discussed later in this chapter, and are described in more detail elsewhere in this book. This sustained constriction often leads to vascular wall remodeling, so that structurally reduced diameters predominate in the established stage of hypertension.¹

Traditionally, the ratio of a vessel’s wall thickness to its lumen diameter (the “wall-to-lumen ratio”) has been used to quantify the changes in vessel wall structure associated with hypertension. However, because this ratio can also change acutely with vascular tone it is not by itself an exclusive index of structural changes. Instead, changes in vessel wall structure and mass are more accurately determined by measuring a vessel’s inner and outer circum-

ference after vascular tone has been abolished, and then calculating the cross-sectional area of the passive wall.

Vessel wall remodeling that would lead to reduced inner diameters can occur through one of two general processes. The first involves inward growth of the wall due to smooth muscle hypertrophy or hyperplasia. Hypertrophy refers to an increase in cell size associated with increased protein synthesis, whereas hyperplasia refers to an increase in cell number associated with DNA synthesis. For resistance vessels, this wall growth most often occurs exclusively by smooth muscle hypertrophy, and is therefore referred to as “hypertrophic inward remodeling.” The second process involves the rearrangement of existing wall elements around a smaller lumen with no net wall growth, referred to as “eutrophic inward remodeling.”⁷ Inward remodeling, whether hypertrophic or eutrophic, leads to increased flow resistance at maximum vasodilation.⁸ More importantly, and particularly in the case of hypertrophic inward remodeling, any prevailing level of vascular tone will produce a smaller inner diameter due to the encroachment of wall elements into the lumen⁹ (Figure 15–1).

As hypertension develops, the larger conduit arteries can also undergo a form of remodeling that is characterized by an increase in wall mass—typically involving a combination of smooth muscle hypertrophy and hyperplasia, with increased extracellular matrix deposition. However, in contrast to the changes that take place in the resistance vessels this wall growth in larger arteries is typically directed outward so that lumen diameter is not reduced (“hypertrophic outward remodeling”).¹⁰

The hypertrophic inward remodeling of resistance vessels can be triggered by numerous stimuli. One major stimulus appears to be blood pressure itself, or more specifically the increase in circumferential vascular wall stress that accompanies a chronic elevation of pressure. Experimentally, protection of a vascular bed from increased pressure during the onset of hypertension has often been found to prevent structural changes from developing in the resistance vasculature.¹⁰ Figure 15–2 illustrates the known elements of the signaling pathway through which a pressure-dependent increase in circumferential wall stress can stimulate inward growth of the resistance vessel wall. This may be expressed as an equation:

$$\text{Circumferential wall stress} = P_t r/W$$

where P_t = transmural pressure (the difference between luminal pressure and pressure outside the vessel, which can also be thought of as vascular distending pressure), r = vessel radius, and W = wall thickness.

This mechanical wall stress is transmitted to the vascular smooth muscle cells via elements of the extracellular matrix, which connect to the cell membrane at focal adhesion sites. A number of different molecules at these adhesion sites could act as primary mechanosensors that would transmit this stress across the cell membrane and into the cell interior. There is strong evidence that the family of membrane-spanning glycoproteins known as integrins often serve this role, triggering a complex intracellular phosphorylation cascade upon activation.^{10,11} Early

Figure 15-1. Types of vascular remodeling associated with hypertension, and the effect of hypertrophic inward remodeling on vascular resistance at different levels of vascular tone. Because a vessel's resistance is inversely related to the fourth power of its radius, a relatively small difference in luminal diameters between the normotensive and hypertensive conditions can translate into a large difference in flow resistance. H, vessel from hypertensive individual; N, vessel from normotensive individual.

in this cascade, focal adhesion kinase (FAK)—which is directly associated with the integrin β -subunit—undergoes both autophosphorylation and additional phosphorylation through interaction with phosphorylated tyrosine kinases such as c-Src. This leads to binding of a complex containing growth factor receptor-bound protein 2 (Grb2) and the guanine nucleotide exchange factor son-of-sevenless (Sos), and then to activation of the small GTP-binding protein Ras. Ras activation triggers activation of the mitogen-activated protein (MAP) kinase cascade and phosphorylation of extracellular signal-regulated kinase (ERK 1/2). Once phosphorylated, ERK 1/2 can translocate to the cell nucleus, where it phosphorylates various transcription factors to alter the expression of proto-oncogenes such as c-fos and c-jun.

Angiotensin II (Ang II) and other endogenous growth factors can also play a central role in the hypertrophic remodeling of resistance vessels.^{6,10} Figure 15-3 illustrates the elements of the signaling pathways through which these factors may promote inward wall growth. The activation of smooth muscle membrane receptors for epidermal growth factor (EGF), platelet-derived growth factor (PDGF), or insulin-like growth factor 1 (IGF-1) triggers activation of Ras and the MAP kinase cascade, leading to increased

ERK 1/2 phosphorylation, with upstream events that include an increase in the activity of c-Src and other tyrosine kinases.¹² Angiotensin II (acting via the G-protein-coupled AT_1 receptor) also activates these pathways, either directly or through an NAD(P)H oxidase-dependent increase in reactive oxygen species (ROS).¹³ Various ROS, most notably superoxide anion and hydrogen peroxide, can serve as important signaling molecules in this process by triggering the phosphorylation and activation of C-src and FAK.¹⁴ Interestingly, Ang II can also induce the transactivation of growth factor receptors, either through ROS generation or other pathways.¹²

Eutrophic inward remodeling is also a complex process, but is currently less well understood than hypertrophic inward remodeling. Eutrophic remodeling is known to involve numerous events, including the rearrangement of vascular smooth muscle cells, changes in extracellular matrix deposition, and changes in cell-cell or cell-matrix interactions.⁶ In contrast to the hypertrophic inward remodeling triggered by elevated wall stress or growth factors, eutrophic inward remodeling apparently does not depend on activation of tyrosine kinases or the MAP kinase cascade.¹⁵ This form of remodeling can be triggered by a chronic increase in vascular tone, which is apparently

Figure 15–2. Known elements of the signaling pathway through which a pressure-related increase in circumferential wall stress leads to hypertrophy of vascular smooth muscle cells. FAK, focal adhesion kinase; cSrc, cSrc kinase; Grb2, growth factor receptor-bound protein 2; Sos, the guanine nucleotide exchange factor son-of-sevenless, Shc is an adaptor protein, Ras is a GTP-binding protein, Raf is a tyrosine kinase; MEK, mitogen-activated protein kinase/extracellular signal-regulated kinase; ERK, extracellular signal-regulated kinase.

linked to subsequent rearrangement of the extracellular matrix through the activity of β -integrins.¹⁵ Recent findings also suggest that this matrix rearrangement depends on the activity of tissue-type transglutaminases, which are constitutively expressed multifunctional enzymes associated with β -integrins and which can catalyze the formation of stabilizing crosslinks between rearranged matrix proteins.¹⁶

Eutrophic remodeling could also occur through apoptosis (programmed cell death) in the outer regions of the vessel wall, which would reduce external vessel diameter, coupled with increased cellular growth toward the lumen, which would reduce internal vessel diameter. However, the exact role of apoptosis in vascular remodeling remains unclear, and this type of eutrophic remodeling may only occur in certain forms of hypertension.⁶

Reduced number of perfused vessels (rarefaction)

In the hypertensive state, vascular rarefaction may be defined as either a reversible closure of vessels due to intense vasoconstriction (“functional rarefaction”) or a frank loss of vessels from the network (“structural rarefaction”). Either scenario will lead to increased vascular resistance

due to the reduction in the number of parallel pathways available for flow conduction at that level of the resistance vessel network (Figure 15–4). Although vessel wall remodeling can occur in both the resistance arteries and true arterioles of hypertensive individuals, rarefaction is generally limited to distal segments of the arteriolar network and to the capillary beds. Arteriolar and capillary rarefaction has been widely documented in many animal models of hypertension,¹ and in the skin, skeletal muscle, conjunctiva, and intestine of hypertensive humans.¹⁷

In a manner somewhat analogous to eutrophic resistance vessel remodeling, there is often a clearly defined progression from constriction-induced functional rarefaction in developing hypertension to structural rarefaction in established hypertension, and this progression offers some insight into the mechanisms that underlie this transition.^{1,18} In early hypertension, an intense constriction of some arterioles can lead to cessation of their perfusion. A sustained lack of perfusion will in turn lead to atrophy and degeneration of endothelial as well as vascular smooth muscle cells (Figure 15–5), resulting in the actual loss of vessels from the network.¹⁹ Because the initial functional rarefaction is a manifestation of intense sustained

Figure 15–3. Known elements of the signaling pathways through which angiotensin II (Ang II) and other growth receptors lead to hypertrophy of vascular smooth muscle cells. EGF, epidermal growth factor; PDGF- β , the β isoform of platelet-derived growth factor; IGF-1, insulin-like growth factor 1. Other abbreviations same as in Fig. 15–2.

vasoconstriction, any mechanism that promotes increased vascular tone in the hypertensive state could theoretically lead to functional rarefaction. These mechanisms include (1) a reduced availability of endothelial nitric oxide or an increased production of endothelium-derived vasoconstrictors such as endothelin, prostaglandin H_2 , or throm-

Figure 15–4. Rarefaction of terminal arterioles and capillaries can contribute to increased vascular resistance (through a reduction in the number of parallel pathways for flow conduction), and can reduce transcapillary solute and water exchange (through a reduction in total capillary surface area and an increase in mean diffusion distance).

boxane A_2 ,²⁰ (2) an increased responsiveness of vascular smooth muscle to oxygen,⁵ neurally released norepinephrine,² or pressure-dependent (myogenic) stimuli,²¹ and (3) a chronic increase in the activity of the sympathetic nervous system.²²

There have been some reports of structural arteriolar rarefaction in hypertensive individuals without any evidence of a preceding functional rarefaction.²³ This raises the possibility that the presence of fewer vessels in the arteriolar network could reflect a decreased capacity for angiogenesis, such that normal network development does not occur in growing individuals who are susceptible to hypertension.²⁴ However, the experimental evidence that directly addresses this hypothesis is modest and at times conflicting,²⁵ and further studies are necessary to critically evaluate this possibility. Structural rarefaction could also occur independently of constriction if the actions of one or more endogenous trophic factors become suppressed, leading to a regression of previously existing vessels. In addition to its well-recognized roles in the control of renal function and systemic hemodynamics, Ang II (acting via the AT_1 receptor) is an important trophic factor necessary to normal angiogenesis and vascular wall growth and to the maintenance of normal vascular wall and network structure.²⁶ In forms of hypertension characterized by suppression of the renin-angiotensin system, microvascular rarefaction has been linked to a decrease in circulating Ang II levels—presumably through the withdrawal of these trophic actions.²⁶

Figure 15-5. The process of structural rarefaction. Shown here are electron micrographs of normal (A) and dissociating (B) arterioles in rat skeletal muscle during reduced renal mass hypertension. In B, smooth muscle (M) cells of the dissociating arteriole have become separated from the endothelium (E). Also evident is the partial or complete loss of the basement membrane and increased presence of collagen in the region underlying the smooth muscle. Arrowheads indicate elastin, and asterisks identify the vessel lumen. Rough endoplasmic reticulum is evident in the vicinity of the open triangle in the M cell to the left. Bar = 1 μm . (Reproduced from Hansen-Smith FM, Morris LW, Greene AS, Lombard JH. Rapid microvessel rarefaction with elevated salt intake and reduced renal mass hypertension in rats. *Circ Res* 1996; 79:324–30, with permission).

GENETICS

Blood pressure is a continuous normally distributed variable that is polygenic (determined by the behavior of many interacting genes) and strongly influenced by environmental variables. Assessing the genetic underpinnings of one particular aspect of hypertension, such as structural changes within the resistance vasculature, is therefore a complex and difficult task. In considering whether there may be a genetically based predisposition among some individuals to develop vascular remodeling or rarefaction with hypertension, it is important to first understand whether these structural changes are actually a cause or consequence of hypertension. A demonstration of remodeling or rarefaction in young individuals who have hypertensive parents, and may therefore be predisposed to hypertension, could yield important information in this regard. However, the current data on this point are somewhat contradictory. For the most part, resistance vessel remodeling and arteriolar rarefaction have been observed in individuals who are already hypertensive,¹⁷ and it has been well documented that vascular wall remodeling and rarefaction can readily occur in response to sustained

increases in pressure (as discussed previously) or blood flow (through changes in luminal shear stress).^{10,27} Therefore, alterations in resistance vessel structure or network architecture associated with hypertension are often considered a secondary response to the hypertensive condition. This, in turn, has given rise to the concept that remodeling and rarefaction represent a form of “structural autoregulation” to maintain normal tissue blood flows over a prolonged period in the face of increased organ perfusion pressures.²³ In this event, such vascular changes would not contribute to the initial rise in peripheral resistance but rather contribute to its maintenance once blood pressure has been increased. Consistent with this view, investigators comparing groups of offspring with and without a family predisposition for hypertension, but with similar blood pressures, have not reported a difference between groups in minimal vascular resistance.¹⁷

However, there is other evidence to suggest that the initiation of structural changes can precede the increase in arterial pressure, and thus contribute to the genesis of hypertension. For example, patients with “borderline hypertension” (in which elevated blood pressure is intermittent and relatively modest) have been found to exhibit the same degree of structural capillary rarefaction as those with established hypertension.²⁸ In addition, some investigators have reported that there is capillary rarefaction in association with a familial predisposition to essential hypertension.²⁹

Thus, in some individuals there may be a genetic predisposition to the development of such structural changes, although the extent to which these early changes would contribute to any subsequent rise in total peripheral resistance is not known. Because remodeling of resistance vessels appears to have a causal role in hypertension-related end-organ damage (see material following), findings of a genetic susceptibility to cardiac and renal damage in hypertensive individuals may also reflect the heritability of structural changes.³⁰

PHYSIOLOGY AND PATHOPHYSIOLOGY

In many forms of hypertension, TPR is elevated in direct proportion to arterial pressure. Cardiac output tends to be normal, and there is often little or no change in its fractional distribution among different organs—indicating a fairly uniform increase in vascular resistance throughout the peripheral circulation.^{31,32} Under these conditions, tissue blood flows are preserved at or near normal values in hypertensive individuals.³² The elevated arterial pressure is transmitted well into the microvasculature, but the increased resistance of small arteries and arterioles effectively dissipates this pressure increase such that pressure in the smallest arterioles is often normal in hypertensive individuals² (Figure 15-6). Therefore, in addition to preventing tissue overperfusion increased precapillary resistance in the hypertensive state can effectively shield most capillary networks from abnormally high hydrostatic pressures, which in turn would prevent excessive transcapillary water filtration and tissue edema. The exact contribution of structural versus functional changes to the overall increase in

Figure 15-6. Shift in peripheral vascular pressure profile associated with hypertension. In the hypertensive individual, the increased slope of the pressure drop across the resistance arteries and arterioles reflects an increased resistance to flow, due in part to vascular remodeling and rarefaction.

precapillary resistance can vary from organ to organ in hypertensive individuals, and (as implied previously) can change with the stage of hypertension.

If structural remodeling of the resistance vasculature leads to reduced luminal diameters at any given level of vascular tone, the hemodynamic resistance of these vessels will clearly be increased. The extent to which this remodeling increases the overall vascular resistance of an organ or tissue will depend not only on the magnitude of the diameter reductions but on the fraction of total resistance that normally resides in the remodeled vessels. The fractional distribution of hemodynamic resistance within any vascular bed can be experimentally determined from localized pressure measurements, which provide information on the network's pressure profile (such as that shown in Figure 15-6) and thereby allowing the investigator to calculate the dissipation of pressure across each of the series-coupled segments (e.g., feed arteries, proximal arterioles, distal arterioles, capillaries, and so on). To date, this detailed information has only been obtained in animal models of hypertension, where it has revealed a considerable degree of variability in the hemodynamic importance of structural changes. For example, a structural reduction in arteriolar diameters has been estimated to account for most of the increased resistance to blood flow in the cremaster muscle of rats with two-kidney one-clip hypertension,³³ whereas similar changes contribute little to increased hindquarter vascular resistance in the SHR.³⁴

Rarefaction is more localized within the resistance network than is remodeling, occurring only among the smallest arterioles.²³ However, because these vessels are responsible for a considerable fraction of total network resistance in many vascular beds the impact of rarefaction on whole-organ resistance can also be substantial. Experimental and theoretical studies indicate that in some forms of hypertension the fraction of the total increase in network vascular resistance due to arteriolar rarefaction can approach that due to active increases in microvascular tone.^{18,35}

Whether occurring through eutrophic or hypertrophic remodeling, a structural reduction in resistance vessel diameters can also provide a mechanical advantage for resistance vessels by reducing circumferential wall stress. In this event, less smooth muscle force generation would be required to maintain resting vascular diameter at any level of transmural pressure.^{4,36} Consequently, a remodeled arteriole can maintain its active diameter and participate in flow regulation at higher luminal pressures than can a normal arteriole^{36,37}—an adaptation that is clearly advantageous in the hypertensive state. This adaptation is evident in some vascular beds during autoregulation, which is defined here as the tendency of an organ to maintain constant blood flow despite changes in perfusion pressure.

As shown in Figure 15-7, the range of pressures over which vascular resistance can be adjusted to preserve normal blood flow (i.e., an organ's "autoregulatory range") can be shifted upward in hypertensive individuals.

The mechanical advantage associated with resistance vessel remodeling can be reinforced if there is also an increased contribution of passive wall elements to total wall tension. This would further reduce the level of active force required to offset elevated luminal pressure.⁴ However, that portion of total wall tension attributable to passive (as opposed to active) tension is largely determined by passive wall distensibility, and studies conducted in hypertensive animals indicate that this characteristic does not uniformly change with hypertension in all vascular beds. For example, passive arteriolar wall distensibility is decreased in the intestine of the SHR⁴ but is increased in the cerebral cortex of the stroke-prone SHR—possibly due to a dispro-

Figure 15-7. Shift in the cerebral circulation autoregulatory curve associated with spontaneous hypertension in rats. (Adapted from Harper SL Bohlen HG. Microvascular adaptation in the cerebral cortex of adult spontaneously hypertensive rats. *Hypertension* 1984;6:408-19).

portionate increase in more distensible wall elements (i.e., smooth muscle and elastin).³⁸ Furthermore, the passive distensibility of mesenteric, coronary, and cremaster muscle resistance vessels from SHR are not different from those of their normotensive counterparts.^{21,39,40}

In many tissues, local blood flow regulation is the result of a complex interplay among metabolic, myogenic, and endothelium-dependent mechanisms. In hypertension, each of these mechanisms can be altered by molecular and/or biochemical changes within the endothelium or smooth muscle of resistance vessels.^{20,41} However, structural changes may also be important in this regard. The magnitude of resistance vessel constriction in response to any stimulus is determined in part by the length/tension relationship of its vascular smooth muscle such that a maximal response will occur only when resting smooth muscle length is within some optimal range. If this resting length is changed by vessel wall remodeling, this could produce a nonspecific change in vascular responsiveness to constrictor stimuli. Furthermore, remodeling not only reduces a vessel's capacity for maximal dilation but can be accompanied by a reduced responsiveness to vasodilators at submaximal concentrations.⁴² To the extent there are changes in responsiveness to vasoconstrictor and/or vasodilator stimuli, and to the extent rarefaction can limit the network's capacity for homogenous flow distribution, structural changes in the resistance vasculature could have profound effects on local blood flow regulation. Mathematical modeling suggests that the ability of a tissue to regulate its own oxygen delivery can become compromised in hypertensive individuals due to the heterogeneous distribution of blood flow that accompanies microvascular rarefaction, leaving the PO_2 in some tissue regions highly sensitive to changes in tissue metabolism.⁴³

The loss of small arterioles, and by extension the capillaries that arise from them, also has important consequences for solute and water exchange between the vascular compartment and surrounding tissue. For example, rarefaction of only the most distal arterioles, which could have a relatively modest effect on total network resistance and blood flow, could dramatically reduce the efficiency of tissue oxygen delivery by increasing the heterogeneity of flow among those capillaries that remain perfused.³⁵ Separate from, but possibly potentiated by, this flow heterogeneity an overall reduction in the number of perfused capillaries and small arterioles will lead to decreased oxygen delivery due to (1) a reduction in the total capillary surface area available for exchange and (2) an increase in the mean diffusion distance between any respiring cell and the nearest perfused vessel (Figure 15–4). This reduction in oxygen delivery has been confirmed with direct measurements of tissue PO_2 in tissues that exhibit arteriolar and capillary rarefaction in the hypertensive state.^{43,44}

CLINICAL IMPLICATIONS AND PERSPECTIVES

Resistance vessels from untreated hypertensive patients often exhibit structurally reduced diameters due to eutrophic remodeling, and in some cases also exhibit hypertrophic

remodeling.^{12,17} In addition to the contribution they make to increased total peripheral resistance, these changes in resistance vessel structure can also play an important role in the development of some types of end-organ damage associated with hypertension. Resistance artery remodeling is clearly evident in patients with mild (early) hypertension before the onset of any clinically relevant end-organ damage.⁴⁵ Other studies have demonstrated that hypertension-associated stroke linked to small vessel infarction is due in part to structural changes in the cerebral microvasculature,²⁹ and that small artery remodeling contributes to the mechanisms of hypertension-associated renal failure.⁴⁶ The prognostic value of these structural changes has also been recognized. The degree to which subcutaneous small arteries are remodeled has been found to be a strong predictor of fatal and nonfatal cardiac, cerebral, and renal events in hypertensive patients— independent of other known cardiovascular risk factors.⁴⁷

The functional and structural rarefaction of arterioles and capillaries is also well documented in untreated hypertensive patients.^{17,28,48,49} The contribution of rarefaction to end-organ damage is less clear, although disruption of normal tissue oxygen and nutrient delivery could clearly lead to compromised organ function.

In light of the importance of resistance vessel remodeling in contributing to end-organ damage, and the possible problems in tissue solute-water transport posed by rarefaction, the normalization of microvascular structure and hemodynamics should be an important goal of antihypertensive therapy. Although such therapy has often been directed toward reversing the abnormal constriction of resistance vessels, recent therapeutic efforts have been increasingly directed toward reducing or reversing the changes in vascular structure associated with hypertension and toward reducing or reversing microvascular rarefaction. In fact, some antihypertensive agents have been found to exert their effects through both an acute change in vascular function (vasodilation) and chronic improvements in vessel and network structure.

Depending on the therapeutic strategy employed and the duration of treatment, antihypertensive therapy may partially or completely reverse the structural remodeling of resistance vessels in hypertensive humans.¹⁷ However, there are clear differences among the major classes of antihypertensive agents with respect to their impact on resistance vessel structure, and these differences are not related to the magnitude of blood pressure reduction. For example, there is little evidence that either diuretics or beta-blockers can reverse vascular remodeling or rarefaction,^{29,50} whereas calcium antagonists are effective in reducing both arteriolar remodeling and capillary rarefaction—at least in animal models of hypertension.⁵¹ Angiotensin-converting enzyme (ACE) inhibitors are also effective in reversing the remodeling of resistance vessels in both animal models and hypertensive patients, although there are conflicting results on the ability of these agents to reverse rarefaction.^{29,50} In some cases, antagonists of Ang II (AT_1) receptors can also reverse microvascular remodeling and rarefaction. Certain combinations of antihypertensive agents are also effective in reversing these

structural changes, and in some cases these combinations can be more effective than either agent given alone.²⁹

Additional studies are required to more clearly determine the extent to which resistance vessel remodeling and rarefaction can be primary (i.e., causal) events in the development of hypertension, and to more completely understand the intracellular signaling pathways that trigger and sustain these structural changes. This is particularly true in the case of eutrophic remodeling, where the possible involvement of cellular apoptosis is intriguing yet poorly understood. Another unresolved issue of obvious importance for hypertension research is the elucidation of those mechanisms responsible for the onset and progression of hypertension-related organ damage, including the exact role of vascular remodeling in these processes. Finally, although not specifically discussed in relation to structural changes studies to evaluate the contributions of inflammation and reactive oxygen species to this target-organ damage also appear to hold much promise in helping to understand these pathologic changes.^{14,41} This information is of obvious value in developing more effective therapeutic strategies for the prevention and treatment of hypertension and its consequences.

SUMMARY

In hypertensive individuals, increased vascular resistance can be due in part to structural changes in the diameter of individual resistance vessels (through vascular wall remodeling) or structural changes in the architecture of resistance vessel networks (through rarefaction). The relative influences of remodeling versus rarefaction on vascular resistance, as well as the fraction of the overall resistance increase attributable to structural versus functional changes in

general, can vary from organ to organ within a hypertensive individual and depends on the form of hypertension and its developmental stage.

The hypertrophic inward remodeling of resistance vessels can be triggered by numerous stimuli, including pressure-dependent increases in vascular wall stress and the actions of different vascular growth factors. In contrast, the eutrophic inward remodeling of these vessels can be triggered by sustained vasoconstriction. Investigators are continuing to make important progress in defining the intracellular signaling pathways through which these and other stimuli lead to inward vascular remodeling. The structural rarefaction of arterioles and capillaries can occur in response to a constriction-dependent cessation of vessel perfusion, leading to degradation of vascular wall elements or to a decrease in the availability of one or more endogenous vascular growth or trophic factors.

It is unclear whether some of these structural changes within the resistance vasculature can precede the onset of hypertension (and therefore contribute to its development) or whether they represent a secondary adaptation to the hypertensive state (and therefore contribute to the maintenance of increased TPR and arterial pressure). Nevertheless, it is becoming apparent that in addition to their effects on TPR these changes may also have important effects on the regulation of tissue blood flow and transcapillary exchange.

Because resistance vessel remodeling may also play a role in the development of hypertension-related end-organ damage, the reversal of changes in vascular structure is becoming an important focus of antihypertensive therapy. However, additional studies are needed to clearly determine which classes of hypertensive agents (alone or in combination) are most effective in achieving this goal.

The RhoA/Rho-Kinase Signaling Pathway in Vascular Smooth Muscle Contraction: Biochemistry, Physiology, and Pharmacology

Cleber E. Teixeira and R. Clinton Webb

Key Findings

- Contraction of the vascular smooth muscle is initiated, and to a lesser extent maintained, by a rise in the concentration of free Ca^{2+} in the cell cytoplasm. As a result, several signaling pathways trigger a Ca^{2+} /calmodulin interaction to stimulate phosphorylation of the myosin light chain (MLC).
- It is well established that the Ca^{2+} signal is not the sole factor that regulates vascular smooth muscle contraction, because alterations of the Ca^{2+} sensitivity in the contractile apparatus are also known to play an important role. Ca^{2+} sensitivity of smooth muscle reflects the ratio of activities of MLC kinase and MLC phosphatase, which determines the level of MLC phosphorylation.
- Ca^{2+} sensitization of the contractile proteins is widely attributed to the monomeric G protein RhoA and mediated by its effector, Rho-kinase, to inhibit the dephosphorylation of MLC in the presence of basal (Ca^{2+} dependent or independent) or increased MLC kinase activity, thereby maintaining force generation.
- In animal and human studies, the Ca^{2+} sensitization mediated by the Rho-kinase signaling pathway has been shown to be substantially involved in the pathogenesis of hypertension, vasospasm, atherosclerosis, pulmonary hypertension, stroke, and heart failure.
- Because changes mediated by the abnormal activation of the RhoA/Rho-kinase signaling are implicated in the pathogenesis of several cardiovascular diseases, intervention with this pathway may potentially have therapeutic consequences.

INTRODUCTION

Sheets or layers of smooth muscle cells constitute the walls of various organs and tubes in the body, including the blood vessels, stomach, intestines, bladder, airways, uterus, and the penile and clitoral cavernosal sinuses. In its differentiated state, the primary function of smooth muscle is mechanical, to generate force. This force may be utilized to perform many functions, including maintenance and regulation of circulation, gastrointestinal motility, expulsion of the fetus, regulation of light admitted to the retina, regulation of intraocular pressure in the eye, and the behavior of the urogenital tract. When made to contract, the smooth muscle cells shorten and propel the luminal

content of the organ, or the cell shortening varies the diameter of a tube to regulate the flow of its content. Smooth muscle cells lack the striated banding pattern found in cardiac and skeletal muscle, and they receive neural innervation from the autonomic nervous system. In addition, the contractile state of smooth muscle is controlled by hormones, autocrine/paracrine agents, and other local chemical signals. Smooth muscle cells also develop tonic and phasic contractions in response to changes in load or length. Regardless of the stimulus, smooth muscle cells use cross-bridge cycling between actin and myosin to develop force, and Ca^{2+} ions serve to initiate the underlying molecular signaling that leads to contraction.

The vascular smooth muscle cell is a highly specialized cell whose principal function is contraction. It expresses a variety of contractile proteins, ion channels, and signaling molecules that regulate the contractile process. Upon contraction, vascular smooth muscle cells shorten, thereby decreasing the diameter of a blood vessel in order to regulate the blood flow and pressure. In this chapter, we focus primarily on the contractile phenotype of vascular smooth muscle cells and describe the molecular signaling pathways involved in the regulation of contraction, particularly the role of the RhoA/Rho-kinase signaling in contractile processes and the pathophysiological implications of this pathway.

THE CONTRACTILE MECHANISM OF THE VASCULAR SMOOTH MUSCLE

In the intact body, the process of smooth muscle cell contraction is regulated principally by pharmacomechanical (ligand-mediated activation of cell surface receptors) and electromechanical (stretch, intraluminal pressure) activation of the contractile proteins myosin and actin.¹ A change in membrane potential, brought on by the firing of action potentials or by activation of stretch-dependent ion channels in the plasma membrane, can also trigger contraction. For contraction to occur, myosin light-chain kinase (MLC kinase) must phosphorylate the 20-kDa light chain of myosin, enabling the molecular interaction of myosin with actin. Energy released from ATP by myosin ATPase activity results in the cycling of the myosin cross-bridges with actin for contraction.^{2,3} Counteracting the pulling forces exerted by external tension, cells can generate contractile force. Actin-

myosin fibers contract following myosin light-chain phosphorylation, and by insertion of these fibers into focal contacts associated with the plasma membrane tension develops within a cell, accompanied by inward cell contraction.

The extent of cell contraction depends on the external tension pulling outward. Eventually, a state of equilibrium between internal contractile force and external tension is achieved. There are two types of contractility: isotonic contraction (in which there is shortening of actin-myosin filaments and therefore cell contraction) and isometric contraction, in which filament shortening does not occur but tension increases. Thus, contractile activity in smooth muscle is determined primarily by the phosphorylation state of the light chain of myosin, a highly regulated process. In some smooth muscle cells, the phosphorylation of the light chain of myosin is maintained at a low level in the absence of external stimuli (i.e., no receptor or mechanical activation).⁴ This activity results in what is known as vascular tone, which can be defined as the degree of constriction of a blood vessel relative to its maximal diameter in the dilated state.

Under basal conditions, most resistance and capacitance vessels exhibit some degree of smooth muscle contraction that determines the diameter or tone of the vessel. Vascular tone is also partially determined by a multitude of vasoconstrictor factors such as norepinephrine, angiotensin II, vasopressin, and 5-hydroxytryptamine—as well as by vasodilator factors such as nitric oxide, bradykinin, and prostacyclin. These factors can be divided into extrinsic factors (which originate outside the blood vessel) and intrinsic factors, which originate in the vessel itself. Extrinsic factors primarily serve the function of regulating arterial pressure by altering systemic vascular resistance, whereas intrinsic mechanisms are concerned with regulation of local blood flow within an organ.⁵

Ca²⁺-dependent contraction

The state of contraction of smooth muscle is known to depend on cytosolic Ca²⁺ levels. A rise in the concentration of cytoplasmic Ca²⁺ is the trigger for vascular contraction.⁶ However, contraction in smooth muscle, unlike striated muscle, is regulated to a large extent by a mechanism independent of membrane potential—in which agonists induce contraction without membrane depolarization. Contraction of smooth muscle is initiated by a Ca²⁺-mediated change in the thick (myosin) filaments, whereas in striated muscle Ca²⁺-mediated contraction is initiated by changes in the thin (actin) filaments. In response to specific stimuli in smooth muscle (for instance, the α -adrenoceptor agonist norepinephrine released from the sympathetic nerve endings within the arterial wall), the intracellular concentration of Ca²⁺ rapidly increases and then declines to a level that is elevated above basal in the continued presence of the agonist.⁷ This initial increase in cytosolic Ca²⁺ arises from Ca²⁺ released from intracellular stores (sarcoplasmic reticulum) and the latter as of entry from the extracellular space via receptor-operated Ca²⁺ channels.⁸

The biochemical signals that trigger Ca²⁺ release involve activation of phospholipase C (PLC) by heterotrimeric G-

proteins upon binding of agonists to the seven transmembrane receptors on the smooth muscle cell membrane.⁹ PLC is specific for the membrane lipid phosphatidylinositol 4,5-bisphosphate (PIP₂) to catalyze the formation of two potent second messengers, inositol 1,4,5-triphosphate (IP₃) and diacylglycerol (DAG). The binding of IP₃ to specific receptors on the sarcoplasmic reticulum results in the release of Ca²⁺ into the cytosol. The primary target protein of this initial rise in intracellular Ca²⁺ is believed to be calmodulin (CaM). A Ca²⁺-CaM complex allows a subsequent interaction with MLC kinase, resulting in a conformational change of the CaM-MLC kinase and thus exposing the catalytic site. This sequence of events leads to the activation of MLC kinase and the phosphorylation of Ser19 of the 20-kDa regulatory light chain of myosin (MLC₂₀). It is widely accepted that the degree of MLC₂₀ phosphorylation is the essential factor that determines the extent to which the vascular smooth muscle contracts: MLC₂₀ phosphorylation promotes contraction whereas MLC₂₀ dephosphorylation, following a reduction in intracellular Ca²⁺, results in relaxation.

The second messenger (DAG) activates protein kinase C (PKC), which phosphorylates specific target proteins. There are several PKC isozymes in smooth muscle cells, such as PKC α and β (DAG and Ca²⁺ dependent) or PKC ϵ (DAG dependent), and each has a tissue-specific role. In many cases PKC has contraction-promoting effects such as phosphorylation of many kinases, as well as various ion channels and ion transporters. Phorbol esters constitute a group of synthetic compounds known to activate PKC, mimic the action of DAG, and cause contraction of smooth muscle.^{10,11} Finally, L-type Ca²⁺ channels (voltage-operated Ca²⁺ channels) in the membrane also open in response to membrane depolarization induced by stretch of the smooth muscle cell, which has been proposed to play an important role in myogenic reactivity and tone.^{5,12}

Ca²⁺ sensitization mechanism

Using fluorescence Ca²⁺ indicators to measure intracellular Ca²⁺, it has been revealed that the Ca²⁺ concentration does not necessarily parallel the degree of smooth muscle contraction.¹³ Subsequent studies in permeabilized vascular smooth muscle showed that GTP γ S and G-protein-coupled receptor agonists could increase contractile force without increasing intracellular Ca²⁺.^{14,15} The extent of MLC₂₀ phosphorylation or force of contraction induced by agonist stimulation is higher than that predicted by the actual Ca²⁺ concentration in the cell, the so-called Ca²⁺ sensitization. Thus, an additional mechanism of regulation that can modify the levels of MLC₂₀ phosphorylation and degree of contraction independently of Ca²⁺ concentration has been proposed. Most importantly, it is understood that the increased MLC₂₀ phosphorylation via a GTP-binding protein is due to the inhibition of MLC phosphatase rather than to activation of MLC kinase.^{16,17} The small GTPase RhoA (a member of the Rho subfamily of the Ras superfamily of monomeric GTPases) and its effector Rho-associated kinase (Rho-kinase) are responsible for the Ca²⁺ sensitization induced by agonist stimulation and are thought to act by inhibiting MLCP activity.¹⁸

SIGNAL TRANSDUCTION REGULATING Ca^{2+} SENSITIVITY

Until recently, the molecular mechanism by which RhoA regulates smooth muscle contraction was largely unknown. However, the signaling pathway that involves the downstream effector of RhoA (Rho-kinase) has been shown to play a crucial role in the Ca^{2+} sensitization of smooth muscle contraction.^{19,20} Further, analyses using inhibitory probes specific for Rho-kinase have revealed that Rho-kinase-mediated Ca^{2+} sensitization is involved in a variety of cardiovascular diseases, suggesting that Rho-kinase could be a therapeutic target.²¹

Small Rho GTPases

Rho family GTPases function to control a multitude of cellular processes, including actin cytoskeletal rearrangements, cell movement, and smooth muscle contraction.^{22,23} These proteins act as binary molecular switches that are turned on and off (i.e., cycle between an inactive GDP-bound and an active GTP-bound state) in response to a variety of stimuli. To become activated, RhoA must be targeted via its geranylgeranylated C-terminus to the membrane. In the GTP-bound active state, RhoA is conformationally primed to engage downstream effectors such as Rho-kinase in order to transduce signals that influence diverse biological responses. When the bound GTP is hydrolyzed to GDP, RhoA returns to the inactive basal state.²²

Regulation of RhoA activity

Three classes of regulatory proteins are involved in balancing RhoA between the GTP-bound active and GDP-bound inactive states: (1) GTPase-activating proteins (GAPs), which act by negative regulation through increases in the intrinsic GTPase activity of RhoA to accelerate the return of the protein to the inactive state, (2) guanine nucleotide dissociation inhibitors (GDIs), which sequester the GDP-bound form of RhoA and regulate the intracellular localization of the protein by preventing binding to the membrane, and (3) Rho-specific guanine nucleotide exchange factors (GEFs), which stimulate the GTP-GDP exchange reaction (Figure 16–1).

RhoGDIs

Three isoforms of RhoGDI have been identified to date: the ubiquitously expressed RhoGDI $_{\alpha}$ (GDI1), the hematopoietic cell-selective RhoGDI $_{\beta}$ (GDI2), and RhoGDI $_{\gamma}$, which is restricted to lung, brain, and testis.^{24,25} RhoGDI acts as an endogenous inhibitor for RhoA through two mechanisms: stabilizing RhoA in its inactive GDP-bound form, and translocating RhoA-GDP to the cytosol after extracting it from the membrane. Although RhoGDI is able to interact with both the GTP- and GDP-bound Rho, the binding of GDP to Rho increases the affinity for RhoGDI more than ten times.²⁶ Overexpression or exogenous administration of high concentrations of RhoGDI in tissues inhibits Rho-mediated biological activity.^{27,28} In a cell-free system derived from rat kidney, RhoA is extracted from the brush border membrane after addition of a glutathione S-trans-

Figure 16–1. Regulation of RhoA activity. Rho GTPases function as molecular switches that control cell function by cycling between two interconvertible forms: a GDP-bound “inactive” form and a GTP-bound “active” form. In resting cells, the cytosolic inactive form of RhoA is complexed with RhoGDI (guanine nucleotide dissociation inhibitor). The rate-limiting step of the GDP/GTP exchange (which is the dissociation of GDP) is promoted by the association of a GEF (guanine nucleotide exchange factor), the activity of which may be regulated by an upstream signal such as the activation of heterotrimeric G-proteins. The GTP-bound form of RhoA is converted into the GDP-bound form due to its intrinsic GTPase activity, which is stimulated by a GAP (GTPase-activating protein).

ferase (GST)-GDI fusion protein.²⁹ The ability of RhoGDI to extract RhoA from the plasma membrane is not solely dependent on the exchange of nucleotide on RhoA. Phosphorylation of RhoA on Ser188 by cyclic AMP-dependent protein kinase (PKA) has been shown to increase the RhoA interaction with RhoGDI, even at the GTP-bound state.³⁰ Forskolin, an adenylyl cyclase activator, markedly reduces the amount of active RhoA in renal CD8 cells according to RhoA-GTP pull-down assay and Western blot analysis. Phosphorylation of RhoA and decreased membrane fraction of GDI by forskolin treatment lead to increased RhoGDI-RhoA complexes in the cytosol.³¹ Transfection of human microvascular endothelial cells with adenovirus encoding the PKA inhibitor gene blocks the inhibitory effect of forskolin on RhoA.³² These studies suggest that phosphorylation of RhoA is an alternative mechanism to inhibit RhoA activity, independently of its nucleotide-bound state.

RhoGEFs

RhoGEFs receive upstream signals that trigger the various signal transduction cascades that involve small GTP-binding proteins, and for that reason they are regarded as the main regulators of RhoA activity.^{33,34} A group of RhoGEFs characterized by a unique motif resembling a “regulator of G-protein signaling” (RGS) domain at the N-terminal have been identified and these were shown to bind to the activated α -subunit of heterotrimeric G-proteins.³⁵ Currently, this group of RhoGEF proteins comprises three members: p115RhoGEF, PDZ-RhoGEF, and leukemia-associated RhoGEF (LARG). The RGS domain of these GEFs also functions as a GAP, accelerating G_{α} -intrinsic GTPase

activity.^{36,37} Binding of G_{α} subunits to these proteins stimulates GEF activity toward RhoA, and as a consequence RhoGEFs operate as nodes connecting signal transduction cascades modulated by large and small GTPases.^{33,35} It has been reported that $G_{\alpha12}$ and $G_{\alpha13}$ (the members of the G_{12} family) can physically associate with p115RhoGEF, PDZ-RhoGEF, and LARG.³⁸⁻⁴⁰ Mutation of $G_{\alpha13}$ on residues Glu229, Lys204, or Arg232 attenuates the activation of p115RhoGEF and LARG—as well as the subsequent RhoA activation.^{41,42} In addition, $G_{\alpha q}/G_{\alpha11}$ was also reported to activate RhoGEFs and thus lead to the activation of RhoA.^{43,44}

These RhoGEFs, like other GEFs, contain a Dbl homology (DH) domain and a pleckstrin homology (PH) domain linked in tandem. Crystallographic studies provided the physical evidence that RhoGEFs directly interact with RhoA via both DH and PH domains.⁴⁵ The DH domain is thought to be responsible for catalyzing the nucleotide exchange reaction, whereas the PH domain may stabilize the binding of DH domain to RhoA and direct the subcellular localization of RhoA to the membrane, allowing RhoA to interact with actin.^{46,47} In some cases, the PH domain can also modulate the nucleotide exchange activity of the DH domain.⁴⁸ Indeed, it has been demonstrated that the DH/PH domains of LARG catalyze nucleotide exchange more efficiently than the DH domain alone.⁴⁹ In their inactive state, the RGS domain and the DH domain have reciprocal inhibitory effects. When G_{α} is activated, the RGS domain of RhoGEF binds to G_{α} and exposes the DH domain (which is able to interact with RhoA and initiate nucleotide exchange).³⁵ It has also been demonstrated that p115RhoGEF mediates thrombin-induced cytoskeletal rearrangement, and a direct phosphorylation of p115RhoGEF by PKC α is observed within 1 minute of thrombin stimulation.⁵⁰ Inhibition of PKC α results in attenuation of thrombin-induced RhoA activation, suggesting that G_{12} and PKC α pathways may run in parallel to modulate RhoGEF activity.

RhoGAPs

The RhoGAP family is defined by the presence of a conserved RhoGAP domain in the primary sequences that consists of about 150 amino acids and shares at least 20% sequence identity with other family members. The RhoGAP domain is distinct from the GAP modules responsible for turning off other classes of GTPases (e.g., Ras, Ran, or ARF), and it is sufficient for the binding to GTP-bound Rho proteins and accelerating their GTPase activity.⁵¹ RhoGAPs inhibit RhoA through enhancing the intrinsic rate of GTP hydrolysis, and thus active RhoA is converted into inactive RhoA-GDP. The basic mechanism of GTPase stimulation relies on the stabilization of the highly mobile switch regions and the transition state of the GTP-hydrolysis reaction by supplying a catalytic arginine to the active site.⁵²⁻⁵⁵ This mechanism is predicted based on crystallographic studies demonstrating that Arg85 on RhoGAP engages the GTPase active site and stabilizes the transition state of the GTP hydrolysis.⁵⁶ Therefore, GAPs position the catalytically crucial Gln63 in an appropriate conformation toward a nucleophilic water molecule, which

hydrolyses GTP and neutralizes developing negative charges on the leaving group during the phosphoryl-transfer reaction. Replacement of this so-called “arginine finger” by an Ala greatly diminishes the catalytic capacity of the respective GAPs, which are still able to bind the GTPase with high affinity.⁵⁷⁻⁵⁹ Several GAPs have been identified to selectively interact with Rho, such as Graf, p122RhoGAP, and p190RhoGAP.⁶⁰⁻⁶²

Measurement of RhoA activity

Activation of the RhoA protein is associated with the exchange of GDP for GTP and the translocation of the active GTP-bound RhoA from the cytosol to the membrane.^{63,64} RhoA activation can therefore be assessed by both measurement of the amount of cellular GTP-RhoA and detection of the RhoA protein in membrane fractions by Western blot analysis. These approaches are commonly used for the assessment of RhoA activity.^{63,65-67} The method used for measuring the amount of GTP-RhoA is based on the specific binding of GTP-RhoA (but not GDP-RhoA) to the RB domain of RhoA effectors.⁶⁸ The RB domain of rhotekin⁶⁸ and mDia⁶⁹ are used in this pull-down assay to precipitate active GTP-RhoA from protein extracts from cells or tissues. Activation of RhoA based on increased GTP binding has been more difficult to demonstrate, but a few groups have reported increased binding of radiolabeled guanine nucleotides to RhoA following receptor stimulation. Formylmethionyleucylphenylalanine (fMLP) increased both [³²P]GTP- and [³²P]GDP-bound RhoA in leukocytes.^{70,71} [³⁵S]GTP γ S binding to RhoA was increased in response to fMLP in leukocytes and in response to thrombin in rat aortic smooth muscle cells.^{71,72} α_2 -Adrenergic receptor stimulation increased [³²P]GTP binding to RhoA and decreased [³²P]GDP-RhoA binding in preadipocytes.⁷³ Expression of various constitutively activated G_{α} subunits of heterotrimeric G proteins in COS-7 cells has also been shown to increase RhoA-[³²P]GTP binding.⁷⁴

Rho-associated kinase and MLC phosphorylation

The identification and functional analysis of RhoA effectors shed light on the signaling pathway linking RhoA to the regulation of the MLC phosphatase activity (i.e., the MLC₂₀ phosphorylation level). As described previously, although RhoA may mediate Ca²⁺ sensitization an intact plasma membrane is required for this event because RhoA does not inhibit MLC phosphatase directly.⁷⁵ Following the demonstration that the membrane translocation of RhoA is temporally associated with Ca²⁺ sensitization,⁶⁵ and given that the active RhoA-GTP complex is presumably membrane bound whereas MLC phosphatase is cytosolic, a “diffusible cofactor” would be necessary to establish the signal transduction pathway. Rho-kinase was then identified as the downstream effector of RhoA mediating Ca²⁺ sensitization. Indeed, Rho-kinase is one of the best characterized RhoA effectors and exists in two isoforms: ROK α (also called ROCK2) and ROK β (also known as p160ROCK or ROCK1).⁷⁶ In addition to Rho-kinase, several other proteins have been identified as effectors of Rho, including protein kinase N (PKN), rhophilin, rhotekin, citron,

p140mDia, and citron kinase.^{77,78} However, the roles of those effectors of Rho other than Rho-kinase remain to be examined.

Rho-kinases are serine/threonine protein kinases that contain an N-terminal catalytic kinase domain, a coiled-coil domain in the middle portion, and a putative C-terminal PH domain split by an insertion of a cystein-rich region.⁷⁶ The Rho-binding (RB) domain of Rho-kinase is localized in the C-terminal portion of the coiled-coil domain, and Rho-kinase activity is enhanced by binding GTP-RhoA.^{76,79,80} The expression of Rho-kinase is accelerated by inflammatory stimuli (such as angiotensin II and IL-1 β) through PKC/NF- κ B pathway,⁸¹ with a negative modulation by physiological concentrations of estrogen and a positive modulation by clinical concentrations of nicotine.⁸² Remnant lipoproteins also upregulate Rho-kinase in human coronary vascular smooth muscle cells.⁸³ Indeed, mRNA expression of Rho-kinase is enhanced at the inflammatory and arteriosclerotic arterial lesions in animals^{84,85} and humans,⁸⁶ causing hypercontraction of the artery.

The targets of Rho-kinase have been identified, and include the myosin-binding subunit (MBS) of myosin phosphatase, ERM (ezrin, radixin, moesin) family, adducin, intermediate filament (vimentin), Na⁺-H⁺ exchanger, and LIM-kinase1.⁸⁷ Among these, one of the main substrates of Rho-kinase is MLCP, which is physiologically responsible for the dephosphorylation of the MLC₂₀ of myosin II. This phosphatase comprises three subunits: a 37-kDa phosphatase catalytic subunit, a 110- to 130-kDa myosin binding subunit (MBS)—also called myosin phosphatase target subunit (MYPT1)—and a 20-kDa subunit with unknown function.^{88,89} MBS is ubiquitously expressed with a relatively higher concentration in smooth muscle cells. With the PP1c-binding domain on the N-terminal region and the myosin binding domain on the C-terminal region, MBS targets MLC phosphatase to the myosin filaments and increases the catalytic activity of PP1c.⁹⁰ Phosphorylation of MBS at Thr696 is believed to decrease PP1c catalytic activity, which inhibits MLC phosphatase and maintains the MLC₂₀ phosphorylation level. Activated Rho-kinase phosphorylates the MBS to inhibit MLC phosphatase activity.⁹¹ Therefore, Rho-kinase and MBS are believed to regulate the level of MLC₂₀ phosphorylation cooperatively, and this regulatory mechanism plays important roles in a variety of cellular functions, particularly in smooth muscle contraction. Indeed, agonists such as prostaglandin F_{2 α} , lysophosphatidic acid, and angiotensin II have been shown to increase phosphorylation of MBS at Thr696 and to enhance Ca²⁺ sensitivity through activation of Rho-kinase.^{91–93} In chicken amnion smooth muscle and rat tail artery, Rho-kinase inhibits MLC phosphatase through phosphorylation of MBS at Thr850 and thus reduces the binding of MLC phosphatase to MLC.^{94–96}

TOOLS AND METHODS TO PROBE THE RHOA/RHO-KINASE PATHWAY

The C3 exoenzyme isolated from *Clostridium botulinum* is the most commonly used toxin for the examination of

the functional role of RhoA because it specifically inhibits RhoA through ADP-ribosylation at Asn41 and has little effect on other proteins of the Rho family. The inhibition of RhoA by C3 exoenzyme is thought to block the dissociation of RhoA and RhoGDI complex and prevent the activation of RhoA by RhoGEF, in that the RhoA activators GTP γ S and PIP₂ are unable to release RhoA from RhoGDI in the presence of C3.⁹⁷ ADP-ribosylation of RhoA does not appear to interfere with its nucleotide binding, RhoGTPase activity, or interaction with downstream effectors such as Rho-kinase.^{63,97,98} On the other hand, cytotoxic necrotizing factors (CNF)-1 and -2 (first isolated from *Escherichia coli*) have been shown to turn RhoA into a constitutively active form by deamidating Gln63 to Glu, which blocks the RhoGAP-increased GTP hydrolysis.^{99,100} CNF-1 and -2 also affect other RhoGTPases, such as Rac and CDC42.¹⁰¹ Recently, CNF_Y identified in *Yersinia pseudotuberculosis* strains has been demonstrated to selectively activate RhoA without activation of Rac or CDC42.¹⁰² The kinase activity-deficient form of Rho-kinase or the C-terminal fragments that lack the kinase activity should theoretically serve as the dominant-negative form of Rho-kinase in cells.¹⁹ Thus, the C-terminal fragment of Rho-kinase that contains the RB domain—deficient in Rho-binding activity after point mutations and the PH domain [RB/PH(TT)]—serves as the dominant-negative form that specifically inhibits Rho-kinase.^{19,85}

Several compounds have been developed and reported to specifically inhibit Rho-kinase activity in an ATP competitive manner. As a result, the availability of specific Rho-kinase inhibitors has enabled the evaluation of the physiological roles of Rho-kinase in vascular smooth muscle. The pyridine derivative Y-27632 ((R)-(+)-*trans*-N-(4-pyridyl)-4-(1-aminoethyl)-cyclohexanecarboxamide), a highly selective inhibitor of Rho-kinase, has proved to be a useful pharmacological tool to examine the role of Rho-kinase in various cellular functions.¹⁰³ It competes for the ATP binding site on Rho-kinase, thus preventing the Rho-kinase-mediated phosphorylation of MLC phosphatase and resulting in relaxation of smooth muscle. Y-27632 is transported into cells by a carrier-facilitated diffusion mechanism to inhibit Rho-kinase activity. Therefore, the extracellular concentration of Y-27632 is similar to the intracellular concentration. The K_i value of Y-27632 for Rho-kinase is approximately 200-fold lower than that for other protein kinases involved in smooth muscle contractility, such as PKC, PKA, and MLC kinase.^{103,104} Although Y-27632 is relatively less selective for the Ca²⁺-dependent PKC isoforms, it is a potent inhibitor of the Ca²⁺-independent PKC δ and PKC ϵ isoforms, which have been shown to mediate Ca²⁺ sensitization.^{104,105} Y-27632 has minimal effects on intracellular Ca²⁺ at the low micromolar range, whereas it significantly inhibits the rise of cytosolic Ca²⁺ levels at higher concentrations.^{106–109}

Another family of compounds derived from isoquinolinesulfonamide shows selectivity for Rho-kinase. The compound HA-1077, or fasudil hydrochloride ((5-isoquinolinesulfonyl)homopiperazine)—with a K_i value of 0.3 μ M—also competes for the ATP binding site on Rho-kinase. However, HA-1077 is also a potent inhibitor

of PKA and PKC—with K_i values of approximately 1 μM and 9.3 μM , respectively.¹¹⁰ It has been recently demonstrated that hydroxyfasudil, a major active metabolite of fasudil after oral administration, has a more specific inhibitory effect on Rho-kinase.^{111,112} The K_i value of hydroxyfasudil is 0.17 μM for Rho-kinase, 18 μM for PKC, and 140 μM for MLC kinase.¹¹¹ The compound H-1152 ((S)-(+)-2-methyl-1-[(4-methyl-5-isoquinoliny)sulfonyl]homopiperazine) is similar in structure to fasudil, with the exception of two extra methyl groups, which significantly enhance its inhibitory effect and selectivity for Rho-kinase. Its K_i value for Rho-kinase is approximately 1.6 nM, which makes this compound 400 times more potent to inhibit Rho-kinase among other kinases, such as PKA, PKC, and MLC kinase.¹¹³

The biological activities of RhoA and Rho-kinase can also be manipulated by overexpression of constitutively active and dominant-negative mutants of RhoA or Rho-kinase as well as the RhoGTPase regulators. The dominant-negative RhoA (T19NRhoA) is generated by substitution of Asp for Thr at position 19, which leads to increased affinity for RhoGEF and decreased GTP binding—competing with exogenous RhoA for RhoGEF.¹¹⁴ The substitution of Leu for Glu at position 63 results in a constitutively active RhoA (V14RhoA). Rho-kinase dominant-negative and active mutants are also used to investigate RhoA/Rho-kinase-mediated Ca^{2+} sensitization.^{115,116} Recently, small-interference RNA (siRNA) has emerged as a new powerful tool to selectively silence the expression of the target gene. This post-transcriptional gene silencing by these 21 to 25 nucleotides leads to degradation of target mRNAs. Anti-RhoA siRNA has been reported to successfully knock down RhoA expression in cells.^{117,118}

RHO-KINASE AND VASCULAR SMOOTH MUSCLE CONTRACTION

Agonists (norepinephrine, endothelin, thromboxane, and so on) that bind to G-protein-coupled receptors produce contraction by increasing both the cytosolic Ca^{2+} concentration and the Ca^{2+} sensitivity of the contractile apparatus (Figure 16–2).¹¹⁹ The increased sensitivity toward Ca^{2+} results from inhibition of MLC phosphatase activity, leading to increased MLC₂₀ phosphorylation and tension at a constant Ca^{2+} concentration. This Ca^{2+} -sensitizing effect is ascribed to the activation of RhoA that stimulates Rho-kinase, which in turn phosphorylates the regulatory subunit of MLC phosphatase and inhibits its activity.^{19,20,119} Y-27632 has been widely used to inhibit Rho-kinase and was originally developed as a relaxant of vascular smooth muscle. This compound completely inhibits agonist-induced contraction of both intact and permeabilized strips of vascular smooth muscle.¹⁰⁴ In addition, the Rho-kinase inhibitor fasudil antagonizes contractions of rabbit aortic smooth muscle in response to prostaglandin $\text{F}_{2\alpha}$ ($\text{PGF}_{2\alpha}$), which has been shown to comprise a Ca^{2+} -sensitizing mechanism characterized by the inhibition of MLC₂₀ dephosphorylation through Rho-kinase-induced MBS phosphorylation.⁹³

Smooth muscle cells, especially in the smaller arteries and arterioles, are intrinsically active—and this myogenic responsiveness plays a key role in blood flow control and regulation of peripheral resistance. Although an increase in intracellular Ca^{2+} is necessary for the initiation of myogenic responsiveness, a major component of myogenic activation results from an increase in Ca^{2+} sensitivity—as demonstrated by the ability of Y-27632 to suppress myogenic tone without significant changes in the intracellular Ca^{2+} levels.¹²⁰ In addition, it has been shown that ROK α is expressed in mesenteric and celiac arteries, contributing to the control of perfusion pressure.^{121,122} These studies underlie the physiological importance of the RhoA/Rho-kinase signaling pathway in the maintenance of microvascular constriction and ultimately in the control of vascular resistance.

With regard to the involvement of Rho-kinase in the regulation of Ca^{2+} sensitivity in human arteries, Y-27632 has been demonstrated to strongly relax agonist-induced but not KCl-induced contraction.¹²³ In addition, the relaxation produced by Y-27632 was not dependent on a decrease in cytosolic Ca^{2+} , suggesting that a Rho-kinase-associated pathway is involved in agonist-induced Ca^{2+} sensitization of human small omental arteries.¹²³ Several additional reports demonstrate that the RhoA/Rho-kinase signaling plays a key role in agonist-induced contraction of other types of smooth muscle, including cerebral arteries, coronary artery, and pulmonary vasculature.^{124–126} Recently, the increase in intracellular Ca^{2+} concentrations induced by either membrane depolarization or receptor stimulation has been shown to activate the RhoA/Rho-kinase pathway in vascular smooth muscle and thus contribute to the regulation of Ca^{2+} sensitivity.^{106–109} However, the upstream signaling pathways that regulate the mechanism of Ca^{2+} -mediated activation of RhoA and the identification of the GEF involved, if any, still remain largely unidentified.

As illustrated previously, several studies have helped to clarify the biochemical basis for the regulation of MLC₂₀ phosphorylation and dephosphorylation, which coordinate the degree of contraction in the vascular smooth muscle. The involvement of the RhoA/Rho-kinase signaling pathway in the regulation of the Ca^{2+} sensitivity, and to a certain extent of Ca^{2+} handling, is at present evident. However, the intracellular signal transduction that connects the contractile stimulation to such molecular networks regulating the Ca^{2+} sensitivity has yet to be revealed. Hence, even though several reports have discussed the involvement of the RhoA/Rho-kinase pathway in the regulation of the vascular tone and Ca^{2+} sensitivity it remains to be elucidated as to how this pathway is activated by the contractile stimuli that cause Ca^{2+} sensitization.

REGULATION OF THE RHOA/RHO-KINASE PATHWAY BY NO

Relaxation of vascular smooth muscle results from a decrease in cytosolic Ca^{2+} concentration and/or reduced Ca^{2+} sensitivity of the contractile apparatus. Physiologically released

Figure 16–2. Ca^{2+} -dependent and -independent pathways in vascular smooth muscle. Stimulation of G-protein-coupled receptors (GPCR) leads to stimulation of phospholipase C (PLC), which catalyzes the formation of inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 activates receptors located on the sarcoplasmic reticulum (SR), causing Ca^{2+} release and subsequent increases in intracellular Ca^{2+} concentration. Following binding to calmodulin (CaM), the Ca^{2+} /CaM complex stimulates the myosin light-chain kinase (MLCK), which phosphorylates the myosin light chain (MLC₂₀) and results in smooth muscle contraction. Opening of L-type Ca^{2+} channels due to membrane depolarization also causes intracellular Ca^{2+} to increase and elicit contraction. After activation by DAG, protein kinase C (PKC) phosphorylates the PKC-potentiated inhibitor protein of 17 kDa (CPI-17), which decreases myosin phosphatase (MLCP) activity through phosphorylation. Activation of GPCR also stimulates RhoA activity, secondary to the stimulation of a Rho guanine nucleotide exchange factors (GEFs). The activated RhoA stimulates Rho-kinase, which in turn phosphorylates the myosin binding subunit of MLCP—leading to increased MLC₂₀ phosphorylation in a Ca^{2+} -independent manner. This process is hence referred to as Ca^{2+} sensitization.

endothelium-derived nitric oxide (NO) elevates cGMP, the second messenger responsible for relaxation of vascular smooth muscle and subsequently enlargement of the vessel lumen.¹²⁷ Cyclic GMP-induced relaxation involves activation of the cGMP-dependent protein kinase (cGK). The potent vasodilator action of the NO/cGMP pathway has been ascribed to a decrease in cytosolic Ca^{2+} through activation of multiple mechanisms, which might involve reduced IP_3 synthesis, inhibition of Ca^{2+} release from IP_3 -sensitive stores, or phosphorylation of Ca^{2+} and K^+ channels.¹²⁸ In addition, the NO/cGMP signaling pathway has been demonstrated to phosphorylate recombinant RhoA via cGK at Ser188,⁶⁶ which results in inhibition of RhoA-induced stress fiber formation. In addition, the NO donor sodium nitroprusside and constitutively active cGK

were shown to inhibit the phenylephrine-induced translocation of RhoA from the cytosolic to the membrane fraction in rat aorta, indicating that the NO/cGMP pathway mediates inactivation of RhoA.⁶⁶ Indeed, endogenous NO-induced vasorelaxation has also been demonstrated to be mediated in part by inhibition of RhoA/Rho-kinase signaling in rat aorta and celiac artery.^{122,129} Another study demonstrated that NOS inhibition in intact rats enhances α_2 -adrenoreceptor-stimulated RhoA/Rho-kinase in isolated aortic segments. Acute and chronic NOS inhibition augmented sensitivity to Y-27632-induced relaxation in α_2 -adrenoreceptor-constricted aorta, supporting the concept that the inhibitory effect of NO on RhoA/Rho-kinase signaling is less active in chronic NOS-inhibited hypertensive aorta.¹³⁰

RHOA/RHO-KINASE SIGNALING IN CARDIOVASCULAR DISEASES

The contractile state of vascular smooth muscle controls the vessel lumen size, and an abnormal increase in vascular smooth muscle tone is involved in the pathogenesis of vascular diseases. Consequently, a better understanding of the molecular mechanism regulating vascular tone is crucial to establish new strategies for the prevention and management of vascular diseases, such as hypertension and atherosclerosis. Increased vascular resistance is centrally involved in the pathogenesis of hypertension, but the molecular mechanisms leading to increased resistance are not well defined. Alteration of RhoA/Rho-kinase-mediated regulation of vascular tone has attracted considerable attention because it emerges as a potential cause of increased vascular resistance. For that purpose, pathological as well as physiological roles of Rho-kinase have been evaluated using the aforementioned Rho-kinase inhibitors.²¹

Hypertension

In spontaneously hypertensive rats (SHRs), agonist-induced Ca^{2+} sensitization was found to be enhanced, and both expression and activity of Rho-kinase are elevated even before the development of hypertension.¹³¹ Administration of Y-27632 preferentially reduced systemic blood pressure in various rat models of systemic hypertension irrespective of the mechanisms of hypertension.¹⁰⁴ On the other hand, comparable doses of Y-27632 did not significantly affect blood pressure in normotensive animals, suggesting that the RhoA/Rho-kinase pathway is substantially involved in the pathogenesis of hypertension. Application of Rho-kinase inhibitors or dominant-negative Rho-kinase into the nucleus tractus solitarius causes sustained decrease in heart rate and blood pressure in SHRs but not in normotensive Wistar-Kyoto (WKY) rats, suggesting that Rho-kinase may also be involved in the regulation of the central mechanisms of hypertension.⁹³

The precise mechanisms for the activation of the RhoA-Rho-kinase signaling pathway in vascular smooth muscle in hypertensive models have not been fully determined. In this regard, molecular and functional studies have addressed the contribution of the RhoA-Rho-kinase signaling pathway in vascular smooth muscle cells as well as in ring segments obtained from hypertensive animals. The finding that Y-27632-induced dilation of the basilar artery *in vivo* is enhanced during chronic hypertension provided evidence that basal Rho-kinase activity may be enhanced in the cerebral circulation in this disease.¹³² Interestingly, angiotensin II has been recently shown to elicit constriction of isolated basilar arteries via Rho-kinase signaling, an effect that may be enhanced during chronic hypertension.¹³³ Conversely, no apparent role for RhoA or Rho-kinase has been demonstrated in altered carotid artery contractility observed during chronic angiotensin-II-induced hypertension,¹³⁴ reflecting signaling differences between vascular beds. RhoA activation is usually detected in the aortae of various hypertensive rat models—namely, stroke-prone spontaneously hypertensive rats (SHRSP), L-NAME-treated rats, renal hypertensive rats, and DOCA-salt rats—where

it is not in normotensive controls.^{135,136} The increased levels of active RhoA could be ascribed to either a shift in the balance of GDP-RhoA/GTP-RhoA or to increased expression of RhoA in the hypertensive state. For example, both the activation of RhoA and the resultant phosphorylation of MBS at Thr696 by Rho-kinase were enhanced when compared to WKY in aortic smooth muscle cells isolated from SHRSP,¹³⁶ suggesting an increased activity of this pathway in this hypertensive model.

Although some reports have shown increased expression and activation of RhoA and the upregulation of Rho-kinase RNA, others have detected no significant differences in the expression of the molecular components of this pathway.^{135,136} It is likely that alterations in the RhoA-Rho-kinase pathway could be consequential to a causative upstream event in the hypertensive state. In this scenario, the demonstration of increased mRNA expression of the three RGS-containing RhoGEFs (PDZ-RhoGEF, LARG, and p115RhoGEF) in the aortas from 12-week-old SHRSP (REFS), in a stage where mean systolic blood pressure was higher (187 ± 5 mmHg) when compared to normotensive WKY rats (126 ± 2 mmHg), suggests that the activation of RhoA is a consequence rather than a cause of hypertension.¹³⁷

Intra-arterial administration of fasudil induced marked vasodilator responses of the forearm circulation (along with a decrease in vascular resistance) in hypertensive patients compared with normotensive control subjects, whereas those in response to sodium nitroprusside were similar between the two groups.¹³⁸ This suggests that Rho-kinase is also implicated in the increased peripheral vascular resistance observed in human hypertension. It remains to be elucidated whether long-term inhibition of Rho-kinase also alleviates hypertensive vascular disease or cardiac hypertrophy in humans.

Coronary vasospasm

Coronary vasospasm plays an important role in a wide variety of ischemic heart diseases, not only in variant angina but in other forms of angina pectoris, myocardial infarction, and sudden death.¹³⁹ Experimental studies using a porcine model of coronary vasospasm have demonstrated evidence for an involvement of Rho-kinase in this disorder, whereby both arterial spasm and the associated increase in MBS phosphorylation are sensitive to Y-27632.⁸⁴ Furthermore, increased Rho-kinase mRNA expression is localized to the spastic site of the artery. Gene transfer of dominant-negative Rho-kinase has also been found to abolish coronary vasospasm, as well as to decrease the phosphorylation levels of ERM proteins (which are known downstream targets of Rho-kinase).¹¹⁵ In addition, direct PKC activation has been shown to induce coronary spasm, which was attenuated by hydroxyfasudil and associated with increased levels of membrane-bound RhoA.¹⁴⁰ This was the first study to suggest an interaction between PKC and RhoA/Rho-kinase in coronary artery spasm, with RhoA/Rho-kinase presumably located downstream of PKC in the signaling pathway. Thus, Rho-kinase may represent a more specific and therefore preferable target for the treatment of coronary vasospasm.

In other studies, long-term treatment with a nonhypotensive dose of fasudil significantly suppressed coronary vascular lesion formation in SHR^s,¹⁴¹ strongly indicating that Rho-kinase is also involved in the pathogenesis of hypertensive vascular disease (which is distinct from that of systemic hypertension). The therapeutic effects of fasudil were also studied in a rat model with long-term infusion of angiotensin II, which is also characterized by hypertension and coronary vascular lesions. Similarly, fasudil significantly suppressed the coronary vascular lesion formation and improved the endothelial vasodilator function along with a decrease in the endothelial production of superoxide anions.¹¹²

In patients with vasospastic angina pectoris, intracoronary fasudil markedly inhibited acetylcholine-induced coronary spasm as well as the related myocardial ischemia, suggesting that Rho-kinase is largely involved in the pathogenesis of coronary spasm in humans.¹⁴² In addition, fasudil is effective in treating patients with microvascular angina, indicating an involvement of Rho-kinase-mediated hyper-reactivity of coronary microvessels.¹⁴³ Clinical trials on the antianginal effects of fasudil in patients with stable effort angina have demonstrated that the long-term oral treatment with the Rho-kinase inhibitor is effective in ameliorating exercise tolerance in patients with adequate safety profiles.¹⁴⁴ Furthermore, fasudil is useful for the treatment of intractable coronary spasm resistant to maximal vasodilator therapy with calcium channel blockers and nitrates after coronary artery bypass surgery.¹⁴⁵

Cerebral vasospasm

Cerebral vasospasm is a potentially fatal complication that can occur when major cerebral arteries are exposed to clotted blood following subarachnoid hemorrhage (SAH). The involvement of Rho-kinase in cerebral vasospasm was first demonstrated in a canine model of SAH where spasm and associated enhanced phosphorylation of both MLC and MBS in the basilar artery were inhibited by Y-27632.¹⁴⁶ Increased expression of both RhoA and Rho-kinase mRNA have also been detected in rat basilar artery following SAH,¹⁴⁷ which may account for the apparent enhanced activity of this pathway during SAH. More recently, increased phosphorylation of MLC phosphatase was reported in basilar arteries of rabbits after SAH—and increased vasoconstriction to serotonin was found to be markedly reduced by fasudil¹⁴⁸—suggesting that augmented Rho-kinase activity contributes to the exaggerated cerebral artery contractility following SAH.

Oxyhemoglobin is a central candidate as a mediator of cerebral vasospasm after SAH, in that it is a constrictor released during clot lysis. Y-27632, fasudil, and the PKC inhibitor Ro-32-0432 have been reported to relax rabbit basilar arteries precontracted with oxyhemoglobin. In addition, oxyhemoglobin also induces the translocation of RhoA (as well as PKC α and PKC ϵ) in cultured cerebrovascular smooth muscle cells and intact basilar arteries.¹⁴⁹ Taken together, these observations support the notion that oxyhemoglobin may elicit cerebral artery spasm through the activation of both the RhoA/Rho-kinase and the PKC signaling pathways.¹⁵⁰

Atherosclerosis

Atherosclerosis is characterized by vascular abnormalities including endothelial dysfunction, poor availability of NO, and inflammation. The first evidence for a link between RhoA/Rho-kinase signaling and regulation of NO production was the observation that RhoA can negatively regulate endothelial NO synthase (eNOS) mRNA expression in cultured human endothelial cells.¹⁵¹ More recent studies have demonstrated that Rho-kinase may contribute to the regulation of the expression of plasminogen activator inhibitor-1 (PAI-1), whose increased production is thought to contribute to the development of atherosclerosis. For example, Y-27632 and dominant-negative Rho-kinase have both been shown to prevent angiotensin-II-induced increases in PAI-1 mRNA expression.^{152,153} In addition, chronic administration of Y-27632 decreases atherosclerotic plaque size and inflammatory cell accumulation within atherosclerotic plaques in mice,¹⁵⁴ providing the first direct link between Rho-kinase and atherosclerotic lesion formation.

A recent report showed that thrombin stimulation of endothelial cells can lead to increased arginase activity, which in turn competes with eNOS for the substrate L-arginine and limiting NO production. Inhibition of RhoA or Rho-kinase has been reported to prevent the thrombin-evoked increases in arginase activity, whereas constitutively active RhoA or Rho-kinase could enhance enzyme activity.¹⁵⁵ Higher RhoA expression and arginase activity were also found in atherosclerotic aortae of apoE-deficient mice, thus introducing the concept that by increasing arginase activity the RhoA/Rho-kinase signaling pathway may suppress NO production and lead to endothelial dysfunction and atherosclerosis. Another mechanism linking RhoA/Rho-kinase to vascular NO production is the inhibition of endothelial Rho-kinase that increases phosphatidylinositol 3-kinase (PI3K) activity and phosphorylated Akt, resulting in enhanced NO production.^{156,157} These findings raise the possibility that Rho-kinase may tonically inhibit PI3K activity in the endothelium and the consequent NO production.

Both *in vivo* gene transfer of dominant-negative Rho-kinase¹⁵⁸ and long-term treatment with a Rho-kinase inhibitor^{159,160} have also been shown to suppress balloon-injury-induced neointimal formation in animals *in vivo*. Long-term treatment with MCP-1 and oxidized low-density lipoproteins (ox-LDL) causes vascular lesions characterized by neointimal formation and constrictive remodeling in porcine coronary arteries *in vivo*. Long-term oral treatment with fasudil significantly suppressed this vascular lesion formation, caused at least in part by the inhibition of macrophage migration *in vivo*.¹⁶¹

Pulmonary hypertension

Primary pulmonary arterial hypertension is a fatal disease characterized by endothelial dysfunction, vascular smooth muscle cell hypercontraction and proliferation, and inflammatory cell migration, in which Rho-kinase may also be substantially involved. Long-term treatment with fasudil suppresses the development of monocrotaline-induced pulmonary hypertension in rats when started simulta-

neously with (and even induces a marked regression when started after) establishment of pulmonary hypertension.¹⁶² Inhalation of fasudil may also be effective in reducing pulmonary vascular resistance in animal models of pulmonary hypertension with various etiologies.¹⁶³ Because prostacyclin lacks inhibitory effects on Rho-kinase, a combination therapy with prostacyclin and a Rho-kinase inhibitor may provide a useful therapeutic strategy for this fatal disorder.¹⁶⁴ Intravenous infusion of fasudil significantly reduces pulmonary vascular resistance in patients with pulmonary hypertension, indicating an involvement of Rho-kinase pathway in the pathogenesis of pulmonary hypertension in humans.¹⁶⁵

Stroke

In a rat model of stroke (lacunar infarction) caused by pharmacological damage of endothelial cells and subsequent thrombotic occlusion, intraperitoneal administration of fasudil shortly after the endothelial damage reduces cerebral infarct size and resultant neurological deficit.¹⁶⁶ In a rat model of microembolization stroke, intravenous administration of hydroxyfasudil prevents neutrophil accumulation, reduces cerebral infarct size, and improves neurological functions,¹⁶⁷ suggesting the efficacy of fasudil/hydroxyfasudil for the treatment of ischemic brain damage. A clinical trial with an intravenous form of fasudil in the acute phase of stroke demonstrates that the Rho-kinase inhibitor exerts beneficial effects on ischemic neuronal damage without serious adverse effects.¹⁶⁸

Heart failure

In a dog model of tachypacing-induced heart failure, the Ca^{2+} -sensitizing mechanism of conduit artery (femoral artery) is augmented, resulting in the enhanced vasoconstrictor response to norepinephrine. Treatment with Y-27632 attenuates this response without a significant change in intracellular Ca^{2+} concentrations in the vascular smooth muscle cells, suggesting an involvement of the RhoA/Rho-kinase pathway in the increased vasoconstrictor response in heart failure.¹⁶⁹ In patients with heart failure, intra-arterial infusion of fasudil causes a preferential increase in forearm blood flow compared with control subjects, suggesting an involvement of the Rho-kinase pathway in the increased peripheral vascular resistance in heart failure in humans.¹⁷⁰

RHO-KINASE INHIBITORS FOR THE TREATMENT OF CARDIOVASCULAR DISEASE

Small molecule inhibitors are extremely useful for dissecting complex cellular events that require that coordination and regulation of many proteins. By inhibiting a specific component of a biochemical network, one can deduce its function in the process. Following G-protein-coupled receptors, protein kinases have become the second most important class of targets for drug discovery over the last 20 years. Although only four kinase inhibitors have reached the market to date (Fasudil for Rho-kinase,

Rapamycin for TOR, Gleevec for BCR-Abl, and Iressa for EGFR), many more are already in clinical development.

Fasudil was approved in 1995 for the treatment of cerebral vasospasm, a painful and potentially deadly result of subarachnoid hemorrhage. This drug has significant vasodilatory activity¹⁷¹ and is currently undergoing clinical trials for the treatment of angina pectoris.¹⁴⁴ Fasudil has a heptameric homopiperazine ring at the position of the methyl-piperazine ring of H7, and further derivitization of fasudil led to H-1152—with two additional methyl groups, one at the isoquinoline ring and the other at the homopiperazine ring. H-1152 has a better inhibitory profile than fasudil and Y-27632, with an IC_{50} value for Rho-kinase in the low nanomolar range and a reportedly enhanced selectivity (Figure 16–3).¹¹³

The common feature of all protein kinases is the ATP binding at highly conserved binding interactions at the ATP binding site. The prevalence of cardiovascular diseases associated with Rho-kinase dysregulation underscores the need for therapeutic Rho-kinase inhibitors, with the caveat that they must be highly selective for their dysregulated targets to avoid inhibition of other ubiquitous kinases—in that most protein kinase inhibitors are ATP competitive and as such should be tested rigorously for cross-reactivity with other kinases. The effects of fasudil are attributed to

Figure 16–3. Structures of Rho-kinase inhibitors.

Several inhibitors with a relatively high degree of specificity toward Rho-kinase have been developed over the past few years. The most widely used is Y-27632, which inhibits agonist-induced contraction of vascular smooth muscle and shows efficacy in normalizing high blood pressure in different rat models of hypertension. This is therefore a potential therapeutic drug. This drug was originally reported to inhibit the two isoforms of Rho-kinase, and to exert its antihypertensive effect by preventing Rho-kinase from inhibiting myosin phosphatase. Such an effect causes a decrease in MLC20 phosphorylation and vascular smooth muscle relaxation, and hence dilation of blood vessels. The compound HA-1077, also known as fasudil hydrochloride, shows efficacy for the treatment of cerebral vasospasm and causes vasodilation of the forearm circulation in hypertensive patients. H-1152 is a parent molecule of the latter compound and is a novel inhibitor showing higher selectivity and potency in inhibiting Rho-kinase.

inhibition of Rho-kinase,⁷⁹ although its *in vitro* activity is not strictly limited to Rho-kinase because other protein kinases (such as PKA, PRK2, MSK1, and S6K1) are also inhibited by fasudil, although to a lesser extent.¹⁷² Likewise, Y-27632 and the close molecule Y-32885 inhibit PRK2 and Rho-kinase at similar concentrations.¹⁷²

Recently, a large number of structurally unrelated scaffolds of Rho-kinase inhibitors have been designed using pharmacophore information obtained from the results of high-throughput screening and structural information from a homology model of Rho-kinase. Consequently, potent platforms for developing Rho-kinase inhibitors (such as pyridine, 1H-indazole, isoquinoline, and phthalimide) were identified using a docking simulation based on the ligand-binding pocket of Rho-kinase. Thus, potent and selective Rho-kinase inhibitors were obtained with little cross-reactivity against other kinases, such as MAP kinase, PKA, PKC, and some receptor tyrosine kinases.¹⁷³

The development of cell-permeant Rho-kinase inhibitors has great advantages for the study of signaling transduction, in that they can be rapidly used to assess the physiological roles of Rho-kinase in cells and tissues. Inhibition of the endogenous enzyme avoids the need for overexpression of dominant-negative and constitutively active Rho-kinase, which can cause the specificity of signaling to lead to erroneous conclusions. Although fasudil is the only clinically available Rho-kinase inhibitor at present with minimal adverse effects so far, careful development of more selective and potent Rho-kinase inhibitors is needed because clinical studies suggest that Rho-kinase inhibition may be useful for the treatment of a wide spectrum of cardiovascular diseases—including angina pectoris, hypertension, and heart failure. Therefore, the availability of potent and selective Rho-kinase inhibitors is extremely useful in helping to delineate their pharmacological profile, safety, and therapeutic potential in the treatment of cardiovascular disorders.

PERSPECTIVES

Much has been learned in the past several years about the involvement of the RhoA/Rho-kinase pathway in a variety of cardiovascular diseases, although many aspects of

signaling upstream and downstream of this pathway remain unclear. In various animal models, Rho-kinase inhibitors can be used to treat these diseases. These findings make the RhoA/Rho-kinase-mediated signaling pathway a promising new target for therapeutic interventions in diseases as common as hypertension. The near future will probably bring an increasing number of clinical trials to evaluate new strategies aiming at the inhibition of RhoA/Rho-kinase pathway with Rho-kinase inhibitors or gene-therapeutic approaches. It remains unclear whether the disorders associated with the RhoA/Rho-kinase pathway observed in animal models are indeed applicable to human patients. Studies aiming to elucidate the role of Rho-kinase in the pathogenesis of cardiovascular diseases have already been started, and more studies are needed to confirm the potential therapeutic importance and clinical usefulness of Rho-kinase inhibitors. Nevertheless, Rho-kinase is widely expressed in the organism and although the clinical trials with fasudil demonstrated its efficacy and safety profile in humans this should be interpreted with cautious optimism. RhoGEFs receive the upstream signals that trigger the various signal transduction cascades that involve small GTP-binding proteins. Therefore, the ability to block them specifically could be useful as a therapeutic intervention for the treatment of hypertension. The suitability of this family of RGS-containing RhoGEFs as therapeutic targets represents a daunting task, basically due to the limited knowledge about their role in physiologic and pathophysiologic processes in the cardiovascular system. Further, the mechanisms of regulation and the cellular contexts within which they act still need to be elucidated. How each RhoGEF interacts with RhoA in a tightly regulated manner poses the major challenge of this field. The revelation of the nature of this interaction may then provide the basic framework for developing novel therapeutic strategies for treating hypertension.

Matrix Metalloproteinases and the Extracellular Matrix

Muzahir H. Tayebjee and Gregory Y. H. Lip

Key Findings

- The extracellular matrix (ECM) has structural and functional roles.
- In hypertension, changes in the cardiac and vascular ECM are manifested, for example, as left ventricular hypertrophy.
- Matrix metalloproteinases (MMPs) and their inhibitors, tissue inhibitors of matrix metalloproteinases (TIMPs), have key roles in modulating the structure and function of ECM.
- In hypertension, the assessment of circulating MMP and TIMP may be useful noninvasive markers of tissue structure and function and provide prognostic information.

The extracellular matrix (ECM) is the connecting tissue that surrounds the cellular elements of solid organs. Like tissue cement, it forms a substrate to hold cells together. The ECM is also a dynamic structure that is integral to organ function. Apart from providing structural support, the ECM is fundamental to cell-cell signaling.

The ECM is composed of structural proteins (collagen and elastin), specialized proteins (e.g., fibrillin and fibronectin), and proteoglycans. Within this complex network are signal receptor proteins and enzymes that control the turnover of this highly complex system. The ECM, although ubiquitous, has variable composition in different organs. Various factors can affect the structure of ECM, including stretch and pressure, inflammation, perfusion or ischemia, and prevailing growth factors. In disease states, the changes in ECM can be important in organ repair but also detrimental. For example, a growing body of evidence suggests that the composition of cardiac ECM changes as hypertension progresses.

Matrix metalloproteinases (MMPs) and their endogenous inhibitors, tissue inhibitors of metalloproteinases (TIMPs), are ubiquitous to ECM and are thought to play a major role in ECM remodeling. Indeed, there is growing evidence that these compounds are involved in tissue turnover in normal physiology as well as in pathology (e.g., as seen in the cardiac fibrosis associated with hypertensive left ventricular hypertrophy).

The study of MMPs and TIMPs is important because they could have potential diagnostic and therapeutic value. This might allow identification of groups of patients where matrix turnover is damaging the heart or vascular response

to injury. Furthermore, understanding the mechanisms of these responses might allow the development of novel pharmacological agents alone or in combination with other treatment to prevent deterioration in heart and vascular function—seen, for example, in end-stage heart failure.

ANATOMY/BIOCHEMISTRY

There are more than 20 identified MMPs important in the ECM, and they have been classified according to their substrate specificity [i.e., collagenases, gelatinases, stromelysins, matrilysin, macropage elastase, and membrane-type MMP (MT-MMP)]. Each enzyme has also been given a numerical classification. For example, interstitial collagenase is MMP-1. This numerical classification scheme is used in this text.¹

Each MMP is made up of a propeptide active site and a zinc-binding domain. To activate the enzyme, the propeptide must be cleaved to allow water to bind to zinc (Figure 17–1). Apart from MMP-7, all other MMPs contain a carboxyterminal hemopexin (PEX) domain. Calcium occupies a “hole” within this site. It is this site that determines the enzyme interactions. For example, this site is important for the interaction of TIMP-1 with MMP-9. Various other domains also exist. For example, fibronectin repeats in MMP-2 and MMP-9, which bind gelatin.² Nevertheless, it should be noted that the enzymes responsible for forming ECM precursors are located intracellularly, and post-translational modification occurs within the ECM (e.g., cleavage of the amino terminal of procollagen by procollagen N proteinase).

The composition of ECM at any given time is dependent on the balance between the rate of formation and breakdown. The regulation of ECM components is controlled at the transcriptional level and is mediated by growth factors such as human growth hormone and platelet-derived growth factor. The main control systems of current interest are in the regulation of the key structural MMPs.

The MMP activity associated with ECM turnover can be effected at the transcriptional level, where local cytokine production (TNF α or decorin) can regulate synthesis of both MMP and TIMP. The peptide is produced as an inactive proenzyme, and constant background expression occurs at a low level over and above which many of the MMP series are induced during pathological processes. Metalloproteinases are generally not stored in large quantities, and need to be actively transcribed for activity. However, neutrophils during the inflammatory response are unique

Figure 17-1. The 3D structure of MMP-1. (From Van den Steen PE, Opdenakker G, Wormald MR, et al. Matrix remodelling enzymes, the protease cascade and glycosylation. *Biochimica et Biophysica Acta* 2001;1528:61–73, with permission.)

in that they do manufacture, store, and quickly release MMPs. Control over MMP activity can also be exerted at the post-translational (zymogens and inhibitory enzyme) level. In molecular terms, the enzyme activity can be modulated by a cysteine switch mechanism whereby the MMP is folded by the binding of cysteine via a disulphide bond to the zinc molecule in the active site, which prevents access to the enzyme active site. *In vitro* treatments such as proteolysis, heat, or alkylation allow a change in its conformation to facilitate analysis of the total fraction of enzymatic activity.³

There is a substantial body of evidence that ECM turnover is regulated by the renin-angiotensin-aldosterone system, which in turn regulates MMPs and TIMPs. Tissue culture experiments using rat fibroblasts have shown that

collagen synthesis is stimulated by angiotensin II (in high concentrations) and aldosterone when added to the culture medium. This increased synthesis could be inhibited by adding specific aldosterone and angiotensin II receptor antagonists. Angiotensin II has been found to stimulate collagen synthesis and regulate collagen degradation by increasing the concentration of TIMP-1 and hence attenuating endothelial cell interstitial MMP-1 activity. The balance between MMP-1 and TIMP-1 is thought to be important in the pathology of hypertensive heart and vascular disease.⁴

Growth factors and cytokines have also been closely implicated in the regulation of MMP/TIMP function and synthesis. Tumor necrosis factor alpha (TNF α), a pro-inflammatory and immunoregulatory cytokine, regulates (and in turn can be regulated by) TIMPs and MMPs. The exact nature of the control system is yet to be determined, but TIMPs prevent post-translational activation of TNF α . Moreover, anti-TNF α therapy seems to be associated with a reduction in serum MMP-1 and MMP-3. Similarly, platelet-derived growth factor (PDGF) and interleukin-1 (IL-1) both stimulate MMP synthesis. Conversely, transforming growth factor beta (TGF β), heparin, corticosteroids, TIMP-1 (inducible by cytokines), TIMP-2 (mainly constitutive), and TIMP-3 inhibit MMP synthesis and activity. Metalloproteinases may also play a role in regulating cytokine activity. For example, MMP-9 can activate IL-1 β , and MMP-3 is able to degrade activated IL-1 β .⁵

Given the important role of the tissue-blood interface in the process of vascular function and clotting, it is of considerable importance that components of the clotting cascade affect the post-translational activity of MMPs. Indeed, plasmin is a potent activator of most MMPs, and can cleave precursor MMP propeptides to the active molecules. Human urokinase-type plasminogen activator (uPA) and uPA receptors are expressed by monocytes and macrophages and can activate MMPs. Because macrophages accumulate at “sites of inflammation,” this localized presentation of MMP activators results in localized proteolytic activity (e.g., at leading edges of cells). MMP-3 can cleave plasmin, which can activate even more MMP-3 and thus result in positive feedback mechanisms that amplify enzyme activity in a manner similar to that of the clotting cascade (as well as interacting with it). Furthermore, thrombin has been shown to result in the activation of active MMP-2. This can occur either directly by increasing the catalysis of pro-MMP-2 or indirectly by increasing the expression of MT-1 MMP, and by speeding the intracellular transit of this enzyme to the cell surface (where MT1-MMP proceeds to activate transcribed MMP-2).³

Using human umbilical vein endothelial cells and abdominal aorta endothelial cell tissue culture, it has been suggested that oxidized low-density lipoprotein can induce the expression of MMP-1 and reduce the synthesis of TIMP-1, therefore favoring collagen degradation. This is a key interaction because it may be one of the mechanisms leading to plaque progression and instability. Raised serum ox-LDL has been associated with increased circulating

MMP-9 levels in patients with increased generalized cardiovascular risk factors and appears to play a supporting role for MMPs as a means by which lipoproteins interact in atherosclerotic plaque pathology.⁶

Finally, these enzymes also have effects on the cell cycle. MMP-7 can cleave the Fas ligand to produce soluble FasL, which is able to induce apoptosis. Moreover, using rat smooth muscle tissue culture techniques and transfecting cells with TIMP-1, -2, and -3 it was found that TIMP-1 did not affect cell proliferation but TIMP-2 overexpression caused a dose-dependent reduction in proliferation, and overexpression of TIMP-3 actually increased apoptosis.⁷

GENETICS

This is a relatively new area in MMP and TIMP biology. There is little clinically relevant information about this topic, which is covered in the next section.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Hypertension has a major impact on the circulation, and hence on many organ systems. For example, the development of LVH and diastolic and systolic heart failure, myocardial infarction, and stroke occur along with increasing atherosclerosis and renal failure because of the effect of raised blood pressure on the microcirculation. Most of these changes relate to altered structure of the ECM, and because of this it is likely that MMPs and TIMPs are involved in this process.

To date, the majority of studies have focused on changes in collagen turnover (the predominant cardiovascular ECM protein) and cardiac structure that can occur in hypertension and on how MMPs and TIMPs may have a role in this process. In particular, there is increased deposition of collagen, a change in the ratio of collagen subtype, and differential cross linking. The synthesis and breakdown of collagen leads to the production of end peptides; for example, carboxy-terminal propeptide of procollagen type I (PCIP) (a marker of collagen type I synthesis). These fragments are released into tissue and the systemic circulation and can be measured by radioimmunoassay. Circulating peptides are reliable surrogates of ECM turnover and have an established role in clinical medicine. In animal experimental models of hypertension, these markers can be used to assess ECM turnover in tissue extracts. Indeed, the serum PCIP is increased in spontaneously hypertensive rats, mirroring quantitative increases in type I collagen in the myocardium when compared with normotensive Wistar-Kyoto rats.⁸ These results therefore demonstrate altered collagen turnover in hypertension and possibly contribute to an increase in myocardial stiffness. Cell culture studies of myocardial fibroblasts from genetically hypertensive rats have also indicated that these fibroblasts play an important role in fibrosis by producing increased amounts of types I and III collagen.⁹

What role could MMPs and TIMPs play in abnormal ECM turnover in hypertension? In hypertensive salt-

sensitive rats, TIMP-2, TIMP-4, and MMP-2 expression is increased in the myocardium—particularly at the time when LVH progresses to left ventricular dilatation and failure.¹⁰ The activity of MMP-2 appears to be increased during the development of LVH before heart failure develops in untreated hypertensive rats, although other MMPs may have roles as well. Furthermore, it is thought that MMP-2 may also be involved in facilitating muscle growth by digesting surrounding ECM (in that the tensile strength of cardiac muscle is reduced by incubating myocytes with excess MMP-2) and that this effect is reversed by anti-MMP-2 antibody and TIMP.¹¹ Although there is controversy as to the timescale of MMP-2 activation, it is clear that MMP-2 is important in the progression of LVH to ventricular dilatation and the emergence of heart failure—an effect it probably mediates by reducing matrix binding. Although MMP-2 has been highlighted, it is more than likely that other MMPs and TIMPs are involved in this process.

Animal studies have postulated a role for MMPs and TIMPs in abnormal ECM turnover. However, it is generally accepted that results obtained from experimental animal models cannot be extrapolated directly to humans. Indeed, the etiology of human hypertension is multifactorial and takes time to develop. Animal studies, on the other hand, often rely on surgical, severe dietetic, or genetic manipulation to cause hypertension. Furthermore, obtaining tissue samples from humans is difficult (and often impossible) for ethical reasons. Therefore, much of the evidence about the importance of MMPs and TIMPs in humans has come from plasma and serum analysis together with noninvasive tissue assessment. Fortunately, there are similarities between results obtained in animal experiments and humans, allowing inferences on pathophysiology to be made. Because these are more relevant clinically, they are focused on here.

Work from our laboratory and others have demonstrated an increase in circulating MMP-9 and TIMP-1 in hypertension but a reduction in MMP-1 compared with healthy human controls. These changes were associated with an increase in levels of plasma PCIP and carboxy-terminal telopeptide of type I collagen (CITP) (marker of collagen degradation), which constitutes indirect evidence that MMPs and TIMPs could be implicated in abnormal ECM turnover in hypertension. A crucial question is what abnormal ECM turnover occurs in hypertension? Hypertension is a systemic disease and affects many major organs (in particular, the arterial tree and the heart), and circulating MMPs and TIMPs could therefore originate from many places in the body. The clinical value of measuring circulating MMPs and TIMPs relies on knowledge of their origin, but as discussed previously human tissue studies are difficult and other indirect methods are required in locating the source.⁴

Recently, there have been several studies using echocardiography as a noninvasive assessment of cardiac structure and function to demonstrate a link between abnormalities in ECM and MMPs and TIMPs in hypertension. Echocardiography can give an estimate of left ventricular mass, and Doppler imaging allows the study

of blood flow patterns within the heart. Tissue Doppler imaging in particular has played an important role in characterizing diastolic dysfunction. This modality offers better assessment of left ventricular relaxation during diastole as compared to transmitral flow assessment because e' (which represents early left ventricular relaxation) decreases progressively as disease advances but E (passive ventricular filling as measured by standard Doppler assessment) decreases and then pseudonormalizes and becomes higher than normal as disease advances.

Tissue inhibitor of metalloproteinase-1, which is raised in patients with hypertension, is associated with several abnormal echocardiographic parameters. Circulating TIMP-1 correlates positively with left ventricular mass (E/e') and negatively with e' (Figure 17–2). Furthermore, a strong link was seen between a TIMP-1 value of >500 ng/mL and reversal of the Doppler E/A ratio of transmitral flow. These findings, although not directly from cardiac tissue, are interesting because they do suggest a role for TIMP-1. Collagen type 1 is a principal determinant cardiac ECM and is therefore a major determinant of left ventricular compliance. Collagen type I is composed of thick strands, imparting strength and rigidity to the ECM. However, excess type I collagen will result in loss of ventricular compliance and elasticity. Hence, passive left ventricular filling in diastole is reduced, as the ventricle is less compliant. Tissue inhibitor of metalloproteinase-

1 is thought to increase tissue concentrations of collagen type I by inhibiting MMPs. Therefore, TIMP-1 may be a key mediator of left ventricular diastolic dysfunction through definition of the ventricular matrix composition and may have a role in the development of symptomatic diastolic heart failure.^{12,13}

Of note, there is an interesting link between MMP-1 and TIMP-1. In patients with untreated hypertension, serum CITP and MMP-1 decrease and levels of TIMP-1 rise. In the presence of LVH, MMP-1 and CITP levels are lower and predictably TIMP-1 levels are higher. Following a year's treatment with angiotensin-converting enzyme therapy, levels of CITP and MMP-1 increased but levels of TIMP-1 decreased. Collagen type 1 is a major substrate for MMP-1, and is degraded by MMP-1. Therefore, it is not surprising that there is an inverse relationship between TIMP-1 and MMP-1, and modulation of either may have potential clinical benefit⁴ (Figure 17–3).

Left ventricular hypertrophy is not an ideal prognostic marker in hypertension. Although echocardiography is a simple technique, it requires time and expertise to perform. The resting ECG is not sensitive enough. Because there is a relationship between TIMP-1 and left ventricular structure it is plausible that measurement of circulating TIMP-1 could be used to track LVH over a period of time, and may provide prognostically useful information. Although appealing, carefully conducted

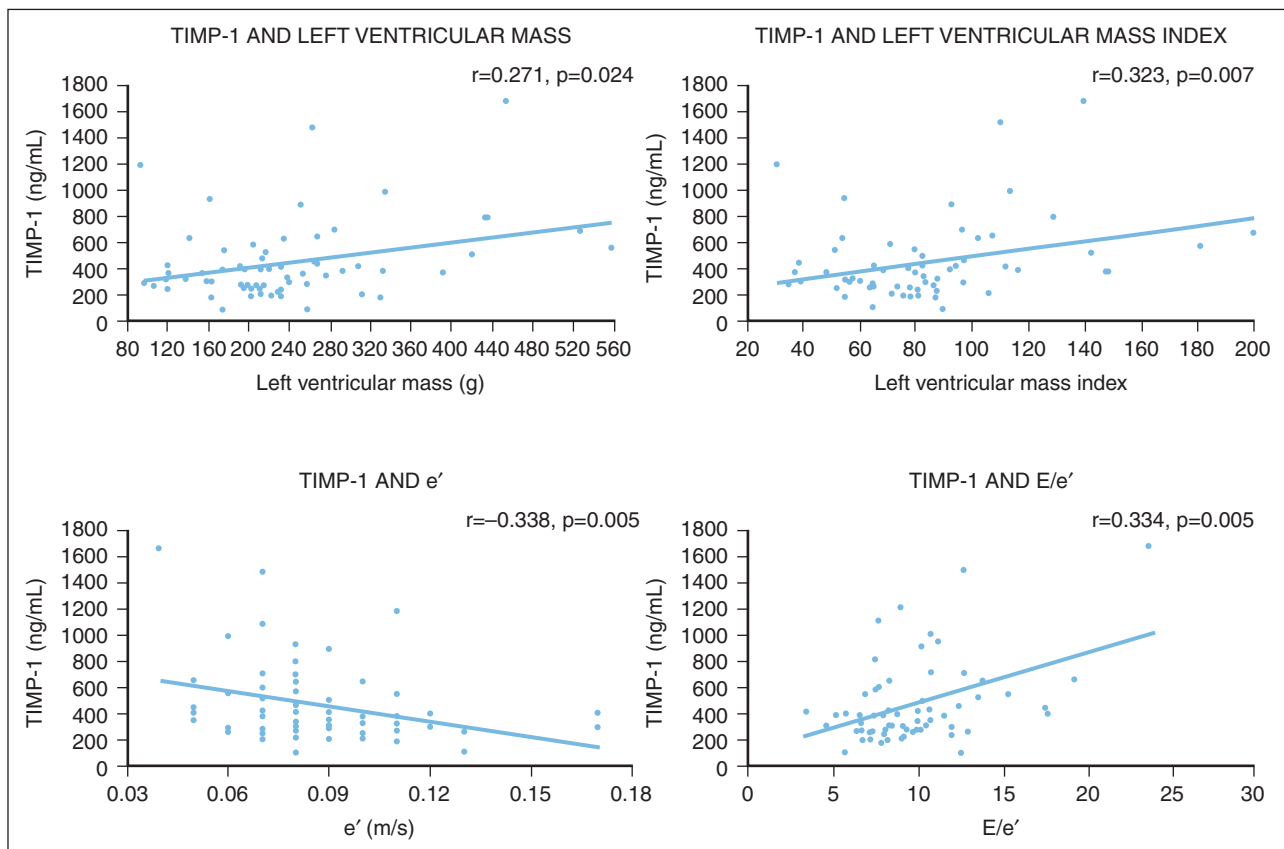

Figure 17–2. The relationship between echocardiographic parameters of left ventricular mass and diastolic function and TIMP-1. (Adapted from Tayebjee MH, Nadar SK, MacFadyen RJ, Lip GY. Tissue inhibitor of metalloproteinase-1 and matrix metalloproteinase-9 levels in patients with hypertension: Relationship to tissue Doppler indices of diastolic relaxation. *Am J Hypertens* 2004;17:770–74 with permission from *The American Journal of Hypertension Ltd.*)

Figure 17-3. In hypertension, a change in tissue concentrations of MMP-1 and TIMP-1 would alter cardiac matrix turnover and affect ventricular mechanics. These changes may be central to abnormal ventricular remodeling and diastolic dysfunction. (MMP-1, matrix metalloproteinase-1; TIMP-1, tissue inhibitor of metalloproteinase-1).

prospective studies are necessary before bringing this into practice. Further, to date no studies have demonstrated a prognostic role for TIMP-1.

Matrix metalloproteinase-9 (MMP-9), on the other hand, has shown some promise as a prognostic marker. Raised circulating levels have been observed in hypertension, coronary artery disease (both stable and unstable), diabetes, and peripheral vascular disease. It is a gelatinase, and is unique in that it can be released rapidly from neutrophils by exocytosis. For this reason it has been implicated in the pathophysiology of plaque rupture in unstable coronary artery disease. This effect is in part mediated by weakening of plaque ECM following release by plaque inflammatory cells. In a large study of patients with stable coronary artery disease, higher circulating levels of MMP-9 were associated with a poorer outcome from cardiovascular events. Moreover, certain alleles of MMP-9 are associated with a poorer prognosis. In patients with hypertension, there is a modest correlation with MMP-9 and Framingham cardiovascular risk scores. Interestingly, treatment of hypertension reduces MMP-9.³

From a matrix turnover point of view, what is the role of MMP-9? As discussed previously, increasing arterial stiffness is well recognized and is associated with alterations in the ECM that are principally associated with increased deposition of type I collagen at the expense of the other constituents. For these changes in the ECM composition to occur, there must be a shift in the turnover of ECM. Collagen type I is not a major substrate for MMP-9, and hence raised tissue activity and concentrations may reflect the breakdown of components other than collagen type I in order to facilitate collagen changes mediated by other MMPs. Circulating concentrations of MMP-1 (involved principally in the breakdown of collagen type I) appear to be seen in lower levels in patients with hypertension, and this will favor the maintenance of a stiffer and more fibrous myocardial and/or arterial ECM. Therefore, increased MMP-9 in cardiac and vascular tissue may be “making more space” for the deposition of collagen type I.¹⁴

Patients with long-standing hypertension sometimes develop hypertensive dilated cardiomyopathy. However, little is known about the changes in MMP and TIMP activity in humans in the context of transition from normal to impaired left ventricular function. There is evidence from studies of myocardial infarction and dilated cardiomyopathy that metalloproteinase activity changes as the ventricle remodels and dilates. Myocardial MMP-9 has shown to be upregulated (and MMP-1 downregulated¹⁵), and there is an increase in the MMP-9-to-TIMP-1 and MMP-9-to-TIMP-2 ratio.^{16,17} MMP-2 and MMP-3 both rise during the development of nonischemic dilated cardiomyopathy and could represent a similar pattern to that seen during hypertensive heart failure. The precise roles of MMPs and TIMPs are unknown, but they almost certainly have a pivotal role in changing the structure and function of cardiac ECM. Indeed, assessment of these MMPs and TIMPs in patients may help in identifying individuals at risk, and therefore it has been speculated that these markers may be of prognostic value.

CLINICAL IMPLICATIONS AND PERSPECTIVES

There is growing evidence now of the fact that MMPs and TIMPs could potentially be used to track the changes in the structure of ECM and may therefore have clinical use. Diastolic dysfunction has been studied more extensively, and results indicate that TIMP-1 may be a useful predictor of this. Nevertheless, the precise role of TIMP-1 in clinical practice has yet to be defined by large-scale studies. One of the potential drawbacks is the large variance in TIMP-1 even in normal individuals. In addition, although assessment of circulating TIMP-1 is easy it must be borne in mind that the total concentration will be a result of “tissue leak” from many organs and is hence not cardiac or vascular specific. Future studies could examine whether there are cardiac-specific isoforms that would increase the specificity of the analysis.

Assessment of matrix metalloproteinase, on the other hand, could have a role in predicting cardiovascular prognosis in patients with hypertension. This could help in better risk stratification. However, because of variance and specificity this analysis will depend on larger-scale studies to determine clinical value. In clinical practice there is a tendency to measure concentration rather than activity, the former being easier. Unfortunately, there is not always a direct link between the two and enzyme activity could be low in the context of high concentration because of inactive enzyme. This point is crucial, especially in the case of MMP-9, where its role in plaque turnover (for example) is a consequence of its activity. More work is needed to decide on whether concentration can be used as a surrogate of activity.

It is being recognized that it may be more useful to study the MMP/TIMP ratio or examine MMP-TIMP complexes rather than the assessment of a single MMP. We have recently demonstrated in gestation hypertension that in normal pregnancy the MMP/TIMP ratio is higher and that with the development of hypertension this ratio

falls. In normal pregnancy, the rise in the MMP/TIMP ratio favors activated metalloproteinase activity, and among other actions suggests favoring ECM breakdown. Theoretically, this will obviously be important in the invasion of the uterine wall by the cytotrophoblast. The significant fall in this ratio during gestational hypertension does suggest a milieu that acts against myometrial invasion. The subsequent compromise to placental perfusion can result in relative or absolute fetal hypoxia and disordered placental function. It is important to recognize that this does not provide any information on enzyme

Figure 17–4. Speculative interaction among MMP-1, MMP-9, and TIMP-1 in hypertension.

activity. Nevertheless, this model does suggest that MMPs and TIMPs could be useful assessments of matrix structure—especially because the tissue being studied is relatively large (i.e., placenta versus heart).¹⁸

What about the use of MMP and TIMP modulators clinically? Unfortunately, specific compounds that inhibit MMPs have not really proved beneficial. This may be due to the fact that systemic therapy is not organ or tissue targeted; that is, whereas enzyme inhibition will be beneficial in one area the effects of this would be detrimental in another. Indeed, there is evidence that MMP and TIMP levels vary in different cells. However, indirect manipulation of MMP and TIMP activities has been shown to be beneficial. Use of antihypertensive therapy, drugs that affect the renin-angiotensin-aldosterone system, and statins have reversed altered MMP and TIMP levels when assessed in tissue and in blood.^{4,14}

SUMMARY

Clearly changes in the cardiac and vascular ECM occur in hypertension, the former resulting in left ventricular hypertrophy, diastolic dysfunction, and in some cases hypertensive dilated cardiomyopathy. Arterial stiffness and atherosclerosis are potential consequences of the latter (Figure 17–4). Matrix metalloproteinases and their inhibitors have key roles in mediating these changes. Their main role clinically could be in the noninvasive assessment of tissue structure and prognosis rather than therapy. However, because of the large numbers of MMPs and TIMPs and roles that are not yet clearly defined much more work is needed before they can be considered useful clinical markers.

Chapter
18Cell Membranes (Blood Cell
and Platelet Membranes in
Human Essential Hypertension)

Dieter Roszkopf

Key Findings

- Enhanced activities of Na^+/Li^+ countertransport and Na^+/H^+ exchange in blood cells is a frequent finding in hypertension.
- The physiological roles and the molecular identity of Na^+/Li^+ countertransport remain to be resolved.
- Studies with cell lines from hypertensive individuals indicate that the enhanced activity of Na^+/H^+ exchange is genetically fixed.
- The Na^+/H^+ exchanger isoform 1 (NHE1), the sole mediator of this transport in blood cells, has been excluded as a candidate gene in hypertension.
- An altered regulation of NHE1 is the most likely cause of the observed abnormality.
- Polymorphisms in signaling proteins (e.g., in the G protein $\beta 3$ subunit) may contribute to the genetically fixed enhancement of NHE1 activity.

INTRODUCTION

Blood cells have been intensively studied in hypertension research for several reasons. First, blood cells are easily accessible and can be obtained noninvasively in contrast to other (more obvious) target tissues in hypertension research. Given the huge number of cells, purification of blood cells and of blood cell membranes is simple. Packed erythrocytes or red cell ghosts (i.e., erythrocyte membrane particles devoid of hemoglobin) can be obtained in large volumes, which was essential for early biochemical and cell physiologic studies. Second, platelets were addressed as model “cells” for vascular smooth muscle and endothelial cells because they share similar receptor systems and signal transduction pathways. In addition, platelets are involved in the pathogenesis of thromboembolic and atherosclerotic processes frequently associated with hypertension (a topic separately addressed in the following chapter).

Third, as molecular biology and genetics emerged, lymphocytes were the prime source of blood DNA. Furthermore, lymphocytes (together with macrophages) are the only blood cells that can be kept alive for several days in cell culture. Immortalization of human B lymphocytes with Epstein-Barr virus (EBV) is (other than outgrowth of

fibroblasts from skin specimens) the only method for the routine establishment of human cell lines for limitless supply of biological material from a given human individual. Fourth, in recent years macrophages have been intensively studied for their involvement in atherosclerosis [with special emphasis on inflammation (together with granulocytes and lymphocytes), lipid metabolism, and as models for angiogenesis]. Fifth, abnormalities observed in blood cells are in part considered “intermediate phenotypes” in hypertension. Following this concept, intermediate phenotypes are genetically determined, do not contribute directly to the pathogenesis of hypertension, and may be useful in classifying different types of hypertension and in identifying causative (genetic) factors.

The “model function” (or better “surrogate function”) of blood cells, however, involves inherent problems. First, it has been postulated that abnormalities identified in blood cells are representative of similar alterations in key mechanisms of blood pressure regulation (including renal ion handling or cell signaling in resistance vessels). Modern transcriptome or proteome analyses, however, indicate a limited overlap in the expression of such systems between different cell types.

Second, taking blood cells *ex vivo* from hypertensive donors in search of intermediate phenotypes inherently presents the problem that these cells have “experienced” a hypertensive circulation and a hypertensive neuro-humoral milieu. Therefore, it is often impossible to distinguish between primary and secondary effects (i.e., between causative factors and epiphenomena of a hypertensive circulation). One possible solution to this dilemma is the mentioned immortalization of human B lymphocytes with EBV and their subsequent characterization after long-term culture. Alterations observed under such conditions have a high probability of indicating a primary defect.

Third, red blood cells lack a nucleus and platelets are subcellular components shed from megakaryocytes (thus preventing the application of advanced techniques from molecular biology and genetics). It is impossible to review here all findings on blood cells in hypertension given the limited space of this chapter and the conjecture that many known biological systems expressed in blood cells have been investigated for a role in hypertension. Many of these systems are extensively covered in other chapters of this book, where their key relevance is obvious. Here we focus on those systems for which guiding contributions originated from the investigation of blood cells.

With the emergence half a century ago of evidence that altered renal sodium processing may contribute to the pathogenesis of hypertension, cellular cation homeostasis became an important research area.¹ Intracellular Na^+ concentration was reported to be increased in red and white blood cells in hypertension, although this notion was later challenged. Likewise, there exist many reports of altered blood cell Na^+ transport mechanisms (including passive Na^+ fluxes, Na^+/K^+ ATPase activity, and $\text{Na}^+/\text{K}^+/\text{Cl}^-$ transport activity).² (See also Figure 18–1.) With the advent of prophylactic lithium therapy in mood disorders, a Na^+/Li^+ countertransport (SLC) activity was discovered in red blood cells that set the intracellular Li^+ concentration below the serum concentration.³ More than a quarter of a century ago, Canessa and co-workers reported in a seminal publication an enhanced SLC activity in hypertension, a finding that set in motion many clinical, epidemiologic, and genetic studies. There are currently more than a thousand reports on this subject.^{4,5,6}

Today, enhanced SLC activity is the best-characterized intermediate phenotype in hypertension. Because Li^+ is virtually absent from body fluids, SLC activity was considered an artificial transport mode. Hence, it was logical that the discovery of Na^+/H^+ transport mechanisms gave rise to the notion that Na^+/Li^+ countertransport is only a peculiar transport mode under highly artificial conditions. Thus, many groups moved to the analysis of cellular Na^+/H^+ transport activity, which was subsequently found to be enhanced in hypertension.^{7–10} Despite many efforts, it remains still open whether blood cell Na^+/Li^+ and Na^+/H^+ exchange is mediated by an identical protein. Searches for genetic polymorphisms in the gene for the Na^+/H^+ exchanger isoform expressed in blood cells remained unsuccessful, and genome-wide linkage analysis excluded this gene as a candidate gene in hypertension.¹¹ Likewise, the variation in SLC activity could not be attributed to genetic markers in the NHE1 gene.¹² Na^+/H^+ exchanger activity is modulated by many different intracellular signaling systems.

Taking into consideration that Ca^{2+} concentrations are elevated in platelets from hypertensive subjects, the interplay between Na^+/H^+ exchange activity and cellular signaling was intensively studied and led to the identification of a polymorphism in a heterotrimeric G protein supposed to be linked to enhanced Na^+/H^+ exchange activity (a notion that still awaits formal proof).¹³ Following this route, we will focus here on abnormalities in Na^+/H^+ exchange and Na^+/Li^+ countertransport, and we will address basic functions and abnormalities of G protein signaling in hypertension.

ANATOMY, BIOCHEMISTRY, AND PHYSIOLOGY

Fundamental information on the generation, function, and fate of blood cells and the key organs involved can be found in many excellent textbooks of hematology and physiology.

Cation transport mechanisms in blood cells: Na^+/Li^+ countertransport

With concepts of abnormal renal Na^+ handling¹ and based on the at that time unproven assumption that relevant ion carriers could exist in blood cells and display similar abnormalities as in the kidney, a multitude of studies have utilized the ready availability and suitability of erythrocytes for transport studies in hypertension.^{2,10} Transport physiologists have characterized several Na^+ transport systems in blood cells and most of them could meanwhile be attributed to distinct transporter proteins/genes on a molecular level (Figure 18–1). These Na^+ transport systems include the amiloride-sensitive Na^+/H^+ exchanger, the ouabain-sensitive Na^+ pump, sodium-dependent and -independent $\text{Cl}^-/\text{HCO}_3^-$ exchangers (inhibited by DIDS, a stilbene sulphonate), and a furosemide-sensitive $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter.

Under physiological conditions, the Na^+ pump (also called the Na^+/K^+ ATPase) transports Na^+ out of cells and thus constitutes the driving force behind the other transport systems (which cause an influx of Na^+). Measurements of the maximum Na^+ transport rates for these transporter modes indicate that Na^+/H^+ exchange exhibits the highest Na^+ transport capacity, followed by the Na^+ -dependent $\text{Cl}^-/\text{HCO}_3^-$ exchange (most likely a coupled transport process), and finally by the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter differing by almost one order of magnitude each. Furthermore, using radioactive Na^+ isotopes transport modes as Na^+ -coupled Na^+ transport have been described (today best attributed to concerted actions of the previously cited transporters and the sodium pump). Of note, all of these transporters accept lithium ions for sodium ions, a fact that mirrors similar electrochemical properties of Na^+ and Li^+ .

An Na^+/Li^+ exchange activity was identified in red cells with the introduction of lithium therapy.³ For measure-

Figure 18–1. Major cation transporters in blood cells. Shown is the physiological transport mode and indicated are typical inhibitors.

ment of SLC, red cells are loaded with lithium (according to the standard procedure in the seminal report by Canessa et al.) to 13 mmol/L, and aliquots are allowed to leak into ouabain-containing medium in the presence or absence of 150 mmol/l Na^+ .⁴ Here, Na^+ influx is coupled in a 1:1 stoichiometry to Li^+ efflux. In comparison with the other Na^+ transporters mentioned previously, maximum Na^+ influx rates mediated by SLC are one order of magnitude lower than Na^+ influx by Na^+/H^+ exchange and are in the range of $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransport. SLC activity is inhibited by phloretin. Exposure to N-ethylmaleimide, an alkylating agent, results in altered SLC kinetics which was taken as an early hint for the involvement of a transport protein. Initially, SLC was thought to be confined to red blood cells.^{5,6} Subsequent studies, however, demonstrated SLC activity in fibroblasts and lymphoblasts^{14,15} among others.

The physiological role of SLC is a puzzling question because plasma is normally lacking Li^+ . One concept proposes that SLC catalyzes an equimolar Na^+/Na^+ exchange that is physiologically silent and of low activity compared with other Na^+ transport modes. Such a concept, however, is again not a satisfying answer to its physiological role. This led to concepts that Na^+/Li^+ exchange is a special transport mode of Na^+/H^+ exchangers.

Na^+/H^+ exchange

Na^+/H^+ exchange (NHE) as a transport mode was first described in 1976. Its first isoform (NHE1) was cloned¹⁶ in 1989, followed by the identification and cloning of at least five more NHE isoforms.¹⁷ NHE1, the ubiquitously expressed “housekeeping” isoform, is of key importance for intracellular pH (pH_i) regulation and cellular volume control. NHE2, NHE3, and NHE4 are predominantly expressed in polarized epithelia, and NHE5 is confined to the brain. In concerted actions together with carbonic anhydrase enzyme and $\text{Cl}^-/\text{HCO}_3^-$ exchange mechanisms, the epithelial isoforms mediate vectorial Na^+ transport thereby driving water fluxes and bicarbonate transport. Newly identified isoforms (NHE6 through NHE9) have been localized to intracellular structures, and their precise functions remain elusive. A novel nomenclature for the respective genes refers to SLC9A1-9 for NHE isoforms 1 through 9.¹⁸⁻²⁰

Here, we will focus on NHE1, the isoform expressed in blood cells. In addition to its “housekeeping” functions in pH_i and volume regulation, NHE1 activity has been implicated in cell cycle regulation, proliferation, migration, adhesion, and resistance to apoptosis. The transporter is an integral plasma membrane protein and mediates under physiological conditions the exchange of intracellular H^+ for extracellular Na^+ , with the Na^+ gradient established by the Na^+/K^+ pump as the driving force. Intracellular acidification activates the exchanger, which acts to reestablish the pH_i to a certain set point. Kinetically, this is an allosteric regulation by intracellular H^+ mediated by a proposed H^+ sensor in the molecule which is further modified by additional regulatory modifications of the transport protein.

Subtle fluctuations in steady-state pH_i affect the action of many biomolecules and may even be used for regulatory purposes. Therefore, the fine control of pH_i is of fundamental importance in sustaining a suitable milieu for stable enzymatic activity, protein interactions, and ultimately cell function and survival. To this end, cells express several pH_i -regulating mechanisms, including Na^+/H^+ exchange and Na^+ -dependent and -independent $\text{Cl}^-/\text{HCO}_3^-$ exchangers. Under hypoxic conditions (e.g., during myocardial or cerebral ischemia) an uncontrolled acidification by excess metabolic acid production occurs, causing gross damage to the cell. Here, pH_i -regulating processes (including NHE1) guard against uncontrolled acidification by maintaining intracytoplasmic acid/base balance.²¹

Cellular volume control is of similar vital importance, and adaptations are obviously necessary during cell growth and division. Protons (in contrast to Na^+ ions) are not osmotically active. Thus, an exchange of intracellular H^+ for extracellular Na^+ is accompanied by a net influx of water and NHE1 activation, an important mechanism in fighting volume shrinkage and in inducing volume increase. The fine control of such processes, however, requires the concerted action of several ion-transporting systems other than NHE1.²⁰ Potent inhibitors of NHE1 are pyrazone derivatives (amiloride, dimethylamiloride, ethylisopropylamiloride) and benzoylguanidine derivatives (cariporide, HOE694, eniporide).²¹ Available evidence suggests that these compounds affect the interaction of NHE1 with Na^+ . Kinetic properties, molecular and cellular regulations, and susceptibilities to inhibitors differ considerably among various NHE isoforms.

On a molecular level, NHE1, the prototypic Na^+/H^+ exchanger, consists of 12 conserved membrane-spanning domains at the N-terminus of the protein, followed by a long intracellular C-terminus. This intracellular domain comprises numerous predicted phosphorylation sites for different kinases and binding sites for other ancillary factors. It thus appears to serve as the major regulatory domain of NHE1 (Figure 18–2A). The extended loop between transmembrane domains 9 and 10 is supposed to form part of the ion conduction pathway. There is some limited evidence suggesting a higher order of NHE1 molecules *in vivo* (for instance, as homodimers or tetramer complexes).

Na^+/H^+ exchangers are subject to an intensive and complex regulation in addition to their kinetic control by Na^+ and H^+ ions. Many hormones, neurotransmitters, and growth factors activate NHE1, thereby causing an intracellular alkalinization and volume increases that frequently precede cell proliferation. Hence, NHE1 has also been considered a “growth factor activatable” Na^+/H^+ exchanger. Such stimuli (e.g., serum, growth factors, thrombin, angiotensin II, α -adrenoceptor agonists, and many more) are transmitted by membrane receptors of the G protein-coupled receptor family or by the family of receptor tyrosine kinases. This activation converges on the common mitogen-activated protein kinase (MAP kinase) pathway and involves a mitogen-activated extracellular-signal-related kinase (MEK-ERK)-p90^{rk}.

Figure 18–2. (A) Topological model of the Na^+/H^+ exchanger isoform 1. The transporter consists of 12 transmembrane domains and a long cytoplasmic domain, which is involved in regulation of the transport activity. Indicated are the putative binding sites for interacting proteins: CaM (Ca/Calmodulin), HSP70 (heat shock protein), PIP₂ (phosphatidylinositol-4,5-bisphosphate), ERM (esrin-radixin-moesin protein binding), and CHP (calcineurin-homolog protein). (B) Gene structure and alternative splicing leading to the putative variant DNHE1. Parts from exons 1 and 2 that are alternatively spliced are indicated in red. (C) Putative structure of DNHE1, a variant of NHE1 assumed to mediate Na^+/Li^+ exchange.

This latter kinase phosphorylates a conserved serine of NHE1, which in turn can bind multifunctional scaffolding proteins of the 14-3-3 class that can mediate a further assembly of additional signaling molecules. NHE1 is also a substrate for the p160 Rho-associated kinase (p160ROCK), which transduces signals from integrin receptors involved in cell adhesion and spreading. The platelet-derived growth factor receptor can activate NHE1 by a second pathway in addition to the MAP kinase pathway, which involves an Nck-interacting kinase (NIK). The mechanism whereby phosphorylation of the intracellular NHE1 C-terminus translates into increased cation transport remains unexplained. Available evidence suggests that NHE1 forms a multiprotein complex, and it has been proposed that carbonic anhydrase binds to modified sites on NHE1. The local production of H^+ could in turn stimulate NHE1 by the common kinetic mechanisms.

In addition to 14-3-3 proteins and carbonic anhydrase, Ca^{2+} /calmodulin is an important binding partner that increases NHE1 transport activity and appears to integrate signals from stimuli that lead to an increase in cellular Ca^{2+} concentrations. The Ca^{2+} -binding phosphoproteins CHP1 and CHP2 (calcineurin B homologous protein) and tescalcin also bind to NHE1. Association with these proteins is also accompanied by an increase in steady-state pH_i . Furthermore, binding of the phosphoinositide phosphatidylinositol 4,5 bisphosphate (PIP₂) has been demonstrated to be critical for optimal NHE1 activity, which would connect the exchanger to a complex regulation by systems affecting the phosphoinositide content.^{19–23}

Finally, NHE1 can interact with members of the ERM family of actin-binding proteins (which include ezrin, radixin, and moesin). Here, NHE1 serves as a membrane anchor for cytoskeleton proteins and can act as a scaffold protein to generate multiprotein complexes in signal transduction. In accord with the distribution of such interacting proteins, NHE1 molecules are not evenly distributed on the plasma membrane but accumulate in certain microdomains. The interaction with ERM proteins is important for the reorganization of the actin cytoskeleton and in turn for the control of cell morphology, adhesion, and migration. Interestingly, this function appears to be at least in part independent of the cation transporting function. Taken together, we have to envisage NHE1 not only as an important ion transporter that fundamentally affects cellular homeostasis but as a highly complex integrator for a vast array of different extracellular signals (Figure 18–3 summarizes some of these pathways).

Given this complex regulation and the ubiquitous expression of NHE1, it is difficult to predict its physiological role *in vivo*, a question that has now been addressed with several mouse models. In one spontaneous mutant mouse model, a nonsense mutation (Lys442) in NHE1 occurs that causes a highly reduced transport activity. These mice are termed SWE (slow-wave epilepsy) mice,

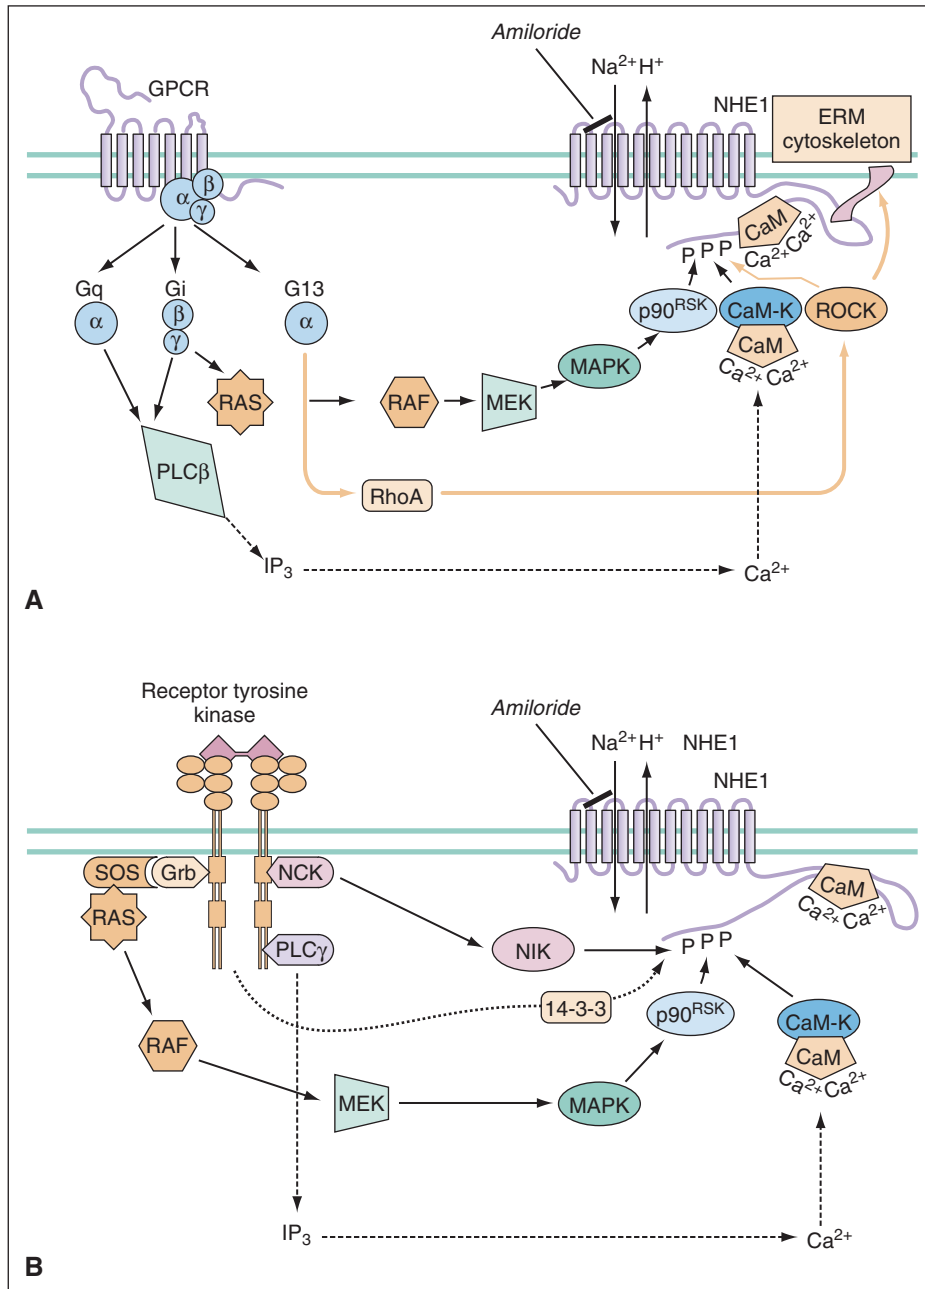

Figure 18-3. Examples for the complex regulation of NHE1 by signal transduction events. (A) Activation by G protein-coupled receptor. (B) Receptor tyrosine kinases (e.g., platelet-derived growth factor receptor). Pathways have been explained in the main body of the text.

referring to one characteristic of a more complex phenotype in homozygous animals that includes growth retardation, seizures (grand mal and petit mal), locomotor ataxia, and high mortality before weaning.²⁴ In a targeted NHE1 knockout animal model a similar phenotype has been observed.²⁵ In addition, these mice had a reduced parotid gland secretion, were resistant to experimental cardiac ischemia/reperfusion injuries, and exhibited a decreased renal HCO₃⁻ absorption and a distinctly altered gene expression in the brain.

Heterotrimeric G proteins

We will learn in the “Pathophysiology” section of this chapter that increased activity of NHE1 is a frequent observation in primary hypertension. Genetic studies argued against a genetic defect in NHE1 that causes hypertension, a notion that sparked an intensive search for abnormalities in the complex regulation of NHE1 in hypertension. One approach was to investigate G protein-coupled signal transduction in hypertension, which resulted in the identification of a functional poly-

morphism in a G protein β subunit. Here, we present some essential information on the functions of heterotrimeric G proteins.^{26–30} Their name relates to two main characteristics: their ability to bind guanine nucleotides and their composition of three different subunits termed $G\alpha$, $G\beta$, and $G\gamma$. $G\beta$ and $G\gamma$ form a stable dimer and act as a functional monomer.

The $G\alpha$ subunit carries the enzymatic activity of the complex in that it mediates the hydrolytic conversion of GTP into GDP. The crucial function of heterotrimeric G proteins is to relay the activation from an agonist-bound receptor to various intracellular effector systems. The family of G protein-coupled receptors (GPCR) counts more than one thousand members (the largest family of membrane receptors in our genome). All GPCR consist of seven membrane-spanning domains, which led to the synonyms *heptahelical receptors* and *serpentine receptors*. Typical members of this class of receptors are all adrenergic receptors, angiotensin II receptors, thrombin receptors, and many more.

The inactive heterotrimeric G protein consists of a $G\alpha$ subunit and a $G\beta\gamma$ dimer. The $G\alpha$ subunit has bound GDP. Upon interaction with an activated GPCR, the $G\alpha$ subunit changes its conformation and releases GDP (Figure 18–4). The GDP is replaced by GTP and in its GTP-bound state the $G\alpha$ subunit takes an activated conformation with low affinity for the $G\beta\gamma$ dimer. Subsequently, GTP-bound $G\alpha$ subunits interact with their respective effector systems (e.g., adenylyl cyclases) and modulate their activity. Like-

Figure 18–4. The GTPase cycle of heterotrimeric G proteins. Binding of a ligand to a heptahelical receptor induces a conformational change that is transduced to interacting $G\alpha$ proteins² (GDP-bound, inactive). An ensuing conformational change of the $G\alpha$ subunits induces a GDP/GTP exchange³ and the dissociation of the now activated $G\alpha$ subunit (GTP-bound) from the $G\beta\gamma$ dimer and the receptor. $G\beta\gamma$ subunit and activated $G\alpha$ subunit modulate effector systems.⁴ The endogenous GTPase activity of the $G\alpha$ subunit hydrolyzes GTP to GDP and leading to a reassociation and potentially another round of the GTPase cycle.^{5,6}

wise, free $G\beta\gamma$ dimers are also effective regulators of many effector systems. The GTPase activity of the $G\alpha$ subunit mediates a hydrolytic cleavage of GTP into GDP, which terminates its active conformation. Upon association of the GDP-bound $G\alpha$ with a $G\beta\gamma$ dimer, the “GTPase cycle” is closed and the heterotrimeric G protein is ready for another round of activation.

At present, more than 20 $G\alpha$, 5 $G\beta$, and 12 $G\gamma$ genes have been identified in the human genome. Together, they give rise to (theoretically) more than a thousand different heterotrimers, which may explain the observed receptor and effector specificity in G protein-mediated cell signaling. Currently, G proteins are further subdivided according to their $G\alpha$ subunit. $G\alpha_s$, the “stimulatory G protein,” was identified based on its ability to activate adenylyl cyclases. Likewise, $G\alpha_i$ (the “inhibitory G protein”) diminishes the activity of adenylyl cyclase isoforms. There are actually several isoforms in the $G\alpha_i$ family ($G\alpha_{i1}$, $G\alpha_{i2}$, $G\alpha_{i3}$, $G\alpha_o$), with sometimes distinct functions. In addition to inhibiting adenylyl cyclase activity, activation of $G\alpha_i$ has been linked to many more cellular effects, including activation of potassium channels, activation of kinase pathways, and initiation of cell proliferation. Most likely, these latter functions are attributable to the release of $G\beta\gamma$ subunits.

Another subfamily of G proteins, the $G\alpha_q$ family, with the members $G\alpha_q$, $G\alpha_{11}$, $G\alpha_{14}$, and $G\alpha_{15}$ is predominantly involved in the activation of phospholipase C β isoforms, which results in the generation of inositol trisphosphate and ultimately in an increase of intracellular Ca^{2+} . $G\alpha_{12}$ and $G\alpha_{13}$ mediate the activation of small G proteins of the rho family, which are implicated in the regulation of cell shape and motility. Free $G\beta\gamma$ dimers are also important and versatile regulators of many effector systems, including adenylyl cyclases, phospholipase C β isoforms, PI3 kinases, potassium and calcium channel isoforms, and several kinase systems associated with cell proliferation. In principle, $G\beta\gamma$ dimers are released upon activation of any $G\alpha$ subunit. $G\alpha_i$ proteins, however, are the most frequently expressed $G\alpha$ class of G proteins on a molar level, which makes them a main source of free $G\beta\gamma$ subunits.

Historically, G proteins have also been classified according to their susceptibility to modification by bacterial toxins. Hence, $G\alpha_s$ proteins are activated by treatment with cholera toxin whereas members of the $G\alpha_i$ family are inhibited upon exposure to pertussis toxin. Therefore, $G\alpha_i$ proteins are frequently referred to as “pertussis toxin-sensitive” or “PTX-sensitive” G proteins.

The crucial advantage of this highly complex system of different G proteins and effector systems is its ability to integrate and fine-tune many different signals into a cellular response. For instance, adenylyl cyclase activity (and thus the generation of cAMP) is stimulated by the $G\alpha_s$ pathway, is inhibited by $G\alpha_i$ proteins, and can further be modulated by released $G\beta\gamma$ subunits and Ca^{2+} transients elicited by activation of $G\alpha_q$. Within the last decade, additional regulators of this system have been identified that deserve mention. RGS proteins are “regulators of G protein signaling” and serve to accelerate the GTPase activity of $G\alpha$ subunits and thus to terminate G protein-mediated signals.³¹

Similarly, G protein receptor kinases (GRKs) inhibit once-activated GPCRs, thus counteracting unbalanced cell activation.³² In the context of hypertension research, GRK4 has attained some interest because genetic polymorphisms of this gene have been associated with hypertension.³³ GRK4 expression is confined to the kidneys, where it regulates dopamine receptor 1 activity. One polymorphism causes an amino acid exchange of the gene, which becomes constitutively active resulting in a sustained down-regulation of dopamine receptor signaling.³³

PATHOPHYSIOLOGY

Na⁺/Li⁺ countertransport

Following the seminal report by Canessa et al. of an enhanced SLC activity in primary hypertension, more than hundred independent reports confirmed this result.⁴⁻⁶ Subsequent studies showed that enhanced SLC activity is also associated with type I diabetes, especially in the context of hypertension (i.e., insulin resistance, hyperlipidemia, gravidity with and without hypertension, and renal and cardiac hypertrophy). Increased SLC activity has also been demonstrated in rapid progressive IgA nephropathy and in diabetic patients with proliferative retinopathy.⁴⁻⁶ Enhanced SLC activity is one of the strongest predictors for diabetic nephropathy. Within the context of hypertension, SLC activity has been associated with phenotypes of non-modulating hypertension and an enhanced total body exchangeable Na⁺.

An increase in SLC activity has not only been confined to red blood cells from hypertensive individuals but has been detected *ex vivo* in skin fibroblasts¹⁵ and lymphoblasts from hypertensive patients,¹⁴ which may be taken as a clue for a generalized membrane abnormality that prevails in cell culture indicating a genetic determination. It is important to note that these findings always refer to the mean Na⁺/Li⁺ exchange activity in hypertension and that there is a considerable overlap between values of normotensive and hypertensive subjects. SLC activity is modulated by different factors. Addition of insulin in physiological concentrations to erythrocytes from fasted individuals results in increased maximal SLC transport rates. Alcohol intake or use of steroids also affects SLC activity.

Despite intensive efforts, the mechanisms that contribute to altered SLC kinetics are currently not understood. Several hypotheses have been proposed, including concepts of genetic variants in the (so far, unidentified) transporter gene or of circulating factors in hypertension that activate SLC with insulin. According to another model, enhanced SLC activity mirrors (more or less nonspecifically) an altered lipid composition of the plasma membrane that results in an enhanced “membrane viscosity.”³⁴ Experimental modification of the lipid composition has been accompanied by changes in SLC activity and studies in normo- and hyperlipidemic individuals or upon treatment with lipid-lowering agents have demonstrated modulatory effects on SLC activity. Despite considerable efforts, a consistent model demonstrating

how changes in the lipid composition cause altered SLC activity is still missing.

Based on the observation that exposure of red cells to N-ethylmaleimide result in a modulation of SLC activity, speculations have been put forward that thiol modifications (e.g., by oxidation) of transporters or associated proteins contribute to the observed kinetic abnormalities.³⁵ Taken together, the exact mechanisms that cause altered SLC activity remain to be unraveled. A major hindrance in these attempts is the unresolved question of which protein mediates SLC such that the direct investigative modification of the systems by methods of modern molecular biology is prevented. Hence, it is generally understood that SLC does not constitute a physiologically relevant ion exchange that directly causes hypertension, but rather represents a sensitive indicator for aspects of a membrane abnormality that may cause (or is itself caused by) the underlying pathology (i.e., primary hypertension). In this scenario, enhanced SLC activity remains a valuable marker for a predisposition to essential hypertension and for the rate of progression of several renal diseases and diabetic complications.

Na⁺/H⁺ exchange

Based on the still unproven hypothesis that SLC is a specialized transport mode of Na⁺/H⁺ exchange,⁷ many groups have tested this assumption in different cell types from hypertensive humans and in animal models of hypertension. A considerable body of evidence on this topic has been accumulated that correlates an increased Na⁺/H⁺ exchange activity with hypertension, although with some controversy.^{9,36,37} Increased activity of Na⁺/H⁺ exchange was first described in human platelets, followed by similar reports in erythrocytes and lymphocytes.^{7,8}

In these cell types, Na⁺/H⁺ exchange activity is almost exclusively mediated by the NHE1 isoform, which was subsequently considered a target gene for hypertension research. In addition, enhanced Na⁺/H⁺ exchange activity was also observed in various tissues from spontaneously hypertensive rats, including vascular smooth muscle cells.^{36,37} Furthermore, an enhanced NHE1 activity was also observed in patients with diabetic nephropathy, analogous with findings with SLC.³⁸ Another similarity with SLC is the substantial overlap in NHE1 activities between normotensive and hypertensive individuals, which precludes its use for diagnostic purposes.

Several hypotheses were put forward about how an increase in Na⁺/H⁺ exchange activity could translate in a rise in blood pressure. First, it was claimed that an enhanced Na⁺/H⁺ exchange upon expression of an analogous activity in the kidney could cause an increased Na⁺ reabsorption. Current evidence, however, suggests that NHE3 is crucial for this function. Other concepts attributed increased NHE1 activity (e.g., in vascular smooth muscle cells) to elevated intracellular Na⁺ levels that could inhibit Na⁺/Ca²⁺ exchange and ultimately result in increased Ca²⁺ concentrations (which were again frequently but not unequivocally observed in blood platelets).³⁹ Alternatively, it has been suggested that high NHE1 activity leads to an

increased proliferation, and ultimately by media hyperplasia of blood vessels to hypertension. None of these concepts has been proven so far.

The cloning of NHE1 allowed extending this research to a molecular level.¹⁷ Most authors agree that in humans and in SHR animals enhanced NHE1 activity is not accompanied by an enhanced expression of NHE1 transcripts or NHE1 protein.⁴⁰⁻⁴³ This is in striking contrast to the finding that unselective overexpression of NHE1 in transgenic mice causes a salt-sensitive form of hypertension.⁴⁴ On the one hand, this underscores that NHE1 may actually contribute to blood pressure regulation. On the other hand, it demonstrates that animal models are sometimes of limited relevance for human hypertension.

As explained in the introduction to this chapter, research on blood cells in hypertension bears the inherent challenge of discriminating between cause and effect, i.e., between potential primary factors and epiphenomena of the disease. One way of circumventing this problem is the use of cell lines from individuals with a certain hypertension-associated cellular phenotype. If such a phenotype is sustained in many generations of cell culture, it is plausible to conclude that a genetic basis for this observation exists.

Two principal models allow for the generation of individual human cell lines: (1) the immortalization of B lymphoblasts with the EBV and (2) the outgrowth of skin fibroblasts from tiny biopsies. Using EBV-transformed lymphoblasts from patients with hypertension^{40,43} and from patients with diabetes⁴⁵ and diabetic nephropathy,⁴⁶ a sustained increase in NHE1 activity could be demonstrated that prevailed in cell culture. Later, some findings were repeated with human skin fibroblasts.⁴⁷ Again, the enhancement of NHE1 activity was not related to an increased NHE1 transcript or protein expression. Together, these observations strengthened the notion that NHE1 is a prime candidate gene of human hypertension. Extensive sequencing efforts and linkage analyses, however, ruled out this possibility.¹¹

NHE1 is subject to a complex and multifaceted regulation integrating many different outside and inside signals of mammalian cells. Current concepts suggest that the increased NHE1 activity is a genetically determined marker for alterations in the upstream regulation of NHE1. This notion is further strengthened by experimental evidence showing an increased phosphorylation of the NHE1 proteins in hypertension with increased NHE1 activity in humans and rats.^{48,49} In diabetic nephropathy, however, increased NHE1 activity was not accompanied by an altered phosphorylation of the protein.⁵⁰ Furthermore, increased phosphorylation was not the only factor involved in the increased NHE1 activity in hypertension.

Because NHE1 is a substrate for several kinases, one strategy for unraveling an “initial” abnormality is to systematically follow these signaling pathways from the NHE1 protein upstream. Hence, an increased activity of the MAP kinase cascade has been reported in cells with enhanced NHE1 activity.⁵¹ Again, it is not clear whether this is the prime cause of enhanced NHE1 activity. Thus,

it remains open whether we will ever find such an “initial” abnormality. The chances are that there exist different factors contributing to an enhanced sensitivity of cells from hypertensive subjects. In such a scenario, an enhanced NHE1 activity could be a common integrator of various factors with a strong genetic basis.

G proteins and hypertension

Tightly linked to concepts of an enhanced reactivity of cells from some hypertensive patients, as mirrored by an enhanced NHE1 activity, we systematically began to investigate signal transduction upstream of NHE1 using the generated EBV lymphoblasts and skin fibroblasts.^{52,53} A crucial observation was that Ca^{2+} signals, elicited by typical GPCRs, are also increased in cells lines from hypertensive individuals. Treatment with pertussis toxin abolished these differences, indicating the involvement of $G\alpha_i$ type G proteins.⁵² A systematic sequencing strategy resulted in the discovery of a genetic polymorphism in *GNB3* (C825T), the gene for the $G\beta_3$ subunit associated with hypertension.¹³

Mechanistically, this polymorphism is associated with the occurrence of two alternative splice variants termed $G\beta_3s$ and $G\beta_3s2$.^{13,54} $G\beta$ subunits together with $G\gamma$ subunits in a stable dimer are potent regulators of many effector systems.²⁷ Protein crystallization studies have resolved the structure of the $G\beta\gamma$ dimer. The $G\beta$ protein consists of seven regular protein motifs called WD domains. These seven domains, which are highly conserved in all eukaryotes, form a propeller protein that exhibits a very compact and stable structure. This highly coordinated stable structure allows $G\beta$ proteins to assemble and coordinate other proteins which is how $G\beta\gamma$ dimers regulate effector systems.⁵⁵ The splicing to $G\beta_3s$ or $G\beta_3s2$ causes the loss of the equivalent of one WD domain upon translation of such transcripts (Figure 18–5).⁵⁴

Expression of these variants is associated with an increased signal transduction, as indicated by enhanced Ca^{2+} signals, accelerated proliferation, or increased

Figure 18–5. Models of $G\beta_3s$ and $G\beta_3s2$. Based on the protein crystallization data obtained from the highly homologous protein $G\beta_1$, the structure of the $G\beta_3$ protein is depicted (without $G\alpha$ and $G\gamma$). The picture shows the typical propeller structure consisting of seven WD domains (“propeller blades”) and an N-terminal helical extension. The yellow ribbons indicate the structural elements that are missing in $G\beta_3s$ and $G\beta_3s2$, caused by alternative splicing. In both cases the equivalent of one WD domain is missing, leading to a proposed structure of six WD domains.

stimulated GTP γ S binding (a measure of G protein activation).⁵⁶ It is difficult to explain how the loss of one WD domain translates into the gain-of-function of the system. One theory suggests that G $\beta\gamma$ dimers containing G β 3s or G β 3s2 are less suited to stabilize a G α subunit in its GDP-bound form as a heterotrimer. This could result in an increased sensitivity of such a heterotrimer toward activation by a receptor.⁵⁶ Although these concepts contain some plausibility, conclusive proof is missing.

Overexpression of G β 3s or G β 3s2 in different cell types and model systems mimics some of these issues, whereas other features are missing (e.g., the activation of certain effector systems by G β 3s or G β 3s2).^{54,57} Overexpressing G protein components into cell lines is a routine method of analyzing this system but bears some problems because it grossly disturbs a finely controlled balance of endogenous G-protein-signaling components. Presently, we have to conclude that despite considerable efforts the molecular nature by which a polymorphism in *GNB3* translates into a complex phenotype is as yet unresolved which contrasts with the considerable amount of data from genetic association studies.

Given that the 825T allele of the mentioned *GNB3* C825T polymorphism sensitizes signal transduction in all cell types where G β 3 is expressed, it is relatively easy to speculate that an enhanced signal transduction may affect vessel reactivity, the activity of the vegetative nerve system, or the signaling by vasoactive agonists (including angiotensin II and endothelins). This could ultimately result in hypertension. Again, a final proof of these concepts is missing. The discovery of the *GNB3* C825T polymorphism is a sequel of studies on NHE1 exchange activity. A convincing association, however, of the *GNB3* 825T allele with enhanced NHE1 activity (or SLC activity) in large human samples has not been demonstrated. A small sample could not describe a linkage between cation transport activities and *GNB3* polymorphisms.⁵⁸ Other relevant results from association studies pertaining to G β 3 are summarized in the section following.

GENETICS

SLC activity has been shown to be heritable to a high extent, but the genetic mechanisms have been difficult to identify so far. Several studies suggest that 50 to 80% of the population variation in SLC activity is attributable to genetic effects, with additional evidence for segregation at a single locus.⁵⁹ Increased SLC activity is already detectable in children and adolescents.⁶⁰ Similar associations between SLC activity and the phenotypic characteristics described have been demonstrated in many ethnic groups, including whites, Asians, and blacks.⁶¹ In blacks, however, absolute SLC activity is lower than in the other ethnic groups.

An important yet unresolved question is whether Na⁺/Li⁺ countertransport is an artificial transport mode of the ubiquitous NHE1, a debate starting shortly after the discovery of SLC. NHE1 and SLC differ in their susceptibility to inhibitors. Whereas NHE1 is potently blocked by amiloride derivatives, these compounds do not affect

SLC activity which is inhibited by phloretin, a compound that, conversely, does not affect NHE1.

The cloning strategy for NHE1 involved the application of a suicide selection process that relied on the acceptance of Li⁺ for Na⁺.¹⁷ Expression of the NHE1 cDNA in *Xenopus* oocytes conferred both Na⁺/H⁺ exchange and Na⁺/Li⁺ exchange activity.⁶² At first glance, this might represent a convincing argument for the molecular identities of NHE1 and SLC. The observation, however, that SLC became amiloride sensitive in *Xenopus* oocytes was difficult to understand and could be interpreted as the susceptibility to inhibition changes in oocytes or the fact that NHE1 is able to mediate SLC but only in the amphibian system.⁶²

Two more recent reports addressed this issue again. In 2001, Kammerer et al. reported an analysis of the variances in SLC activity in 634 non-inbred baboons comprising 11 pedigrees, a primate model for primary hypertension.⁶³ The heritability attributable to SLC activity in this model was almost 60%. In a multipoint genome-wide screen they found evidence for a possible quantitative trait locus (QTL) on baboon chromosome 5, which is homologous to human chromosome 4. This locus, which comprises a wide-stretched region of chromosome 5, was calculated to contribute two-thirds of the observed total genetic variability of SLC activity. This finding contrasts with the localization of the human NHE1 gene (*SLC9A1*) on chromosome 1. On the other hand, it is not imperative that genetic abnormalities that affect transport activity reside in the transporter gene itself. Polymorphisms in regulating pathways or interacting proteins can also cause genetically fixed transport abnormalities. Hence, these results underscore again the heritability of SLC but do not answer the question of identity.

In 2003, Zerbini et al. argued that SLC is mediated by a splice variant of NHE1 referred to as DNHE1.⁶⁴ Here, alternative splicing occurs with non-canonical splice sites in exon 1 and exon 2 (Figure 18–2B and C). By immunoblotting they demonstrated the existence of an immunoreactive protein with the predicted size of DNHE1 together with NHE1 in membranes from red cells and reticulocytes in similar amounts. Upon expression of the respective cDNA in fibroblasts lacking NHE1, an amiloride-insensitive but phloretin-sensitive SLC activity was measured. By semi-quantitative RT-PCR, an enhanced transcript expression of NHE1 plus DNHE1 was observed in mRNA prepared from whole blood of individuals with high SLC activity compared to subjects with low SLC activity. For a final answer, these results require independent reproduction. Notably, alternative splicing at non-canonical sites is a rare event and the predicted topology of DNHE1 raises some concern.

As mentioned in the “Pathophysiology” section of this chapter, the NHE1 has been considered an important candidate gene for hypertension research (which would also be true for a finally identified SLC gene). Intensive searches for polymorphisms in *NHE1*, however, did not result in the identification of functional or otherwise useful polymorphisms. Conversely, genetic linkage analyses provide good evidence that there is no relevant association between the locus for NHE1 and hypertension.^{11,12}

Searching for genetic polymorphisms in genes of proteins involved in NHE1 regulation led to the discovery of a C825T polymorphism in the gene *GNB3* encoding the G β 3 subunit of heterotrimeric G proteins. In association studies, the T allele of *GNB3* has been associated with the risk for hypertension. Interestingly, a common polymorphism in *GNAS* (the gene for G α_s) has also been associated with essential hypertension.⁶⁵

Pertaining to the *GNB3* C825T polymorphism, several reports reproduced the original finding whereas other groups could not.^{66–69} A major problem is the fact that there is a considerable variance in genotype distribution within different ethnicities.⁷⁰ Whereas the C allele is the predominant allele in Caucasians, in blacks the T allele prevails. Asians have intermediate frequencies. Hence, there is a high risk for disparate population admixture in case-control studies. The *GNB3* gene comprises a comparably short stretch of 6 kB DNA on chromosome 12. This explains why in Caucasians two haplotypes explain more than 95% of the observed variability.^{71,72} In other words, genotyping at the C825T locus provides information for six additional tightly linked polymorphisms. In Asians and in blacks, the situation is more complicated. Because we do not know which of the identified polymorphisms are ultimately necessary for alternative splicing to G β 3s or G β 3s2 different ethnic-dependent haplotype structures could be one solution to some discrepancies observed.

Numerous association studies dealing with the *GNB3* C825T polymorphism have provided additional information on the phenotype of hypertension linked to this polymorphism, although the results remained controversial.⁷³ There is no obvious association between *GNB3* polymorphisms and the severity of hypertension.⁷³ Several studies, however, suggest a higher risk for left ventricular hypertrophy⁷⁴ and stroke⁷⁵ in carriers of the *GNB3* 825T allele. The 825T allele was further linked to lower renin levels in hypertension.⁶⁷ Normotensive carriers with this allele were shown to exhibit reduced peripheral resistance and increased renal plasma flow.

The 825T allele was also linked to obesity and speculations were raised whether this gene contributes to the pathogenesis of a metabolic syndrome.⁷⁰ Of note, birth weight was also influenced by this polymorphism, an interesting finding as to the ongoing debate on birth weight and cardiovascular risk.⁷⁶ Of special interest is the observation that carriers of the 825T allele are subject to a better response to treatment with thiazide diuretics, a finding that was further modulated by effects of gender and ethnicity.⁷⁷ Altogether, the T allele of the *GNB3* C825T polymorphism is associated with a complex phenotype. Some results in this field are promising. Nevertheless, many questions regarding the mechanisms remain unanswered.

CLINICAL IMPLICATIONS AND PERSPECTIVES

At present, increased SLC activity is a well-described intermediate phenotype in hypertension and related diseases. The enhanced activity precedes the development

of primary hypertension and diabetic nephropathy. The measurement of SLC activity is comparably easy and its reproducibility in different laboratories is high. Furthermore, SLC activity remains rather constant within one individual over time. Nevertheless, enthusiasm for measuring SLC has diminished for three main reasons. First, there is considerable overlap in SLC activity between normotensive and hypertensive patients or between diabetic patients with and without nephropathy. Refined kinetic analyses that determine V_{\max} and K_M values for external Na^+ may lead to a better prediction, but they increase costs considerably. Second, knowledge about SLC activity does not change the therapeutic regimes for hypertension or diabetic nephropathy. Third, we have not yet understood the reasons for the kinetic abnormalities on a molecular level and the final pieces of this puzzle are still missing, which include the questions of its molecular identity and which genotypes are linked to SLC activity. There is first direct evidence that a splice variant of NHE1 mediates SLC. However, available evidence excludes the NHE1 gene as a candidate gene for hypertension. Together, this may explain why SLC activity determination has not become a routine method in clinical medicine.

The NHE1 gene has been excluded as contributing to hypertension pathogenesis. Other attempts, however, have studied the role of NHE1 in cardiovascular diseases especially in the context to reperfusion injury and an increased Na^+ load upon intracellular acidosis. Therapeutic drugs have been developed to inhibit these mechanisms, unfortunately without a significant benefit. These attempts have left several novel compounds for inhibition of NHE1. We are beginning to learn that NHE1 is not only an ion carrier but an integrator of many signals and an anchor protein for the regulation of the cytoskeleton. In the area of translational medicine, such NHE1-blocking compounds could in the end be useful for treating disease states not identified so far.

More than 200 studies have investigated the *GNB3* C825T polymorphism and described a complex phenotype that extends from cardiovascular medicine into other fields, including psychiatry and psychology, which is compatible with the diverse functions of G proteins expressed in all human cells. Although promising, the predictive value of this polymorphism (e.g., for individualized medicine, in diagnosis, or for pre-identification of responders) is limited. Observed effects with this polymorphism result from statistical comparisons between groups and are relevant for basic science purposes but have limited value for individual subjects or individualized medicine.

For scientific purposes, especially with case-control studies, it is of utmost importance to exclude confounding effects by different ethnic admixtures in case-control studies because *GNB3* C825T genotype frequencies vary extremely among the major ethnicities. Nevertheless, one can imagine that the *GNB3* C825T polymorphism together with other polymorphisms will be addressed in innovative diagnostic tools (e.g., in the field of pharmacogenetics with “SNP chip” or similar approaches).

SUMMARY

Enhanced activity of SLC, first identified in human red cells, is a well-characterized intermediate phenotype in hypertension and diabetic nephropathy. Its physiological role, however, remains elusive. Some speculate that SLC is an artificial transport mode Na^+/H^+ exchanger, especially of the Na^+/H^+ exchanger isoform NHE1. Different susceptibilities toward inhibitors argue against this notion. A recent report claims that SLC is mediated by a cryptic splice variant of NHE1, termed DNHE1, and not by the mature NHE1 protein.

Increased activity of Na^+/H^+ exchange is also a well-characterized characteristic of blood cells from hypertensive subjects. In both cases, however, there is a broad overlap between values from normotensive and hypertensive subjects (which diminishes the value for individualized diagnostic and, ultimately, for therapeutic decisions). The increased activity observed in blood cells is attributable to the activity of NHE1. Fundamental functions of NHE1 are protection from intracellular acidification and cell volume control. The activity of this transporter is subject to a complex regulation by phosphorylation and by interactions with ancillary proteins. Current understanding suggests that NHE1 is a multi-protein complex with tight connections to the cytoskeleton and other pH-regulating mechanisms.

In cell lines from hypertensive individuals (immortalization of B lymphocytes with the EBV or generation of human skin fibroblasts), the enhanced activity is retained

under cell culture conditions implying genetic mechanisms. Studies with cells taken *ex vivo* and experiments with immortalized cells indicate that alterations in the expression of NHE1 transcripts or protein do not contribute to the observed abnormality. Refined analyses present evidence that the phosphorylation of NHE1 is enhanced in hypertension. The NHE1 is a highly regulated transporter and available evidence suggests that upstream signaling systems may contribute to the activation of this exchanger in hypertension.

G proteins relay signals from many receptors to intracellular effectors. They consist of three different subunits termed $\text{G}\alpha$, $\text{G}\beta$, and $\text{G}\gamma$. Experiments with immortalized cells from hypertensive individuals indicated that the sensitivity of this system is increased in hypertension, that this propensity to enhanced signal transduction remains stable under cell culture conditions, and that such an enhanced signal transduction could cause the activation of NHE1. Systematic sequencing of many genes from components of this system led to the discovery of a polymorphism (C825T) in the gene of the G protein subunit $\text{G}\beta 3$ (*GNB3*).

Several association studies have reproduced these findings. Controversial reports, however, also exist. The distribution of the *GNB3* alleles varies significantly between different ethnicities, a potentially important confounder. Although the contribution of this polymorphism to the genesis of hypertension is limited, promising results indicate that this polymorphism could be used for prediction of an antihypertensive therapy (pharmacogenetic use) as shown for diuretics.

Chapter
19Arterial and Venous Function
in Hypertension

*Keshari M. Thakali, James J. Galligan, Gregory D. Fink,
and Stephanie W. Watts*

Key Findings

- Arteries carry blood away from the heart to tissues at a relatively high pressure. By contrast, veins carry blood back to the heart at considerably lower pressures.
- Arteries and veins are structurally and compositionally different, with arteries providing elastic resistance to flow and veins providing blood storage capacity.
- Arteries and veins are innervated by both the sympathetic and sensory nervous systems.
- Differences in vessel innervation, mechanics, receptor handling, endothelial cell function, and vascular smooth muscle cell growth exist between arteries and veins.
- Venous adaptations in response to high blood pressure have not been adequately studied as they have been in arteries, and hypertension-induced changes in contractility and remodeling are likely to occur differently in arteries and veins.
- An index of venomotor tone is increased in hypertension, suggesting that venous function contributes to this disease.

Hypertension has long been associated with arterial changes that increase total peripheral resistance in hypertension (see Chapters 16 and 30). Although there is no question of the relevance of arterial function to hypertension, the role of the venous system in hypertension is far from clear. The venous system, the “other half” of the vascular component of the cardiovascular system, has not been heavily studied because it is a low-pressure system that does not determine total peripheral resistance and has thus been viewed as largely unimportant in acute or chronic changes in blood pressure. However, a growing body of literature suggests that the ability of the venous system to redistribute functional blood volume can significantly alter blood pressure in a manner relevant to hypertension. The goal of this chapter is to present basic facts about arterial and venous vessels, highlighting differences where they are known. These facts are integrated into a picture of a current viewpoint as to how these differences may influence the physiology and pathophysiology of hypertension. In this chapter, we do not discuss the pulmonary and portal circulations, nor pulmonary and portal hypertension, and invite the reader to consult recent excellent reviews on these subjects.^{1–4} It should be noted that many of the comments that follow are general and necessarily broad sweeping. Vessel function and responsiveness—be it

arterial or venous—can be tissue and species dependent, and thus care should be taken in applying statements made here to all arteries and all veins.

ANATOMY/BIOCHEMISTRY

A safe rule of thumb to remember with respect to vessel function is that structure determines function. Arteries carry blood away from the heart at a relatively high pressure, whereas veins carry blood back to the heart at a relatively low pressure. This movement of blood, dependent on the pumping action of the heart, is critical for providing necessary oxygen and nutrients to all tissues—allowing for exchange of nutrients and waste products, and then for returning the blood to the heart for reoxygenation and removal of gaseous waste. Because the duties of arteries and veins are different, one can appreciate that their structure would be different.

The arterial and venous circulations are connected through capillaries, the site at which gas and solutes are exchanged. The development of the artery/capillary/venous system is coordinated. In development, arterial endothelial cells provide the ligand Ephrin B2, which can interact with the venous EphB4 tyrosine kinase receptor.⁵ Interactions between the Eph receptors and Eph ligands have emerged as a dominant theme in cell movement and tissue boundary development.⁶ The expression of Ephrin B2 in arterial and EphB4 in venous endothelial cells, respectively, is faithfully carried on into adulthood—and thus is described as a stable difference between arterial and venous vascular smooth muscle cells.⁵ Thus, the ephrin system (at least in the developing and adult mouse) is one that demarks arterial and venous tissue.

Structure

Fig. 19–1 depicts a cross section of a rendered artery and vein. Both artery and vein are composed of the following similar layers.

- The innermost layer (or tunica intima), which contains functioning endothelial cells, and in the case of the artery an elastic lamina.
- The tunica media, which is largely composed of smooth muscle, elastin, and collagen.
- The tunica adventitia, which is collagenous but sometimes composed of smooth muscle cells. The vasa vasorum (small blood vessels that integrate into the adventitia) provide nutrients to the blood vessel itself.

Figure 19-1. Structure of arteries and veins. Blood vessels are comprised of three layers: the innermost tunica intima, the tunica media, and the tunica adventitia.

Several differences exist between the structure of an artery and a vein. The layers of the blood vessel are more clearly delineated in an artery compared to a vein, and this is particularly illustrated when viewing the thoracic vena cava versus the thoracic aorta from the same rat (Figure 19-2, A). This is less apparent when comparing arteries and veins from humans (Figure 19-2, B). The media of an artery is typically thicker than that of a vein, and the elastic component of a vein is small when compared to that of an artery. Similarly, larger veins possess venous valves that in conjunction with contraction of the vessel assist in moving blood toward the heart. Collectively, these differences enable the arterial side to handle the high pressures produced by cardiac contraction and the necessity of bringing the blood to tissues, whereas the venous side acts in capacitive circulation—allowing blood to pool and serve as a low-pressure reservoir for blood. The ability of veins to accommodate a large percentage of total circulating blood volume (~70%) is an important fact for understanding how venous function could influence blood pressure.

Innervation

The sympathetic and sensory nervous systems innervate both arteries and veins.^{7,8} There have been few reports of nitroxidergic (nitric oxide, NO) autonomic nerves innervating blood vessels.⁹ Interestingly, whereas most systemic blood vessels have been described as being largely independent of parasympathetic innervation studies in the human greater saphenous vein demonstrate the presence of acetylcholinesterase-containing nerve fibers in the adventitial medial border.¹⁰ Axons of sympathetic and sensory neurons travel from ganglia paravascularly, ultimately arborizing in the adventitia and penetrating the vessels. Figure 19-3, A depicts fluorescence of norepinephrine in an artery versus a vein (sympathetic innervation), as well as staining of the sensory neuropeptide calcitonin gene-related peptide (Figure 19-3, B; CGRP, a marker for sensory nerves). Both vessel types are innervated by the sympathetic nervous system. However, it is apparent that the venous system is less densely innervated than the arterial system and that the sympathetic fibers that innervate veins are limited to

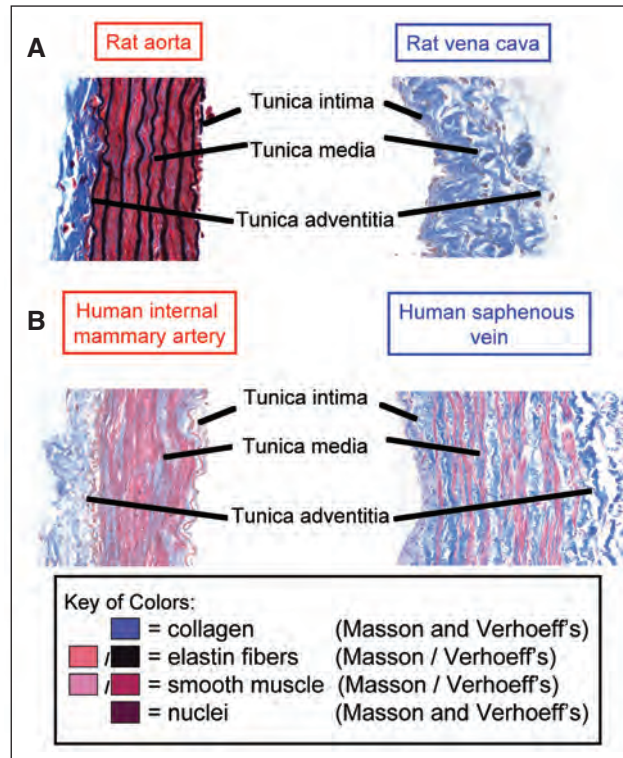

Figure 19-2. Histologic sections of Verhoeff-Masson-trichrome-stained rat thoracic aorta and vena cava (A) and Masson-trichrome-stained human internal mammary artery and saphenous vein (B). Verhoeff-Masson trichrome stain key: blue = collagen, pinkish purple = smooth muscle, black = elastin fibers, and dark purple = nuclei. Masson trichrome stain key: blue = collagen, pinkish purple = smooth muscle, red = elastin fibers, and dark purple = nuclei.

primarily venous adventitia, whereas sympathetic fibers on arteries typically penetrate the media.¹¹

Nonetheless, there is an important difference in how the sympathetic nervous system stimulates the artery and vein, thereby causing them to contract. Veins respond to a lower frequency of stimulation compared to arteries. If one performs a frequency response curve for a vein versus an artery, the response of the vein will be shifted leftward compared to the artery. An example of this is the mesenteric vascular bed in which veins respond to nerve stimulation at a frequency of 1 to 2 Hz, whereas arteries respond at a higher frequency (10 to 20 Hz).^{7,12} Thus, at any nonmaximal level of stimulation veins will respond with a greater contraction compared to arteries. Another difference between arterial and venous innervation is the fact that these two blood vessel types receive their innervation from separate sympathetic postganglionic neurons¹³ and perivenous sympathetic nerves release more norepinephrine when compared to norepinephrine release from periarterial sympathetic nerves.¹⁴ Finally, veins (of the mesentery) lack the ATP-dependent rapid excitatory junction potentials observed in arteries.¹²

Function

An exhaustive list of functional differences between arteries and veins is beyond the scope of this chapter. Here, we

Figure 19–3. Comparison of sympathetic (A) and sensory (B) innervation of rat mesenteric arteries and veins. Sympathetic innervation of arteries and veins was compared using glyoxylic acid fluorescence staining of catecholamines. Calcitonin-gene-related peptide (CGRP) immunoreactivity was used to compare sensory innervation of arteries and veins.

focus on those aspects of vessel function that are likely relevant to changes in vessel activity in hypertension.

Contractility

Change in the tone of an artery will result in alterations of total peripheral resistance, whereas similar changes in the vein results in changes in compliance/capacitance. Ours and other laboratories have observed numerous differences in arterial versus venous contractile responsiveness, and these differences range from the basic to agonist specific.

Because of smaller muscular content, a vein is not able to contract with the same magnitude of force as does an artery and is thus not handled in the same way experimentally. For example, if a comparably sized rat thoracic vena cava and rat thoracic aorta ring were mounted in isolated tissue baths for measurement of isometric contraction, the passive tension applied to the vein to bring smooth muscle cells to their optimum length is less (aorta, 4 g; vena cava, 1 g) and the maximum contraction to a receptor-independent agonist (e.g., KCl) is also less (e.g., 100-mM KCl aorta, 1.5 to 2.5 g; vena cava, 0.5 g). When one views the speed of contraction of an isolated vein compared to an artery, veins respond more quickly than

do arteries. This is evidenced by experimental measures such as time to half-maximal contraction (Figure 19–4). One can argue that this might be influenced by the receptor agonist used to elicit the concentration response curve. However, this same difference in speed of contraction is seen when the largely receptor-independent agonist potassium chloride (KCl) is used. Thus, the speed of mechanical contraction is different. We have begun to understand these differences by studying the forms of myosin heavy chains (MHCs) expressed in an artery and vein that contribute to the rate of actin/myosin association.

Similarly, differences in endothelial cell function exist. Our laboratory has not been able to obtain maximum relaxation to an agonist that stimulates production of vasorelaxant substances from the endothelial cell of the vein. A similar disparity was observed in the left circumflex artery versus middle cardiac vein of the pig,¹⁵ and in comparison of acetylcholine-induced relaxation in the human saphenous vein and internal mammary artery.¹⁶ A direct measure of NO in endothelial cells suggests that venous endothelial cells produce lower basal levels of NO compared to arterial endothelial cells, yet veins express a greater density of NOS proteins compared to arteries.¹⁷ A comparison of other endothelial-cell-derived substances has not been performed.

Differences in general sensitivity to adrenergic stimuli have been observed. For example, isolated veins (large and small) do not respond with a robust contraction to agonists of adrenergic receptors when compared to arteries, yet both arteries and veins are innervated by the sympathetic nervous system. Perez-Rivera has demonstrated that mesenteric veins (mouse) do not desensitize to adrenergic stimuli to the same degree observed in mesenteric

Figure 19–4. Representative tracings of arterial and venous contraction (measured in milligrams of tension) to the vasoconstrictor endothelin-1 (ET-1) demonstrate that veins contract faster than arteries. The time to half-maximal contraction to ET-1 (100 nM) is significantly shorter in rat thoracic vena cava compared to thoracic aorta.

arteries from the same bed¹⁸ and may have a complement of adrenergic receptors not present in arteries. Similarly, venous and arterial adrenergic vasoconstriction differs in response to hypoxia and metabolic inhibition in that veins appear to be relatively insensitive to hypoxia inhibition whereas arterial tone is potentially antagonized by the same signals.¹⁹ Intuitively, this makes sense because the veins necessarily operate under low-oxygen conditions.

One of the most interesting differences observed between arteries and veins is their intrinsically different response to endothelin-1 (ET-1). ET-1 is a vasoactive peptide produced within the endothelial cells of both veins and arteries. ET-1 exerts its physiological effects through combination with plasma membrane receptors, the ET_A and ET_B receptor. When the responses of multiple arteries and veins from different species are compared, three striking differences can be culled. First, veins are more sensitive to the contractile effect of ET-1 (threshold for initiating response is lower) and ET-1 is more potent (EC₅₀ value or effective concentration necessary to cause a half-maximal contraction is lower).²⁰ Second, veins respond to agonist of the ET_B receptor such as sarafotoxin 6C (S6c) or IRL-1620 with contraction, whereas arteries generally do not contract to these same agonists (Fig. 19–5). Third, arteries desensitize completely to ET-1, whereas veins maintain at least a partial response to ET-1 in the same conditions that would cause an artery to desensitize.²¹ These findings suggest that veins may be more responsive or continue to respond to ET-1 in conditions of chronic ET-1 exposure.

Growth

The previous section listed differences in arterial versus venous contractile responses. Differences are also observed in the parameter of growth (or mitogenesis). Specifically, isolated smooth muscle cells from a vein and artery behave differently in response to stretch. In cells placed in a Flexercell (an apparatus that provides cyclical and constant stretch to cells plated on flexible substrate), venous smooth muscle cells responded to cyclical stretch with mitogenesis/growth and arterial smooth muscle cells did not.²²

There has been the suggestion that in venous-to-arterial grafts it is the venous smooth muscle cell and *not* the surrounding arterial smooth muscle cells that are responsible for the arterialization of the vein. In other words, it is the vein that provides the cells that allow it to change to resemble an artery (thicker media). This is supported by the findings that smooth muscle cells from human saphenous vein have a higher growth rate than those from a human internal mammary artery.²³ Comparable findings were observed in rabbit saphenous vein and internal mammary artery.²⁴ An interesting difference between the arterial and venous smooth muscle cells in the rabbit was that arterial smooth muscle cells produced greater levels of the inhibitory proteoglycan decorin.²⁴ The lack of sufficient decorin production may be one reason for the greater synthetic rates of venous smooth muscle cells.

The endothelial cell of the vein seems particularly capable of producing signals that stimulate cellular growth.²⁵ Previously, we suggested that venous endothelial cells may produce less NO compared to arterial endothelial cells—another means by which growth may be promoted. Moreover, endothelial cells from veins do not respond with proliferation to minimally oxidized LDL as do arterial endothelial cells.²⁶

Reactive oxygen species (ROS)

Both NO and superoxide have been measured in arteries and veins. These reactive substances have been associated with altered contractility and remodeling of blood vessels. Guzik et al.¹⁶ demonstrated lower steady-state levels of both NO and reactive oxygen species (superoxide, peroxynitrite) in the human saphenous vein when compared to the human internal mammary artery, but the vessels were similar when parameters of NO bioavailability and superoxide/peroxynitrite production were compared. This suggests that although the overall systems of vasoactive ROS production may be lower in a vein than in an artery there does not appear to be differences in the balance between superoxide production and NO availability. This group has also shown that the source of superoxide in a

Figure 19–5. Differences in arterial and venous ET_B receptor function. Veins from sham normotensive and DOCA-salt hypertensive rats contract to sarafotoxin 6c (S6c), an ET_B receptor-specific agonist, whereas arteries for sham normotensive and DOCA-salt hypertensive rats do not contract to this agonist. Data are represented as mean \pm SEM. NE, norepinephrine; PE, phenylephrine.

human vein and artery differs, with the NAD(P)H oxidase system being a proportionately greater source in veins and xanthine oxidase the predominant producer in arteries. In addition, the subunit composition of the NAD(P)H oxidase enzyme differed in arteries versus veins. Veins expressed more nox 2, whereas arteries expressed quantitatively greater more nox 4. These measures in human vessels were preceded by measures in rats in which venules and arterioles of both Dahl salt-sensitive (Dahl-S) and salt-resistant (Dahl-R) were stained for tetranitroblue tetrazolium dye as a measure of superoxide content.²⁷

Superoxide is converted to hydrogen peroxide (H_2O_2) by the catalytic action of superoxide dismutases, and hydrogen peroxide has received significant attention as a long-lived signaling molecule compared to superoxide. Veins responded to exogenous H_2O_2 with greater contraction than did arteries.²⁸ The work described here suggests intrinsic differences in the ROS produced by an artery and a vein and how arteries and veins utilize ROS in signaling. We invite readers to consult Chapter 30 for further details on reactive oxygen species.

GENETICS

There is little relevant information about differences in molecular genetics that control function of a normal artery versus a normal vein, although venous function is highly heritable in humans.²⁹ Even less information is available in regard to how this control may change in hypertension. Adams et al. compared expression of 4048 genes in macaque aorta and vena cava and observed that mRNA expression of 68 out of 4048 genes were elevated in aorta compared to vena cava, with the largest difference in mRNA occurring in a regulator of G-protein signaling (RGS) 5. A similar pattern of increased RGS5 expression was also observed in rat arteries compared to veins.³⁰ RGS proteins are GTPase activating proteins and function to inhibit GPCR signaling. RGS5 overexpression inhibits endothelin-1-induced increases in intracellular calcium.³¹ On a purely speculative note, increased arterial RGS5 expression may explain differences in venous and arterial reactivity to vasoactive hormones and peptides, although this has yet to be shown experimentally.

One recent study investigated the impact of NOSIII gene polymorphism (T-786C, G894T) on endothelium-dependent and -independent venodilation in the human, but findings were negative in that vasodilation to bradykinin and sodium nitroprusside did not differ between wild-type humans and those with a single nucleotide polymorphism.³² Thus, differences in the gene expression between arteries and veins is an area ripe for investigation.

PHYSIOLOGY AND PATHOPHYSIOLOGY: FOCUS ON HYPERTENSION

A large body of work exists to support changes in arterial structure, function, and biochemistry in hypertension, and Chapter 12 in this book reviews this work. In general, arteries demonstrate changes in both their contractile ability and their structure.

Structurally, arteries undergo a process of remodeling in hypertension, an adaptive response of the artery to preserve its structural integrity against higher-than-normal pressures. The vascular smooth muscle cells in the media can become larger in size (hypertrophy), undergo mitogenesis (hyperplasia), and rearrange themselves such that the lumen of the blood vessel is smaller. This remodeling is accompanied by altered patterns of collagen secretion and activation of matrix metalloproteases and growth factors. Figure 19–6 shows Masson Trichrome staining of small mesenteric arteries and veins from sham normotensive and deoxycorticosterone acetate (DOCA)-salt hypertensive rats in which smooth muscle is stained pinkish-purple, collagen is stained blue, and nuclei are stained dark purple. The mesenteric artery wall from the DOCA-salt hypertensive rat is thicker when compared to the mesenteric artery from the sham normotensive rat. Other modifications can occur, but the end result is a stronger artery with a functional reduction in the lumen diameter. Because the resistance to blood flow is inversely related to the fourth power of the radius of the diameter, the changes in wall thickness and lumen diameter that occur in hypertension contribute to the disease. Functionally, arteries from hypertensive subjects show the following *in vitro* characteristics: (1) a general increase in sensitivity to contractile agonists such as serotonin, (2) a general decrease in sensitivity to relaxant agonist such as isoproterenol or acetylcholine, and (3) generation of spontaneous tone and oscillatory contractions.

Changes in venous reactivity have not been comparably studied, and venous structure under the condition of hypertension is not well investigated. For example, Aalkjaer et al. observed increased wall thickness and decreased lumen diameter in small mesenteric arteries from spontaneously hypertensive rats compared to their normotensive WKY counterparts, but did not observe any difference in wall thickness or lumen diameter from corresponding small mesenteric veins.³³ Figure 19–6 demonstrates that there are few obvious changes in structure in mesenteric veins from DOCA-salt hypertensive rats compared to sham normotensive rats, in that wall thickness is not different. It is unclear whether venous lumen diameter is consistently decreased in hypertension. Contractile experiments using isolated veins suggest that unlike an artery a vein does not dramatically change its response to agonists such as ET-1 and NE.^{14,20} Similarly, there appears to be little change in neurogenic responses of splanchnic veins in hypertension (DOCA-salt based) yet a potentiated neurogenic response in arteries from the same rats.¹⁴ Thus, in hypertension veins do not appear to possess the same altered structural characteristics as do arteries, and venous function seems uncompromised. A question therefore arises as to whether veins play a role in the development and maintenance of high blood pressure.

VENOCONSTRICTION AS A CAUSE AND/ OR CONTRIBUTOR TO HYPERTENSION

Ultimately, the differences in arterial and venous structure and function enable these two blood vessel types to

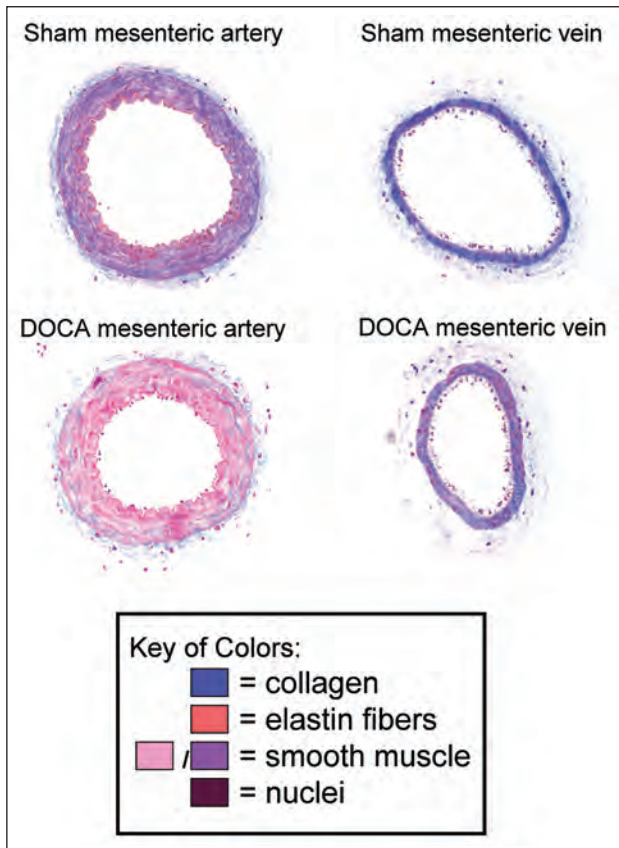

Figure 19-6. Masson trichrome staining of small mesenteric arteries and veins from sham normotensive and DOCA-salt hypertensive rats. Masson trichrome stain key: blue = collagen, pinkish purple = smooth muscle, red = elastin fibers, and dark purple = nuclei.

serve a different but complementary physiologic purpose in the body and specifically for determination of blood pressure. One model that encapsulates the complementary function of the venous and arterial system is the Coleman-Guyton model (Figure 19-7). One can immediately envision how changes in arterial function change total peripheral resistance (TPR) and thus blood pressure, whereas changes in venous function can alter venous return and modify cardiac output (CO). There is ample evidence to support the important role of arterial function in both maintenance of normal and elevated blood pressure. Drug treatment of human hypertension relies heavily upon reducing arterial function through blockade of adrenergic receptors, L-type voltage gated calcium channels, or formation of the vasoconstrictor angiotensin II. The reader is directed to Section IV in this book, which highlights these treatments. The present chapter briefly presents what is understood as to the physiologic and pathophysiologic roles of the venous system in determination of blood pressure.

The spontaneously hypertensive rat (SHR) shows an elevation of CO early in hypertension,³⁴ and this is validated in the young human with mild or borderline essential hypertension who has an elevated CO in the absence of an elevated TPR in early stages of blood pressure elevation.³⁵ These data suggest that changes in venous function may be an initiating factor in these cases of hypertension. A measure of venous function *in vivo* is mean circulatory filling pressure (MCFP). This is the average resting pressure throughout the circulation when the pumping action of the heart is stopped. It is determined by both blood volume and venomotor tone. Our group has recently measured MCFP in DOCA-salt animals immediately following implantation of DOCA. If

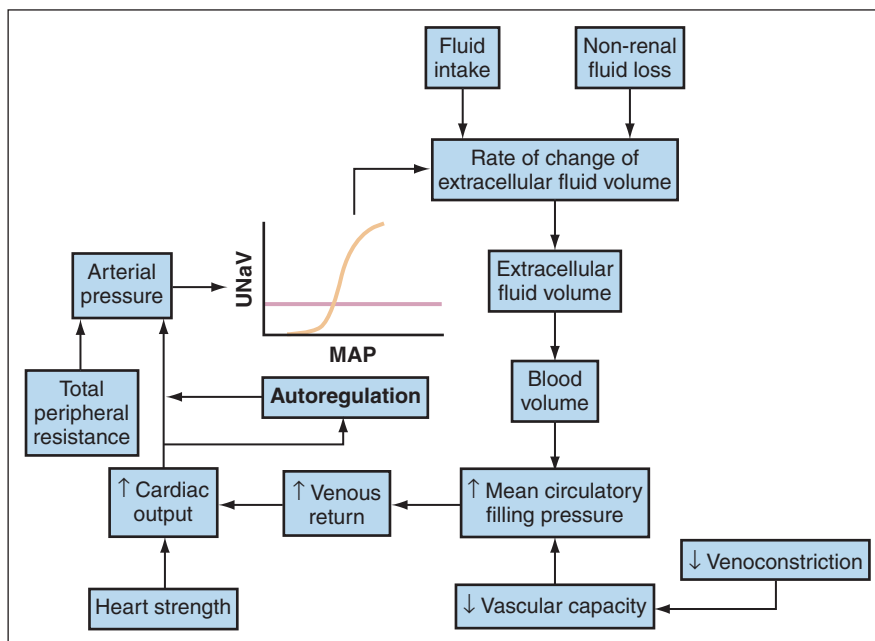

Figure 19-7. Guyton's model of the circulatory system demonstrates how both increases in arterial and venous tone can elevate blood pressure.

the hypothesis that MCFP (and thus venous functioning) is important to the initiation of blood pressure elevation, MCFP should rise before a rise in blood pressure or blood volume. This is, in fact, what we observed.³⁶ These important data suggest that venous function contributes to the rise in blood pressure. Others have observed an increase in MCFP in the adult SHR compared to WKY.³⁷ The question then becomes what causes venoconstriction. The finding by Martin et al. that pharmacologic ganglionic blockade resulted in a larger fall in MCFP in SHR compared to WKY suggests that the sympathetic nervous system may play a role in elevation of MCFP in the SHR. Similar observations have been made in the DOCA-salt model. This idea is supported by studies in which sympathetic input to small mesenteric resistance veins on the SHR and reduced-renal mass hypertensive rats was enhanced compared to normotensive controls.³⁸ If tone is elevated similarly in sympathetic neurons that innervate arteries and veins, changes in tone in veins may be greater than in arteries.

Venous changes observed in experimental settings of normal and high blood pressure are also observed, to some degree, in the human. In 1969, Walsh demonstrated that venous distensibility (and thus compliance) was reduced in essential hypertension.³⁹ Safar and London^{40,41} measured a decreased capacitance of the venous system in human hypertension, suggesting that venous contractility or structure had been altered. These were followed by studies suggesting that central (or trunk) blood volume (but not total blood volume) was increased in hypertension.⁴²

Genetic polymorphisms may play an important role in the decreased venous capacitance observed in human

essential hypertension. A polymorphism (C825T) in the G-protein $\beta 3$ (*GNB3*) subunit has been associated with hypertension.⁴³ The 825T allele of *GNB3* is characterized by enhanced G-protein signaling, and carriers of the 825T allele exhibit increased responsiveness to vasoactive hormones and peptides.^{44,45} Mitchell et al. observed that carriers of the C825T polymorphism of *GNB3* responded with enhanced venoconstriction to ET-1 and adrenergic agonists.⁴⁶ Whether enhanced venoconstriction in response to vasoactive peptides or increased sympathetic activity is causally linked to essential hypertension in carriers of the 825T allele of *GNB3* has yet to be established.

CLINICAL IMPLICATIONS AND PERSPECTIVES

The important message from this collective work is that venous function should be viewed as a parameter that can be modified for potential therapeutic treatment of hypertension. At the very least, venous changes and participation in blood pressure determination should be considered in evaluating physiologic models of hypertension.

SUMMARY

This chapter summarized both *in vitro* and *in vivo* experimental findings that underscore important basic differences in arterial versus venous structure, function, and signaling (Figure 19–8). These two different sides of the circulation respond to hypertension in different manners, such that the manipulation of the venous side presents an interesting and unique means of altering elevated blood pressure.

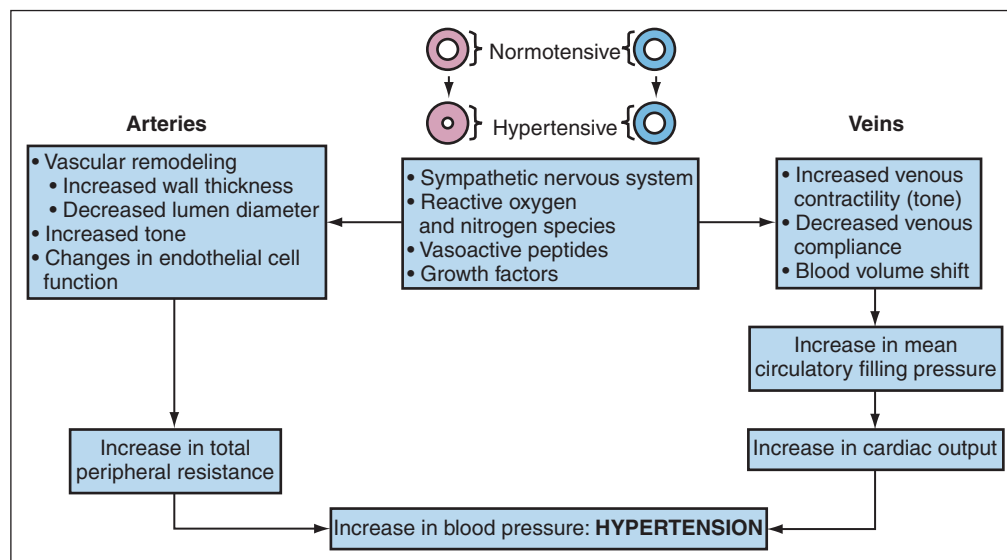

Figure 19–8. Summary of changes in arterial versus venous structure, function, and signaling that occur during the development and maintenance of hypertension.

Sodium Pumps

*Peter A. Doris***Definition**

The sodium pump is a membrane ion transport complex that plays a central role in renal sodium reabsorption.

Key Findings

- Renal transport of ions by the sodium pump is subject to regulation.
- Disturbances in pump function may be linked to hypertension through alterations in the pump itself, as reported in the Dahl salt-sensitive rat.
- Abnormal regulation may also alter function: defective dopaminergic regulation of the pump occurs in the spontaneously hypertensive rat, whereas defective interactions with cytoskeletal components participating in pump regulation create hypertension in the Milan hypertensive rat.

Clinical Implications

- Abnormalities in pump activity in rat models suggest that human hypertension may also be influenced by polymorphisms in pump structural or regulatory genes.

Few aspects of cell biology are more fundamental than the fact that cells are separated from their surrounding environment by a membrane. This cell membrane encloses the soluble cell proteins and is largely impermeable to them. These proteins (at normal cellular pH) are predominantly negatively charged and are neutralized by potassium ions, which are much more abundant in the intracellular fluid (~150 mmol/L) compared to the extracellular fluid (~4 mmol/L). The cell membrane is permeable to potassium ions, allowing these ions to enter to neutralize proteins. However, the proteins generate an osmotic effect that tends to draw water into the cells across the relatively water-permeable membrane. Swelling of cells is prevented by opposing the osmotic pressure generated by intracellular proteins with a high concentration of sodium ions outside the cell (~140 mmol/L), while maintaining a low intracellular sodium content (~15 mmol/L).

A central question in cell physiology for several decades in the middle of the last century concerned the mechanism producing this distribution of ions, essential to protect the cell from bursting as a result of osmotic swelling. Among the alternative explanations considered, the possibility that the cell membrane was impermeable to sodium was favored—in part because it exempted the cell from the high-energy cost implicit in any biological process to

redistribute ions. However, the fact that there is some sodium inside the cell suggested that this explanation might be false. The alternative explanation proposed that the transmembrane gradient of sodium is sustained by an energy-dependent secretory process to remove sodium from inside the cell. This explanation was proven to be correct and ignited a search to find and characterize the protein responsible for this activity. The work of Jens Skou, Robert Post, and others led to the identification of a membrane ATPase that could transport sodium ions asymmetrically from inside the cell in exchange for potassium ions outside the cell and showed that this enzymatic activity could be inhibited by plant-derived steroids and steroid glycosides related to digitalis.^{1,2} By this means, the activity and eventually the identity of the sodium pump became known. With these fundamental observations achieved, the path was opened to develop ever more detailed understanding of the sodium/potassium-ATPase that is the sodium pump. This understanding now extends beyond the key role played by the pump in solving the osmotic problem of the cell and includes understanding of its role in creating the membrane potential in excitable cells, coupling the transport of other substances into and out of cells, and (of greatest significance to this chapter) its role in achieving directional transepithelial ion transport.

Among the ion transporting epithelia, the renal epithelium (comprised of about 1 million nephrons per kidney) is remarkable for the enormous quantity of fluid and electrolytes that pass across it. The adult kidneys filter about 150 L of fluid from the blood each day. The majority of this fluid (>99%) and the solutes it contains (principally sodium and chloride) are reabsorbed, leaving only a fraction of the filtered material to be excreted. The sodium pump provides the main driving force of renal reabsorption. Extensive evidence now shows that blood pressure links to renal sodium reabsorption via the pressure-natriuresis mechanism.^{3,4} Elevation of blood pressure in the vessels perfusing the kidneys results in reduced reabsorption of fluid and electrolytes by the nephrons and consequently increased sodium excretion. This relationship appears to be altered in hypertension so that a higher level of blood pressure is required to maintain sufficient sodium excretion. In this manner, the persistently elevated blood pressure of hypertension can be regarded as an adaptive response directed toward maintenance of sodium homeostasis.⁴ Given the key role played by the sodium pump in this process, there has been great interest in the possibility that abnormality of sodium/potassium-ATPase function or its

regulation can be a causative factor in the pathogenesis of hypertension. This chapter examines the structure/function relationships of the sodium pump, its distribution and regulation, and evidence implicating the sodium pump in the pathogenesis of hypertension.

BIOCHEMISTRY

The P-type ATPase family includes four known mammalian isoforms of the alpha subunit of sodium/potassium-ATPase, as well as the sarcoplasmic reticulum and plasma membrane calcium-ATPases and the gastric and non-gastric H⁺/K⁺-ATPases (Table 20–1). In the kidney, only the alpha 1 isoform of the Na⁺/K⁺-ATPase is expressed. The 100-kD alpha subunits of Na⁺/K⁺-ATPase, as well as the H⁺/K⁺-ATPases, are associated with a glycoprotein beta subunit that is required via co-translational assembly for maturation, stability, targeting, and functional activity of the protein.^{5,6} Several isoforms of this beta subunit are encoded in the genome, but only the beta 1 subunit is expressed in the kidney.⁷ The kidney alpha-beta heterodimers have an additional subunit that is a member of the FXYP family of proteins, named for an invariant amino acid motif present in family members.⁸ Many of the seven members of the FXYP family have been shown to be associated with the sodium pump, but in the kidney only FXYP2 (gamma subunit) and FXYP4 (CHIF, corticosteroid hormone-inducible factor) are expressed and appear to modulate some aspects of pump function.

The sodium pump is an integral membrane protein in which the alpha subunit possesses 10 transmembrane spanning domains, whereas the beta subunit and any associated FXYP proteins each have a single transmembrane domain⁹ (Figure 20–1). The family feature uniting the

P-type ATPases arises from the existence of a transient phosphorylated intermediate during the pump cycle. This intermediate is formed as the gamma phosphate of ATP is transferred to the aspartate residue in a motif (DKTGT) that is common to the P-type ATPase. Although the high-resolution structure of the sodium/potassium-ATPase has not been obtained directly it has been inferred by homology mapping to the closely related sarcoplasmic reticulum Ca-ATPase (SERCA), whose crystals have been analyzed at 2.6Å resolution.¹⁰ This provides an important opportunity to begin to connect the extensive biochemical and physiologic understanding of the pump to its three-dimensional structure.

PHYSIOLOGY

To effect unidirectional transport across the renal epithelium, the sodium pump is distributed to the basolateral border of the nephron and occurs throughout its length. However, highest abundance occurs in the proximal tubules, the medullary thick ascending limb, and the distal tubule and adjacent connecting tubule.¹¹ The bulk of salt and water reabsorption occurs in the proximal tubule and is reflected in the high abundance of sodium pump in this region. Distal regions of the nephron are responsible for adjusting the final reabsorption of sodium, with aldosterone providing a dominant role in regulation at this site by controlling access of sodium ions to intracellular sites where sodium can be engaged by the pump and reabsorbed.¹² Distal tubule adjustments provide fine control of sodium excretion, whereas proximal tubule reabsorption contributes to the bulk recovery of filtered plasma fluid and electrolyte. Sodium reabsorption driven by the sodium pump in the ascending limb and distal convolution occurs in a region

THE P-TYPE ATPASES		
Group	Gene	Function
Ib	ATP7A	Cu ⁺⁺ -transporting ATPase, alpha polypeptide
	ATP7B	Cu ⁺⁺ -transporting ATPase, beta polypeptide
IIa	ATP2A1	Sarcoplasmic reticulum Ca ⁺⁺ -ATPase (SERCA1)
	ATP2A2	Sarcoplasmic reticulum Ca ⁺⁺ -ATPase (SERCA2)

	ATP1A4	Na ⁺ , K ⁺ -ATPase, alpha 4 subunit
	ATP4A	Gastric H ⁺ -K ⁺ -ATPase, alpha subunit

The P-type ATPases are a large and ubiquitous family of proteins with a characteristic pattern of conserved amino acid residues, including the DKTGTLT motif providing the aspartate residue (D) that is transiently phosphorylated by ATP during the pump cycle. This transmembrane protein generally has 10 membrane-inserted helices with large and conserved domains in the cytoplasmic loops linking M2 and M3 and M4 and M5. This table provides the members of the major groups represented in mammals. Many groups contain members that are present only in lower organisms.

Table 20–1. The P-Type ATPases

Figure 20–1. The structure of the sodium pump complex in kidney incorporating catalytic (alpha), structural (beta), and modulatory (gamma) subunits. The catalytic alpha subunit contains 10 membrane-inserted helices. The intracytoplasmic N-terminus is an important site of regulatory phosphorylation leading to engagement with the clathrin-coated pit mechanism of endocytosis. The second (large) intracytoplasmic loop contains the ATP catalytic site that is transiently phosphorylated during the ion transport cycle. The beta subunit is glycosylated at its extracytoplasmic surface.

of the nephron that is highly water impermeable, thereby allowing dilution of the tubular content as a result of pump-mediated fluid reabsorption. At the same time, osmolarity of the adjacent interstitial fluid is increased, providing a key mechanism allowing the establishment of a medullary concentration gradient by which renal concentration can occur. Thus, sodium pump function is adapted to perform specialized physiologic roles in different nephron regions. Although its action does not differ, its role is modified by virtue of the other properties of those regions and of the effect of upstream handling of renal filtrate that determines what is delivered.

REGULATION

The subcellular localization of the sodium pump has been the subject of much recent investigation that has revealed that the pump can be found in both plasma membrane and endosomal membranes.¹³ In this regard, the pump is not unlike G-protein-coupled membrane receptors that can undergo internalization from the plasma membrane after binding ligand.¹⁴ Just as G-protein-coupled receptors can be in locations providing or preventing access to ligand, so too the sodium pump appears to exist in pools distributed between the basolateral membrane from which pump-mediated transepithelial sodium reabsorption can occur and intracellular endosomal membrane compartments from which site net transepithelial reabsorption cannot be driven.

Although the sodium pump is synthesized *de novo* in the endoplasmic reticulum as a membrane-resident protein and is transported through the Golgi to the cell surface, its presence in the plasma membrane appears to require stabilizing interactions with the actin cytoskeleton.¹⁵ These interactions with actin involve ankyrin, fodrin, and adducin. Furthermore, the interaction between plasma-membrane-

inserted sodium pump and the actin cytoskeleton is a dynamic one in which movement out of the cell membrane by interaction with AP2 protein and clathrin via clathrin-coated pits can result in withdrawal of the sodium pump into endosomal membranes.^{16–18} Although this pump movement has been studied most extensively in the proximal tubule, it appears to represent a pump recycling mechanism by which the level of transepithelial ion transport can be modulated by altering the distribution of the pump between internal and external cell membranes. Interactions with AP2 and clathrin appear to be initiated by post-translational modification of the sodium pump on the alpha subunit, and considerable effort has been made to determine the kinases involved and the amino acid targets subject to phosphorylation.

The sodium pump also incorporates an extracellular receptor. The existence and identity of an endogenous ligand for this receptor continues to be a persistent controversy in sodium pump biology.^{19,20} The receptor clearly is able to bind cardiotonic steroid drugs, such as the plant-

derived cardiac steroid glycosides of the digitalis family, as well as structurally similar non-glycoside steroids produced as skin venoms by some amphibians. That these drugs and venoms evince an ion transport inhibitory action in response to liganding of the receptor is clear. This ion transport inhibition by cardiotonic steroids appears to be the biological basis of their therapeutic action²¹ that has been, and continues to be, exploited as an effective remedy for heart failure in Western medicine for hundreds of years and in traditional Chinese medicine for several millennia. The functional significance of endogenous ligand binding to the receptor site has remained obscured by several critical gaps in knowledge and understanding. For example, difficulties in identification of the chemical structure of the endogenous ligand continue to pose a real obstacle to the acceptance of the concept that this receptor site functions as an evolutionarily conserved tool of homeostasis.²² Another problem is that the universal distribution of the sodium pump suggests a lack of specificity of response to sodium pump ligands. An endogenous ligand could potentially affect essentially all cells in the body, and lack of specificity is a reasonable concern. In some species, the binding affinity of the receptor site incorporated in the alpha 1 subunit shows a high ligand off-rate.²³ This results in rapid ligand dissociation kinetics and thus proves problematic for a concept that invokes a role of the endogenous ligand as an inhibitor of the ion transport action of the pump wherein the biological consequence of ion transport inhibition presumably requires a shift in transmembrane ion gradients that are more readily achieved by ligands that have low receptor off-rates and so provide a persistent inhibition of ion transport. Indeed, some recent evidence suggests that the endogenous ligand is not a glycoside but rather a cardiotonic steroid similar or identical to a major cardiotonic steroid produced by amphibians.²⁴ Aglycone cardiotonic steroids

lack the stabilizing influence on receptor binding that is provided by the sugar residues incorporated in glycosides.²⁵

Recent information has come to light suggesting that existing concepts of the actions of cardiotonic steroids on the sodium pump are incomplete and pointing to a role of the ligand-sodium pump complex that lies outside ion transport. This new evidence suggests that ligand binding of the cardiotonic steroid site of the alpha subunit creates a signal transduction complex that results in activation of mitogen-activated kinase pathways leading to a number of potential biological outcomes, notably cell growth and proliferation.²⁶⁻³⁰ Additional evidence suggests interaction between the ouabain-liganded sodium pump and the inositol trisphosphate receptors that contribute to signaling via the induction of calcium oscillations.³¹ A substantial body of evidence from several sources has now accumulated in support of this signal transduction property,^{32,33} and a model encompassing some of the notable features is presented in Figure 20-2. This raises anew the question of the existence

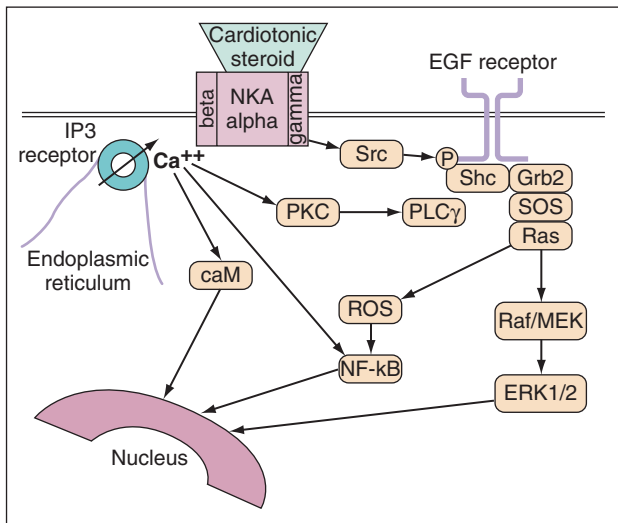

Figure 20-2. The signal transduction pathways proposed for cardiotonic steroid signaling through Na/K-ATPase. Na/K-ATPase may interact directly with the IP3 receptor in ER and initiate calcium oscillations, perhaps via a calcium-induced calcium release mechanism. Na/K-ATPase may also transactivate EGF receptor through Src, leading to association of Shc with phosphorylated EGFR, recruitment of Grb2, SOS, and conversion of Ras to its GTP-bound form. Ras-GTP signaling may activate mitochondrial reactive oxygen species generation (ROS) and operate through Raf1 (MAP3K) to initiate ERK1/2 signaling via MAP2K (MEK1). Interestingly, ERK1/2 activation by EGFR appears to result from internalized EGFR present in endosome and can be blocked when internalization is blocked. Thus, early endosomes may act as a signal coordination complex in which CS redirect Na/K-ATPase to the early endosomes and receptor tyrosine kinase acts on endosomal EGFR to initiate ERK1/2 signaling. Both ROS and calcium oscillations may act to suppress I- κ B inhibition of NF- κ B. These and signals resulting from activation of calmodulin (CaM) may all contribute to activation of transcriptional programs increasing cell growth and division. The role of Na:Ca exchange to elevate intracellular calcium that may be important in the inotropic action of cardiac glycosides in the heart is not included in this diagram because there is little evidence of this mechanism in kidney.

and functional role of endogenous cardiotonic steroids and offers some solutions to dilemmas that impede elucidation and acceptance of endogenous cardiotonic steroids. For example, the problem of organ or cell type specificity of endogenous cardiotonic steroid binding to the sodium pump might be accommodated by the coupling of the pump to second-messenger signaling functions only in selective tissues or cell types. The problem of cardiac glycoside-resistant isoforms is also resolved because signal transduction mechanisms do not require the persistent binding and sustained inhibition of ion transport to mediate their effects. Receptor-ligand interactions in signaling processes are generally highly transient and utilize rapid receptor on- and off-rates. Indeed, the rat isoform of the sodium pump that has a rapid ligand binding on- and off-rate and is thus highly resistant ($IC_{50} = 10^{-5}M$ to $10^{-6}M$) to the ion transport inhibition of cardiotonic steroids is fully sensitive to the signal transduction activation resulting from ligand-sodium pump interaction with ERK activation and growth responses detectable at $10^{-9}M$ and below.³²

The continuing evolution of insight into sodium pump biology suggests that there remains much unexplored scope to increase understanding of the role of the pump in the genesis of hypertension. However, much existing evidence has been developed already, particularly as the result of genetic investigations in animal models of hypertension in which the diversity and complexity of the disease phenotype is more restricted than in human populations.

GENETICS

The role of heritable factors in the genesis of essential hypertension demonstrates an extreme range when considered from the perspective of individual patients. Very rarely, mutations in a single gene can create hypertension.³⁴ Such mutations (because of the resulting hypertensive end-organ injury) can be seriously maladaptive, and barring the sustained intervention of modern therapies (and probably even in spite of them) are rapidly selected against in nature. The presence in the population of Mendelian forms of hypertension reflects both a small number of new mutations arising in pedigrees that were previously unaffected as well as a limited degree of transmission of these mutations from founders to their progeny. Many of the single gene mutations that produce hypertension do so by directly or indirectly affecting mechanisms of renal sodium reabsorption that are ultimately driven by the action of the sodium pump.³⁵

In most hypertensive patients, genetic factors play a significant but smaller role. This role is strongly modified by environmental variables and aging processes. Heritability represents the degree of similarity in a trait that can be attributed to the sharing of alleles that occurs among related individuals. Twin studies were the first to demonstrate that blood pressure is a heritable trait,^{36,37} and broader family studies confirm the heritability of blood pressure levels.^{38,39} Overall, blood pressure has a heritability of about 30 to 40%. However, and in contrast with single-gene Mendelian forms of hypertension, this heritability shows no simple pattern of transmission within families. This fact suggests that the

inheritance of blood pressure levels and hypertension susceptibility may be polygenic and that susceptibility alleles of multiple genes may interact within individuals as well as between the individual and their environment (diet, lifestyle, exercise, stress, and so on) to create the heritability of blood pressure. Although remarkable progress has been made to uncover gene mutations contributing to rare Mendelian forms of hypertension, efforts to identify genes and the variation they contain that contribute to common polygenic hypertension are confronted by substantial obstacles arising not only in the effect of environmental variation but from within the genetic architecture of disease susceptibility.^{40–42} These arise from the possibility that the allelic variation contributing to hypertension is greater in society as a whole than within affected families. Thus, the causal alleles segregating in two different families might partially overlap, or may be completely independent. This allows an unknown degree of genetic heterogeneity. Given the fact that blood pressure is subject to regulation via an extremely broad range of physiologic systems (endocrine, vascular, autonomic, renal), the potential for variation in a very large number of genes to contribute to population patterns of hypertension occurrence cannot be discounted. Each additional gene involved in hypertension in the population reduces the power of population gene mapping studies to localize that gene to a particular region of a particular chromosome, the first step necessary on the path to identifying the gene. The task is made more difficult by the likelihood that some hypertension gene variants are capable of epistatic interaction.^{43,44} This interaction means that the effect of the gene variant on the phenotype is affected by other gene variation in a multiplicative, rather than simple additive, way. This can increase the difficulty of gene identification because the effect of the causative allele in a given individual is strongly affected by variation at other sites within the genome.

Given the complexity of the heritability of hypertension in humans it is not surprising that animal models of the disease that provide a homogenous genetic mechanism and allow greater opportunities to extend genetic evidence directly to altered function have been a useful means of understanding the mechanism of polygenic hypertension. Several rat models of hypertension have been inbred to genetic homogeneity. Inbreeding results in identical copies of each gene at every locus on every diploid chromosome, which thus further simplifies the genetic background in which hypertension alleles function. These models have taken advantage of natural allelic variation affecting blood pressure and hypertension susceptibility. By selecting from outbred rat populations those individuals with higher blood pressures (at baseline or under salt loading) and selectively breeding these individuals to concentrate hypertension alleles within individual animals, numerous inbred models of hypertension have been developed—including the SHR (and various substrains),⁴⁵ the Dahl salt-sensitive rat,⁴⁶ the Milan hypertensive rat,⁴⁷ the Sabra rat,⁴⁸ and the New Zealand hypertensive rat.⁴⁹ In the first three of the strains mentioned, evidence suggests that sodium pump function is directly or indirectly altered as part of the genetic mecha-

nism leading to hypertension. This is perhaps not completely surprising because of the key role of the sodium pump in renal transepithelial sodium reabsorption. It also stresses the importance of a full understanding of sodium pump biology as an important aid to uncovering the genetic and pathogenetic basis of hypertension in humans.

The Dahl salt-sensitive rat (SS) possesses a nonsynonymous mutation in the alpha 1 subunit of the sodium pump.⁵⁰ This polymorphism results in the substitution of leucine for glutamine at amino acid position 276 (Q276L), which alters the hydrophobicity of a region of the pump that is involved in the formation of the transmembrane pore. There has been considerable controversy over the existence of this sequence variation, and before exploring the evidence that this variant is responsible for a pump-mediated role in the genesis of hypertension the main facts of the controversy should first be considered.

The initial report identified the polymorphism and indicated that it alters the hydrophobicity profile of a region of the protein believed to be involved in coordination of ion binding, resulting in a reduction in potassium ion transport and a putative role in hypertension.⁵⁰ This report appeared almost concurrently with a co-segregation study performed by another group that addressed whether a restriction fragment polymorphism located in or nearby the alpha 1 subunit was associated with blood pressure levels in Dahl SS measured by tail cuff. These authors concluded that it was not, or rather that it did not act with sufficiently large effect to be detected by the rather imprecise tail cuff blood pressure measurements used.⁵¹ Similarly, only pulse pressure showed a significant positive association with inheritance of SS alleles of the sodium pump when blood pressures were determined in directly cannulated anesthetized animals.⁵² Another study using more precise telemetry measurements did report linkage between the alpha 1 subunit in Dahl SS and inheritance of blood pressure.⁵³ The sodium pump polymorphism reported in Dahl SS rats could not be confirmed by another group using restriction digestion at the mutant site of PCR-amplified genomic DNA and was also undetected by resequencing the gene.⁵⁴ The polymorphism reported creates an interesting stem-loop structure that might contribute to sequencing errors or to amplification-induced mutation. The absence of the reported nonsynonymous polymorphism was also confirmed by another group using restriction digestion of PCR-amplified DNA as well as mini-sequencing reactions.⁵⁵

Because of this contradictory data, the initial report of sodium pump polymorphism has been extended and confirmed by its originators very thoroughly using a range of techniques directed to DNA and RNA sequence coding the alpha 1 subunit gene as well as to the pump protein itself.^{56,57} Furthermore, the generation of a transgenic rat in which the Dahl salt-resistant (SR) rat gene was reconstructed (including the proximal 5' regulatory sequence and some 3' untranslated sequence) and expressed in the Dahl SS rat resulted in phenotypic shifts in blood pressure, renal injury, and extended life span—all consonant with a role of the Dahl SS sodium pump in hypertension.⁵³ Although this transgenic model is not as complete a genetic test as would be achieved by a knock-out/knock-

in strategy, it is still supportive of the role of the Dahl SS allele in the generation of hypertension. Furthermore, a recent report indicates that amino acid sequencing of the alpha subunit from Dahl SS confirms the expected amino acid change, that decreased potassium and increased sodium affinity of the partially purified pump protein is observed in Dahl SS kidney, and that susceptibility to proteolytic cleavage differs in a manner consonant with altered hydrophobicity of the pump predicted from the amino acid substitution.⁵⁶

This contradictory evidence may find a rational explanation, although one that accounts for all of the discrepant results that have been recorded among investigations of Dahl SS is not yet forthcoming. Before reaching a conclusion about the role of the sodium pump in Dahl SS hypertension, it is important to recognize that all gene variation exists in haplotypes that distinguish one allele from another by sequence variation at one or more sites within the gene and adjacent chromosomal sequence. It has become clear from investigation of this model that even excluding the Dahl Q276L polymorphism at least two haplotypes of the alpha 1 subunit exist and differ between Dahl SS and Dahl SR rats. This is apparent because detailed sequence analysis performed during the course of investigating the Dahl SS rat has revealed additional intronic polymorphisms^{52,55} in this gene. At least one of these polymorphisms is also present in some other inbred laboratory rat strains.⁵⁵ It is worthwhile to consider where and how such gene haplotypes arise. Haplotypes represent adjacent sequence variation on the same haploid chromosome. Most often this is single-nucleotide polymorphism, although deletions, insertions, and sequence repeats are not uncommon. By virtue of its close proximity in the same genomic locus, the resulting sequence variation tends to be inherited as a unit and is separated from adjacent sequence variation by recombination only very rarely. A new haplotype can be created by a novel mutation or by a recombination event occurring at the locus of the haplotype that creates a new combination of existing sequence variation on the same chromosome. By genetic drift or natural selection, the newly created haplotype may become more frequent in a wild population.

Genes (such as the alpha 1 subunit gene) that are multi-exon genes covering tens of thousands of bases may contain extensive natural variation in wild animals that has been carried forward in laboratory strains—allowing the possibility that two distinct haplotypes of the alpha 1 subunit gene might become fixed when generating any contrasting inbred strains. At present, five single-nucleotide polymorphisms in the rat alpha 1 subunit gene are recorded in the public NCBI database (dbSNP). These five SNPs permit the existence of up to 25 different haplotypes of the rat alpha 1 subunit. Because much of the gene sequence outside the specific polymorphisms that have been the subject of investigation in Dahl SS and other hypertensive rat strains has gone uninvestigated or incompletely investigated, it is not yet possible to determine whether all functional sequence variation responsible for an effect of the alpha 1 subunit on sodium pump function has been uncovered.

In addition to the well-validated but controversial studies of sodium pump gene variation in the genesis of hypertension in Dahl SS rats, it is notable that disease gene mapping studies have placed hypertension susceptibility in the same locus as the alpha subunit of the sodium pump in another distinct model of the disease, SHR (and SHR-SP).^{58–60}

In SHR, extensive physiologic evidence indicates an abnormality in the regulation of proximal tubule sodium reabsorption that precedes the development of hypertension. Nephron micropuncture studies in young SHR have demonstrated increased proximal sodium reabsorption.^{61,62} This has been extended to conscious animals in studies using fractional reabsorption of lithium, an indicator of proximal sodium reabsorption that provides further support of altered renal sodium handling in SHR.⁶³ In older SHR animals, changes in proximal sodium reabsorption are lost.⁶¹ However, sustaining proximal sodium reabsorption in mature hypertensive animals required a much higher renal perfusion pressure, indicating that the pressure/natriuresis relationship is shifted to allow the acquisition of sodium balance by sustaining a higher level of blood pressure. Similar abnormalities of proximal tubular sodium reabsorption have been observed using lithium clearance in the Dahl SS model of hypertension.⁶⁴ Because the sodium pump drives proximal sodium reabsorption, it must have primary or secondary involvement in the abnormal sodium reabsorption.

As indicated previously, regulation of sodium pump activity is achieved in part by phosphorylation events that are the output of signal transduction systems.^{65,66} Dopamine clearly plays an important role in regulation of proximal tubule sodium reabsorption and appears to do so through regulation of the activity of both proximal tubule luminal sodium entry pathways and the active transport of sodium by the pump in proximal tubule basolateral membranes.^{65,67} Felder and Jose have developed an extensive series of studies demonstrating that dopamine-mediated inhibition of proximal tubule sodium reabsorption, which occurs via the cAMP-coupled D1 receptor, is deficient in SHR in spite of increased local renal dopamine production.⁶⁸ This is accompanied by a redistribution of dopamine receptors from the cell surface that is similar to the ligand-induced G-protein-coupled receptor desensitization/internalization phenomenon.⁶⁹ This work has led to vigorous investigation of sequence variation in the dopamine receptor as well as its regulatory kinase (GRK4). Unfortunately, none of these gene targets has resulted in evidence for gene variation in the induction of hypertension in SHR. The issue of whether dopamine signaling deficits are secondary to changes in ion transport mechanisms that are autonomously able to increase sodium reabsorption that then drives secondarily increased dopamine-mediated inhibitory responses (and consequently leads to receptor desensitization) has not been finally answered. What is clear at present is that among the genes involved in dopamine signaling of increased proximal tubule sodium reabsorption and elevated blood pressure in SHR the alpha 1 subunit of the pump is notable in being located in a chromosomal region that has consistently been shown to associate with the inheritance of elevated blood pressure.

Positional mapping evidence that the chromosomal locus containing the alpha 1 subunit is involved in the genesis of hypertension has been further strengthened by the generation of a congenic SHR substrain in which substitution of this locus with the corresponding one from WKY results in a significant reduction in blood pressure.⁵⁸ Abnormalities in the sodium pump in young SHR include the pump's altered subcellular distribution with a greater proportion of the available pump protein present in the basolateral membrane (Figure 20–3) and a smaller portion in endosomal compartments.⁷⁰ This shift is apparent during the period when proximal tubule sodium reabsorption is increased prior to the onset of hypertension. When hypertension is mature, this altered distribution is restored to normal. Here again, however, it is unclear whether the altered subcellular targeting of the pump protein is a primary genetic phenomenon or secondary to dysregulation in some other pathway.

Whether genetic alterations in the sodium pump are responsible *per se* for elevation of blood pressure in SHR and Dahl SS rats is not yet completely clear. In the case of SHR, the field might be moved forward by determining whether the dopamine signaling deficits and sodium pump subcellular localization alterations are repaired in the congenic model in which the SHR alpha 1 sodium pump locus is replaced by that of WKY. Such insight could begin to sort out whether dopamine signaling defects and altered subcellular localization are attributable to sequence variation in a locus containing the renal alpha subunit or whether they arise from another region of the genome.

By selective breeding from out-bred Wistar rats, Bianchi and colleagues created another rat model of hypertension: the Milan hypertensive strain (MHS).⁴⁷ This model unequivocally indicates the capacity of mechanisms altering renal sodium pump function to generate increased blood pressure.

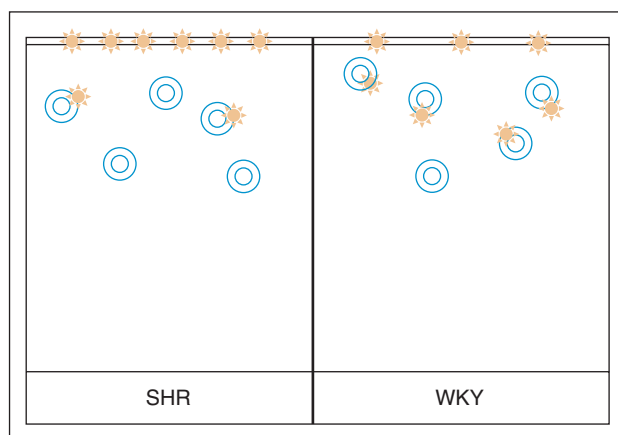

Figure 20–3. Altered subcellular distribution of Na/K-ATPase in basolateral membrane of renal proximal tubules in SHR. Sodium pumps (star) are distributed between endosomes (double circle) and the basolateral membrane (upper border). In young SHR, the abundance of sodium pump protein in the basolateral membrane is almost twice that in WKY, whereas pump abundance in the late endosomes is reduced in SHR compared to WKY. This mistargeting may contribute to the excess sodium reabsorption observed during the development of hypertension in this model.

Early investigations pointed to a renal abnormality in MHS with increased proximal tubule sodium reabsorption as a key element.⁷¹ Alterations of ion handling were also observed in other cell types, including erythrocytes.⁷² Ultimately, the alpha subunit of adducin (one of several cytoskeletal proteins believed to influence actin cytoskeleton dynamics) was found to be polymorphic in MHS.⁷³ Reciprocal congenic strains isolating the two adducin variant alleles in normotensive and hypertensive rats confirms the effect of variation at this locus on blood pressure.⁷⁴ This adducin polymorphism expressed in cultured renal proximal tubule cells impairs dopamine-mediated endocytosis of the sodium pump and blocks the interaction between the sodium pump and adaptin subunits necessary to mediate the cytoskeletal interactions that effect internalization of the pump.⁷⁴ Consequently, there is increased stability of pump protein inserted in the basolateral membrane, inhibition of the normal recycling of pump protein from the basolateral membrane to intracellular membrane sites, and an increase in both sodium pump activity and sodium reabsorption.

This work in MHS stimulated an investigation of the existence of polymorphisms in the alpha, beta, and gamma subunits of adducin in humans. The identification of such variation has led to a number of studies that have not yet generated a completely clear consensus of the likely role of naturally occurring common variation in these genes in the pathogenesis of hypertension in humans. Indeed, the challenges that must be confronted by such studies are rather great. First, a decision must be made to study a categorical (hypertension versus normotension) or a quantitative trait (blood pressure level). Second, it must be recognized that there is likely genotypic heterogeneity in hypertension in humans and that the portion of phenotypic variation, if any, affected by adducin polymorphism may make identification difficult unless populations are large and the susceptibility allele is reasonably frequent and able to modify the trait substantially. Furthermore, the hypertension phenotype is heterogeneous, and various classifiers may be used to distinguish subtypes that meaningfully relate to the underlying genetic mechanism. Depending on the unknown extent of genetic heterogeneity and the size of the study population, it may be necessary to select a subgroup of hypertensives (e.g., salt sensitive) to demonstrate the effect of adducin polymorphism. This may explain the dissonant findings that have emerged in human genetic studies of adducin. Several studies examining linkage and association of variation in or around adducin genes report positive findings, whereas others do not. A recently published meta-analysis of these many studies summarizes the evidence for adducin involvement in salt-sensitive hypertension and reaches an understandably cautious conclusion.⁷⁵ This cautious conclusion in humans contrasts with that in rats and may be related to the fact that clear and consistent functional consequences of MHS adducin polymorphism on membrane ion transport are apparent in MHS. Similar evidence at the *in vitro* cellular level of functional consequence of human adducin variation is limited and is derived principally from studies of erythrocytes,^{76,77} with evidence of altered renal ion transport limited to indirect studies.⁷⁸

PHARMACOLOGY

The observations of a key abnormality in sodium-pump-mediated renal sodium reabsorption in MHS has led to a pharmacological approach to alter sodium pump function as a means of treating hypertension and related disorders. Part of the rationale of this approach appears to reside in the finding of increased immuno- and bioassay measurement of levels of endogenous cardiotonic steroid in MHS⁷⁹ and the potential role of this material in elevation of blood pressure. This stimulated the identification of a cardiac glycoside, PST2238, which has reduced cardiac activity and is able to correct the abnormal sodium pump function and blood pressure in MHS.^{80,81} It is interesting that PST2238 appears to be able to regulate sodium pump function in hypertension, whereas the dopamine inhibition of the pump is suppressed. These effects appear to develop over relatively long time courses. Dopamine regulation of sodium pump activity leading to transepithelial ion transport is inhibited in MHS, and this appears related to its inability to initiate sodium pump internalization from the basolateral membrane to internal endosomes.⁸² Ouabain has recently also been shown to be able to cause internalization of the sodium pump in renal epithelial cells. If PST2238 acts as a ouabain agonist with respect to internalization, this might explain the inhibitory effect on pump function activated by adducin polymorphism. However, exposure to ouabain appears to mimic the adducin polymorphism in producing increased pump activity, and PST2238 also antagonizes this effect. Other antagonistic effects of PST2238 on ouabain-induced pump function have recently been reported.⁸³ Clearly, considerable fundamental pharmacological investigation is required to understand the mechanism of PST2238 action. However, present evidence in this nascent field suggests that abnormal pump function

contributing to hypertension may be corrected by specific pharmacotherapies targeting the cardiotonic steroid binding site of the pump.

SUMMARY

Sodium pump activity drives renal sodium reabsorption and provides a potential mechanism by which altered regulation can contribute to hypertension. Altered regulation of the pump can be primary or secondary. In animal models, evidence consonant with a primary role of the pump attributable to allelic variation in the pump has been obtained in animal models. In the Dahl SS rat, this evidence is centered on polymorphism in the renal catalytic subunit of the pump but has been disputed. In SHR and New Zealand hypertensive rat models, positional mapping approaches point to an important hypertension locus in the region of the renal catalytic subunit gene, and in SHR there is a shift in subcellular targeting of the pump in the renal proximal tubule during the development. SHR also shows altered regulation of proximal tubule pump activity by dopaminergic signaling. Further work is required to determine whether alterations in pump function in these models are due to primary genetic variation in the gene encoding the renal catalytic unit of the pump, although this is consistent with available data. In human essential hypertension, many obstacles impede the identification of genes and their pathogenetic process in contributing to hypertension susceptibility, although in some hypertensive subgroups interesting parallels have been observed between rat models and human hypertension—including altered proximal tubule sodium handling and abnormal regulation of the renal sodium pump by dopamine signal transduction mechanisms.

Chapter
21Platelet and Coagulation
Abnormalities

George I. Varughese and Gregory Y. H. Lip

Key Findings

- Hypertension is associated with the flow of blood under high pressures, yet the complications of hypertension, such as myocardial infarction or stroke are paradoxically thrombotic rather than hemorrhagic.
- Increasing evidence suggests that hypertension fulfills the prerequisites of the Virchow triad for thrombogenesis, leading to a prothrombotic or hypercoagulable state.
- Hypertension leads to changes in platelets, endothelium, and coagulation and fibrinolytic pathways that help to promote the induction and the maintenance of this prothrombotic state.
- Study of the prothrombotic state in hypertension is of paramount importance, as understanding the pathophysiologic processes underlying it can help prevent many of the thrombosis-related complications associated with hypertension.

Clinical Implications

- The prothrombotic state in hypertension can to a certain extent be reversed by the treatment of hypertension, although different antihypertensive agents may have variable effects in reversing these changes.
- Some of the effects are related to blood pressure normalization, but drugs such as those acting on the renin-angiotensin-aldosterone system appear to have an effect over and above this.
- Antiplatelet agents have been shown to confer a degree of benefit to high-risk hypertensive patients, as long as their blood pressure is well controlled.

Hypertension is a well-recognized risk factor for coronary artery disease, atherosclerosis, and cerebrovascular disease. In hypertension, the arterial walls are exposed to the flow of blood under high pressures; nonetheless the common complications of hypertension (such as myocardial infarction or stroke) are ironically thrombotic rather than hemorrhagic—the so-called “thrombotic paradox of hypertension.”¹ Hypertension fulfills the basic rudiments of the Virchow’s triad—that is, abnormalities in the vessel wall, bloodstream, and blood constituents—described more than 150 years ago, thus enhancing thrombogenesis.² In the 21st century, we recognize “abnormalities of the vessel wall” to comprise endothelial damage or dysfunction, while “abnormalities in the blood constituents” include abnormalities in hemostatic and fibrinolytic factors, as

well as platelet activation, and “flow abnormalities” as abnormal shear stress and impaired flow reserve. While Virchow originally referred to venous thrombosis, the basic concepts of the triad can be applied to arterial thrombosis in hypertension. These have also had considerable clinical importance due to the prospect for reversing some of the underlying pathologic mechanisms by effective treatments.

PLATELET ABNORMALITIES AND CHANGES IN HYPERTENSION

Platelets in patients who have hypertension differ from those of normotensive subjects in their size, shape, volume, and life span, and they also demonstrate an increased tendency to aggregate.^{3–5} Abnormal platelet aggregation as well as increased plasma markers of platelet activation are present in the setting of hypertension.^{6–9} Biochemical indices released from platelets in those with hypertension such as beta-thromboglobulin^{10,11} and soluble P-selectin^{12,13} also show evidence of increased platelet activation, as reflected by abnormalities in their levels.^{14–16} In addition, there is evidence of raised intraplatelet calcium levels^{17–19} in the setting of hypertension.

The increased shear stress contributes to platelet activation in hypertension, leading to an increased release of platelet microparticles.²⁰ Platelet microparticles are a relatively novel discovery²¹ and high levels of platelet microparticles are seen in patients with severe hypertension compared to normotensive individuals.²² These microparticles may add to a prothrombotic state by promoting thrombin generation and platelet adhesion to the vessel wall. Indeed, they contain glycoproteins IIb and IIIa, as well as P-selectin and thrombospondin, leading to binding to the subendothelial matrix causing even greater platelet activation and binding, thus causing a vicious cycle of a greater propensity to thrombosis.

Neuroendocrine factors, such as alterations in angiotensin II and catecholamine levels can also affect the platelets in patients with hypertension, which are more sensitive to increased levels of catecholamines²³ that in turn are potential stimulators for platelet activation and aggregation (Box 21–1). Other subtle factors, such as the increased expression of adrenoceptors²⁴ and increased viscosity of the blood in hypertensive patients, enhance platelet activation.²⁵

Finally, many commonly coexistent conditions with hypertension, such as diabetes,²⁶ atrial fibrillation, and congestive heart failure, are also well recognized to activate platelets.^{27,28}

Box 21-1**Abnormalities of Platelets
in Hypertension****Physiologic Abnormalities**

Increased size, volume, and turnover
Distortion in shape
Decreased life span

Biochemical Abnormalities

Increased levels of intracellular free calcium and sensitivity to catecholamines
Decreased levels of intracellular catecholamines, serotonin, and intraplatelet nitric oxide
Decreased calmodulin levels and capability to take up monoamines such as serotonin

Functional Abnormalities

Increased potential for spontaneous aggregation
Increased potential for platelet adhesion
Increased ability for platelet aggregation

**ABNORMALITIES OF ENDOTHELIUM
IN HYPERTENSION AND IMPLICATIONS
IN PLATELETS**

The endothelium, which forms the margin between the blood and the vessel wall, is also exposed to increased pressure forces in patients with high blood pressure. This can cause a variety of insults to the endothelium resulting in endothelial damage and dysfunction, which eventually leads to platelet aggregation (Box 21-2). The endothelium plays a crucial role in cardiovascular pathophysiology, being the preliminary target for initiating the prothrombotic disease process.^{29,30} The integrity of the endothelium is important in order to prevent atherothrombotic disease,³¹ as it has many pro- and anti-coagulant properties.³² Hence endothelial perturbation in hypertension can culminate in even more definitive vascular damage and atherosclerosis.

Nitric oxide (NO), which is mainly derived from the endothelium, plays a significant part in controlling vascular tone and it has been proposed that a reduction in endogenous NO is associated with impaired vasodilatation and a rise in peripheral vascular resistance in hypertension. Studies have shown that resting NO activity is reduced in people with high blood pressure.³³ This fact is further substantiated by reports suggesting that the excretion of the metabolic end product of NO is decreased in the urine

Box 21-2**Abnormalities of Endothelium
in Hypertension**

Endothelial damage due to shear force
Oxidative stress
Reduced nitric oxide activity
Increased tendency for platelet adhesion and aggregation

of patients with high blood pressure in comparison to the normotensive population.³⁴

Endothelium-dependent vasodilatation in response to acetylcholine (which is NO mediated) has been noted to be impaired both in the forearm circulation³⁵⁻³⁸ and coronary vascular bed³⁹ in patients with hypertension.

The role of superoxide anion (O_2^-) and its involvement in oxidative stress has also been related to various cardiovascular diseases as well as hypertension.⁴⁰ The availability of superoxide anion (O_2^-) influences the synthesis of NO, and hence can alter endothelial function.⁴¹ Consequently, a decrease in NO leads to impaired vasodilatation and a subsequent increase in peripheral vascular resistance, contributing further to hypertension,^{42,43} again setting up a vicious cycle (Figure 21-1, A).

Vascular endothelial growth factor (VEGF) is recognized to act on the endothelium (Figure 21-1, B) to induce differentiation and proliferation and therefore angiogenesis due to paracrine or autocrine effects.⁴⁴ VEGF may also induce a procoagulant state in the endothelium.⁴⁵⁻⁴⁷ Platelets carry VEGF,⁴⁸ and once thrombus formation occurs, a dysfunctional endothelium will have impaired antiplatelet activity.³¹ VEGF is higher in the setting of hypertension^{49,50} could also have other implications, such as the development of collaterals. Paradoxically, the high levels

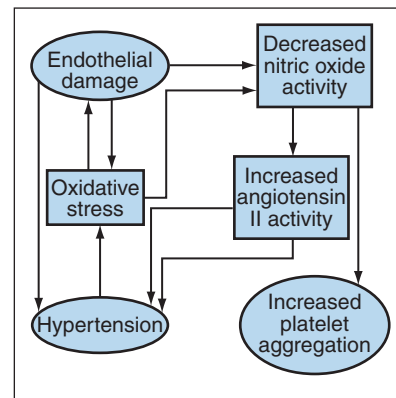

**A****B**

Figure 21-1. A, Hypertension, endothelial damage, and platelet dysfunction. B, Effects of vascular endothelial growth factor on the endothelium and platelets.

of VEGF seen in hypertension may also be the result of release from platelets when they form thrombi.⁵¹

ABNORMALITIES OF FIBRINOLYSIS AND COAGULATION IN HYPERTENSION

The whole process of thrombogenesis is due to a fine equilibrium between the coagulation and fibrinolytic pathways, and many of the blood constituents associated with hypertension and its complications are components of these pathways.

For example, the fibrinolytic system is crucial in averting intravascular thrombosis (Figure 21–2), and the final outcome of the fibrinolytic activity depends on the equilibrium between plasminogen activators, such as tissue-type plasminogen activator (t-PA) and plasminogen activator inhibitors (PAI). These components are synthesized in the endothelial and smooth muscle cells of the vascular wall.

The progression of events in fibrinolysis involves the activation of plasminogen to plasmin. Plasmin then helps in the lysis of fibrin and also enhances the activation of certain anti-inflammatory cytokines, such as transforming growth factor-beta (TGF- β). The latter also inhibits the migration and proliferation of smooth muscle cells. This inhibition is important, as it is a vital phase in the formation of atherosclerotic lesions.

The abnormalities in coagulation and fibrinolytic pathways associated with hypertension may lead to an increased risk of thrombotic events due to the enhanced coagulability and impaired fibrinolysis.^{52–56} Certainly there is an obvious association between rising blood pressure and impaired fibrinolysis in hypertensive patients without established cardiovascular disease, or known risk factors for cardiovascular disease, even after correcting other variables

like age, gender, and body mass index.⁵⁷ Similarly, high fibrin D-dimer levels (a degradation product of fibrin) have been reported in patients with hypertension,⁵⁸ and are an index of ongoing intravascular fibrin formation and thrombogenesis. Such fibrin degradation products may be of prognostic value in determining arterial thrombotic events.⁵⁹ Hypertension can lead to atrial fibrillation, which in itself can cause a prothrombotic state.^{60–63} The duration of atrial fibrillation is not relevant, and even in patients with new onset nonrheumatic atrial fibrillation (nonsustained and <48 hours duration), there are increased concentrations of soluble thrombomodulin and von Willebrand factor (vWf) (as indices of endothelial damage or dysfunction) and fibrin D-dimer (an index of thrombogenesis); the latter persist up to 30 days after cardioversion.⁶⁰ Hemostatic markers for platelet activity, such as platelet factor-4 and beta-thromboglobulin (TG), have also been shown to be raised in patients with nonvalvular atrial fibrillation.⁶¹ The raised plasma levels of vWf in this condition are even predictive of vascular events and stroke.⁶²

Congestive heart failure (CHF) carries a poor prognosis with a high mortality rate, frequent hospitalizations, and an increased risk of thrombotic complications, such as stroke. Cytokines may contribute to the progression and prothrombotic state of CHF, including the proinflammatory interleukin-6 (IL-6). The procoagulant properties of these cytokines may be mediated via tissue factor (TF), a potent clotting activator. Indeed, IL-6 and TF are predictors of poor prognosis in chronic CHF.⁶⁴ Abnormal levels of soluble P-selectin, vWF, and hemorheological indices may also contribute to a hypercoagulable state in CHF,⁶⁵ especially in female patients and in those with the more severe New York Heart Association class.⁶⁶ Treatment with angiotensin-converting enzyme inhibitors improves the prothrombotic state in these patients.

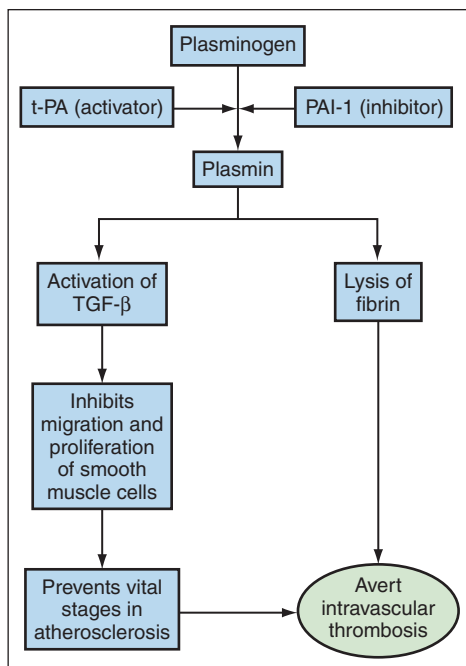

Figure 21–2. Role of the fibrinolytic system in averting thrombosis.

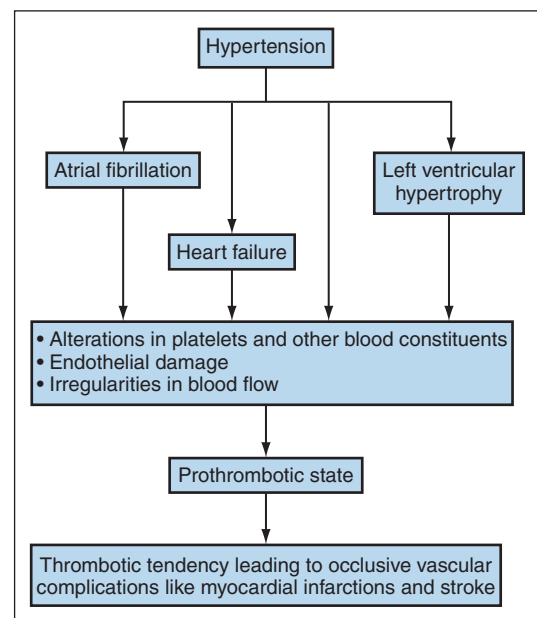

Figure 21–3. Sequence of events in hypertensive cardiovascular disease leading to the prothrombotic state.

Patients with left ventricular (LV) hypertrophy are at high risk for complications associated with hypertension.⁵⁸ Unsurprisingly, hypertensive patients with LV hypertrophy (defined as a LV mass index >134 g/m² in men or >110 g/m² in women) had higher plasma fibrinogen compared with those without LV hypertrophy. The high plasma fibrinogen levels were related to blood pressures, LV mass index (and LV hypertrophy), and left atrial size.⁵⁸

A flow diagram illustrating an overview of the mechanisms in the pathogenesis of the prothrombotic state in patients with hypertension and hypertensive cardiovascular diseases is shown in Figure 21–3.

CONCLUSIONS

Abnormalities in hemorheologic factors and abnormal thrombogenesis and endothelial damage/dysfunction may act synergistically to increase the risk of thrombogenesis and atherosclerosis in hypertensive patients. Thus hypertension leads to abnormalities in platelets, coagulation, and fibrinolysis that eventually lead to a prothrombotic state, causing deaths related to cardiovascular disease and stroke.⁶⁷ Many of these abnormalities can be related to hypertensive target organ damage, and effectively reversed by antihypertensive treatment.⁶⁸

Chapter
22Role of Cytokines and
Inflammation in Hypertension

Michael J. Ryan

Key Findings

- Numerous studies suggest an association between increased serum cytokines and essential hypertension, although a causal relationship has yet to be definitively determined.
- Cytokines have pleiotropic effects to mediate immune responses. The physiologic actions of cytokines are dependent on intracellular pathways activated by cell surface receptors.
- Inflammatory cytokines may regulate neurohumoral pathways like the renin-angiotensin or endothelin system, and alter vascular, heart, and renal function to promote hypertension.
- Cytokines are thought to play an integral role in the progression of certain forms of hypertension including preeclampsia, pulmonary hypertension, and autoimmune and metabolic disorders.
- Single nucleotide polymorphisms that occur in cytokine gene sequences may be genetically associated with hypertension.
- Inflammation and cytokines may become important therapeutic targets as more is understood about their role in the progression of hypertension.

Inflammation is a complex physiologic response to tissue injury that is mediated by numerous cell types and peptides called cytokines. A typical inflammatory response involves increased blood flow and vascular permeability along with recruitment of macrophages and monocytes to an injured area. Recently, the notion that inflammation may be important in the development of cardiovascular disease has been bolstered by evidence that atherosclerosis, once thought to be a lipid storage disease, requires cytokines, adhesion molecules, and immune cells (reviewed in Libby, Ridker, and Maseri¹). Cytokines have also been suggested to play an important role in the progression of heart disease, stroke, aneurysm, renal disease, and hypertension.

Historically, investigators attempting to understand the pathogenesis of hypertension have focused on renal, vascular, cardiac, neurohumoral, genetic, and environmental factors. However, like atherosclerosis, investigators have observed a relationship between inflammatory cytokines and blood pressure suggesting that hypertension may be a chronic inflammatory condition. As a result, attention has turned toward understanding the role that these inflammatory cytokines play in the development of hypertension. While

growing evidence suggests an association between hypertension and several markers of inflammation, the mechanisms by which chronic increases in pro-inflammatory cytokines promote hypertension are just now being examined. Thus this is an important and emerging area of research interest. The focus of this chapter will be to examine what is currently known about the relationship between inflammatory cytokines and hypertension. Particular attention will be given to this relationship in humans and animal models of hypertension, as well as neurohumoral and organ systems that are affected by cytokines.

CYTOKINES

Cytokines comprise a group of proteins that are secreted by cells of the innate and adaptive immune system, but can be produced and released by virtually any cell type. The physiologic actions of these proteins are the result of a balance between pro-inflammatory and anti-inflammatory cytokines that are released when the immune system is challenged with either a foreign microbe or some other antigen.

There are three main classes of cytokines based on their functional properties. These include cytokines involved in the innate immune response, the adaptive immune response, and those that promote leukocyte maturation. The biological actions of cytokines are diverse, but most often promote increased cell adhesion molecule expression (endothelial activation), increased production and release of cytokines from endothelial and immune cells, recruitment of lymphocytes and monocytes, and generation of reactive oxygen species important for the oxidative burst to destroy foreign antigens. During severe inflammatory reactions, similar to what is observed during sepsis, cytokines mediate increased body temperature (fever), reduced food intake, and impaired vascular smooth muscle and heart contractility. The latter actions promote reduced blood pressure and shock. Indeed, a great deal is understood about the effect of large increases in inflammatory cytokines on vascular function and blood pressure. In contrast, despite recent evidence suggesting that hypertension may be a mild chronic inflammatory condition, there has been relatively little attention paid to the effects of chronic moderate increases in cytokines and how they regulate blood pressure.

At the cell level, cytokines bind to plasma membrane receptors of which there are several types mediating multiple and complex signaling pathways. These pathways

have been extensively reviewed by others.²⁻⁶ Tumor necrosis factor alpha (TNF- α) and interleukin-1 (IL-1) have similar pro-inflammatory signaling pathways. The intracellular domain of the receptor activates MAP-kinase signaling pathways (p38MAPK, JNK) and leads to phosphorylation of Jun and an increase in the AP1 transcription factor. Activation of these receptors also leads to inhibition of I κ B (by phosphorylating it), thus allowing NF κ B to regulate gene expression. This is considered the inflammatory signaling pathway. Alternatively, these cytokines can activate an apoptotic pathway, although it is not yet clear how activation of this pathway is chosen over the inflammatory path. Other cytokines, including interleukins 4, 6, 10, and 12, and interferon gamma (IFN γ) typically activate the JAK/STAT signaling cascade. After receptor binding, STAT proteins are recruited to the cytoplasmic domain of the receptor containing a Janus kinase (JAK). JAK phosphorylates the inactive STAT proteins, allowing them to form a homodimer and translocate to the nucleus where they can regulate gene transcription. Activation of these pathways has been implicated in the regulation of blood pressure, and therefore may be important clinical targets for the treatment of hypertension.

CYTOKINES AND ESSENTIAL HYPERTENSION

Evidence that chronic inflammation may be important in the progression of hypertension stems from data showing that cytokines are increased in the serum of individuals with essential hypertension. While there are numerous cytokines, this chapter will focus primarily on TNF- α , interleukin-6 (IL-6), and C-reactive protein (CRP), which have been implicated in the development of hypertension.

Tumor necrosis factor alpha

TNF- α is the principal cytokine that mediates inflammatory responses, and typically acts in a paracrine or autocrine fashion. When produced in high amounts, TNF- α can be detected in the circulation. It is primarily produced by phagocytes, T cells, natural killer cells, and mast cells, but can also be released from other cell types including endothelial cells. Newly generated TNF- α is formed as a 27-kD membrane-bound protein that is cleaved by metalloproteinases to form a 17-kD protein. These form a homotrimer that can bind to cell surface receptors (TNFR1 and TNFR2) located on virtually every cell type in the body. Binding to its receptor leads to downstream activation of NF κ B to regulate the expression of numerous genes and also promotes cleavage of the receptors to generate soluble TNF- α receptors (sTNFR1, sTNFR2). These have been used as a serum marker for increased TNF activity and inflammation.

In humans there is growing evidence that TNF- α is elevated in individuals with essential hypertension. For example, TNF- α appears to be an independent risk factor for predicting hypertension in adults, even after adjusting for body mass index, age, and family history of previous cardiovascular disease.⁷ The relationship between TNF- α and blood pressure is also evident in apparently healthy

individuals.⁸ The authors of these studies suggested that hypertension may be promoting inflammation; however, whether cytokines are a causal factor in the progression of hypertension has not been determined. There is some evidence to suggest that TNF- α could promote hypertension through activating the potent vasoconstrictor endothelin-1 (ET-1).⁹

Further understanding of how TNF- α can promote hypertension will most certainly be aided through studies of experimentally induced hypertension in animal models. Similar to humans, a relationship between blood pressure and serum levels of TNF- α has been reported in rats with hypertension induced by DOCA salt, nitric oxide synthase inhibition, or the two-kidney-one-clip model.¹⁰ These animals, in addition to hypertension, have increased blood pressure variability and decreased baroreceptor sensitivity, which suggests a role for cytokines in mediating central regulation of blood pressure.

There is also evidence at the cellular level consistent with a role for TNF- α in promoting hypertension. For example, treatment of human umbilical vein endothelial cells (HUVEC) with either TNF- α or lipopolysaccharide (LPS, endotoxin) induces endothelial expression of cell-adhesion molecules, a response that is inhibited by a p38 MAP-kinase antagonist. Importantly, pharmacologic inhibition of p38 MAP kinase in stroke-prone spontaneously hypertensive rats prevented hypertension and improved renal function in this model.^{11,12} These data implicate TNF- α signaling pathways as potentially important for the progression of hypertension.

Interleukin-6

IL-6 is one of the few inflammatory cytokines that acts in an endocrine fashion. Its primary function is to recruit neutrophils to inflamed tissue and stimulate antibody release from B lymphocytes. IL-6 also promotes the release of acute-phase reactants such as CRP from the liver, which will be discussed in greater detail below. In humans, several lines of evidence suggest that IL-6 is associated with, and often predictive of, the development of hypertension. Numerous studies report that elevated serum IL-6 levels are observed in individuals with hypertension independent of other cardiovascular risk factors.^{7,10,13} Like TNF- α , these studies largely promote the notion that inflammation is caused by hypertension; however, plasma levels of IL-6 can be used to predict the development of hypertension. As an example, enhanced IL-6 response to stress in normotensive individuals predicted the development of hypertension at a 3-year follow-up visit.¹⁴

Recently, the role for IL-6 in the progression of hypertension has become clearer through experimentation in animal models. It has been recently shown that angiotensin-mediated hypertension (Figure 22-1) and psychosocial stress-induced hypertension (placing a male mouse into a cage formerly occupied by another male mouse) are attenuated in IL-6 knockout mice.^{15,16} These data and those from human studies support an important pathophysiological role for IL-6 in the development of hypertension. The cellular mechanisms by which IL-6 can promote hypertension have not yet been clearly defined,

Figure 22–1. Infusion of angiotensin II causes an increase in blood pressure that is significantly attenuated in interleukin-6 knockout mice. Experiments were performed in wild-type and knockout mice placed on a high salt diet and measurements of blood pressure were made using radiotelemetry. (Redrawn from Lee DL, Sturgis LC, Labazi H, Osborne Jr JB, Fleming C, Pollock JS, et al. *Am J Physiol Heart Circ Physiol* 2005;209:H935–40. Used with permission.)

although like $\text{TNF-}\alpha$, there is evidence that IL-6 can promote oxidative stress. In addition, IL-6 is a potent stimulator of acute-phase reactants from the liver, which may also play a role in the progression of hypertension.

C-Reactive protein

Acute-phase reactants are liver-derived plasma proteins that increase in response to infection. C-reactive protein (CRP) belongs to this class of circulating peptides and is a widely used clinical marker for inflammation. It is important for opsonization (making an antigen susceptible to the actions of phagocytes) and also activates the complement cascade. Several studies have reported elevated CRP in hypertensive patients and that it predicts the development of hypertension in otherwise healthy individuals.^{17–20} The degree to which CRP levels associate with hypertension varies among ethnic populations. For example, among hypertensive individuals, the highest levels of CRP are observed in Chinese, followed by African Americans and Caucasians.²¹ Similar correlations between CRP and hypertension were also reported in Korean and Colombian populations.^{22,23} No relationship was observed among participants of Hispanic descent.²¹ Although some studies suggest that there are no gender differences in serum CRP levels as they relate to hypertension,²¹ there is evidence that hormone replacement therapy in postmenopausal women is associated with increased serum CRP in apparently healthy women.²⁴ This may be an important area for further investigation given the current debate on safety, particularly with regard to cardiovascular outcomes, in women who are prescribed hormone therapy.

To date, animal studies examining the role of CRP in the development of hypertension have not been performed.

However, two recent studies have begun to address the potential cellular mechanism for how CRP might promote hypertension. In isolated human aortic endothelial cells (HAEC), CRP has been shown to attenuate the production of the potent vasodilators prostacyclin and nitric oxide. CRP can also attenuate expression of the thrombolytic enzyme tissue plasminogen activator (tPA), which is an important anticoagulant.²⁵ In a separate study, investigators showed a potential mechanism for CRP-mediated endothelial dysfunction. They demonstrated that CRP activated HAECs in culture leading to increased monocyte adhesion. Endothelial activation was promoted by impairing endothelial nitric oxide synthase (eNOS) activity caused by reduced phosphorylation at ser1179.²⁶ Thus the ability of CRP to cause endothelial dysfunction may be an important contributing mechanism to the subsequent development of hypertension.

Other cytokines

In addition to those already discussed, numerous other cytokines have been implicated in the development of hypertension in humans and/or animal models, including IL-1 β , monocyte chemoattractant protein 1 (MCP-1), interleukin 2 (IL-2), regulated on activation normal T expressed and secreted (RANTES), and transforming growth factor β (TGF- β).^{27–29} TGF- β is considered to be an anti-inflammatory cytokine that inhibits the proliferation of lymphocytes and leukocytes. However, evidence suggests that TGF- β directly correlates with mean arterial pressure, systolic pressure, and diastolic pressure in patients with end-stage renal disease.³⁰ TGF- β can promote hypertension through activation of the RAS or endothelin systems^{30,31}; however, profibrotic actions of TGF- β have also been implicated in target organ damage that contributes to hypertension. This is supported by evidence that TGF- β is significantly associated with renal injury and hypertension independently of blood pressure.²⁹ Therefore, a large number of studies on the role of TGF- β in promoting hypertension have focused on tissue injury.

Although much of the evidence discussed above indicates a prohypertensive relationship between cytokines and blood pressure, there is evidence for antihypertensive actions of cytokines. For example, subcutaneous injection of IFN- γ once a week for 10 weeks lowered blood pressure and reduced glomerular sclerosis in Dahl salt-sensitive (DahlSS) rats on a high-salt diet.³² Similarly, subcutaneous infusion of interleukin-2 (IL-2) prevented the development of hypertension when administered to young spontaneously hypertensive rats (SHR) and normalized blood pressure in SHRs with established hypertension.³³ Therefore, the effects of cytokines on blood pressure are likely the result of a balance between pro- and anti-inflammatory actions of these immune response mediators.

NEUROHUMORAL AND ORGAN SYSTEMS AFFECTED BY CYTOKINES

The mechanisms by which inflammatory cytokines contribute to the development of hypertension have become an important area of research. While cellular and molecular mechanisms for cytokine actions continue to be uncovered, there is considerable evidence for the effect of cytokines on organ systems that are vital for the regulation of blood pressure. This section will focus on neurohumoral, vascular, renal, central, and cardiac effects of pro-inflammatory cytokines.

Renin-angiotensin system

The renin-angiotensin system (RAS) is the most powerful endocrine system in the body, and is critical for regulating renal function, body fluid homeostasis, and vascular tone. The well-known biochemical cascade for the generation of angiotensin II (Ang II) begins with renin release from juxtaglomerular cells of the kidney and culminates in the generation of Ang II by angiotensin converting enzyme (ACE). The effects of Ang II to increase blood pressure can be attributed to altered renal function, increased peripheral vascular resistance, and increased sympathetic nerve activity. In addition to its renal, vascular, and central effects, there is now evidence supporting a pro-inflammatory mechanism for Ang II in the progression of hypertension.

In humans, several studies demonstrate that blockade of RAS, either with angiotensin receptor blockers (ARB) or ACE inhibitors, lowers serum amounts of cytokines including TNF- α , IL-6, CRP, and MCP-1.^{34–36} The expression of TGF- β is also modified by blockade of RAS. For example, treatment of individuals with newly diagnosed, but never treated, essential hypertension had increased serum levels of TGF- β that were markedly reduced following treatment with the ARB losartan.³⁷ In peripheral blood monocytes isolated from individuals with essential hypertension, *in vitro* stimulation with Ang II caused an increased production of IL-1 β that was prevented by preincubation with an ARB.³⁸ Thus Ang II can have direct effects on the physiologic function of cells from the immune system.

The pro-inflammatory actions of Ang II have been reported in animal models of hypertension as well. Increased aortic expression IL-1 β , TNF- α , IL-6, and their downstream signaling mediator NF κ B, are attenuated after treatment with ARBs in the SHR model of hypertension. Triple therapy, however, did not alter cytokine expression in this study, demonstrating that RAS was critical for the increased inflammatory markers.³⁹ In transgenic rats over-expressing human renin and in the two-kidney-one-clip model of hypertension, serum levels of MCP-1 and renal macrophage infiltration were significantly reduced, along with blood pressure, after treatment with the ARB valsartan.⁴⁰ Finally, the effect of RAS to promote inflammation was demonstrated in numerous studies using a rat transgenic for human renin and human angiotensinogen. This model has hypertension, cardiac hypertrophy, and renal damage. In addition, TNF- α , adhesion molecule, and monocyte attachment have been reported in renal vessels and kidney homogenates from these animals. Treatment of these rats

with ARB or ACE inhibitors lowers blood pressure and attenuates the expression of these inflammatory markers.^{41–43} Therefore, data from human and animal studies support a pro-inflammatory role for RAS in the progression of hypertension and suggest another important therapeutic benefit for administering ARBs and ACE inhibitors to lower blood pressure.

Currently available data regarding the regulation of RAS by cytokines are conflicting. Experiments using an *in vitro* model of juxtaglomerular cells suggest that TNF- α and IL-1 β inhibit renin gene transcription.^{44–46} To the contrary, TNF- α and IL-1 β have been shown to increase renin release in rat renal cortical slices⁴⁷ and a bolus infusion of IL-1 β in Wistar rats increases blood pressure (measured by tail cuff) and plasma renin activity.⁴⁸ Using similar amounts of TNF- α in HepG2 cells (liver carcinoma) it has been shown that TNF- α stimulates transcription of the angiotensinogen gene.⁴⁹ While differences in the models and methodologies used may account for the disparities, these experiments were all performed with an acute exposure to inflammatory cytokines. The effect of chronically elevated cytokines on components of RAS in whole animals remains to be elucidated.

Endothelin

Another endocrine peptide that has been implicated in the development of hypertension is ET-1. ET-1 is a 21-amino acid peptide generated from cleavage of the precursor pre-proendothelin and is widely recognized as the most potent vasoconstrictor. Like Ang II, it has vascular, renal, and central effects (Reviewed in Miyauchi and Masaki⁵⁰, and Simonson⁵¹) to mediate blood pressure. Although it has not been extensively examined in humans, presently available data suggest a relationship among ET-1, inflammation, and hypertension.^{9,28}

Several studies using animal models of hypertension have examined this relationship. For example, stroke-prone SHR rats fed a high-salt diet have increased renal expression of pre-proendothelin and TGF- β , the latter of which is attenuated by pharmacologic blockade of the ET α receptor.⁵² Evidence also indicates that inflammatory cytokines promote the generation and release of ET-1, suggesting a feed-forward mechanism to promote inflammation. For example, incubation of vascular smooth muscle cells (VSMC) with TNF- α causes NF κ B and STAT1 translocation to the nucleus and increased expression of ET-1.⁵³ Inhibitors of NF κ B and STAT1 abrogated the ET-1-stimulating actions of TNF- α .

Vascular

The vascular wall is an important target for the physiologic actions of both Ang II and ET-1. Activation of vascular endothelial cells is critical to the inflammatory response as it facilitates the attachment of monocytes and can lead to impaired endothelial function. Endothelial dysfunction can be promoted through numerous mechanisms, including reductions in the generation and availability of nitric oxide or in the generation of reactive oxygen species. Impaired vascular function promotes end organ damage and leads to increased peripheral vascular resistance that each contribute to the development of hypertension.

In humans with hypertension, considerable data support a role for inflammatory cytokines to alter vascular function. Levels of TNF- α , IL-6, and CRP have been shown to independently associate with increased arterial stiffness, velocity, and thickness in humans with essential hypertension.^{54–57} Individuals with high levels of circulating CRP were more likely to develop peripheral artery disease and hypertension, making CRP a potential predictor of future peripheral vascular disease in apparently healthy men.⁵⁸ The effects of CRP to alter vessel function are supported by data showing that elevated levels of CRP are associated with impaired forearm blood flow in patients with coronary artery disease. Interestingly, individuals that also had elevated serum interleukin 10 (IL-10), an anti-inflammatory cytokine, did not have impaired flow responses. The mechanism by which IL-10 protected the endothelium was through reduced oxidative stress.⁵⁹ This study demonstrates the important balance that exists between pro- and anti-inflammatory cytokines.

The effects of inflammatory cytokines on vascular function have often been studied in animals given LPS, which causes a large increase in the generation of TNF- α . LPS impairs endothelial-dependent relaxation through generation of reactive oxygen species. There is also evidence for a large increase in iNOS during these acute reactions. High levels of nitric oxide can be toxic to cell function. While these studies suggest a role for cytokines in modulating endothelial function, the infusion of LPS leads to a reduction in blood pressure similar to what occurs during sepsis. Therefore, these large increases in cytokines do not reflect levels observed during hypertension. The effect of chronic moderately elevated inflammatory cytokines on endothelial function is not yet clear. Circulating and attached monocytes with increased expression of cell adhesion molecules have been reported in SHR but not Wistar Kyoto (WKY) or Sprague Dawley (SD) rats. In addition, vascular tissue isolated from SHRs has higher expression and releases greater amounts of TNF- α and IL-1 β compared to controls,⁶⁰ suggesting that vessels during hypertension may be sensitized to generate cytokines and contribute to impaired function. Other studies have shown that infusion or incubation with IL-6 or TNF- α (at levels observed during hypertension) can cause impaired endothelial-dependent relaxation in peripheral conduit vessels.^{61–64} While these data are important, studies using conduit vessels have greater significance for understanding the progression of atherosclerosis and less for the development of hypertension. Therefore, it will be critical to examine the effect of inflammatory cytokines on smaller resistance vessels from the kidneys, which are important for long-term blood pressure regulation.

Renal

The importance of the kidneys in the long-term regulation of blood pressure is well known, and there is evidence to suggest that inflammation may play an important role in altering renal function. For example, high levels of CRP are associated with increased blood pressure, and those with renal damage (measured by microalbuminuria) had the highest serum CRP levels.⁶⁵ However, while serum CRP

levels correlate with blood pressure and cardiovascular risk, it does not always associate with renal function.⁶⁶ Thus the association between serum CRP and renal function in humans is not clear. Studies on the relationship between other inflammatory cytokines and renal function in humans is limited with the exception of TGF- β levels that correlate with not only hypertension but also with proteinuria and renal fibrosis.³⁷

Recent evidence demonstrates a potentially critical role for TGF- β in the regulation of kidney function and blood pressure in animal models. For example, treatment of DahlSS rats with a neutralizing antibody to TGF- β lowered blood pressure, reduced fibrosis, proteinuria, and sclerosis in rats on a high-salt diet.⁶⁷ The effect of TGF- β on renal microvessel autoregulation was assessed *ex vivo* using the juxtamedullary nephron technique. In this study, the authors demonstrated that TGF- β , but not other growth factors, completely abolished the autoregulatory response of rat renal afferent arterioles. The mechanism by which this occurred was dependent on the generation of reactive oxygen species, since autoregulatory responses were restored after treatment with tempol.⁶⁸ Therefore, similar to other cytokines, reactive oxygen species may be an important mechanism contributing to the effects of TGF- β on blood pressure.

Evidence suggests that other cytokines may also modulate renal function. Inhibition of p38 MAP kinase, a key downstream signaling mechanism mediating the cellular actions of cytokines, has been shown to reduce renal damage and attenuate TNF- α and IL-1 β expression in kidneys from DahlSS rats.⁶⁹ The RAS transgenic rat model of hypertension described above has increased renal expression of TNF- α and renal vascular expression of cell adhesion molecules that is attenuated by treatment with the corticosteroids, Etanercept (TNF- α antagonist), MMF (inhibitor of T/B cell proliferation), or blockade of RAS.^{42,43} TNF- α expression has also been shown to be increased in the medullary thick ascending limb in rats with Ang II-mediated hypertension.⁷⁰ Taken together, studies in humans and animal models support a role for inflammatory cytokines in modulating renal function.

Central nervous system

The central nervous system is recognized as a short-term regulator of blood pressure, but also has important long-term effects in arterial pressure through altered renal sympathetic nerve activity. It has long been recognized that inflammatory cytokines have central effects to increase activity of the hypothalamic pituitary axis. HPA activation increases the release of adrenocorticotropin hormone (ACTH) leading to increased corticosteroid production. Corticosteroids have general immunosuppressive actions; however, chronic increases can promote hypertension by augmenting sodium and water retention in the kidneys.

The actions of specific inflammatory cytokines on central nervous system-mediated changes in blood pressure and renal function were recently examined in a study by Zhang et al.⁷¹ The authors examined, in anesthetized rats, the effect of acute forebrain TNF- α infusion on sympathetic

nerve activity, blood pressure, and heart rate. Infusion of TNF- α increased arterial pressure, heart rate, and renal sympathetic nerve activity through the actions of prostaglandins in the paraventricular nucleus. Others have demonstrated that intracisternal or intravenous infusion of IL-1 β increases blood pressure in a prostaglandin-dependent manner in rats.⁷² The circumventricular organ, area postrema, and choroid plexus are likely sites of cytokine action since these regions do not have a blood-brain barrier. While these studies indicate a prohypertensive action of cytokines in the brain and central nervous system, there are studies that suggest a role for cytokines to suppress sympathetic activity. Ye et al.⁷³ showed that infusion of IL-1 β into the lateral ventricle of rats causes a decrease in blood pressure that is reversed by using a neutralizing antibody to IL-1 β . They further demonstrated that IL-1 β has a tonic inhibitory effect on sympathetic nerve activity.⁷⁴ These data indicate that the effect of cytokines on central control of blood pressure may be subject to regional actions within the brain.

Another cytokine that acts in the brain to regulate blood pressure is leptin. Leptin is typically associated with metabolism and is recognized as a satiety factor in rodents; however, it promotes immune responses and increases renal sympathetic nerve activity and blood pressure through centrally mediated mechanisms. The leptin receptor is similar in structure to the IL-6 receptor. Predominantly produced by adipocytes, leptin is increased during obesity and metabolic syndrome, of which one of the major phenotypes is hypertension. The role of inflammatory cytokines during hypertension and metabolic syndrome will be discussed later in this chapter.

Cardiac

Heart function may also be affected by inflammatory cytokines under pathologic conditions. Individuals with heart failure have a deteriorating condition where the failing heart cannot supply enough blood and oxygen to meet metabolic demand. This leads to activation of RAS and increased sodium and water retention, which exacerbates hypertension and heart failure. Recent evidence supports a role for cytokines in the progression to heart failure. Data from the Framingham Heart Study show that the incidence of heart failure was increased with increased inflammatory markers IL-6, TNF- α , and CRP. IL-6 was the best predictor of heart failure in this study.⁷⁵ Other studies showed that as heart failure progresses, levels of CRP, IL-1 β , and TNF- α , along with soluble receptors for TNF- α , increase.^{76,77} Additionally, individuals with rheumatoid arthritis (a chronic inflammatory disease) have an increased risk for developing heart failure and patients treated with anti-TNF- α therapy were less likely to have heart failure.⁷⁸

Similar to humans, evidence from animal models suggests a role for inflammation in heart failure. For example, cardiac muscle from SHR has increased number of mast cells that express high levels of TNF- α , IL-6, NF κ B, and TGF- β .⁷⁹ In addition, treatment of DahlSS rats with ARB or ACE inhibitors reduces cardiac macrophage infiltration, IL-6, and TGF- β expression.⁸⁰

SPECIAL EXAMPLES OF INFLAMMATION AND HYPERTENSION

Preeclampsia

Preeclampsia is defined by hypertension and proteinuria during the third trimester of pregnancy that resolves upon delivery of the placenta. One cause of preeclampsia is thought to be due to reduced uterine perfusion pressure to the fetus. Women with preeclampsia have increased cardiovascular risk later in life as do infants born to preeclamptic mothers. Growing evidence points to a role for inflammatory cytokines as a causative factor in the development of preeclampsia. Several studies in humans suggest that serum cytokines including IL-2, TNF- α , IL-6, and CRP are elevated in women with preeclampsia and can even be predictive for the development of preeclampsia when measured early in the pregnancy.⁸¹⁻⁸³ Interestingly, in a 20-year follow-up after a preeclamptic pregnancy, women have an increased ratio of pro-inflammatory to anti-inflammatory cytokines.⁸⁴

Our understanding of the pathophysiology of preeclampsia has been aided by the development of animal models. Alexander et al.⁸⁵ demonstrated a potential role for cytokines in preeclampsia when infusion of TNF- α caused hypertension in pregnant but not virgin rats. The Granger laboratory has recently developed a reduced uterine perfusion pressure (RUPP) model of preeclampsia in the rat by restricting blood flow in the uterine arteries. These animals develop hypertension, general endothelial dysfunction, and proteinuria similar to what is observed in humans. LaMarca et al.^{86,87} demonstrated that these rats, like humans, have elevated levels of TNF- α (Figure 22-2), and that hypertension mediated by TNF- α infusion in pregnant rats can be ameliorated with blockade of the endothelin system. Increased levels of TNF- α or IL-6 can cause endothelial dysfunction in pregnant rats, suggesting that inflammatory cytokines are also important for the impaired vessel function during preeclampsia.^{61,62,64} Infusion of IL-6 either during early or late pregnancy in the rat leads to hypertension in the offspring by age 5 weeks, which supports a role for cytokines in not only causing preeclampsia but also for increasing cardiovascular risk in offspring.⁸⁸

Metabolic syndrome

Metabolic syndrome is a disorder that can be characterized by insulin resistance, obesity, hyperglycemia, and hypertension. Oftentimes this leads to the development of type II diabetes. Although this disorder is an amalgamation of numerous phenotypes, several studies have reported increased serum cytokines in individuals with metabolic syndrome as a potential underlying mechanism. TNF- α , IL-6, CRP, TGF- β , and leptin are all directly correlated with increased body mass index,⁸⁹ and CRP and IL-6 have been shown to associate with fasted insulin levels in addition to blood pressure.⁹⁰ Studies suggest that increased cytokines can raise the likelihood of developing metabolic syndrome.⁹¹ Elevated cytokines can also promote diabetes through negatively regulating insulin receptor signaling.

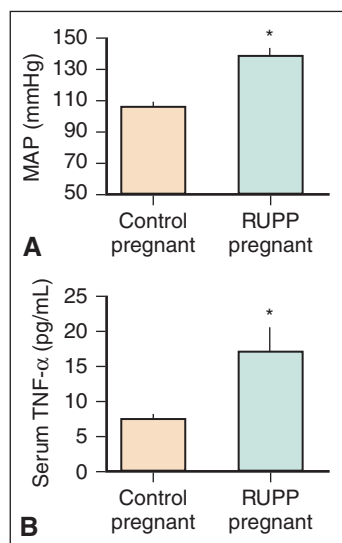

Figure 22-2. MAP and serum concentration of TNF- α are significantly increased in RUPP rat model of preeclampsia at day 19 of gestation. MAP, mean arterial pressure; RUPP, reduced uterine perfusion pressure. (Adapted from Babbette B, LaMarca D, Bennett WA, Alexander BT, Cockrell K, Granger JP. *Hypertension* 2005;46(4):1022–5.)

The mechanisms by which inflammatory cytokines might promote metabolic syndrome are not yet clear.

Pulmonary hypertension

Pulmonary hypertension results from altered vascular function (constriction and thickening) that leads to increased pressure in the arteries supplying the lungs. Inflammatory cytokines have been implicated in vascular dysfunction that is prevalent during pulmonary hypertension. Serum levels of IL-1 β and IL-6 are reportedly increased,²⁷ and lung biopsies from individuals with primary pulmonary hypertension showed increased expression of RANTES.⁹² RANTES attracts T lymphocytes and monocytes, which are the most abundant infiltrates in pulmonary hypertension. Like other cytokines, RANTES activates ET-1,⁹³ which plays an important role in the pathogenesis of pulmonary hypertension.⁹⁴

A role for cytokines has also been demonstrated in experimental models of pulmonary hypertension. For example, transgenic mice overexpressing TNF- α develop pulmonary hypertension,⁹⁵ while TNF- α receptor knockout mice do not develop pulmonary hypertension in response to bleomycin, an anticancer therapy that induces pulmonary fibrosis and hypertension in rodents.⁹⁶ Bleomycin-induced pulmonary hypertension in mice is mediated by TNF- α and downstream mediators NF κ B and AP1.⁹⁶ IL-6 infusion has been shown to cause pulmonary hypertension in rats that is preventable by neutralizing IL-6 antibodies.⁹⁷ ET-1 may also play an important role in IL-6-mediated pulmonary hypertension based on data from cell culture studies

showing that pulmonary artery smooth muscle cells have an augmented production of pre-proendothelin and ET-1 in response to TNF- α or IFN- γ .⁹⁸ These data are consistent with a role for the endothelin system in cytokine-mediated hypertension, and is similar to what has been reported in preeclampsia.

Chronic inflammatory disease

Individuals with chronic inflammatory diseases (systemic lupus erythematosus [SLE], rheumatoid arthritis, scleroderma, sarcoidosis, etc.) are at great risk for the development of cardiovascular disease in general and hypertension in particular. For example, studies have shown that more than 50% of patients with SLE, the prototypical autoimmune disorder, have hypertension that is not necessarily dependent on renal damage typically associated with SLE.^{99–101} Individuals with SLE have been shown to have increased circulating and tissue levels of inflammatory cytokines. An association with CRP was observed in patients with SLE and hypertension and cardiovascular risk,¹⁰² and serum from patients with SLE increases IL-6 release from isolated endothelial cells.¹⁰³ Despite this high level of cardiovascular risk and hypertension, there have been surprisingly few studies aimed at investigating the role that inflammatory cytokines play in the progression of hypertension during chronic inflammatory disorders such as SLE.

GENETIC VARIATION OF CYTOKINES

From individual to individual there is variation in the DNA sequences that determine genetic makeup. Throughout the human genome, thousands of single nucleotide substitutions have been identified and are referred to as single nucleotide polymorphisms (SNP). These SNPs may have significant effects on whether a DNA sequence is appropriately transcribed and translated or have no effect at all. SNPs can be used as genetic markers to identify relationships with certain diseases. For example, consider a base pair change from G to C at position X in a gene that is vital for blood pressure regulation. If the mutation occurs at a high frequency in a population of hypertensive patients, that SNP is considered to be associated with hypertension. While a genetic association suggests a relationship between genotype and phenotype, it does not provide information on functional changes that occur as a result of the polymorphism. Furthermore, investigators often come to different conclusions about genetic associations because numerous factors, including population size and makeup, can influence the results. Many studies have been performed in humans by examining common SNPs that associate with hypertension, including SNPs identified in inflammatory cytokines.

Tumor necrosis factor alpha

In humans, there is evidence that the TNF- α gene locus associates with obesity-related hypertension.¹⁰⁴ Within the TNF- α gene, two common SNPs have been identified in the promoter region (G-238A and G-308A). There is evidence supporting an association of these SNPs with hypertension in Japanese and Argentine populations^{105,106;}

however, this association was not evident in Chinese subjects.^{107,108} These disparate results can likely be attributed to different populations studied. Whether mutations in TNF- α are important for the development of hypertension remains to be elucidated.

Interleukin-6

Several SNPs for IL-6 have been identified in humans including a G-174C and G-636C in the promoter region, and an intronic C1691G. The G-636C allele is associated with hypertension in Japanese women, while the C1691G allele is associated with hypertension in men.¹⁰⁹ A separate study of Japanese women found no association between several IL-6 polymorphisms and blood pressure. The G-174C allele in the IL-6 promoter has been shown to be significantly associated with hypertension. However it is interesting to note that in one study, individuals with the GC or CC genotype were at greatest risk for having increased diastolic pressure and left ventricular hypertrophy¹¹⁰ while other investigators found the GG genotype to have the strongest association with hypertension.¹¹¹

C-Reactive protein

Although numerous studies demonstrate an association between serum levels of CRP and blood pressure, the evidence supporting genetic associations between CRP SNPs and hypertension is weak. The G1059C polymorphism for CRP was previously reported to be a marker for cardiovascular risk.¹¹² However, while the frequency of this SNP has been associated with blood pressure, the association was not significant when adjusted for other cardiovascular risk factors.¹¹³

Other cytokines

Polymorphisms in other cytokines have been examined with respect to hypertension, but have failed to reveal a genetic association (TGF- β , T10C; IFN- γ , T874A; and IL-1 β ; taq dimorphism +3892) with the exception of an arginine allele in codon 25 of TGF- β that is increased in hypertensive patients.¹¹⁴

IMPLICATIONS FOR THERAPY

Although the mechanisms by which inflammatory cytokines contribute to the progression of hypertension continue to be elucidated, it is clear that they play an important role. Therefore, treatments that mitigate inflammation will likely have great benefit for patients with hypertension. Blockade of the RAS with ARBs or ACE inhibitors is one of the most common pharmacologic treatments for hypertension. These drugs have a myriad of cardiovascular benefits to which anti-inflammation can be added. Many patients use HMG CoA reductase inhibitors, or statins, to safely regulate cholesterol and reduce cardiovascular risk. Importantly, statins have been shown to be anti-inflammatory.^{115,116} While they may not have significant blood pressure-lowering capabilities acutely, the long-term benefit of statin therapy on hypertension could be significant.

The thiazolidinedione (TZD) drug family was developed over the past 15 years, and is currently used to improve insulin sensitivity in otherwise resistant patients. TZDs are potent activators of the nuclear transcription factor, peroxisome proliferator activated receptor gamma (PPAR γ). Evidence suggests in human and animal models that they reduce blood pressure and attenuate the expression of pro-inflammatory cytokines. There is currently a great deal of research regarding the potential cardiovascular benefits of these drugs.

Corticosteroids are commonly used as general immunosuppressive therapy for patients with chronic inflammatory disease. Unfortunately, chronic corticosteroid use can lead to increased blood pressure as a result of its mineralocorticoid actions to increase sodium and water retention by the kidneys. This precludes corticosteroids from being an effective anti-inflammatory treatment of hypertension. To the contrary, there are anti-inflammatory therapies commonly recommended for humans to reduce cardiovascular risk. Many physicians prescribe a low-dose, nonsteroidal, anti-inflammatory regimen (i.e., aspirin) for individuals with increased cardiovascular risk. Aspirin is also commonly used to treat symptoms of chronic inflammatory diseases. Cyclosporine is a general immunosuppressive drug that prevents lymphocytes from producing inflammatory cytokines. It is used in humans who have undergone organ transplants or in those with chronic inflammatory disease. Evidence in rodents suggests that the inhibition of cytokines by cyclosporine can reduce blood pressure.¹¹⁷ As more is learned about the role that inflammatory cytokines play in the progression of cardiovascular disease, anti-inflammatory drugs may become more common for the treatment of hypertension.

CONCLUSIONS

The role that inflammation and cytokines play in the progression of hypertension is an emerging area of research interest that will continue to garner attention. There is strong supporting evidence to show that increased cytokines are associated with numerous forms of hypertension. These inflammatory mediators can regulate, and be regulated by, neurohumoral pathways that have long been implicated in the development of hypertension. The effect of cytokines on the development of hypertension is not limited to these endocrine systems, but rather can be vital to altering function in multiple organ systems, including the brain, kidneys, heart, and vasculature. Moreover, there is evidence to support genetic associations between variant SNPs in cytokines and hypertension. Despite growing evidence supporting a role for cytokines in the progression of cardiovascular disease, there are few studies that demonstrate a direct role for cytokines in the progression of hypertension. Therefore, providing definitive evidence and mechanisms for the role of cytokines in hypertension will be important for the development of future therapies.

Chapter
23Role of the Kidney
in Hypertension

Joey P. Granger and John E. Hall

Key Findings

- Experimental and theoretical evidence strongly support a central role for the kidneys in the long-term regulation of body fluid volume and arterial pressure.
- A pivotal part of the renal-body fluid feedback control system for long-term blood pressure regulation is the renal-pressure natriuresis mechanism whereby increases in renal perfusion pressure lead to significant increases in sodium and water excretion.
- Renal-pressure natriuresis is abnormal in all types of experimental and clinical hypertension.
- Hypertension is an important compensatory mechanism that allows maintenance of sodium balance when renal-pressure natriuresis is impaired.
- Impaired renal-pressure natriuresis and chronic hypertension can be caused by factors that either reduce glomerular filtration rate and/or increase tubular reabsorption.
- A shift of renal-pressure natriuresis can occur as a result of intrarenal abnormalities such as enhanced formation of angiotensin II, reactive oxygen species, and endothelin (via ET_A receptor activation) or decreased synthesis of nitric oxide or natriuretic prostanoids. In other instances, the altered kidney function is caused by extrarenal disturbances, such as increased sympathetic nervous system activity or excessive formation of antinatriuretic hormones such as aldosterone.

Although severe kidney disease has been recognized for more than 100 years to be closely associated with hypertension, the importance of more subtle renal dysfunction in the pathogenesis of essential hypertension has not been as well appreciated, partly because there are no obvious renal defects in most hypertensive patients. Many of the measurements that are commonly used to evaluate kidney function, such as glomerular filtration rate (GFR), renal blood flow, serum creatinine, and sodium excretion are often within the normal range, at least in the early stages of primary (essential) hypertension. On the other hand, increased total peripheral vascular resistance is an obvious abnormality found in most patients with hypertension, leading many to focus mainly on the mechanisms of peripheral vasoconstriction as a cause of hypertension.

An interesting fact to consider is that almost all forms of experimental hypertension are caused by obvious insults to the kidneys that alter renal hemodynamics or tubular reabsorption. For example, constriction of the renal arteries

(e.g., Goldblatt hypertension), compression of the kidneys (e.g., perinephritic hypertension), or administration of sodium-retaining hormones (e.g., mineralocorticoids or angiotensin II [Ang II]) are all associated with either initial reductions in renal blood flow and GFR or increases in tubular reabsorption prior to development of hypertension. As blood pressure rises, the initial renal changes are obscured by compensations that restore kidney function toward normal. The rise in blood pressure then initiates a cascade of cardiovascular changes, including increased peripheral vascular resistance that may be more striking than the initial disturbance of kidney function. For this reason the importance of renal dysfunction in causing hypertension has often been underestimated.

Although specific abnormalities of kidney function are difficult to identify in most patients with primary hypertension, there is one aspect of kidney function, the renal-pressure natriuresis mechanism, that is abnormal in all types of experimental and clinical hypertension.¹⁻³ Renal-pressure natriuresis refers to the effects of increased arterial pressure to raise sodium excretion and is usually accompanied by “pressure diuresis” (increased water excretion). In hypertension, a normal rate of sodium excretion (equal to sodium intake) is maintained despite elevated blood pressure, which would normally cause natriuresis and diuresis.¹⁻³ This indicates that pressure natriuresis and diuresis are reset in hypertensive subjects. Although the causes of this resetting have been examined in many forms of experimental hypertension and secondary forms of human hypertension, the mechanisms that cause abnormal pressure natriuresis in patients with primary hypertension are not completely understood. Before discussing factors that contribute to abnormal pressure natriuresis in hypertension, we will briefly discuss the basic feedback systems that link renal excretion of sodium and water with altered blood pressure regulation in hypertension.

RENAL–BODY FLUID FEEDBACK SYSTEM FOR LONG-TERM BLOOD PRESSURE REGULATION

Arterial pressure is the product of cardiac output and total peripheral vascular resistance, and moment-to-moment regulation of blood pressure is closely linked to factors that alter either cardiac function or peripheral vascular resistance. However, long-term blood pressure regulation is more complex because it is closely intertwined with control of body fluid volume, which is determined by the balance between fluid

intake and renal excretion. Even transient imbalances between fluid intake and excretion can alter extracellular fluid volume and cardiac output, and eventually peripheral vascular resistance, through autoregulatory mechanisms that are activated secondary to changes in blood pressure.^{1,4}

Under steady-state conditions, there must be a precise balance between the intake and output of fluid and electrolytes. Otherwise, continued expansion or contraction of body fluid volumes would eventually lead to complete circulatory collapse. In fact, it is much more critical to maintain water and electrolyte balances than to maintain a normal level of blood pressure and, as discussed later, chronic hypertension provides a means of restoring fluid balance when intrarenal and neurohumoral mechanisms are unable to maintain a normal rate of fluid excretion, equal to intake, after a disturbance that impairs kidney function.

Pressure natriuresis, a key component of renal–body fluid feedback

The effect of increased blood pressure to cause natriuresis and diuresis can be shown in acute studies, and is even more impressive with chronic increases in blood pressure.^{1,3} If kidney function is not impaired, increased arterial pressure raises sodium excretion, and as long as excretion exceeds intake, extracellular fluid volume continues to decrease, reducing venous return and cardiac output until blood pressure returns to normal and fluid intake and output are re-established (Figure 23–1). Conversely, when blood pressure falls below normal, the kidneys retain sodium and water until arterial pressure is restored to the normal set-point. In this way, pressure natriuresis acts as a key component of a feedback system that normally stabilizes blood pressure and body fluid volumes.

An important feature of renal pressure natriuresis is that various hormonal and neural control systems can amplify or blunt the basic effect of blood pressure on sodium and water excretion.^{2,3} For example, during chronic increases in sodium intake, only small changes in blood pressure are needed to maintain sodium balance in many people. One of the reasons for this insensitivity of blood pressure to salt intake is that secretion of antinatriuretic hormones

(e.g., Ang II and aldosterone) is reduced and secretion of natriuretic hormones (e.g., atrial natriuretic peptide) is increased; the hormonal changes then enhance the effectiveness of pressure natriuresis and allow sodium balance to be maintained with minimal increases in blood pressure. Excessive activation of these antinatriuretic systems or deficiency of natriuretic hormones, however, can reduce the effectiveness of pressure natriuresis, thereby necessitating greater increases in blood pressure to maintain sodium balance (as discussed later in this chapter).

Another important characteristic of renal-pressure natriuresis is that it is part of an integral control system with infinite feedback gain.¹ This means that it continues to operate until blood pressure is restored to the original set-point, which is determined by the various intrarenal and neurohumoral mechanisms that control the kidney's ability to excrete sodium and water. Therefore, as long as renal-pressure natriuresis is unaltered, disturbances that tend to raise blood pressure, such as increased cardiac pumping ability or increased peripheral vascular resistance, will not cause chronic hypertension. For sodium balance to be maintained in the face of increased arterial pressure, there must be a concomitant shift of pressure natriuresis to higher blood pressures.

Renal-pressure natriuresis impairment in all forms of experimental and human hypertension

In all forms of hypertension that have been studied, there is a shift of renal-pressure natriuresis that sustains the hypertension.^{1–4} The shift of pressure natriuresis can be caused by *intrarenal* disturbances that increase tubular reabsorption or reduce renal blood flow and GFR in some cases. In other instances, the altered kidney function is caused by *extrarenal* disturbances, such as increased sympathetic nervous system (SNS) activity or excessive formation of antinatriuretic hormones, which reduce the kidney's ability to excrete sodium and water, shift pressure natriuresis, and eventually raise arterial pressure.

As discussed later, some renal abnormalities (e.g., increased preglomerular resistance caused by renal artery stenosis) cause a parallel shift of pressure natriuresis toward higher blood pressures without reducing the slope, and are therefore associated with hypertension that is relatively salt-insensitive; thus, the degree of hypertension is not greatly exacerbated by high sodium intake. Other abnormalities of kidney function (e.g., excessive sodium reabsorption in distal parts of the nephron) reduce the slope of pressure natriuresis and cause salt-sensitive hypertension.^{2,3} Effective treatment of hypertension therefore requires correction of abnormal pressure natriuresis, either by directly increasing renal excretory capability or indirectly by reducing extrarenal antinatriuretic and antidiuretic influences on the kidneys.

MECHANISMS OF IMPAIRED RENAL-PRESSURE NATRIURESIS IN HYPERTENSION

Impaired renal-pressure natriuresis and chronic hypertension can be caused by factors that either reduce GFR or

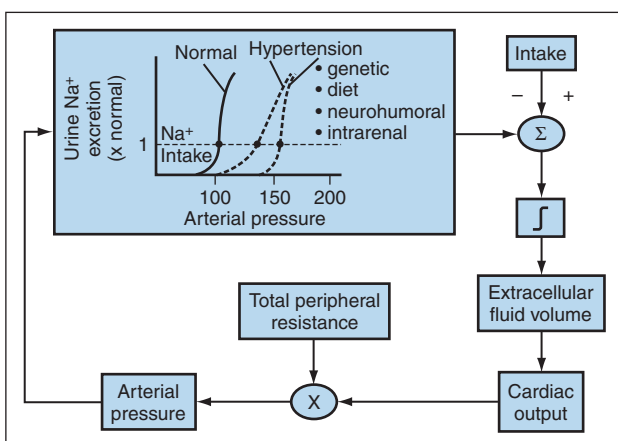

Figure 23–1. Basic renal–body fluid feedback mechanism for long-term regulation of blood pressure and body fluid volumes.

increase tubular reabsorption. Since tubular reabsorption and GFR are both approximately 100-fold greater than urinary excretion of sodium and water, relatively small changes in either of these variables can potentially have large effects on urinary excretion. Under steady-state conditions, a chronic reduction in GFR must be perfectly compensated for by mechanisms that decrease tubular reabsorption if renal excretion is to be returned toward normal and sodium and fluid balance are maintained. Likewise, a sustained increase in tubular reabsorption must be compensated for by increased GFR. Otherwise, fluid retention would continue, eventually causing circulatory collapse.

If intrinsic renal mechanisms or neurohumoral adjustments are capable of returning renal excretion to normal in the face of insults to the kidneys, hypertension may not develop—even with major disturbances—such as loss of functional kidney mass. However, the fact that hypertension occurs so frequently indicates that intrinsic renal mechanisms and neurohumoral controls may not be powerful enough to completely prevent alterations in renal excretion when there are major abnormalities of glomerular filtration or tubular reabsorption. In these instances, increased arterial pressure helps to maintain perfect glomerulotubular balance and normal rates of sodium and water excretion, equal to intake, despite abnormal kidney function. The general types of renal abnormalities that can cause chronic hypertension include (1) increased preglomerular resistance, (2) decreased glomerular capillary filtration coefficient, (3) reduced numbers of functional nephrons, and (4) increased tubular reabsorption (Figure 23–2 and Table 23–1).

Hypertension caused by generalized increases in preglomerular resistance

Examples of a generalized increase in preglomerular resistance are those caused by suprarenal aortic coarctation or

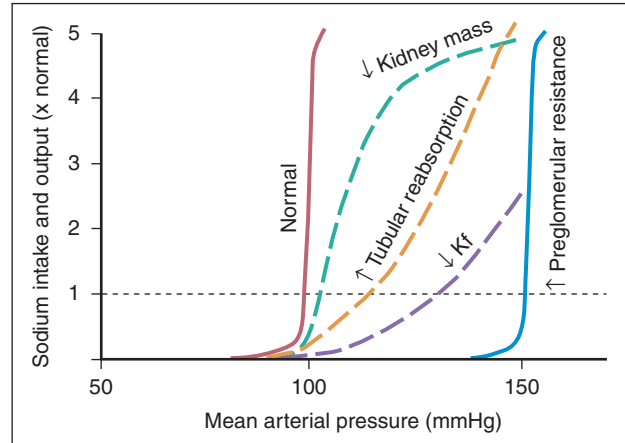

Figure 23–2. Steady-state relationships between arterial pressure and urinary sodium excretion and sodium intake for subjects with normal kidneys and four general types of renal dysfunction that cause hypertension: decreased kidney mass, increased reabsorption in distal and collecting tubules, reductions in glomerular capillary filtration coefficient (K_f), and increased preglomerular resistance. Note that increased preglomerular resistance causes *salt-insensitive* hypertension, whereas the other renal abnormalities cause *salt-sensitive* hypertension.

constriction of one of the renal arteries and removal of the contralateral kidney (e.g., one-kidney, one-clip Goldblatt hypertension). Immediately after constriction of the renal artery or aortic coarctation, renal blood flow is reduced to the kidneys and there is a rapid rise in plasma renin activity and transient sodium retention. Within a few days, sodium excretion returns to normal and sodium balance is reestablished. If sodium intake is normal and adequate volume is available, plasma renin activity also returns to normal in

CAUSES AND CHARACTERISTICS OF SALT-SENSITIVE AND SALT-INSENSITIVE HYPERTENSION						
Causes	Blood Pressure	Pressure Natriuresis	Renal Blood Flow	Glomerular Filtration Rate	Plasma Renin Activity	Glomerulosclerosis ^a
Salt-Sensitive Hypertension						
1. Decreased kidney mass	↑, ↔	Decreased slope	↓	↓	↓	Yes
2. Decreased glomerular capillary filtration coefficient (K_f)	↑	Decreased slope	↑	↓, ↔	↑, ↔	Yes
3. Increased distal and collecting tubule reabsorption	↑	Decreased slope	↑	↑	↓	Yes
Salt-Insensitive Hypertension						
1. Increased preglomerular resistance	↑	Parallel Shift	↓, ↔	↓, ↔	↑, ↔	No
2. Increased reabsorption in proximal tubules and loops of Henle	↑	Parallel Shift	↑	↑	↑, ↔	Yes

^aGlomerulosclerosis is predicted to occur secondary to hypertensive stimuli that cause chronic increases in glomerular hydrostatic pressure and/or hyperfiltration of surviving nephrons.

Table 23–1. Causes and Characteristics of Salt-Sensitive and Salt-Insensitive Hypertension

the established phase of hypertension. At this point, most indices of renal function are nearly normal, including pressure distal to the stenosis if the constriction is not too severe. The rate at which renal function returns to normal and the time course for development of hypertension depend on the severity of the stenosis, sodium intake, and rate of Ang II formation.^{1,5}

How do these experimental models of increased preglomerular resistance relate to human hypertension, other than the obvious conditions of aortic coarctation or renal artery stenosis? When Harry Goldblatt⁶ first produced hypertension in dogs by constricting the main renal artery, his goal was to produce an experimental model that mimicked the pathologic changes found in human essential hypertension. As a pathologist, Goldblatt noted that many hypertensive patients at autopsy had nephrosclerosis, and he hypothesized that essential hypertension might be caused by diffuse renal arteriolar sclerosis, particularly in preglomerular vessels. Presumably, functional or pathologic increases in preglomerular resistance at other sites besides the main renal arteries, such as the interlobular arteries or afferent arterioles, could also increase arterial pressure through the same mechanisms activated by clipping the renal artery. For example, widespread structural increases in afferent arteriolar resistance (e.g., nephrosclerosis) or functional increases in resistance caused by excessive activation of the sympathetic nervous system or high levels of catecholamines (e.g., pheochromocytoma) would also cause hypertension through the same mechanisms as constriction of the main renal artery.

An observation that led many investigators to question whether Goldblatt hypertension is relevant to human essential hypertension was the finding that many hypertensive patients have no obvious indication of renal ischemia. Renal blood flow and GFR are nearly normal and plasma renin activity may be normal (or even slightly reduced) in many hypertensive patients. However, as previously discussed there is little indication of renal ischemia, even in experimental Goldblatt hypertension after compensatory increases in blood pressure have occurred.

It is interesting to note that some patients with primary hypertension have the same characteristics seen in the one-kidney, one-clip Goldblatt model of hypertension, including nearly normal levels of GFR and plasma renin activity, a parallel shift of pressure natriuresis to higher blood pressures, and a relatively salt-insensitive form of hypertension.^{1,2,5} Indeed, studies in hypertensive patients have shown that drug therapy which decreases preglomerular resistance, such as calcium channel blockers, causes a parallel shift of pressure natriuresis toward lower blood pressures.⁷ Thus, primary hypertension in some patients may be caused by functional or pathologic increases in preglomerular resistance. This is almost certainly the case in patients who have severe atherosclerotic lesions in the renal blood vessels.

Hypertension caused by nonhomogeneous, patchy increases in preglomerular resistance

In the two-kidney, one-clip Goldblatt model of hypertension, there is a nonhomogeneous increase in preglomerular

resistance with ischemia occurring in nephrons of the clipped kidney, while nephrons in the contralateral untouched kidney have increased single nephron blood flow and GFR. The underperfused clipped kidney secretes large amounts of renin, whereas the untouched kidney secretes very little renin.^{1,3}

An important distinction between a generalized increase in preglomerular resistance and patchy, nonhomogeneous increases in preglomerular resistance is the evolution of renal injury associated with hypertension. When there is a generalized increase in preglomerular resistance, caused by renal artery stenosis of a single kidney, the glomeruli are protected from the damaging effects of increased blood pressure. In the two-kidney, one-clip model, however, the glomeruli of the untouched kidney are subjected to the full effects of increased blood pressure. With prolonged hypertension, pathological changes in the untouched kidney add to the impairment of overall renal excretory capability. At this stage, removal of the clipped kidney only partially restores arterial pressure to normal. However, removal of the contralateral untouched kidney and unclipping the stenotic kidney normalizes blood pressure. Thus, in this model chronic exposure to high blood pressure in the untouched kidney apparently causes structural changes as well as functional changes that in turn contribute to the progression of hypertension.

The relevance of experimental models of nonhomogeneous increases in preglomerular resistance to human hypertension is obvious in cases of stenosis in only one renal artery with the contralateral kidney being unaffected. Eventually, the contralateral kidney becomes injured, leading to further amplification of hypertension and loss of kidney function if the hypertension is untreated. In some patients with essential hypertension, there may also be patchy nephrosclerosis within each kidney providing a clinical counterpart to the two-kidney Goldblatt model of hypertension. In these instances, the ischemic nephrons secrete large amounts of renin and the nonischemic nephrons vasodilate and initially have increased single nephron GFR.⁸ However, the combined effects of hypertension and hyperfiltration eventually damage the nephrons that were initially nonischemic, leading to progressive nephron loss.

Hypertension caused by decreased glomerular capillary filtration coefficient

Reducing the glomerular capillary filtration coefficient (K_f) initially lowers GFR and sodium excretion. Renal vasodilation of afferent arterioles and increased renin release occur via macula densa feedback due to reduced NaCl delivery to the macula densa. The initial sodium retention and increased Ang II formation lead to increased arterial pressure, which helps to restore GFR and renin release toward normal. After these compensations, the main persistent abnormalities of kidney function are reduced filtration fraction, increased glomerular hydrostatic pressure, and increased renal blood flow.

Unfortunately, these compensatory increases in arterial pressure and glomerular hydrostatic pressure, which are needed to offset a fall in K_f and to restore sodium excretion to normal, may also lead to additional renal dysfunction

over a period of years by causing further glomerular injury; this further reduces K_f and requires additional increases in blood pressure to maintain normal water and electrolyte balances. Such a sequence may initiate progressive kidney damage.

The clinical counterparts of this sequence may be found in hypertension caused by glomerulonephritis or by other conditions that cause thickening and damage to the glomerular capillary membranes, such as chronic diabetes mellitus.⁹

Effects of reduced numbers of functional nephrons

A factor that contributes to salt sensitivity of blood pressure and decreased plasma renin activity in some hypertensive patients is a loss of functional nephrons. Complete loss of nephrons (such as surgical reduction of kidney mass) in the absence of other abnormalities usually does not lead to significant hypertension.^{1,3} In contrast, loss of functional nephrons due to ischemia or infarction of renal tissue usually causes marked hypertension that is initially due to increased renin secretion in the early stages and then is eventually mediated by additional abnormalities, such as immunological renal injury, in the established phase of the hypertension.¹⁰

Considering our previous discussion, one might predict that reductions in the number of functional nephrons should impair renal excretory capability and cause hypertension regardless of whether the loss was associated with renal ischemia. Yet, experimental studies have shown that surgical removal of large amounts of the kidney, to the point that uremia occurs, rarely causes severe hypertension as long as sodium intake is normal.^{1,11} The reason that loss of entire nephrons *per se*, without ischemia in the remaining nephrons, does not usually cause marked hypertension is that overall glomerular filtration and tubular reabsorption capability are simultaneously reduced so that balance between filtration and reabsorption can be maintained without major adaptive changes in blood pressure. However, reducing the number of functional nephrons makes the kidneys very susceptible to additional insults that impair their function or to additional challenges of sodium homeostasis. Thus, hypertension associated with excess mineralocorticoids is much more severe after reducing kidney mass. Likewise, the kidney's ability to increase sodium excretion in response to the additional challenge of high sodium intake is accompanied by much larger increases in blood pressure when kidney mass is reduced.^{1,3,11}

With the loss of entire nephrons, each surviving nephron must excrete greater amounts of sodium and water to maintain balance. This is achieved by increasing GFR and decreasing reabsorption in the remaining nephrons, resulting in increased sodium chloride delivery to the macula densa and suppression of renin release. This, in turn, impairs the kidney's ability to further decrease renin release during high sodium intake. Therefore, after loss of kidney mass blood pressure become very salt sensitive.

Although the functional effects of nephron loss may not cause hypertension in the absence of high salt intake or other insults to the kidney, compensatory changes that

take place after nephron loss may eventually damage the surviving nephrons.⁹ For example, renal vasodilation and increased single-nephron GFR may, over long periods of time, lead to glomerulosclerosis and reductions in K_f . These pathologic changes, in addition to the loss of functional nephrons, may eventually shift pressure natriuresis sufficiently to cause severe hypertension.

What is the relevance of experimental models produced by surgically removing kidney mass to human hypertension? With normal aging there is gradual loss of functional nephrons after age 40 and this loss of nephrons is accelerated by renal diseases, such as glomerulonephritis, diabetes mellitus, or long-standing hypertension. Thus, even though hypertension may not begin with loss of nephrons, chronic elevations in glomerular pressure and other metabolic abnormalities that are often associated with hypertension may eventually cause injury to the glomeruli and progressive nephron loss that amplifies the hypertension and makes blood pressure more salt sensitive.

Loss of functional nephrons by partial renal infarction

The experimental model of surgical reduction of kidney mass should not be confused with the model of infarction hypertension produced by tying off branches of the renal artery, the so-called "5–6 ablation" model. This model is usually produced by removing one kidney and obstructing two of the three branches of the renal artery of the remaining kidney. In the infarction model, hypertension develops even without a high sodium intake due to ischemia of the surviving nephrons, activation of the renin-angiotensin system, and immune-mediated injury of the kidney.^{9,10} In reality, the 5–6 renal ablation hypertension is a model of severe patchy renal ischemia with characteristics similar to that described for the one-kidney, one-clip Goldblatt model or nonhomogeneous patchy glomerulosclerosis.

Hypertension caused by increased tubular reabsorption

Hypertension can also be caused by factors that raise tubular reabsorption, such as excessive formation of mineralocorticoids or Ang II. The severity of hypertension depends on the degree to which tubular reabsorption is stimulated and on other factors such as the functional kidney mass and sodium intake. When kidney function is otherwise normal, mineralocorticoids may have only moderate hypertensive effects.^{1,3} However, with loss of functional nephrons, the hypertensive potency of mineralocorticoids is greatly enhanced.

Increased distal and collecting tubule reabsorption causes salt-sensitive hypertension

One feature of hypertension caused by increased distal or collecting tubular reabsorption is that it is usually salt sensitive, with increased sodium intake exacerbating the hypertension. Increased reabsorption at sites beyond the macula densa, such as the distal tubules and collecting tubules, causes a salt-sensitive form of hypertension because it also elicits chronic increases in sodium chloride delivery to the macula densa that, in turn, suppresses

renin secretion.¹⁻⁴ The increased distal tubule sodium chloride delivery occurs as a compensation for increased distal and collecting tubular reabsorption in order to maintain sodium balance. The reduction of renin secretion to very low levels, characteristic of disorders associated with increased distal or collecting tubular reabsorption, prevents further suppression of Ang II formation during high sodium intake, and therefore makes blood pressure salt sensitive.

In addition, blood pressure caused by increased tubular reabsorption is often associated with a tendency toward extracellular volume expansion. However, when increased tubular reabsorption is associated with marked peripheral vasoconstriction, such as occurs with very high levels of Ang II, the degree of volume expansion depends on the relative effects of the vasoconstrictor on the peripheral blood vessels and the renal blood vessels.^{1,12} With severe peripheral vasoconstriction and decreased vascular capacitance, relatively small amounts of volume retention can lead to marked hypertension.

Increased proximal reabsorption causes salt-insensitive hypertension

If increased tubular reabsorption occurs in the proximal tubules or loop of Henle, prior to the macula densa, a salt-insensitive form of hypertension usually results. Increased tubular reabsorption prior to the macula densa tends to increase renin secretion and elicits a compensatory renal vasodilation that raises GFR and renal plasma flow. However, as hypertension develops, the macula densa sodium chloride delivery and renin secretion return to nearly normal, and the renin-angiotensin system (RAS) is fully capable of responding to additional challenges such as increased sodium intake. Therefore, high sodium intake is accompanied by appropriate suppression of renin release and Ang II formation, which permits sodium balance to be maintained with only small increases in blood pressure.^{3,12} Nevertheless, the pressure natriuresis mechanisms are shifted to higher blood pressures parallel to the normal curve, and the severity of the hypertension depends on the degree to which reabsorption is increased in the proximal tubules and loops of Henle.

SALT-SENSITIVE AND SALT-INSENSITIVE HYPERTENSION

Salt sensitivity of blood pressure is a quantitative phenotype, rather than following the bi-modal categorization of “salt sensitive” or “salt insensitive,” and there is considerable heterogeneity of blood pressure responses to changes in sodium intake in normotensive as well as in hypertensive subjects.^{13,14}

Although various methods have been used to assess salt sensitivity, most protocols involve relatively short-term changes in sodium intake, typically over a few days. Weinberger et al.¹³ defined salt sensitivity as a 10-mmHg or greater change in mean blood pressure from the level measured after a 4-hour infusion of 2 liters of normal saline compared to the level measured the morning after 1 day of a low (10 mmol) sodium diet and administration of three doses of furosemide. With this definition, 51% of hyper-

tensive and 26% of normotensive subjects were found to be salt sensitive.¹³ However, there has been little effort to determine the repeatability of salt sensitivity in the same persons over long periods of time (years), and it is not known whether short-term blood pressure responses reliably predict the long-term effects of changes in salt intake.

What are the factors that contribute to salt sensitivity of blood pressure? From clinical observations it is clear that there are many demographic and pathophysiologic conditions associated with salt sensitivity.^{3,12} Older individuals are usually more salt sensitive than young people, and African-Americans are often more salt sensitive than Caucasians. It should be recognized, however, that there are many exceptions to these generalizations and considerable heterogeneity exists in the blood pressure responses to changes in salt intake even in these populations.

Genetic factors independent of race have been linked to salt sensitivity of blood pressure. For example, genetic abnormalities that increase distal and collecting tubule sodium reabsorption or that cause excess secretion of sodium-retaining hormones (e.g., mineralocorticoids) cause salt-sensitivity of blood pressure.^{14,15} Also, diabetes mellitus, renal diseases that cause loss of nephron function, and abnormalities of the RAS are all associated with increased salt sensitivity of blood pressure.¹²⁻¹⁴ All of these examples appear to share two common pathways to the salt sensitivity of blood pressure: (1) loss of functional nephrons, or (2) reduced responsiveness of the RAS.

Loss of functional nephrons as a major cause of salt-sensitive blood pressure

As discussed previously, the effect of nephron loss to enhance salt sensitivity has been well established from experimental and clinical studies. Figure 23-3 shows the effect of surgically reducing kidney mass on salt sensitivity in dogs. As long as sodium intake was normal, surgical reduction of kidney mass by 25%, or even as much as 70%, did not markedly alter blood pressure.¹¹ However, after loss of kidney mass, blood pressure became exquisitely sensitive to changes in sodium intake, and with high sodium intake blood pressure rose by approximately 40 mmHg.

How is this experimental study conducted in dogs relevant to human hypertension? Even in normal healthy people, there appears to be about a 10% decrease in the number of functional nephrons per decade of life after age 40.^{16,17} By age 70 the average healthy individual would be predicted to have at least a 30% decrease in the number of functional nephrons. When there is underlying renal disease, hypertension, or diabetes, the loss of nephrons with aging is greatly exacerbated. Other less common causes of nephron loss include primary renal diseases such as glomerulonephritis, acquired renal disease caused by analgesic abuse, uncontrolled diabetes mellitus, and developmental causes due to poor maternal nutrition or placental ischemia.

Reduced responsiveness of the RAS as a major cause of salt-sensitive blood pressure

The RAS is the most powerful hormonal system in the body for controlling sodium excretion and therefore plays

Figure 23-3. The effect of reducing kidney mass on salt sensitivity in dogs. Note that as long as sodium chloride intake was normal, surgical reduction of kidney mass by 25% or even 70% did not markedly alter arterial pressure. However, after loss of kidney mass, blood pressure became exquisitely sensitive to high sodium chloride intake. (Data from Langston JB, Guyton AC, Douglas BH, Dorsett PE. *Circulation Res* 1963;12:508–12.)

a major role in determining salt sensitivity of blood pressure.¹⁸ With high sodium intake, suppression of the RAS permits normal excretion of sodium and water without substantial increases in blood pressure. Conversely, activation of the RAS is a primary mechanism for preventing a reduction in blood pressure during low sodium intake.

Figure 23-4 shows the importance of changes in Ang II formation in maintaining blood pressure relatively constant during variations in salt intake from 5 mmol/day up to 80, 240, and 500 mmol/day for 8 days at each level.

Figure 23-4. Changes in mean arterial pressure during chronic changes in sodium intake from a low level of 5 mmol/day to 80, 240, and 500 mmol/day in normal control dogs, after ACE inhibition, or when Ang II was infused at a constant low dose (5 ng/kg/min) to prevent Ang II from being suppressed when sodium intake was raised. (Data from Hall JE, Guyton AC, Smith MJ Jr, Coleman TG. *Am J Physiol* 1980;239:F271–80.)

In normal dogs, with a functional RAS, there were only small increases in blood pressure associated with this 100-fold range of sodium intakes.¹⁹ However, when Ang II was infused at a low level that had initially little effect on blood pressure but which prevented Ang II from being suppressed as sodium intake was raised, blood pressure became very salt sensitive. After blockade of Ang II formation, blood pressure also became salt sensitive, although pressure was maintained at a much lower level, especially when sodium intake was low.¹⁹ Thus, one of the major functions of the RAS is to permit wide variations in intake and excretion of sodium without large fluctuations in blood pressure that would otherwise be needed to maintain sodium balance.

What clinical conditions can lead to reduced responsiveness of the RAS? Focal nephrosclerosis or patchy preglomerular vasoconstriction, as occurs with renal infarcts, leads to increased renin secretion in ischemic nephrons and suppressed renin secretion in overperfused nephrons.⁸ In ischemic as well as overperfused nephrons, the ability to adequately suppress renin secretion during high salt intake is impaired.

Another cause of reduced responsiveness of the RAS is increased distal and collecting tubular sodium reabsorption, as occurs with mineralocorticoid excess or mutations that increase distal and collecting tubule reabsorption (e.g., Liddle's syndrome). In these conditions, excess sodium retention causes almost complete suppression of renin secretion, and therefore an inability to further decrease renin release during high sodium intake. As a result, blood pressure becomes very salt sensitive. It is interesting that every known form of monogenetic hypertension discovered in humans thus far is mediated by a common pathway—excess renal tubular sodium chloride reabsorption that, in turn, impairs renal-pressure natriuresis and causes salt-sensitive hypertension.¹⁵

As discussed previously, not all renal abnormalities cause salt-sensitive hypertension. Some, such as generalized diffuse increases in preglomerular resistance, cause a parallel shift of pressure natriuresis and hypertension, but do not cause salt sensitivity of blood pressure. Salt sensitivity is not increased in this form of hypertension because the RAS system is fully capable of appropriate suppression during high sodium intake, and sodium balance is maintained with minimal increases in blood pressure.

Salt-sensitive subjects may have greater target-organ injury

What is the clinical significance of salt sensitivity besides the obvious fact that it provides insight into the pathogenesis of hypertension and it indicates which patients may benefit most from reduction of salt intake? Perhaps less obvious is that salt sensitivity may also predict which patients are at greatest risk for hypertensive target-organ injury. Salt-sensitive forms of hypertension caused by increased distal tubular reabsorption, nephron loss, or inability to suppress Ang II formation are usually associated with glomerular hyperfiltration and increased glomerular hydro-

static pressure that is further amplified by the hypertension^{3,12} (Table 23–1). Together the hypertension and renal hyperfiltration promote glomerular injury and may eventually cause loss of nephron function. Clinical studies support this concept and have demonstrated that salt-sensitive subjects typically have an increase in glomerular hydrostatic pressure and albumin excretion when given a salt load, whereas salt-resistant subjects have lower glomerular hydrostatic pressure and less urinary albumin excretion.²⁰

There is also evidence that salt-sensitive subjects may die earlier than subjects who are salt resistant. In a study by Weinberger et al.²¹ in which subjects were followed for more than 20 years, normotensive subjects with increased salt sensitivity died almost at the same rate as hypertensive subjects and much faster than salt-resistant subjects who were normotensive. Whether this increased risk was related to hemodynamic or blood pressure effects of salt or to other effects is still unclear. It is also not known whether long-term high salt intake, lasting over many years, may cause a person who is initially “salt insensitive” to become “salt sensitive” due to gradual renal injury.

THE RENIN-ANGIOTENSIN SYSTEM

The RAS is perhaps the most powerful hormone system for regulating body fluid volumes and arterial pressure, as evidenced by the effectiveness of various RAS blockers in reducing blood pressure in normotensive and hypertensive subjects. Although the RAS has many components, its most important effects on blood pressure regulation are exerted by Ang II, which participates in both short-term and long-term control of arterial pressure. Ang II is a powerful vasoconstrictor and helps maintain blood pressure in conditions associated with acute volume depletion (e.g., hemorrhage), sodium depletion, or circulatory depression (e.g., heart failure). The long-term effects of Ang II on blood pressure, however, are closely intertwined with volume homeostasis through direct and indirect effects on the kidneys.

When the RAS is fully functional, the chronic renal-pressure natriuresis curve is steep, and sodium balance can be maintained over a wide range of intakes with minimal changes in blood pressure (Figure 23–5). One reason for the effectiveness of the normal pressure natriuresis mechanism is that Ang II levels are suppressed during high sodium intake and increased when sodium intake is restricted, thereby adjusting renal sodium excretion appropriately without the need to invoke large changes in blood pressure to maintain sodium balance.

Blockade of the RAS, with Ang II–receptor blockers (ARBs) or angiotensin-converting enzyme (ACE) inhibitors increases renal excretory capability so that sodium balance can be maintained at reduced blood pressures.¹⁹ However, blockade of the RAS also reduces the slope of pressure natriuresis and makes blood pressure salt sensitive.¹⁹ Inappropriately high levels of Ang II reduce renal excretory capability and impair pressure natriuresis, thereby reducing the slope and necessitating increased blood pressure to maintain sodium balance.

Figure 23–5. Steady-state relationships between arterial pressure and sodium intake and excretion under normal conditions with a fully functional renin-angiotensin system, after blockade of Ang II formation with an ACE inhibitor, and after Ang II infusion at a low dose to prevent Ang II levels from being suppressed when sodium intake was increased. The numbers along the curves are estimated Ang II levels expressed as times normal. (Modified from data in Hall JE, Guyton AC, Smith MJ Jr, Coleman TG. *Am J Physiol* 1980;239:F271–80.)

Mechanisms for the potent antinatriuretic effects of Ang II include renal hemodynamic effects as well as direct and indirect effects to increase tubular reabsorption.¹⁸ In most physiologic conditions, such as reduced sodium intake or renal ischemia, increased Ang II causes renal vasoconstriction but does not reduce GFR.¹⁸ Instead, Ang II increases renal sodium reabsorption through multiple hemodynamic and tubular effects.

Ang II–mediated efferent arteriolar constriction attenuates GFR reductions in underperfused kidneys

Physiological activation of the RAS usually occurs as compensation for conditions that cause underperfusion of the kidneys, such as sodium depletion or hemorrhage. The RAS usually acts in concert with other autoregulatory mechanisms, such as tubuloglomerular feedback (TGF) and myogenic activity, to maintain a relatively constant GFR when kidney perfusion is threatened.^{18,22} In these cases, administration of ARBs or ACE inhibitors may further reduce GFR, even though renal blood flow is preserved. The impairment of GFR after RAS blockade is due, in part, to inhibition of the constrictor effects of Ang II on efferent arterioles, as well as reduced arterial pressure.¹⁸

The effects of Ang II appear to be most important when renal perfusion pressure is reduced to low levels, near the limits of autoregulation, or when other disturbances such as sodium depletion are superimposed on low perfusion pressure. Clinically, the importance of the constrictor effects of Ang II on efferent arterioles becomes especially important in patients with renal artery stenosis and/or sodium depletion who may have substantial decreases in GFR when treated with RAS blockers.^{23,24}

The relatively weak constrictor action of Ang II on preglomerular vessels is related, in part, to selective protec-

tion of these vessels by autacoid mechanisms such as prostaglandins or nitric oxide (NO). After blockade of prostaglandin synthesis or inhibition of EDNO, Ang II infusion caused marked constriction of preglomerular as well as postglomerular vessels (see Hall¹⁸ and Hall et al.²⁵ for review). When the ability of the kidneys to produce these autacoids is impaired by treatment with nonsteroidal anti-inflammatory drugs or by chronic vascular disease (e.g., atherosclerosis), increased levels of Ang II may reduce GFR by constricting afferent and efferent arterioles.

Increased Ang II exacerbates glomerular injury in overperfused kidneys

Although blockade of the vasoconstrictor effects of Ang II on the efferent arterioles may cause a further decline in GFR in underperfused nephrons, RAS blockade may be beneficial when nephrons are hyperfiltering and Ang II is not appropriately suppressed. For example, in diabetes mellitus and in certain forms of hypertension associated with glomerulosclerosis and nephron loss, Ang II blockade, by decreasing efferent arteriolar resistance and arterial pressure, lowers glomerular hydrostatic pressure and attenuates glomerular hyperfiltration.^{25–27} Clinical and experimental studies indicate that RAS blockers are more effective than other antihypertensive agents in preventing glomerular injury, even with similar reductions in blood pressure^{28,29}; this appears to be due partly to a greater reduction in glomerular hydrostatic pressure caused by vasodilation of efferent arterioles after blockade of the RAS.

Do nonhemodynamic effects of Ang II cause renal injury?

Ang II has also been suggested to cause glomerular injury through direct actions that promote vascular smooth muscle, increased collagen formation, and production of extracellular matrix by mesangial cells, in addition to its hemodynamic effects.^{30,31} Much of the evidence supporting this hypothesis comes from *in vitro* studies, often using supra-physiologic concentrations of Ang II. Although *in vivo* studies have demonstrated greater renoprotective effects of RAS blockers compared to other antihypertensive drugs, decreases in glomerular hydrostatic pressure due to efferent arteriolar vasodilation may have contributed to these beneficial effects. Moreover, in studies where arterial pressure was measured very accurately using 24-hour telemetry, the renoprotective effects of RAS blockade appear to be due largely to hemodynamic effects including the reductions in arterial pressure.³²

The concept that Ang II directly mediates renal injury independent of blood pressure is difficult to reconcile with the finding that physiologic activation of the RAS is not associated with vascular, glomerular, or tubulointerstitial injury as long as the kidney is not overperfused or exposed to high blood pressure. For example, sodium depletion does not cause renal injury despite marked increases in renal Ang II levels. Also, the clipped kidney of the two-kidney, one-clip Goldblatt model of hypertension is exposed to high Ang II levels, but is protected from increased arterial pressure by the clip on the renal artery and has no visible injury as long as the stenosis is not too severe.

However, the nonclipped kidney, exposed to lower Ang II concentrations but higher blood pressures, has marked focal segmental glomerular sclerosis as well as tubulointerstitial changes characteristic of hypertension.³³ These observations suggest that the hemodynamic effects of Ang II are necessary for many of the glomerular, tubular, interstitial proliferative, and other phenotypic changes that occur in Ang II-dependent hypertension.

Ang II-mediated changes in peritubular capillary dynamics promote increased tubular reabsorption

Ang II-mediated constriction of efferent arterioles stabilizes GFR, but also reduces renal blood flow and peritubular capillary hydrostatic pressure, and increases peritubular colloid osmotic pressure as a result of increased filtration fraction.¹⁸ These changes, in turn, reduce the hydrostatic pressure of renal interstitial fluid and raise interstitial fluid colloid osmotic pressure, thereby increasing the driving force for fluid reabsorption across tubular epithelial cells and reducing back-leak of sodium from the intercellular spaces into the tubules.

The effects of Ang II on renal hemodynamics and interstitial fluid dynamics may also alter reabsorption in more distal parts of the tubule. For example, reductions in renal medullary blood flow due to efferent arteriolar constriction or to direct effects of Ang II on the vasa recta may enhance reabsorption in the loop of Henle and collecting ducts.^{18,34} Thus, there are several pathways by which subtle changes in renal hemodynamics, without major changes in GFR, may mediate the effects of Ang II to enhance renal sodium reabsorption.

Ang II directly stimulates proximal tubular sodium reabsorption

The proximal tubule was the first site at which Ang II was shown to directly stimulate sodium and fluid transport in the nephron. This effect occurs at very low Ang II concentrations (10^{-13} to 10^{-10} M) and is mediated by actions on the luminal and basolateral membranes³⁵ (Figure 23–6). Ang II stimulates the sodium-hydrogen antiporter on the luminal membrane and increases sodium-potassium-ATPase activity as well as sodium-bicarbonate co-transport on the basolateral membrane. These effects appear to be due in part to inhibition of an adenyl cyclase and increased phospholipase C activity. These combined actions of Ang II greatly enhance proximal tubular sodium reabsorption by increasing sodium entry into the epithelial cells, sodium extrusion into the interstitial fluid, and uptake of sodium and fluid into the peritubular capillaries.³⁶

Ang II increases sodium reabsorption in loop of Henle, macula densa, and distal nephron segments

In vivo microperfusion studies have shown that Ang II, in physiologic concentrations, increases bicarbonate reabsorption in the loop of Henle and stimulates sodium-potassium-2-chloride transport in the medullary thick ascending loop of Henle (TALH).^{37,38} Ang II stimulates multiple ion transporters in the distal parts of the nephron, which include

Figure 23–6. Ang II increases proximal tubular reabsorption by binding to receptors on the luminal and basolateral membranes and stimulating Na^+/H^+ antiporter, $\text{Na}^+/\text{HCO}_3^-$ co-transport, and Na^+/K^+ ATPase activity. ANG II also increases reabsorption by increasing interstitial fluid colloid osmotic pressure and decreasing interstitial fluid hydrostatic pressure.

hydrogen-ATPase activity as well as epithelial sodium channel activity in the cortical collecting ducts.^{34,39}

Ang II may also stimulate ion transport in the macula densa epithelial cells, a nephron site that may be particularly important in determining the final urine excretion of sodium. The macula densa is a crucial component of TGF, which operates to maintain a relatively constant delivery of sodium chloride to the distal tubules by feedback regulation of afferent and efferent arteriolar resistances and therefore GFR. Ang II amplifies TGF feedback sensitivity, probably by stimulating macula densa sodium chloride transport.^{25,40} In this way, enhanced feedback sensitivity permits a decrease in distal sodium chloride delivery without compensatory increases in GFR via TGF. Decreased distal tubular sodium chloride delivery, caused by the multiple proximal tubule and vascular actions of Ang II, combines with other actions of Ang II on the distal nephron sites to reduce sodium excretion and exert powerful antinatriuretic effects. For this reason, Ang II is one of the most powerful sodium-retaining hormones in the body, and therefore exerts important effects on renal pressure natriuresis and long-term blood pressure regulation. Conversely, blockade of Ang II provides a means of enhancing renal excretory capability, thereby allowing sodium balance to be

maintained at greatly reduced arterial blood pressures.

ALDOSTERONE

Aldosterone is also a powerful sodium-retaining hormone, and consequently has important effects on pressure natriuresis and long-term regulation blood pressure. The primary sites of actions of aldosterone on sodium reabsorption are in distal tubules, cortical collecting tubules, and collecting ducts where aldosterone stimulates sodium reabsorption and potassium secretion. These effects are due mainly to binding of aldosterone to intracellular mineralocorticoid receptors (MR) and activation of transcription by target genes.⁴¹ These, in turn, stimulate synthesis or activation of the sodium-potassium ATPase pump on the basolateral epithelial membrane and activation of amiloride-sensitive sodium channels on the luminal side of the epithelial membrane. These effects are termed “genomic” because they are mediated by activation of gene transcription and require 60 to 90 minutes to occur after administration of aldosterone.

Aldosterone is also thought to exert more rapid *nongenomic* effects on the kidney and cardiovascular system.⁴² Aldosterone increases the sodium current in the principal cells of the cortical collecting tubule through activation of the amiloride-sensitive channel and stimulates the sodium-hydrogen exchanger in a few minutes after application (see Funder⁴² and Wehling et al.⁴³ for reviews). In vascular smooth muscle cells, aldosterone stimulates sodium influx by activating the sodium-hydrogen exchanger in less than 4 minutes. Acute aldosterone administration may rapidly reduce forearm blood flow in humans,⁴⁴ although some investigators have found either no change or an increase in blood flow.⁴⁵ The putative membrane receptor and the cell-signaling mechanisms responsible for these rapid nongenomic actions of aldosterone have not been identified, especially with physiologic levels of aldosterone. Thus, the importance of the nongenomic effects of aldosterone on long-term regulation of renal-pressure natriuresis and blood pressure are still unclear.

The overall effects of aldosterone on renal pressure natriuresis are similar to those observed for Ang II. With low sodium intake, increased aldosterone helps prevent sodium loss and reductions in blood pressure. Conversely, during high sodium intake, suppression of aldosterone helps to prevent excessive sodium retention and attenuates an increase in blood pressure.

Excess aldosterone secretion reduces the slope of pressure natriuresis so that blood pressure becomes very salt sensitive. Thus, increasing plasma aldosterone 6- to 10-fold

cause marked hypertension when sodium intake is normal or elevated, but there is very little effect on blood pressure when sodium intake is low.^{1,46}

In recent years, interest has turned once again to the role of aldosterone and activation of MR in human hypertension. Some investigators have suggested that hyperaldosteronism or excess activation of MR may be more common than previously believed, especially in patients with resistant hypertension. For example, the prevalence of primary aldosteronism has been reported to be almost 20% among patients referred to specialty clinics for resistant hypertension. Many of these resistant patients are overweight or obese.⁴⁷

Regardless of the prevalence of primary aldosteronism, there is emerging evidence that antagonism of MR may provide an important therapeutic tool for preventing target organ injury and reducing blood pressure in hypertension.⁴⁷⁻⁴⁹ We have previously shown, for example, antagonism of MR attenuated sodium retention, hypertension, and glomerular hypofiltration in obese dogs fed a high-fat diet.⁵⁰ This finding was somewhat surprising in view of the fact that plasma aldosterone concentration was only slightly elevated in obesity.⁵¹ However, even mild increases of plasma aldosterone may contribute to increased blood pressure when accompanied by marked sodium retention and volume expansion since aldosterone greatly enhances salt sensitivity of blood pressure.

Another possible explanation for the effectiveness of MR antagonists in obese, insulin-resistant patients is that there may be enhanced sensitivity to the effects of aldosterone due to increased abundance of epithelial sodium channels (ENaC), which would amplify the effects of MR activation on sodium reabsorption and blood pressure. It is also possible that the marked effects of MR blockade to reduce blood pressure in obesity are mediated partly by glucocorticoid activation of the MR. Normally the MR is “protected” from activation by glucocorticoids due to the effects of 11 β -hydroxysteroid dehydrogenase 2 (11 β -HSD2) which converts active cortisol into inactive cortisone (see Chapter 68). Reductions in 11 β -HSD2 in the renal tubules would therefore lead to increased MR activation by cortisol, causing sodium retention, hypokalemia, and hypertension. Although studies in some experimental models of hypertension, such as the Dahl salt-sensitive rat, have shown reduced expression of 11 β -HSD2 in the kidney, there have been few studies that have assessed the potential role of this mechanism in human obesity hypertension.

THE SYMPATHETIC NERVOUS SYSTEM

The SNS is an important short-term and long-term controller of arterial pressure. Sympathetic vasoconstrictor fibers are distributed to almost all regions of the vasculature as well as to the heart, and activation of the SNS can raise blood pressure in a few seconds by causing vasoconstriction, increased cardiac pumping capability, and increased heart rate. Conversely, sudden inhibition of SNS activity can decrease arterial pressure to as low as half normal within less than a minute. Therefore, changes in SNS activity caused by various reflex mechanisms, central nervous system

(CNS) ischemia, or activation of higher centers in the brain provide powerful and rapid, moment-to-moment regulation of arterial pressure.

The SNS plays an important role in long-term regulation of arterial pressure and in the pathogenesis of hypertension by activation of the renal sympathetic nerves.⁵² There is extensive innervation of the renal blood vessels, the juxtaglomerular apparatus, and the renal tubules and excessive activation of these nerves causes sodium retention, increased renin secretion, and impaired renal-pressure natriuresis.⁵² Except for extreme circumstances, such as severe hemorrhage or other conditions associated with marked circulatory depression, activation of the renal sympathetic nerves is usually not great enough to cause marked reductions in renal blood flow or GFR. However, even mild increases of renal sympathetic activity stimulate renin secretion and sodium reabsorption in multiple segments of the nephron, including the proximal tubule, the loop of Henle, and more distal segments.⁵² Thus, the renal nerves provide a mechanism by which the various reflex mechanisms and higher CNS centers can contribute to long-term regulation of arterial pressure.

The preganglionic neurons that synapse with the renal sympathetic postganglionic fibers are located in the lower thoracic and upper lumbar segments of the spinal cord and receive multiple inputs from various regions of the brain, including the brain stem, forebrain, and cerebral cortex. These complex neural pathways provide multiple pathways by which neural reflexes and higher CNS centers can influence renal SNS activity and chronic regulation of arterial pressure.^{53,54}

Evidence for a role of the renal nerves in hypertension comes from multiple studies showing that renal denervation reduces blood pressure in various models of experimental hypertension.⁵² For example, complete renal denervation attenuates the development of hypertension in spontaneously hypertensive rats⁵² as well as in obese hypertensive dogs.⁵⁵ Renal denervation may also delay or attenuate increased blood pressure in several forms of experimental hypertension, although some studies have not found an important role for the renal nerves in various forms of secondary hypertension. In Ang II hypertension, for example, *decreased* renal sympathetic activity appears to attenuate the rise in blood pressure.⁵⁶

Human primary hypertension, especially when associated with obesity, is often associated with increased renal sympathetic activity.⁵⁷ Although the mechanisms that cause activation of renal sympathetic nerves in primary hypertension or in most experimental models are still unclear, we will briefly discuss three that have attracted considerable interest.

Resetting of baroreceptor reflexes in hypertension

The importance of the arterial baroreceptors in buffering moment-to-moment changes in blood pressure is clearly evident in baroreceptor-denervated animals in which there is extreme variability of blood pressure caused by normal daily activities.⁵⁸ Although blood pressure increases to very high levels or falls to low levels throughout the day after

baroreceptor denervation, the average 24-hour mean arterial pressure is not markedly altered.

Although the arterial baroreceptors provide a powerful means for moment-to-moment regulation of arterial pressure, their role in long-term blood pressure regulation has been controversial. One reason that the baroreceptors have often been considered to be relatively unimportant in chronic regulation of blood pressure is that they tend to reset within a few days to the level of blood pressure to which they are exposed.⁵⁸ Therefore, in most forms of chronic hypertension, the arterial baroreflexes are reset to higher blood pressures. To the extent that resetting of baroreceptors occurs, this would attenuate their potency as a long-term controller of blood pressure.

Some experimental studies, however, suggest that the baroreceptors may not completely reset and therefore contribute to long-term blood pressure regulation (see Chapter 24). Thus, with prolonged increases in arterial pressure, the baroreflexes may contribute to *reductions* in renal sympathetic activity and promote sodium and water excretion. This, in turn, may attenuate the rise in arterial blood pressure.⁵⁶ Although impairment of baroreflexes contributes to increased lability of blood pressure, there is little evidence that baroreceptor dysfunction plays a major role in *causing* chronic hypertension.

Although impaired baroreflexes may not cause chronic hypertension directly by altering SNS activity, increased blood pressure lability, accompanied by periodic large increases in blood pressure, may cause gradual renal injury and eventually lead to chronic hypertension. Studies in experimental animals have shown that baroreceptor-denervated animals have significant structural changes in the kidneys, including glomerular injury.⁵⁹

Does chronic stress cause hypertension by SNS activation?

Acute physiologic stresses, including pain, exercise, exposure to cold, and mental stress, can all lead to increased SNS activity and transient hypertension. It is also widely believed, however, that chronic stress may lead to long-term increases in blood pressure. Support for this concept comes largely from a few epidemiological studies showing that populations or groups, such as air traffic controllers and lower socioeconomic groups, who are believed to lead more stressful lives also have increased prevalence of hypertension.⁶⁰ (See Chapter 42 for further discussion of psychosocial stress and hypertension.) Currently, however, there is limited evidence for a direct cause-and-effect relationship between psychosocial stress and chronic hypertension. Further experimental studies are needed to determine (1) if intermittent psychosocial stresses can indeed lead to chronic SNS activation hypertension, and (2) the mechanisms that link psychosocial stresses to chronic hypertension.

Obesity as major cause of SNS activation in primary hypertension

Population studies indicate that excess weight gain is one of the best predictors for development of human primary hypertension (see Chapter 38). Risk estimates from the Framingham Heart Study, for example, suggest that approxi-

mately 78% of hypertension in men and 65% in women can be attributed to excess weight gain.⁶¹

The mechanisms responsible for obesity hypertension appear to be closely linked to increased renal SNS activity. Obese persons have elevated SNS activity in various tissues, including the kidneys and skeletal muscle, as assessed by microneurography, tissue catecholamine spillover, or other methods.⁵¹ Studies in experimental animals and humans indicate that combined α - and β -adrenergic blockade markedly attenuates the hypertension associated with obesity.^{51,57,62} Moreover, the renal sympathetic efferent nerves mediate much of the chronic effects of SNS activation on blood pressure in obesity since bilateral renal denervation greatly attenuates the sodium retention and hypertension in obese dogs.⁵⁵ Thus, obesity increases renal sodium reabsorption, impairs pressure natriuresis, and causes hypertension in part by increasing renal SNS activity.

The mechanisms that increase renal SNS activity in obesity have not been fully elucidated, although several potential mediators have been suggested including hyperinsulinemia, increased Ang II, activation of chemoreceptor-mediated reflexes associated with sleep apnea, and hyperleptinemia. One of the most promising of these mechanisms is hyperleptinemia.⁶³

Leptin is released by adipocytes in proportion to the degree of adiposity and acts on various regions of the hypothalamus to regulate body weight by decreasing appetite and increasing energy expenditure due to increased SNS activity (Figure 23–7). Studies in rodents indicate that increases in plasma leptin to levels comparable found in severe obesity can also raise arterial pressure via SNS activation.⁶⁴ Support for the possibility that leptin may be an important link among obesity, renal SNS activation, and hypertension is the finding that rodents with leptin deficiency or mutations of the leptin receptor have little or no increase in blood pressure despite severe obesity when compared to their lean controls.^{63,65} Also, obese children with leptin gene mutations have early-onset morbid

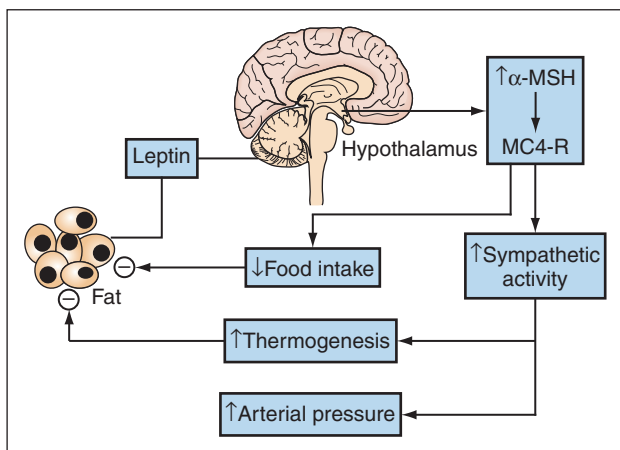

Figure 23–7. Possible links among leptin and its effects on the hypothalamus, sympathetic activation, and hypertension. Leptin may mediate much of its effects on appetite and sympathetic activity by stimulating other neurochemical pathways, including α -melanocyte-stimulating hormone, which activates melanocortin 4-receptors (MC4-R).

obesity, but no indication of the SNS activation that would usually accompany obesity.⁶⁶ These observations suggest that hyperleptinemia may be an important factor in linking obesity with renal SNS activation and hypertension in humans as well as in rodents (see Chapter 38).

The stimulatory effect of leptin on SNS activity is mediated by interaction with other hypothalamic factors, especially the proopiomelanocortin pathway. In a recent study, antagonism of the melanocortin 3/4 receptors (MC3/4R) completely abolished the acute effects of leptin on renal SNS activity as well as the chronic effects on blood pressure.⁶⁷ Likewise, the chronic hypertensive effects of leptin were completely abolished in MC3/4R knock-out (KO) mice.⁶⁸ These observations indicate that a functional MC-4R is important in linking obesity and hyperleptinemia with increased SNS activity and hypertension.

Thus, obesity is a key factor in causing primary hypertension in many patients via activation of renal sympathetic activity. The leptin-hypothalamic-melanocortin system appears to link excess adiposity with increased SNS activity in rodents and may be important in humans, although further studies are needed to determine the quantitative importance of this pathway.

THE ENDOTHELIN SYSTEM

In 1988, Yanagisawa et al.⁶⁹ characterized an endothelial-derived vasoconstrictor, a 21 amino acid peptide subsequently called endothelin. Endothelin-1 (ET-1) is derived from a 203 amino acid peptide precursor, proendothelin, which is cleaved after translation to form proendothelin.⁷⁰⁻⁷⁴ In the presence of a converting enzyme located within the endothelial cells, proendothelin or big endothelin is cleaved to produce the 21 amino acid peptide, endothelin. ET-1 receptor-binding sites have been identified throughout the body with the greatest numbers of receptors in the kidneys and lungs.⁷⁰⁻⁷⁴

While the biochemical and molecular nature of endothelin has been well characterized, the physiologic importance of endothelin in the regulation of renal and cardiovascular function has yet to be fully elucidated.⁷⁰⁻⁷⁴ ET-1 can either elicit a prohypertensive, antinatriuretic effect by activating ET_A receptors in the kidneys or an antihypertensive, natriuretic effect via renal ET_B receptor activation.⁷⁵ Thus, the ability of ET-1 to influence blood pressure regulation and renal-pressure natriuresis is highly dependent on where ET-1 is produced and which ET receptor type is activated (Figure 23-8).

Endothelin-1 reduces pressure natriuresis and increases blood pressure via endothelin Type A receptor activation

ET_A receptors are primarily located on vascular smooth muscle cells. These receptors are thought to be involved in mediating ET-1 vasoconstriction and cellular proliferation in various disease states.⁷⁰⁻⁷⁴ Although ET_A receptors may play a role in certain forms of hypertension, these receptors do not appear to have a major influence on cardiovascular and renal function under normal physiologic conditions.

ET-1, via ET_A receptor activation, exerts a variety of actions within the kidney that, if sustained chronically, could contribute to the development of hypertension and progressive renal injury.⁷⁰⁻⁷⁴ ET-1 decreases GFR and renal plasma flow through vascular smooth muscle and mesangial cell contraction. Long-term effects of ET-1 on the kidney include mesangial cell proliferation and extracellular matrix deposition as well as vascular smooth muscle hypertrophy in renal resistance vessels.⁷⁰⁻⁷⁴ Previous studies have indicated that expression of ET-1 is greatly enhanced in animal models of severe hypertension with renal vascular hypertrophy and in models of progressive renal injury.⁷⁶⁻⁸¹ In addition, treatment with endothelin receptor antagonists attenuated the hypertension and small-artery morphologic changes and improved kidney function in these models.^{77,81}

Several lines of evidence suggest that ET-1 may play an important role in salt-sensitive forms of hypertension. Dahl salt-sensitive (DS) rats placed on a high sodium diet are characterized by an attenuated pressure natriuresis, development of hypertension, and extensive renal lesions in the form of glomerulosclerosis, renal arteriolar and tubular injury, and progressive renal failure in late phases of the disease. There is growing evidence to support the hypothesis that ET-1, acting via an ET_A receptor, may play a role in mediating some of the renal injury of DS hypertension. Studies have demonstrated that prepro-ET-1 mRNA and vascular responsiveness to ET-1 are increased in the renal cortex of DS rats compared with Dahl salt-resistant (DR) rats.^{76,77} In addition, a positive correlation between ET-1 generation in the renal cortex and the extent of glomerulosclerosis has been reported in DS hypertensive rats.⁷⁰⁻⁷⁴ Also supporting a role of ET-1 in DS hypertension is a study indicating that acute infusion of a nonselective ET_A-ET_B receptor antagonist directly into the renal interstitium improved renal hemodynamic and excretory functions in DS rats but not in DR rats.⁷⁶ Moreover, chronic blockade of ET_A receptors attenuates the hypertension and proteinuria, and ameliorates the glomerular and tubular damage associated with high salt intake in DS rats.⁷⁷ An important unanswered question is whether the beneficial effect of the ET_A blockade in reducing renal injury is mediated through reducing blood pressure or through direct renal mechanisms.

Recent studies have also suggested an important interaction between ET-1 and the RAS. Renal ET-1 synthesis is enhanced in various animal models of chronic Ang II-induced hypertension.⁷⁸⁻⁸² In addition, the renal and hypertensive effects of Ang II are markedly attenuated or completely abolished by ET_A receptor antagonists.⁷⁸⁻⁸² The quantitative importance of ET-1 in mediating the chronic hypertensive actions of Ang II may depend on the level of dietary sodium intake.

ET-1 is also involved in the pathophysiology of hypertension in the pregnancy disorder pre-eclampsia. Pre-eclampsia is associated with hypertension, proteinuria, and endothelial dysfunction.⁸³⁻⁸⁵ Because endothelial damage is a known stimulus for ET-1 synthesis, increases in the production of ET-1 and activation of ET_A receptors may participate in the pathophysiology of hypertension during

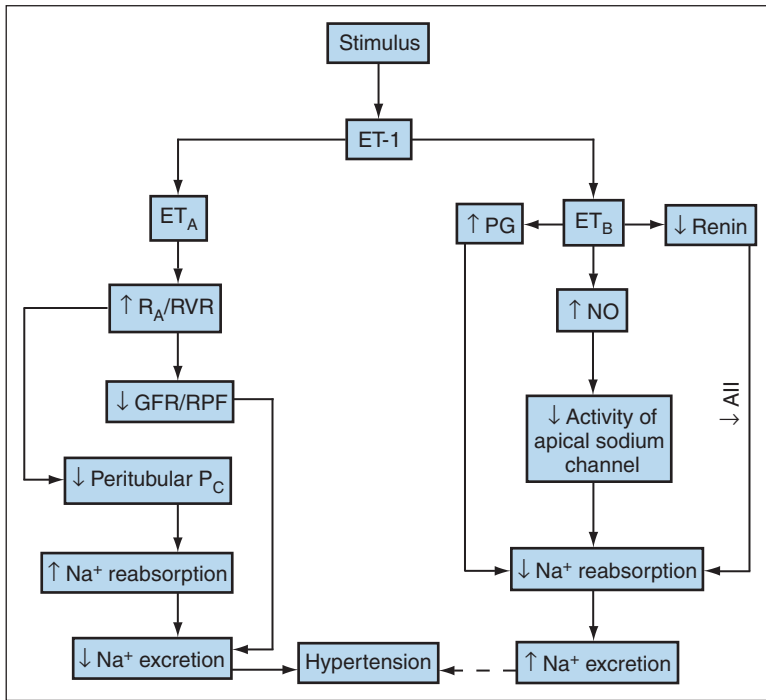

Figure 23-8. Summary of the pro- and anti-hypertensive actions of endothelin-1 (ET-1). The ability of ET-1 to influence blood pressure regulation and renal pressure-natriuresis is highly dependent on where ET-1 is produced and which renal ET receptor type is activated. ET-1 can elicit a prohypertensive antinatriuretic effect by activating ET_A receptors in the kidneys. Activation of renal ET_A receptors increases renal vascular resistance (RVR), which decreases renal plasma flow (RPF) and glomerular filtration rate (GFR), and enhances sodium reabsorption by decreasing peritubular capillary hydrostatic pressure (P_C). The net effect of renal ET_A receptor activation would be increases in sodium retention and blood pressure. Conversely, ET-1 can elicit an antihypertensive natriuretic effect via ET_B receptor activation. Activation of the renal ET_B receptor leads to enhanced synthesis of nitric oxide (NO) and prostaglandin E₂ (PG) and suppression of the renin-angiotensin system. The net effect of renal ET_B receptor activation would be decreases in sodium retention and blood pressure.

pre-eclampsia. Alexander et al.⁸⁶ examined the role of ET-1 in mediating the hypertension in a placental ischemic model of pre-eclampsia.⁸⁷ Using an RNase protection assay, they found that renal expression of preproendothelin was significantly elevated in both the medulla and the cortex of the pregnant rats with chronic reductions in uterine perfusion pressure compared with control pregnant rats. Moreover, they reported that chronic administration of the selective ET_A receptor antagonist markedly attenuated the increase in mean arterial pressure in pregnant rats with chronic reductions in uterine perfusion pressure. In sharp contrast to the response in reduced uterine perfusion pressure rats, ET_A receptor blockade had no significant effect on blood pressure in the normal pregnant animal. These findings suggest that ET-1 plays a major role in mediating the hypertension produced by chronic reductions in uterine perfusion pressure in pregnant rats.

Sera from pregnant rats exposed to chronic reductions in uterine perfusion increases endothelin production by cultured endothelial cells.⁸⁸ The exact mechanism linking enhanced renal production of ET-1 to placental ischemia in pregnant rats or in women with pre-eclampsia is unknown.

One potential mechanism for enhanced ET-1 production is via transcriptional regulation of the ET-1 gene by tumor necrosis factor alpha (TNF- α). TNF- α is elevated in pre-eclamptic women and has been implicated in the disease processes. Chronic infusion of TNF- α in pregnant rats, at a rate to mimic plasma levels (two- to three-fold increase) observed in women with pre-eclampsia significantly increases blood pressure.⁸⁹ The increase in arterial pressure produced by a two- to three-fold elevation in plasma levels of TNF- α in pregnant rats is associated with significant increases in local production of endothelin in the kidney, placenta, and vasculature.⁹⁰ Moreover, the increase in mean arterial pressure in response to TNF- α is completely abolished in pregnant rats treated with an ET_A receptor antagonist.⁹⁰ Collectively, these findings suggest that endothelin, via ET_A receptor activation, plays an important role in mediating TNF- α -induced hypertension in pregnant rats.

Endothelin-1 enhances sodium excretion and minimizes salt-induced increases in blood pressure via ET_B receptor activation

While much attention has been given to the role of ET-1 in the pathophysiology of cardiovascular and renal disease acting via an ET_A receptor, recent studies indicate an important physiologic role for ET-1 in the regulation of sodium balance and arterial pressure via ET_B receptor activation.⁹¹⁻⁹⁷ The most compelling evidence that the endothelin

system may play a significant role in the regulation of sodium balance and arterial pressure are the reports that transgenic animals deficient in ET_B receptors develop severe salt-sensitive hypertension.⁹⁵ Additional evidence comes from studies indicating that pharmacologic antagonism of ET_B receptors produces significant hypertension in rats.^{96,98}

Although systemic ET_B receptor blockade produces significant hypertension that is salt sensitive, the physiologic mechanisms involved in mediating the hypertension are still unknown. Since ET_B receptors are located on multiple cell types through the body, including endothelial cells and renal epithelial cells, both intrarenal and extrarenal mechanisms may mediate the hypertension produced by chronic disruption of ET_B receptor. However, several recent studies suggest that the renal endothelin system plays a major role in controlling blood pressure under high sodium intake conditions. To examine the role of endothelial cell ET_B receptors in salt-sensitive hypertension, Bagnall et al.⁹⁹ generated an endothelial cell-specific ET_B receptor KO mice using a Cre-loxP approach. They reported that ablation of ET_B receptors exclusively from endothelial cells produces endothelial dysfunction in the absence of hypertension. In contrast to models of total ET_B receptor ablation, the

blood pressure response to a high-salt diet was unchanged in endothelial cell-specific ET_B receptor KO mice compared to control mice. These important findings suggest that nonendothelial cell ET_B receptors are important for regulation of blood pressure.

The renal medulla and hypertension: Role of endothelin-1 and ET_B receptors

There is growing evidence that ET-1, acting through the renal medullary ET_B receptors, is involved in the regulation of sodium balance and blood pressure under normal physiologic conditions.^{75,100–103} The kidney is an important site of ET-1 production, and ET_B receptors are expressed at important renal sites of ET-1 synthesis, particularly in the renal medulla.⁷⁵ Some of the first studies using synthetic ET-1 demonstrated that nonpressor doses of ET-1 produced significant natriuresis and diuresis.⁷² It is now known that ET_B receptors are located in various parts of the nephron, including the proximal tubule, medullary thick ascending limb, collecting tubule, and the inner medullary collecting duct.^{72,102,103} The highest concentration of ET_B receptors appears to be on the inner medullary collecting duct in the renal medulla.^{75,92–94} Activation of ET_B receptors has been reported to inhibit sodium and water reabsorption along various parts of the nephron.⁷² Taken together, these data indicate that ET-1, via ET_B receptors, may influence the renal handling of sodium and water. The exact mechanism whereby ET_B receptor activation inhibits sodium reabsorption is unclear but could involve other autacoid factors such as nitric oxide, PGE₂, and/or 20 HETE (Figure 23–9).

For the renal ET-1 system to be an important control system for the regulation of sodium balance, the production of renal ET-1 should change in response to variations in sodium intake. Moreover, blockade of ET_B receptors

should result in a salt-sensitive form of hypertension. Although there are ample data showing that ET-1 can influence sodium reabsorption, there is a paucity of data in the literature examining the relationship between sodium intake and renal production of ET-1. A study by Pollock and Pollock,⁹⁸ however, has shown a positive correlation between sodium intake and renal excretion of ET-1. Convincing evidence for a role of renal ET-1 in controlling sodium excretion and arterial pressure during chronic changes in sodium intake has come from several other studies. Garipey et al.⁹⁷ demonstrated that rats deficient in ET_B receptor expression display salt-sensitive hypertension. Likewise, Pollock and Pollock⁹⁸ reported that chronic pharmacological blockade of the ET_B receptor in rats resulted in hypertension that was sensitive to dietary sodium intake. Moreover, Ohuchi et al.¹⁰¹ reported elevation in blood pressure by genetic and pharmacologic disruption of the ET_B receptor in mice.

In a recent report by Ge et al.,¹⁰⁰ selective disruption of the ET_B receptor in the collecting duct cells of mice was found to produce significant hypertension that was salt sensitive (Figure 23–9). Collecting duct ET_B KO mice on a normal sodium diet were hypertensive.¹⁰⁰ Collecting duct ET_B KO mice on a high-sodium diet had worsened hypertension, reduced urinary sodium excretion, and weight gain.¹⁰⁰ These findings provide strong evidence that the collecting-duct ET_B receptor is an important physiologic regulator of renal sodium excretion and blood pressure.

Role of endothelin in human hypertension

Although ET-1 clearly plays a significant role in the pathogenesis of some forms of experimental hypertension, especially salt-sensitive models, its role in human primary hypertension is unclear. Bosentan, a combined ET_A/ET_B receptor antagonist, significantly lowered blood pressure in a large double-blind clinical trial, indicating that the endothelin system plays a role in maintaining blood pressure in human hypertension.¹⁰⁴ However, the magnitude of the blood pressure reduction by bosentan was almost the same as that observed in normotensive humans. While this observation suggests that endothelin probably does not play a major role in contributing to increases in blood pressure in most patients with essential hypertension, blockade of the antihypertensive ET_B receptor may have masked an important role of endothelin in essential hypertension via ET_A receptor activation. Therefore, the importance of ET-1 in human essential hypertension deserves further investigation.

NITRIC OXIDE

The vascular endothelium releases a short-acting substance called nitric oxide (NO) that induces local relaxation. Intravenous infusion of competitive inhibitors of the enzyme responsible for NO production (nitric oxide synthase) induced rapid increases in blood pressure in various species of animals.¹⁰⁵ These effects were rapidly reversed with intravenous infusion of L-arginine, the substrate for NO synthase. These studies suggested that tonic release of nitric oxide by vascular endothelium may be important for

Figure 23–9. Collecting duct-specific knockout of the endothelin B receptor (CD ET_B KO) causes a hypertensive shift in the pressure natriuresis relationship. (Data from Ge Y, Bagnall A, Stricklett P, Strait K, Webb D, Kotelevtsev Y, et al. *Am J Physiol Renal Physiol* 2006 [Epub before print].)

regulation of vascular function. To investigate this concept further, the long-term effects of nitric oxide synthase inhibitors were examined in various animal models and were found to cause sustained hypertension associated with reductions in renal hemodynamics and pressure natriuresis.¹⁰⁵ The magnitude of the increase in blood pressure was also dependent on the dietary sodium intake.¹⁰⁵ These findings have led to the concept that NO is not only important in the long-term regulation of sodium balance and blood pressure, but also to the notion that abnormalities in NO production result in altered pressure natriuresis and a salt-sensitive form of hypertension.

Nitric oxide enhances pressure natriuresis via hemodynamic and tubular mechanisms

The renal effector mechanisms whereby reductions in NO synthesis alter pressure natriuresis can be divided into hemodynamic and tubular components, each of which may be modulated by processes that are intrinsic and extrinsic to the kidney (Figure 23–10). For example, reductions in NO synthesis could lead to a decrease in renal sodium excretory function by directly increasing basal renal vascular resistance or by enhancing the renal vascular responsiveness to vasoconstrictors such as Ang II or norepinephrine.^{105–114} Reductions in NO synthesis also reduce sodium excretory function either through direct effects on tubular transport or through changes in intrarenal physical factors such as renal interstitial hydrostatic pressure or medullary blood flow.^{106–108} Inhibition of NO synthesis reduces renal interstitial fluid hydrostatic pressure (RIHP) and urinary sodium excretion.¹⁰⁹ Furthermore, normalization of the blunted pressure natriuretic response in Dahl S rats pro-

duced during stimulation of NO production results from improvement in the kidney's ability to generate RIHP in response to changes in renal perfusion pressure.¹⁰⁹ Thus, changes in RIHP appear to be an important component of the effect of NO on sodium reabsorption *in vivo*.

Most investigators attribute the alterations in RIHP to changes in flow and pressure in the medullary circulation.¹⁰⁷ Consistent with this hypothesis are observations that the acute infusion of an NO synthase inhibitor directly into the renal medulla significantly reduces papillary blood flow, RIHP, and urinary sodium and water excretion without affecting the GFR or systemic pressure.^{107–109} Chronic medullary interstitial infusion of NO synthase inhibitors in conscious rats results in sustained reductions in medullary blood flow, sustained sodium and water retention, and hypertension, which are all reversed when the infusion is discontinued.¹⁰⁷ These findings demonstrate that reductions in medullary blood flow may be another important mechanism whereby inhibition of NO in the kidney leads to a hypertensive shift in pressure natriuresis.

Inhibition of NO synthesis may have direct effects on renal tubule transport. NO has direct effects on sodium uptake in cultured cortical collecting duct cells by altering apical sodium channels.¹⁰⁶ Sodium transport in the cortical collecting duct *in vivo* is mediated through changes in cyclic GMP. Micropuncture studies have shown NO synthase inhibitors decrease proximal tubule reabsorption in anesthetized rats.¹⁰⁶ This effect has been attributed to antagonism of Ang II–mediated sodium transport. An effect of NO on proximal reabsorption has also been inferred from changes in lithium clearance induced during inhibition of NO production. Thus, NO can affect sodium reabsorption via direct effects on tubular transport or indirectly via alteration in medullary blood flow or renal interstitial hydrostatic pressure.

Nitric oxide interacts with the renin-angiotensin system

Another mechanism whereby NO synthesis inhibition may reduce pressure natriuresis is via activation of the RAS.¹⁰⁵ Inhibition of NO production enhances renin release from rat cortical kidney slices. Inhibitors of NO synthesis also increase plasma renin activity *in vivo*, an effect that is dependent on the macula densa mechanism.¹¹¹

Several lines of evidence suggest that impaired NO production may play an important role in the regulation of sodium balance and in pathogenesis of salt-sensitive hypertension.^{108,110} An increase in renal NO production or release as evidenced by increased urinary excretion of NO metabolites or the NO second messenger, cyclic GMP, has been

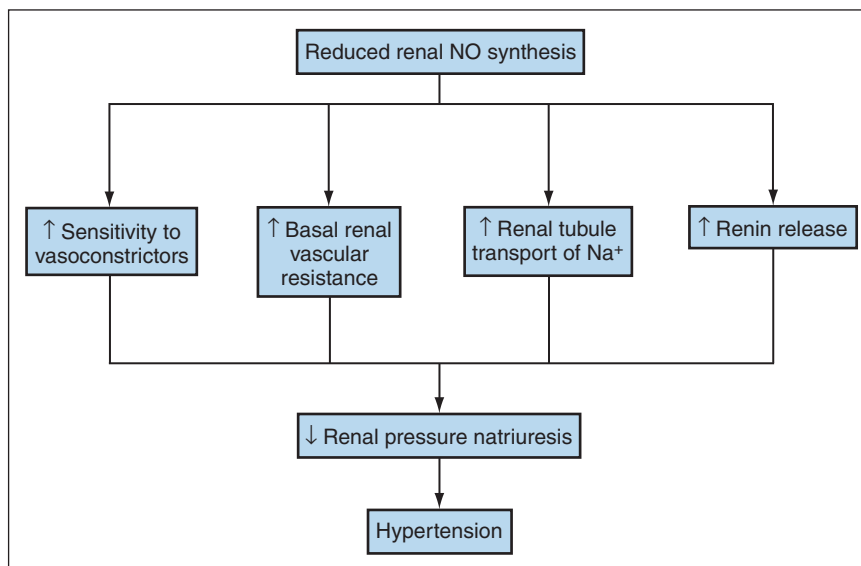

Figure 23–10. The renal effector mechanisms whereby reductions in NO synthesis decrease pressure natriuresis and increase blood pressure. A reduction in nitric oxide (NO) synthesis leads to a decrease in renal sodium excretory function by directly increasing basal renal vascular resistance, enhancing renal vascular responsiveness to vasoconstrictors such as ANGII or norepinephrine, or activating the renin-angiotensin system. Reductions in NO synthesis also reduce sodium excretory function through direct effects on tubular transport or through changes in intrarenal physical factors such as renal interstitial hydrostatic pressure or medullary blood flow.

reported to be essential for the maintenance of normotension during a dietary salt challenge. Prevention of this increase in renal NO production resulted in salt-sensitive hypertension.¹¹⁰

There is also ample experimental evidence demonstrating that NO synthesis is impaired in some vascular beds in human essential hypertension. The extent to which these observations reflect effects of the hypertensive process or reflect important mechanisms for the pathogenesis of the hypertensive condition remains unclear.

ATRIAL NATRIURETIC PEPTIDE

Atrial natriuretic peptide (ANP) is a 28 amino-acid peptide synthesized and released from atrial cardiocytes in response to stress. Once ANP is released from the atria, it enhances sodium excretion through extrarenal and intrarenal mechanisms.^{115,116} ANP increases GFR while having no effect on renal blood flow. However, increased GFR is not a prerequisite for ANP to enhance sodium excretion. ANP may alter tubular sodium reabsorption either directly by inhibiting the active tubular transport of sodium or indirectly via alterations in medullary blood flow, physical factors, and intrarenal hormones.¹¹⁵

ANP inhibits renin and aldosterone synthesis

Atrial natriuretic peptide also has important actions at several sites of the RAS cascade.¹¹⁵ Intrarenal or intravenous infusion of ANP reduces the renin secretion rate by a macula densa mechanism, since ANP failed to reduce renin secretion in nonfiltering kidneys. The reduction in renin secretion decreases intrarenal levels of Ang II, which could contribute to ANP-induced natriuresis. When intrarenal levels of Ang II were prevented from decreasing, the natriuretic effects of ANP were blunted.^{115,116}

ANP also decreases aldosterone release from the adrenal zona glomerulosa cells.^{115,116} Two mechanisms for ANP-induced suppression of aldosterone release have been suggested: (1) direct action on adrenal glomerulosa cells, and (2) reduced circulating levels of Ang II due to suppressed renin secretion under *in vivo* conditions.¹¹⁵ Although the suppression of aldosterone release would not play a role in mediating the acute natriuretic responses to ANP, decreases in circulating levels of aldosterone could contribute to the long-term actions of ANP on sodium balance and arterial pressure regulation.

ANP plays role in short-term and long-term volume regulation

Plasma levels of ANP are elevated in numerous physiologic conditions associated with enhanced sodium excretion.^{115,116} Acute saline or blood volume expansion consistently elevates circulating levels of ANP. Some, but not all, investigators have reported that chronic increases in dietary sodium intake raise circulating levels of ANP. Several studies have reported that infusions of exogenous ANP at rates that result in physiologically relevant plasma concentrations, comparable to those observed during volume expansion, have significant renal and cardiovascular effects.¹¹⁵⁻¹¹⁷

Infusion of ANP at a rate that causes a twofold increase in plasma ANP elicits significant natriuresis, especially in the presence of other natriuretic stimuli, such as high renal perfusion pressure.¹¹⁵⁻¹¹⁷ Long-term physiologic elevations in plasma ANP also shift the renal-pressure natriuresis relationship and reduce arterial pressure.¹¹⁷

Blockade of ANP system produces salt-sensitive hypertension

The development of genetic mouse models that exhibit chronic alterations in expression of the genes for ANP or its receptors (NPR-A, NPR-C) have also provided compelling evidence for a role of ANP in chronic regulation of renal pressure natriuresis and blood pressure.¹¹⁸ Transgenic mice overexpressing ANP gene are hypotensive relative to the nontransgenic litter mates, whereas mice harboring functional disruptions of the ANP or NPR-A genes are hypertensive. The ANP gene “knock-out” mice develop a salt-sensitive form of hypertension in association with failure to adequately suppress the RAS. These findings suggest that genetic deficiencies in ANP or natriuretic receptor activity could play a role in the pathogenesis of salt-sensitive hypertension.

RENAL EICOSANOIDS

Renal eicosanoids are thought to be important mediators of vascular function, sodium and water homeostasis, and renin release.¹¹⁹ Cyclooxygenase metabolizes arachidonic acid into prostaglandin (PG) G₂ and subsequently to PGH₂, which is then further metabolized by tissue-specific isomerases to PGs and thromboxane.

Although the kidney produces many types of PGs with multiple functions, the major renal prostaglandin that controls sodium excretion is probably PGE₂.¹¹⁵ However, production of other arachidonate acid metabolites, such as prostacyclin, thromboxane, and 20-HETE, may also influence renal-pressure natriuresis and blood pressure regulation. The largest production of PGE₂ occurs in the medulla with decreasing synthesis in the cortex. PGE₂ is synthesized and rapidly inactivated and, once synthesized, is released and not stored. Once released, PGE₂ influences sodium transport by several intrarenal mechanisms.

Despite numerous reports that PGs may contribute to the natriuresis of acute physiologic perturbations, the importance of endogenous renal PGs in the long-term regulation of sodium balance remains unclear.¹¹⁵ Increases in dietary sodium intake have little or no effect on urinary PG excretion. In addition, nonspecific cyclooxygenase inhibitors do not affect the sodium excretory or blood pressure responses to chronic alterations in dietary sodium intake. Thus, it appears that endogenous renal PGs may not play a major role in regulating sodium excretion during chronic changes in sodium intake.¹¹⁵

While long-term administration of PG synthesis inhibitors has very little effect on volume and/or arterial pressure regulation under normal physiologic conditions, renal PGs may be important in pathophysiologic states associated with enhanced activity of the RAS.¹¹⁵ *In vitro* and *in vivo* studies indicate that renal PGs protect the preglomerular

vessels from excessive Ang II–induced vasoconstriction.¹¹⁵ In the absence of this protective mechanism in pathophysiologic states, the renal vasculature could be exposed to the potent vasoconstrictor actions of Ang II. This could lead to significant impairment of renal hemodynamics, reduced excretory function, and hypertension.

Inhibitors of COX-2 enzyme increase blood pressure and reduce renal-pressure natriuresis

There are at least two distinct cyclooxygenases, COX-1 and COX-2.⁵³ COX-1 is called the *constitutive* enzyme because of its wide tissue distribution, while COX-2 has been termed as *inducible* because of its more restricted basal expression and its upregulation by inflammatory and/or proliferative stimuli.¹¹⁹ Based on the concept that COX-1 performs cellular housekeeping functions for normal physiologic activity, and COX-2 acts at inflammatory sites, it was initially hypothesized that the renal effects of nonsteroidal anti-inflammatory drugs might be linked to COX-1 inhibition.¹¹⁹ However, increasing experimental and clinical evidence has indicated that COX-2 metabolites may play a role in the regulation of renal function under various physiologic and pathophysiologic conditions.¹¹⁹ COX-2 inhibition has been shown to decrease urine sodium excretion and induce mild to moderate increases in arterial pressure. Moreover, blockade of COX-2 activity can have deleterious effects on renal blood flow and GFR. In addition to physiologic regulation of COX-2 expression in the kidney, increased renal cortical COX-2 expression is seen in experimental models associated with altered renal hemodynamics and progressive renal injury. Long-term treatment with selective COX-2 inhibitors ameliorates functional and structural renal damage in these conditions.¹¹⁹

Eicosanoids produced by cytochrome P450 monoxygenase metabolism of arachidonic acid alter renal-pressure natriuresis

In addition to renal PGs generated via the COX pathway, other eicosanoids that inhibit tubular sodium transport are produced by cytochrome P450 (CYP) monoxygenase metabolism of arachidonic acid.¹²⁰ CYP enzymes metabolize arachidonic acid primarily to 20-hydroxyeicosatetraenoic acid (20-HETE) and epoxyeicosatrienoic acids (EETs). 20-HETE is a potent constrictor of renal arterioles that may have an important role in autoregulation of renal blood flow and tubuloglomerular feedback (Figure 23–11).¹²⁰ 20-HETE and EETs also inhibit sodium reabsorption in the proximal tubule and TALH (Figure 23–11). Compelling evidence suggests that the renal production of CYP metabolites of arachidonic acid is altered in genetic and experimental models of hypertension, and that this system

contributes to the resetting of pressure natriuresis and the development of hypertension. In the spontaneously hypertensive rat (SHR), the renal production of 20-HETE is increased, and inhibitors of the formation of 20-HETE decrease arterial pressure.¹²⁰ Blockade of 20-HETE synthesis also reduces blood pressure or improves renal function in deoxycorticosterone acetate (DOCA) salt, Ang II-infused, and Lyon hypertensive rats.¹²⁰ In contrast, 20-HETE formation is reduced in the thick ascending limb of Dahl S rats and this contributes to elevated sodium reabsorption.¹²⁰ Enhanced 20-HETE synthesis improves pressure natriuresis and lowers blood pressure in Dahl S rats, whereas inhibitors of 20-HETE production promote the development of hypertension in Lewis rats.¹²⁰

Studies in humans also suggest that CYP metabolites may play a role in sodium homeostasis. Urinary 20-HETE excretion is regulated by salt intake and is differentially regulated in salt-sensitive versus salt-resistant subjects.^{121,122} Moreover, there appears to be a strong negative relationship between the excretion of 20-HETE and body mass index, suggesting that some factor related to obesity may be responsible for decreased synthesis or excretion of this eicosanoid in hypertension.^{121,122} These observations support the possibility that impaired renal production of 20-HETE could contribute to attenuated renal-pressure natriuresis in human hypertension, especially when associated with obesity. However, further mechanistic studies are needed to test the importance of 20-HETE in human hypertension.

OXIDATIVE STRESS

Oxidative stress occurs when the total oxidant production exceeds the antioxidant capacity. Recent studies suggest that reactive oxygen species (ROS) may play a role in the initiation and progression of cardiovascular dysfunction

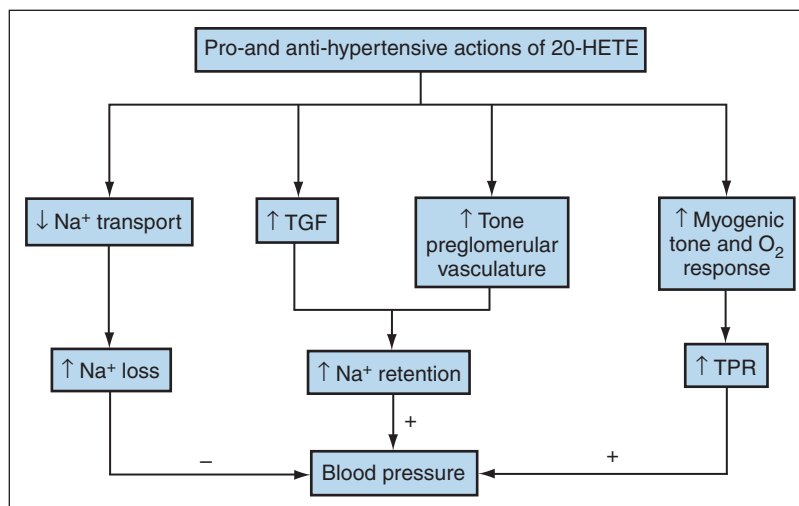

Figure 23–11. Summary of the pro- and anti-hypertensive actions of 20-HETE. 20-HETE produced in the renal tubules inhibits sodium transport and lowers blood pressure. In the renal vasculature and glomerulus, 20-HETE is a constrictor that lowers glomerular filtration rate, promotes sodium retention, and increases arterial pressure. In the peripheral circulation, 20-HETE increases vascular tone and increases blood pressure. TGF, tubuloglomerular feedback; TPR, total peripheral resistance. (Redrawn from Roman RJ. *Physiol Rev* 2002;82:131–85. Used with permission.)

associated with diseases such as hyperlipidemia, diabetes mellitus, and hypertension.^{123–127} In many forms of hypertension, the increased ROS are derived from NAD(P)H oxidases, which could serve as a triggering mechanism for uncoupling endothelial NOS by oxidants.¹²³

ROS produced by migrating inflammatory cells and/or vascular cells have distinct functional effects on each cell type.¹²³ These effects include endothelial dysfunction, renal tubule sodium transport, cell growth, migration, inflammatory gene expression, and matrix regulation. ROS, by affecting renal hemodynamics and renal tubule cell function (Figure 23–12), can alter renal pressure natriuresis and blood pressure regulation.^{123–127}

Growing experimental evidence supports a role for ROS in various animal models of sodium-sensitive hypertension.^{125–129} The Dahl salt-sensitive (S) rat has increased vascular and renal superoxide production and increased levels of H₂O₂. The renal protein expression of superoxide dismutase is decreased in the kidney of Dahl S rats, and long-term administration of Tempol, a superoxide dismutase mimetic, significantly decreases arterial pressure and renal damage. Another salt-sensitive model, the stroke-prone spontaneously hypertensive rat (SHRSP), has elevated levels of superoxide and decreased total plasma antioxidant capacity. Superoxide production is also increased in the deoxycorticosterone acetate (DOCA)-salt hypertensive rat. Treatment of the DOCA-salt rats with apocynin, an NADPH oxidase inhibitor, decreases aortic superoxide production and arterial pressure.

The importance of oxidative stress in human hypertension is unclear. An imbalance between total oxidant production and the antioxidant capacity in human hyper-

tension has been reported to occur in some but not all studies.¹²³ The equivocal findings in human studies are most likely due to the difficulty of assessing oxidative stress in humans. Moreover, most recent human studies have found that vitamin E and C supplementation has little or no effect on blood pressure.¹²³

INFLAMMATORY CYTOKINES

Epidemiologic and experimental studies have revealed an association between biochemical markers of systemic inflammation and cardiovascular disease such as atherosclerosis, heart failure, and hypertension.^{130–134} While significant progress has been made in our understanding of the role of inflammatory cytokines in pathogenesis of atherosclerotic disease, the quantitative importance of cytokines in the pathogenesis and progression of hypertension has yet to be fully elucidated.

Important blood-pressure regulatory systems such as the RAS and SNS interact with the proinflammatory cytokines such as interleukin-6 (IL-6) and tumor necrosis factor- α (TNF- α). The SNS stimulates the release of proinflammatory cytokines and sympathetic nerves may also serve as a source of cytokines.¹³⁵ There is also experimental evidence that proinflammatory cytokines may activate the SNS.¹³⁵ Ang II enhances the synthesis of TNF- α and IL-6, and stimulates chemokine monocyte chemoattractant protein-1 (MCP-1) and nuclear factor-kappa B.¹³⁶ Ang II also increases the production of ROS, including hydrogen peroxide, that participate in the process of inflammation.^{137,138}

Proinflammatory cytokines also affect vascular function and endothelium-derived factors involved in cardiovascular regulation. TNF- α and IL-6 have both been shown to induce structural as well as functional alterations in endothelial cells.^{131,139,140} These cytokines enhance the formation of a number of endothelial cell substances such as endothelin, reduce acetylcholine-induced vasodilatation, and destabilize the mRNA of endothelial NO synthase.^{131,140} Thus, endothelial dysfunction associated with many forms of hypertension may, in part, be mediated by proinflammatory cytokines.

Also supporting a potential role for cytokines in the regulation of arterial pressure are findings that plasma levels of proinflammatory cytokines correlate with increased blood pressure in certain forms of human hypertension and experimental animal models of hypertension.^{131,139} Moreover, several recent studies have demonstrated that chronic increases in plasma levels of cytokines, comparable to concentrations observed in hypertension associated with pre-eclampsia, result in significant and sustained increases in arterial pressure. For example, Alexander et al.¹⁴¹ and Lamarca et al.⁸⁹ reported that a twofold elevation in the plasma levels of TNF- α significantly increased arterial pressure and renal vascular resistance in pregnant rats, and Orshal et al.¹⁴²

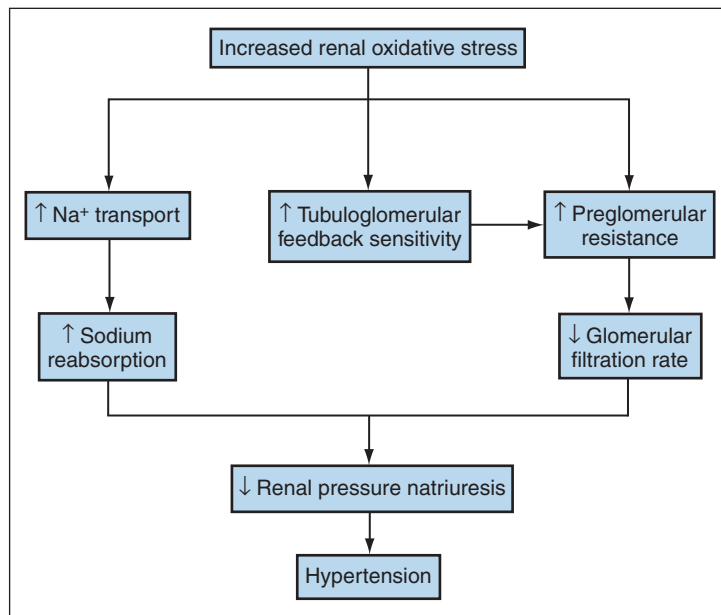

Figure 23–12. Renal effector mechanisms whereby reactive oxygen species decrease pressure natriuresis and increase blood pressure. An increase in renal oxidative stress decreases renal pressure natriuresis by increasing basal renal vascular resistance or enhancing tubuloglomerular feedback, both of which would decrease the glomerular filtration rate. Renal oxidative stress also reduces sodium excretion by direct effects on renal tubular transport.

reported similar findings infusing IL-6 for 5 days in pregnant rats. While these studies demonstrate that increasing plasma levels of cytokines comparable to concentrations observed in certain forms of hypertension can lead to significant elevations in blood pressure, the quantitative role of endogenous cytokines in mediating increases in arterial pressure in various forms of hypertension associated with enhanced formation of proinflammatory cytokines remains unclear.

A recent study by Lee et al.¹⁴³ tested the role of endogenous IL-6 in mediating the hypertension caused by Ang II in male C57BL6 and IL-6 KO (IL-6 KO) mice. The major finding from this study was that the hypertension caused by chronic Ang II excess depends significantly on the presence of IL-6. Mice with the knock-out of IL-6 had significantly lower mean arterial pressure than wild-type mice during 2 weeks of Ang II infusion. While these findings clearly demonstrate a quantitatively significant role for IL-6 in mediating the chronic hypertensive response to angiotensin II in mice, the importance of inflammatory cytokines in the pathogenesis and progression of the various forms of human hypertension is unclear and is currently an important area of investigation.

SUMMARY

Experimental evidence collected over the last several decades has clearly demonstrated a central role of renal-

pressure natriuresis in long-term blood pressure regulation and its impairment in all forms of hypertension, including human essential hypertension. Although the exact causes of impaired renal-pressure natriuresis in hypertension are still unclear, it is likely that multiple extrarenal neurohumoral and intrarenal defects contribute to abnormal pressure natriuresis and increased blood pressure in various forms of human hypertension. Intrarenal defects may include abnormalities such as enhanced formation of angiotensin II, reactive oxygen species, and endothelin (via ET_A receptor activation) or decreased synthesis of NO or natriuretic prostanoids. In other instances, extrarenal disturbances, such as increased SNS activity or excessive formation of antinatriuretic hormones such as aldosterone may lead to a reduction in renal-pressure natriuresis. With longstanding hypertension, structural damage in the kidney may further shift pressure natriuresis and exacerbate hypertension.

Because of the central role for the kidneys in the long-term regulation of arterial pressure and its importance in the pathophysiology of hypertension, a better understanding of the various factors that contribute to impaired renal-pressure natriuresis is warranted. Identification of factors that influence renal-pressure natriuresis will continue to lead to novel therapies for treating hypertension, one of the major risk factors of cardiovascular diseases.

The Baroreflex in the Pathogenesis of Hypertension

Thomas E. Lohmeier and Heather A. Drummond

Key Findings

- Experimental studies have clearly demonstrated incomplete baroreflex resetting of sympathetic activity during chronic alterations in arterial pressure.
- Baroreflex suppression of renal sympathetic nerve activity is sustained in experimental hypertension, a response expected to attenuate the rise in arterial pressure.
- Chronic electrical activation of the carotid baroreflex has sustained effects to suppress sympathetic activity and to lower arterial pressure, especially when hypertension is associated with increased sympathetic activity, such as in obesity.
- Acute determinations of baroreflex function in human subjects indicate that baroreflex suppression of sympathetic outflow is impaired in obesity hypertension, but whether this contributes to chronic sympathetic activation is unclear at present.

There is now considerable evidence that the sympathetic nervous system plays a key role in the pathogenesis of primary hypertension, but the determinants of sympathetic activation are unresolved.¹⁻⁸ In contrast to primary hypertension, some forms of secondary hypertension appear to be associated with suppression of the sympathetic nervous system.⁹⁻¹¹ Because the arterial baroreflex is a powerful buffering mechanism that counteracts short-term fluctuations in arterial pressure by mediating reciprocal changes in sympathetic and parasympathetic activity, there has been considerable interest in the possibility that this reflex might also play a role in long-term control of arterial pressure. This is highlighted by reports that primary hypertension is often associated with baroreflex dysfunction.^{3,5} However, the possibilities that sustained activation of the baroreflex account for the apparent sympathoinhibition present in secondary hypertension, and that impaired baroreflex function leads to increased sympathetic activity in hypertension, are merely conjecture at the present time. This uncertainty is due, in part, to the paucity of techniques available to assess the long-term effects of the baroreflex on sympathetic activity and organ function.

Until the last several years, there has been little direct evidence that either supports or refutes the possibility that baroreflexes play a role in pathogenesis of hypertension. Nonetheless, as recently reviewed,¹² two key observations, made decades ago, are often mentioned to discount the potential role of baroreflexes in long-term

control of arterial pressure: (1) baroreceptors reset, and (2) baroreceptor deafferentation (sinoaortic denervation) (SAD) produces little or no sustained increase in arterial pressure.

Regarding the baroreceptor resetting argument, it is well established that baroreceptors reset in the direction of change in arterial pressure, which diminishes the initial alteration in sympathetic activity induced by the baroreflex in response to a disturbance in arterial pressure.^{13,14} Consequently, resetting of the baroreceptors decreases the ability of the baroreflex to serve as a long-term compensatory mechanism for the control of arterial pressure. However, because of technical limitations inherent in long-term recordings of nerve activity, the degree of baroreflex resetting associated with chronic changes in arterial pressure has not been determined with any certainty. Most direct information relating to sympathetic baroreflex resetting has come from *acute* studies in anesthetized animals subjected to various experimental preparations designed to mimic blood pressure–baroreceptor interactions under more physiologic conditions. Electrophysiologic techniques used in anesthetized animals to record baroreceptor afferent nerve activity in chronic hypertension also support the concept of baroreceptor resetting. However, these studies too are incapable of determining the precise degree of chronic baroreceptor resetting that occurs under normal daily activity. Therefore, although considerable resetting of the baroreflex occurs both acutely and chronically, the time course and extent of chronic resetting is unclear. Consequently, the uncertainty regarding the *long-term* baroreflex relationships between arterial pressure and sympathetic activity in response to interventions that result in sustained alterations in arterial pressure prohibit any definitive conclusions regarding the ability of the baroreflex to chronically alter sympathetic activity and regulate arterial pressure.

The other argument frequently made to discount an important role of the baroreflex in the pathogenesis of hypertension is that the rise in arterial pressure following SAD is largely transient, and that little or no hypertension occurs chronically.¹⁴⁻¹⁶ The presumption then is that if complete loss of the sympathoinhibitory effects of baroreceptor input fails to chronically increase central sympathetic output, then it is unlikely that natural alterations in baroreceptor activity could have long-term effects on sympathetic activity and arterial pressure. However, because of technical limitations precluding chronic measurement of nerve activity, time-dependent changes in sympathetic

activity following SAD have not been directly established. Instead, they are often assumed based on changes in arterial pressure or circulating levels of norepinephrine (NE). Both represent imprecise indices of alteration in sympathetic activity. Therefore, one cannot discount the possibility that SAD produces sustained increases in sympathetic activity, but no hypertension, because non-neural compensatory mechanisms are activated to reduce arterial pressure. An additional concern with using SAD as a model for understanding baroreflex function is that central reorganization of baroreflex circuitry occurs after baroreceptor deafferentation, which appears to diminish the efferent sympathetic response to loss of baroreceptor input.¹⁷ Furthermore, as discussed later in this chapter, recent studies by Thrasher^{16,18} in chronically instrumented dogs clearly illustrate a dichotomy between complete loss of baroreceptor input by deafferentation and the more physiologic response to sustained reductions in baroreceptor activity when arterial pressure is chronically reduced.

In light of the uncertainties regarding the sustained effects of baroreflexes on sympathetic activity, what new information is needed to better understand the role of baroreflexes in long-term control of arterial pressure? Because the kidneys play a critical role in long-term regulation of arterial pressure by virtue of their ability to regulate body fluid volumes,^{19,20} it is critical to determine whether baroreflexes have sustained effects on renal excretory function.¹² As illustrated in Figure 24–1, and discussed later, one way that the baroreflex could alter the function of the renal body–fluid feedback mechanism for long-term control of arterial pressure is by producing chronic changes in renal sympathetic nerve activity (RSNA). This chapter will emphasize recent studies that support the hypothesis that baroreflex suppression of RSNA is

sustained in hypertension, which leads to increased renal excretory function, a response that favors a reduction in arterial pressure.

ANATOMY/BIOCHEMISTRY

Afferent limb of baroreflex

Arterial baroreceptors are located in the aortic arch and carotid sinuses, and are formed by small nerve endings present in the adventitia of these vessels (Figure 24–2, A).^{21,22} In most species, baroreceptor nerve endings are located near the adventitial-medial border. Baroreceptors are mechanosensors that are activated by pressure-induced vessel wall stretch or strain.²¹ Mechanosensitive ion channels are believed to be a critical component of such mechanosensors.^{23,24} As illustrated in Figure 24–2, B, activation of these channels increases permeability to sodium and calcium, leading to a generator potential in the mechanoreception zone.^{23,24} In turn, the current from the mechanoreception zone flows into the spike initiation zone, which activates voltage-gated Na⁺ channels resulting in axonal discharge. Thus the process of mechanotransduction is the initiating step in baroreception that results in an electric signal (neural discharge).^{23,24}

The mechanosensing property of baroreceptors is likely due to the coupling of mechanosensitive ion channels with cytoskeletal membrane and extracellular proteins.

Terminals of myelinated and unmyelinated baroreceptors intertwine within the adventitia, making it difficult to study baroreceptor pressure encoding.^{22–24} Because of experimental limitations, understanding the molecular identity and mechanisms of baroreceptor mechanotransduction has required investigators to apply information from other organisms and sensory systems to unravel the mystery of baroreceptor mechanotransduction. Specifically, research on mechanosensory transduction in the nematode *Caenorhabditis elegans* has advanced our understanding of mechanotransduction.^{25–28} Genetic screens in the nematode revealed a number of genes required for the nematodes' ability to respond to touch. It is now known that these genes are related to a group of mammalian genes in the degenerin/epithelial Na⁺ channel (DEG/ENaC) family, which includes members of the acid-sensing ion channel (ASIC) family.^{27,28} Several studies suggest that ENaC and/or ASIC proteins may form the pore of mechanosensitive ion channel complexes in baroreceptor neurons.^{27–29} The role of other mechanosensitive ion channels from other gene families is unknown.²⁷

The presence of two distinct types of baroreceptors is well known.²¹ Generally speaking, baroreceptors are classified based on their discharge properties and degree of myelination.³⁰ One group is formed by neurons with large myelinated afferent fibers. These baroreceptors have lower activation thresholds and fire more rapidly upon stimulation. These are often referred to as type I baroreceptors. The other group is formed by neurons with unmyelinated or small poorly myelinated afferent fibers. These baroreceptors tend to have higher activation thresholds and discharge at lower frequencies. They are referred to as

B

type II baroreceptors. These two receptor types may have a differential role in the regulation of arterial pressure.³¹ For example, type II baroreceptors show less resetting than type I baroreceptors and, therefore, may be more important in long-term control of arterial pressure.³² How differences in mechanotransduction might account for the specific discharge properties of baroreceptor subtypes is poorly understood.

Baroreceptor afferents from the carotid sinus travel in the carotid sinus nerve (Hering's nerve) before joining the glossopharyngeal nerve. The afferent fibers from aortic baroreceptors pass centrally via the vagus nerves. Baroreceptor afferents in both the glossopharyngeal and vagus nerves terminate in the nucleus of the tractus solitarius (NTS) in the medulla of the brain.

Central baroreflex circuitry

An article by Pilowsky and Goodchild³³ updates recent advances in understanding the central baroreflex pathways and neurotransmitters mediating the sympathetic baroreflex, and interested readers are referred to this excellent review. A simplified diagram of the medullary circuitry comprising the sympathetic baroreflex and its integration into the chronic feedback control of arterial pressure is provided in Figure 24–3. Since the renal body–fluid feedback mechanism plays a central role in the long-term control of arterial pressure, this schema for the chronic regulation of arterial pressure is based upon alterations in RSNA linking baroreflex induced changes in central sympathetic output to renal excretory function. Renal sympathetic outflow consists of neuronal discharges from sympathetic preganglionic motor neurons in the intermediolateral cell column of the spinal cord. These motor neurons are controlled, in part, by bulbospinal sympathoexcitatory neurons located in the rostral ventrolateral medulla (RVLM), a nucleus whose activity is modu-

lated by the baroreflex. Specifically, acute recording studies have demonstrated that baroreflex inhibition of the RVLM is achieved by a circuit which activates neurons in the NTS, the site of termination of baroreceptor inputs. In turn, NTS neurons activate inhibitory neurons in the caudal ventrolateral medulla (CVLM) that project to the RVLM. Consequently, if baroreflex resetting is incomplete in chronic hypertension, then activation of neurons in the NTS and CVLM and attendant suppression of sympathoexcitatory RVLM neurons should be sustained responses to hypertension. This would favor sustained suppression of RSNA. Studies discussed later in this chapter support this hypothesis.

Efferent limb of baroreflex

The postganglionic fibers to the kidneys innervate the vasculature, tubules, and renin containing juxtaglomeru-

lar cells.^{34,35} Increases in RSNA decrease sodium excretion by promoting sodium reabsorption, decreasing renal blood flow and glomerular filtration rate, and increasing renin release.^{34,35} The NE released from adrenergic nerve terminals exerts direct vasoconstrictor and tubular effects that decrease sodium excretion by activation of postjunctional α_1 -adrenoceptors receptors. Additionally, because increases in RSNA stimulate renin secretion, the generation of ANG II contributes indirectly to the antinatriuretic effects of noradrenergic stimulation (Figure 24–1). ANG II increases sodium reabsorption and reduces blood flow by acting on ANG II-type AT_1 receptors located on the tubules and vasculature.

Stimulation of renin secretion by the renal nerves is achieved by activation of both α_1 - and β_1 -adrenoceptors.^{34,35} Noradrenergic stimulation of α_1 -adrenoceptors may increase renin secretion in two ways: (1) by reducing the stretch of the afferent arteriole and the associated juxtaglomerular cells (the intrarenal baroreceptor) through constriction of the upstream vasculature, and (2) by decreasing the delivery of sodium chloride to the macula densa through promotion of sodium reabsorption in the proximal tubule and loop of Henle. Noradrenergic stimulation of renin secretion is also achieved by activating β_1 -adrenoceptors located on the juxtaglomerular cells themselves.

Numerous acute studies have been conducted to elucidate the complex interactions between the renal sympathetic nerves and the renin-angiotensin system in the control of renal function.^{34,35} However, while much progress has been made in understanding the acute interactions between these pathways in the control of renal function, a precise definition of the long-term quantitative interrelationships is still needed. An understanding of the direct versus the indirect effects of the renal nerves on renal function is complicated by the time dependency of these interactions, which prohibit extrapolation of the findings from acute studies to chronic conditions such as hypertension. There are few chronic studies that have attempted to determine the relative importance of the direct and indirect pathways in promoting sodium retention. The evidence we have suggests that the indirect pathway has an increasingly important role in promoting sodium retention, as angiotensin II (Ang II) is generated during more prolonged periods of adrenergic stimulation.^{35–37}

PHYSIOLOGY

Long-term regulation of arterial pressure is closely linked to volume homeostasis through the renal body–fluid feedback mechanism (Figure 24–1).^{19,20} Increases in body fluid volume and arterial pressure cause the kidneys to increase salt and water excretion. In turn, the pressure natriuresis and diuresis reduces body fluid volume until arterial pressure returns to control levels. Conversely, when arterial pressure falls too low, the kidneys retain fluid, and body fluid volume increases, returning arterial pressure toward normal.

In response to disturbances in body fluid volume and arterial pressure, there are changes in several extrarenal

and intrarenal factors. These contribute to long-term regulation of arterial pressure by affecting the sensitivity of the pressure natriuresis mechanism.²⁰ One especially important feedback mechanism for long-term blood pressure control is the renin-angiotensin-aldosterone system. Under normal conditions, elevations in body fluid volume suppress this potent sodium-retaining system. Suppression of the renin-angiotensin-aldosterone system increases the sensitivity of pressure natriuresis and minimizes increments in body fluid volume and arterial pressure. Just the opposite changes occur for regulation of arterial pressure when body fluid volume is reduced. In contrast to the well-established role of the renin-angiotensin-aldosterone system, it is unclear whether, and to what extent, the arterial baroreflex also contributes to long-term feedback control of arterial pressure.

The baroreflex plays an important role in short-term regulation of arterial pressure by mediating changes in peripheral resistance, vascular capacity (a determinant of mean circulatory filling pressure and, thus, venous return), and cardiac function (Figure 24–1). However, due to the renal body–fluid feedback mechanism for long-term control of arterial pressure, these autonomic responses, even if sustained chronically, would not be expected to produce long-term changes in arterial pressure, unless they were associated with a simultaneous effect on pressure natriuresis.^{12,19,20} In the absence of a change in renal excretory function, any sympathetically mediated alterations in arterial pressure would result in similar directional changes in the renal excretion of sodium, which would return body fluid volume and arterial pressure toward control. Consequently, if the baroreflex were to play a role in the chronic regulation of arterial pressure during disturbances in body fluid volume and arterial pressure, then the baroreflex must in some way have a sustained effect to alter renal excretory function. Because chronic changes in renal adrenergic activity alter renal excretory function,^{12,36,38} one way in which the baroreflex could alter pressure natriuresis and produce long-term changes in arterial pressure is by chronically influencing RSNA (Figure 24–1).

Chronic unloading of baroreceptors results in neurogenic hypertension

To examine the role of baroreflexes in mediating sustained alterations in sympathetic activity, Thrasher determined arterial pressures responses for up to 5 weeks of carotid baroreceptor unloading in chronically instrumented dogs.^{16,18} In these studies, baroreceptors in the aortic arch and one carotid sinus were denervated, leaving one carotid sinus with intact innervation. After several days of control measurements, baroreceptor unloading was achieved by ligation of the common carotid artery proximal to the innervated sinus. In response to unloading of carotid baroreceptors, there was sustained hypertension for the duration of the study (5 weeks). The initial days of baroreceptor unloading were associated with sodium retention and increased renin secretion, responses consistent with increased RSNA. In the chronic phase of the hypertension, however, increments in plasma renin activity were

not statistically significant, presumably due to the effects of increased arterial pressure to counteract neurally mediated renin secretion. These studies are consistent with the hypothesis that increased RSNA and attendant activation of the renin-angiotensin system are sustained baroreflex responses to reduced arterial pressure. However, confirmation of this hypothesis must await the demonstration that renal denervation markedly attenuates or completely abolishes baroreflex-mediated hypertension.

Thrasher¹⁶ also compared chronic arterial pressure responses in dogs with SAD to dogs subjected to baroreceptor unloading. In contrast to the sustained hypertension produced by chronic unloading of baroreceptors, increases in arterial pressure following SAD were transient, persisting ~2 weeks. Thus the dichotomy between the arterial pressure responses to SAD and baroreceptor unloading questions the relevance of the former traditional approach for elucidating chronic baroreflex-mediated sympathetic responses. The sustained hypertension following chronic baroreceptor unloading suggests that complete central resetting does not occur in response to a more physiologic stimulus—reduced pulse synchronous input from baroreceptors—and indicates that resetting of the baroreflex is incomplete when arterial pressure is chronically reduced. These studies support the concept that the baroreflex can have long-term effects on sympathetic activity and arterial pressure.

Role of baroreflexes in chronic regulation of arterial pressure during increased sodium intake

Increased salt intake is a frequent challenge to the regulation of body fluid volume and arterial pressure. During chronic increases in salt intake, it is widely recognized that suppression of the renin-angiotensin-aldosterone system minimizes volume expansion and increments in arterial pressure by increasing renal excretory function. In contrast, the role of the nervous system in defending against chronic perturbations in body fluid volume and arterial pressure is unclear. To determine whether baroreflex-induced suppression of sympathetic activity contributes to the chronic regulation of arterial pressure during sustained increases in sodium intake, arterial pressure responses to increased salt intake have been assessed in rats with and without intact arterial baroreflexes.^{39–41} The results of these studies are consistent in that they demonstrate little or no change in arterial pressure in response to chronic increases in salt intake when baroreflexes are intact but significant increases in arterial pressure following SAD. While these studies indicate that sustained activation of the baroreflex contributes to arterial pressure regulation during chronic increases in salt intake, they do not address the efferent mechanisms that mediate this neural response. Neural mechanisms do promote sodium excretion by inhibiting RSNA during acute increments in body fluid volume and renal denervation impairs the natriuretic response to an acute salt load.^{34,35} Therefore, if baroreflex-mediated inhibition of RSNA were a sustained response to chronic increases in salt intake, the resultant increase in renal excretory func-

tion would be expected to minimize volume retention and concomitant increments in arterial pressure.

The issue of whether reflex-induced renal sympathoinhibition is a long-term response for defending volume homeostasis is unsettled because of technical difficulties in long-term monitoring of changes in RSNA and the attendant sodium excretory responses. Therefore, the effects of the baroreflex on renal excretory function during chronic increases in salt intake have been deduced from sodium balance determinations in rats with and without intact baroreflexes.^{40,41} Unfortunately, the results from this approach have been inconsistent. In one study, DiBona and Sawin⁴¹ found that the reported salt-sensitive hypertension in rats with SAD was associated with greater retention of sodium than in control rats subjected to a high-salt intake, suggesting that baroreflex activation normally minimizes volume expansion by chronically enhancing renal excretory function, presumably by inhibiting RSNA. In contrast to these findings, an earlier study by Osborn and Hornfeldt⁴⁰ found no significant difference in sodium balance between baroreceptor-intact and baroreceptor-denervated rats fed a high-salt diet, despite an increase in mean arterial pressure (MAP) present only in rats with SAD. However, it should be emphasized that one confounding issue in interpreting sodium balance studies in the face of changes in neural activity is that alterations in the sympathetic nervous system simultaneously modulate vascular capacity and renal excretory function, responses that have opposing effects on blood volume. Specifically, baroreflex-induced renal sympathoinhibition would promote sodium excretion and decrease blood volume, whereas baroreflex-induced decreases in sympathetic constriction of the vasculature would favor sodium retention and increase blood volume. For this reason, in the absence of knowledge about the volume-holding capacity of the circulatory system (which can not be directly measured), changes in sodium balance provide limited insight into the impact of neurally induced alterations in body fluid volume on arterial pressure. Long-term changes in arterial pressure are not necessarily related to alterations in blood volume *per se*, but are instead related to the ratio of blood volume to the volume holding capacity of the circulation (the mean circulatory filling pressure, which can be measured).¹⁹ Thus the long-term influence of alterations in reflex function on renal excretory function and the attendant changes in arterial pressure cannot be deduced with certainty from measurements of sodium balance alone. This point is clearly evident from the response to direct electrical activation of the carotid baroreflex. As illustrated below, chronic electrical activation of the carotid baroreflex produces a sustained reduction in arterial pressure, but this response is associated with the retention and not the loss of sodium.^{42,43}

To determine whether the renal nerves contribute to sodium homeostasis during chronic increments in salt intake, Lohmeier et al.⁴⁴ conducted studies in dogs with unilateral renal denervation and surgical division of the urinary bladder into hemibladders to allow separate 24-hour urine collection from denervated and intact kidneys. This is a powerful model for exposing a functional role

of the renal nerves because both kidneys are exposed to the same perfusion pressure and hormonal influences. Consequently, any differences in sodium excretion between the kidneys can be attributed to the effects of the renal nerves on renal excretory function. In this study, sodium excretion rates in the two kidneys were approximately equal during the control period. However, when sodium intake was chronically increased eight-fold, the innervated kidney excreted significantly more sodium than the contralateral denervated kidney. Taken in the context of the rat SAD studies and experiments in dogs with both NE and Ang II hypertension, these results are consistent with the hypothesis that baroreflex-mediated renal sympathoinhibition is a sustained response that promotes sodium excretion during increments in salt intake, thus contributing to the chronic regulation of body fluid volume and arterial pressure.

Renal nerves chronically promote sodium excretion in secondary hypertension Norepinephrine-induced hypertension

Activation of the sympathetic nervous system, including sympathetic outflow to the kidneys, is commonly associated with primary hypertension.¹⁻⁸ In contrast, results from microneurographic studies in human subjects suggest that the sympathetic nervous system is suppressed in secondary hypertension.⁹⁻¹¹ However, whether this sympathoinhibition includes the neural outflow to the kidneys has not been established.

We reasoned that the split-bladder preparation, in combination with unilateral renal denervation, might provide a novel and effective approach for determining whether inhibition of RSNA and attendant increments in renal excretory function are long-term compensatory responses following the induction of secondary hypertension. However, an initial concern was whether the denervated kidney in the split-bladder preparation might be supersensitive to circulating NE.³⁴ If so, this could confound interpretation of the renal responses to NE. Therefore, we first elected to investigate renal excretory responses during the induction of hypertension induced by chronic infusion of NE.⁴⁵ Figure 24-4 illustrates changes in the relative 24-hour excretion rates of sodium from denervated (DEN) and innervated (INN) kidneys in dogs after 4 to 5 days of progressively higher rates of NE infusion. In this study, infusion of NE at rates producing increments in plasma levels of NE as high as ~3000 pg/mL or ~30 times normal had no influence on the relative excretion rates of sodium between the innervated and denervated kidneys (DEN/INN). This indicated that denervated kidneys were not supersensitive to either physiologic or pathophysiologic increases in plasma NE concentration. However, at the highest tested infusion rate of NE which produced pharmacologic levels of NE (~70 times normal) and hypertension, there was a persistently higher rate of sodium excretion from innervated compared to denervated kidneys, as reflected by the decrease in the DEN/INN. This last finding is consistent with the possibility that denervated kidneys are supersensitive to pharmacologic levels of circulating NE. Alternately, the higher rate of sodium

Figure 24-4. Chronic effects of NE infusion on plasma NE conc., mean arterial pressure, and the relative 24-hour excretion rates of sodium from DEN and INN kidneys. * $p < 0.05$ versus control before NE infusion. conc., concentration; DEN, denervated kidneys; INN, innervated kidneys; NE, norepinephrine.

excretion from innervated versus denervated kidneys at rates of NE infusion causing hypertension, also suggest another possibility—that sustained sympathoinhibition and attendant loss of sodium might be a long-term compensatory response to the hypertension. If so, similar changes in the relative excretion rates of sodium between innervated and denervated kidneys might also be expected in other forms of secondary hypertension. Further, if renal sympathoinhibition and attendant increments in sodium excretion are mediated by the baroreflex, then SAD should abolish this response.

Angiotensin II-induced hypertension

In view of the well-established sympathoexcitatory effects of Ang II and studies in rats suggesting that the sympathetic nervous system contributes to Ang II hypertension,⁴⁶ we reasoned that the Ang II infusion model of hypertension would provide a particularly challenging test of the baroreflex suppression hypothesis. That is, if Ang II-mediated increases in RSNA contribute to hypertension and are more pronounced than the actions of the baroreflex in suppressing renal sympathetic outflow, then there should be *less* sodium excreted from innervated than denervated kidneys during Ang II infusion. In fact, just the opposite response occurred.⁴⁷ During a 5-day infusion of Ang II, which produced a three- to five-fold

increase in plasma levels of the peptide, MAP increased 30–35 mmHg in the absence of a change in heart rate (Figure 24–5). Additionally, during Ang II infusion, total sodium excretion (from both kidneys) decreased for 1 to 2 days before sodium balance was subsequently achieved at the elevated MAP (Figure 24–6). Moreover, as in NE-mediated hypertension, the hypertension induced by Ang II infusion in dogs with an intact baroreflex was associated with a relative *increase* in sodium excretion from innervated versus denervated kidneys, as reflected by the *fall* in the DEN/INN. This differential effect on sodium excretion occurred in the absence of differences in either glomerular filtration rate or renal plasma flow between kidneys, indicating the predominant influence of the renal nerves was mediated via actions on tubular function. In a subsequent investigation of longer duration, the sustained decrease in the DEN/INN for sodium excretion was found to persist for 10 days of Ang II infusion,⁴⁸ supporting the longevity of this response. These studies are consistent with earlier findings in chronically instrumented dogs indicating decreased renal NE spillover (an indirect index of RSNA) during long-term infusion of Ang II.⁴⁹ More recently, Barrett et al.⁵⁰ have confirmed this regional sympathetic response to Ang II hypertension by making direct recordings of RSNA in chronically instrumented rabbits. Using elegant technology to directly record RSNA, 24 h/day, these investigators demonstrated distinct suppression of RSNA throughout the duration of a 7-day period of hypertension induced by Ang II infusion. Thus taken together, the above studies in chronically instrumented animals provide no support for the hypothesis that increased RSNA impairs sodium excretion and con-

Figure 24–5. tributes to Ang II hypertension. Rather, these studies indicate that suppression of RSNA is a chronic compensatory response, which may actually attenuate the antinatriuretic and hypertensive effects of Ang II.

Recent studies in both the dog and rabbit strongly support the hypothesis that the arterial baroreflex produces sustained inhibition of RSNA during Ang II hypertension. After determining the hemodynamic and renal excretory responses to chronic Ang II infusion in the intact state, dogs with split bladders and unilateral renal denervation were subjected to deafferentation of cardiopulmonary and sinoaortic baroreceptors (CPD+SAD). This was followed by repeating the 5-day infusion of Ang II (Figures 24–5 and 24–6).⁴⁷ In contrast to the baroreflex intact state, in which there was no change in heart rate during Ang II hypertension, there was sustained tachycardia throughout the 5 days of Ang II infusion following CPD+SAD. Because the denervation procedure abolished the vagal innervation of the heart, the increase in heart rate during Ang II infusion indicates prolonged activation of cardiac sympathetic outflow. Regarding the kidneys, following CPD+SAD the DEN/INN for sodium excretion actually *increased* during Ang II infusion, a response diametrically opposite to that observed when the reflexes were intact. Thus in the absence of the baroreflexes, increased circulating levels of Ang II decreased renal excretory function more in innervated kidneys than denervated ones, presumably by increasing RSNA. That the functional differences in sodium excretion between innervated and denervated kidneys are truly related to differences in RSNA is strongly supported by direct 24-hour recordings of RSNA in rabbits chronically infused with Ang II.⁵¹ In this study, the suppression of RSNA that was previously reported in rabbits with Ang II hypertension was totally abolished following SAD. Thus

these studies clearly indicate that arterial baroreflexes have sustained effects in Ang II hypertension to inhibit RSNA and promote renal excretory function, suggesting a potential compensatory role in attenuating hypertension. However, despite the ability of baroreflex activation to increase renal excretory function in both dogs and rabbits with Ang II hypertension, it should be noted that baroreceptor deafferentation did not influence the degree of hypertension in these studies, confirming an earlier report by Cowley and DeClue.⁵² This may indicate that baroreflex inhibition of RSNA has a relatively weak capacity to shift pressure natriuresis to a lower arterial pressure level in the presence of high circulating levels of the potent sodium-retaining hormones Ang II and aldosterone. This contention receives direct support from the MAP responses to chronic electrical activation of the carotid baroreflex in dogs with Ang II hypertension,⁴³ as discussed below. The unimpressive effects of baroreflex activation on MAP in Ang II hypertension, however, do not discount the possibility that the baroreflex may have an important compensatory role in attenuating the severity of other more prevalent forms of hypertension.⁵³

Sustained activation of neurons in central baroreflex pathway in both primary and secondary hypertension

To further test the hypothesis that the baroreflex is chronically activated in hypertension, we used Fos-like (Fos-Li) protein immunohistochemistry to determine sites of neuronal activation in the baroreflex pathway. This methodology is based on the principle that stimulation of neurons results in the activation of immediate early genes, including *c-fos*, which in turn lead to the expression of transcriptional regulatory proteins, including Fos and Fos-related proteins. Fos and Fos-related proteins can be measured by immunohistochemistry and, therefore, quantification of Fos-Li staining can serve as a convenient marker for neuronal activation.⁵⁴ Advantages of this methodology include the fact that: (1) it can be used to map a large number of activated neurons rather than just the activity of individual neurons, and (2) it can be used in animals that remain conscious during the induction of hypertension circumventing the confounding influence of anesthesia and surgical stress on neuronal activation.

Angiotensin II-induced hypertension

To complement the results discussed above from the Ang II model of hypertension, Ang II was infused both acutely (2 hours) and chronically (5 days) into two groups of dogs, and Fos-Li staining in these dogs was compared to that of a third control group administered saline alone.⁵⁵ Responses to chronic Ang II infusion are illustrated in Figure 24-7. MAP increased ~20 and 35 mmHg after acute and chronic Ang II infusion, respectively, and was unchanged in controls. During acute Ang II infusion, there were significant increases in Fos-Li staining in the NTS and CVLM, but no increase in staining in RVLM neurons. As baroreflex suppression of sympathoexcitatory neurons in the RVLM is mediated by activation of NTS and CVLM neurons (Figure 24-3), these acute responses were

Figure 24-7. Numbers of Fos-Li-positive neurons per section in various regions of the medulla in control dogs and in dogs chronically infused with Ang II, fed a high-fat diet, and subjected to prolonged electrical activation of the carotid baroreflex. Ang II, angiotensin II; CVLM, caudal ventrolateral medulla; NTS, nucleus of the tractus solitarius; RVLM, rostral ventrolateral medulla. * $p < 0.05$ versus control.

expected and they confirmed the findings of others in both the rat and rabbit.^{56,57} Moreover, a novel finding in this study was that this same pattern of central activation was observed during *chronic* infusion of Ang II. Therefore, this study further supports the hypothesis that the baroreflex is chronically activated in this model of secondary hypertension.

Obesity-induced hypertension

Given the dogma that baroreflexes reset and are an unimportant, long-term determinant of sympathetic activity and arterial pressure, and the mounting experimental evidence that the sympathetic nervous system is activated in primary hypertension, the contention that baroreflex inhibition of sympathetic activity is a sustained response in most forms of clinical hypertension meets with considerable skepticism. While the results from the Ang II model of hypertension clearly indicated that sustained activation of the baroreflex is present for as long as 10 days of hypertension (the duration of the studies), critical support for prolonged baroreflex activation in long-standing hypertension was still needed. This was provided from a study in dogs with chronic obesity hypertension.⁵⁸ In this study, dogs were fed either a regular diet or an identical diet with the addition of 0.5 to 0.9 kg of cooked beef fat to induce obesity hypertension, the most prevalent form of primary hypertension in human subjects. After 6 weeks on the high-fat diet, MAP was elevated ~15 mmHg in association with an increase in body weight of ~50%. There were no changes in either body weight or MAP in the control group. Results of Fos-Li immunoreactivity in medullary neurons are illustrated in Figure 24-7. The number of Fos-Li-positive cells in the NTS and the CVLM were three to five times greater in obese than in control dogs, results qualitatively similar to those observed during chronic Ang II hypertension (Figure 24-7). This suggests

that neurons subserving the baroreflex were chronically activated in this clinically relevant model of primary hypertension. However, a notable difference between the models of hypertension was the increased staining of RVLM neurons in obese dogs. As spinally projecting neurons in the RVLM provide tonic excitatory input drive to sympathetic preganglionic neurons that control sympathetic output to the peripheral circulation, the increased Fos-Li staining in RVLM neurons is consistent with reports of increased sympathetic activity in obesity hypertension.^{1,2,4-6,59} Taken together, these results suggest that sympathoexcitatory inputs into the RVLM predominate over the inhibitory effects of the baroreflex in obesity hypertension. Nonetheless, these results suggest sustained activation of the baroreflex in primary as well as secondary hypertension. As baroreflex inhibition of sympathetic nerve activity is progressively impaired during the evolution of obesity hypertension,^{5,6} baroreflex dysfunction may make an increasingly important contribution to sympathetic activation in the later stages of this form of hypertension.

Chronic electrical activation of carotid baroreflex

To determine the time dependency and underlying mechanisms of the blood pressure-lowering effects of the baroreflex, independent of temporal alterations in mechanotransduction at the level of the baroreceptors, we revitalized an earlier approach for the nonpharmacologic treatment of hypertension—chronic electrical activation of the carotid baroreflex.^{42,43,53,60} While experimental and clinical studies initiated in the mid-1960s established that the severity of hypertension could be attenuated by electrical activation of the carotid baroreflex, the results of these studies were sketchy, nonquantitative, and fraught with technical complications.⁶⁰ Using state-of-the-art technology, studies have been conducted in dogs that have provided quantitative insight into the temporal and

mechanistic responses to prolonged electrical activation of the baroreflex. These studies were achieved by chronically implanting electrodes around both carotid arteries and using an externally adjustable pulse generator to electrically activate the carotid baroreflex.

Responses in normotensive dogs

Because of the dogma that baroreflexes are unable to produce sustained alterations in sympathetic activity and arterial pressure, the first study using this new technology was designed to critically evaluate the cardiovascular, neurohormonal, and renal excretory responses to prolonged baroreflex activation (PBA) in normotensive dogs.⁴² To achieve this goal, chronically instrumented dogs maintained on a fixed diet to facilitate water and electrolyte balance determinations were subjected to 7 days of PBA after control measurements. Immediately following baroreflex activation, MAP decreased ~25 mmHg in association with a modest reduction in heart rate. These acute responses reflect the reciprocal effects of baroreflex activation to suppress the sympathetic and stimulate the parasympathetic nervous systems. Moreover, both the hypotension (Figure 24–8) and the bradycardia were sustained throughout the entire 7 days of PBA with no evidence for temporal diminution of these responses. Sustained reductions in MAP were associated with a ~35% decrease in plasma NE concentration, a response consistent with suppression of the sympathetic nervous system. Taken together, these data indicate that PBA can lead to substantial reductions in MAP by suppressing the sympathetic nervous system. Further, because baroreceptor afferent activity is constant during PBA, these sustained responses may indicate that central mechanisms do not normally make an important contribution to baroreflex resetting.

An additional observation was that PBA leads to chronic activation of neurons contributing to the baroreflex pathway (Figure 24–7). While not unexpected, this finding lends credence to the results from the Fos-Li studies discussed previously, indicating sustained activation of the baroreflex in experimental models of both primary and secondary hypertension.

Before daily sodium balance was achieved at a reduced arterial pressure, a moderate amount of sodium was retained during the first 24 hours of PBA (Figure 24–9). Maintenance of sodium balance at a reduced arterial pressure indicates PBA produces sustained increases in renal excretory function, presumably by chronically suppressing RSNA.¹² However, despite the renal actions of PBA favoring the excretion of sodium, there was net sodium retention, not sodium loss, during chronic baroreflex-mediated suppression of

Figure 24–8. Effects of prolonged bilateral electrical activation of the carotid baroreflex on mean arterial pressure and heart rate. * $p < 0.05$ versus control.

Figure 24-9. Effects of prolonged bilateral electrical activation of the carotid baroreflex on daily rates of sodium and potassium excretion. * $p < 0.05$ versus control.

the sympathetic nervous system. Net sodium retention during the first 24 hours of PBA reflects the ability of sympathoinhibition to increase vascular capacity and decrease arterial pressure.^{12,19} As discussed earlier, sodium balance determinations do not necessarily reflect the true impact of changes in neural activity on renal excretory function. It should be emphasized once again that if baroreflex activation had not simultaneously increased renal excretory capacity, the initial fall in MAP during PBA would not have been sustained, despite a persistent decrease in vasoconstriction induced by sympathetic inhibition.^{12,19}

A possible mechanism for mediating the long-term blood pressure-lowering effects of the baroreflex is suppression of RSNA. This may be the critical response that links decreased central output to increased renal excretory function, but this remains to be evaluated experimentally. In this regard, a particularly important finding in the study illustrated in Figures 24-8 and 24-9 was that plasma renin activity and plasma aldosterone concentration did not increase concomitantly with the fall in arterial pressure induced by PBA. Quantitative studies in chronically instrumented dogs have demonstrated that reductions in renal perfusion pressure greater than ~15 mmHg normally result in substantial increases in renin secretion.⁶¹⁻⁶³ Therefore, the failure of plasma renin activity to increase despite reductions in MAP of 20 to 25 mmHg would indicate that PBA exerts sustained inhibitory effects on renin secretion. Because alterations in renal adrenergic activity produce directionally similar changes in renin secretion, reflex suppression of RSNA may be the primary mechanism that accounts for the sustained inhibitory effects on renin secretion during PBA.⁶² Furthermore, because the renin-angiotensin-aldosterone system has powerful long-term effects on renal excretory function and arterial pressure, baroreflex-mediated suppression of renin secretion may

contribute importantly to the chronic blood pressure-lowering effects of the baroreflex. That is, in the absence of the renal sympathoinhibitory effects on renin secretion, pressure-dependent activation of the renin-angiotensin-aldosterone system may greatly diminish the blood pressure-lowering effects of PBA. Thus suppression of both the direct and indirect (via renin release) actions of the renal nerves on sodium reabsorption likely contributes to the chronic effects of the baroreflex to reduce arterial pressure (Figure 24-1).

Responses in angiotensin II hypertension

To evaluate quantitatively the impact of increased activity of the renin-angiotensin-aldosterone system on the long-term blood pressure-lowering response to PBA, the baroreflex was chronically activated after induction of hypertension by infusion of Ang II.⁴³ MAP responses to PBA under control conditions and after the induction of Ang II hypertension in the same dogs are illustrated in Figure 24-10. Under control conditions, MAP (93 ± 1 mmHg) decreased ~20 mmHg in association with a ~55% decrease in plasma NE concentration during PBA, but there were no significant changes in plasma renin activity. These responses under control conditions were comparable to those reported in our earlier study (Figures 24-8 and 24-9). During chronic infusion of Ang II, there was a threefold elevation in plasma aldosterone concentration and MAP increased 30 to 35 mmHg (to 129 ± 3 mmHg). Additionally, plasma NE concentration decreased ~25%. Most importantly, during the next 7 days of baroreflex activation/Ang II infusion, reductions in MAP (Figure 24-10) and plasma NE concentration were markedly diminished compared to responses in the control state. In fact, during PBA, plasma NE concentration failed to decrease significantly from its already depressed values during Ang II infusion. This presumably reflects prior

Figure 24-10. Effects of prolonged bilateral electrical activation of the carotid baroreflex on mean arterial pressure in the normotensive control state and then after the induction of Ang II hypertension. * $p < 0.05$ versus control. Ang II, angiotensin II.

activation of the baroreflex. The final reduction in arterial pressure was less than 25% of the control response. While the natural engagement of the baroreflex during Ang II hypertension undoubtedly contributed to the reduced sympathetic response to PBA, it is unlikely that this was a major factor in the diminished MAP response to PBA. If endogenous activation of the baroreflex produced appreciable sympathoinhibitory reductions of MAP in Ang II hypertension, then one would expect SAD to exacerbate Ang II hypertension. As mentioned above, it does not.^{51,52} Therefore, despite baroreflex suppression of RSNA in Ang II hypertension, it would appear that neurally induced increments in renal excretory function are markedly depressed by high circulating levels of the potent sodium-retaining hormones Ang II and aldosterone. Presumably, it is for this reason that PBA has reduced blood pressure-lowering effects in Ang II hypertension. Whether this is the primary reason that accounts for the diminished blood pressure response, this study emphasizes the potential importance of renin inhibition in permitting a robust fall in arterial pressure during PBA.

Responses in obesity hypertension

Excess weight gain and obesity are believed to play a major role in causing increased arterial pressure in the majority of patients with primary hypertension.^{1,2,59} Although the mechanisms that account for obesity-induced hypertension are not clearly understood, there is considerable evidence from experimental and clinical studies that activation of the sympathetic nervous system, including sympathetic outflow to the kidneys, plays a causal role in promoting increased arterial pressure.^{1,2,5-7,59} Additionally, because increased RSNA increases renin release, the renin-angiotensin system may also contribute to obesity hypertension.⁵⁹ Consequently, if the baroreflex has the capacity to chronically inhibit RSNA, this form of hypertension may be especially sensitive to PBA.

The influence of PBA on arterial pressure was studied in dogs with obesity-induced hypertension.⁵³ After 4 weeks of a high-fat diet, body weight and MAP were increased by ~50% and 15%, respectively, in association with an

approximate twofold elevation in plasma NE concentration, consistent with sympathetic activation. Although plasma renin activity increased substantially during the initial weeks of the high-fat diet, values returned to control levels as the hypertension progressed. This temporal normalization of plasma renin activity during the evolution of obesity hypertension may reflect the opposing effects of increased arterial pressure and sympathetic activity on renin secretion. Most importantly, the sympathetic and arterial pressure responses to PBA during week 5 of obesity hypertension were dramatic. Throughout the entire 7 days of PBA, plasma NE concentration and MAP were reduced to or below control levels. Furthermore, despite the fall in MAP, plasma renin activity did not increase during PBA. These findings emphasize the potential importance of the baroreflex in opposing the activation of the sympathetic nervous system and the hypertension often associated with obesity. Once again, these findings are also consistent with the hypothesis that reflex suppression of renin secretion contributes importantly to the long-term antihypertensive effects of PBA.

CLINICAL IMPLICATIONS AND PERSPECTIVES

While novel approaches in animals provide strong evidence linking increased renal excretory function to sustained baroreflex activation in chronic hypertension, it should be emphasized that experimental observations have been made over weeks to months, rather than months to years. Thus the duration of experimental studies may be inadequate to truly reflect baroreflex function in clinical hypertension. Further, the techniques used in experimental studies have been invasive and, in most instances, not feasible for human investigation. Therefore, because of experimental limitations, there is little direct evidence from human studies to indicate that sustained baroreflex activation is a relevant long-term compensatory mechanism in human hypertension. A major impediment in advancing this concept is that physiologic and pathophysiologic alterations in sympathetic activity are regionally heterogeneous (Table 24-1), and assessment of sympathetic outflow to the kidneys is not readily achieved in human subjects, particularly in regards to baroreflex function. Consequently, support for this concept and, therefore, its clinical importance, are largely based on a surrogate for RSNA-sympathetic outflow to skeletal muscle, which is measured by microneurography. Another caveat in the interpretation of the clinical studies is that direct assessment of baroreflex modulation of sympathetic activity in human hypertension by traditional techniques is based solely on *acute* changes in nerve traffic in response to either spontaneous or induced changes in arterial pressure. It is not clear from these *acute* studies whether diminished arterial baroreflex buffering of sympathetic nerve traffic translates into *long-term* alterations in sympathetic outflow.

Efferent postganglionic nerve traffic in subcutaneous nerves distributed to skeletal muscle (and skin) vasculature can be measured directly by microneurography, and

Table 24–1. Regional Sympathetic Activity in Pathophysiologic Conditions

this technique has been used extensively to determine changes in sympathetic activity and baroreflex function in various pathophysiologic states, including hypertension and heart failure (Table 24–1). In contrast, regional sympathetic activation to internal organs, including the heart and kidneys, cannot be measured directly and must be inferred from measurement of organ-specific NE spillover (Table 24–1). While the NE spillover technique does permit estimation of sympathetic activity to internal organs, it cannot be used to assess dynamic changes in sympathetic activity, which are measured by microneurography to assess sympathetic baroreflex function. Consequently, baroreflex control of RSNA must be surmised from measurements of sympathetic outflow to skeletal muscle. Simultaneous measurements of efferent postganglionic muscle sympathetic nerve activity and renal NE spillover do indicate a correlation between the two in resting, healthy normotensive men.⁶⁴ Further, while it is not uncommon for there to be a disparity between sympathetic outflow to skeletal muscle and to internal organs, including the heart, this disparity does not appear to apply to the renal circulation (Table 24–1).^{3,5–7,65} As illustrated in Table 24–1, there appears to be a concordance between sympathetic outflow to skeletal muscle and the kidneys in a number of pathophysiologic states, but this may not always hold.

Microneurographic studies in patients with secondary hypertension

Activation of the sympathetic nervous system is not commonly present in secondary hypertension.^{3,9–11} In fact, microneurographic studies in patients with secondary hypertension are consistent with the hypothesis that the baroreflex responds to hypertension by chronically suppressing RSNA, thus increasing sodium excretion in a compensatory fashion. In patients with adrenal pheochromocytoma, measurements of sympathetic nerve activity to skeletal muscle indicate that the hypertension induced by high circulating levels of catecholamines is associated with decreased central sympathetic outflow.¹⁰ This finding is also consistent with the sustained increase in neurally-induced sodium excretion that occurs in dogs with hypertension induced by chronic infusion of NE, and suggests that the sympathoinhibition in patients with pheochromocytoma may include the sympathetic outflow to the

kidneys, as well as to skeletal muscle. Additionally, sympathetic outflow to skeletal muscle is suppressed in patients with primary aldosteronism,⁹ another form of secondary hypertension. In contrast to patients with pheochromocytoma and primary aldosteronism, microneurographic studies in patients with renovascular hypertension are inconsistent and have indicated increased, normal, or decreased sympathetic activity.^{3,9,11,66,67} As renovascular hypertension may be associated with activation of the renin-angiotensin system, the basis for these inconsistent findings may lie in the opposing effects of circulating levels of Ang II and baroreflex inhibition on sympathetic activity. Recall that RSNA is suppressed in experimental hypertension induced by infusion of Ang II as long as the inhibitory effects of the baroreflex are operative. However, following deafferentation of the baroreceptors, the sympathoexcitatory effects of high plasma levels of Ang II appear to manifest, resulting in either normal or increased RSNA.^{47,51} Indeed, in renovascular hypertension, there is a direct relationship between increments in sympathetic activity and circulating levels of Ang II.⁶⁶ The various sympathetic responses recorded in renovascular hypertension may thus reflect the net temporal opposing effects of Ang II and the baroreflex.

Microneurographic and regional norepinephrine spillover studies in patients with primary hypertension

Microneurographic recordings of efferent postganglionic sympathetic nerve traffic to skeletal muscle vasculature and measurements of whole-body and region-specific NE spillover have provided strong evidence for increased sympathetic activity in primary hypertension.^{1–8} As sympathetic activation occurs both in the initial and sustained phases of primary hypertension, and includes the renal circulation, these responses are consistent with the notion that increased RSNA plays a causal role in impairing pressure natriuresis and in promoting increased arterial pressure throughout the entire evolution of the hypertensive process. However, while net sympathetic outflow is increased in primary hypertension, this does not necessarily exclude a sustained inhibitory influence of the baroreflex on sympathetic activity. Rather, this may indicate that central excitatory inputs predominate over the inhibitory effects of the baroreflex on sympathetic activity.

If this notion is correct, then baroreflex dysfunction may provide an additional stimulus to increased central sympathetic outflow.

The mechanisms that account for activation of the sympathetic nervous system in primary hypertension have not been determined with certainty. Numerous hypotheses have emerged over the years, including attributing the sympathoexcitation to increased plasma levels of Ang II and leptin. One of most long-standing hypotheses is that impaired baroreflex restraint of sympathetic nerve traffic leads to increases in sympathetic activity in primary hypertension. Initial support for this hypothesis was based on studies demonstrating impaired baroreflex control of heart rate in patients with hypertension. However, subsequent microneurographic studies demonstrated that while there is impaired baroreflex modulation of vagal tone, baroreflex control of sympathetic activity is not abnormal in lean hypertensive patients.^{3,5} Thus if one were to extrapolate these acute baroreflex responses to long-term modulation of sympathetic outflow to the kidneys, it would appear that an impaired ability of the baroreflex to inhibit sympathetic activity cannot account for the increased RSNA and arterial pressure in nonobese subjects with primary hypertension. Still, this reasoning may not apply to patients with primary hypertension associated with obesity.

Many patients with primary hypertension are overweight. As in lean patients with primary hypertension, activation of the sympathetic nervous system, including sympathetic outflow to the kidneys, is a characteristic feature of obesity hypertension.^{1,2,5-7,59} Further, as in lean patients with hypertension, the mechanisms that account for sympathetic activation in obesity remain uncertain. Much interest has been directed to the possibility that leptin released from adipose tissue acts centrally to stimulate sympathetic activity. The results from microneurographic studies in patients with obesity hypertension present an additional possibility. These studies have demonstrated that patients with obesity hypertension, in contrast to lean hypertensive subjects, have impaired baroreflex control of sympathetic activity.^{5,6} Therefore, it is conceivable that impaired baroreflex restraint of sympathetic outflow might result in the activation of the sympathetic nervous system and contribute to the hypertension commonly present in obesity. However, in the context of this chapter, it should be emphasized that this explanation is dependent upon the following unsubstantiated physiologic responses. First, the baroreflex must produce sustained inhibition of sympathetic activity in obesity hypertension. This possibility receives support from the observations indicating there is sustained activation of the baroreflex in dogs with chronic obesity hypertension.⁵⁸ Second, impaired baroreflex restraint of sympathetic activity must include sympathetic outflow to the kidneys, as well as to skeletal muscle. Finally, deficiencies in baroreflex function must include *long-term*, as well as *acute*, alterations in renal sympathetic outflow. It is not likely that these critical issues will be resolved with the current methodology available for human investigation. Nonetheless, because PBA has potent sympathoinhibi-

tory and antihypertensive effects in experimental obesity-induced hypertension,⁵³ the possibility that baroreflex dysfunction may contribute importantly to the pathogenesis of obesity hypertension should not be dismissed and merits further investigation.

Baroreflex and antihypertensive therapy

Sympathetic responses to chronic antihypertensive therapy, as assessed by microneurography, are inconsistent and probably influenced by differences in drug class, pharmacokinetics, and pharmacodynamics, as well as experimental protocols. Nonetheless, observations in several studies are consistent with the hypothesis that baroreflex resetting is incomplete during antihypertensive therapy. Although reflex activation of the sympathetic nervous system is neither a surprising nor an uncommon response to acute drug-induced reductions in arterial pressure, some studies employing microneurography have reported sustained increases in sympathetic activity in hypertensive subjects during chronic antihypertensive therapy.^{21,27,68} While these clinical studies may be interpreted to support the notion of incomplete baroreflex resetting, it is problematic to attribute increases in sympathetic activity during either dietary sodium restriction or diuretic administration to baroreceptor unloading and not to the sympathoexcitatory effects associated with concomitant activation of the renin-angiotensin system. However, increases in sympathetic outflow to muscle have been reported even when reductions in arterial pressure have been achieved with either a diuretic-Ang II blocker combination or an Ang II receptor blocker alone,^{68,70} antihypertensive drugs that attenuate the actions of Ang II.

If baroreflex unloading does lead to sustained sympathetic activation, as recent experimental studies suggest, this obviously would be an undesirable response because reflex tachycardia and sympathoexcitation have untoward effects on the heart and oppose the blood pressure-lowering effects of antihypertensive therapy. Sympathetic antagonism with either drugs that act centrally or device-based therapy for baroreflex activation are logical choices to reduce the sympathetic activation commonly associated with primary hypertension. The marked sympathoinhibitory and antihypertensive responses to PBA in obesity-induced hypertension provide a strong rationale for sympathetic antagonism in the treatment of primary hypertension, and highlight the potential importance of the baroreflex in the pathogenesis of hypertension.

SUMMARY

Because SAD does not lead to sustained hypertension, and resetting is a common feature of the baroreflex, the prevailing dogma for the latter part of the 20th century was that baroreflexes do not chronically influence sympathetic activity and arterial pressure. More recently, the interpretation of these studies has been challenged as novel experimental approaches in chronically instrumented animals have provided solid evidence that baroreflex resetting is incomplete during chronic alterations in arterial pressure. Recent experimental studies have also shown

that baroreflex suppression of sympathetic activity, including sympathetic outflow to the kidneys, is a sustained response in chronic hypertension. Because baroreflex suppression of RSNA persistently increases the renal excretion of sodium, contrary to established dogma, these studies indicate that the baroreflex may play a compensatory role in attenuating the severity of hypertension. While the above observations in hypertensive animals have been made over a time course of weeks to over a month, a caveat in the interpretation of these studies is that their duration may be too short to provide an accurate indication of baroreflex function in clinical hypertension persisting for many years. Thus future studies must include hypertensive protocols lasting for at least several months. Unfortunately, current technology is inadequate for elucidating the long-term functional effects of the baroreflex in human subjects.

Although further experimental validation is needed, the renal nerves may be the critical link between baroreflex-induced alterations in central sympathetic outflow and renal excretory responses that lead to long-term changes in arterial pressure. Consequently, difficulties inherent in monitoring RSNA in human subjects pose a major obstacle to determining the role of the baroreflex in the pathogenesis of clinical hypertension. Despite this imposing limitation, studies using microneurography to directly measure postganglionic sympathetic nerve activity in skeletal muscle as a surrogate for RSNA have provided some intriguing results. First, microneurographic studies suggest that sympathetic activity may be suppressed in patients with secondary hypertension. This observation, while not providing direct evidence, supports the possibility advanced by animal experiments that activation of the baroreflex may account for sustained renal sympa-

toinhibition in hypertension, a response expected to attenuate the increase in arterial pressure. Another potentially relevant observation from microneurographic studies is that the evolution of obesity hypertension is associated with progressive baroreflex dysfunction. If this impairment in the ability of the baroreflex to evoke *acute* changes in muscle sympathetic nerve activity also reflects *long-term* alterations in sympathetic outflow to the kidneys, then impaired baroreflex restraint of nerve traffic may contribute to the increased renal sympathoexcitation and increased arterial pressure in this most prevalent form of primary hypertension. This possibility merits serious consideration because PBA has potent sympathoinhibitory and antihypertensive effects in experimental obesity hypertension.

Technology allowing chronic activation of the carotid baroreflex by electrical stimulation has provided new insight into the role of the baroreflex in long-term control of arterial pressure. A unique aspect of this technology is that it permits a critical, quantitative assessment of the mechanisms that mediate the long-term blood pressure-lowering effects of the baroreflex. Initial studies using this approach have demonstrated impressive sustained reductions in arterial pressure in both normotensive and hypertensive dogs. In fact, baroreflex-induced reductions in arterial pressure have been so dramatic that human clinical trials have already been initiated to evaluate the clinical application of this technology in the treatment of resistant hypertension.⁶⁰ In addition to providing a better understanding of long-term baroreflex control of arterial pressure in humans, these clinical trials may pave the way for a novel, nonpharmacologic approach for the treatment of hypertension.

Chapter
25**Central Nervous System
Control of Blood Pressure***Carrie A. Northcott and Joseph R. Haywood***Definitions**

- The central nervous system (CNS) consists of a network of interconnected neurons located in the brain and spinal cord that receives, interprets, and responds to various stimuli through humoral and neurochemical signals controlling physiologic functions.

Key Findings

- The CNS plays a significant role in blood pressure maintenance by maintaining a balance that occurs between output systems which include the sympathetic and parasympathetic divisions of the autonomic nervous system, pituitary hormones, and the renin-angiotensin system.

Clinical Implications

- Central mechanisms controlling blood pressure are complex, and the full potential of central approaches to treatment will not be realized until a better understanding of brain function is achieved.

The contribution of the central nervous system (CNS) to the development and maintenance of hypertension has long been the subject of speculation and investigation. While many early studies described the central actions of neurochemicals and their antagonists on blood pressure, the development of modern neurobiologic techniques has permitted substantive progress in recent years. The application to the study of cardiovascular function of neural pathway tracing techniques, immunocytochemistry, cellular electrophysiology, molecular biology, imaging, and other methods, have provided new insights into how the brain interacts with the cardiovascular system in pathophysiologic states.

The sympathetic nervous system is the principal effector system that mediates changes in blood pressure originating from the brain. The sympathetic nerves and the adrenal medulla comprise a powerful control mechanism that causes large rapid changes in arterial pressure. Complex interactive neural pathways regulate the sympathetic nervous system controlling cardiovascular function in response to internal and external stimuli. CNS pathways contributing to hypertension are activated in response to chemical (e.g., sodium), hormonal (e.g., angiotensin II [Ang II]) and neural stimuli (e.g., baroreceptor afferent nerves). These stimuli can act independently or in concert to stimulate

sympathetic nerve activity. In addition, hormones and neural reflex mechanisms can modulate normal or elevated levels of neural activity in the brain to further increase sympathetic nerve activity or release hormones from the brain that lead to hypertension. Dysfunction of these interactions contributes to the multifactorial nature of the hypertensive process.

While many questions remain to be answered concerning central neural mechanism triggering and maintaining the hypertensive state, much has been learned about the many stimuli that can activate (or inhibit) complex neural pathways and networks leading to hypertension. This chapter will review the anatomic pathways and neurotransmitters involved in blood pressure control, discuss some of the physiologic mechanisms that dysfunction to cause an elevated blood pressure, and then present the clinical implications of current therapeutic approaches.

ANATOMY AND BIOCHEMISTRY**Anatomy of central neural pathways**

The influence of the brain on blood pressure is mediated through four principal effector systems. The first principal effector system is the sympathetic nervous system. Sympathetic preganglionic neurons originate from cell bodies in the intermediolateral column in the thoracolumbar region of the spinal cord to paravertebral and prevertebral ganglia and the adrenal medulla. The second effector system is the parasympathetic vagal control of the heart by two nuclei in the hindbrain—the dorsal motor nucleus and the nucleus ambiguus. The vagus exerts predominant neural control on heart rate in most species and is usually activated as a compensatory mechanism to increased blood pressure or is inhibited to enhance rises in arterial pressure. The third principal effector system is the posterior pituitary. Vasopressin released from the posterior pituitary can contribute to sodium-dependent hypertension.¹ Oxytocin, which is also released from the posterior pituitary, has been implicated in the hypertensive process as well. The final effector system is the anterior pituitary, which is responsible for the release of hormones such as adrenocorticotrophic hormone (ACTH) that, in turn, stimulates the release of cortisol from the adrenal cortex. Glucocorticoids are known to have direct effects on vascular function, but appear also to have significant indirect actions in modulating brain function and fetal programming of hypertension.²

The foundation of understanding central nervous system control of blood pressure in hypertension is supported by our knowledge of the neural pathways that are involved in the maintenance of blood pressure. Observations by Strack and Lowey³ first demonstrated the principal nuclei that project to the intermediolateral cell column of the spinal cord. Five areas of the brain were shown to project directly to the intermediolateral cell column of the spinal cord: hindbrain structures including the rostral ventrolateral medulla (RVLM), rostral ventromedial medulla (RVMM), and the raphe pallidus nucleus (caudal portion of the raphe); the midbrain A5 catecholamine cell bodies; and the hypothalamic paraventricular nucleus (PVN). Figure 25–1 provides an overview of the organization of the brain in influencing neural and hormonal outputs controlling blood pressure. Higher complex center function funnels into basic autonomic and hormonal mechanisms. The discussion below starts with the hindbrain and describes connections to higher centers.

Hindbrain

The RVLM has long been considered the principal part of the vasomotor center largely because of the significant fall in blood pressure associated with chemical inhibition or ablation of the area.⁴ The vasomotor area includes the C1 epinephrine-containing cell bodies, as well as cell bodies in the surrounding area with different neurochemical phenotypes.⁵ These neurons have been shown to have an intrinsic rhythm, they are modulated by the baroreflex, and they project to the preganglionic sympathetic neurons in the spinal cord. The RVMM and the raphe pallidus have also been shown to have direct connections to the intermediolateral cell column influencing

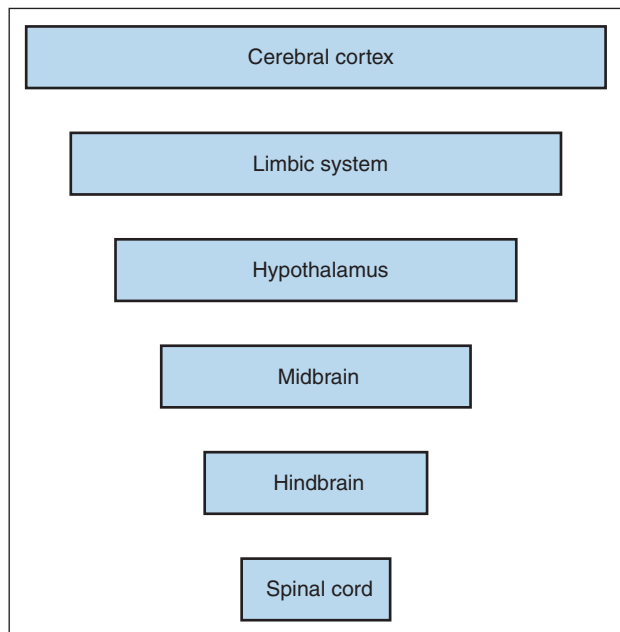

Figure 25–1. This schematic represents the layers of complexity of neural pathways contributing to the regulation of the autonomic function controlling the cardiovascular system.

sympathetic preganglionic neurons. These areas do not possess intrinsic rhythms; however, one subpopulation of cells in these areas is important in cardiovascular function and is sensitive to baroreflex control. This group of neurons receives input from other brainstem areas such as the lateral tegmental area, which may be involved in mediating baroreflex control in some species.⁶ Another subpopulation of neurons is insensitive to baroreflex control and has a less direct role in cardiovascular function regulating thermogenesis, lipolysis, and cutaneous circulation.

The glossopharyngeal nerve or cardiopulmonary receptors via the vagus terminate in the nucleus tractus solitarii (NTS) providing afferent input to the brain from the carotid and aortic arch high pressure baroreceptors. Second-order excitatory neurons from the NTS project to the caudal ventrolateral medulla, which contains GABAergic inhibitory neurons that limit sympathetic outflow and hypothalamic neuroendocrine mechanisms. Projections to the PVN and supraoptic nucleus (SON) modulate vasopressin and ACTH release while the pathway to the RVLM regulates sympathetic activity. The NTS also projects to the dorsal motor vagal nucleus and the nucleus ambiguus to influence vagal control of the heart rate. Other reflex afferent neurons project to the NTS and affect autonomic and cardiovascular regulation, including chemoreflexes, renal afferent nerves, skeletal muscle afferents, and gastrointestinal inputs. The NTS is also modulated by the area postrema (AP), a circumventricular organ that lacks a blood–brain barrier and permits access of peptides and other circulating chemicals to the NTS neurons to facilitate or diminish reflex function.⁷

Midbrain

Hindbrain sites receive direct projections from midbrain and hypothalamic areas. In the midbrain, the parabrachial nucleus serves as a relay station for projections to and from the forebrain. Afferent projections from the NTS to the parabrachial nucleus carry visceroreceptive, nociceptive afferents, respiratory, and cardiovascular information to the hypothalamus.⁸ Descending projections to the parabrachial nucleus extend from the PVN, amygdala, and dorsomedial hypothalamic nuclei. The parabrachial nucleus relays information to the NTS and RVLM. Many descending pathways from the hypothalamus to the hindbrain and spinal cord pass through the periaqueductal gray. The area contains synapses as well as fibers of passage.⁹ Another major midbrain site to receive projections from the hypothalamus is the A5 area. The A5 is one of the principal nuclei that projects to the preganglionic sympathetic neurons; it also projects to the RVLM and NTS. The A5 receives input from the PVN and other hypothalamic nuclei.

Hypothalamus

The hypothalamus serves as a higher level of integration for cardiovascular regulation. The principal nuclei integrating the hormonal and sympathetic neural responses in the hypothalamus are the paraventricular and dorsomedial nuclei. It appears, however, that these nuclei mediate different responses. The dorsomedial hypothalamus

(DMH) is more involved with stress-related stimuli while the PVN contributes to mechanisms maintaining overall body homeostasis. The PVN has received a great deal of attention in cardiovascular regulation because it sends direct excitatory projections to the intermediolateral column of the spinal cord, RVLM, and parabrachial nucleus, and an inhibitory projection to the NTS.^{10,11} The DMH projects to the midbrain and hindbrain cardiovascular centers to modulate autonomic function including blood pressure and heart rate. The posterior hypothalamus is involved in sympathetic regulation as well, but appears to have a less pivotal role in blood pressure control than the PVN and DMH. Both the PVN and DMH receive innervation from the parabrachial nucleus. The PVN also receives input from the NTS and the CVLM as part of the cardiovascular baroreflex loop. Another potential projection in the reflex loop is to the anterior hypothalamic area (AHA). Increases in blood pressure stimulate catecholaminergic activity in the AHA.¹² The AHA sends a GABAergic projection to the PVN, which provides a significant amount of the GABA innervation in the PVN that can reduce sympathetic outflow.^{13–15} Other input to the PVN and DMH from areas such as the lateral and ventromedial hypothalamic nuclei can also modulate cardiovascular function. These areas and others serve as relay stations carrying inputs from sensory areas in the hypothalamus and the hindbrain.

There are also sensory areas of the hypothalamus that can activate neural pathways influencing cardiovascular function. Two sites, the organum vasculosum of the lamina terminalis (OVLT) and the subfornical organ (SFO), are circumventricular organs like the AP where peptides can exert their actions. The OVLT and the SFO are both important for the central actions of Ang II, sodium, and cytokines that result in the activation of the PVN and descending autonomic pathways as well as the SON, PVN for neuroendocrine stimulation of vasopressin and oxytocin from the posterior pituitary, and ACTH from the anterior pituitary. The OVLT and SFO also converge on the nucleus medianus in the rostral portion of the third ventricular wall where they synapse with neurons projecting to the PVN and SON. The OVLT and the nucleus medianus are the principal structures of the anteroventral third ventricle region (AV3V) of the hypothalamus.⁷ The arcuate nucleus is sensitive to circulating leptin, which is released by adipose tissue in obesity. Leptin activates proopiomelanocortin (POMC) pathways and inhibits neuropeptide Y (NPY) pathways to the DMH, PVN, and other areas of the hypothalamus to increase sympathetic outflow, decrease food intake, and stimulate lipolysis¹⁶ (see Chapter 38). Other hormones and chemicals such as insulin, aldosterone, and free fatty acids stimulate the brain through these sites. Other sensory modalities also act through the hypothalamus. Light/dark balance, which acts through the suprachiasmatic nucleus, controls circadian rhythms and modulates cardiovascular and neuroendocrine function through the PVN, SON, and other nuclei.¹⁷ Thermosensitive neurons in the medial preoptic area connect with the DMH to regulate sympathetic outflow to brown adipose tissue and the heart.¹⁸

Limbic system and cerebral cortex

Higher brain centers also influence neural and hormonal control of the circulation. The limbic system includes the limbic lobe of the cortex and deep-lying structures beneath the cortex that include the amygdala, fornix, hippocampus and other areas involved in behavioral responses composing the defense response or alerting behavior. The autonomic and hormonal systems linked to these areas permit the manifestation of responses associated with behavior. The amygdala is the principal structure that links the limbic system to the lateral hypothalamus, the parabrachial nucleus, the RVLM, vagal nuclei, and the NTS to evoke the autonomic components of the response.¹⁹ The amygdala also receives projections from the NTS and the parabrachial nucleus. The limbic system drives acute cardiovascular responses associated with emotional behaviors; however, it also is involved in affective disorders such as depression that may contribute to the long-term control of blood pressure. Areas of the cerebral cortex have also been shown to modulate neurohumoral mechanisms controlling blood pressure. The insular cortex and the medial prefrontal cortex receive input from the NTS and parabrachial nucleus through projections that pass through the midbrain and the thalamus.^{19,20} The somatic motor and sensory cortex receive projections from the limbs and viscera that are integrated in responses associated with exercise and cardiac pain. Descending projections extend to the hypothalamus and downstream sites in the midbrain and hindbrain that are associated with the integrated autonomic, hormonal, and motor responses. These areas are linked to cognitive behavioral influences on blood pressure and “central command” of cardiovascular function during exercise.

In summary, there a number of effector systems that influence and regulate blood pressure alterations and maintenance. These mechanisms involve numerous reciprocal projections between various structures throughout the brain. These interactions are responsible for the checks and balances that are typical in the maintenance in blood pressure. Figure 25–2 illustrates the intricate nature of the interactions in brain regions that are involved in blood pressure regulation. The complex nature of these networks contributes to the puzzle of neural pathways regulating cardiovascular control.

Biochemistry of neurotransmitters

The neurochemical control of blood pressure involves a wide range of neurotransmitter and neuromodulator systems. The same sequence of rapid to slower, more prolonged acting neurochemical mechanisms are involved in these pathways similar to other neuronal systems. In the brain, fast-acting amino acid neurotransmitters are important as both inhibitory and excitatory systems. The actions of the rapid systems are modulated by monoamine and cholinergic systems. Then peptides released by action potentials or formed in the extracellular fluid contribute a further level of modulation. Synapses are a complex organization of multiple inputs resulting in many different neurotransmitters that are actively released from both neurons and glia. The ultimate effect is a summation of

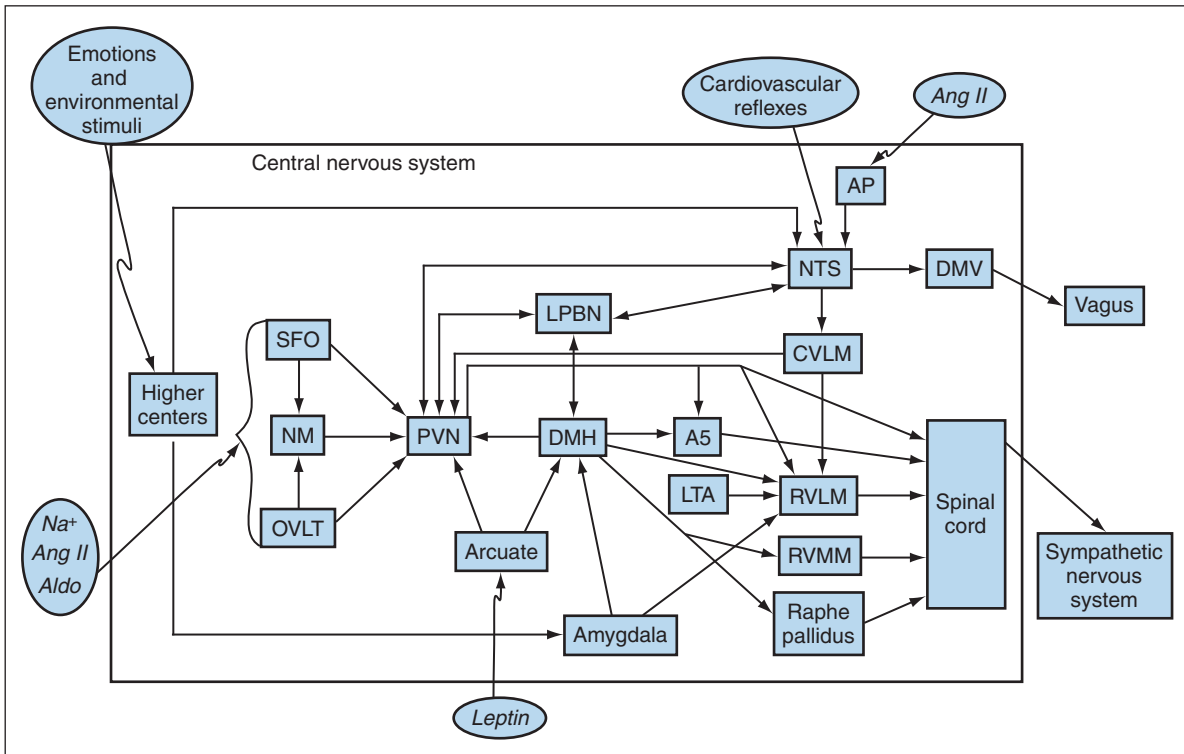

Figure 25–2. The schematic depicts the nuclei within the central nervous system (CNS) involved in the hypertensive process and their interconnections by neural pathways. Stimuli are represented in ovals, and their site of action is illustrated by the thickened arrows. Vagal and sympathetic nervous system outputs are shown outside the CNS.

chemical effects that will stimulate or inhibit the cell bodies or axons. Major neurotransmitter systems, the receptors they use, and the general signaling system are summarized in Table 25–1.

Amino acid neurotransmitters are fast-acting excitatory and inhibitory chemicals that include glutamate, γ -aminobutyric acid (GABA), glycine, and others. Glutamate and GABA are the principal neurotransmitters, and they act through specific receptors. Glutamate is used as the primary excitatory neurotransmitter in the CNS. The glutamate receptor is composed of two families of receptors: the first is the G-protein–coupled metabotropic glutamate receptors and the second is composed of the ionotropic glutamate receptors. The eight G-protein–coupled receptors belong to the seven transmembrane-spanning domain superfamily of receptors, and are comprised of three separate subgroups based on similarities in their amino acid sequences, second messengers, and their respective pharmacology.²¹ The G-protein–coupled glutamate receptors are found throughout the CNS and are found post- and pre-synaptic. They are involved in the activation of signaling molecules, long-term potentiation, long-term depression, neuronal death, and synaptic plasticity.²² The ion channel families of glutamate receptors are multimeric in composition and are comprised of three different subtypes based on pharmacologic structural similarities: N-methyl-D-aspartate (NMDA), α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA), and kainate. The NMDA receptors are localized postsynaptically and their activation leads to calcium influx into the post-

synaptic cells and they are known to regulate excitatory neurotransmission.²³ Neurotransmission occurs more slowly than that with AMPA receptors, but it lasts much longer. AMPA receptors are ubiquitously expressed throughout the CNS and mediate fast synaptic transmission in the CNS.²³ Kainate receptors are localized both pre- and post-synaptically, and due to lack of pharmacologic tools, their physiologic role is still not completely understood; however, it is suggested that they are involved in fast synaptic transmission, suppression of transmission (presynaptic), and synaptic plasticity.^{23,24}

GABA is the main inhibitory neurotransmitter found in the CNS. It acts upon three different classes of receptors: GABA_A, GABA_B, and GABA_C. The GABA_A and GABA_C receptors are ionotropic, whereas the GABA_B receptors are metabotropic. GABA_A and GABA_C are Cl⁻ channels that mediate fast synaptic inhibition; however, they differ biochemically, pharmacologically, and physiologically. GABA_A receptors are the primary fast-acting inhibitory receptors in the CNS. GABA_B receptors are G-protein coupled and activate second-messenger systems, phospholipase C and adenylate cyclase, as well as activate K⁺ and Ca²⁺ ion channels. These receptors are localized both post- and pre-synaptically.²⁵ Synaptic activation of the GABA_B receptor leads to a slow inhibitory postsynaptic potential unlike the fast inhibitory post-synaptic potential that is observed with GABA_A receptors.²¹ Glycine is another major inhibitory neurotransmitter in the CNS. It acts primarily at the glycine receptor, which is a ligand-gated Cl⁻ channel. It has both inhibitory postsynaptic function and can also

MAJOR NEUROTRANSMITTER SYSTEMS AND THEIR RECEPTORS, AND GENERAL SIGNALING SYSTEM		
Transmitter	Receptors	G-Protein Coupled vs. Ionotropic
GABA	GABA A	Ionotropic receptor
	α , β , γ , δ , σ isoforms	
	GABA B GABA C	G-protein coupled ionotropic receptor
Glutamate	AMPA	Ionotropic receptor

	AT2	G-protein coupled
Ang 1–7	Mas	G-protein coupled

Table 25-1. Major Neurotransmitter Systems and Their Receptors, and General Signaling System

act as an excitatory neurotransmitter, by acting as a coagonist of the NMDA glutamate receptor. Several of the major excitatory and inhibitory neurotransmitters localized to the CNS have been discussed thus far.

Catecholaminergic pathways have also been studied extensively with regard to the CNS. Neurons projecting from cell bodies containing norepinephrine (A1, A2, A5, A6), epinephrine (C1, C2), and to a lesser extent dopamine (A13), significantly influence synaptic activity. There are multiple receptor subtypes that are activated by norepinephrine/epinephrine including, α_1 , α_2 , and β receptors. These receptors have multiple subtypes, are widely distributed, and can be found at both central and peripheral sites. These receptors are activated by norepinephrine released at synaptic terminals or epinephrine released from the adrenal medulla. α_1 -Adrenoreceptor activation in the CNS generally results in depolarization and an increase in the firing rate; α_2 -adrenoreceptor activation in the brainstem results in an inhibition of sympathetic outflow; and finally, prejunctional α_2 -adrenoreceptor—activation and stimulation-evoked neurotransmitter release. These are just several of the actions mediated by these receptors. Serotonin (5-hydroxytryptamine; 5-HT) is another neurotransmitter that is found in the CNS that

is involved in blood pressure regulation. Serotonergic systems mainly originate from the raphe nuclei and have receptors that are localized in multiple brain regions. There are seven main types of 5-HT receptors, each with multiple subtypes that have a wide variety of endpoints. Activation of 5-HT receptors in the brain alters cardiovascular function by affecting autonomic outflow, as well as water and salt intake, reflexes, and more.

Amines can cause excitation or inhibition in synapses depending on the receptor subtype binding. They can also modulate sensitivity to other neurotransmitters and neuromodulators. Acetylcholine (Ach) is synthesized from acetyl coenzyme A and choline by acetyltransferase. Neuronal acetylcholinesterase quickly breaks down Ach in the brain. Ach acts on two main classes of receptors: nicotinic, which are ligand-gated cation channels, and muscarinic, which is G-protein coupled. Each receptor/subclass has different actions on neuronal activity.

In addition to the above mentioned neurotransmitters, there are numerous neuropeptides that are involved in blood pressure regulation. Angiotensin peptides represent a family of neuropeptides in that they have a role in the regulation of blood pressure. Ang II is the principal peptide that acts on two different receptor subtypes, the AT1

and AT2 receptors. The AT1 receptor has been localized in the hypothalamus, midbrain, and hindbrain. Additionally, Ang II has been found to be elevated in hypertensive models of hypertension.²⁶ Several angiotensin peptides have also been shown to act in the brain to increase blood pressure and stimulate thirst.^{27,28} Ang 1–7, an angiotensin peptide, has been localized in the brain and is the product of angiotensin-converting enzyme 2 (ACE 2) on Ang II or endopeptidase on Ang I.^{29,30} It acts through the mas receptor to cause a fall in arterial pressure. Other neuropeptides also act in areas of the brain to increase or decrease arterial pressure. This is just a very brief summary of the complex actions of numerous neurotransmitters that act in the brain and are involved in high blood pressure control.

GENETICS

Individual susceptibility to hypertension depends on multiple genetic and environmental factors affecting both physiologic and biochemical mechanisms that control blood pressure. As a result, determination of the genetic involvement in hypertension is a difficult endeavor. Since the development of the strain of rats developed by Smirk and Hall,³¹ the use of genetic models that resulted from natural mutations has been a useful approach to understanding the pathophysiology of hypertension. So far it has not been apparent that any of these strains of rats or mice have developed hypertension as a result of a specific neural defect.

The polygenic, and therefore multifactorial, nature of the hypertensive process has been underscored by the investigation of these models over the years. However, it remains uncertain whether basic genetic defects in brain function of other genetic alterations leading to central neural dysfunction is the critical mechanism driving the hypertension in many of these models. One concern that has arisen is the lack of true controls for genetic strains; one example is the Wistar Kyoto (WKY) is commonly used as the control animal for the spontaneously hypertensive rat (SHR). The SHR is but one of several models that is used to examine the genetic role of blood pressure. It is commonly thought that changes between the models may be a result of strain differences or may be due to genetic drift.³² Nevertheless, genetic alterations have been found in the brains of spontaneously hypertensive rats and Dahl salt-sensitive animals. For example, in the SHR, occurrence of NMDA-receptor splice variants NR2C and NR2D gene expression are significantly lower than in observed normotensive controls.³³ Receptor radioligand-binding studies have demonstrated increased numbers of angiotensin-binding sites in cardiovascular relevant brain areas of SHR.^{34,35} In contrast, AT1 receptor mRNA levels are higher in the hypothalamus of the SHR compared to that of normotensive controls.²⁶ While genetic models have assisted further exploration of the genetic component of cardiovascular diseases, there are still many gaps in current knowledge. Many of the studies are observational versus descriptive; moreover, information on genetic involvement in CNS–cardiovascular disease interaction is still limited.

To investigate the potential of altered expression of neural genes to cause hypertension, overexpression of a specific gene candidate (transgenic) and deletion or knocking down of the genes are effective approaches. Overexpression of the gene assists in elucidating the normal tissue- and cell-specific expression patterns of a gene and can lead to information about the gene-specific physiologic changes that occur.³⁶ Deletion of the gene allows for interpretations of its function by examining physiologic response when the gene is missing.³⁶ With the identification of Ang II–immunoreactive fibers in specific brain regions,^{37–41} a series of Ang II–related transgenic animals have been developed to investigate the role of the brain angiotensin system. Double-transgenic mice expressing human angiotensinogen (hAGT) or human renin (hREN) under the control of glial-specific glial fibrillary acidic protein (GFAP) promoter were developed and exhibited a modest Ang II type 1 receptor–dependent increase in blood pressure.^{42,43} In addition, glial-specific deletion of AGT was performed in mice, and arterial pressure was found to be significantly lower in the overexpressors and unchanged from nontransgenic control mice. These results suggested a major contribution of glial AGT to the hypertensive state.⁴⁴

In a transgenic mouse model with brain-restricted overexpression of Ang II 1a receptors (NSE-AT(1a)), mice underwent two-kidney/one-clip surgery to induce hypertension, which resulted in an early exacerbation of blood pressure increases.⁴⁵ A particularly interesting new transgenic model overexpresses a nonsecreted form of renin.⁴⁶ α 2A-adrenergic receptors play a key role in cardiovascular regulation; moreover, they are widely expressed in the CNS. D79N mice, which lack functional α 2A-adrenergic receptors, display no increase in blood pressure after injection with atrial natriuretic peptide (ANP) or α 2 receptor agonists into the anterior hypothalamic nucleus. This result is unlike the changes observed in control C57BL/6 mice. These data support the concept that in the anterior hypothalamic nucleus of the mouse α 2A-adrenergic receptors mediate both sympathoinhibitory responses to ANP and α 2-adrenergic receptor agonists.⁴⁷ These are just a few examples in which brain-specific transgenic animals are used to understand the potential role of genetic influence in the CNS in the development of blood pressure. Investigators have used other genetic tools such as gene transfer and cre-lox systems to study timed gene expression in specific nuclei as well as the whole brain.

Another approach to examine genetic involvement in blood pressure is the use of gene arrays to examine gene expression profiles in hypertensive models. High-throughput gene profiling has permitted the examination of a large number of genes at one time, thus providing an opportunity to study changes in a large number of genes. While sequential and proximal gene effects may influence the results, potential intergene relationships can be studied using extensive software analysis. In addition, with the advent of proteomic technology, these strategies can be further exploited. Even these approaches are stymied by secondary effects such as the influence of elevated blood pressure causing baroreflex-related changes in gene

expression rather than primary defective changes. Nevertheless, studies utilizing gene profiling in primary hypothalamic neuronal cultures have revealed differential expression of 299 genes and 109 expressed sequence tags (ESTs) between neuronal cultures treated with Ang II and control neurons. In addition, Ang II treatment resulted in the differential expression of 128 genes and 52 ESTs between WKY and SHR neurons.⁴⁸ These genes were involved in neurotransmission, signal transduction, ion transport, immune response/cytokines, proteolysis, and other areas.⁴⁸ This technique also assists in further elucidation of changes in underlying signaling in neurons that may influence changes in blood pressure. The information that the genetic profiling provides is useful; the challenge lies in determining the physiologic relevance of these genes. Hence the combination of the abovementioned techniques is required to fully evaluate the genetic involvement in the development and maintenance of hypertension.

PHYSIOLOGY

While many stimuli can cause an acute elevation in arterial pressure through central mechanisms, few stimuli are chronically activated, making it difficult to account for long-term control of blood pressure. For example, stressful situations can cause acute increases in sympathetic activity and hormonal responses; however, stressors are usually not sustained. Similarly, sodium and hormones can act on the brain to trigger increases in blood pressure, but these stimuli are linked to either the rhythmicity of hormone release or meal-associated increases in sodium.⁴⁹ The “error signal” for a stimulus to cause a sustained rise in blood pressure must be a result of a dysregulation of physiologic control and disposition of hormones and/or nutritional mediators or a neural memory mechanism that alters the sensitivity to the pressor stimuli. Of course, these mechanisms alone are not enough to result in the CNS drive because baroreflex mechanisms should restore excursions in blood pressure to normal. Hence, a further central dysregulation of volume and/or baroreflexes must occur for a long-term rise in blood pressure. The change in the “set point” for blood pressure during hypertension has been the focus of many studies and much speculation. Although the resetting of the baroreflex to a higher level and even a reduced sensitivity of the reflex has been demonstrated repeatedly for many years, the neural mechanism has been elusive. Recent work by Mifflin and colleagues⁵⁰ has suggested that an increase in presynaptic GABA_B function in the NTS may contribute to the process of resetting blood pressure to a higher level.

Most evidence points to a dysfunction of the renin-angiotensin-aldosterone system as a major culprit in the hypertensive process. The peripheral vascular and renal actions of Ang II combined with the central actions of the hormones support the concept of hypertension as a multifactorial and multiple-organ dysfunction disease. The excitatory pathway cascade currently hypothesized in hypertension starts with circulating Ang II acting on the SFO and OVLT leading to the activation of the PVN, RVLM, and spinal cord preganglionic neurons, and thus

leads to increased sympathetic outflow and ultimately elevation of blood pressure.⁵¹ However, the physiology of CNS-mediated hypertension does not appear to be this straightforward because Ang II can also contribute to the hypertensive process through a number of other central mechanisms. Three examples of the complexity of Ang II will be discussed below to demonstrate principles brain involvement in hypertension. Included are the actions of Ang II working in concert with sodium and other circulating hormones to trigger the hypertensive process, evidence that Ang II synthesized in the PVN and RVLM that supports the role of a brain renin-angiotensin system, and the activation of cell signaling systems to mediating the actions of Ang II and modulating the function of other neurotransmitter systems.

Sodium-dependent hypertension is often associated with a dysregulation of the renin-angiotensin system. It has been suggested that the levels of Ang II and aldosterone are high in some forms of hypertension for the level of total body sodium.⁵² The main Ang II- and sodium-sensitive region of the brain includes the SFO and the AV3V. The mechanisms of interaction of sodium and Ang II are not clear; however, the presence of sodium enhances the actions of Ang II. The presence of epithelial-like sodium channels and Ang II receptors in the OVLT and the SFO provide the structural machinery for them to work together to stimulate central neural pathways. Recent evidence has suggested that aldosterone may also be important in amplifying the actions of Ang II since mineralocorticoid receptors are also present in these areas.⁵³ Aldosterone antagonists also interfere with the pressor actions of sodium. While aldosterone can activate sodium channels to alter cell sodium content and sensitivity to Ang II, evidence is only starting to emerge to support the exact mechanisms. Another example of multiple stimuli acting centrally through merging pathways is in obesity. Obesity is associated with an increase in leptin, Ang II, and aldosterone.⁵⁴ The actions of Ang II on the forebrain were previously discussed.

Leptin also has a forebrain action through the arcuate nucleus to increase sympathetic nervous system activity. Liberated by adipose tissue, leptin activates excitatory melanocortin and inhibits NPY inhibitory pathways to the PVN to regulate feeding and sympathetic function. It is unknown whether the convergence of the SFO/OVLT and the arcuate pathways activate the same descending sympathoexcitatory mechanisms; however, the PVN plays a major role in mediating the responses.¹⁶ Together these observations support the concept that multiple humoral systems are activated in hypertension, which can act at the same or different locations in the brain to stimulate the similar pathways.

The concept of a brain renin-angiotensin system has been discussed for many years. Confirmation of tissue-specific formation of Ang II has evolved rapidly with the advent of gene manipulation techniques. It is now clear that Ang II can be formed in the synapse and in some neurons.⁴⁴ Assay limitations make it difficult to actually measure the release of Ang II and satisfy the requirements for classification as a neurotransmitter. However, one of

the interesting aspects of the brain Ang II system has been that sequential neural pathways were capable of using Ang II to mediate their activation.³⁸ Projections from the SFO to the nucleus medianus are stimulated by circulating Ang II and appear to use Ang II to, in turn, stimulate the projection to the PVN. As previously discussed, the PVN then sends more diffuse projections to activate the sympathetic nervous system. At least one of these projections to the RVLM also appears to use Ang II to mediate part of its actions.⁵⁵ As cotransmitters, peptides play important roles in enhancing and prolonging the actions of faster neurotransmitters like glutamate. The repeated occurrence of a peptide like Ang II in functional neural pathways presents a therapeutic opportunity to interfere with a pathophysiologic mechanism at more than one site of action.

In the brain, Ang II and glutamate use several cell-signaling systems to increase intracellular calcium levels and depolarize neurons. Among these systems is the nitric oxide/superoxide signaling system. Nitric oxide increases following Ang II stimulation as a compensatory mechanism to decrease the actions of Ang II. In contrast, both Ang II and glutamate activate the superoxide system to increase free radicals that work with other signaling systems to elevate calcium levels. The family of reactive oxygen species includes superoxide, hydroxyl ion, and the relatively stable and diffusible moiety, hydrogen peroxide, which is the product of superoxide dismutase. Superoxide also combines with nitric oxide to form peroxynitrites, which can bind to cellular proteins and alter their function. The formation of peroxynitrites also reduces the bioavailable concentration of nitric oxide limiting its activity. Components of the nitric oxide and superoxide systems act both intracellularly and extracellularly to alter neurotransmitter release. Nitric oxide has a paracrine function diffusing out of the cell and increasing the release of GABA from adjacent neurons.⁵⁶ Glutamate release can be altered by hydrogen peroxide. Thus, Ang II, working with glutamate, alters the balance between the nitric oxide and superoxide systems, and thus facilitates excitatory neurotransmission. Evidence suggests that this mechanism occurs in each of the sites where Ang II acts to stimulate a neural pathway.

The role of the underlying signaling processes and their involvement in neurotransmitter release and their involvement in blood pressure regulation has gained recent interest. Alterations in mitogen-activated protein (MAP) kinase and the phosphatidylinositol-3 kinase (PI3-kinase) families of proteins have been implicated in neuronal involvement in blood pressure regulation. MAP kinase has been found to be involved in Ang II-induced transcription of catecholamine-synthesizing enzymes.⁵⁷ Moreover, the PI3-kinase-Ang II signaling pathway has been observed in primary hypothalamic cell cultures from spontaneously hypertensive rats but not in cultures from control rats.⁵⁸ Inhibitors of these pathways when microinjected into the RVLM have demonstrated that the MAPK pathway contributes to resting arterial pressure, and the PI3-kinase pathway is important in maintaining the elevation in blood pressure observed in hypertensive animals.⁵⁹ In

addition, elevated levels of PI3-kinase activity have been detected in brain areas involved in blood pressure control in the SHR.⁴⁸ Underlying signaling mechanisms have been of great interest in the periphery and have been found to play important roles in blood pressure regulation; however, the understanding of signaling mechanisms in the central control of blood pressure is in its infancy. Further research will add to the further understanding of the involvement of signaling processes in the brain and their involvement in hypertension.

The mechanisms involved in the long-term control of blood pressure are difficult to assess. In the study of factors contributing to increased arterial pressure, many different mechanisms have been investigated, but little has been done to determine the evolution of changes in factors sustaining blood pressure over time. No doubt environmental and dietary influences are major factors; however, compensatory mechanisms are also likely involved. Early studies by Bianchi, et al.⁶⁰ were among the first to indicate that when blood flow to the kidney is reduced, renin-angiotensin system activity is not sustained over a long period of time. Other work has suggested that even though the sympathetic nervous system may contribute to elevated blood pressure during the onset and maintenance phases of hypertension, different central mechanisms may be involved.^{61,62} Decreases in GABAergic function in the PVN are decidedly reduced during the onset of renal wrap hypertension; however, chronic a functional GABA system is slightly increased in the PVN. These and other observations suggest that further work into mechanisms that cause these changes may lead to a clearer understanding of the hypertensive process as well as provide insights into the long-term control of blood pressure.

CLINICAL IMPLICATIONS AND PERSPECTIVES

The clinical relevance of understanding changes in the brain in hypertension extends beyond the role of potential causative mechanisms. Investigations into the central mechanisms of blood pressure control have been important in delineating the neural connections among specific nuclei. Studies related to the integration of peripheral stimuli by the brain, the pathways that the stimuli activate, and the physiologic responses that are elicited have also been critical for our understanding of how the brain processes information. The control of blood pressure is clearly linked to emotional and cognitive function in higher brain centers. Observations demonstrating impaired task performance and short-term memory in hypertensive patients suggest long-term patient impact other than peripheral end-organ failure and stroke.⁶³ Further, an association among depression, stress, and cardiovascular diseases including hypertension emphasizes the integrative relationship between the brain and blood pressure control mechanisms.⁶⁴⁻⁶⁶ Understanding the cause-effect relationship between brain function and blood pressure regulation will be essential to the ultimate treatment of cardiovascular disease.

Although we have a working knowledge of the neurotransmitters that mediate chemical neurotransmission, we know very little about how they interact in a synapse or how excitatory or inhibitory responses prevail. Further, the role of glia in regulating neurotransmission remains a looming question since glia around neurons and cerebral blood vessels performs a number of functions such as a chemical storage depot, barrier to chemicals, and cell-to-cell communication. The control of cellular and paracrine signal transduction systems are critical for the transmission of neural signals. Work aimed at understanding of how ion channels and signaling systems interact, and what determines the output signals from neurons and glia cells, has only begun. Then, of course, the roles of growth factors, neural regeneration, and apoptosis in the brain have received little attention. Similarly, the factors that determine gene expression and the ultimate phenotype of neurons determining the function and innervation patterns in the brain have only started to be explored. Finally, the integration of neural pathways to form circuits and interactions with other neural functions in the whole animal and patient will be the final pieces of the brain puzzle. Once these pieces have been put together, then we can develop better modes of treatment and intervention to lower blood pressure and improve lifestyle.

SUMMARY

The role of the brain in hypertension remains controversial. It is clear that neural pathways in the CNS are involved in blood pressure control. There is further evidence that specific stimuli such as reflex mechanisms, circulating hormones, and stressful behavioral situations can stimulate the brain to increase blood pressure. In addition, well-defined output systems such as the sympathetic and parasympathetic nervous systems and circulating hormones permit evaluation of the impact of stimuli to the brain. Evidence strongly points to a role for the renin-angiotensin-aldosterone system in stimulating central neural pathways and integrating responses to peripheral stimuli that lead to increased arterial blood pressure. However, the essential and complex integrative role that the brain plays also limits our ability to quantify the contribution of the CNS to blood pressure control. As our understanding of brain function and evolution of technology advances, the mysteries of how the brain works in many different circumstances will provide insights into blood pressure control and the hypertensive process.

Chapter
26**Aldosterone and Other Steroids***John W. Funder***Definitions**

- Aldosterone is a uniquely modified (18CHO) adrenal steroid, with a well-described physiologic action of promoting unidirectional transepithelial sodium transport.
- Mineralocorticoid receptors are high-affinity binding sites in epithelial and nonepithelial tissues for aldosterone and the physiologic glucocorticoids cortisol and corticosterone.
- 11 β Hydroxysteroid dehydrogenase type 2 is a very efficient, operationally unidirectional enzyme catalyzing the metabolism on cortisol to cortisone (and corticosterone to 11-dehydrocorticosterone) in aldosterone target tissues. Thus, by lowering active glucocorticoid levels and increasing those of NADH, under physiologic conditions aldosterone selectively activates mineralocorticoid receptors in tissues expressing the enzyme.

Key Features

- Rare syndromes (glucocorticoid remediable aldosteronism, apparent mineralocorticoid excess, hypertension of pregnancy) have proven useful in establishing current (patho)physiology.
- Patients with hypertension (and heart failure) characteristically have plasma aldosterone concentrations in the normal range.
- Mineralocorticoid receptors can be activated by cortisol under conditions of 11 β hydroxysteroid deficiency/blockade, or by redox change attendant on generation of reactive oxygen species.

Clinical Implications

- Mineralocorticoid receptor blockade is therapeutically beneficial regardless of aldosterone status in hypertension (and heart failure).
- If shown to be vascular protective in larger clinical trials, mineralocorticoid receptor blockade should be widely used in cardiovascular disease.
- Blockade may similarly be useful in other chronic inflammatory (e.g., autoimmune) disorders.

For over 50 years aldosterone excess has been known to raise blood pressure in humans (Conn's syndrome), and over 60 years ago the combination of deoxycorticosterone and salt was shown to do so in experimental animals. In both instances renal sodium and water retention was inculcated as the initial effector mechanism, with the resultant increase in circulatory volume followed by an

increased cardiac output, in turn normalized by elevation of blood pressure. Subsequently, steroids with predominantly glucocorticoid activity were also shown to raise blood pressure, an effect that was not blocked by spironolactone, thus presumably mediated via glucocorticoid rather than mineralocorticoid receptors, and which appears to be mediated by reduced nitric oxide availability.¹ In experimental animals, administration of high levels of testosterone causes hypertension, by blockade of the adrenal enzyme (CYP11B1) needed for glucocorticoid production, causing elevation of ACTH and deoxycorticosterone levels.

Although knowledge of the epithelial action of aldosterone, and that of glucocorticoids in decreased production/increased scavenging of nitric oxide, is far from complete, over recent years evidence has accrued for a range of other ways in which adrenal steroids may be/are involved in blood pressure regulation. The role of the specificity-conferring enzyme 11 β hydroxysteroid dehydrogenase type II (11 β HSD2) has been defined, at least in part, in allowing aldosterone selectively to activate mineralocorticoid receptors (MR) in epithelia.^{2,3} MR have been demonstrated in nonepithelial tissues, in some of which (e.g., vascular wall, NTS, placenta) 11 β HSD2 is also expressed⁴⁻⁶; in others (hippocampus, cardiomyocytes, AV3V neurons), the enzyme is at low levels or absent.^{7,8} Regardless of whether 11 β HSD2 is co-expressed, activation of MR in some of these sites (e.g., vascular smooth muscle cells [VSMC] and AV3V neurons) can have major effects on blood pressure. In terms of the genesis of steroid-induced hypertension, the focus has in many senses shifted from aldosterone acting at epithelia to mineralocorticoid receptor activation, by aldosterone or other steroids, in both epithelial and nonepithelial tissues. The sections of this chapter to follow attempt to illustrate this complexity, from basic biochemistry through physiology and pathophysiology to implications for clinical practice, focusing on aldosterone and other steroids that can activate MR, in classic mineralocorticoid target tissues and elsewhere, and the contexts in which this occurs to modulate blood pressure levels.

ANATOMY/BIOCHEMISTRY

Aldosterone and the physiologic glucocorticoids are classically produced in the zona glomerulosa of the adrenal cortex, under the stimulus of ACTH, and for aldosterone in addition (and predominantly) angiotensin II and plasma

[K⁺]. Over the past decade there have been numerous reports of the ectopic synthesis of corticosteroids in general, and aldosterone in particular, in vasculature,⁹ heart,¹⁰ and brain.¹¹ In the glomerulosa cell the enzymes responsible for the biosynthesis of corticosteroids are exquisitely localized to particular intracellular compartments, allowing relatively confined distribution (and thus relatively high local concentration) of successive substrates. In the proposed sites of ectopic synthesis mRNA levels for the biosynthetic enzymes are reported to be 10³- to 10⁶-fold lower than in whole adrenal (of which glomerulosa cells are commonly only a very small minority in terms of number), with no evidence for intracellular compartmentalization; at such levels each enzymatic step would appear to be rate limiting, making substantial biosynthesis of the end-product problematic.

The claim of cardiac synthesis of aldosterone, stimulated by both angiotensin II and (counterintuitively) by raised sodium intake, caused considerable interest; this claim is not supported by studies on angiotensin II-infused rats on 0.9% NaCl solution, where the gross coronary/cardiac inflammatory response was abrogated by adrenalectomy as well as by systemic MR blockade.¹² Recent reexamination of cardiac mRNA levels for steroid biosynthetic enzymes has been interpreted as evidence against cardiac aldosterone synthesis.^{13,14} The much more extenuated disappearance curve of aldosterone compared with corticosterone in the heart of rats post-adrenalectomy, and the findings of higher levels of aldosterone in the heart than plasma of intact rats, may reflect the sequestration of the noncyclized form of aldosterone ($\leq 1\%$ of total), by adduct formation via the 18-aldehyde group.¹⁴

In terms of biochemistry, the biosynthesis of aldosterone from deoxycorticosterone in many species is effected by CYP11B2 (aldosterone synthase), which in a three-step process catalyzes the formation of 18-hydroxydeoxycorticosterone, 18-hydroxycorticosterone, and finally aldosterone. In other species, notably the bovine, the enzyme CYP11B1 (11 β hydroxylase) is responsible for oxidation at both C11 and C18 to yield aldosterone. In terms of evolution, the primordial enzyme appears closer to CYP11B2 (which has 11 β hydroxylase activity) than CYP11B1; this notwithstanding, the ability to synthesize aldosterone appears routinely late in evolution, in terrestrial vertebrates. This contrasts with mineralocorticoid

receptors, which are clearly present in fish,¹⁵ prefiguring roles as high-affinity receptors, essentially always occupied by normal levels of glucocorticoids, in mammalian non-epithelial tissues, physiology poorly understood.

Aldosterone is unusual in that it is secreted in very low amounts, and circulates either free (40% to 50%) or loosely bound to albumin, so that its clearance is relatively rapid. The evolutionary gain in exploiting a pre-existing receptor, rendered aldosterone-selective by the co-expression of 11 β HSD2, to regulate sodium flux in epithelia—rather than selecting for an inherently aldosterone-specific receptor—is not currently obvious. What is obvious, however, is that even modest elevations of aldosterone above the normal upper limit can be accompanied by markedly aggravated cardiovascular pathology, to an extent considerably greater than seen in uncomplicated essential hypertensives with the same blood pressure elevation. Both the very low plasma levels (1/1000 to 1/2000 those of glucocorticoids) and the rapid clearance may both thus reflect the potentially deleterious effects of inappropriate aldosterone for salt status, as seen in primary aldosteronism and various models of experimental hypertension.¹⁶

GENETICS

That hypertension may reflect a particular genetic makeup, external environment constant, is clear from both animal and human epidemiologic studies. Successive matings over 20 generations between rats registering higher blood pressures produced spontaneously hypertensive rats from the Wistar Kyoto breeding stock. In the clinic, three congenital conditions producing hypertension have proven prismatic—for aldosterone, for the selectivity-conferring enzyme 11 β HSD2, and for the mineralocorticoid receptor—and will be illustrated in brief detail.

Glucocorticoid remediable aldosteronism (GRA), also known as glucocorticoid suppressible hypertension, was first described over 40 years ago, and its genetic basis reported in 1992.¹⁷ The syndrome—of familial hypertension with elevated aldosterone levels, often at a relatively young age—reflects the operation of a chimeric steroid biosynthetic enzyme, in turn the product of a chimeric gene. The genes coding for CYP11B1 (11 β hydroxylase, the signature enzyme for glucocorticoid activity) and for CYP11B2 (aldosterone synthase) lie adjacent on human

chromosome 8, and show higher than 94% sequence identity. This high degree of homology is commonly construed as evidence for a relatively recent gene duplication event, consistent with the relatively recent (terrestrial) emergence of aldosterone; it also reflects an unequal crossing-over at meiosis, in the founder line, between the two genes to produce a chimeric gene—5' CYP11B1, 3' CYP11B2. Different pedigrees show different points of cross-over between exons 1–4, but all have the same net result—production of aldosterone in response to

Figure 26-1. Molecular forms of aldosterone *in vivo*: (i) 11,18 hemiacetal, $\geq 99\%$; (ii) noncyclized form.

ACTH, and throughout the adrenal cortex rather than confined to the glomerulosa.

Apparent mineralocorticoid excess (AME), as its name implies, is not a disorder of inappropriate aldosterone production, but rather one of inappropriate mineralocorticoid receptor activation reflecting deficient or absent action of the specificity-conferring enzyme 11 β HSD2.¹⁸ Unlike GRA, which is dominantly inherited, AME is recessive, and thus is less infrequently seen in offspring of consanguineous unions. When 11 β HSD2 activity is deficient or absent, mineralocorticoid receptors (which in epithelial tissues are normally largely occupied¹⁹ but not activated by normal circulating glucocorticoid levels) are both occupied and activated by glucocorticoids, to produce a syndrome of often severe juvenile hypokalemia, sodium retention, and hypertension.

Factitious AME can similarly follow enzyme blockade by glycyrrhizin/glycyrrhetic acid, the active principle of licorice, widely used as a sweetener in confectionery. Its ability to raise blood pressure and circulatory volume had similarly been noted, well before the mechanism of AME was elucidated—which in turn proved to be a defining moment in establishing the physiology of aldosterone action in epithelia.

The final example that has proven illustrative is the S810L mutation of the human mineralocorticoid receptor, which produces juvenile hypertension very much exacerbated by pregnancy.²⁰ This rare mutation of a single nucleotide results in a receptor which is ~27% constitutively (absent steroid) active, and which sees progesterone and spironolactone as agonists, whereas they are antagonists of the wild-type human mineralocorticoid receptor. The aberrant pattern of activation reflects the altered geometry of the steroid binding cleft, and van der Waal's interactions between the leucine at residue 810 and the alanine at residue 773, which do not occur with the serine at residue 810 in the wild-type. The amino acid pairing in MR is quite distinct from that in closely related glucocorticoid/androgen/progesterone receptors, where the equivalent amino acids are methionine and glycine. In the S810L mutant, the leucine–alanine pairing is identical to that found in the more distantly related

estrogen and retinoic acid receptors, and perhaps evidence for a primordial ancestry of MR in the MR/GR/AR/PR subfamily.²¹

PHYSIOLOGY AND PATHOPHYSIOLOGY

Classically, aldosterone was considered to raise blood pressure primarily by its effects on fluid and electrolyte retention in the kidney, and by central effects on mineralocorticoid receptors in the AV3V area of the brain.²² More recently, aldosterone has been claimed to have direct deleterious effects in the heart, based on the undisputed therapeutic advantage conferred by MR blockade in progressive (RALES²³) or post-infarct (EPHESUS²⁴) cardiac failure. On the basis of current evidence, however, all these interpretations appear to be inadequate: renal effects do not appear to be the primary blood pressure drivers,²⁵ aldosterone under normal circumstances appears unable to access AV3V neuron mineralocorticoid receptors,²⁶ and finally, the steroid activating MR in cardiomyocytes in heart failure (or VSMC in hypertension) is almost certainly cortisol, not aldosterone.^{27–29}

The case against a primarily renal action of aldosterone in elevating blood pressure is exemplified by a recent meta-analysis of clinical trials of the novel MR antagonist eplerenone in patients with essential hypertension.²⁵ In these trials patients were given eplerenone as monotherapy, with dosage titrated to effect (a diastolic blood pressure of <90 mmHg). After 4 weeks of treatment, of a total 397 patients started on 50 mg/day, just over 40% reached goal blood pressure at four weeks, and continued on this dose level, with the remainder up-titrated to 100 mg/day for weeks 5–8. On this dose a third (or 20% of the total) achieved goal diastolic blood pressure at the 100-mg dose. The remaining ~40% were further up-titrated to 200 mg/day for weeks 9–12, whereupon half reached goal blood pressure and half did not.

Table 26–1 shows the exact figures, and two unanticipated findings. First, at each dose the responders showed very large blood pressure reduction on average, and the nonresponders very little. The starkest comparison is at the 200-mg dose, where ~20% of the total cohort are

Table 26–1. Dose-Titration of Eplerenone as Monotherapy in Essential Hypertensive Patients: Effects on Attainment of Goal (Diastolic <90 mmHg) Blood Pressure, and Plasma [K⁺]

essentially unresponsive to MR blockade. Second, at no dosage was there any sign of a correlation between responder/nonresponder status and change in plasma potassium values. These are not balance studies, but plasma $[K^+]$ determination is the physician's yardstick for the obligate side effect of current anti-MR therapy; and there is no indication of any relationship between blood pressure and renal responses.

There is little doubt that in many species activation of MR in the AV3V region is followed by a rise in blood pressure. In rats, intracerebroventricular infusion of minute doses of aldosterone—at levels 100-fold lower than required systemically to raise blood pressure—raises blood pressure, an effect accelerated when the rats are maintained on 0.9% NaCl solution to drink.³⁰ Similarly, ICV infusion of RU28318, the water-soluble MR antagonist, completely blocks the rise in blood pressure that normally follows when salt-sensitive (jr/s) rats are placed on such a high salt intake.³¹

The evidence, however, is firmly against such blood pressure elevation being normally aldosterone-driven on several grounds. First, co-infusion of corticosterone, the physiologic glucocorticoid in rats, at doses one to two times those of aldosterone, progressively lowers the blood pressure response,⁸ thus excluding the possibility of a “protected” (by 11β hydroxysteroid dehydrogenase) MR, and making selective aldosterone occupancy of the receptor in AV3V neurons highly improbable. Second, there appears to be no correlation between circulating aldosterone levels and the extent of AV3V MR activation: in rats on very low, normal, or very high salt diets, systemic aldosterone levels are very different, yet all respond to ICV infusion of RU28318 by a blood pressure fall of 20–30 mmHg, with no significant difference between groups.²⁶

On this basis, it would appear that whereas experimentally administered aldosterone can elevate blood pressure via an AV3V involving pathway, *in vivo* AV3V MR are overwhelmingly always occupied by physiologic glucocorticoids.³² The mechanisms whereby such glucocorticoid-occupied MR are activated, and the pathways involved, await exploration. These pathways presumably involve neural input, and it will be of considerable interest to see whether such input produces changes in intracellular redox change, as appears to be the case in the renal tubule and cardiomyocyte (see below) in response to 11β hydroxysteroid dehydrogenase deficiency¹⁸ or reactive oxygen species generation.³³ The studies noted above, on exposing jr/s rats to salt, are consistent with inputs from the amygdala and the osmoreceptor area of the hypothalamus, and with possible vasopressinergic effects on AV3V neurons.

The third area—that of the presumed pathophysiologic role of aldosterone in hypertension and heart failure—has received considerably more attention over the past decade. The central issue is the assumption that the steroid-activating cardiomyocytes or vascular wall MR under such circumstances are aldosterone: the fact that baseline aldosterone levels in all three major trials of eplerenone (RALES, EPHEBUS, 4E³⁴) were in the low

normal range, and sodium status unremarkable, is conveniently overlooked. This assumption is demonstrably not the case, witness the proven pathogenesis of apparent mineralocorticoid excess, where renal tubular MR are clearly cortisol-activated. The evidence that in VSMC and cardiomyocytes the pathophysiology is commonly driven by glucocorticoid-activated mineralocorticoid receptors is very strong.

In 11β hydroxysteroid dehydrogenase expressing tissues (which include VSMC), the enzyme normally protects against MR activation by normal levels of endogenous glucocorticoids,^{4,19} but *not* (as was initially postulated, and still commonly assumed) glucocorticoid occupancy of such receptors. The enzyme is expressed at high levels in aldosterone target tissues, and has a remarkably low K_m (high affinity) for the physiologic glucocorticoids. If, however, one does the mathematics³⁵—or better still, the experiment¹⁹—the enzyme is clearly incapable of reducing intracellular glucocorticoid levels to an extent allowing selective aldosterone occupancy (and activation) of MR, in a renal principal cell for example. What the enzyme does is to debulk intracellular glucocorticoids by ~90%, which still leaves intracellular free glucocorticoid levels 10-fold or higher than those of aldosterone—and thus presumably, 90% of renal MR normally occupied but not activated by endogenous glucocorticoid hormones.

The other thing that the enzyme does is to convert cosubstrate NAD to NADH, stoichiometrically, one molecule of NADH for every molecule of cortisone generated. Normally NAD is at considerable excess, of the order of 600-fold; operation of the enzyme thus can generate steep increases in NADH product, with minimal depletion of substrate NAD levels. In other systems, NADH has been reported to activate co-repressors, and thus affect transcriptional regulation by nuclear transactivating factors;³⁶ the mechanism whereby the resultant redox change activates glucocorticoid-occupied MR awaits exploration. In *Drosophila*, the E75 nuclear receptor was recently shown, for example, to have its binding cleft constitutively occupied by heme, and to be activated (or not) by redox state.³⁷

The evidence for activation of MR by normal levels of endogenous glucocorticoids in the context of tissue damage and reactive oxygen species generation is both indirect and direct. In pigs subjected to experimental coronary angioplasty, eplerenone from day -5 until sacrifice at day 28 preserved luminal integrity compared with placebo-treated pigs. Neither group received administered mineralocorticoid or a high salt intake, raising the question (as in RALES, EPHEBUS, and the 4E trials) of just what the antagonist was excluding from MR.³⁸ Second, uninephrectomized rats receiving deoxycorticosterone and maintained on 0.9% NaCl to drink responded by coronary inflammation and cardiac fibrosis, well established by 4 weeks, and thereafter modestly increasing by 8 weeks. If deoxycorticosterone is given for 8 weeks, but eplerenone given over weeks 5–8, then inflammation and fibrosis are reversed to baseline levels. In contrast, rats given deoxycorticosterone for 4 weeks, and then vehicle for weeks 5–8, showed coronary and cardiac pathology equivalent to that

seen in rats killed immediately after 4 weeks of mineralocorticoid exposure (i.e., substantially higher than controls). Our interpretation of these data is that the pathology is continued by continued activation of VSMC MR occupied by glucocorticoids in the context of established tissue damage.³⁹

The direct demonstration of the bivalent nature of glucocorticoids in MR is to date preliminary, and shown for a rapid nongenomic (and possibly nonphysiologic) effect of aldosterone via classical MR in rabbit cardiomyocytes.^{33,40} Aldosterone at 15 minutes shows a 10-fold increase in pump current, reflecting a rapid direct effect on the Na⁺/K⁺/2Cl⁻ cotransporter and subsequent activation of Na⁺/K⁺ ATPase by the increased intracellular [Na⁺]. Cortisol at 100 nM alone has no effect, but co-administered with aldosterone stoichiometrically blocks its effect, evidence for a normal tonic inhibitory action of cortisol in MR. Oxidized glutathione (GSSG), administered alone via the broad-tipped pipette, has no effect. However, when cortisol is administered with GSSG, the latter to mimic reactive oxygen-species generation and redox change, cortisol becomes a MR agonist, mimicking the effect of aldosterone and elevating pump current.

To deal with pathophysiology first, in a section on physiology and pathophysiology, may appear counterintuitive—but in fact bears witness to the pathophysiologic and clinical studies having driven the reexamination of the biology of aldosterone (and MR) over the past decade. One element of physiology and one of pathophysiology remain unchallenged in the context of this reevaluation. In terms of physiology, the crucial role for MRs in epithelial sodium retention under conditions of limited sodium intake, has been reemphasized by the neonatal mortality in MR knock-out mice absent additional administered sodium.⁴¹ One warning note, however, might be sounded by comparing the neonatal mortality (100%) in MR knock-out mice with that of “only” 30% in aldosterone synthase null mice, on a comparable (i.e., nonsupplemented) sodium intake.⁴² In terms of pathophysiology, primary aldosteronism (Conn’s syndrome) is increasingly recognized as accounting for 8%–13% of unselected populations with essential hypertension⁴³; importantly, the markedly higher risk of stroke, myocardial infarct, and associated cardiovascular pathology than in uncomplicated essential hypertension with equivalently elevated blood pressure is testament to the potentially deleterious effects of even modestly elevated aldosterone secretion in the context of a high (i.e., normal Western) sodium intake.⁴⁴

If the primary mechanism of aldosterone action in terms of blood pressure control is neither renal nor via AV3V neuron stimulation, the question arises of its likely locus. More than two decades ago, the vascular wall was shown to express both MR and the protective enzyme 11 hydroxysteroid dehydrogenase, making it a candidate physiologic aldosterone target tissue.⁵ In a variety of studies, this has been shown to be the case via both genomic and nongenomic mechanisms. Two illustrative examples of the latter, both human experiments, point to VSMC being the likely primary target for the blood pressure effects of aldosterone.

In the first, close intra-arterial infusion of aldosterone into the nondominant brachial artery, at a rate to mimic excursions in the physiological range and to cause no systemic rise in aldosterone levels, was shown to rapidly lead to vasoconstriction, with flow reduced to 60% of baseline levels, with an equally brisk return upon cessation of infusion.⁴⁵ In the second, aldosterone was shown to elevate intracellular pH in human uterine VSMC within 5 minutes; cortisol was without effect, until the 11 β hydrogenase blocker carbenoxolone was introduced, when it mimicked aldosterone, with an identical dose–response curve and equivalently blocked by the MR antagonist RU28318.⁴

No consideration of the physiology of aldosterone can be complete without attention paid to the physiologic control of its secretion. Perhaps reflecting the undoubted clinical utility of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, most prominence has been given to angiotensin as the driver of aldosterone secretion in response to low salt intake. Studies on angiotensin knock-out mice would appear to dispute this emphasis, in that knock-out and wild-type mice raised their plasma aldosterone levels indistinguishably in response to 5 or 14 days low-sodium diet. The two groups, however, differed when given a diet low in both Na⁺ and K⁺ for 5 days: wild-type mice showed a muted response compared with low Na⁺ alone, but knock-out mice aldosterone plasma levels were considerably lower than in wild-type mice.⁴⁶

In evolutionary terms, the drivers of aldosterone secretion were arguably (1) acute volume depletion, following catastrophic diarrhea or blood loss, with sympathetic nervous system activation releasing renin to produce angiotensin, at once vasoconstrictor and salt-retaining (and thus volume-restoring) via increased aldosterone secretion; (2) chronic low-sodium/high-potassium intake to conserve sodium and unload potassium by the direct stimulatory effect of elevated plasma [K⁺] on aldosterone biosynthesis; and (3) orthostasis, a mechanism of aldosterone elevation currently not completely clear, but consistent with the rapid vasoconstrictor role shown above, given the rapid elevation of aldosterone upon assuming the upright posture.

CLINICAL IMPLICATIONS AND PERSPECTIVES

A number of candidate agents are in use or have been proposed to reduce aldosterone action. These include renin antagonists, still under consideration but historically facing solubility problems; the commonly used angiotensin-converting enzyme inhibitors, which block the generation of angiotensin II; and angiotensin receptor blockers, which block its action on the adrenal glomerulosa (*inter alia*). Further down the pathway are aldosterone synthase inhibitors, currently in clinical trials, and MR antagonists, both nonselective (spironolactone) and selective (eplerenone).

While it was commonly assumed that ACE inhibition/AT₁R blockade would produce maintained low levels of plasma aldosterone, this has conclusively been shown not

always to be the case for hypertensive patients, even on high-dose combination therapy.⁴⁷ Aldosterone synthase inhibition is at first sight an attractive concept, in the context of primary aldosteronism and the much reported possibility of ectopic aldosterone synthesis. Even in these circumstances, it appears to have no particular therapeutic advantage over MR blockade, and some considerable disadvantages.

The preference for MR blockade is that it blocks any agent from activating MR, and not just aldosterone. An experimental study in support of this—eplerenone from weeks 5–8 in rats receiving deoxycorticosterone completely reversing coronary inflammation and cardiac fibrosis, steroid withdrawal allowing inflammation and fibrosis to be maintained over weeks 5–8—has already been cited.³⁹ The clinical implications are thus clear—that MR blockade is the primary therapy for patients with Conn's syndrome (primary aldosteronism) not suitable for surgical intervention, and useful additional treatment in many patients with essential hypertension. This is particularly the case among patients with so-called resistant hypertension (blood pressure remaining elevated while on three or more antihypertensive agents), where the addition of low-dose spironolactone (12.5/25 mg) is reported to often be effective in causing blood pressure to fall.

Although extrapolation from animal studies to the clinic needs considerable caution, there are both animal and clinical studies supporting the utility of MR blockade even without blood pressure reduction. First, when stroke-prone spontaneously hypertensive rats are given an MR antagonist, they show dramatic falls in brain damage and proteinuria, with no change in the grossly raised blood pressure.⁴⁸ Clinically, when normotensives with familial hyperaldosteronism type 2 (inherited primary aldosteronism without the chimeric gene and enzyme characterizing glucocorticoid-remediable aldosteronism, FH1) are compared with age- and sex-matched controls, they show aldosterone-induced abnormalities in cardiac structure and function.¹⁶ Even the 20% of essential hypertensives who did not respond in terms of blood pressure (SBP 2, DBP 1 mmHg fall) to 200-mg eplerenone²⁵ may thus be afforded vascular/renal/cardiac protection by MR blockade despite no fall in blood pressure.

Given experimental and clinical demonstrations that MR activation is proinflammatory in the context of inappropriate aldosterone for salt status, or by normal levels of endogenous glucocorticoids in the context of tissue damage/redox change, MR blockade may be efficacious in conditions other than frank aldosterone excess. These include cardiovascular disease where baseline aldosterone levels are commonly normal—for instance, the RALES/EPHESUS/4E trials—including heart failure, essential

hypertension, and atherosclerosis.⁴⁹ They may also include chronic inflammatory conditions of autoimmune or other provenance, quite distinct from hypertension or heart failure. The anecdotal success of adjuvant use of low-dose spironolactone in the treatment of the ptosis of myasthenia gravis, reported over 40 years ago, may represent one example of such a previously inexplicable therapeutic benefit.^{50,51}

In terms of unanswered questions in hypertension, direct demonstration of vascular protection in humans following MR blockade, independent of effects on blood pressure, is central. If the question is answered in the affirmative, a good case can be made to generalize its use across the spectrum of hypertensive patients. This constitutes a clear future direction of research at the clinical level; at the basic level, the development of renal tubule-sparing MR antagonists, with less effectiveness in terms of raising plasma $[K^+]$, is a question currently being addressed to assuage fears of hyperkalemia, which has followed the careless use of spironolactone in very elderly patients with progressive cardiac failure.⁵² Finally, a question yet to be systematically addressed at the basic or clinical level is the untapped potential of MR blockade to act as an anti-inflammatory therapy in conditions other than those affecting the cardiovascular system, ranging from cognitive disorders to autoimmune disease to premature labor.

SUMMARY

Whereas a decade ago it was taught that aldosterone normalized low blood pressure following volume loss by epithelial sodium and water retention, and that primary aldosteronism represented <1% of all hypertensives, from the vantage point of today neither of these appear correct. Over that decade a role for aldosterone in the pathophysiology of hypertension (and heart failure) was posited on the basis of experimental studies on inappropriate mineralocorticoid for salt status, and clinical studies using spironolactone and eplerenone. Subsequently, it appears that baseline levels of aldosterone, contrary to common assumptions, are usually low or normal in hypertension and heart failure, and that in these conditions, spironolactone/eplerenone are blocking the effect of ligands other than aldosterone (most probably cortisol) to activate MR in the context of redox change following tissue damage. The implications of this evolving pathophysiology are that MR blockade may be therapeutically useful in terms of end-organ protection in hypertension regardless of levels of aldosterone, and that such blockade may have a place in other conditions in which MR may be inappropriately activated in the context of tissue damage, for example, autoimmune disease.

Chapter
27

The Renin-Angiotensin System in the Pathophysiology of Essential Hypertension

Robert M. Carey

Definitions

- The renin-angiotensin system (RAS) is a major hormonal regulatory system in the control of blood pressure (BP) and hypertension (HT).
- The primary means by which the RAS contributes to acute changes in extracellular fluid volume and BP homeostasis is by adjusting the level of renin in the circulation.

Key Findings

- Local tissue RASs, independently of the circulating RAS, also may play a role in the pathophysiology of HT.
- Several new components of the RAS have recently been identified, including a prorenin/renin receptor, angiotensin converting enzyme-2 (ACE-2), and angiotensin-1-7.
- Angiotensin II (Ang II), the major effector peptide of the RAS, binds to two major receptors, AT₁ and AT₂, which generally oppose each other.
- The RAS contributes to increased vascular resistance and remodeling in early HT; remodeling may be a cause and/or a consequence of HT.
- Major phenotypes of primary HT involving the RAS in humans include low-renin HT, nonmodulating HT, and salt-sensitive HT.
- Blockade of the RAS has been central to the treatment of hypertension, and its complications such as heart failure, atrial fibrillation, and coronary artery disease.

The renin-angiotensin system (RAS) is a major hormonal regulatory system in the control of blood pressure (BP) and the pathogenesis of hypertension (HT).¹ Because many new components of the RAS have been described during the past 5 years (Figure 27–1), the various RAS components and their actions initially will be discussed, followed by an analysis of the evidence for a role of the systemic and local tissue RAS in the pathophysiology of HT.

The traditional RAS begins with the biosynthesis of the glycoprotein hormone, renin, by the juxtaglomerular (JG) cells of the renal afferent arteriole. Renin is encoded by a single gene and renin mRNA is translated into preprorenin, containing 401 amino acids.² In the JG cell endoplasmic reticulum, a 20–amino-acid signal peptide is severed from preprorenin, leaving prorenin, which is packaged into secretory granules in the Golgi apparatus, where it is further processed into active renin by cleavage of a 46–amino-acid peptide from the N-terminal region of the molecule.

Mature, active renin is a glycosylated carboxypeptidase with a molecular weight of approximately 44 kDa. Active renin is released from the JG cell by an exocytotic process involving stimulus-secretion coupling. However, inactive prorenin is released constitutively across the cell membrane. Prorenin is converted to active renin by a trypsin-like activation step.³

In the past, renin has been considered to have no intrinsic biological activity, serving solely as an enzyme cleaving angiotensinogen (Agt), the only known precursor of Ang peptides, to form the decapeptide angiotensin I (Ang I). Liver-derived Agt provides the majority of systemic circulating Ang peptides, but Agt also is synthesized and constitutively released in other tissues, including heart, vasculature, kidney, and adipose tissue. Ang-converting enzyme (ACE), a glycoprotein (molecular weight 180 kDa) with two active carboxy-terminal enzymatic sites, hydrolyzes the inactive Ang I into biologically active Ang II.⁴ ACE exists in two molecular forms, soluble and particulate. ACE is localized on the plasma membranes of various cell types, including vascular endothelial cells, the brush border (microvilli) of epithelial cells (e.g., renal proximal tubule cells), and neuroepithelial cells. In addition to cleaving Ang I to Ang II, ACE metabolizes bradykinin (BK), an active vasodilator and natriuretic autacoid, to BK-(1-7) an inactive metabolite.⁵ ACE, therefore, increases the production of a potent vasoconstrictor, Ang II, while simultaneously degrading a vasodilator, BK.

Unlike renin and Agt, which have relatively long plasma half-lives, Ang II is degraded within seconds by peptidases, collectively termed angiotensinases, at different amino-acid sites, to form fragments, mainly des-aspartyl¹-Ang II (Ang III), Ang-(1-7), and Ang-(3-8) (Ang IV). Ang II is converted to Ang III by aminopeptidase A and Ang III is converted to Ang IV by aminopeptidase N-(1).

The vast majority of cardiovascular, renal and adrenal actions of Ang II are mediated by the Ang type-1 (AT₁) receptor, a seven-transmembrane G protein-coupled receptor that is widely distributed in these tissues, is coupled positively to protein kinase C and negatively coupled to adenylyl cyclase.⁶ AT₁ receptors mediate vascular smooth muscle cell contraction, aldosterone secretion, thirst, sympathetic nervous system stimulation, renal tubular Na⁺ reabsorption, and cardiac inotropic and chronotropic responses. Ang II also binds to another cloned receptor, the Ang type-2 (AT₂) receptor, but until recently the cell signaling mechanisms and functions of the AT₂ receptor were unknown.⁶

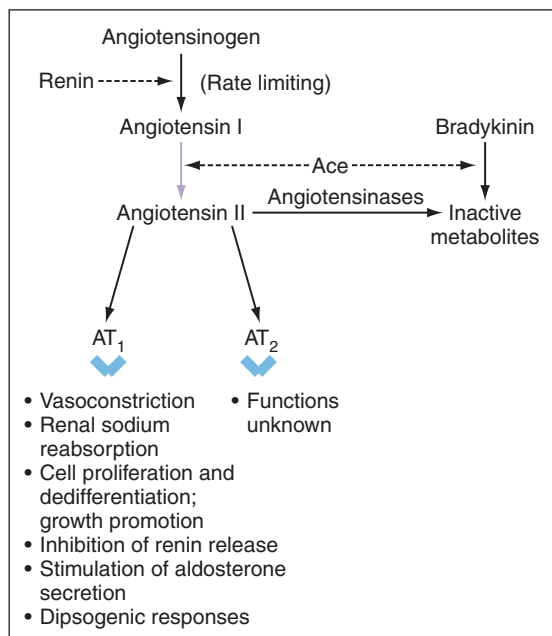

Figure 27–1. Schematic representation of the components of the RAS. (Adapted from Carey RM, Siragy HM. *Endocrinol Rev* 2003;24:261–71. Copyright 2003, The Endocrine Society.)

Biochemically, renin is the rate-limiting step in the RAS in most species, although angiotensinogen may be rate limiting in some species (e.g., mice) that have very high levels of renin.³ The renal JG cell is probably the only source of circulating renin, because following bilateral nephrectomy renin quantitatively disappears from the circulation.⁷ On the other hand, nephrectomy does not alter circulating levels of prorenin, indicating that nonrenal tissues not only produce prorenin but also secrete it into the circulation. In addition, many organs, such as the heart, can take up renin from the circulation by an unknown mechanism.⁸

The primary means by which the RAS contributes to acute changes in extracellular fluid volume and BP homeostasis is by adjusting the level of renin in the circulation. This process is mediated by active renin release from the secretory granules of JG cells. A primary mechanism of renin release is the afferent arteriolar baroreceptor, which increases renin release when arterial (and renal) perfusion pressure decreases, and vice versa. In addition, JG cells are innervated by sympathetic neurons, the activation of which stimulates norepinephrine release and subsequent stimulation of β_2 -adrenergic receptors triggering renin release. JG cells also express both AT_1 and AT_2 receptors, and circulating Ang II participates in a short-loop negative feedback mechanism to inhibit renin release by binding to these two receptors.⁹ Conversely, blockade of the RAS increases renin release and circulating renin levels. Indeed, chronic RAS blockade by AT_1 receptor antagonists or ACE inhibitors induces the recruitment of new renin-secreting cells in renal microvessels, further augmenting renin secretion.¹⁰ Another renin secretory control mechanism resides in the *macula densa* segment of the early distal tubule, which relays a signal to the JG cell to increase renin release when a reduction in Na^+ and Cl^- in the distal tubule is detected.

Although renin has been considered as the enzyme responsible for cleaving the decapeptide Ang I from substrate Agt, and has been thought to have no direct biological actions, recent studies demonstrate that renin can bind to human glomerular mesangial cells in culture and that binding causes cell hypertrophy and increased levels of plasminogen-activator inhibitor.¹¹ The bound renin was not internalized or degraded. A renin receptor has now been cloned from mesangial cells, and its functional significance has been partially clarified.¹² The receptor is a 350-amino-acid protein with a single transmembrane domain that specifically binds both renin and prorenin.¹² Binding induces the activation of the extracellular signal-related mitogen-activated protein kinases (ERK 1 and ERK 2) associated with serine and tyrosine phosphorylation and a fourfold increase in the catalytic conversion of Agt to Ang I. The receptor is localized in renal mesangial cells and in the subendothelial layer of both coronary and renal arteries, associated with vascular smooth muscle cells, and co-localizes with renin.¹² Although recent data support the possibility of a direct functional role of renin and prorenin via the renin/prorenin receptor, the importance of this receptor in the biology of the RAS awaits further investigation.

ACE inactivates two vasodilator peptides, BK and kallidin. BK is both a direct and an indirect vasodilator via stimulation of NO and cGMP and also by release of the vasodilator prostaglandins, PGE_2 , and prostacyclin.¹³ Thus, when an ACE inhibitor is employed, not only is the synthesis of Ang II inhibited but also the formation of BK, NO and prostaglandin is facilitated. ACE inhibition induces cross-talk between the BK B_2 receptor and ACE on the plasma membrane, abrogating B_2 receptor desensitization, and potentiating both the levels of BK and the vasodilator action of BK at its B_2 receptor.¹⁴

Another ACE has recently been discovered. ACE-2 is a zinc metalloproteinase consisting of 805 amino acids with significant sequence homology to ACE.¹⁵ Unlike ACE, however, ACE-2 functions as a carboxypeptidase rather than a dipeptidyl-carboxypeptidase. In contrast to ACE, ACE-2 hydrolyzes Ang I to Ang-(1-9), Ang II to Ang-(1-7) and BK to [des-Arg⁹]-BK, an inactive metabolite. In marked contrast to ACE, ACE-2 does not convert Ang I to Ang II and its enzyme activity is not blocked with ACE inhibitors. Thus, ACE-2 is effectively an inhibitor of Ang II formation by stimulating alternate pathways for Ang I degradation. ACE-2 has been localized to the cell membranes of cardiac myocytes, renal endothelial and tubule cells and the testis. ACE-2 gene ablation does not alter BP, but impairs cardiac contractility and induces increased Ang II levels, suggesting that ACE-2 may at least partially nullify the physiologic actions of ACE.¹⁶

The heptapeptide fragment of Ang II, Ang-(1-7), has been discovered to have biological activity.¹⁷ Ang-(1-7) can be formed directly from Ang I by a two-step process involving conversion to Ang-(1-9) by ACE-2 followed by conversion to Ang-(1-7) by endopeptidases. On the other hand, Ang-(1-7) can be formed directly from Ang II by the action of ACE-2. Interestingly, the major catabolic pathway for inactivation of Ang-(1-7) is by ACE, and ACE inhibitor administration markedly increases the level of Ang-(1-7).¹⁸ The

kidney is a major target organ for Ang-(1-7). The peptide is formed in the kidney, where it has specific actions via a non-AT₁ or -AT₂ receptor. These actions include increased GFR, inhibition of Na⁺/K⁺ATPase, vasorelaxation, and downregulation of AT₁ receptors, all of which are blocked by the specific Ang-(1-7) antagonist (D-Ala⁷)-Ang-(1-7) and are mediated at least in part by NO and prostacyclin.¹⁹ Most of these effects of Ang-(1-7) oppose those of Ang II via the AT₁ receptor. Although a specific Ang-(1-7) receptor has not been cloned, the peptide is an endogenous ligand for the *mas* oncogene, which mediates many of its actions.²⁰

Ang II, the major effector peptide of the RAS, binds to two major receptors AT₁ and AT₂, that generally oppose each other.⁶ The AT₁ receptor is widely distributed in the vasculature, heart and kidney.²¹ Actions of Ang II mediated by the AT₁ receptor (Box 27–1) include vasoconstriction, sympathetic nervous system (SNS) activation, plasminogen activator inhibitor biosynthesis, platelet aggregation, thrombosis, cardiac contractility, superoxide formation, vascular smooth muscle cell growth, collagen formation, and aldosterone, vasopressin, and endothelin secretion. These actions are conducted by both G protein-coupled and -independent pathways and involve phospholipases C, A₂ and D activation, increased intracellular Ca⁺⁺ and inositol (1,4,5)-triphosphate, activation of MAP kinases, ERKs and the JAK/STAT pathway, enhanced protein phosphorylation and stimulation of early growth response genes.⁶ Tyrosine phosphorylation appears to be the major signaling pathway for AT₁ receptors.²²

The AT₂ receptor is highly expressed in fetal tissues but regresses substantially in the postnatal period.²³ However, the AT₂ receptor is still expressed at low copy in the adult vasculature, especially in the endothelium and renal vasculature, JG cells, glomeruli, and tubules.²⁴ The AT₂ receptor

acts via the third intracellular loop by a G_i protein-mediated process involving stimulation of protein tyrosine phosphatases and reduction of ERK activity.²⁵ The AT₂ receptor also induces sphingolipid and ceramide accumulation.²⁵ A major mechanism of action of AT₂ receptors is BK release (probably via kininogen activation through cellular acidification), with consequent NO and cGMP generation.^{26,27} The AT₂ receptor mediates vasodilation, inhibition of cell growth, and possibly natriuresis.²⁸

At least some of the actions of Ang II may be related to heterodimerization. If AT₁ and AT₂ receptors are expressed in the same cell, the physical association of these receptors on the cell membrane may inhibit the action of AT₁ receptors in a ligand-independent manner.²⁹ Similarly, there is evidence for AT₁ receptor and BK B₂ receptor heterodimerization resulting in increased AT₁ receptor effects via G-protein activation and AT₂-B₂ receptor heterodimerization resulting in increased cGMP formation.^{30,31}

ROLE OF SYSTEMIC RAS IN THE PATHOPHYSIOLOGY OF HYPERTENSION

Demonstration that the RAS is activated and participates in the pathophysiology of human HT has been difficult. Past clinical studies classified patients with primary HT into three categories with respect to plasma renin activity (PRA), the standard clinical laboratory measurement of systemic RAS activity in humans. Of patients with primary HT, 60% have normal PRA, 15% have high PRA, and 25% have low PRA as compared with PRA measurements in the normotensive population³² (Figure 27–2). Originally it was thought that the circulating renin classification would help define the role of the RAS in primary HT. Low-renin hypertensives were thought to have extracellular fluid volume expansion as a cause of their HT, possibly related to excess production of a “cryptic” mineralocorticoid other than aldosterone.^{33,34} Indeed, BP in low-renin primary hypertension generally responded to mineralocorticoid receptor antagonist or diuretic therapy with normalization or near-normalization of BP.³⁵ However, studies failed to demonstrate excess of a nonaldosterone mineralocorticoid in low-renin primary HT,³⁶ and to date the pathophysiology of low-renin primary HT is unknown.³⁷ Possible causes of low circulating renin in HT are illustrated in Table 27–1. Similarly, high-renin primary HT was thought to be a disorder in which activation of the RAS was clearly involved in the pathogenesis of the HT, which could be reversed by lowering PRA using β-adrenergic antagonists, or blocking Ang II formation or action by ACE inhibitors or Ang receptor blockers, respectively.^{33,35} Patients with HT and high circulating renin were demonstrated to have more severe HT than patients with normal or low PRA and increased prevalence of ischemic heart disease, cardiovascular morbidity, and mortality than patients with normal or low PRA.³⁸ However, multiple later studies demonstrated that this was not always the case, and “renin profiling” to study the pathophysiology, diagnosis, and treatment of HT has largely been abandoned.

In spite of the disappointment that the profiling of circulating renin yielded little useful information concerning

Box 27–1

Effects of Ang II via AT₁ Receptors

- Vasoconstriction
- Cardiac and vascular remodeling
- Activation of the sympathetic nervous system
- Superoxide anion production; nitric oxide destruction
- Aldosterone, vasopressin, and endothelin secretion
- Vascular smooth muscle hypertrophy, migration, proliferation, and growth
- Cardiac contractility
- Vascular remodeling and fibrosis
- Renin inhibition
- Decreased vascular compliance
- Sodium and water retention
- Collagen synthesis: fibrosis
- PA1-1 synthesis, platelet activation, aggregation and adhesion: thrombosis
- Activation of cytokine production by monocytes and macrophages: inflammation

Figure 27-2. Plasma renin activity (PRA) and urinary aldosterone concentrations of patients with primary HT plotted against urinary Na^+ excretion. Data for normal nonhypertensive subjects is plotted inside the dashed lines. (Adapted from Brunner HR, Laragh JH, Baer L, Newton MA, Goodwin FT, Krakoff LR, et al. *N Engl J Med* 1972;286:441–49. Copyright 1972 Massachusetts Medical Society.)

the pathogenesis of primary HT, the RAS has been implicated in the pathophysiology of the “nonmodulating” hypertensive phenotype. Nonmodulation, a disorder of renal vascular and adrenal aldosterone secretory responses to Ang II, occurs in approximately 40% of patients with primary HT. Nonmodulators are characterized as having abnormal (blunted) aldosterone responses to Ang II in subjects ingesting low dietary Na^+ and abnormal (blunted) renal vasoconstriction to Ang II when they were placed on a high dietary Na^+ intake.³⁹ Nonmodulators are unable to handle a Na^+ load, have salt-sensitive HT, and have normal to high circulating renin levels. A striking family history of HT and concordance of responses to Ang II in sibling pairs suggested a genetic disorder. *Agt* gene polymorphisms were present in the nonmodulators and the HT was completely reversible with ACE inhibitor treatment.³⁹ The nonmodulating phenotype has been validated by a number of independent research groups. However, not all studies have confirmed the existence of nonmodulation, and further work is required to determine whether the nonmodulating phenotype is due to increased RAS activity alone or whether other mechanisms play a role. Furthermore, nonmodulation appears to be a quantitative rather than a qualitative trait, so that its pathophysiology may be complex.

Whereas it has been difficult to demonstrate *in vivo* activation of the RAS in early or established HT, there is no question that inhibition of the RAS is effective in lowering BP in patients with primary HT.⁴⁰ The results of multiple clinical trials demonstrate that blocking the RAS with ACE inhibitors or angiotensin receptor blockers (ARBs) demonstrate their beneficial effects to lower BP and reduce cardiovascular morbidity and mortality.^{41–46} Not only does blocking the RAS lower BP, but also these interventions reduce BP variability, an independent risk factor for cardiovascular events and overall mortality.^{47–50}

Perhaps the earliest pathophysiologic change demonstrable in primary HT is the process of vascular remodeling, a term employed to describe the functional, mechanical and structural changes in small resistance arteries (100 to 300 microns) that leads to reduction in lumen size and increased peripheral vascular resistance.^{51,52} Increased peripheral vascular resistance is the hallmark of HT. However, even though vascular remodeling is already present in pre-HT or stage-1 HT, it is still unclear whether remodeling is a primary process that initiates HT or reflects early target organ damage as a result of the early increase in BP. Small resistance artery remodeling in HT is characterized by an increased media:lumen ratio that may derive from

CLINICAL CONDITIONS INFLUENCING PRA IN HUMANS	
Decreased PRA	Increased PRA
Expanded fluid volume	Shrunken fluid volume
Salt loads, oral or intravenous	Sodium restriction
Primary salt retention	Fluid losses
—Liddle's syndrome	—Diuretic induced
—Gordon's syndrome	—Gastrointestinal losses
Mineralocorticoid excess	—Hemorrhage
Primary aldosteronism	Decreased effective plasma volume
Cushing's syndrome	Upright posture
Congenital adrenal hyperplasia	Cirrhosis with ascites
Deoxycorticosterone (DOC), 18-hydroxy-DOC excess	Nephrotic syndrome
11 β -hydroxysteroid dehydrogenase inhibition (licorice)	Decreased renal perfusion pressure
Sympathetic inhibition	Renovascular hypertension
Autonomic dysfunction	Accelerated-malignant hypertension
Therapy with adrenergic neuronal blockers	Chronic renal disease (renin dependent)
Therapy with β -adrenergic blockers	Juxtaglomerular hyperplasia
Hyperkalemia	Sympathetic nervous system activation
Decreased Agt	Therapy with direct vasodilators
Androgen therapy	Pheochromocytoma
Decrease in renal tissue mass	Stress: exercise, hypoglycemia
Hyporeninemic hypoaldosteronism	Hyperthyroidism
Chronic renal disease (volume dependent)	Sympathomimetic agents (caffeine)
Anephric state	Hypokalemia
Increasing age	Increased Agt
Unknown	Pregnancy
Low-renin primary hypertension	Estrogen therapy
African-American race/ancestry	Decreased feedback inhibition
Autonomous renin hypersecretion	Low Ang II levels (angiotensin-converting enzyme inhibitor [ACEI] therapy), AT ₁ receptor blockers
Renin-secreting tumors	Unknown
Acute damage to juxtaglomerular cells	High-renin primary hypertension
Acute glomerulonephritis	

Table 27-1. Clinical Conditions Influencing PRA in Humans

a number of processes including vascular smooth muscle (VSM) cell growth (hyperplasia and hypertrophy), apoptosis, elongation of cells and altered biochemical composition of the extracellular matrix.^{53,54} Ang II stimulates VSM cell hyperplasia, a process that increases VSM cell number accompanied by DNA synthesis.⁵⁵ Ang II also stimulates VSM cell hypertrophy by increasing protein synthesis and by activating transmembrane influx of ions and water. In experimental animal models of HT, both hyperplasia and hypertrophy contribute to vascular remodeling. In VSM cells from humans with primary HT, Ang II stimulates both hypertrophy and hyperplasia to a greater extent than in cells from non-HT patients.⁵⁶ However, most of the *in vivo* studies showing this effect employed large, nonphysiologic concentrations of Ang II (e.g., 10^{-6} M). In mild primary HT, eutropic remodeling may also be a function of apoptosis. Inhibition of the RAS with ACE inhibitors or Ang receptor blockers may contribute to a growth imbalance by stimulating apoptosis.⁵⁷ Factors contributing to increased

vascular resistance in HT are depicted in (Figure 27-3). However, it must be kept in mind that much of the evidence suggests that the vascular remodeling observed in early HT is the consequence rather than the cause of increased BP.

In addition to the changes in lumen size typical of vascular remodeling, vascular injury in HT is characterized by inflammation.^{51,52} Small arteries in HT have increased expression of surface adhesion molecules, inflammatory cell infiltration, cytokine production, chemokine release, and oxidative stress.⁵⁸⁻⁶⁰ Indeed, evidence is present that vascular disease in HT is an inflammatory process and that chronic vascular inflammation may be a primary cause of HT.⁵² The inflammatory process is composed of three components: increased vascular permeability, leukocyte extravasation (adhesion, migration, and chemotaxis) and tissue repair (cell growth and fibrosis).^{52,60} Ang II is now recognized as a major inflammatory mediator in the vasculature, inducing its effects largely via oxidative stress.^{61,62}

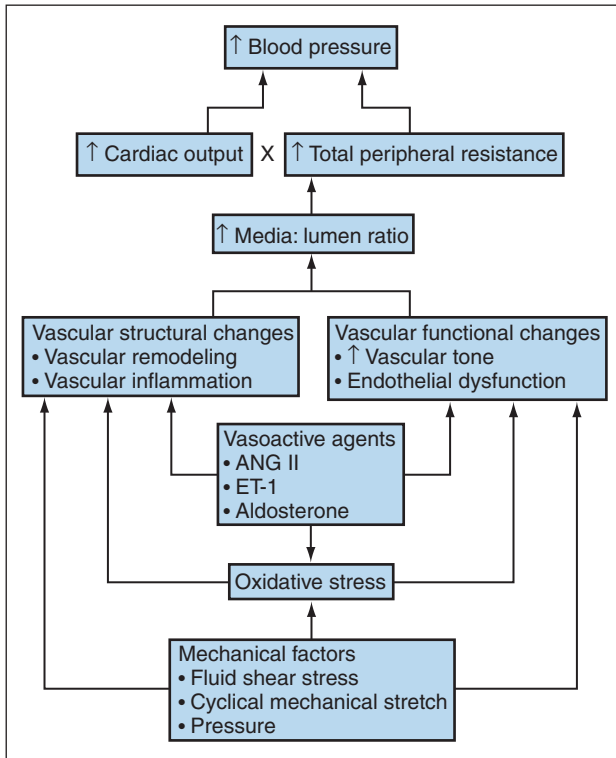

Figure 27–3. Blood pressure (BP) is the product of cardiac output and total peripheral vascular resistance. In general, increased vascular resistance is the major hemodynamic factor contributing to elevated BP in primary hypertension (HT). Flow diagram depicting vascular mechanisms contributing to increased vascular resistance, the hallmark of HT. Vasoactive agents, mechanical factors and oxidative stress interact to influence vascular structure and function. ↑, increase; ↓, decrease. (Adapted from Schiffrin EL, Touyz RM. *Am J Physiol Heart Circ Physiol* 2004;287:H435–46.)

The molecular and cellular mechanisms whereby Ang II influences vascular structure in HT are shown in Figure 27–4. Ang II via the AT_1 receptor induces vascular permeability and inflammation via stimulation of vascular endothelial growth factor (VEGF) in VSM⁶³ and endothelial cells.⁶⁴ Ang II upregulates VEGF expression through transcriptional regulation by redox-sensitive pathways.⁶⁵ VEGF is an important mediator of vascular inflammation because VEGF inhibition attenuates Ang II–induced vascular inflammation and remodeling without influencing BP.⁵⁶ Ang II also stimulates vascular production of prostaglandins, which can increase vascular permeability.⁶⁶

Leukocyte adhesion, transmigration, and chemotaxis are important components of the inflammatory process. Ang II regulates multiple steps in leukocyte recruitment into the vessel wall. Ang II stimulates the production of a host of pro-inflammatory molecules—including growth factors, chemokines, cytokines, and other mediators (Box 27–2)—enhances the adhesion of leukocytes to endothelial cells, and induces trans-endothelial migration via chemokines and cytokines.⁶⁷ Ang II induces leukocyte rolling, adhesion, and migration in the absence of vasoconstriction, suggesting a BP-independent mechanism.⁶⁸ In cultured endothelial cells, Ang II increases expression of vascular cell adhesion

molecule-1 (VCAM-1), intracellular adhesion molecule-1 (ICAM-1), and E-selectin via generation of reactive oxygen species (ROS).^{69,70} In VSM cells, Ang II via the AT_1 receptor stimulates the production of VCAM-1, the chemokine monocyte chemoattractant protein-1 (MCP-1), and inflammatory cytokines and chemokines (IL-6, IL-8, and osteopontin).^{71,72} Also, in whole animal studies, Ang II increases VCAM-1 and ICAM-1 expression in the vasculature. These processes are redox dependent and involve stimulation of MAP kinase. The role of Ang II in vascular inflammation has been confirmed by studies in apo E-deficient mice, whose increased MCP-1 expression was reversed by AT_1 receptor blockade.⁷³ Also, in hypercholesterolemic rabbits, AT_1 receptor blockade reduced neointimal proliferation and expression of P-selectin and MCP-1.⁷⁴ In mice lacking macrophage-colony stimulating factor, Ang II induced less vascular inflammation and remodeling than in wild-type controls.⁷⁵ In hypertensive patients, AT_1 receptor blockade decreased circulating MCP-1, tumor necrosis factor alpha (TNF α), and plasminogen activator inhibitor-1 (PAI-1).⁵⁹

Vascular fibrosis is an important component of the reparative process in the setting of inflammation. Fibrosis involves the accumulation of extracellular matrix proteins, especially collagen and fibronectin, in the vascular media, resulting in structural remodeling. Ang II stimulates a number of fibrotic signaling pathways that increase the synthesis of collagen and fibronectin,^{76,77} mitogenic factors such as transforming growth factor- β (TGF- β), platelet-derived growth factor (PDGF), and endothelin-1.⁷⁸ Ang II also promotes collagen degradation by reducing interstitial matrix metalloproteinase (MMP) and increasing a tissue inhibitor of MMP-1 production.⁷⁹ All of these mechanisms increase fibronectin, proteoglycans, and collagen deposition that contribute to vascular remodeling in HT.

Ang II mediates many of its cellular actions by stimulating the formation of intracellular reactive oxygen species (ROS), including superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), hydroxyl free radical (OH^\cdot), and peroxynitrite ($ONOO^-$).⁸⁰ Mediated by multiple redox-sensitive signaling pathways, ROS are involved in virtually every stage of the inflammatory process, including vascular cell permeability, leukocyte adhesion, transmigration, and chemotaxis, cell growth, and fibrosis. Although there are many potential sources of ROS (cyclooxygenase, lipoxygenase, hemeoxygenase, cytochrome P450 monooxygenase, xanthine oxidase, and leakage from the electron transport chain), membrane-bound nicotinamide adenine dinucleotide phosphate oxidase, reduced form (NAD[P]H oxidase) has been demonstrated to be of major critical importance in Ang II–induced vascular remodeling in HT.⁷³

Ang II is a potent stimulator of vascular NAD(P)H oxidase⁸¹ (Figure 27–5). Ang II increases the expression of NAD(P)H oxidase subunits, activates the enzyme, and increases the production of ROS both in cultured VSM cells and in intact arteries. Cell signaling pathways by which Ang II stimulates NAD(P)H oxidase include phospholipase D, phospholipase A_2 (PLA $_2$), protein kinase C (PKC), c-Src, PI-3 kinase, and Rac.⁷³ In HT, these processes are upregulated resulting in increased NAD(P)H oxidase activity and

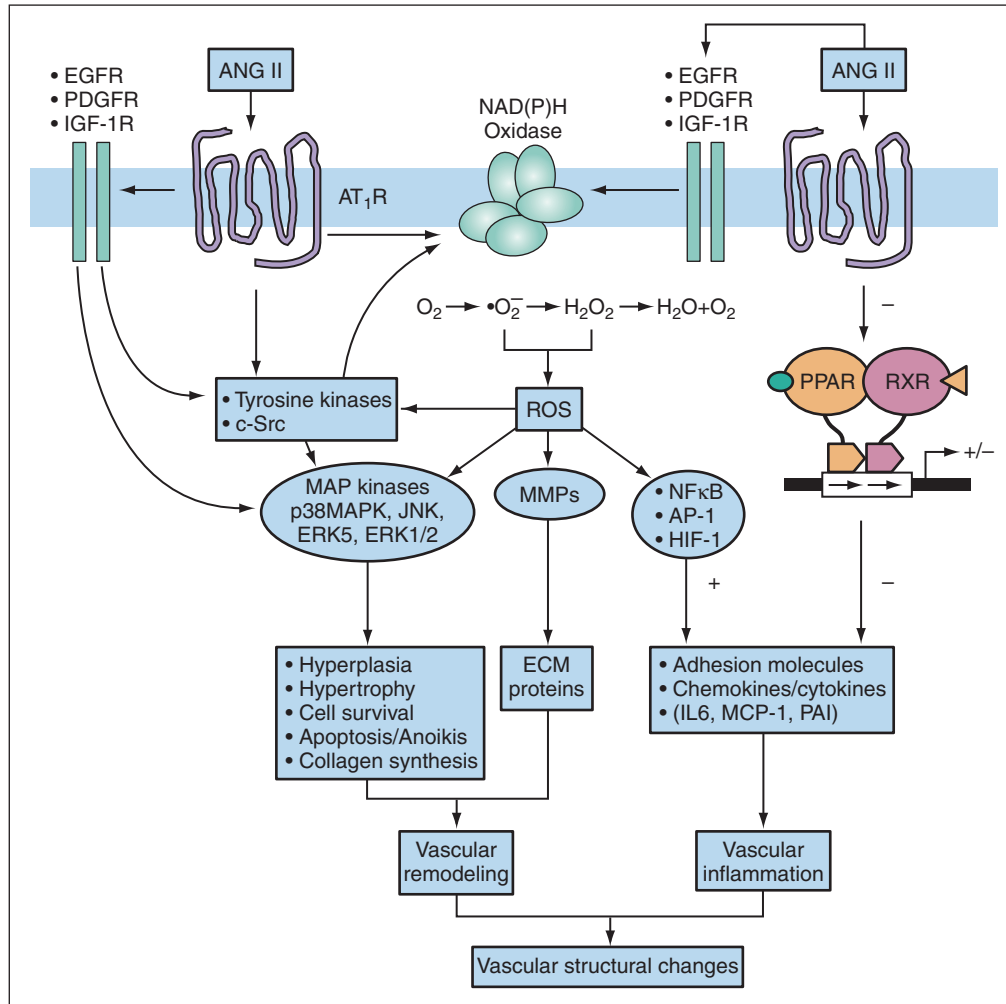

Figure 27–4. Molecular and cellular mechanisms whereby Ang II influences vascular structure in primary hypertension. Ang II binds to the AT₁ receptor leading to activation of receptor tyrosine kinases, such as the epidermal growth factor receptor (EGFR), platelet-derived growth factor receptor (PDGFR), and insulin-like growth factor-1 receptor (IGF-1R), and nonreceptor tyrosine kinases, such as c-Src. Ang II-AT₁ receptor binding also leads to activation of NAD(P)H oxidase, resulting in intracellular generation of ROS that influences redox-sensitive cell-signaling molecules such as mitogen-activated protein (MAP) kinases (p38 MAP kinase, JNK, ERK 1/2 and ERK5), transcription factors (NF- κ B, AP-1, and hypoxia-inducible factor [HIF-1]) and matrix metalloproteinases (MMP). Ang II downregulates peroxisome proliferator activator receptors (PPARs), which have antiinflammatory effects, enhancing vascular inflammation. These cell-signaling events regulate VSM cell growth, extracellular matrix (ECM) formation, and inflammatory responses. In HT, altered Ang II signaling leads to altered vascular growth, fibrosis, and inflammation, which govern structural remodeling of HT. PAI, plasminogen activator inhibitor; RXR, retinoid X receptor. oxidative stress in the vasculature.⁸² Vascular O₂⁻ and H₂O₂ function intracellularly as second messengers activating redox-sensitive signaling molecules, which induce VSM cell contraction, cell growth (hypertrophy and hyperplasia), apoptosis, and accumulation of extracellular matrix proteins.⁸³ In addition, some of the beneficial effects of ACE inhibitors and AT₁ receptor blockers in HT have been attributed to direct inhibition of NAD(P)H oxidase activity as well as to direct antioxidant actions of these blockers.⁸⁴

In general, Ang II elicits enhanced vasoconstrictor responses in human primary HT (Figure 27–6). This action of Ang II may either be direct or indirect via stimulation

of SNS activity. The augmented Ang II-induced VSM cell contraction is attributed to increased cytoplasmic free Ca⁺⁺ concentration.⁸⁵ In addition, increased Ang II sensitivity of the VSM cell contractile machinery has been ascribed to RhoA/Rho kinase-dependent pathways.⁸⁶

In terms of vascular growth, as well as contraction, c-Src has been identified as a critical kinase that is immediately phosphorylated in response to Ang II.⁸⁷ Ang II-induced activation of c-Src is augmented and is related to increased VSM cell growth in cells from hypertensive patients.⁸⁸ C-Src is a major cellular regulator of many cell signaling pathways, including PLC- β , Pyk2, FAK, JAK, Shc, MAP kinases, PI-3

kinase, and NAD(P)H oxidase.⁸⁹ These molecules affect cell survival, metabolism, cytoskeletal arrangement, and membrane trafficking processes that promote growth.⁸⁹

In VSM cells, Ang II activates the MAP-kinase signaling pathways, including ERK 1/2, p38 MAP kinase, c-Jun NH2-terminal kinases (JNKs), and ERK 5.⁹⁰ These MAP kinases influence cell survival, apoptosis, differentiation, inflammation, and growth. In vascular tissue from rats and VSM cells from hypertensive patients, Ang II stimulation of MAP kinases is augmented^{91,92} leading to VSM cell growth, inflammation, fibrosis, and increased contractility.

Ang II can also trans-activate receptor tyrosine kinases on the cell membrane, including the EGF, PDGF, and IGF-1 receptors.⁹³ Transactivation of these receptors may be mediated by activation of nonreceptor tyrosine kinases (Pyk2 and Src), redox-sensitive processes, and possibly mutation of MMPs releasing heparin-binding EGF.⁹³ Ang II also increases the production of vasoactive hormones and growth factors in HT, including endothelin-1, PDGF, TGF- β , basic FGF, and IGF-1, which could contribute to cell proliferation, protein synthesis, and fibrosis and, in turn, arterial remodeling.

Ang II activation of the AT₁ receptor is a major factor in eutropic inward remodeling observed in the earliest stages of HT. In patients with primary HT, AT₁ receptor blockade and β -adrenergic receptor inhibition both induce similar BP reduction, but only AT₁ receptor blockade corrects resistance arterial structure.⁹⁴ Also, in SHR either ACE inhibition or AT₁ receptor blockade normalizes resistance artery structure. Although it is now clear that Ang II plays a major role in vascular remodeling, it is still unclear whether Ang II has a primary initiating role in HT, or whether Ang II simply mediates the vascular damage, even at an early stage, resulting from a primary increase in BP due to other causes. These issues await future investigation.

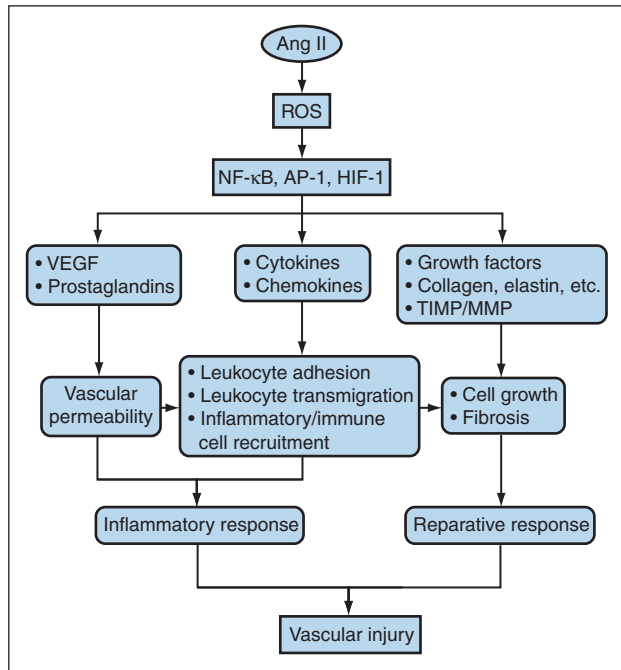

Figure 27-5. Ang II stimulates NAD(P)H oxidase to generate ROS, which activates redox-sensitive transcription factors (nuclear factor- κ B [NF- κ B], activating protein-1 [AP-1], hypoxia-inducible factor-1 [HIF-1]). These transcription factors release vascular endothelial growth factor (VEGF), prostaglandins, cytokines and chemokines, growth factors, matrix metalloproteinases (MMP), and tissue inhibitor of matrix metalloproteinase (TIMP). These signaling pathways lead to inflammatory and reparative processes inducing vascular injury. (Adapted from Touyz RM. *Curr Opin Nephrol Hypertens* 2005;14:125–31.)

ROLE OF LOCAL TISSUE RENIN-ANGIOTENSIN SYSTEMS IN THE PATHOPHYSIOLOGY OF HYPERTENSION

The circulating RAS is only one component of the overall RAS, and tissue RASs that can operate independently of the circulating RAS have been identified in brain, kidney, heart, blood vessels, and adrenal gland. While it is possible that tissue RASs are activated even when the circulating RAS is normal or suppressed, this has been difficult to establish in HT. In particular, it has been difficult to show the relative roles of the intrarenal RAS as opposed to the systemic RAS in the control of BP and HT. This issue has been considered important because the long-term regulation of BP has been thought to involve the kidney and the ability to sustain a hypertensive process chronically has been regarded as requiring renal Na⁺ retention.⁹⁵ Indeed, the key sites that determine the level of BP could not be localized precisely utilizing AT₁ receptor blockers which inhibit the RAS in all tissues or by conventional gene targeting experiments.

Recently, however, the tissue sites whereby the RAS regulates BP have been clarified through a novel cross-transplantation approach in AT_{1A} receptor-deficient mice.⁹⁶ Rodents have two AT₁ receptors termed, AT_{1A} and AT_{1B}.

Figure 27–6. Molecular and cellular mechanisms whereby Ang II influences vascular function in HT. Ang II increases intracellular free Ca^{2+} concentrations [Ca^{2+}]_i by stimulating Ca^{2+} influx through mobilization from sarcoplasmic reticular (SR) stores, the latter in response to inositol (1,4,5)-triphosphate produced by activation of phospholipase C (PLC). Increased activity of RhoA/Rho kinase Ca^{2+} -sensing pathway and protein kinase C (PKC)-dependent pathways (dashed line) also influence vascular contractility. Ang II-induced stimulation of NAD(P)H oxidase generates superoxide ($O_2^{\cdot-}$) and hydrogen peroxide (H_2O_2) that quench NO formation, resulting in decreased cGMP and increased peroxynitrite formation compromising vasodilation. In HT, altered Ang-II signaling leads to contraction, reduced dilation, and consequent increased vascular tone. DAG, diacylglycerol; MLC, myosin light chain; GEF, guanine nucleotide exchange factor; p, phosphorylated; G, G protein; \uparrow , increase; \downarrow , decrease. (Adapted from Schiffrin EL, Touyz RM. *Am J Physiol Heart Circ Physiol* 2004;287:H435–46.)

The AT_{1A} receptor mediates the majority of actions of Ang II. In terms of expression, AT_{1A} receptors predominate in most organs except the adrenal gland and certain regions of the central nervous system (CNS), where AT_{1B} receptor expression is relatively more prominent. Absence of AT_{1A} receptors exclusively in the kidney, with normal receptors elsewhere, was sufficient to lower BP by about 20 mmHg⁹⁶

(Figure 27–7). Thus, renal AT_1 receptors were deemed to have a unique and nonredundant role in the control of BP. As aldosterone levels were unaffected in these experiments, BP appears to be regulated by the direct action of AT_1 receptors on kidney cells, independent of mineralocorticoid secretion. However, in addition to the kidney, AT_1 receptors outside the kidney made an equivalent, unique, and

Figure 27-7. (Adapted from Crowley SD, Gurley SB, Oliverio MI, Pazmino AK, Griffiths R, Flannery PJ, et al. *J Clin Invest* 2005;115:1092–99.)

nonredundant contribution to BP control: animals with a full complement of AT_1 receptors in the kidney, but without AT_1 receptors in extrarenal tissues, also had BP reduction of about 20 mmHg⁹⁶ (Figure 27–7). This finding also was independent of aldosterone levels. Taken together, the new evidence suggests that AT_1 receptors either in the vasculature or the CNS mediate the component of BP control that is independent of the kidney. However, it is not completely clear that the extrarenal effects to increase BP do not ultimately influence kidney function. Indeed, pressure natriuresis is reset in these experiments. In addition, Ang II–induced HT has been shown not to occur in the absence of renal AT_1 receptors. Therefore, more work needs to be done to be certain that the RAS induces HT by renal-independent mechanisms.

It is clear that Ang I and II are synthesized in tissue sites. Indeed, most, if not all, tissue Ang II is synthesized locally from tissue-derived Ang I.⁹⁷ In addition, the beneficial actions of RAS blockers are most likely due to interference with tissue Ang II rather than Ang II in the circulation.⁹⁸ Although it was originally thought that the renin required for local Ang I synthesis was synthesized locally, studies in nephrectomized animal models proved that this was not the case.⁹⁹ In many tissues such as the heart and blood vessels, local Ang synthesis depends on tissue uptake of kidney-derived renin.¹⁰⁰ In other tissues such as the kidney, adrenal gland, and brain, renin is synthesized locally.¹⁰¹ In addition, prorenin, the inactive precursor of renin, may contribute to Ang I generation at tissue sites.¹⁰² This would require either activation of prorenin to renin following uptake from the systemic circulation or direct prorenin stimulation of the renin/prorenin receptor.

Intrarenal RAS in hypertension

The intrarenal RAS was first recognized when selective intrarenal inhibition of the RAS was demonstrated to increase GFR and renal Na^+ and water excretion.^{103,104} Since that

time, the intrarenal RAS has increasingly been recognized a critical system in the regulation of Na^+ excretion and the long-term control of BP.¹⁰⁵ Indeed, there is growing recognition that inappropriate activation of the intrarenal RAS prevents the kidney from maintaining normal Na^+ balance at normal arterial pressures and is an important cause of HT.¹⁰⁵

Several experimental models support an overactive intrarenal RAS in the development and maintenance of HT.¹⁰⁵ These include 2-kidney, 1-clip (2K1C) Goldblatt HT, Ang II–infused HT, transgenic rat (TGR) mRen2 HT with an extra renin gene, the remnant kidney HT model, and several mouse models over-expressing the renin or AGT gene. Indeed, there is increasing recognition that in many forms of HT development of renal function occurs that is due to inappropriate activation of the intrarenal RAS, which limits the ability of the kidney to maintain Na^+ balance when perfused at normal arterial pressure.¹⁰⁵ In addition to Na^+ and fluid retention and progressive HT, other long-term consequences of an inappropriately activated intrarenal RAS include renal vascular, glomerular and tubulointerstitial injury, and fibrosis.¹⁰⁶

Evidence for over-activation of the intrarenal RAS in HT has accumulated for many of the components of the intrarenal RAS. In Ang II–dependent HT, renal vascular and glomerular AT_1 receptors are downregulated, but proximal tubule receptors are either upregulated or not significantly altered.¹⁰⁵ In some forms of HT (e.g., 2K1C Goldblatt HT, Ang II–induced HT and TGR [mRen2] HT), net intrarenal Ang II content is increased due to the intrarenal production of Ang II as well as increased uptake of the peptide from the circulation via an AT_1 receptor–mediated process.^{105,107} Sustained increases in circulating Ang II cause progressive accumulation of Ang II within the kidney in these models. A substantial fraction of the increase in intrarenal Ang II is due to AT_1 receptor–mediated endocytosis.^{105,108} In the 2K1C Goldblatt model, intrarenal Ang II was elevated in both the clipped and unclipped kidneys, both during the development phase (1 week) and up to 12 weeks following clipping.¹⁰⁹ These increases in intrarenal Ang II were present even in the absence of increases in plasma Ang II. Renal interstitial Ang II levels also are elevated in several Ang II–dependent models of HT, including the 2-kidney, 1-wrap (2K1W) Grollman model and the Ang II–infused HT model.^{110,111} However, renal tubule fluid Ang II is similar in control and HT rats.¹¹² Because Ang II that binds to the AT_1 receptor is internalized by receptor-mediated endocytosis, endosomal accumulation of Ang II in renal cells has been studied in Ang II–infused HT. Endosomal Ang II was increased and the endosomal Ang II accumulation was blocked by an ARB.¹⁰⁸ At least some of the internalized Ang II remains intact and contributes to the increased total Ang II content as measured in renal cortical homogenates in this model.^{108,113} The internalized Ang II could be recycled and secreted, being available to act at plasma membrane AT_1 receptors, or may act at cytosolic receptors, as has been described for VSM cells.^{105,114} Another possibility is that Ang II could exert genomic effects in the nucleus as a part of an intracrine system.¹¹⁵ Because Ang II may exert positive feedback stimulation of

Agt mRNA, intracellular Ang II may upregulate Agt or renin gene expression in renal proximal tubule cells.¹¹⁶

Agt is the only known precursor of Ang II, and most of the intrarenal Agt mRNA and protein is localized to proximal tubule cells, suggesting that intratubular Ang II is produced from locally formed Agt.¹¹⁷ Both Agt and its metabolite Ang II derived from proximal tubule cells are secreted directly into the tubule lumen.¹¹⁸ In response to a 2-week infusion of Ang II, intrarenal Agt mRNA and protein were upregulated.¹¹⁷ Therefore, an intrarenal positive feedback loop may be present whereby increased Ang II stimulates its requisite precursor, leading to markedly increased Ang peptide levels in HT.¹⁰⁵ For confirmation, this needs to be demonstrated *in vitro* in a proximal tubule cell preparation.

Renin is not only synthesized and secreted in the JG cells of the afferent arteriole but also by connecting tubules, indicating that renin is probably secreted directly into distal tubule fluid.¹¹⁸ Because intact Agt is present in urine, it is possible that some of the proximally formed Agt is converted to Ang II in the distal nephron.^{118,119} Indeed, Ang II infusion significantly increased urinary Agt in a time- and dose-dependent manner associated with increased renal Ang II levels.^{116,119} Furthermore, collecting duct renin is upregulated by Ang II via the AT₁ receptor.¹²⁰ Therefore, several intrarenal mechanisms seem to provide positive feedback control to enhance Ang II concentrations at both proximal and distal tubule sites, where Ang II has potent Na⁺-retaining actions.¹²¹ A schematic depiction of the intrarenal RAS is shown in Figure 27–8.

In addition to aforementioned work suggesting the pivotal role of kidney AT₁ receptors in the production of HT, recent studies have demonstrated that production of renin

and Agt in the proximal tubule can increase BP independently of the circulating RAS.¹²² Transgenic mice expressing human Agt selectively in the proximal tubule via the kidney androgen-regulated protein (KAP) promoter, when bred with mice expressing human renin systemically, had a 20-mmHg increase in BP despite having normal circulating Ang II levels. The increase in BP could be abolished with AT₁ receptor blockade, indicating Ang II-dependent HT. This experiment constituted the first demonstration of systemic HT from isolated renal tissue activation of the RAS. Furthermore, when purely proximal tubule overexpression of both human renin and Agt was achieved, HT also was present, supporting the concept that intrarenal tubular RAS activation can induce HT. In these studies it is unclear whether Ang I was first generated within the proximal tubule cell from intracellular cleavage of Agt by renin or whether the renin and Agt interaction occurred in the tubule lumen after secretion. In addition, whether the HT is due to increased proximal or distal Na⁺ reabsorption, or both, remains unanswered.

Brain RAS in hypertension

Although many tissues express all of the RAS components necessary for the biosynthesis and action of Ang II, the ability of the tissues to actually produce Ang II and the specific role of locally generated Ang II has only been proven for the kidney. An independently functioning RAS in the brain remains controversial because the level of the rate-limiting component, renin, is extremely low and difficult to detect. There is no question that acute administration of exogenous Ang II centrally increases BP, sympathetic outflow, vasopressin release, drinking behavior, and attenuation of baroreceptor reflex activity, and that these effects

Figure 27–8. Concentrations and sources of renal proximal tubule (RPT) and interstitial Agt, Ang I, and Ang II. Ang II is internalized into endosomes via the AT₁ receptor. High interstitial Ang I and Ang II concentrations suggest local formation, but substrate may be from systemically delivered or locally produced Agt. AA, afferent arteriole; EA, efferent arteriole; JGA, juxtaglomerular cells. (Adapted from Navar LG, Harrison-Bernard LM, Nishiyama A, Kobori H. *Hypertension* 39(2 pt 2):316–22.)

are abolished by AT₁ receptor blockade.¹²³ In addition, specific brain nuclei clearly mediate Ang II responses, including the ventrolateral medulla (VLM), nucleus tractus solitarius (NTS), paraventricular nucleus (PVN), and subfornical organ (SFO), among several other nuclei.¹²⁴ Although all of the RAS components are present in various regions of the brain, renin expression in very low levels has been detected in the pituitary and pineal glands, choroids plexus, hypothalamus, cerebellum, and amygdala as well as other locations.¹²³ At the cellular level, renin has recently been detected in both neuronal and glial tissue.^{125,126} If a neuronal source of renin is coupled with a glial source of Agt, Ang II could derive from secreted precursors in the extracellular space. However, recent studies have demonstrated colocalization of Agt with a novel nonsecreted form of renin, opening the door to intracellular Agt synthesis and possible action.¹²⁶

Because brain renin levels are low, investigators have searched for a renin-independent Ang II-generating system in the brain. Many enzymes are present in brain which can generate Ang II either from Ang I or directly from Agt, including trypsin, tonin, elastase, cathepsin C, kallekrein, chymase, and chemostatin-sensitive Ang II-generating enzyme.¹²⁷

In addition to nonrenin pathways, some investigators have suggested the involvement of non-Ang II peptides, including Ang III (des-Aspartyl¹-Ang II), Ang IV (Ang[3-8]), and Ang(1-7) as important regulators of BP.¹²⁸ In particular, Ang III appears to have a prominent role.¹²⁹ Aminopeptidase A (APA), which metabolizes Ang II to Ang III is present in the brain.¹³⁰ Ang II and Ang III are equally potent pressor substances when infused directly into the brain, and the pressor action of Ang II was abolished by pre-administration of an APA inhibitor, suggesting that conversion to Ang III may be required.^{131,132} Ang II and Ang III have equal affinity for the AT₁ receptor and both also are agonists at the AT₂ receptor. However, the Ang III-mediated increase in BP appears to be mediated by the AT₁ receptor, as its action can be blocked with an AT₁ receptor blocker. In addition, inhibition of endogenous brain Ang III formation by intracerebroventricular, but not intravenous, APA inhibitor induced a large, dose-dependent reduction in BP in conscious SHR and the deoxycorticosterone acetate (DOCA)-salt rat, a RAS-independent model of HT.^{131,132} On the other hand, administration of an inhibitor of aminopeptidase N (APN), which metabolizes Ang III to Ang IV, into the brain induces a pressor effect that is abolished with an AT₁ receptor blocker.¹³¹ Thus, increasing endogenous brain Ang III levels increases BP via the AT₁ receptor. Moreover, the pressor action of an APN inhibitor could be blocked with an APA inhibitor, confirming the existence of an endogenous brain Ang III cascade in the control of BP.¹³¹ Finally, work employing the nonmetabolizable peptide analogs, D-Asp¹-Ang II, and D-Asp¹-Ang III, demonstrated that Ang III is a centrally active agonist of the brain RAS.¹³⁰

There is also evidence that Ang IV may be an endogenous ligand of the brain RAS. When Ang IV is over-expressed specifically in the brain, these transgenic mice developed HT that was abolished by an AT₁ receptor antagonist.¹³³

The role of Ang-(1-7) as a counter-regulatory peptide to the pressor actions of Ang II is the subject of current studies.^{127,128} These studies take on additional importance due to the recent discovery of ACE-2, which converts Ang II directly to Ang-(1-7) and the identification of the *mas* oncogene as a major Ang-(1-7) receptor.²⁰ With the cloning of the renin/prorenin receptor, which is highly expressed in brain,¹² it is possible that the renin receptor may enhance the formation of Ang peptides at selective neuronal sites within the CNS.

Vascular tissue RAS in hypertension

Evidence for local RASs have been found in the heart, large blood vessels, adrenal, uterus, ovaries, testes, placenta, and pancreas.^{134,135} This evidence demonstrates that local systems may act independently of the circulatory system to produce Ang II. Within the vasculature, molecular expression of Agt has been found within the walls of large vessels, including the saphenous and umbilical vein and aorta.¹³⁶ Renin and Agt mRNA also have been detected within the aorta,¹³⁷ and in isolated small resistance arteries in skeletal muscle.¹³⁸ Microvessels also express AT₁ and AT₂ mRNA and protein.¹³⁹ There is functional evidence of a local vascular RAS,¹⁴⁰⁻¹⁴² and the concentration of Ang II within microvessels is much higher than in plasma.¹³⁸ Of note, renin or prorenin have been identified in fetal microvessels in the kidney¹⁴³ and in renal vessels of adult animals after ACE inhibition.^{144,145} Thus, recent evidence would suggest the concept that renin is synthesized in vessels, even though this has been a topic of controversy. Since anephric patients and nephrectomized animals have undetectable circulating renin, local microvascular production of renin does not contribute to circulating renin.¹⁴⁶ Thus, the local vascular RAS is likely to act locally within the vessels. Whether the local vascular RAS contributes to vascular tone is currently unknown. However, some studies report an increase in the local microvessel concentration of renin and Ang II in SHR compared to Sprague-Dawley or WKY control rats,^{137,141} suggesting the possibility of an overactive local vascular RAS that could play a pathophysiologic role in HT.

Cardiac RAS in hypertension

The importance of the cardiac renin-angiotensin-aldosterone (RAAS) is illustrated by the fact that blockade of the RAAS (with ACE inhibitors and angiotensin receptor blockers) has been central to treatment of HT, and its various complications such as heart failure, atrial fibrillation, and coronary artery disease.

Renin and its mRNA have been found in the heart.¹⁴⁷ Conclusive evidence exists that all of the necessary RAS components for synthesis of Ang II are present in the heart and that peptide formation does indeed occur.^{135,148} Renin, Agt, ACE, and AT₁ and AT₂ receptors are present in the myocardium.¹³⁵ The majority of the Ang II localized in the heart derives from myocardial synthesis of Ang I and not from uptake into the myocardium from the systemic circulation.¹⁴⁹ The RAS components for Ang II biosynthesis are distributed among cardiomyocytes and myocardial fibroblasts as well as the endothelium and VSM of the

coronary arteries and veins.¹³⁵ Although myocardial concentrations of renin and Agt are 1% to 4% those of plasma, cardiac interstitial fluid concentrations of Ang I and Ang II are greater than 100-fold those of plasma.¹⁴⁸ Cardiac interstitial fluid probably represents a separate tissue compartment from the systemic circulation, whereby Ang II may exert cell-to-cell (paracrine) actions. Intracardiac conversion of Ang I to Ang II may occur via chymase, which in contrast to ACE does not degrade BK.¹⁵⁰ In the human heart, chymase converts approximately 90% of Ang I to Ang II.¹⁵¹

Several recent studies have complicated the role of the intracardiac RAS in the pathophysiology of HT and cardiac hypertrophy. First, a cardiac renin receptor has been identified in cardiomyocytes that leads to the internalization of renin, the generation of Ang II in the cytoplasm and induces cardiac pathology.¹⁵² Second, an alternative renin transcript that lacks the sequences encoding the secretory signal is retained in the intracellular space of the synthesizing cell. The product is in the active rather than the prorenin form. Upregulation of this form of renin has been observed in the left ventricle postmyocardial infarction.¹⁵³ Third, a novel intracrine mechanism has recently been described for Ang II-induced cardiac hypertrophy that does not require Ang II-AT₁ receptor interactions at the cell membrane.¹⁵⁴

Although there is substantial evidence that all of the components of the RAS are present within the heart and that cardiac biosynthesis of Ang II occurs and is regulated, controversy remains as to whether Ang II synthesized in the heart acts as an autocrine/paracrine/intracrine regulator of cardiac function. However, the possible participation of the local cardiac RAS is suggested by transgenic animal studies showing that selective over-expression of Agt in the ventricles induces hypertrophy in the absence of HT.^{135,155}

RAS AND ARRHYTHMIAS SUCH AS ATRIAL FIBRILLATION

Hypertension is frequently associated with atrial fibrillation, and increasing interest has been focused on the role of the RAS in atrial remodeling and arrhythmia.¹⁵⁶ Ang II is released from cardiomyocytes during atrial stretch and has been linked to atrial fibrosis. AT₁ receptors are upregulated in the atria of patients with atrial fibrillation and the ACE gene polymorphism is associated with both left ventricular hypertrophy and atrial fibrillation. Although these observations are intriguing, the role of the RAS in the pathophysiology of atrial fibrillation remains to be determined.

Perspectives

The RAS is a hormonal cascade of major critical importance to the control of BP and the pathophysiology of HT. Although this system has been carefully studied for many decades, its ultimate role in the etiology of HT and its target organ damage is still unclear. The recent discovery of several new components of the RAS coupled with the functional characterization of its previously known parts has opened the door to an understanding of the role of the RAS as a progenitor and effector of the HT disease process. Potential RAS therapeutic targets in HT now include the renin receptor, the enzymatic activity of renin, ACE-2, Ang(1-7), the *mas* oncogene, and the AT₂ receptor, among others. While the RAS is reasonably well understood at the cellular and molecular levels, its role in human primary HT remains largely enigmatic. Increased efforts in translational research, particularly the identification and characterization of phenotypes of human HT, will be required. Direct cellular studies in human tissues combined with molecular genetic approaches will create powerful leverage in dissecting the role of the RAS in this complex disease.

The Endothelin System

Ernesto L. Schiffrin

Definition

- Endothelins (ETs) are potent vasoconstrictor, growth-promoting, and proinflammatory peptides. In blood vessels the most abundant ET is ET-1.

Clinical Findings

- Production of ET-1 is increased in the endothelium and the kidney in salt-dependent hypertension (e.g., deoxycorticosterone acetate–salt rats and Dahl salt-sensitive rats, in salt-loaded stroke-prone spontaneously hypertensive rats (SHRsp), in angiotensin II–infused and in diabetic rats).
- ET receptor antagonism decreases blood pressure and vascular hypertrophic remodeling and corrects endothelial dysfunction in these hypertensive models.
- Transgenic mice overexpressing human prepro-ET-1 in the endothelium develop hypertrophic vascular remodeling and endothelial dysfunction.

Clinical Implications

- Patients with stage 2 essential hypertension have enhanced vascular expression of ET-1.
- ET receptor antagonists lower blood pressure in hypertensive patients.
- Side effects of ET receptor blockers have prevented their development for this indication. ET antagonists have only been approved for the treatment of primary pulmonary hypertension.

The 21–amino-acid peptide endothelin (ET) was isolated and cloned in 1985 by Yanagisawa et al.¹ ET-1 (Figure 28–1), -2 and -3 are isopeptides with different functions, and there are as well bigger 31- and 32-amino-acid peptides.² ET-1 is the most abundant ET produced in blood vessels and the kidneys, whereas ET-3 is mainly a neuropeptide. Endothelial cells are thus only one of the cell types that produce and release ETs. They secrete ET-1 toward underlying smooth muscle, with little spillover into the circulation (Figure 28–2).³

In endothelial and other cells, furin and other enzymes act on pro-ETs to generate 38– to 39–amino-acid peptides (big ETs) that are converted into mature 21–amino-acid ETs by zinc-dependent endoproteases, termed endothelin-converting enzymes (ECE-1 and 2). ECes cleave big ET-1 at the Val²¹-Trp²² bond, yielding the potent vasoconstrictor ET-1[1-21]. ECE-1, of which there are four differentially spliced isoforms encoded by a single

gene (ECE-1a, ECE-1b, ECE-1c, and ECE-1d) resulting from four alternative promoters, is present in endothelial cells.⁴ The four isoforms of ECE-1 differ by their N-terminal amino-acid, which is responsible for their cellular localization. ECE-1a, -1c, and -1d are extracellular, whereas ECE-1b is an intracellular enzyme. ECE-1b heterodimerizes with other ECE-1 isoforms and regulates their activity.⁵ ECE-2 is found on smooth muscle cells and converts big ET-1 to ET-1 in the vicinity of ET receptors, which may protect the peptide from degradation. There are other enzymes that generate ETs such as matrix metalloproteinase-2 that cleaves the Gly³²-Leu³³ bond to generate ET-1[1-32],² chymase from mast cells that cleaves big ET-1 at the Tyr³¹-Gly³² peptide bond, yielding ET-1[1-31], and neutral endopeptidase,⁶ but their importance in this process is unclear. However, this suggests that there is differential expression of different pathways of activation of big ET-1, depending on the tissue localization of the activating protease.

ET production in blood vessels is modulated by inhibitors such as shear stress⁷ and nitric oxide (NO), and agents that stimulate its production, such as epinephrine, thrombin, angiotensin II (Ang II), vasopressin, cytokines, insulin, growth factors (TGF- β 1), and hypoxia. NO may be the mediator of the effect of increased shear stress on ET-1 generation.⁸ Leptin stimulates ET-1 generation by endothelial cells,⁹ which may be a mechanism involved in the link between ET-1 and obesity, thus contributing to the vascular injury, which is found in the metabolic syndrome and in type 2 diabetes mellitus. Peroxisome proliferator-activated receptor (PPAR) α activators (lipid-lowering fibrates) and γ agonists (insulin-sensitizing thiazolidinediones or glitazones) inhibit *in vivo* ET-1 production in deoxycorticosterone acetate (DOCA)–salt rats.¹⁰

ET-1 acts on ET_A and ET_B receptors. In the vascular wall, ET_A and ET_B receptors are present on smooth muscle cells, whereas endothelial cells only possess ET_B receptors. ET_A and ET_B receptors on vascular smooth muscle cells induce vasoconstriction and growth. They are present in systemic arteries, veins¹¹ and pulmonary vessels,^{12–14} and in all vessels ET_A receptors predominate over ET_B. ET_B receptors on endothelial cells stimulate the production of nitric oxide (NO) and prostacyclin, exerting a vasodilator action. Whether physiologically ETs are vasoconstrictors or vasodilators remains unclear, but under pathophysiologic conditions when large amounts of ET-1 are produced by endothelial or smooth muscle cells, its effects appear to be mainly vasoconstrictor and mitogenic,

Figure 28–1. Molecular structure of ET-1, the major vascular member of the endothelin system. ET-2 and ET-3 exhibit two and five amino acid differences, respectively. ET-1[1-31] is an additional peptide of the system produced in the vasculature and the airway that functions as a vasoconstrictor of tracheal and vascular smooth muscle and could be involved in allergic inflammation. ET-1[1-32] is generated in the vascular wall by the action of matrix metalloproteinase-2. ET, endothelin.

inducing growth and inflammation. In other organs, the effect of ET receptors varies with the function of the organ. ET_A or ET_B receptors appear to predominate in the adrenal gland depending on the species. ET_A receptors predominate in the kidney. ET_B receptors appear to be the predominant ones in the brain.

EFFECTS OF PREPRO-ENDOTHELIN-1 OR ENDOTHELIN RECEPTOR GENE DELETION

Naturally occurring mutations or experimental deletion of ET peptide or receptor genes have demonstrated the importance of the system in development. Inactivation in

mice of the ET-1 gene or the ET_A receptor gene results in slight blood pressure (BP) elevation, which appears to be a consequence of abnormal craniofacial development that interferes with breathing and raises BP through anoxia.^{15,16} The aorta exhibits as well developmental abnormalities, and consequently the phenotype resembles the Pierre Robin syndrome.

ET-3 is the cognate ligand of ET_B receptors and acts mainly on neural or neurally derived tissue. ET-3 regulates migration of neural crest cells. Mutations or gene inactivation of ET_B receptors induce aganglionic megacolon and pigmentary abnormalities.¹⁷ Hereditary and sporadic human aganglionic megacolon (Hirschprung's disease) may result in many cases from mutations of the ET_B receptor gene. Heterozygous ET_B receptor knockout mice have slightly elevated BP, which supports the hypothesis that the physiologic action of ET_B receptors is vasodilatory.^{18,19}

MECHANISM OF ACTION OF ENDOTHELINS

ET receptors mediate their actions through activation of phospholipase C, inositol trisphosphate generation, and calcium release. Activation of the calcium–calmodulin pathway, production of diacylglycerol, and stimulation of protein kinase C contribute to trigger vascular smooth muscle cell constriction. As well, the ras-raf-mitogen activated kinase (MAPK) cascade is stimulated and contributes to the growth-promoting action of ETs,

Figure 28–2. The vascular endothelin system is depicted. ET-1 is released mostly toward the underlying smooth muscle cells. Different agents stimulate or inhibit ET-1 release by the endothelium. ET-1 then acts on ET_A or ET_B smooth muscle receptors inducing contraction and growth. ET-1 acts as well as an autocrine or paracrine agent stimulating release of NO or PGI₂. It may thus induce relaxation and inhibition of growth. ANP, atrial natriuretic peptide; AVP, arginine-vasopressin; Ang II, angiotensin II; ET, endothelin; NO, nitric oxide; PGI₂, prostacyclin; VSMC, .

although p38MAPK does not appear to be activated by ET-1. Nonreceptor tyrosine kinases also participate in the intracellular cascade initiated by ET receptor stimulation.^{20,21}

In DOCA-salt hypertensive rats, which have an important ET-1-dependent component,²² enhanced generation of reactive oxygen species (ROS) has been well documented.^{23,24} ROS are produced by reduced nicotinamide adenine dinucleotide phosphate (NAD(P)H) oxidase, xanthine oxidase, mitochondria, and uncoupled NO synthase.²⁵ Uncoupling of NO synthase is the result of low concentrations of folic acid-derived tetrahydrobiopterin. In contrast to angiotensin, which stimulates generation of ROS mostly from NAD(P)H oxidase, human smooth muscle cells stimulated by ET-1 generate superoxide principally from mitochondria, particularly complex III.²⁶ In rat vessels, xanthine oxidase and mitochondria also appear to be important sources of ROS.²⁷ In mice, superoxide stimulated by ET-1 is derived mainly from NA(D)PH oxidase.²⁸ ROS stimulated by ET receptor activation contribute to intracellular signaling via growth factor-receptor transactivation and MAPK activation.²¹ As well, ROS are potent stimulators of ET-1 synthesis by endothelial cells,²⁹ which could participate in a dangerous positive feedback mechanism.

Through the mechanisms mentioned above, ET-1 induces vasoconstriction and remodeling. Inward remodeling of small arteries in organoid culture resulted from sustained contraction,³⁰ which may involve collagen reorganization through β_3 -integrins. Indeed, an antibody to β_3 -integrins blocked this remodeling. In small arteries in organoid culture, stimulation with ET-1 induced significant increase in *c-fos* mRNA that was inhibited by staurosporine and the calcium chelator BAPTA, but not by inhibitors of MAP kinases, protein kinase C, or tyrosine kinases, suggesting a role for intracellular calcium in ET-1-induced vascular remodeling.³¹

ET_A receptors were found to induce both cell growth and apoptosis through NF κ B activation.³² ET_B receptors may also have apoptotic effects on cells.³³ However, the final effect of ET-1 appears to be a survival effect as a consequence of reduced activation of caspase-3.^{33,34}

PATHOPHYSIOLOGY OF ENDOTHELIN SYSTEM IN EXPERIMENTAL MODELS

The endothelin system plays a pathophysiologic role in hypertension, atherosclerosis, coronary artery disease, heart failure, subarachnoid hemorrhage and cerebral vasospasm, diabetes, primary pulmonary hypertension (the only approved indication of ET antagonists), pulmonary fibrosis, scleroderma, diabetic and nondiabetic renal disease, renal failure, hepatorenal syndrome, glaucoma, prostate cancer and its metastasis, and so on. Of these, only the role of endothelin in experimental and clinical hypertension will be discussed.

Vascular effects of endothelin-1 in experimental hypertension

Enhanced production of ET-1 in experimental hypertension²³ participates in the mechanisms that are respon-

sible for the remodeling of large and small arteries.^{35,36} This occurs principally in salt-dependent models of experimental hypertension such as DOCA-salt hypertension or Dahl salt-sensitive rats, and in severe hypertension (Box 28–1). There appears to be little role of ETs in spontaneously hypertensive rats (SHR).^{23,37} Nevertheless, in stroke-prone SHR (SHRsp), the endothelin system is activated and plays a role, particularly in salt-loaded rats,³⁸ or in SHRsp treated with the NO synthase inhibitor L-NAME.³⁹ In salt-loaded and low-renin models, hypertrophic remodeling of resistance arteries with increased cross-sectional area is found, rather than the “eutrophic” remodeling without true vascular hypertrophy more often found in essential hypertension and in SHR. This hypertrophic remodeling in hypertensive rats is shown to be ET dependent by the regression of these changes that occurs after treatment with ET antagonists.³⁵ Systolic BP, plasma ET, systemic oxidative stress, and vascular NADPH activity are increased in association with small-artery hypertrophic remodeling after infusion of aldosterone in place of aldosterone.⁴⁰ Increased vascular collagen, fibronectin, and intercellular adhesion molecule (ICAM-1) were decreased by ET_A receptor antagonism, underlining the role of ET in these changes.

In a genetically engineered mouse that transgenically overexpresses human prepro-ET-1 in the endothelium by use of the endothelium-specific promoter Tie-2,²⁸ small-artery hypertrophic remodeling and endothelial dysfunction occurred despite the fact that BP was not elevated. This demonstrates the ability of ET-1 to induce BP-independent vascular remodeling.

Box 28–1

Activation of Endothelin System in Experimental Models of Hypertension

Experimental models in which endothelin system is activated

Deoxycorticosterone acetate (DOCA) salt
Spontaneously hypertensive rats-stroke prone (SHRsp)
DOCA-salt-treated SHR
Dahl salt-sensitive
Angiotensin II-infused
Female Tg Ren-2
Human Agt/human renin Tg
L-NAME-treated SHR
Fructose-fed
Streptozotocin treated
1-K, 1C Goldblatt
Chronic L-NAME induced

Experimental models in which endothelin system does not appear to be significantly activated

Tg Ren-2 (in some studies)
2-K, 1 C Goldblatt
SHR (in some studies)

Renal effects of endothelin-1 in experimental hypertension

Whereas salt loading stimulates ET-1 production, activation of renal ET_B receptors inhibits sodium reabsorption and helps to reestablish sodium balance.⁴¹ Ang II infusion combined with high salt increased renal ET-1.⁴² In transgenic rats overexpressing the ren2 gene (TGR(mRen2)27) treated with the selective ET_A receptor blocker darusentan or the ET_A/ET_B receptor antagonist LU420627,⁴³ BP and mortality, proteinuria and glomerulosclerosis, tubulointerstitial damage, and renal osteopontin mRNA expression were unchanged, suggesting that ET-1 does not play a role in renal damage in renin-dependent hypertension. However, in Ang II-infused mice the dual ET_A/ET_B receptor blocker bosentan partially prevented activation of the procollagen gene,⁴⁴ and rats overexpressing human angiotensinogen and human renin, which develop malignant hypertension, exhibited reduced renal and myocardial damage after treatment with bosentan.^{45,46} The latter thus suggest that the endothelin system may mediate part of Ang II actions on the kidney as it does on the vasculature of Ang II-infused rats.⁴⁷ Whether ET-1 does or does not mediate actions of Ang II remains controversial.^{48,49}

In salt-loaded SHRsp, in which the endothelin system is activated,³⁸ increased expression of ET-1 were associated with enhanced generation in the kidney of transforming growth factor (TGF)-β1, basic fibroblast growth factor (bFGF), procollagen I expression, and matrix metalloproteinase (MMP)-2 activity, and were reduced by a selective ET_A antagonist.⁵⁰ This demonstrates that ET-1 participates in renal fibrosis by initiating an inflammatory response and stimulation of growth factors.

Cardiac effects of endothelin-1 in experimental hypertension

TGF-β1 expression and collagen deposition in the heart of DOCA-salt hypertensive rats are increased, and may be prevented by ET_A blockade.⁵¹ ET_A receptor antagonism also blocked the expression of inflammatory mediators (NFκB and adhesion molecules) and the antiapoptotic molecule X inhibitor of apoptosis peptide (xIAP).⁵² Indeed, the antiapoptotic and hypertrophic actions of ET-1 on the heart were abrogated by inhibition of NFκB.⁵³ ROS generated by NAD(P)H oxidase and activation of MAPK contributed to ET-1's cardiac hypertrophic action.⁵⁴ The expression of ET-1 is stimulated in aldosterone-infused rats, and accordingly, ET_A receptor blockade prevented aldosterone-induced cardiac and fibrosis, which suggests that ET-1 mediates in part effects of aldosterone on the heart and blood vessels.^{55,56}

Endothelin-1 in essential hypertension

In primary human hypertension, plasma concentrations of immunoreactive ET are normal in Caucasians,⁵⁷ but elevated in African Americans who have a volume-expanded low-renin form of hypertension.⁵⁸ High plasma ET levels may be related to subclinical renal dysfunction and smoking rather than hypertension.⁵⁹ However, vascular mRNA levels of prepro-ET are increased in stage

2 hypertension of the JNC 7 (Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure) classification⁶⁰ (Figure 28–3).

ET_A receptor antagonists caused greater vasodilatation in the forearm of hypertensive than normotensive subjects, suggesting that ET_A receptors play an important role in ET-1-dependent vascular tone in essential hypertension.⁶¹ The ET_A antagonist BQ-123 improved the impaired vasodilatation found in hypertensive patients. The ET_B blocker BQ-788 constricted forearm resistance arteries in normotensive subjects, which suggests that ET_B receptors are vasodilators in normotensive subjects.⁶² BQ-788 dilated the forearm in hypertensive subjects, suggesting that ET_B receptors are vasoconstrictors in hypertensive patients.⁶² An increase in vascular smooth muscle vasoconstrictor ET_B receptors has been documented in African-American hypertensive subjects.^{63,64} Whereas in normotensive subjects, forearm blood flow response to BQ-123 was similar in white and black subjects, ET_A receptor blockade was a more potent vasodilator in blacks than in whites among hypertensive individuals.⁶⁵ However, ET-1 vasoconstricted equally in white and black hypertensive patients. Increased ET_A-mediated vasoconstriction may contribute to BP elevation in hypertensive blacks.

Intravenous infusion of Ang II increased BP and renal vascular resistance, and accordingly decreased renal plasma flow and glomerular filtration rate in humans, changes that were unaffected by ET_A receptor antagonism.⁶⁶ Thus, pressor responses to Ang II in humans were not mediated by ET-1, a point already discussed.⁴⁸ However, a lower BP increase or a decrease in renal blood flow and glomerular filtration with an ET_A receptor antagonist added to Ang II supports the opposite conclusion.⁶⁷

ET-1 at concentrations of 10⁻¹¹ mol/L may potentiate other vasoconstrictors (e.g., phenylephrine or serotonin).⁶⁸ This mechanism is under the influence of the *EDN1 K198N* polymorphism in the coding region of the prepro-ET-1 gene,⁶⁹ and could be enhanced in hypertension and contribute to BP elevation.⁷⁰

Patients with essential hypertension, primary aldosteronism, or renovascular hypertension have enhanced ultrasound backscatter signals resulting from tissue heterogeneity in the myocardium, which correlates with plasma aldosterone and immunoreactive ET.⁷¹ This finding suggests that as in experimental animal models, aldosterone and ET-1 contribute to myocardial fibrosis in human hypertension.^{51,52,55}

Clinical trials have been performed with ET antagonists in human hypertension with the combined ET_A/ET_B antagonist bosentan and the ET_A antagonist darusentan. Bosentan lowered diastolic BP in essential hypertensive patients similarly to the ACE inhibitor enalapril.⁷² Darusentan also reduced systolic BP.⁷³ However, bosentan may induce liver damage and liver enzyme elevation, which was not reported with darusentan.

ET receptor antagonists have not yet been approved for the treatment of essential hypertension and target organ damage associated with high BP because of side effects that include headache (an NO-related effect, therefore

Figure 28–3. Representative microphotographs of *in situ* hybridization of gluteal subcutaneous fat biopsies from normotensive subjects, and mild and severe hypertensive patients, using human endothelin-1 cRNA probes. Original magnification of microphotographs shown was $\times 100$, bar in A corresponds to $30\ \mu\text{m}$ for all panels, except for panels H and I, for which original magnification was $\times 50$, and bar in A represents $60\ \mu\text{m}$. **A**, Small artery from gluteal subcutaneous fat in normotensive subject. **B**, Small artery from gluteal subcutaneous fat in mild hypertensive patient. Small arteries of these subjects exhibit scant labeling when using the antisense endothelin-1 cRNA probe, similar to labeling found with the sense endothelin-1 cRNA probe (not shown). **C, D, F, H**: Small arteries from subcutaneous fat in biopsy material from severe hypertensive patients, hybridized with the endothelin-1 antisense probe, demonstrating increased density of labeling of the endothelium by specific grains. **E, G, I**: Increased density was not found with the sense endothelin-1 cRNA probe on adjacent sections of the same vessels. (From Schiffrin EL, Deng LY, Sventek P, Day R. *J Hypertens* 1997;15:57–63.)

interestingly lower in hypertensives who have impaired endothelial function than normotensives), and liver enzyme elevation, which make the use of these agents difficult in a chronic disease. However, there are ongoing trials of ET_A antagonists in resistant hypertension.

MOLECULAR GENETICS OF ENDOTHELIN SYSTEM

A polymorphism (*EDN1 K198N*) in the coding region of the prepro-ET-1 gene has also been associated with hypertension in overweight individuals.⁷⁴ This is the same polymorphism associated with increased vasoreactivity.⁶⁶ *ECE1 C-388A* is a polymorphism present in the 5'-regulatory region of the ECE-1b gene that results in a binding site for the transcription factor E2F-2 and induces increased promoter activity. The A allele may raise expression of ECE-1b, with increased generation of ET-1. This polymorphism was found in untreated hypertensive German women in whom the A allele had a co-dominant effect on daytime and nighttime systolic and diastolic BP.⁷⁵ The association of BP and this polymorphism in

the French epidemiologic study, Étude du Vieillissement Artériel, was found only in women,⁷⁶ suggesting that there may be a recessive effect of this variant in this cohort. The *EDN1 K198N* polymorphism of the prepro-ET-1 gene was not associated with BP values in either men or women in this study, but interacted with the *ECE1 C-338A* variant to influence systolic and mean BP levels in women. The *EDN1* variant did not correlate with BP, but the effect of the *ECE1 C-338A* variant on BP was only present in homozygous *EDN1 KK* women. Stimulation of ET by androgens could explain the absence of effect in males.

SUMMARY

ET-1 is a potent vasoconstrictor that also promotes cardiac, vascular, and renal inflammation, hypertrophy, and fibrosis. ET-receptor antagonists could prevent some of the complications of hypertension, atherosclerosis, and diabetes, and it is possible that they could achieve BP-independent effects on cardiovascular pathology. However, because of side effects, their potential usefulness in

hypertension, heart failure, atherosclerosis, chronic renal failure, and diabetes and other diseases cannot be currently exploited. The only approved indication to date of endothelin blockade is for the ET_A/ET_B receptor antagonist bosentan in primary pulmonary hypertension.

Nitric Oxide

Marcela Herrera, Pablo A. Ortiz, Guillermo B. Silva,
and Jeffrey L. Garvin

Definition

- Nitric oxide (NO) is a reactive free radical produced by three gene products: NO synthase 1, 2, and 3.

Key Findings

- Transcription and translation are differentially regulated. mRNA can be spliced alternatively.
- The enzymes are regulated differently and have different patterns of expression in the kidney.
- Although the half-life of NO is less than 30 seconds, it may diffuse more than 100 μm to affect processes distant from the site of production.
- NO promotes renal excretion of salt and water and tends to lower blood pressure.
- NO dilates renal vessels, increases glomerular filtration, inhibits salt and water absorption by the nephron, blunts pressure natriuresis, and can either inhibit or stimulate renin release.
- Defects in production and/or actions of NO promote salt retention and contribute to salt-sensitive hypertension.

At the time of its discovery in 1980 by Furchgott and Zawadzki,¹ nitric oxide (NO) was referred to as endothelium-dependent relaxing factor. NO is a gaseous free radical, and as such is highly reactive. It is produced by a family of three different gene products originally referred to as neuronal, inducible, and endothelial NO synthase (NOS). As their names imply, neuronal NOS was first described in nervous tissue and endothelial NOS was first cloned from endothelial cells. Inducible NOS was first cloned from macrophages, and was referred to as inducible because its activity was originally thought to be regulated primarily by changes in transcription and translation rather than via allosteric modulation like the other two. With the discovery that neuronal and endothelial NOS are expressed in other tissues, and that inducible NOS can be allosterically regulated, the neuronal, inducible, and endothelial NOS isoforms are now generally referred to as NOS-1, -2, and -3, named for the order in which they were cloned.

NO is an extremely important regulator of blood pressure. Acute inhibition of NO production in animal models can increase blood pressure by more than 40 mmHg.² Its antihypertensive effects are due to actions on essentially every organ and tissue important to the regulation of blood pressure. NO is produced in neurons of the peripheral and

central nervous systems, where it acts as a neurotransmitter.³ It is produced by endothelial cells and diffuses to vascular smooth muscle cells, where it reduces total peripheral resistance by dilating the arteries.⁴ In the heart, it acts as both a negative chronotropic and inotropic agent.⁵ However, it is in the kidney where NO has perhaps its greatest and best described influences on blood pressure.

In the kidney, NO is produced by several different cell types and by various NOS isoforms. NO is produced by renal endothelial cells lining the vasculature. It can also be produced by mesangial and interstitial cells. Finally, it has been shown to be produced by the epithelial cells of nearly all segments of the nephron. NO production by each tissue is regulated by a unique set of humoral, chemical, and physical factors. In the kidney, NO can act as an autocrine or paracrine factor. Generally, renal NO induces natriuresis and diuresis through a variety of different mechanisms. However, there are instances in which the actions of NO appear contradictory, as is the case with its effects on renin release. The significance of the actions of NO in the kidney is best evidenced by the fact that inhibition of renal NO production causes salt-sensitive hypertension,⁶ and defects in the production of or response to NO have been implicated in genetic models of hypertension.⁷

ANATOMY AND BIOCHEMISTRY

Nitric oxide production and regulation

The NOS family of enzymes is a group of dimeric proteins that catalyze the conversion of L-arginine and O_2 to citrulline and NO. All NOS family members contain oxygenase and reductase domains. The functional protein is a homo-dimer. Each monomer has binding sites for nicotinamide adenine dinucleotide phosphate (NADPH), flavin adenine dinucleotide (FAD), and flavin adenine mononucleotide (FMN) located in the reductase domain on the carboxy terminus. The oxygenase domain is on the amino terminus and has binding sites for L-arginine, tetrahydrobiopterin (BH_4), and iron protoporphyrin (Fe-PpIX). A calcium/calmodulin (Ca/CaM) binding site resides between the reductase and oxygenase domains (Figures 29–1 and 29–2).

Catabolism of L-arginine to citrulline and NO occurs in two cycles: mono-oxygenation I and II. L-arginine binds NOS only after dimer formation, near the BH_4 binding site and Fe-PpIX. Once L-arginine is bound, one electron

Figure 29-1. Linear order of binding domains of NOS. This is a schematic representation of NOS binding domains. In reality, they are not contiguous along the protein backbone. BH₄, 5,6,7,8-tetrahydrobiopterin; FAD, flavin adenine dinucleotide; FMN, flavin adenine mononucleotide; NADPH, nicotinamide adenine dinucleotide phosphate; NOS, nitric oxide synthase.

from NADPH is conducted by the FAD and FMN of one NOS monomer to the Fe³⁺-PpIX of the second molecule of the dimer, reducing it to Fe²⁺-PpIX. Electron transfer between NADPH and FAD/FMN requires a conformational change caused by Ca/CaM binding. Once Fe is reduced, O₂ then binds it, resulting in a ferric-superoxide complex. BH₄ donates a proton to the bound superoxide to form hydroperoxide. The hydroperoxide intermediate gains a second proton, cleaving the oxygen-oxygen bond to produce water and a ferryl-iron intermediate with a protein-bound cation radical. The cation radical is highly reactive and rapidly oxygenates arginine, resulting in N-hydroxy-L-arginine. The second round of mono-oxygenation begins with one electron from the reductase domain reducing Fe³⁺-PpIX to Fe²⁺-PpIX. Oxygen again binds to Fe, generating a ferrous-oxy complex that deprotonates N-hydroxy-L-arginine. The results are a hydroperoxy complex and a radical, arginine-O•. After conformational rearrangement of unstable intermediates, NO and H₂O are generated and the oxygen atom originally bound to N-hydroxy-L-arginine is reduced, producing citrulline. Conformational changes occurring during the degradation

of unstable intermediates and the rearrangement of the atoms in order to produce NO, H₂O and citrulline also lead to re-oxidation of Fe-PpIX (Figure 29-3).

Under some circumstances, NOS can produce superoxide instead of NO. This is referred to as the “superoxide shunt.” Superoxide production occurs in NOS mono-oxygenation I when the NOS dimer is not formed due to lack of cofactors needed for its formation and stability, such as BH₄. Superoxide formation by NOS is commonly called “NOS uncoupling.”^{8,9}

The activity of the various NOS isoforms can be regulated by post-translational modifications. These include phosphorylation, protein-protein interactions, and acylation.

Phosphorylation may increase or decrease NOS activity by inducing conformational changes that affect the binding of cofactors, substrates, and protein regulators. These conformational changes may also increase or decrease the rate of electron transfer. Each of the NOS isoforms can be phosphorylated at different sites.

NOS-1 was originally shown to be phosphorylated by cAMP-dependent protein kinase, but changes in enzyme activity were not reported.¹⁰ Subsequently it was shown that NOS-1 could be phosphorylated by Ca/CaM-dependent kinase isoforms Iα, IIα, and IV at serine position 847 (Ser⁸⁴⁷). In rat suprachiasmatic nuclei, NOS-1 phosphorylation causes activity to increase.¹¹ However, studies with a recombinant enzyme showed a decrease in activity when NOS-1 is phosphorylated at this site.¹² The explanation for this discrepancy is unclear. NOS-1 can also be phosphorylated at Ser⁷⁴¹ by Ca/CaM-dependent kinase I, which will inhibit enzyme activity.¹³

Scant information is available regarding NOS-2 phosphorylation. A study using phosphotyrosine antibodies in Raw 264.7 cells showed that after induction with LPS and interferon γ, NOS-2 is phosphorylated at tyrosine residues¹⁴; however, the effect on activity was not studied.

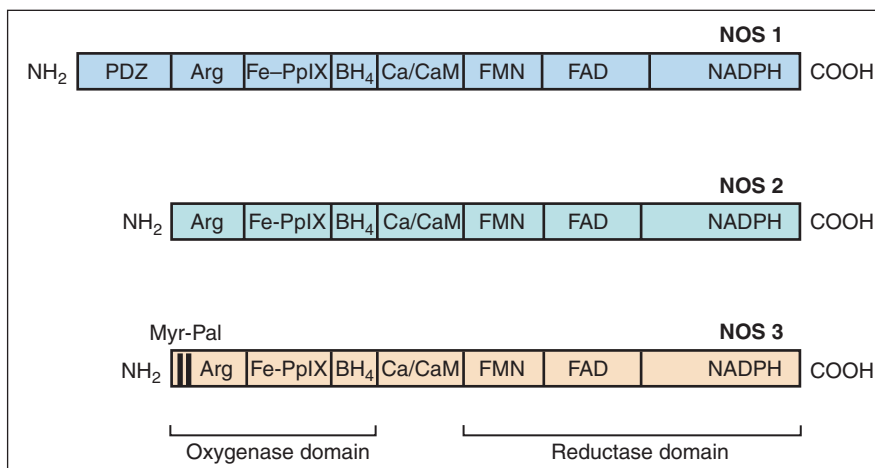

Figure 29-2. Generation of NO from L-arginine. Figure 29-3. The functional NOS complex. Dimer formation is required for NOS activity. BH₄, 5,6,7,8-tetrahydrobiopterin; Ca/CaM, calcium/calmodulin; FAD, flavin adenine dinucleotide; Fe³⁺, iron protoporphyrin IX; FMN, flavin adenine mononucleotide; NADPH, nicotinamide adenine dinucleotide phosphate; NOS, nitric oxide synthase.

The lack of data concerning NOS-2 phosphorylation may be a result of NOS-2 being regulated primarily by transcription and translation.

Phosphorylation is a major regulator of NOS-3 activity. Protein kinase B,^{15,16} Ca/CaM-dependent kinase II,¹⁷ and cAMP- and cGMP-dependent protein kinases^{18,19} can phosphorylate NOS-3. All of these kinases have been shown to phosphorylate Ser¹¹⁷⁷; however, phosphorylation of this amino acid under physiologic circumstances is due primarily to activation of protein kinase B. Phosphorylation of Ser¹¹⁷⁷ enhances NO production by increasing the affinity of the Ca/CaM binding site.¹⁵ Under some circumstances, Ser⁶³³ can also be phosphorylated by cAMP- and cGMP-dependent protein kinases.¹⁸ This is also a positive regulatory site. In contrast, when Thr⁴⁹⁵ is phosphorylated by protein kinase C²⁰ or AMP kinase, enzyme activity decreases and superoxide production may increase.^{17,21} NOS-3 can also be phosphorylated at Ser¹¹⁴. This region of the enzyme contains a consensus sequence for ERK1/2 that may function as a switch between NO and superoxide production. However, this conclusion is based primarily on the proximity of the phosphorylation site to the BH₄ binding site.^{22,23} Finally, phosphorylation of Ser⁶¹⁵ increases Ca/CaM affinity without altering maximum enzymatic activity.²⁴

Our current understanding of NOS phosphorylation indicates that it is an important physiologic regulator of enzyme activity. As such, it is necessary to keep in mind that not only kinase but phosphatase activity is important for this process. Additionally, when considering the impact of phosphorylation/dephosphorylation of a given amino acid in any of the NOS family members, one must consider

that the measured effect is a consequence of not only the phosphorylation of interest, but the state of other potential phosphorylation sites and interactions with regulatory proteins.

In addition to phosphorylation, NOS activity can be enhanced or diminished by interactions with other proteins. The first such interaction to be reported was binding of Ca/CaM. Ca/CaM is necessary for activation of NOS due to its induction of allosteric changes that modify the kinetics of the electron transfer in the flavin domains.²⁵ Originally, only the so-called constitutive NOS family members 1 and 3 were thought to bind Ca/CaM. However, it is now recognized that, in fact, NOS-1 and -3 have a significantly lower affinity for Ca/CaM than NOS-2. Consequently, an increase in intracellular Ca is required to elevate Ca/CaM concentrations sufficiently to bind NOS-1 and -3, and factors that change intracellular calcium levels are important regulators of NOS-1 and -3 activity.

In addition to Ca/CaM, NOS-1 binds a number of other proteins that alter its activity. Several studies demonstrated that heat shock protein 90 (HSP90), a multiclient chaperone protein, binds NOS-1, and that formation of the NOS-1-HSP90 complex increases NO production.²⁶ HSP90 may also increase NOS-1-Ca/CaM binding, thereby increasing NOS-1 function.²⁷ NOS-1 also binds proteins that inhibit its activity, including the membrane-scaffolding protein caveolin-3.²⁸ NOS-1 activity is regulated by the so-called protein inhibitor of NOS (PIN), which is expressed in the endothelial cells of the glomeruli, vasa recta, and luminal membranes of collecting ducts.^{29,30} NOSIP (nitric oxide synthase interacting protein) co-localizes with NOS-1 and has recently been found to help regulate the activity and distribution of NOS-1. Studies both *in vitro* and *in vivo* show that NOS-1-NOSIP interaction decreases NOS-1 activity.^{31,32}

Finally, NOS-1 interacts with a number of proteins whose effects on activity are unclear, primarily via PDZ domains. PSD-93, CAPON, and PSD-95 are proteins with PDZ domains that are reportedly associated with or serve as linkers in protein complexes with NOS-1.³³ In the macula densa, PSD-93 and NOS-1 have been found to be co-localized, presumably due to interactions of PDZ domains.³⁴

Similar to NOS-1, NOS-2 interacts with a number of other proteins. NAP-10 is a protein expressed in macrophages that prevents dimerization of NOS-2 by binding to the amino terminal close to the active site. Interaction of NAP-10 and NOS-2 is thought to blunt NO production during inflammation. Kalirin also prevents NOS-2 dimerization.³⁵ Caveolin-1 binds to NOS-2, inducing proteolysis and decreased activity,³⁶ and caveolin-3 has a similar effect.³⁷ In apical membranes of proximal tubule cells, NOS-2 binds to EBP-50, possibly serving as an anchor to direct NO production in the regulation of ion transport.³⁸ PIN also binds NOS-2 and inhibits its activity as it does with other NOS family members, but this effect is small compared to its effect on NOS-1 or NOS-3.³⁹ Localization of NOS-2 within the cell is regulated by binding of Rac 1/2; however, they do not inhibit NOS-2 activity and in fact may play a role in its activation.^{33,40}

NOS-3 activity is also regulated through a number of protein–protein interactions. HSP90 is involved in NOS-3 activation and translocation in endothelial cells⁴¹ and thick ascending limbs⁴² in the kidney. HSP90 interacts with Akt and NOS-3, forming a ternary complex that facilitates NOS-3 phosphorylation and thus increases its activity.^{43,44} NOS-3 also binds dynamin-2, a GTPase that interacts with the FAD domain of NOS-3, enhancing electron transfer and NO production. Dynamin-2 is also involved in the correct targeting of NOS-3 to caveolin-enriched fractions in endothelial cells.^{45,46}

In endothelial cells, but not thick ascending limb cells, NOS-3 binds caveolin-1, and this interaction inhibits NO production. However, when NOS-3 binds Ca/CaM, NOS-3 is released from caveolin-1.⁴⁷ Caveolin-3 has similar inhibitory properties.³⁷ NOS-3 activity is also suppressed when it forms a complex with NOSIP. NOSIP binds to the carboxy terminal region of NOS-3, inducing translocation from the plasma membrane to the cytoskeleton, and in the process inhibiting NO production. NOSIP is expressed in the kidney.⁴⁸ NOSTRIN, a NOS trafficking inducer, is also involved in NOS-3 translocation. This is a cytoskeleton-related protein that induces NOS-3 subcellular redistribution. Overexpression of NOSTRIN triggers NOS-3 redistribution and decreases NOS-3 activity.⁴⁹ Finally, *in vitro* studies demonstrate that in addition to NOS-1, PIN can also bind NOS-3 and disrupt its dimerization and L-arginine binding.³⁹

NOS-3 is the only isoform known to contain acylation sites. Palmitic acid and myristic acid can be reversibly and irreversibly added, respectively.^{9,50} There are two palmitoylation sites at Cys¹⁵ and Cys²⁶, but only one site for myristoylation on an N-terminal glycine.⁹ Both acylations are necessary for the trafficking and membrane binding of NOS-3.⁵¹

Nitric oxide synthase localization

Localization of specific NOS isoforms can be controversial, and one must exercise caution when judging published results. For instance, immunohistochemistry may not be sensitive enough to detect low levels of expression. In contrast, reverse transcriptase-polymerase chain reaction (RT-PCR) may detect a protein mRNA that has such a low copy number that it has no physiologic significance. Both antibodies and inhibitors may not be as selective as anticipated, or selectivity may change under certain conditions. Studies *in vivo* and *in situ* using knockout mice may be confounded by systemic effects of genetically deleting the protein of interest, or changes in physiology that mitigate the effect of the knockout. In the end, use of multiple techniques is required before one can state with any certainty whether a tissue expresses a given NOS isoform.

NOS-1 is distributed in a wide variety of tissues. It is expressed in both central and peripheral nerves and in the heart. In the kidney, NOS-1 is located in the neuronal somata of ganglionic nerves located around the interlobular artery and the wall of the renal pelvis, as well as the corresponding postganglionic fibers.⁵² mRNA and immunocytochemical studies have shown that NOS-1 is expressed in principal cells of the collecting duct, but not

in intercalated cells.⁵³ It has also been found in the macula densa using several techniques. NADPH diaphorase and immunohistochemical assays support NOS-1 expression in the endothelial cells of the efferent arteriole.⁵⁴ Knockout of NOS-1 reportedly inhibited proximal tubule transport, but it is unclear whether these results were due to deletion of the enzyme from proximal tubule cells or systemic effects of the deletion.⁵⁵ NOS-1 has likewise been shown to be expressed in vascular smooth muscle cells of mesenteric vessels,⁵⁶ but it is unclear whether this is also true of renal vessels.⁵⁴

NOS-2 mRNA has been detected in all tubular segments of the kidney.⁵⁷ Functional experiments using NOS-2 knockout mice indicate that NOS-2 is expressed in the proximal nephron,⁵⁸ but its physiologic significance in this segment is unclear because disparate effects have been reported.⁵⁹ mRNA for NOS-2 has been found in the outer medullary thick ascending limb,⁵⁷ but functional studies showed that inhibiting NOS-2 had no effect on NaCl absorption.⁶⁰ NOS-2 has also been found in the inner medulla by Western blot, but it is not clear which cell type(s) in this region was responsible. In the vasculature, significant amounts of NOS-2 have been detected in renal smooth muscle cells from patients with chronic allograft nephropathy,⁶¹ but this is likely attributable to induction of the enzyme as the result of the disease.

NOS-3 is present in the endothelial cells along the entire vascular tree of the kidney, including the renal artery, interlobar artery, arcuate artery, afferent and efferent arterioles, glomerular capillaries, and vasa recta.⁵⁴ NOS-3 is also expressed in the proximal tubule, thick ascending limb, distal convoluted tubule, and collecting duct.⁶²

GENETICS

NOS-1, -2, and -3 are encoded by different genes with a conserved sequence of 80% to 90% across various mammalian species. There is also strong similarity in the sequence and gene structure between the three NOS isoforms in terms of exon size and location of the intronic splice junctions. Despite these similarities in gene structure, transcriptional control of each NOS isoform is different and occurs in a cell- and tissue-specific manner, allowing specificity for NO signaling in physiologic and pathologic conditions.

The human NOS-1 gene has been mapped to chromosome 12, whereas homologous genes in the rat and mouse have been mapped to chromosome 12 and 5, respectively. Besides neuronal cells, NOS-1 is also expressed in the skeletal muscle, lung, kidney, testis, penis, and adrenal and pituitary glands. Its expression is regulated by a variety of physiologic stimuli such as oxygen tension and cellular stress as well as several hormones and neurotransmitters. However, regulation of NOS-1 expression is cell type-specific and extremely complex due to transcriptional variants of the NOS-1 gene as described below.

The human NOS-1 gene is present as a single copy in the human genome and is scattered over a region of approximately 200 kb. Potential sites for transcription factors upstream from the NOS-1 gene include AP-2,

transcriptional enhancer factor-1/M-CAT binding factor, CREB, cFOS, Ets, nuclear factor-1, and NF κ B. The nucleotide sequence coding for the most abundant neuronal transcript is encoded in 29 exons, and the full open reading-frame codes for a protein of 1434 amino acids with a predicted mass of 161 kDa. This full-length (1–1434) NOS variant is usually called NOS-1 α .

In addition to NOS-1 α , multiple mRNA transcripts for NOS have been reported. They are produced by three different mechanisms: (1) use of multiple promoters and 5' transcription start sites, (2) alternative splicing, and (3) use of alternative polyadenylation signals in exon 29. Alternative promoters in the various exon 1's result in different mRNAs containing alternative 5' untranslated regions with varying translational efficiency. However, since all possible exon 1's are spliced to the same exon 2, only one protein is transcribed.

Alternative mRNA splicing of NOS-1 transcripts produces four splice variants called NOS-1- β , - γ , - μ and -2. In mice, alternative splicing of exon 2 produces the N-terminal truncated NOS-1 variants β (amino acids 236–1434) and γ (amino acids 336–1434) that lack the PDZ binding domain. In humans, an mRNA transcript similar to mouse NOS-1 γ has been detected exclusively in testis Leydig cells, where its function is unknown. NOS-1 μ is an extended splice variant detected in humans, rats, and mice that contains a 34-amino-acid insertion between the calmodulin- and flavin-binding domains. This splice variant is most highly expressed in skeletal muscle and the heart. Its kinetic parameters for NO production are similar to NOS-1 α , but it has two important differences. First, the μ variant is degraded more slowly than NOS-1 α , and it has a lower rate of NADPH oxidation.⁶³ Another NOS-1 alternative splice variant (NOS 1-2) has been detected in the mouse brain. This variant contains a 105-amino-acid in-frame deletion of residues 504–608. An opposing functional role of NOS-1 and NOS-1-2 has been proposed in morphine analgesia in mice. Finally, the human NOS-1 exon 29 contains three potential polyadenylation sites; however, the effect of these 3'-end variations on transcription of NOS-1 mRNA is unknown.

NOS-2 was originally cloned from mouse macrophages and from human macrophages and chondrocytes. The NOS-2 gene consists of 27 exons spanning a 40 kb genomic region located on human chromosome 17. The translation start codon is located on exon 2 and the stop codon on exon 27. The nucleotide sequence is 85% to 90% homologous among humans, rats, and mice. As an inducible enzyme, NOS-2 expression is tightly controlled at the transcriptional level by means of promoter regulation. It is also regulated by the stability of its mRNA.

In most cells, NOS-2 is induced by bacterial lipopolysaccharides (LPS) and cytokines such as interferon- γ and interleukins 1 β and 6 among others. The NOS-2 promoter contains a TATA box 30 bp upstream from the transcription start site. The NOS-2 promoter contains binding sites for the transcription factors NF- κ B, IL6, activating protein-1 (AP-1), CCAAT-enhancer box binding protein/EBP, cAMP-responsive element binding protein (CREB), interferon regulatory factor-1 (IRF-1), serum response

factor (SRF), octamer factor-1 (Oct-1), and STAT 1 α . Recent data indicate that NOS-2 promoter activity is inhibited under basal conditions by hypermethylation, which would explain the low basal expression of NOS-2 in most cells.

In addition to transcriptional regulation by promoter activation, NOS-2 expression is controlled by mRNA stability. Sequence analysis of NOS-2 mRNA showed that four sequence motifs (AUUUA) in the 3'-untranslated region confer destabilization of NOS-2 mRNA. Several RNA-binding proteins have been identified that bind the 3' untranslated region of NOS-2 mRNA. Interaction of NOS-2 mRNA with some RNA-binding proteins, such as the embryonic lethal abnormal vision protein HuR, increases mRNA stability and augments cytokine-induced expression. In contrast, binding of NOS-2 mRNA to other proteins, such as hnRNP/AUF-1, decreases mRNA stability and diminishes NOS-2 expression. Since the discovery that NOS-2 mRNA stability plays a role in regulating expression, the number of proteins that bind the 3' untranslated region of NOS-2 mRNA has grown steadily. Some new proteins of this family include tristetraprolin, the T-cell-restricted intracellular antigen-1-like (TIAR) protein, KH-type, splicing regulatory protein (KSRP), and the poly A tract binding protein (PABP).

Similar to NOS-1, the NOS-2 gene is also subject to alternative splicing. Alternative splice variants of NOS-2 mRNA have been detected in humans, rats, and mice. In addition, alternative splicing produces mRNA variants with deletions corresponding to exon 5; exons 8 and 9 (_{-8-9 del}); exons 9, 10, and 11 (_{-9-10-11 del}); and exons 15 and 16 (_{-15-16 del}).⁶⁴ The physiologic role of most of these NOS-2 variants is still unknown. The only variant studied in detail is NOS-2 (₋₈₋₉), which codes for a monomeric protein that does not produce NO, but retains NADPH diaphorase activity when expressed in cultured cells.⁶⁵ Recently a new splicing variant lacking exon 14 (NOS-2_{14del}) has been detected in human B lymphocytes.⁶⁶

NOS-3 was originally cloned from vascular endothelial cells. This enzyme is constitutively expressed in the vasculature and in many cell types including epithelial cells, cardiac and smooth muscle cells, fibroblasts, hepatocytes, platelets, lymphocytes, and some neuronal cells among others. The human NOS-3 mRNA is encoded by 26 exons spanning 22 kb of genomic DNA. The gene is present as a single copy in the human genome and has been localized to chromosome 7. Full-length NOS-3 cDNA encodes for a predicted 133-kDa protein. The nucleotide sequence for the NOS-3 gene is 90% conserved across mammalian species, with greater conservation (95%) in the amino acid sequence.

One important characteristic of the NOS-3 gene is that it is highly polymorphic. Single nucleotide polymorphisms have been observed in various vascular diseases ranging from hypertension to atherosclerosis and metabolic syndrome. The best-studied polymorphism is NOS-3 Glu298Asp, which appears to influence the blood pressure response to exercise. This variant is also associated with endothelial function and may be involved during the adaptive vascular changes of pregnancy, such that carriers of NOS-3 Asp298 may be at risk of developing preclamp-

sia. Most studies show that intact NOS-3 Asp298 has equivalent enzymatic activity to NOS-3 Glu298, but in some cells it undergoes selective proteolysis, increasing protein turnover rate and reducing active NOS-3. In addition, carriers of NOS-3 Asp298 may be at increased risk of developing atherosclerosis and cerebrovascular disease.

NOS-3 expression is regulated in a cell-type specific manner by a large array of physiologic factors; among the most important are shear stress, hypoxia, cell proliferation, estrogens, lipoproteins, glucose, angiotensin II, and cAMP. Analysis of the 5'-region indicates that the NOS-3 promoter does not have a TATA box, but shows proximal promoter elements of constitutively expressed genes like Sp1 and GATA binding motifs. It also contains consensus sequences for binding of transcription factors AP-1, AP-2, NF-1, nuclear factor IL6, NF κ B, PEA-3, heavy metal, shear stress, CREB, and sterol-regulatory *cis*-elements. In addition to promoter activity, NOS-3 expression is regulated by mRNA stability. For example, NOS-3 mRNA levels are approximately four- to six-fold higher in proliferating than in growth-arrested endothelial cells, a difference that cannot be explained by varying transcription rates. Hypoxia and cytokines, such as TNF, downregulate eNOS mRNA levels by decreasing the half-life of eNOS mRNA. NOS-3 mRNA half-life is regulated by a process involving the induction and expression of at least two cytosolic proteins (51 kDa and 60 kDa) that bind to a C-rich region within the 3'-untranslated region of NOS-3 mRNA. To date, there are no known alternative splice variants of NOS-3. However, polyadenyl 3' tails of different lengths in NOS-3 mRNA have recently been shown in endothelial cells, where they affect mRNA stability and mediate the fast regulation of NOS-3 expression by shear stress.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Nitric oxide produced within the kidney by the three NOS isoforms regulates many physiologic processes. Endothelial, epithelial, and other cells in the kidney can generate NO. Once produced, NO can act as either an autocrine or paracrine factor, regulating vascular tone, ion and solute transport along the nephron, pressure natriuresis, and tubuloglomerular feedback.⁶⁷⁻⁷¹ Because NO produced by different NOS isoforms has the same physiologic effect on all processes studied thus far (with the exception of renin release), it is easier to discuss the actions of NO according to physiologic effect rather than the isoform responsible for its production.

Renal vasculature

NOS-3, the endothelial isoform of NOS, is expressed in the glomerular arterioles as well as in the vasa recta, where it is functionally active and produces NO.⁷² Increased luminal flow is the primary stimulator of NOS-3 in vascular endothelial cells.⁷¹ Luminal flow activates phosphatidylinositol 3-OH kinase, although the exact mechanism is unknown. This enzyme generates phosphatidylinositol 3,4,5 trisphosphate, enhancing activity of phosphatidylinositol-dependent kinase, which in turn phosphorylates and stimulates protein kinase B. Protein kinase B then

phosphorylates and activates NOS-3. NO produced by NOS-3 in the endothelium of the afferent and efferent arterioles, the major resistance vessels in the kidney, diffuses to the vascular smooth muscle cells where it activates guanylate cyclase. This leads to generation of cGMP and activation of cGMP-dependent protein kinase I. cGMP-dependent protein kinase I phosphorylates inositol 1,4,5 triphosphate-receptor-associated protein kinase I substrate (IRAG) located at the endoplasmic reticulum membrane. cGMP-dependent phosphorylation of IRAG inhibits calcium release into the cytoplasm, decreasing intracellular calcium.⁷³ This decrease in calcium inactivates calcium-dependent myosin light chain (MLC) kinase and induces dephosphorylation of MLC by myosin phosphatase 1. Moreover, cGMP diminishes the sensitivity of the contractile machinery to calcium.⁷⁴

In addition to NOS-3, NOS-1 may also regulate vascular tone in the kidney. NOS-1 is reportedly expressed in the endothelial cells of the efferent arteriole, but its functional significance is unknown. NOS-1 is also present in vascular smooth muscle cells of mesenteric resistance vessels, where it produces NO and directly affects vascular tone in an endothelium-independent fashion,⁷⁵ but it is unclear whether this occurs in the renal vasculature as well. NO-dependent vasodilatation increases blood flow to the glomeruli, which tends to raise the glomerular filtration rate.

NO production within the renal vasculature can be stimulated under physiologic situations by many factors. Systemic and intrarenal administration of the arginine analogues that inhibit NO production increased renal vascular resistance by 30% to 50%.⁷⁶ In addition, infusion of NO donors in the presence of NOS inhibition restored renal blood flow.⁷⁷ Thus *in vivo* and *in vitro* data from various species indicate that basal release of NO helps maintain the relative low vascular resistance that characterizes the renal circulation.⁷⁶ In addition to vascular NOS-3, NO can be produced by other structures located close to vascular cells, such as the tubular epithelium, and it is possible that NO produced by these structures also affects renal vascular tone.

In addition to NOS-3-derived NO, NO generated in the macula densa by NOS-1, the neuronal isoform of NOS, helps control glomerular hemodynamics via tubuloglomerular feedback and modulation of renin release.⁷⁸⁻⁸⁰ Tubuloglomerular feedback is an important regulator of renal hemodynamics. When NaCl concentration in the lumen of the distal nephron rises, resistance of the afferent arteriole increases while resistance of the efferent arteriole decreases, a phenomenon known as tubuloglomerular feedback. This results in decreased glomerular filtration and increased sodium retention. Tubuloglomerular feedback starts at the macula densa. The macula densa plaque senses changes in luminal NaCl concentration via activation of luminal Na/K/2 Cl co-transport, setting in motion a number of signaling events that result in basolateral release of ATP and constriction of afferent arteriole diameter.^{81,82} Increases in luminal NaCl also initiate a cascade that limits the magnitude of tubuloglomerular feedback. Increased NaCl enhances Na/H exchange in the macula densa, which raises intracellular pH. This in turn

stimulates NOS-1 activity.⁸³ NO produced by NOS-1 in the macula densa attenuates tubuloglomerular feedback by increasing cGMP, activating cGMP-dependent protein kinase and inhibiting Na/K/2 Cl co-transport.⁸⁴

The renin-angiotensin-aldosterone system plays an important role in blood pressure stabilization and electrolyte and fluid homeostasis. Angiotensin increases total peripheral resistance, reduces renal blood flow, enhances tubuloglomerular feedback and augments salt and water absorption primarily by the proximal nephron, while at the same time aldosterone increases salt absorption primarily by the distal nephron. The activity of the renin-angiotensin-aldosterone system in the circulation is mainly dependent on the protease renin, which is produced in the kidney by the juxtaglomerular granular cells. Their release of renin is influenced by NO produced by both NOS-3 from the afferent arteriole and NOS-1 from macula densa cells.^{85,86}

The regulation of renin release is a unique case in which NO produced by different enzymes appears to have different effects on a physiologic process. Recent data suggest that the actions of NO on renin release depend critically on intracellular cAMP concentrations in the juxtaglomerular cells and thus the signaling cascades activated.⁸⁶ NO derived from the endothelial cells of the vasculature inhibits renin release via activation of soluble guanylate cyclase and cGMP-dependent kinase II. In contrast, NO derived from macula densa NOS-1 is thought to stimulate renin secretion via inhibition of phosphodiesterase 3 (which cleaves cAMP), increases in cAMP levels, and reductions in intracellular calcium (renin release is stimulated by reductions in calcium similar to parathyroid hormone). Whether the stimulatory or inhibitory effect of NO predominates is thought to depend on factors that alter intracellular cAMP or factors that stimulate cAMP, such as sympathetic nerve activity or prostaglandin production. However, additional research is required to fully understand how NO is involved in the regulation of renin release as well as its mechanisms of action.

Nephron transport

In addition to its actions in the renal vasculature, NO can induce natriuresis and diuresis without altering renal blood flow or glomerular filtration, suggesting that it regulates sodium and water reabsorption by the nephron.⁶⁹ NOS has been found in most tubular segments, implying that it can act as an autacoid to influence salt and water transport. However, NO produced by surrounding structures, such as the vasculature, can potentially affect transport as well.

In the proximal tubule, the data regarding the effect of NO on transport are controversial, with reports of inhibitory, stimulatory, and biphasic effects. *In vitro* and cell culture experiments have shown that NO inhibits both Na/H exchange (the primary route of Na entry into proximal tubule cells) and Na/K ATPase (the primary route of exit). In contrast, *in vivo* micropuncture experiments using knockout and wild-type mice and NOS inhibitors^{58,87} indicate that NO acting as either an autocrine or paracrine factor stimulates transport in this segment. While

the resolution of these issues is uncertain, the micropuncture experiments may have been confounded by systemic effects of the knockout and effects of the inhibitors on surrounding tissues.

In the thick ascending limb, NO exogenously added by NO donors or produced endogenously inhibits NaCl absorption. This inhibition on its own would be expected to increase not only Na excretion but also urinary volume, due to reduction of the corticomedullary osmotic gradient. Suppression of net NaCl absorption is due to inhibition of Na entry via luminal Na/K/2 Cl co-transport and Na/H exchange. Na exit via Na/K ATPase does not appear to be affected. Reduction of both Na/K/2 Cl co-transport and Na/H exchange occurs via activation of soluble guanylate cyclase and increases in cGMP. However, the former is due to activation of cGMP-stimulated phosphodiesterase II, which in turn decreases cAMP levels, whereas the latter occurs via activation of cGMP-dependent protein kinase.⁶⁹ The NOS isoform responsible for producing NO in the thick ascending limb is NOS-3. L-arginine, the substrate for NOS, inhibits NaCl absorption by thick ascending limbs from wild-type, NOS-2 and NOS-1 knockout mice but not from NOS-3 knockout mice.⁶⁰ Furthermore, when NOS-3 is restored in thick ascending limbs from NOS-3 knockout mice, inhibition by L-arginine is also restored.⁸⁸ Acutely, NO production by this segment can be stimulated by factors that enhance NO production in endothelial cells, including endothelin, alpha 2 adrenergic agonists, and luminal flow.

Although NO has been reported to enhance luminal K channel activity, and K recycling across the luminal membrane is necessary for net NaCl absorption, the effect of NO on luminal K channels in the thick ascending limb does not result in enhanced NaCl absorption. The explanation may be that (1) actions of NO on K channel activity were measured by patch clamp, which does not take into account the full measure of cellular processes that may regulate an individual transporter; and/or (2) direct inhibition of luminal Na/K/2 Cl co-transport by NO may overwhelm the small stimulatory effect produced by activation of K channels.

In the collecting duct, exogenously added NO inhibits basal Na absorption and arginine vasopressin-stimulated sodium and water absorption. These actions on their own would tend to cause natriuresis and diuresis. As with the thick ascending limb, the effects of NO in the collecting duct are mediated via activation of cGMP-dependent protein kinase and cGMP-stimulated phosphodiesterase. Stimulation of these cGMP-dependent enzymes decreases both cAMP levels and cAMP-dependent protein kinase activity. Although NOS is highly expressed in the collecting duct, the contribution of endogenously produced NO within this segment to regulation of transport has not been elucidated to our knowledge.⁶⁹

Pressure natriuresis

Pressure natriuresis is a process whereby increases in renal perfusion pressure result in enhanced Na excretion. A number of paracrine and/or autocrine factors have been suggested as mediators of pressure natriuresis, including

NO. Administration of NO synthase inhibitors via the renal artery suppresses pressure natriuresis.⁸⁹ Experiments in dogs have confirmed that there is a direct relationship between changes in arterial pressure and intrarenal NO activity as measured with NO-sensitive microelectrodes inserted in the cortical tissue. Changes in arterial pressure induced parallel alterations in intrarenal NO activity that correlated positively with the changes in sodium excretion rates.⁹⁰ Pretreatment with a NOS inhibitor decreased pressure natriuresis, and infusion of an NO donor reversed this process. However, although sodium excretion was enhanced by an NO donor, it failed to restore the slope of the curve relating arterial pressure to sodium excretion.⁷⁷ These data suggest that not only does NO at least partially mediate pressure natriuresis, but that changes in NO release accompany changes in pressure and that NO release is not static.

The site of action of NO in mediating pressure natriuresis is not clear. Originally, pressure natriuresis was thought to be due to inhibition of sodium transport in the distal nephron. This theory was supported by data showing that amiloride, an inhibitor of collecting duct sodium absorption, could prevent pressure natriuresis.⁹¹ However, recent data indicate that pressure natriuresis may be due to inhibition of sodium absorption by the proximal tubule. Acute increases in renal perfusion pressure have been shown to inhibit Na/H exchange activity in this nephron segment, due to physical relocation of the transport proteins to the base of the brush-border microvilli.⁹² However, there is general agreement that acute changes in arterial pressure alter intrarenal NO production, which inhibits tubular sodium reabsorption and causes pressure natriuresis.

Although NO is known to mediate pressure natriuresis, as far as we know the source(s) of NO have not been determined, nor precisely how the signal of increased perfusion pressure is translated into enhanced NO production. Although it is tempting to suggest that increases in flow through the renal vasculature accelerate NO production by NOS-3 in the endothelium, this seems unlikely. The kidney displays exquisite autoregulation of blood flow, indeed increasing renal perfusion pressure from 70 to 140 mmHg does not significantly increase renal blood flow due to heightened resistance of the afferent arteriole. It should be recognized, however, that this argument does not indicate that NOS-3 is not involved, only that luminal flow is not likely the signal for its activation. While the specific signaling mechanisms that lead to increased NO production are unclear, increases in renal perfusion pressure cause small changes in interstitial hydrostatic pressure (on the order of 4 to 5 mmHg). If the renal capsule is removed, increases in perfusion pressure no longer increase interstitial pressure and pressure natriuresis no longer occurs. How small changes in interstitial pressure lead to enhanced NO release is unknown.

Effect of high-salt intake on renal nitric oxide

The renal NO system is up-regulated in animals fed large amounts of salt, promoting sodium and water excretion. The importance of NO in maintaining blood pressure in

the face of a high-salt diet is best evidenced by the fact that intrarenal infusion of L-NAME, a nonselective NOS inhibitor, causes hypertension in rats on high salt.⁶ Expression of all three NOS isoforms is enhanced by high salt in the renal medulla, but they do not promote natriuresis equally. Conflicting reports concerning NOS-1 have been published. In one study selective inhibition of this enzyme caused salt-sensitive hypertension, while in another it did not. NOS-2 activity does not appear to be necessary for blood pressure homeostasis when animals are given high salt. Although these data suggest that NOS-3 is critical to promoting salt excretion when animals are on high salt, NOS-3 knockout mice are only very modestly salt-sensitive, if at all. However, this could be explained by adaptive mechanisms mitigating the effects of NOS-3 knockout.

The mechanism whereby high salt increases NOS expression has recently been delineated, but only for a single nephron segment. In the thick ascending limb, high salt increases NOS-3 expression and NO production.^{93,94} The increase in NOS-3 expression is mediated via increases in medullary osmolality and release of endothelin-1 and activation of ET_B receptors on thick ascending limb cells.⁹⁵ In support of this, renal ET-1 production is augmented in parallel with sodium intake.⁹⁶ In addition, blockade of ET_B receptors leads to hypertension when rats are fed a high-salt diet, and ET_B-deficient rats display salt-sensitive hypertension. Studies in ET_B-deficient rats showed that the increase in renal NOS activity caused by high salt was diminished.⁹⁷

Although NOS expression is enhanced by a high-salt diet, one cannot necessarily assume that this leads to sustained increases in NO production. In fact, the effect of salt on NOS expression is transient even though animals remain normotensive.⁹⁴ Furthermore, NO production declines faster than NOS expression.⁹⁴ Such data suggest that the response to a given amount of NO may be enhanced at later times.^{93,94}

Hypertension

Defects in the renal NO system are associated with several models of experimental hypertension. This is not surprising because, by definition, pressure natriuresis must be shifted in order to maintain a hypertensive state, and it is at least partially mediated by NO. As discussed above, inhibition of renal NO production causes salt-sensitive hypertension. Defects in the response to or production of NO in the kidney also play a role in a genetic model of salt sensitivity, the Dahl salt-sensitive rat. The defect that causes hypertension in the Dahl rat has been localized to the kidney by cross-transplantation studies. When a kidney from a salt-sensitive animal was placed in a salt-resistant rat, it became salt-sensitive (and *vice versa*).⁹⁸ The renal defect appears to lie in the loop of Henle, because these rats display abnormal NaCl absorption by the loop of Henle, which includes the thick ascending limb and pressure natriuresis. L-arginine supplementation reduces blood pressure and restores pressure natriuresis to normal levels.⁹⁹

Basal sodium reabsorption is enhanced in thick ascending limbs of Dahl salt-sensitive rats compared to normo-

tensive salt-resistant controls. This is at least partially due to the fact that inhibition of sodium transport in response to NO is decreased in this segment.¹⁰⁰ Originally the reduced effects of NO in this model were attributed to decreased production of NO. However, linkage studies between blood pressure and NOS have been difficult to reproduce. Furthermore, recent data indicate that enhanced oxidative stress in this model may be responsible for decreased NO bioavailability. Scavengers of reactive oxygen species have been shown to blunt salt-sensitive hypertension significantly in this model.¹⁰¹

In the spontaneously hypertensive rat (SHR), NO production is normal or even increased. In this model, NO bioavailability within the kidney is reduced. The diminished actions of NO in this model have been studied primarily with regard to tubuloglomerular feedback and macula densa NO. Tubuloglomerular feedback is enhanced in SHR, but so is NOS-1 expression in the macula densa. However, when scavengers of O_2^- are infused, tubuloglomerular feedback is reduced in SHR but not in normotensive Wistar-Kyoto rats. Infusion of tempol, a superoxide dismutase mimetic, dramatically reduces blood pressure in SHR. These data suggest that increased renal oxidative stress is present in this model and blunts the effects of NO. Similar mechanisms may be involved in diabetes-induced hypertension.¹⁰²

Pregnancy

Glomerular filtration rate and renal plasma flow are both increased by 50% to 60% during normal pregnancy via the vasoactive peptide endothelin-1, which, acting through ET_B receptors in the kidney, activates NOS to increase NO. Moreover, the hormone relaxin has recently been implicated in this mechanism. Relaxin is secreted by the corpus luteum during pregnancy and enhances metalloprotease activity, thus increasing cleavage of big endothelin to endothelin. Recent studies suggest that NO deficiency in pregnant rats may contribute to the pathogenesis of preeclampsia, in which renal plasma flow and glomerular filtration rate are decreased compared to normal pregnancy. Promoting NO production by administering L-arginine is known to attenuate pregnancy-induced hypertension.¹⁰³ This may be due to effects on the kidney, because large increases in NO that enhance renal blood flow occur during normal pregnancy.¹⁰⁴⁻¹⁰⁶ The primary dysfunction in preeclampsia is a relative deficiency of available NO (secondary to oxidative degradation) and an excess of peroxynitrite ($ONOO^-$),¹⁰⁷ which together can directly or indirectly initiate the vast majority of physiologic and serologic changes associated with preeclampsia, such as increased blood pressure and glomerular filtration rate and proteinuria.

CLINICAL IMPLICATIONS AND PERSPECTIVES

The potential for the renal actions of NO to have great significance in human hypertension is clearly supported by an extensive literature based on experimental models. Human studies, although not as invasive (and therefore

not as direct) as animal studies, show that the major actions of NO on renal function reported for animal models are also true in humans. L-arginine infusion decreases renal vascular resistance and increases glomerular filtration rate in normal subjects.¹⁰⁸ L-arginine infusion can increase urinary volume and sodium excretion without significant changes in glomerular filtration rate,¹⁰⁹ while inhibition of NO production decreases fractional sodium excretion.¹¹⁰ Taken together, these data indicate that NO can directly inhibit sodium absorption along the nephron. Additionally, changes in the production or actions of NO are part of the adaptation to a high-salt diet.¹¹¹

NO has also been shown to play a significant role in the development of human hypertension, and there is an extensive literature on this subject. However, while this is also true for NO in the kidney, the literature is not as extensive. This is partly due to the fact that the systemic actions of NO confound interpretation of the results, making it difficult if not impossible to study many aspects of renal function noninvasively.

In many forms of hypertension, NO production, bioavailability, or action is reduced in the systemic vasculature. NO production can be reduced by defects in the NOS enzyme, lack of cofactors, or insufficient substrate. Bioavailability can be reduced by increases in oxidative stress, while the actions of NO can be blunted by defects in signaling cascades. To date, all of the data concerning human hypertension associated with defects in the NO system involve either decreases in production or bioavailability.

L-arginine has been shown to decrease renal vascular resistance more dramatically in patients with essential hypertension than normotensive patients, while causing the same decrement in systemic vascular resistance. Thus either production of NO in the kidney at normal circulating L-arginine levels is deficient in essential hypertension¹¹² or else bioavailability of the NO that is produced is reduced. L-arginine infusion has been shown to increase urinary volume and sodium excretion with only modest changes in glomerular filtration rate in offspring from normotensive parents; however, these effects are mitigated in individuals with a family history of hypertension.¹⁰⁹ Such effects may be due to decreased NO production, because at least a subgroup of patients with essential hypertension has been shown to have decreased renal NO production.¹¹³

One of the more interesting developments in the field of renal NO and blood pressure regulation has been the discovery of natural circulating NOS inhibitors such as asymmetric dimethylarginine (ADMA). Acute infusion of ADMA in human volunteers can decrease urinary sodium excretion and increase renal vascular resistance via reductions in cGMP without changes in blood pressure.¹¹⁴ These data suggest that NO produced in the kidney has similar functions in humans to those in animals, and that renal function may be more dependent on NO than cardiovascular function in general. Data showing that ADMA increases filtration fraction similar to L-NAME while decreasing urinary sodium excretion indicate that NO directly inhibits salt absorption along the nephron.¹¹⁵ Thus

the renal actions of ADMA may at least partially account for the hypertension seen in elderly patients with elevated ADMA.¹¹⁶

SUMMARY

NO is a highly reactive free radical produced by a family of enzymes, NOS-1, -2, and -3. NO production is regulated through both changes in enzyme expression and post-translational modifications. The latter include phosphorylation, interaction with other proteins, and acylation. NO production depends on a number of cofactors, including NADPH, FAD, FMN, BH₄, and Ca/CaM. L-arginine is the substrate for NO generation, producing citrulline in

the same process. NO affects many physiologic processes in essentially all organs; however, its effects on the kidney have the greatest impact on regulation of blood pressure. Renal actions of NO include dilatation of the renal vasculature, inhibition of salt and water absorption along the nephron, and blunting of tubuloglomerular feedback. Renin release may either be inhibited or stimulated by NO depending on the conditions involved. Reductions in the production, bioavailability, or actions of NO have been shown to promote hypertension in both animal models and humans. Although we have come a long way in our understanding of the cardiovascular and renal actions of NO, a number of important questions remain.

Chapter
30Reactive Oxygen Species,
Oxidative Stress, and Vascular
Biology in Hypertension

Fatiha Tabet and Rhian M. Touyz

Definition

- Reactive oxygen species (ROS) act as signaling molecules that play an important role in vascular (patho)biology.

Key Findings

- All vascular cell types produce ROS, primarily via membrane-associated non-phagocytic NAD(P)H oxidase. Xanthine oxidase, uncoupled endothelial nitric oxide synthase, and mitochondrial enzymes also contribute to ROS generation in the vessel wall.
- Since ROS are highly reactive biomolecules, the cellular redox state is carefully regulated by antioxidant systems to prevent the deleterious consequences of ROS excess. When this redox balance is perturbed, oxidant stress is increased in the vessel wall and, if not offset, vascular dysfunction and damage occurs. Factors that activate pro-oxidant enzymes remain poorly defined, but likely involve angiotensin II, mechanical stretch, and inflammatory cytokines.
- ROS influence vascular function and structure by modulating cell growth, contraction/dilation and inflammatory responses, via redox-dependent signaling pathways. These processes are critically involved in cardiovascular pathologies and contribute to vascular remodeling associated with arteriosclerosis, diabetes and hypertension.
- Oxidative stress has been demonstrated in experimental and human hypertension.

Clinical Implications

- Therapies targeted against free radicals, by decreasing ROS generation and/or by increasing antioxidants, may be useful in minimizing vascular injury, and thereby preventing or regressing hypertension-associated target-organ damage.

Reactive oxygen species (ROS), such as superoxide anion ($\bullet\text{O}_2^-$), hydrogen peroxide (H_2O_2), hydroxyl anion (OH^-), nitric oxide (NO), and peroxynitrite (ONOO^-) are ubiquitous reactive derivatives of O_2 metabolism found in the environment and in all biological systems.¹ To protect against potentially damaging effects of ROS, cells possess several antioxidant enzyme systems, including superoxide dismutase (SOD) (which reduces $\bullet\text{O}_2^-$ to H_2O_2), catalase, and glutathione peroxidase (which reduces H_2O_2 to H_2O)^{2,3} (Figure 30–1). Oxidative stress is defined as an imbalance between oxidant production and antioxidant capacity, and has been implicated in the vascular damage associated with

cardiovascular pathologies, such as atherosclerosis, diabetes, and hypertension.^{4,5}

In the vasculature, ROS are produced primarily by non-phagocytic NAD(P)H oxidase. This enzyme is regulated by vasoactive peptides, such as angiotensin II (Ang II), growth factors, cytokines, and mechanical forces.^{6,7} Vascular ROS can also be derived from mitochondrial enzymes, xanthine oxidase, nitric oxide synthase (NOS), cyclooxygenase, lipoxygenase, and heme oxygenases.⁸ All vascular cell types, including endothelial, smooth muscle, and adventitial cells, produce ROS.^{6,7,9–11} ROS act as intercellular and intracellular messengers that play an important (patho)physiologic role in vascular biology.^{4,5} Under pathologic conditions associated with oxidative stress, increased ROS production leads to endothelial dysfunction, increased contractility, vascular smooth muscle cell (VSMC) growth and apoptosis, monocyte migration, lipid peroxidation, inflammation, and increased deposition of extracellular matrix proteins, all processes that are critically important in vascular changes associated with hypertension^{12,13} (Figure 30–2).

Convincing evidence from experimental studies and clinical investigations indicates that oxidative stress is involved in the pathogenesis of many cardiovascular diseases including hypertension. In experimental models of hypertension, production of cardiac, renal, neural, and vascular ROS is increased.^{14–16} In human hypertension, plasma and urine levels of thiobarbituric acid–reactive substances (TBARS) and 8-epi-isoprostane, markers of systemic oxidative stress, are elevated.^{17,18} Furthermore, clinical studies have indicated that NAD(P)H oxidase activity/expression is increased, and antioxidant enzyme capacity is decreased in hypertensive patients.^{19,20} The present chapter focuses on the importance of ROS in vascular (patho)biology and highlights the role of vascular oxidative stress in the development of hypertension. It should be stressed that the cardiac, renal, endocrine and nervous systems important in the pathogenesis of hypertension are also major targets for oxidative damage by ROS. However, these systems will not be discussed here, and the reader is referred to excellent reviews on these systems.²¹

VASCULAR PRODUCTION OF REACTIVE OXYGEN SPECIES

Although there are many pro-oxidant enzyme systems that can produce ROS in the vessel wall, four enzymes seem to predominate: non-phagocytic NAD(P)H oxidase,

Figure 30-1. Pro-oxidant and antioxidant enzyme systems in the vessel wall. NAD(P)H oxidase is the primary source of vascular reactive oxygen species (ROS), although xanthine oxidase, mitochondrial enzymes, and uncoupled eNOS also play a role, particularly in pathologic conditions. Major enzymatic defense mechanisms against ROS accumulation are GPx, catalase, TRXP, and SOD. ROS are able to scavenge endothelium-derived NO to form ONOO^- , and thereby contribute to impaired endothelium-dependent vasodilation. eNOS, nitric oxide synthase; GPx, glutathione peroxidase; NO, nitric oxide; ONOO^- , peroxynitrite; SOD, superoxide dismutase; TRXP, thioredoxin peroxidase.

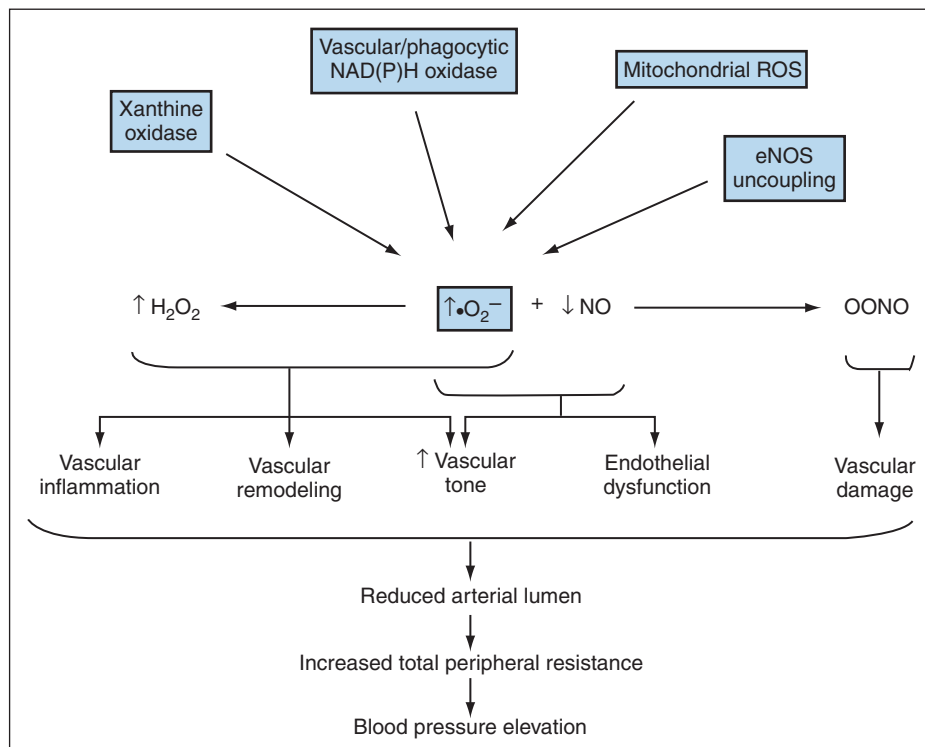

Figure 30-2. Possible role of reactive oxygen species in the pathogenesis of hypertension. Production of vascular reactive oxygen species leads to activation of multiple redox-dependent signaling pathways. These events contribute to vascular inflammation, growth, altered contraction/dilation (vascular tone) and endothelial dysfunction, which lead to vascular remodeling, arterial narrowing, increased peripheral resistance, and consequently to increased blood pressure.

xanthine oxidase, mitochondrial sources, and uncoupled NOS (Figure 30–1). Emerging evidence indicates that these systems interact such that activation of one enzyme system can influence another. This interplay amplifies ROS production contributing to further oxidative stress.²²

NAD(P)H oxidase

NAD(P)H oxidase is a multisubunit enzyme that catalyzes the production of $\bullet\text{O}_2^-$ by the one electron reduction of oxygen using NAD(P)H as the electron donor: $2\text{O}_2 + \text{NAD(P)H} \rightarrow 2\text{O}_2^- + \text{NAD(P)}^+ + \text{H}^+$.^{23,24} The prototypical and best-characterized NAD(P)H oxidase is that found in phagocytes, which comprises at least five subunits: p47phox, p67phox, p40phox, p22phox, and gp91phox (phox for *phagocyte oxidase*).²⁵ In resting cells, p40phox, p47phox, and p67phox exist in the cytosol, whereas p22phox and gp91phox are membrane associated, where they occur as a heterodimeric flavoprotein, cytochrome b558. Following activation, p47phox becomes phosphorylated, leading to the formation of a complex between the cytosolic subunits, which then translocates to the membrane and associates with cytochrome b558 to assemble the active enzyme.^{26,27} In addition, free p47phox can translocate to the membrane by itself.^{28,29} p47phox and p67phox are important in NAD(P)H oxidase assembly and play a critical role in oxidase activation and deactivation.³⁰

Non-phagocytic NAD(P)H oxidase, analogous to the phagocytic oxidase, has been demonstrated in vascular cells^{31,32} (Table 30–1). Vascular NAD(P)H oxidases possess most of the classical NAD(P)H oxidase subunits, but are structurally and functionally different from classical phagocytic oxidase, particularly with respect to gp91phox (Nox2, for NAD(P)H oxidase). Vascular cells possess Nox2 homologues, Nox1 and Nox4, which represent the catalytic subunit of NAD(P)H oxidase when Nox2 is absent. All Nox isoforms possess six transmembrane helices, conserved histidines and binding sites for NAD(P)H and FAD (Figure 30–3). Nox2 is expressed in endothelial cells and adventitial cells of large vessels and in VSMC from resistance arteries.^{33–35} Constitutive Nox1 levels are low in vascular cells, but can be induced by stimuli, such as Ang II, PDGF, and serum.³³ Nox4 is constitutively expressed and constitutively active in VSMC and endothelial cells.³⁴ All Nox enzymes require p22phox, which functions as a

Figure 30–3. Structure of Nox isoforms. All Nox isoforms possess a six-transmembrane domain, conserved histidines, two hemes, and binding sites for NADPH/NADH and FAD. In the process of $\bullet\text{O}_2^-$ production, H^+ is formed. FAD, flavin adenine dinucleotide; NADPH, nicotinamide adenine dinucleotide phosphate.

scaffolding protein for other subunits and that stabilizes the Nox enzymes.³⁶ Nox1 activity requires p47phox and p67phox, regulated by NoxO1 (Nox organizer 1) and NoxA1 (Nox activator 1), respectively.^{37,38} NoxO1 may be constitutively active with its SH3 domains always accessible for binding to Nox1.³⁸ NoxA1 seems to be expressed in a wider range of tissues than NoxO1.³⁹ The exact role of NoxO1 and NoxA1 in the vasculature remains to be clarified.

Enhanced activity of vascular NAD(P)H oxidase and increased expression of oxidase subunits have been demonstrated in spontaneously hypertensive rats (SHR) and in experimental models of hypertension.^{40–42} In cultured VSMCs, cyclic stretch, Ang II, and growth factors increase NAD(P)H oxidase activity and expression, with enhanced effects in cells from hypertensive rats and humans.^{43,44} To further support a role for NAD(P)H oxidase in Ang II-induced hypertension, mice deficient in p47phox, which have reduced oxidative stress, have lower blood pressures than wild-type counterparts.⁴⁵

TABLE 30–1. DIFFERENCES BETWEEN PHAGOCYtic AND VASCULAR NADPH OXIDASE

Characteristic	Phagocytic Oxidase	Vascular Oxidase
State of activity	Basal state inactive	Constitutively active
Mode of activity	Inducible	Inducible
Nox isoform	gp91phox (nox2)	gp91phox/Nox1/Nox4/Nox5
Pattern of $\bullet\text{O}_2^-$ release	Burst-like	Slow and sustained
Concentration released	High	Low (1%–10% of phagocytic)
Site of $\bullet\text{O}_2^-$ release	Extracellular	Intracellular
Substrate	NADPH	NADPH/NADH
Small G protein	Rac2	Rac1

Table 30–1. Differences Between Phagocytic and Vascular NADPH Oxidase

Xanthine oxidase

Xanthine oxidase (XO) generates $\bullet\text{O}_2^-$ by catalyzing the oxidation of xanthine and hypoxanthine during purine metabolism. XO reduces molecular oxygen, leading to the formation of $\bullet\text{O}_2^-$ and H_2O_2 . In the vasculature XO can produce large amounts of ROS under pathophysiologic conditions, such as atherosclerosis and ischemia-reperfusion injury.⁴⁶ This enzyme is expressed not only in vascular and endothelial cells but also circulates in the plasma. Vascular XO activity is regulated by NAD(P)H oxidase, since NADPH-driven generation of H_2O_2 stimulates xanthine oxidase activity.⁴⁷ Hence cellular generation of ROS from one enzymatic source further generates ROS formation from another. A role for XO as a vascular source of ROS in hypertension was suggested on the basis of blood pressure-lowering actions of xanthine oxidase inhibitors, allopurinol and oxypurinol, and by the finding that oxidase activity is increased in SHR.^{48–50} Vascular XO-derived ROS may be particularly important in conditions associated with endothelial dysfunction. Clinical studies demonstrated improved endothelial function by oxypurinol in patients with hypercholesterolemia but not in patients with hypertension.⁵¹ Vascular XO activity correlates inversely with endothelial function in patients with heart failure and atherosclerosis.⁵²

Mitochondrial respiratory electron transport chain enzyme

Mitochondria provide energy to the cell from adenosine triphosphate (ATP) through oxidative phosphorylation by the electron transport chain. Oxidative phosphorylation transfers electrons from NADH (and FADH_2) to O_2 to form H_2O . Mitochondria produce ROS either within the inner mitochondrial membrane by the electron transport chain or externally through the oxidation of monoamines by mitochondrial monoamine oxidase. The electron transport carrier is composed of four complexes: NADH-ubiquinone oxidoreductase complex I, succinate-ubiquinone oxidoreductase complex II, ubiquinol-cytochrome c oxidoreductase complex III, and cytochrome c oxidase complex IV. Only 1% to 2% of electrons leak out to form $\bullet\text{O}_2^-$, and this is scavenged by manganese SOD.⁵³ Under pathophysiologic conditions, the electron transport chain may become uncoupled, leading to increased $\bullet\text{O}_2^-$ production and spillover into the cytoplasm.⁵⁴ The precise contribution of mitochondrial-derived ROS to total ROS production in the vessel wall remains unclear, although it is evident that exposure of vascular cells to exogenous H_2O_2 or ONOO^- leads to mitochondrial damage, which could contribute to vascular oxidative stress.^{55,56} We recently demonstrated that in VSMCs endothelin-1 induces ROS production from mitochondrial sources.⁵⁷

Uncoupled nitric oxide synthase

Under physiologic conditions, the oxidation of L-arginine by eNOS produces L-citrulline and NO, which scavenge ROS. Under certain conditions, eNOS can become uncoupled, such that it produces $\bullet\text{O}_2^-$ rather than NO⁵⁸ (Figure 30–4). Primary determinants for this uncoupling are the availability of the NOS substrate, L-arginine, or the cofactor 5,6,7,8-tetrahydrobiopterin (BH_4).⁵⁹ If levels of L-arginine

Figure 30–4. NOS and xanthine oxidase are able to produce either $\bullet\text{O}_2^-$ or NO. In the presence of adequate substrate L-arginine and O_2 , NOS generates NO, whereas the same enzyme produces $\bullet\text{O}_2^-$ when L-arginine or co-factors, such as BH_4 , are limited. Xanthine oxidase produces $\bullet\text{O}_2^-$ under pathologic conditions, such as in reperfusion post ischemia, whereas NO formation is preferred during hypoxia. BH_4 , 5,6,7,8-tetrahydrobiopterin; NO, nitric oxide; NOS, nitric oxide synthase.

or BH_4 are low, NOS is incapable of transferring electrons to L-arginine, and instead uses oxygen as a substrate for $\bullet\text{O}_2^-$ formation.⁶⁰ This phenomenon is called “uncoupling” of eNOS, and can produce large amounts of $\bullet\text{O}_2^-$ under pathophysiologic condition, especially in situations associated with underlying oxidative stress and in the presence of endothelial damage, such as diabetes, hypercholesterolemia, and hypertension.^{61–63} Treatment of DOCA-salt hypertensive mice with BH_4 “re-couple” eNOS, leading to increased vascular NO production, reduced $\bullet\text{O}_2^-$ formation, and lowering of blood pressure,⁶⁴ suggesting that uncoupled eNOS is involved in blood pressure elevation. However, not all eNOS becomes uncoupled. Some of the enzyme continues to produce NO, favoring production of ONOO^- , which could further contribute to vascular damage.

Cytochrome P450 enzymes and other pro-oxidant enzymes

Cytochrome P450 enzymes are a large group of monooxygenase enzymes responsible for the metabolism of toxic hydrocarbons.^{8,65} CYP2 and CYP4 families are expressed in VSMCs and endothelial cells and have been shown to generate ROS in vascular tissues.^{66,67} The CYP2 family has been associated with endothelium-derived hyperpolarizing factor responses in some vascular beds.^{8,65}

Other enzymatic sources capable of generating ROS in the vasculature are phagocyte-derived myeloperoxidases, cyclooxygenases, lipooxygenases, and heme oxygenases.

VASCULAR ANTIOXIDANT ENZYMES

Superoxide dismutase

Once generated, $\bullet\text{O}_2^-$ is dismutated to H_2O_2 by the activity of superoxide dismutase (SOD).^{68,69} In vascular cells, the

SODs are a major cellular defense mechanism against increased $\bullet\text{O}_2^-$ production. Three different SOD isoforms have been identified: the mitochondrial manganese-containing SOD (Mn-SOD, SOD2), the cytosolic copper/zinc-containing SOD (Cu,Zn-SOD, SOD1), and the extracellular SOD (EC-SOD, SOD3).^{3,70,71} SOD3 is a copper/zinc-containing SOD that is mainly produced and secreted by VSMCs, and binds to glycoaminoglycans in the vascular extracellular matrix on the endothelial cell surface. SOD3 is heavily expressed in the vascular interstitium and plays an important role in the regulation of the oxidant status in the vascular wall.^{68,72} It serves to minimize the $\bullet\text{O}_2^-$ -dependent inactivation of endothelial-derived NO.

Catalase

H_2O_2 that results from the action of SODs is reduced to water by catalase and the glutathione peroxidases (GPx).^{73,74} Catalase is an antioxidant enzyme located mainly in cellular peroxisomes and to some extent in the cytosol. Catalase catalyzes the reaction of H_2O_2 to water and molecular O_2 in a two-step reaction involving compound I. The enzyme is especially important in the case of limited glutathione content or reduced GPx activity, and plays a significant role in the development of tolerance to oxidative stress in the adaptive response of cells.

Glutathione peroxidase

Glutathione peroxidase (GPx) is a selenium-containing antioxidant enzyme that effectively reduces H_2O_2 and lipid peroxides to water and lipid alcohols, respectively, and in turn oxidizes glutathione to glutathione disulfide. Reduced glutathione plays a major role in the regulation of the intracellular redox state of vascular cells by providing reducing equivalents for many biochemical pathways.^{75,76} In the absence of adequate GPx activity or glutathione levels, hydrogen peroxide and lipid peroxides are not detoxified and may be converted to OH⁻ radicals and lipid peroxyl radicals, respectively, by transition metals (Fe^{2+}). The GPx/glutathione system is thought to be a major defense in low-level oxidative stress. Four isoforms of GPx have been identified and characterized: GPx-1 (cellular GPx) is ubiquitous and reduces H_2O_2 and fatty acid peroxides, and has been inversely associated with increased cardiovascular risk.⁷⁷ Esterified lipids are reduced by membrane-bound GPx-4 (phospholipids hydroperoxide GPx), which can use several different low-molecular-weight thiols as reducing equivalents. GPx2 (gastrointestinal GPx) is localized to gastrointestinal epithelial cells. GPx-3 (extracellular GPx) is the only member of the GPx family that exists in the extracellular compartment, and is believed to be the most important extracellular antioxidant enzyme in mammals.⁷⁸⁻⁸⁰

Thioredoxin reductase

Thioredoxin (TRX), via a series of coupled reactions catalyzed by thioredoxin reductase and NADPH, also functions as an antioxidant molecule in the cytosol of vascular endothelial and smooth muscle cells. The thioredoxin system (TRX, TRX reductase, and NADPH) reduces oxidized cysteine

groups on proteins through an interaction with the redox-active center of TRX (cys-gly-pro-cys) to form a disulfide bond, which in turn can be reduced by TRX reductase and NADPH.⁸¹ The enzyme regenerates reduced thioredoxin, which serves as reducing equivalent, and may also directly reduce lipid hydroperoxides. TRX plays an essential role in cell function by limiting oxidative stress directly via antioxidant actions,^{82,83} and indirectly by protein-protein interactions with key signaling molecules, such as thioredoxin-interacting protein (TXNIP).⁸¹ TRX is ubiquitously expressed in vascular endothelial and smooth muscle cells and protects cells from H_2O_2 -induced cytotoxicity.⁸⁴ It is possible that the protective effects of TRX in endothelial cells are mediated in part through MnSOD, since induction of this enzyme by TRX is specific and because other antioxidant enzymes, including copper zinc SOD (Cu/Zn SOD) and catalase, are not induced by TRX.⁸⁵

Thioredoxin function is altered in hypertension. In cardiac, aortic, and renal tissue from SHR and stroke-prone SHR-SP, increased oxidative stress is associated with TRX down-regulation.⁸⁶ In Ang II-infused rats, induction of TRX activity is impaired. Taken together these findings suggest that decreased TRX may contribute to hypertension and its sequelae.⁸¹

Genetic determinants of reduced antioxidant capacity and relation to hypertension

A number of heritable polymorphisms of antioxidant enzymes have been associated with hypertension. In an isolated Chinese population, a variant within the catalase promoter region has been associated with essential hypertension.⁸⁷ GPx-1 deficiency, associated with a polyalanine sequence polymorphism, is associated with endothelial dysfunction, heart failure, and abnormal structural changes in the vasculature and myocardium.⁸⁸ A promoter polymorphism of heme oxygenase-1 gene has been associated with hypertension in a population of Japanese women, but not men; women with the AA genotype had an increased frequency of hypertension and use of antihypertensive agents compared with those with the AT or TT genotype.⁸⁹ Glucose-6-phosphate dehydrogenase (G6PD), the major source of cytosolic reducing equivalents for thiol balance in all cells, is a highly polymorphic gene with many functional variants.⁹⁰ Recent studies demonstrated that individuals with G6PD deficiency have an increased risk of developing hypertension, diabetes, and endothelial dysfunction.^{90,91} Glutathione S-transferase mu type 1, a protein involved in detoxification of reactive oxygen species, has recently been suggested as a positional and functional candidate gene linked to increased oxidative stress and hypertension.⁹² Quantitative real-time polymerase chain reaction showed a highly significant, four-fold reduction of glutathione S-transferase mu type 1 mRNA expression in 5- and 16-week-old SHR-SP compared with the congenic and normotensive Wistar-Kyoto rats. mRNA expression changes were reflected at the protein level, with significant reductions in the SHR-SP glutathione S-transferase mu type, suggesting a pathophysiological role of this protein in hypertension and oxidative stress.⁹³

VASCULAR EFFECTS OF REACTIVE OXYGEN SPECIES

Molecular processes in which ROS influence vascular function and structure involve activation of redox-sensitive signaling pathways. Superoxide anion and H₂O₂ stimulate mitogen-activated protein (MAP) kinases, tyrosine kinases and transcription factors (NFκB, AP-1, and HIF-1), and inactivate protein tyrosine phosphatases.⁹⁴ ROS also increase [Ca²⁺]_i and upregulate proto-oncogene and proinflammatory gene expression.^{95,96} These events occur through oxidative modification of proteins by altering important amino acid residues, inducing protein dimerization, and interacting with metal complexes such as Fe-S moieties. Changes in intracellular redox state through thioredoxin and glutathione systems may also influence signaling events.

It is important to emphasize that under physiologic conditions, ROS serve as integral components of cellular signaling pathways that contribute to normal vascular function. However, exposure to pathologic stimuli results in oxidant stress, which modifies biomolecules to modulate and alter vascular phenotype. It is becoming increasingly evident that increased ROS production may have minimal effects on vascular function and hemodynamics at baseline, but can augment the response to pathogenic stimuli. This is evidenced by recent studies,^{97,98} where smooth muscle overexpression of p22phox or Nox1 resulted in increased ROS production without much effect on blood pressure or vascular reactivity and structure. However, exposure to Ang II resulted in augmented hypertension and vascular remodeling.

Vascular growth effects of reactive oxygen species

ROS play an important role in VSMC growth. During vascular damage in hypertension, when oxidative stress is increased, redox-sensitive growth processes may lead to accelerated proliferation and hypertrophy, further contributing to vascular injury and remodeling.⁹⁹ H₂O₂ induces a dual action on cell growth, depending on its cellular localization and intracellular levels. At high concentrations (>100 μM), H₂O₂ is proapoptotic and induces anoikis (cell detachment and shedding), whereas at lower concentrations it stimulates proliferation, hypertrophy, and differentiation.^{100,101} The importance of ROS compartmentalization and spatial localization have recently been highlighted in studies examining VSMCs deficient in SOD1 (cytosolic SOD) or SOD2 (mitochondrial SOD). In SOD1-deficient VSMCs, proliferation and protein synthesis are enhanced through ERK1/2- and p38MAP kinase-dependent pathways, whereas in SOD2-deficient cells, growth is associated with preferential activation of the JAK/STAT pathway.¹⁰² Whether these differential effects are due to increased •O₂⁻ or decreased H₂O₂ remains unclear. ROS also modulate vascular structure in hypertension by increasing deposition of extracellular matrix proteins, such as collagen and fibronectin and by modulating MMPs, particularly MMP2 and MMP9.¹⁰³ ROS mediate the proliferative response to agonists such as Ang II, platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and thrombin.¹⁰⁴

Vascular inflammation

ROS can promote a vascular proinflammatory state through direct activation of leukocyte adhesion molecule expression, by inducing proinflammatory gene activation and by reducing the availability of NO.⁶⁴ NO has many anti-inflammatory actions, including inhibition of VSMC proliferation and platelet aggregation.^{64,105,106} The imbalance between ROS and NO in the vessel wall further contributes to inflammation by activation of the local renin-angiotensin system.¹⁰⁷ Ang II, which is systemically or locally elevated in various forms of hypertension, is a particularly potent mediator of ROS-dependent vascular inflammation.⁶⁴

Many of the redox sensitive vascular changes that occur in hypertension also exist in atherosclerotic vessels. In VSMCs, Ang II and TNF-α induce proinflammatory genes through the activation of NF-κB in a ROS-dependent manner.^{108,109} Increased activation of vascular NF-κB and AP-1 and associated inflammatory and mitogenic responses have been demonstrated in hypertensive rats.¹¹⁰ These actions have been attributed, in part, to oxidative excess. Oxygen radicals induce endothelial permeability with extravasation of plasma proteins and other macromolecules, and the recruitment of inflammatory proteins and cells, which also impair endothelial function and aggravate vascular damage.^{111,112} Peripheral polymorphonuclear leukocytes, which generate •O₂⁻, participate in the oxidative stress and inflammatory response in patients with hypertension.^{113,114} Interactions between H₂O₂ and peroxidases, particularly myeloperoxidase, lead to the formation of oxidizing and nitrosating species that are proinflammatory and proatherogenic. The importance of Ang II in accelerating the development of atherosclerosis in the setting of hypertension was demonstrated in apo E-deficient mice infused with Ang II. Development of atherosclerosis in these mice was 4.5 times greater than in mice made hypertensive with norepinephrine.¹¹⁵

Vascular contraction/dilation and reactive oxygen species

The direct effect of ROS on VSMC contraction/dilation is controversial. ROS appear to elicit both contraction and dilation, depending on the vascular bed and type of species generated. Hydrogen peroxide causes vasodilation of pulmonary, coronary, and mesenteric arteries, and has been considered to be endothelium derived relaxing factor (EDRF).^{116,117} In rat aorta, Ang II stimulates vasoconstriction via H₂O₂-dependent mechanisms,¹¹⁸ whereas in human and porcine vessels, acute vasoconstriction by Ang II is not mediated via ROS.^{95,119} In aortic and mesenteric arteries from SHR, hydrogen peroxide-mediated contractile effects are enhanced.^{96,120} The apparent discrepancies may be due to the blood vessel studied, the presence or absence of the endothelium, the concentration and species of the free radical studied and the compartment in which •O₂⁻ and H₂O₂ predominate.¹²¹

Vascular cell migration and reactive oxygen species

Vascular smooth muscle cell migration is one of the major features of vascular injury. PDGF-induced VSMC chemo-

taxis is inhibited by catalase overexpression, NAC, DPI, ebselen, and dominant-negative Rac, suggesting that ROS production through NAD(P)H oxidase is critical for agonist-stimulated VSMC migration.^{104,122}

REACTIVE OXYGEN SPECIES AND HYPERTENSION

Extensive experimental and clinical data implicate oxidative excess as being pathophysiologically important in hypertension. This is evidenced by findings that oxidative stress is increased in hypertension and that treatment with antioxidants or agents that inhibit NAD(P)H oxidase-driven generation of ROS reduces, and may even prevent, blood pressure elevation. Furthermore, because ROS serve as signaling molecules involved in VSMC growth and inflammation, they subserve a crucial role in mediating vascular remodeling and maintenance of hypertension.

Genetically hypertensive rats, such as SHR and SHR-SP, exhibit enhanced NAD(P)H oxidase-mediated $\bullet\text{O}_2^-$ generation in resistance arteries (mesenteric), conduit vessels (aorta), and kidneys.^{123–128} Several polymorphisms in the promoter region of the p22^{phox} gene have been identified in SHR, which could contribute to enhanced NAD(P)H oxidase activity.^{127,128} 8-hydroxy-2'-deoxyguanosine, a marker for oxidative stress-induced DNA damage, and protein carbonylation, a marker for oxidation status of proteins are enhanced in aorta, heart, and kidney, whereas endogenous antioxidants, including glutathione peroxidase and thioredoxin, are markedly suppressed in SHR and SHR-SP compared with normotensive Wistar-Kyoto rats (WKY).^{96,128,129} Diminished NO bioavailability as a consequence of enhanced vascular $\bullet\text{O}_2^-$ generation may also contribute to oxidative stress in hypertension as evidenced in eNOS-deficient mice and in rats and humans after pharmacologic blockade of NOS.¹³⁰

Oxidative excess has also been demonstrated in numerous models of experimental hypertension, including Ang II-induced hypertension,^{131,132} Dahl-salt-sensitive hypertension,¹³³ lead-induced hypertension,¹³⁴ obesity-associated hypertension,¹³⁵ mineralocorticoid hypertension,^{136,137} two-kidney, one-clip hypertension,¹³⁸ and in models of postmenopausal hypertension.¹³⁹ Enhanced activation of vascular and renal NAD(P)H oxidase and xanthine oxidase and uncoupling of eNOS have been implicated in enhanced $\bullet\text{O}_2^-$ generation in experimental hypertension.^{140,141} Mitochondrial enzymes and xanthine oxidase may also contribute to oxidative excess in cardiovascular disease.^{141,142} Inhibition of ROS production with apocynin (NAD(P)H oxidase inhibitor), allopurinol (xanthine oxidase inhibitor), quercetin (dietary flavonoid), and scavenging of free radicals with antioxidants or SOD mimetics, such as tempol, reduces oxidative stress, decreases blood pressure, and prevents development of hypertension in most models of experimental hypertension.^{123,125,143–145} These antihypertensive actions have been attributed to improved endothelial function, regression of cardiovascular remodeling, improved renal function and reduced vascular, cardiac and renal inflammation.

Clinical studies have demonstrated that production of ROS is increased whereas levels/activity of antioxidant systems is decreased in hypertensive patients.^{13,146–148} Oxidative excess has been shown in patients with essential hypertension, salt-sensitive hypertension, renovascular hypertension, malignant hypertension, and in preeclampsia.^{149–155} Most of these findings are based on elevated levels of lipid peroxidation by-products, including plasma and urine TBARS, malondialdehyde and 8-epi-isoprostanes.^{151,152} Increased plasma, platelet, and leukocyte $\bullet\text{O}_2^-$ and H_2O_2 concentrations have been demonstrated in hypertensive patients.^{153,154} Treatment with the antioxidant vitamin, vitamin C, significantly reduced blood pressure in young hypertensive patients¹⁵⁶ and had a modest blood pressure-lowering effect in elderly patients.¹⁵⁷ The beneficial actions of vitamin C have been attributed in part to increased bioavailability of NO.

Studies in cultured VSMCs derived from resistance arteries of hypertensive patients revealed enhanced formation of ROS.¹⁵⁸ Increased levels/activity of vascular NAD(P)H oxidase has been implicated as the primary source of excess $\bullet\text{O}_2^-$ in essential hypertension.^{159,160} Polymorphonuclear leukocytes, resident macrophages and platelets, all rich $\bullet\text{O}_2^-$ sources, further participate in vascular oxidative stress and inflammation in hypertensive patients.¹⁶¹ Activation of the renin-angiotensin system has been proposed as a major mediator of NAD(P)H oxidase activation and ROS production in clinical hypertension.^{162,163} Ang II is a potent stimulator of NAD(P)H oxidase and upregulates expression of NAD(P)H oxidase subunits in human VSMCs, fibroblasts, and endothelial cells.^{4–7,164} Because of this interaction between Ang II and $\bullet\text{O}_2^-$ -generating systems, it is not surprising that some of the therapeutic blood pressure-lowering actions of ACE inhibitors and AT₁ receptor blockers may be mediated by inhibiting NAD(P)H oxidase activity and reducing ROS production.^{165,166}

Although experimental evidence and clinical studies provide compelling evidence that oxidative stress is important in the pathophysiology of hypertension, not all human hypertension is redox-dependent. Also, many large clinical trials on antioxidants failed to demonstrate beneficial therapeutic effects on blood pressure and cardiovascular outcomes.^{167–171} Reasons for these discrepancies probably relate to the heterogeneous nature of hypertension and to the complexities of redox biology in the cardiovascular system. However, it is likely that ROS-dependent vascular remodeling and inflammation contributes to renal and cardiac end-organ damage.

SUMMARY

Reactive oxygen species are produced in the vasculature in a controlled and tightly regulated manner. Superoxide and H_2O_2 have important signaling properties, mainly through oxidative modification of proteins and activation of transcription factors that regulate vascular function. In hypertension, dysregulation of enzymes such as NAD(P)H oxidase, NOS, xanthine oxidase, mitochondrial enzymes, or SOD, altered thioredoxin and glutathione systems or reduced scavenging by antioxidants, results in increased

formation of ROS, which have damaging actions on the vasculature. Factors that activate pro-oxidant enzyme systems remain poorly defined, but probably involve Ang II, mechanical stretch, and inflammatory cytokines.

Reactive oxygen species in hypertension contribute to vascular injury by promoting cell growth, extracellular matrix protein deposition, activation of matrix metalloproteinases, inflammation, endothelial dysfunction, and increased vascular tone. In experimental hypertension oxidative stress is increased and antioxidant levels/activity is decreased. Clinical data indicate that hypertensive patients exhibit oxidative

excess. Although inconclusive at present, treatment strategies to alter ROS bioavailability by decreasing production and/or by increasing radical scavenging, may regress vascular remodeling, prevent further vascular injury, and reduce blood pressure in hypertensive patients. Because ROS, particularly H_2O_2 , can diffuse from vascular to parenchymal cells in various organs, it is possible that vascular oxidative excess contributes to target-organ damage and that prevention of ROS formation will lead to end-organ protection in hypertension.

Natriuretic Peptides

Jacob George and Allan D. Struthers

Definition

- Four members of the natriuretic peptide (NP) family are atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP) and dendroaspis natriuretic peptide.
- Natriuretic peptide receptor (NPR) A and NPR B receptors mediate natriuretic peptide action by generating cGMP second messengers.

Key Findings

- NPs are eliminated by a clearance receptor NPR C or enzymatic degradation by neutral endopeptidase.
- Besides natriuresis, ANP, and BNP are antimitogenic and inhibit cardiac fibrosis.
- CNP acts in a paracrine manner in regulation of vascular tone and growth.

Clinical Implications

- ANP and BNP levels are elevated in many diseases such as hypertension and heart failure.
- BNP is useful as a rule-out test in the diagnosis of heart failure but not as a population screening tool.
- NP infusions improve hemodynamic parameters but a mortality benefit in heart failure is unproven.
- Safety concerns with BNP infusion due to increased short term mortality and worsening renal function.
- Neutral endopeptidase inhibitors are potent antihypertensives but increased incidence of angioedema.

Very few significant discoveries in medical research in the last 50 years have generated as much interest and debate as the natriuretic peptide system (NPS). As more information becomes available, we are slowly beginning to comprehend the importance of this system in the maintenance of cardiovascular health and also its role in redressing the balance when pathologic states predominate. The aim of this chapter is to provide an overview of the historical background, our current understanding of the physiology and pathophysiology, and the advances in translating the knowledge we have obtained into clinical application, both diagnostic and therapeutic.

Kisch¹ first observed small granules on electron microscope examination of guinea pig myocytes as early as 1956. Eight years later, Jamieson and Palade² made the discovery that these previously described granules were secretory in nature and found in mammalian atria but not

ventricles. The exact role of these atrial granules remained elusive until 1981, when de Bold et al.³ published what was to become the seminal paper in the history of natriuretic peptides. They injected rat atrial extract into anaesthetized rats and observed a 30-fold increase in urinary sodium excretion, a 10-fold increase in urine volume, increased hematocrit and a sustained fall in arterial pressure. They repeated this with a ventricular extract but found no such effect. These results caused much interest in the scientific community and within 3 years, Kangawa and Matsuo⁴ isolated the atrial natriuretic peptide (ANP) and determined its structure. The ANP gene was then located to the short arm of chromosome 1 and later sequenced.^{5,6}

Brain Natriuretic Peptide (BNP) was then discovered by Sudoh et al.⁷ in 1988 when they reported a peptide in porcine brain (hence the name) with a similar action to ANP. Subsequent studies have shown BNP to be secreted predominantly by ventricular myocardium. In contrast to ANP, which is stored in granules, BNP is constitutively released. The BNP mRNA expression is upregulated in various conditions that will be discussed later. There is a normal physiologic expression of both ANP and BNP in health that underlines the importance of the NPS in maintaining cardiovascular homeostasis.

C-natriuretic peptide (CNP) was then isolated from porcine brain by Sudoh et al. in 1990.⁸ CNP has lower circulating levels than ANP or BNP, and is thought to act in a paracrine manner.⁹ The latest member of the NPS is the dendroaspis natriuretic peptide (DNP) which was isolated by Schweitz et al.¹⁰ from the green mamba snake (*Dendroaspis augusticeps*). It competes with ANP binding to its receptor and causes relaxation of cardiac muscles. There is very little data presently available on DNP and its precise role is still being defined.

The complete picture of the NPS with its receptors and second messengers is slowly emerging, including suggested relationships with osteoporosis and renal disease.¹¹

BIOCHEMISTRY

Structure and synthesis

The three natriuretic peptides each have a 17-amino-acid ring structure that is linked by a disulfide bond between two cysteine residues. The cyclic moiety has an especially high amino acid-sequence homology. Unlike BNP, which shows great interspecies variability, the primary structure of ANP and CNP is conserved between species.

Atrial natriuretic peptide ANP

Pre-pro ANP is a 151–amino-acid precursor which contains a 25–amino-acid signal sequence. Removal of this signal peptide during synthesis gives rise to pro-ANP, also known as a-ANP, a 126–amino-acid peptide that is stored as membrane-bound granules in atrial cardiomyocytes.¹² This is the major storage form in atrial tissue, but humans differ from other species in having β -ANP, an antiparallel dimer of ANP present in atrial tissue of patients with heart failure.¹³ β -ANP, like pro-ANP, has diuretic and natriuretic properties and a longer duration of action than ANP.¹⁴

Upon stimulation, these membrane-bound granules move to the cell surface and release stored pro-ANP,¹⁵ which is cleaved by corin or pro-hormone convertase PCI/3, a transmembrane cardiac serine protease, to produce N-terminal ANP 1-98 (NT-ANP) and the biologically active ANP-28 (or ANP 99-126).¹⁶ This processing probably occurs somewhere between secretion from atrial tissue and the entry of mature ANP into coronary sinus plasma.¹⁸

ANP-28, hereafter referred to simply as ANP, is a 28–amino-acid peptide with a 17–amino-acid ring structure closed by a disulfide bond between the two cysteine residues (see Figure 31–1). It is the major circulating form in humans and the amino acid sequence is highly conserved between species. All mammals have an identical sequence except for a single amino acid substitution.¹⁷ It has a half-life of between 2 to 5 minutes, which is much shorter than the half-life of NT-ANP, which is between 40 to 60 minutes. This explains why plasma concentrations of NT-ANP are higher than ANP.¹⁹ NT-ANP is raised more than ANP in patients with chronic renal failure and congestive cardiac failure.²⁰

In most other hormone systems, the mature hormone is processed from the precursor before storage in granules. ANP is distinct from these systems in that it is stored in a pro-hormone form, and requires a processing mechanism during and after secretion.¹⁷ Under normal conditions, ANP is mainly synthesized in the atria and released into the circulation via the coronary sinus. The quantity of ANP synthesized in the ventricles, under normal circumstances, is approximately 1% of total atrial secretion and the total ANP content of the ventricles is approximately $\frac{1}{30}$ that of the atria.¹¹ The ratios of relative abundance for ANP mRNA was 60:1 (atria–ventricles) and for BNP the corresponding ratio was 4:1.²¹ These ratios alter dramatically in heart failure when synthesis and secretion of ANP in the ventricles markedly increases, equaling production levels in the atria.²² ANP immunoreactivity is also seen in lung, aorta, adrenal, pancreas, kidney, thyroid, thymus, pituitary, salivary gland, skin, and corpus luteum tissue in rats.²³

Brain natriuretic peptide

BNP is initially synthesized as a 134–amino-acid peptide called pre-pro BNP. The secondary cleaving of a 26–amino-acid signal peptide results in the formation of pro-BNP or BNP 1-108. This molecule is cleaved by furin, an endo-protease, into BNP 32 (Figure 31–1) and N-terminal BNP (NT-BNP 1-76).²⁴ Unlike ANP, there is a large biological variation of BNP homology between

species. There is actually a greater homology between ANP and BNP within a species than between BNP molecules from different species.²⁵

BNP mRNA and BNP have been well described in atrial myocytes²⁶ and the major storage form of BNP, which is found in atrial tissue is BNP-32. However, it must be remembered that the bulk of BNP secretion is expressed constitutively, and although BNP levels are higher in atrial than ventricular tissue, the greater mass of the ventricle means that a greater proportion (60%–80%) of plasma BNP originates from the ventricle.^{27,28}

Like ANP, the biologic half life of BNP-32, hereafter referred to simply as BNP, is much shorter than that of NT-BNP (22 min vs. 120 min).²⁹ BNP is the biologically active hormone, and it is tightly regulated by precise endocrine control. NT-BNP is an inactive metabolite of pro-BNP, the blood concentrations of which do not influence the rate of myocardial hormonal secretion. Day-to-day NT-BNP levels, however, have been found to be more consistent suggesting that NT-BNP has more of an “averaging” effect, whereas BNP is more sensitive to acute changes in disease processes.³⁰

Plasma BNP levels in normal subjects range from 0.6 pmol/L to 9.8 pmol/L (these are lower than concomitant ANP levels).³¹ In all populations, women have higher BNP and NT-BNP levels than men.²⁹ In one study, women on hormone replacement therapy (HRT) had significantly higher levels than women not on HRT, suggesting that BNP production may be sensitive to estrogen regulation.³² Obesity is not only linked to lower levels of plasma BNP, but also the attenuated release of BNP and/or increase in BNP clearance. Neither, however, has been proven.³³

C-Type natriuretic peptide

CNP is mainly found in the vascular endothelium and central nervous system. It is the most prevalent natriuretic peptide in the central nervous system.¹⁷ Prepro-CNP is a 126–amino-acid polypeptide which is processed into the 103–amino-acid polypeptide, pro-CNP. Further cleaving of pro-CNP by furin results in the biologically active CNP-22 and a larger biologically inactive CNP-53.¹⁹ The predominant form of CNP in plasma is the inactive CNP-53. CNP-22, hereafter referred to simply as CNP (Figure 31–1), differs from the other natriuretic peptides in that it does not have a carboxy-terminal extension.

Dendroaspis natriuretic peptide

DNP is the latest member of the natriuretic peptide family to be identified. It is a 38–amino-acid peptide with a 17–amino-acid ring linked by a disulfide bond, similar to the other natriuretic peptides. DNP-like immunoreactivity is present in human plasma and atrial myocardium.³⁴ DNP levels are elevated in patients with heart failure and intravenous infusions of synthetic DNP are known to induce natriuresis and increase urinary cGMP in the canine coronary artery³⁵ and human internal mammary arteries.³⁶ However, there is not much more known about its role in cardiovascular hemodynamics, and therefore it will not be discussed further.

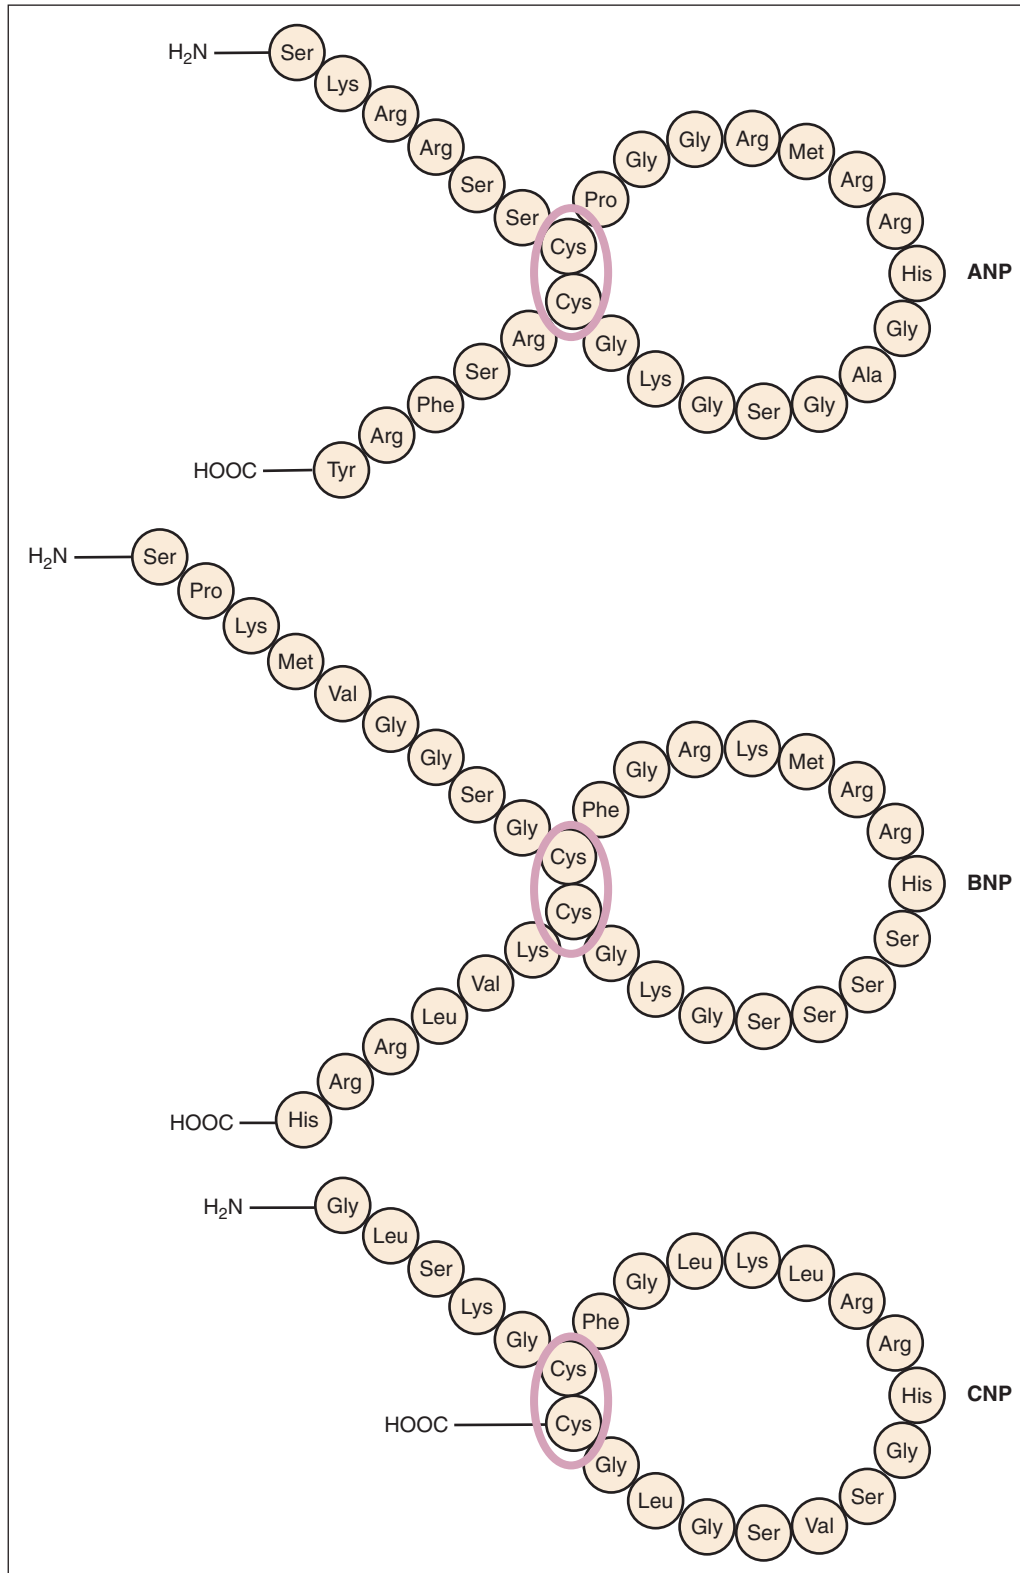

Figure 31-1. Structure of the predominant circulating forms of ANP (atrial natriuretic peptide), BNP (brain natriuretic peptide), and CNP (C-type natriuretic peptide).

GENETICS

Atrial natriuretic peptide

In humans the ANP and BNP genes are tandemly located on chromosome 1p36, only 8 kbp apart from each other.¹¹

The ventricular myocytes are major sites of expression for both ANP and BNP in embryos,³⁷ but there is a rapid reduction in this expression after birth. In patients with left ventricular hypertrophy (LVH), there is a reversion to the fetal genotype with upregulation of the ANP gene

in the ventricle.¹⁹ The ANP gene is one of the most robust responders to diverse hypertrophic stimuli, with an increase in both ANP gene expression and the number of cells producing ANP.³⁸ In spontaneous hypertensive rat (SHR) models, both genes (ANP>BNP) were expressed in the left atrium and left ventricle, but not in the right atrium or ventricle.³⁹ Expression of the gene encoding ANP is considered a marker for hypertrophy. Other genes expressed in hypertrophic myocardium are α -myosin, β -myosin, and α -tubulin.⁴⁰

ANP knockout mice exhibit a chronic salt-sensitive hypertension.⁴¹ However, studies in humans have not revealed a similar relationship between ANP and salt sensitivity of blood pressure. One study investigated ethnic differences in restriction fragment-length polymorphisms for genes encoding for renin and ANP. The investigators looked for an association with blood pressure, and found that there was an association between blood pressure and the BgII and Taq1 polymorphisms for the renin gene but no association was found with the ANP gene.⁴²

Brain natriuretic peptide

As stated earlier, ANP and BNP genes are tandemly located on chromosome 1p36, only 8 kbp apart from each other.¹¹ BNP appears to be an early-responsive gene that is upregulated at an early stage of pressure overload, well before the development of LVH.⁴³ In experimental rats, renal artery clipping produced BNP mRNA upregulation earlier than ANP mRNA but it is a transient phenomenon, indicating the difference between the gene expression of the two natriuretic peptides.²¹ The elevation of BNP gene expression in response to mechanical loading appears to result from both transcriptional and post-transcriptional mechanisms that are very dependent on myocardial pre-load and after-load.¹¹ There is evidence that the mechano-transduction pathway for induction of BNP synthesis involves myocyte cell surface integrins,⁴⁴ protein kinase C, and tyrosine kinase,⁴⁵ but the exact signaling mechanism by which this hemodynamic overload induces a rapid (approximately within 2 hours) increase in BNP mRNA levels has not yet been elucidated.

C-Type natriuretic peptide

Like ANP, CNP is highly conserved between species, and CNP-22 is identical in rat, pig, and humans, whereas CNP-53 differs in only two amino acid positions between these species. The CNP gene is localized to chromosome 2q24.¹¹ It is thought that CNP is the ancestor gene that evolved into ANP and BNP.¹¹ There are four different subtypes of the CNP gene in the animal kingdom, and it is thought that a tandem duplication of CNP-3 gene before the evolutionary divergence of teleosts and tetrapods resulted in the generation of the ANP and BNP genes. The present CNP gene in mammals, however, is thought to have arisen from the CNP-4 gene.⁴⁶

PHYSIOLOGY

The natriuretic peptides have a wide array of effects on cardiovascular hemodynamics. They exert their action by

generation of intracellular cyclic guanosine 3', 5'-monophosphate (cGMP) as second messengers. In this section, we will discuss the actions of the three main natriuretic peptides.

Atrial natriuretic peptide

Plasma ANP concentration is affected by dietary sodium intake, age, posture, and physical activity.⁴⁷ Physiologic maneuvers such as supine posture⁴⁸ and volume expansion⁴⁹ increase plasma ANP levels. Increased circulating levels are seen in congestive cardiac failure (CCF), chronic renal failure (CRF), and hypertension.

ANP mediates its effect over the short term by plasma sequestration and over the long term by promoting renal salt and water excretion as well as antagonizing the renin-angiotensin-aldosterone system (RAAS) at many levels. Both ANP and BNP antagonize the cardiac hypertrophic action of angiotensin II and continue working under conditions where endothelial nitric oxide synthase (eNOS) is compromised in conditions such as diabetes.⁵⁰ It also has inhibitory actions on the other aldosterone secretagogues such as potassium, ACTH, and metoclopramide.²⁸

In vitro studies have shown that ANP inhibits sodium transport in the inner medullary collecting duct via the NPRA receptors and production of cGMP.²⁸ There is also evidence that the release of ANP may be under the control of a neuroendocrine reflex that acts via renal and sinoaortic baroreceptor input to the hypothalamic ANP neurons.^{51,52} This release of intrahypothalamic ANP from the neurohypophysis activates the release of oxytocin, which in turn triggers the release of ANP from the heart using cardiac oxytocin receptors as effectors.⁵³ ANP has also been shown to be released from the olfactory bulb, but its function here is unclear. It has been suggested that it might produce an aversive effect on salt intake by altering salt taste.⁵³

ANP has also shown to be antimetogenic. It attenuates the growth response to adrenergic stimuli and induces apoptosis by decreasing the [³H] leucine incorporation.⁵⁴ This was shown by Klinger et al.⁵⁵ who demonstrated that transgenic overexpression of ANP in mice causes a decrease in heart weight and prevents right ventricular hypertrophy induced by pulmonary hypertension. The blockade of endogenous ANP also induces hypertrophy of cultured rat ventricular myocytes in a study by Horio et al.⁵⁶ This study also showed that endogenous ANP has a direct action on myocyte hypertrophy, which is independent of hemodynamic change. It is thought that ANP mediates its anti-hypertrophic action by a cGMP-dependent process that results in the activation of a cGMP-specific phosphodiesterase inhibitor that suppresses protein synthesis. It is also possible that ANP plays a role in regulation of myocardial growth during development in view of the fact that fetal and neonatal myocardium expresses the ANP gene and peptide even in normal development.⁵⁷

ANP is thought to mediate its hypotensive effects by a combination of increased permeability of the vascular endothelium,²⁴ vasodilation, and increased salt and water excretion. In rats, ANP has been shown to cause dilatation of afferent arterioles and constriction of efferent arterioles

within the kidney. This increases the rate of glomerular filtration and also the capillary pressure.⁵⁸ When the mechanism for arterial pressure control is impaired and body fluid volumes are elevated, such as in heart failure, large increases in atrial pressure and ANP secretion occur. The elevated plasma levels of ANP therefore are seen to exert a sustained natriuretic effect and chronically shift renal-pressure natriuresis to lower arterial pressures.⁵⁹

ANP is generally believed to be released in response to atrial myocardial stretch. The precise mechanism for ANP release is not certain, but it is thought that stretch receptors on myocardial cells are responsible. ANP (but not BNP) levels rise in response to acute atrial or ventricular pacing.⁶⁰ It is known that pacing and tachycardia increases the frequency of depolarization and intracellular inflow of calcium ions, which in turn has the effect of promoting ANP release from secretory granules.¹¹ ANP is released within 2 minutes of stretching atrial and ventricular tissues. However, ventricular secretion wanes subsequently in contrast to atrial secretion which continues to increase.⁶¹ In established heart failure, the ventricle becomes the major source of circulating ANP and it is thought that the presence of myocardial hypertrophy is a requirement for enhancing ventricular ANP gene expression.²⁸

Brain natriuretic peptide

Like ANP, the actions of BNP are mediated by cyclic guanosine 3', 5'-monophosphate (cGMP). Besides its diuretic action, BNP exerts its effect on fluid balance by causing a shift in intravascular fluid from the capillary bed into the interstitium and induces intravascular volume contraction.⁶² The natriuretic and hypotensive effect of BNP is 2-3 times that of ANP but both peptides suppress the RAAS to a similar degree (approximately one-third fall in renin activity and plasma aldosterone).⁶³ Its biological action is mediated by the natriuretic peptide receptor-A (NPR-A) and its elimination is primarily by neutral endopeptidase (NEP) enzymes and the clearance receptor NPR-C, which will be discussed later in this chapter.

Studies have also shown that intravenous BNP inhibits vascular smooth muscle cell proliferation, reduces atheroma formation, and improves endothelial function.⁶⁴ There is also evidence that BNP suppresses cardiac sympathetic activity in humans and therefore shifts sympathovagal balance in a beneficial direction. These actions are mediated by guanylyl cyclase and NP receptors.⁵⁰

All three natriuretic peptides have been shown to be capable of reducing thymidine incorporation in cardiac fibroblasts, which is an important step in the pathogenesis of cardiac fibrosis.⁶⁵ This effect is particularly pronounced with BNP infusions and mice lacking the BNP gene have been shown to develop extensive cardiac fibrosis.⁶⁶

Plasma BNP levels are raised in a wide variety of states, both pathologic and nonpathologic, such as essential hypertension, LVH, chronic heart failure (CHF), right ventricular dysfunction, pregnancy-induced hypertension, aortic stenosis, with increasing age,⁶⁷ subarachnoid hemorrhage, cardiac allograft rejection, and cavo-pulmonary connections.⁶⁸ The rate and level of increase is more significant than ANP in the various cardiovascular

diseases.⁶⁰ BNP levels are also increased by drugs such as beta-blockers, cardiac glycosides, and vasopeptidase inhibitors.

C-Type natriuretic peptide

CNP is thought to play a paracrine role in regulation of vascular tone and growth.⁶⁹ However, the exact actions of CNP remain an area for future research. It has the potential to influence arterial pressure by altering autonomic regulation of vascular tone, but there has been little evidence to translate this to a relationship with human hypertension.

It has recently been suggested that CNP functions as an endothelium-derived hyperpolarizing factor (EDHF) in some vascular beds.⁷⁰ Recent evidence on porcine models suggest a dual role of inhibition of smooth muscle cell proliferation and simultaneous promotion of endothelial cell growth.⁷¹ CNP mRNA expression in bovine endothelial cells is markedly enhanced by TGF- β , further raising the possibility of its role in vascular remodeling.⁷² CNP is also known to possess antiatherogenic properties, as inflammatory cytokines such as IL-1 β , TNF, and lipopolysaccharide are all known to stimulate the release of CNP from endothelial cells.⁷³ In addition to this, CNP also suppresses the production of proinflammatory cyclooxygenase-2 metabolites in isolated cells.⁷⁴ Thrombus formation and neointimal hyperplasia are also significantly suppressed by the presence of CNP, indicating that CNP alters leukocyte-endothelial interactions.⁷⁵

Receptors

Most biologic effects of the natriuretic peptides result from stimulation of the second messenger, cyclic-GMP, linked receptors. In terms of cGMP generation by endothelial cells, CNP is the most potent stimulus for this. BNP is slightly less potent and ANP is the least potent cGMP-generator stimulus of the three natriuretic peptides.⁷⁶ However, CNP binding affinity and stimulatory effect on cGMP production is species dependent.⁷⁷ The natriuretic peptide receptor A (NPRA) preferentially binds ANP and BNP, whereas the natriuretic peptide receptor B (NPRB) preferentially binds CNP. NPRB is the predominant guanylate cyclase-coupled receptor in the ventricle and is downregulated in the presence of LVH.

The genes for NPRA are located on chromosome 1q21, for NPRB on chromosome 9p21, and for NPRC on chromosome 5p14. NPRA and NPRB are single transmembrane domain receptors with a very similar basic structure. The NPRA is a 115-kD glycoprotein with an intracellular protein kinase-like binding domain and a guanylate cyclase (GC) domain with enzymatic activity. Activated GC increases intracellular cGMP levels and modulates downstream proteins, such as phosphodiesterases, ion channels, and cGMP-dependent protein kinases.

Several transmembrane forms of guanylyl cyclase enzymes have been identified. They have a variable extracellular NP-binding domain, a single transmembrane domain, a more conserved intracellular kinase homology domain, and a catalytic domain.⁷⁸ The homology between the protein kinase-like domain of NPRA and NPRB is

63% and 88%, respectively, between the GC domains. The extracellular domains, however, only have a 44% homology.¹¹ The magnitude of biological activity of the natriuretic peptides depends greatly on their ligand selectivity. Kishimoto and Garbers⁷⁹ found that the ligand selectivity for NPRA is greatest for ANP followed by BNP, and much less for CNP. For NPRB, however, the selectivity is greatest for CNP followed by ANP and BNP. The ligand selectivity for NPRC is greatest for ANP followed by CNP and BNP.

ANP and BNP receptors have been found in the kidney, adrenal, vasculature, brain, gonads, and pituitary. Their actions at the latter two sites mainly alter steroidogenesis and pituitary hormone secretion.⁸⁰ Recent studies suggest that NP are also directly involved in moderating the cardiac growth response to hypertrophic stimuli as seen by growth inhibitory properties in noncardiac and cardiac cells *in vitro*.⁸¹ The growth-regulating properties of the NPRA pathway appears to be distinct from the well-characterized MAP-kinase signaling cascade, which is the main effector of angiotensin II, endothelin-1, and α -agonists.⁵⁴ NPR knockout mice have an increased heart weight from birth that persists throughout life. The degree of cardiac hypertrophy in NPR-A-deficient mice is not decreased by normalizing blood pressure using four anti-hypertensive agents, which suggests that NPRA receptors regulate cardiac hypertrophy independent of blood pressure.⁵⁴

However, there are other data that contradict this. In a series of experiments with transgenic mice, Oliver et al.^{82,83} showed that overexpression of NPRA produced significantly lower blood pressure than wild-type mice, whereas NPRA knockout mice develop cardiac hypertrophy and experience sudden death. These studies show that genes for the NPS are closely involved in the mechanism of the development and progression of hypertension. They also show that mutations influencing their transcription activity, receptor binding, and cGMP-producing ability are sufficient to cause significant cardiac consequences.

The clearance receptor or natriuretic peptide receptor C (NPRC) is not linked to cGMP, and has a primary role, as its name suggests, in removal of the natriuretic peptides along with another enzyme, neutral endopeptidase (NEP). The NPRC is thought to act primarily as a clearance receptor and may also activate the phosphoinositol pathway,⁸⁴ inhibit cAMP production⁸⁵ and mediate ANP action on cell proliferation.⁸⁶ The natriuretic peptides are removed by endocytosis and lysosomal degradation.²⁴

Neutral endopeptidase

Neutral endopeptidase (NEP) or endopeptidase 24.11 is a membrane-bound metallopeptidase ectoenzyme with zinc at its active site. It is connected through a single transmembrane segment to the extracellular domain containing the active site of the enzyme.^{87,88} It is expressed in the brush border of the proximal tubule of the kidney, in vascular tissue (particularly of the lung and liver) and on vascular smooth muscle cells. It is also distributed throughout many tissues including the gastrointestinal (GI) system, lymph nodes, and pituitary.⁸⁹ Endopeptidase

24.11 is also involved in the degradation of AI, AII, bradykinin, adrenomedullin, endothelin, enkephalin, and gastrin. It inactivates the natriuretic peptides by opening their ring structure.⁹⁰ Kinetic studies show that CNP is the best substrate for NEP, followed by ANP and BNP.⁹¹

PATHOPHYSIOLOGY

The role of natriuretic peptides has been investigated in many conditions that impact cardiovascular disease either directly or indirectly. In this section, we will focus on its role in the two most studied areas, hypertension and heart failure.

Hypertension

There is a wide variation in NP levels in the population. Both ANP and BNP are elevated in hypertension with ANP:BNP ratios up to 3.8. In contrast, normal subjects have ANP:BNP ratios of 2.8, which suggest that ANP is increased to a greater level in hypertension.⁹² Plasma concentration of ANP in patients with severe or complicated hypertension is elevated and well correlated with both systolic and diastolic arterial pressure,⁴⁷ and levels fall with effective treatment of high blood pressure.⁹³ The picture is not so clear in patients with mild and uncomplicated hypertension.⁴⁷ Most studies show that diuretics and angiotensin converting enzyme (ACE) inhibitors decrease ANP whereas β -blockers have the opposite effect.^{94,95} The precise reason for this latter effect is unknown, although it is thought to be a compensatory mechanism to the central actions of these drugs.⁴⁷

Obese patients have lower plasma BNP and NT-ANP compared to nonobese patients. Diabetic patients also have low plasma NP levels, and the negative effects of obesity and diabetes on NP levels are additive.⁹⁶ This may be part of the reason that obese patients are more likely to be hypertensive. A recent study⁹⁷ showed that in obese patients, ANP levels were mainly influenced by diastolic dysfunction, whereas BNP was influenced by both LVH and LV systolic dysfunction. The authors therefore suggest that ANP and BNP can be considered a useful marker of preclinical cardiac disease in obesity.

Impaired NP responses to dietary sodium may be an early step in the development of hypertension. Ferrier et al.⁹⁸ showed that normotensive offspring of hypertensive patients had impaired plasma ANP responses to dietary sodium. Widgren et al.⁹⁹ also showed that normotensive patients with positive family histories for hypertension had blunted plasma ANP responses to volume loading. Some studies have also shown that BNP is an independent predictor of future hypertension in males and females with a family history of hypertension,¹⁰⁰ while the Framingham Heart Study data suggest that this relationship is only seen in men.¹⁰¹

The etiology of hypertension seems to have an effect on the levels of various NP subsets. Patients with renovascular hypertension have higher NT pro-ANP and BNP levels compared to patients with essential hypertension despite similar blood pressure values, but plasma ANP rises progressively with increasing severity of hypertension

in both renovascular and essential hypertension. However, these NPs are not suitable as screening tools for renovascular hypertension due to their low sensitivity in patients with this condition. NT pro-ANP seems to also be correlated with systolic blood pressure and the suggested cut-off value for hypertension is 530 pmol/L, which produces a sensitivity of 67% and a specificity of 86%.¹⁰¹

Plasma ANP and BNP have been found to positively correlate with the left ventricular mass index (LVMI)^{97,103,104} and plasma BNP, as well as with interventricular septum thickness.¹⁰⁵ However, BNP seems to have a low discriminatory power to distinguish between normal and abnormal LVMI (area under receiver operating characteristic [ROC] curve 0.59–0.62 in various studies) showing that BNP was possibly not a good discriminator (and therefore not a useful screening test) to determine the presence or absence of LVH in hypertensive patients.^{106–108} These data are contradicted by other studies which have shown that hypertensive patients with LVH have higher ANP and BNP levels compared to hypertensive patients without LVH.¹⁰³ This issue is further complicated by data from Murakami et al.,¹⁰⁴ who performed a stepwise multiple regression analysis and showed that it is atrial BNP, not ventricular BNP, which is an independent predictor of ventricular mass in patients with LVH.

It is thought that LV mass is not in itself the cause for elevated BNP levels. Although LVMI was significantly higher in athletes and hypertensive patients than in age-matched controls, plasma BNP levels were significantly higher in the hypertensive cohort compared to the athletes or age-matched controls who had similar BNP levels. This suggests that BNP is elevated in the presence of a pathologically (but not physiologically) increased LV mass.¹⁰⁹ There is a similar correlation between LV mass and the severity of aortic stenosis, suggesting that preoperative BNP level may help identify a subgroup of patients who are likely to have a worse outcome after valve replacement surgery.¹¹⁰ Experimental evidence also suggests that induction of BNP gene expression is one of the earliest responses to hemodynamic pressure overload and occurs before the onset of LVH.¹¹¹

Different patterns of LV hypertrophy seem to be related to specific natriuretic peptides. For example, there is evidence that patients with eccentric hypertrophy and concentric remodeling have raised ANP levels, but patients with concentric hypertrophy have raised levels of ANP and BNP.¹¹² This is further confirmed in patients with hypertrophic obstructive cardiomyopathy (HCM) in whom ANP mRNA is detected in significant quantities in the left ventricle myocytes.¹¹³ Both ANP and BNP levels have been found to be higher in HCM patients with diastolic dysfunction compared to HCM patients without diastolic dysfunction.¹¹⁴ There is evidence that reactivation of the whole embryonic repertoire (ANP, skeletal actin, β -myosin heavy chain) occurs in cardiac hypertrophy.⁶⁵ Of these, ANP gene reactivation is seen as one of the most sensitive markers of cardiac tissue hypertrophy.¹¹⁵

Patients with myocardial dysfunction seem to exhibit greater rises in BNP during exercise. Lim et al.¹¹⁶ found that an exercise-induced BNP rise was a significant pre-

dictor of oxygen consumption as measured by VO_2 max irrespective of the presence or absence of LVH. They have suggested that BNP may potentially act as a homeostatic mechanism that helps limit exercise incapacity in hypertensive patients.

Plasma BNP has also been shown to be an excellent marker for assessing functional impairment in patients with primary pulmonary hypertension as it is thought to parallel the extent of pulmonary hemodynamic changes and the degree of right heart failure.¹¹⁷

Heart failure

The role of BNP in heart failure (HF) diagnosis has been more extensively studied than the other peptides but there is clear evidence that both ANP and BNP are elevated in heart failure (Figure 31–2). Although CNP content in atrial and ventricular tissue is elevated in heart failure,¹¹⁸ plasma CNP and DNP are not significantly elevated in patients with hypertension or heart failure.^{34,119} In patients with congestive cardiac failure, each 1-mmHg rise in atrial pressure causes an approximate rise of 10 to 14 pmol/L in venous plasma ANP concentration.¹²⁰

The natriuretic effects of ANP and BNP, however, are markedly blunted in HF patients.¹⁹ Despite this, there is a significant correlation seen between NT-BNP and echocardiogram-derived LV ejection fraction.¹²¹ BNP levels are seen to rise with increasing severity of HF and may equal or exceed ANP levels³¹ (Figure 31–2). This pattern is also seen in right ventricular (RV) failure secondary to chronic obstructive pulmonary disease as well as patients with right ventricular dysfunction secondary to pulmonary emboli.^{122,123} However, BNP levels do not show a consistent pattern in order to differentiate RV from LV dysfunction.³³

Multivariate analyses of the FRESH-BNP study reveal that plasma NT-BNP and New York Heart Association (NYHA) classification, but not ejection fraction are inde-

Figure 31–2. Relationship between BNP and NT-proBNP and the NYHA functional classification. BNP, B-type natriuretic peptide; NT-BNP, N-terminal-proBNP; NYHA, New York Heart Association. (Data from Roche Diagnostics, ProBrain Natriuretic Peptide package insert. Indianapolis, IN: Roche Diagnostics Inc., 2004; and Biosite, Triage BNP product insert. San Diego: Biosite Inc., 2000.)

pendent predictors of peak O_2 consumption (VO_2 max).¹²¹ In a head-to-head comparison, BNP was found to be more accurate than NT-BNP in identifying patients with LV systolic dysfunction (area under ROC curve 0.83 vs. 0.79).¹²⁴ There are various strengths and weaknesses of measuring BNP or NT-BNP. On the one hand, BNP is available at the point of care, is less influenced by age and renal function and there is a single, approved cut-off point for HF diagnosis (100 pg/mL). On the other hand, the tight relation to renal function makes NT-BNP a better overall indicator of cardio-renal function and its use on large laboratory platforms makes it a much more economical test.²⁹ As many patients with HF have varying degrees of renal impairment, it must also be noted that BNP levels rise significantly in dialysis-dependent patients and does not always fall with dialysis.¹²⁵

The role of NP is not as clear in patients with diastolic dysfunction. Some studies have indicated that BNP may not be useful in identifying diastolic dysfunction in the setting of a normal ejection fraction,¹²⁶ but this is contradicted by others¹²⁷ who have shown that the area under the ROC curve for BNP to detect diastolic dysfunction is as high as 0.92. Yancy³³ suggests that the presence of a normal RV and LV function with an elevated BNP should form a diagnostic tenet for diastolic dysfunction.

Although many patients with HF have chronic disease anemia, there is an association between lower hemoglobin levels and raised BNP that is independent of age, sex, serum creatinine, LV wall motion abnormalities, LVH, history of chronic heart failure, or atrial fibrillation.¹²⁸ There is also evidence to suggest that BNP (but not NT-BNP) is also an independent predictor of sudden death in patients with chronic HF.¹²⁹

The role of BNP in heart failure seems to be as a rule-out tool as it has consistently shown to have a high negative predictive value for the diagnosis of LV dysfunction and HF.³³ The Breathing Not Properly study showed that incorporating BNP into the clinical evaluation of CHF raises diagnostic accuracy by 10% in patients whom emergency department physicians had a high confidence in the diagnosis of HF. The investigators reported 90% sensitivity and 76% specificity when 100 pg/mL was used as a cut-off for the diagnosis of HF.¹³⁰ This was also the finding of the REDHOT study,¹³¹ and is consistent with European guidelines for the diagnosis and treatment of chronic HF, which have incorporated BNP as a diagnostic test for routine clinical practice along with echocardiography and a chest x-ray.¹³² BNP testing is an economically feasible exercise as shown by the BASEL study. The investigators found that using BNP measurement in the initial diagnostic evaluation resulted in 26% lower costs from fewer admissions to the intensive care unit and a shorter overall stay.¹³³

CLINICAL IMPLICATIONS

Natriuretic peptides as population screening tool

Tsutamoto et al.¹³⁴ found that BNP is superior to ANP in predicting mortality in patients with minimally sympto-

matic left ventricular dysfunction. They showed that each 10-pg/mL increase in plasma BNP associated with a 3% increase in cardiac death over the follow-up period of the study. A recent meta-analysis showed that BNP was a strong prognostic indicator for both asymptomatic patients and for patients with heart failure at all stages of disease.¹³⁵

However, BNP testing is probably not appropriate for screening large asymptomatic populations for LV systolic dysfunction.¹³⁶ The pitfalls of BNP as a population screening tool is as predicted by Bayes theorem—the lower the prevalence of the condition screened for, the larger the false-positive rate, and hence the lower the positive predictive value.¹⁹ McDonagh et al.¹³⁷ showed that using BNP to screen for LV dysfunction in the population yielded a high negative predictive value (97.5%), but a low positive predictive value (16%), further strengthening the case for BNP use as a rule-out test. This was further confirmed by Vasan et al.¹³⁸ using data from the Framingham Heart Study.

Natriuretic peptides as treatment modality

There are two ways in which NP levels can be raised: exogenous delivery and preventing degradation. Exogenous natriuretic peptides remain effective as a treatment modality even when endogenous peptide levels are raised.

Atrial natriuretic peptide

ANP infusions in patients with essential hypertension have been shown to induce a six-fold rise in natriuresis, enhance sodium excretion, and halve plasma aldosterone.¹³⁹ Almost 20 years ago, Weder et al.¹⁴⁰ showed that at low doses, ANP inhibits both renin and aldosterone, but at higher doses a substantial fall in blood pressure results in compensatory responses that abolish ANP's effect on renin and aldosterone. As intravenous ANP infusions are not a feasible long-term option, orally active NEP inhibitors that inhibit the breakdown of ANP are being investigated for its therapeutic potential.¹⁴¹

Brain natriuretic peptide

The therapeutic use of BNP is limited to in-hospital care as it is an orally inactivated peptide and delivery requires intravenous infusion. Richards et al.¹⁴² demonstrated the effects of BNP infusions in patients with essential hypertension compared to normal controls. They showed an increase in plasma cGMP and also found that sodium excretion increased by 2.5-fold. Like ANP, plasma aldosterone levels were halved. Crucially, there were no changes to blood pressure or heart rate during the infusion, suggesting that the natriuretic response to BNP appears to be enhanced in hypertensive patients.

The main focus of research into the applicability of BNP infusions has been in the treatment of patients who are admitted to the hospital with acute decompensated heart failure. There is evidence that intravenous BNP infusions have a lusitropic but not a negatively inotropic effect on ventricular myocardium in normal and HF canine models.¹⁴³ Acute intravenous infusions of BNP lower mean systemic arterial pressure, pulmonary artery pressure (PAP), pulmonary capillary wedge pressure (PCWP), and

systemic vascular resistance (SVR). It also increases plasma cGMP and levels of plasma ANP during the first hour of infusion. It has no direct effect of cardiac output or heart rate.¹⁴⁴

In the Vasodilation in the Management of Acute Congestive Heart Failure (VMAC) study,¹⁴⁵ patients hospitalized with acute decompensated HF who were prescribed nesiritide, a recombinant form of human B-type natriuretic peptide, had significantly greater mean reduction in PCWP and fewer adverse events compared to nitroglycerin. However, there were no significant differences in 6-month mortality between the two groups, suggesting that the short-term intravenous BNP infusions may have a role as a first-time agent for hemodynamic and symptomatic improvements in the acute setting of decompensated HF. However, there have been safety concerns with nesiritide recently. The PRECEDENT study looked at the safety of nesiritide, and found that intravenous BNP in patients with decompensated HF produced significantly more hypotension than dobutamine. On the positive side, unlike dobutamine, nesiritide had no effect on arrhythmias.¹⁴⁶ A recent meta-analysis of studies using nesiritide in acute decompensated heart failure¹⁴⁷ suggested that there is an increased short-term risk of death compared to non-inotrope-based therapy. There is also recent evidence that nesiritide significantly increases the risk of worsening renal function in the same population,¹⁴⁸ but the authors caution that further appropriately powered clinical trials are needed to determine whether the worsening renal function seen with nesiritide reflects the hemodynamic effect or renal injury.

Neutral endopeptidase inhibitors

Neutral endopeptidase (NEP) inhibitors prevent the breakdown of NP mainly in vascular tissue and the kidney. In addition to increasing ANP and BNP levels, they have the effect of increasing cGMP and natriuresis. Seymour et al.¹⁴⁹ showed that in spontaneously hypertensive rat (SHR) models, NEP inhibitors potentiated ANP-induced increases in sodium excretion and falls in blood pressure. Other groups have found that in order to achieve similar falls in blood pressure by means of exogenous ANP infusions, an eight-fold rise in plasma ANP was required.

Although single-dose or limited-dose studies using NEP inhibitors show enhanced natriuresis, increased plasma, and urinary cGMP and RAAS suppression, they have demonstrated little effect on blood pressure in either normotensive or hypertensive humans.¹⁵⁰ This is because reductions in blood pressure are offset by the fact that NEP inhibition also increases plasma angiotensin II, endothelin-1, and aldosterone. This is because those substances are also substrates for NEP.^{151,152}

Studies on the effects of NEP inhibitors on BNP suggest that plasma BNP rises with a single dose of candoxatril (a novel oral neutral endopeptidase inhibitor).⁴⁷ The clinically important question of sustained inhibition is not fully known.

As NEP has been shown to be more effective in salt- and volume-dependent rather than renin-dependent hypertension, a combination with an ACE inhibitor has

been effective in treating patients with hypertension and HF.^{153–155} Other effects of this combination therapy include improved endothelial function,¹⁵⁶ increased cardiac output¹⁵⁷ and unlike single therapy with NEP, endothelin-1 levels were not increased.¹⁵⁸

Recent trials on omapatrilat, a dual NEP and ACE inhibitor, have produced inconclusive safety data. The Omapatrilat versus Enalapril Randomized Trial of Utility in Reducing Events (OVERTURE) trial¹⁵⁹ showed non-inferiority of omapatrilat compared to enalapril with regard to risk of death and hospitalization in patients with chronic heart failure. There were similar rates of angioedema in the omapatrilat and enalapril groups (0.8 vs. 0.5%). However, in the recently reported Omapatrilat and Enalapril in Patients with Hypertension: The Omapatrilat Cardiovascular Treatment versus Enalapril (OCTAVE) trial,¹⁶⁰ despite greater reductions in blood pressure on the omapatrilat arm (especially seen in black patients), the relative risk of angioedema with omapatrilat compared to enalapril was 3.17. The authors conclude that the use of omapatrilat may be appropriate in patients with difficult-to-control hypertension and in patients with increased cardiovascular risk where the risk:benefit ratio may be more favorable.

Other peptides

There are two other peptides with natriuretic properties but that have mainly vasoactive action. Thus they have not been universally accepted as major players in the natriuretic peptide system. They are urodilatin and adrenomedullin. We will discuss these two peptides in brief.

Urodilatin

Urodilatin is a peptide consisting of amino acids 95–126 of pro-ANP, and is thought to be derived from pro-ANP by an alternative processing system. It was isolated in 1988 by Schulz-Knappe et al.¹⁶¹ from human urine, and is not thought to circulate in plasma. Its actions are mediated by NPRA. It is inactivated by NPRC and by enzymatic degradation. Urodilatin is more resistant to NEP action when compared to ANP, and therefore has a more potent natriuretic than ANP.¹⁶² Studies in healthy volunteers have shown that even small doses of urodilatin may decrease PCWP, SVR, stroke volume, and cardiac output without changes in plasma volume or blood pressure.¹⁶³ Other studies in healthy volunteers have shown a potent natriuretic response to urodilatin after 1-hour infusions. Higher doses elicit an increase in anti-diuretic hormone/arginine vasopressin levels and therefore attenuate the diuresis. There is also evidence that it plays an important role in smooth muscle dilatation and immune defense.¹⁶⁴

Adrenomedullin

Adrenomedullin (AM) was first discovered from human pheochromocytoma by Kitamura et al. in 1993.¹⁶⁵ The AM gene is found on chromosome 11, which encodes for prepro-AM, a 185-amino-acid peptide. This molecule is then cleaved into a 164-amino-acid peptide called pro-AM and a signaling molecule. Pro-AM is then processed to an immature and inactive molecule with a glycine

extension, AM-Gly. The final AM molecule consists of 52 amino acids with an intramolecular disulfide bond forming a ring structure of six residues.¹⁶⁶ AM mRNA is expressed in all four compartments of the heart, but its main production site is vascular endothelium.²¹ It is also found in the adrenals, kidneys, lungs, GI tract, and uterus.

Its major effect is on vasorelaxation but it has a potent inhibitory action on vascular proliferation.¹⁶⁷ Studies have shown it to be a potent vasodilator in both coronary and pulmonary arteries,^{168,169} and a variety of experimental hypertensive rat models show an AM gene overexpression.²¹ There is very little evidence of a role for AM in heart failure with suggestions of a link with diastolic but not systolic dysfunction.

AM produces marked natriuresis and diuresis in experimental animal models, particularly in the setting of heart failure.¹⁷⁰ There is contradictory data on its natriuretic effect in humans.^{171,172} The effects of AM on other systems are beyond the scope of this chapter. For a thorough and excellent review on AM, see the review article by Bunton et al.¹⁷³

SUMMARY

The concept of the heart as an endocrine organ and the subsequent discovery of the NPS have stimulated much research and debate into how clinicians can effectively use these peptides for diagnostic and therapeutic purposes. There may be other members of this family that are yet to be discovered, and therefore the complete picture of this complex regulatory system is yet to be seen.

As we have seen, the natriuretic and anti-mitogenic effects of the natriuretic peptides attempt to counterbalance pathologic fluid-balance dynamics and hypertensive changes seen in many different clinical conditions such as diabetes, pulmonary hypertension, pregnancy-induced

hypertension, left ventricular hypertrophy, and heart failure. BNP also inhibits cardiac fibrosis by interfering with thymidine metabolism in fibroblasts. The paracrine role of CNP in vascular tone regulation, control of smooth muscle proliferation, and as an anti-inflammatory agent is slowly emerging with its recent identification as an endothelium-derived hyperpolarizing factor.

BNP and NT-BNP are generally regarded to have a higher diagnostic and prognostic accuracy than ANP and NT-ANP, but the use of BNP as a screening tool to detect left ventricular dysfunction in large asymptomatic populations is problematic. Its high negative predictive value does make it more useful as a rule-out test in symptomatic patients. However, as the Breathing Not Properly study¹³⁰ has shown, it may have a role in the evaluation of the acutely breathless patient in the emergency department setting and this has been incorporated into the latest European guidelines.¹³²

The natriuretic peptides have been licensed in countries like Japan (ANP) and the United States (BNP) for treatment of acute heart failure. However, despite its beneficial effects on hemodynamic parameters as seen in the VMAC trial,¹⁴⁵ incorporating intravenous infusions of natriuretic peptides into the management of patients admitted with acute decompensated HF have not shown a significant mortality benefit. In addition to this, intravenous infusions are not a suitable long-term management option. Agents that prevent NP breakdown such as NEP inhibitors show much promise in this respect, especially in combination with ACE inhibitors.

The next few years should see further development of more cost-effective laboratory methods of measuring natriuretic peptides (especially BNP) on larger platforms. Newer and safer vasopeptidase/neutral endopeptidase inhibitors may also emerge.

Chapter
32

Other Peptide and Related Systems including Substance P, Calcitonin Gene-Related Peptide, and Serotonin

Adrian G. Stanley

Key Findings

- Substance P is a member of the tachykinin family and exhibits both vasoconstrictor and vasodilator properties. In humans, substance P can cause vasodilatation, and low levels have been observed in hypertensive subjects suggesting loss of a potential compensatory mechanism.
- Calcitonin gene-related peptide is a potent vasodilator and induces an enhanced vasodilator response in isolated arteries from human hypertensives.
- Serotonin (5-HT) has peripheral arterial vasoconstrictor properties and can trigger platelet aggregation. Any significant influence of 5-HT on blood pressure (BP) regulation is more dependent on 5-HT receptor/transporter expression, as free-circulating concentrations of 5-HT are very low.
- Adenosine is a potent vasodilator, and is released by vascular tissue in response to ischemic or hypoxic stimuli suggesting a compensatory autocrine/paracrine role.
- Enhanced neuropeptide Y activity in the brain results in hypotension, whereas its activity in peripheral resistance vessels is vasoconstricting and has synergistic effects with noradrenaline.
- Parathormone induces a vasodilator response when infused intravenously. Parathormone concentrations in humans are positively correlated with higher BP.
- Urotensin II is the most potent vasoconstrictor known. In some vascular beds, it stimulates nitric oxide synthesis and promotes vasodilatation.

The role of neurotransmitters and other peptides in the pathogenesis and regulation of blood pressure (BP) is highly complex, swamped by contradictory evidence, and rarely taught. At present, there are very few therapeutic agents that have been developed based on the understanding of neurotransmitter activity despite evidence that some play a significant role in BP regulation.

This review will describe each peptide in turn, highlighting its biochemistry before discussing the evidence supporting its role in BP regulation. For a detailed review of the central neurotransmitter activity and baroreceptor mechanisms, readers are directed to the review by Pilowsky and Goodchild.¹

SUBSTANCE P AND OTHER TACHYKININS

Structure, genetics, and metabolism

The tachykinin family consists of substance P (SP), neurokinin A (NKA), neurokinin B (NKB), neuropeptide γ (NP γ), neuropeptide K (NPK), hemokinin 1 and endokinins A through D² and are characterized by a shared carboxyl terminal sequence, Phe-X-Gly-Leu-Met-NH₂ (where X is an aromatic [Phe or Tyr] or hydrophobic [Val or Ile] residue).³ These are deca- or undeca-peptides ranging in length between 9 and 42 amino acids and are derived from three preprotachykinin (PPT) genes: the PPT-A (now renamed TAC1) gene that contains four preprotachykinins (α -, β -, γ -, and δ -PPTA) encoding the sequence of SP, NKA, NP γ , and NPK, respectively; the PPT-B (TAC3) gene encoding the sequence of NKB³; and the PPT-C (TAC4) gene encoding hemokinin 1 and endokinins A through D.²

SP is an 11-amino acid peptide, and is predominantly synthesized in neuronal tissue.⁴ The most significant areas of synthesis are the dorsal root ganglia (DRG) that innervate the blood vessels, viscera and sympathetic ganglia that are surrounded by a dense network of (SP)-immunoreactive fibers.²

SP activity is mediated via tachykinin receptors, which consist of seven hydrophobic transmembrane domains that are connected by extra- and intra-cellular loops and coupled to G-proteins.⁵ There are three types of tachykinin receptors, namely, NK1, NK2, and NK3. Although SP's potency is greatest at NK1 (similarly, neurokinin A and neurokinin B at NK2 and NK3, respectively⁶), all tachykinins share a degree of activity with all receptors.⁷ Calcitonin gene-related peptide (CGRP) is closely associated with SP and is often co-released in neuronal tissue.⁸

Tachykinins are degraded by tissue-specific peptidases.⁹ SP is susceptible to peptidase activity from neprilysin, angiotensin-converting enzyme, dipeptidyl aminopeptidase IV, prolyl endopeptidase, and cathepsin D. The peptide products are inactive, except the neprilysin-generated fragment, which has tachykinin-like central nervous system activity.¹⁰

Generally the physiologic actions of SP include stimulation of salivary secretion, and both smooth muscle (SM) contraction and vasodilatation.¹¹

Blood pressure regulation

There is direct and indirect evidence that tachykinins have a significant influence on BP regulation. Several studies have investigated the activity of SP and other tachykinins directly either by intravenous (IV) or intracerebroventricular (ICV) injection. Intravenous (IV) injection of exogenous SP resulted in a significant vasodilator response in salt-dependent hypertensive rats (SN [subtotal nephrectomy]-salt, DOC [deoxycorticosteroid]-salt rats),¹² the inbred genetically hypertensive strain (GH) of the Otago Wistar rat,¹³ and normotensive Wistar-Kyoto rats (WKY).¹⁴ In contrast, intravenous SP resulted in an increased BP in spontaneously hypertensive rats (SHR).¹⁴

Although the “peripheral” response to SP is predominantly vasodilator, ICV injection of tachykinins or selective NK-receptor agonists increases BP and heart rate in normotensive rats and SHRs,^{15–18} and causes inhibition of renal salt and water excretion.¹⁹ Similarly, tachykinin activity at NK3 receptors in the substantia nigra of SHRs results in a peripheral pressor effect,²⁰ and NK3 receptor activation promotes release of vasopressin from the hypothalamic paraventricular nucleus.^{21,22}

SP induces the release of nitric oxide (NO) and a non-NO hyperpolarizing factor via stimulation of NK1 receptors in endothelial cells,²³ and its activity is dependent on an intact endothelium. Therefore, the vasodilator properties of tachykinins may be based on their ability to mediate their actions via the vasculature, superseding any pressor activity from enhanced central nervous system expression. In both human hypertensive subjects and spontaneously hypertensive rat-stroke prone (SHR-SP) rats, reduced levels of SP have been identified.¹¹ This suggests that SP might contribute to high BP because of insufficient synthesis, and/or release of what may be a counterregulatory hormone. Interestingly, and in contrast to the SHR-SP, the inbred genetically hypertensive strain (GH) of the Otago Wistar rat has greater levels of SP in superior cervical ganglia, and greater numbers of SP-containing sensory neurons compared to a normotensive strain. However, the primary defect causing hypertension in GH rats may be an abnormality in renal prostaglandin catabolism, and the higher SP levels observed in these rats may therefore be a compensatory mechanism.

Further evidence for SP acting as an antihypertensive compensatory mechanism is supported by studies in salt-dependent rat models of hypertension. SP antagonism by spantide-II (a potent NK1 receptor antagonist that crosses the blood–brain barrier) led to significant increases in BP in DOC-salt and SN-salt rats compared to controls.^{8,11} In addition, the SN-salt rat does not have an increase in SP DRG mRNA or peptide synthesis,⁸ suggesting that this SP-induced depressor effect may be mediated via increased vascular sensitivity (i.e., by increased endothelial NK1 receptor expression).

Tachykinin-induced pressor activity is mediated via stimulation of sympathetic ganglia. The pressor response in SHRs to SP is probably mediated by upregulation of ganglionic NK1 receptors. First, NK1 receptors are more abundant in the cervical ganglia of SHRs and NK1 receptor mRNA expression is increased compared to normoten-

sive rats. Second, the NK1 receptor antagonist GR-82334 blocks the pressor actions of the NK1 receptor agonist GR-73632, which acts on sympathetic ganglia in SHRs.²⁴ Third, greater depolarization has been observed in the superior cervical ganglionic cells within the SHRs compared to WKY rats in response to GR-73632.²⁵

In summary, the role of SP in hypertension is contradictory. In acquired models of hypertension, namely salt-dependent hypertensive rats, SP may act as a compensatory mechanism to attenuate the increase in BP, in part, by an increase in endothelial sensitivity to SP. In contrast, in genetic models of hypertension, such as the SHR, there is evidence of a SP-induced pressor effect, which may be mediated by upregulation of NK1 sympathetic ganglionic receptors. However, low levels of SP have been observed in genetic hypertension, including human essential hypertension, and alternatively, this loss of SP antihypertensive activity would be a contributory factor in the development of high BP. The role of SP in human hypertension remains to be fully elucidated.

CALCITONIN GENE-RELATED PEPTIDE

Structure, genetics, and metabolism

CGRP is a 37–amino acid neuropeptide derived from tissue-specific splicing of the calcitonin (CT)/CGRP gene.²⁶ The two CGRP genes (rat α and β , and human I and II) differ in their protein sequences by one and three amino acids, respectively. The biological activity of both peptides is very similar, and *in vivo* and *in vitro* studies have shown that CGRP is a very potent vasodilator with 100 to 1000 times more potency than SP or adenosine.^{27–29}

With similar properties to SP, CGRP synthesis is predominantly located in specific regions of neuronal tissue that innervate the vasculature and viscera (i.e., the DRG)^{28,30,31}; however, CGRP is the predominant neurotransmitter in these capsaicin-sensitive sensory nerves.³² Various stimuli (e.g., low pH, noxious heat, and tumor necrosis factor- α), can activate CGRP release.³³ Importantly, CGRP-specific receptors have been located in the media, intima, and endothelial layer of resistance blood vessels,^{23,28,31,34} and a dense perivascular CGRP neural network is seen around the blood vessels in all vascular beds.³⁵ This suggests a potential role for CGRP in BP regulation.

CGRP is a potent endothelium-independent vasodilator with positive chronotropic and inotropic effects. *In vitro* studies of vascular smooth muscle (SM) cells have shown CGRP stimulation of cyclic AMP (cAMP) through activation of adenylyl cyclase^{36–38} and activation of KATP channels, resulting in enhanced vasodilatation secondary to membrane hyperpolarization³⁰ and activation of endothelium nitric oxide synthase (eNOS).³⁹

Blood pressure regulation

Calcitonin gene-related peptide can selectively dilate multiple vascular beds,^{27,40} particularly the coronary vessels, and systemic administration of CGRP has been shown to decrease BP in a dose-dependent manner in

normotensive and hypertensive animals and humans.⁴¹ The antihypertensive activity of CGRP is thought to be mediated either by upregulation of neuronal CGRP synthesis and release or by enhanced sensitivity of the vasculature to its dilator effects in a similar manner to SP,⁴¹ with most of the evidence determined by animal models.

Synthesis and release of CGRP increases in acquired salt-dependent rat models of hypertension (DOC-salt,⁴² two-kidney, one-clip,⁴³ and SN-salt rats⁴⁴) and L-NAME-induced hypertension during pregnancy.⁴⁵ Although there is an increased neuronal expression of CGRP in DOC-salt rats, there is no change in neuronal expression of CGRP in the SN-salt model.^{46,47} This would suggest that CGRP acts as compensatory vasodilator in an attempt to counteract the BP increase in these acquired forms of hypertension, and in DOC-salt rats this occurs via increased neuronal expression of CGRP.

In genetic animal models of hypertension, the neuronal expression of CGRP is decreased. Compared to age-matched normotensive WKY rats, CGRP mRNA levels in SHR dorsal root ganglia decreased with age, but CGRP activity in the atrium and mesenteric artery of older SHR is greater.²⁹ Similarly, in another genetic animal model of hypertension (Dahl salt-sensitive rats), lower CGRP levels in the DRG have also been observed.⁶ Decreased neuronal CGRP content in the DRG, experimentally induced by capsaicin treatment in neonatal Wistar rats, ultimately leads to higher blood pressure, once these rats were fed a high-salt diet compared to non-capsaicin-treated Wistar rats. In addition, high-salt intake upregulated expression of mesenteric CGRP receptors in both treated and untreated rats without altering CGRP levels in plasma and DRG.^{48,49} These latter experiments suggest that an increased expression of vascular CGRP receptors might play a counter-regulatory role in attenuating salt-induced and genetic models of high BP.

Further evidence for this enhanced vascular sensitivity has been demonstrated in rats influenced by factors affecting the renin-angiotensin system. Long-term intravenous angiotensin II (Ang II) resulted in an increase in CGRP-receptor expression in mesenteric arteries of Wistar rats, but CGRP plasma and DRG concentrations remained normal. The increase in mesenteric CGRP-receptor expression is pressure dependent and these animals exhibited an enhanced hypotensive response to infused exogenous CGRP, which suggests an adaptive functional response of the vasculature.⁵⁰

As noted above, an age-related increase in mesenteric artery CGRP activity was found in SHRs, but not WKY rats. This decrease in CGRP nerve-fiber density was reversed in the mesenteric vessels of SHRs following treatment with temocapril or losartan, but not hydralazine despite similar and effective BP lowering.⁵¹ This suggests that long-term inhibition of the renin-angiotensin system in SHR prevents remodeling of vascular CGRP nerve fibers, and loss of its compensatory function in genetic hypertension.

The interaction of CGRP and noradrenaline has also been explored. In models of phenol-induced hypertension, there is enhanced activity of sympathetic noradrenergic

nerves associated with a decrease in the plasma concentration of CGRP, the content of DRG CGRP, and the density of CGRP nerve fibers in the mesenteric artery.^{52,53} Noradrenaline is capable of inhibiting the neurotransmission in CGRP sensory nerves via a prejunctional mechanism,⁵⁴ and thus it is likely that the decreased activity of CGRP is secondary to increased sympathetic nerve activity.⁵² How this interaction might explain the role of CGRP in human hypertension is not clear.

Few studies have explored the activity of CGRP in human essential hypertension. One study compared the response of isolated segments of small subcutaneous arteries to CGRP from patients with and without hypertension, and revealed an enhanced vasodilator response in the "hypertensive" vessels.⁵⁵ Although CGRP receptor density was not examined, it is possible that human arteries in hypertensive subjects have increased expression of vascular CGRP receptors as a compensatory mechanism similar to that described for genetic animal models of hypertension.

In summary, CGRP is a potent vasodilator. It is often co-expressed with SP in neuronal tissue, but in contrast to SP, there is no evidence of CGRP vasoconstrictor properties. Decreased CGRP neuronal activity has been identified in genetic models of animal hypertension, suggesting a possible role in the pathogenesis of hypertension. However, in most models of experimentally induced high BP, CGRP activity is enhanced. There are conflicting data regarding the exact nature of any compensatory CGRP activity, but there is a preponderance of evidence suggesting that vascular CGRP-receptor expression is either increased or its downregulation prevented.

SEROTONIN

Structure, genetics, and metabolism

Serotonin (5-hydroxytryptamine; 5-HT) is a vasoactive amine that was originally isolated from clotted blood.⁵⁶ It acts on multiple sites including the brain (influencing mood and sleep in addition to BP control), platelets (promoting platelet aggregation), the heart (positive chronotropy), and, of particular relevance to this chapter, blood vessels.

Ninety-five percent of circulating 5-HT originates from enterochromaffin cells in the intestine (via release into the portal circulation); the remainder originates from brain raphe nuclei and lung neuroendothelial cells.⁵⁷ 5-HT is synthesized from tryptophan by tryptophan hydroxylase (TPH) followed by decarboxylation.⁵⁷ Two genes code for TPH: TPH1 on chromosome 11⁵⁸ is preferentially expressed in peripheral tissues, and TPH2 is located on chromosome 12⁵⁹ and expressed predominantly in the brain.⁶⁰

Most of the circulating 5-HT is inactivated by the liver in the portal circulation, or alternatively, a smaller quantity is degraded in pulmonary endothelial cells. The remainder is taken up by platelets and stored within dense granules.⁶¹ Therefore, circulating levels of free 5-HT are usually low unless vascular damage promotes activation of platelets and thus 5-HT release. In turn, 5-HT can promote blood clotting and platelet aggregation through enhanced platelet

(5-HT_{2A}) receptor activation.⁶² Importantly, 5-HT can interact with endothelial and SM cells in the vasculature.⁶³ Seven plasma-membrane 5-HT receptors are known. In vascular tissues, 5-HT_{1B}, 5-HT₂, 5-HT₃, 5-HT₄, and 5-HT₇ are influential,⁶² particularly 5-HT₂, which is discussed in more detail below. In neuronal tissue, the lung and gastrointestinal tract, and now more recently peripheral arterial smooth muscle, a cellular 5-HT transporter (SERT) has been recognized. This is the site of action for selective serotonin re-uptake inhibitors (e.g., fluoxetine and citalopram) in the treatment of depression. This protein is localized to the cell membrane and transports 5-HT away from the cell surface for intracellular metabolism via monoamine oxidase-A forming 5-hydroxyindole acetic acid or for storage in vesicles.⁶⁴ In platelets, SERT facilitates the take-up, storage, and release of 5-HT.⁶²

Blood pressure regulation

The exact role of 5-HT in the development and maintenance of essential hypertension is unclear. Some models of hypertension have been described as 5-HT dependent, including an erythropoietin-driven model⁶⁵ and cyclosporine-induced hypertension.⁶⁶

Studies of genetic and experimental hypertension have met with equivocal and contrasting results, and clinical studies of human hypertension are few in number. In part, differences in the central compared to the peripheral action of 5-HT account for some of the uncertainty. Centrally, 5-HT has been shown to both increase and decrease BP.^{62,67,68} However, the peripheral response to 5-HT is predominantly vasoconstrictor—evidence from the isolated blood vessels of hypertensive rat models and humans reveal hypersensitivity to the effects of 5-HT.^{69–71}

In genetic rat models of hypertension, the central actions of 5-HT support the development and maintenance of hypertension. SHR has higher levels of brain 5-HT than WKY,⁶² and intracranial 5-HT injection in SHR increases BP⁶⁸ via by stimulation of 5-HT₃ receptors in the nucleus tractus solitarius.⁶⁷ However, in cat and dog models, central 5-HT injections decrease BP,⁶⁸ and cranial (intra-cisternal) injections of a serotonergic toxin (5,6-dihydroxytryptamine) did not have any effect on BP in DOC-salt rats⁷² and SHR.⁷³

As noted above, isolated peripheral vessels from hypertensive models demonstrate reactivity to 5-HT. Nevertheless, some investigators have questioned the importance of this peptide in BP regulation because of low circulating concentrations,⁷⁴ whereas others have advocated 5-HT receptor regulation as key to its pathophysiologic role.⁶⁴

Studies to determine the activity of 5-HT on the vasculature by use of a specific 5-HT receptor antagonist, ketanserin (5-HT_{2A/2C} inhibitor), have been SP inconclusive. Ketanserin lowered BP in normal and hypertensive subjects, including humans, but BP reduction was largely attributed to the α -1 adrenergic receptor blockade, rather than the 5-HT₂ receptor blockade.⁷⁵ Additional studies using 5-HT_{2A} receptor antagonists that lacked affinity for the α -1 adrenergic receptor have been mixed: ritanserin did not lower BP in hypertensive humans⁷⁶ and in SHR,⁷⁷ but sarpgrelate lowered BP in the rat.⁷⁸

The differences in response to 5-HT receptor antagonism might be explained by changes in receptor expression in different disease states. In the normotensive rat, the 5-HT_{2A} receptor mediates contraction to 5-HT in the aorta. However, in DOC-salt hypertensive rats, the 5-HT_{2B} receptor is predominant. 5-HT has a 300-fold higher affinity for the 5-HT_{2B} receptor compared with the 5-HT_{2A} receptor.⁶² Interestingly, the 5-HT_{2A} receptor remains the primary contractile receptor in mesenteric resistance arteries,⁶² and these resistance vessels likely exert a greater influence on BP regulation.

In addition to 5-HT receptors, the role of the 5-HT transporter (SERT) has been examined. The hypothesis that SERT may play a role in increasing peripheral concentrations of 5-HT is based on SSRI drugs such as fluoxetine, which have been associated with the “serotonin syndrome” and its use by some to treat orthostatic hypotension. SERT has recently been identified in endothelial cells and vascular SM cells from Sprague-Dawley rats,⁶⁴ suggesting that this may be an area for further investigation in the future.

In human studies, no differences were found in platelet-poor plasma or platelet 5-HT levels from hypertensive compared to normotensive subjects. In addition, no significant correlation was found between plasma or platelet 5-HT and BP. However, plasma 5-HT was associated with supine and standing pulse rates, predominantly in hypertensive individuals, but the significance of this is unclear.⁷⁹ In a study of essential hypertensive patients and matched normotensive healthy subjects, ranging from age 30 to 73 years, reduced uptake of 5-HT by blood platelets was evident in the hypertensive cohort. This decreased uptake was positively correlated with increasing blood pressure and age.⁸⁰ It is not possible to determine whether this finding in hypertensive individuals is in part compensatory, but may explain the higher risk of thrombo-embolism associated with hypertension.

In summary, 5-HT has the potential to cause peripheral vasoconstriction and elevation of BP. However, the exact nature of the relationship between this peptide and genetic hypertension is not clear, but any significant influence is more likely to be dependent on 5-HT receptor, SERT expression, or both, rather than circulating levels of 5-HT *per se*.

ADENOSINE

Structure, genetics, and metabolism

Adenosine (a purine nucleoside) is synthesized by both vascular (endothelial and SM) and cardiac (fibroblasts and cardiomyocytes) cells^{81–85} in response to hypoxic and ischemic stimuli. It is formed by two distinct pathways involving two substrates, namely AMP and S-adenosylhomocysteine.⁸⁶ Hydrolysis of AMP by 5'-nucleotidase to adenosine occurs at both intra- and extra-cellular sites.⁸⁷ The second pathway, hydrolysis of S-adenosylhomocysteine by S-adenosylhomocysteine hydrolase provides a significant source of myocardial cytosolic adenosine.⁸⁸

Four subtypes of adenosine receptors (A_1 , A_{2A} , A_{2B} , and A_3) in mammalian cells have been characterized.^{89,90} The vascular actions of adenosine are mediated by A_1 and A_2 receptors. Activation of A_1 receptors results in inhibition of adenylate cyclase and opening of potassium channels via G1 protein coupling. In contrast, A_2 receptor activation, similarly coupled to G1 proteins, leads to stimulation of adenylate cyclase.⁹¹

Adenosine exhibits properties that are protective against cardiovascular disease, including arterial vasodilatation,⁹² inhibition of platelet aggregation,⁹³ stimulation of nitric oxide release from vascular endothelial cells,⁹⁴ and SM cells,⁹⁵ prevention of reactive oxygen species-induced damage,⁹⁶ reduction of Ang II and noradrenaline by inhibition of renin release,⁹⁷ activation of cellular antioxidants⁹⁸ and inhibition of vascular SM cell and cardiac fibroblast growth.⁸²

Blood pressure regulation

The evidence supporting the role of adenosine in BP regulation is less ambiguous than has been described for other peptides. Arterial vasodilatation is predominately mediated via adenosine A_2 receptors,⁹⁹ and since A_2 receptor-mediated vasodilatation prevails over A_1 receptor-mediated vasoconstriction, adenosine lowers blood pressure when infused systemically.¹⁰⁰

Interestingly, adenosine activity can result in both contraction and relaxation in pulmonary arterial vessels.¹⁰¹ This dual activity seems to be dependent on the resting tone of the artery; when low, adenosine elicits a vasoconstrictor response mediated via A_1 receptors. At a higher tone, adenosine induces vasodilatation via A_2 receptors.¹⁰² In the kidney, adenosine causes vasoconstriction, since A_1 receptor-mediated constriction of the afferent arterioles prevails over the A_2 receptor-mediated vasodilatation.¹⁰³

Further evidence of the contrasting effects of A_1 and A_2 receptors has been identified in chronic and short-term treatment of normotensive rats with adenosine receptor antagonists. DPSPX (1,3-dipropyl-8-sulphophenylxanthine—a nonselective antagonist of adenosine receptors) given for 7 days leads to marked hyperplastic and hypertrophic alterations of the blood vessel walls and increase in blood pressure.^{104,105} In contrast, specific A_1 antagonists KW- and FK-838 attenuated the development of hypertension in the Dahl salt-sensitive rat.^{106,107}

The A_1 and A_2 receptors also differ in their diuretic and natriuretic properties. Selective A_1 receptor antagonists (such as 1,3-dipropyl-8-cyclopentylxanthine; DPCPX), but not selective A_2 receptor antagonists, produce diuresis and natriuresis in animal models including the SHR with a concomitant reduction in BP.¹⁰⁸

An investigation of the role of nitric oxide (NO) in adenosine A_2 receptor-mediated vasodilatation in normotensive (WKY) and hypertensive (SHR) rat aortic ring preparations suggested adenosine A_2 receptor-mediated vasodilatation was in part endothelium dependent, possibly by releasing NO. Thus, endothelial dysfunction may be one of the factors leading to attenuation of adenosine receptor and receptor-mediated responses in SHR.¹⁰⁹ Increased adenosine deaminase activity may also be a factor. In

aortic and renal afferent SM cell culture, increased adenosine deaminase activity led to decreased extracellular levels of adenosine in SHR SM cells compared to WKY rat cells; treatment with an adenosine deaminase inhibitor normalized these differences in extracellular adenosine levels and cell proliferation.¹¹⁰

Differences in the human adenosine receptor gene have been investigated after manipulation of the A_{2A} receptor (ADORA2A) gene was shown to increase blood pressure and heart rate in mice.¹⁰⁶ The results are not conclusive. In a human population of 249 unrelated hypertensive individuals and 249 normotensive control subjects, association analysis for both allele and genotype frequencies for the adenosine-receptor gene variants (ADORA1, ADORA2A, and ADA) did not reveal any significant differences.¹¹¹ In a Caucasian American population,¹¹² the A_1 receptor (ADORA1) chromosome 1 band q was shown to have the highest logarithm of odds (LOD) score (2.96) linked to diastolic blood pressure.

The renin-angiotensin system may be involved in hypertension induced by nonselective adenosine receptor blockade (DPSPX). Plasma Ang II levels were higher, plasma renin activity increased,¹¹³ and the maximum contractile effect of Ang II was lower in DPSPX-treated hypertensive rats compared with control rats.¹¹⁴ Similarly, co-treatment of DPSPX-treated rats with captopril (angiotensin-converting enzyme inhibitor) or losartan (an angiotensin-II receptor antagonist) prevented DPSPX-induced hypertension and morphologic changes.^{113,115} Atenolol (a β -adrenoceptor blocker) prevented the rise in blood pressure,¹¹⁵ but not the morphologic changes.

In human studies, exogenous adenosine intravenous infusion into the left anterior descending coronary artery stimulates the release of renin and Ang II from the coronary arteries of essential hypertensive patients, but not normotensive control subjects. This observation was negated by angiotensin-converting enzyme inhibition.¹¹⁶ In eight patients with essential hypertension, the administration a 100-mg single dose of FK453 (novel A_1 receptor antagonist) resulted in increased sodium excretion, decreased BP, and increased heart rate, the latter occurring once the natriuresis was complete. The natriuretic and BP-lowering actions of FK453 was short-lasting, as continued daily treatment of FK453 for 7 days did not reveal long-lasting effects.¹¹⁷

In summary, adenosine is synthesized by vascular tissue in response to hypoxic stimuli, and its activity on blood vessels is greatest at the A_2 receptor, which results in vasodilatation, suggesting a compensatory role. There is some evidence of synergism with NO and the renin-angiotensin system in experimental animal models and human hypertensive subjects. However, the role of adenosine in the pathogenesis of hypertension is not conclusive.

NEUROPEPTIDE Y

Structure, genetics, and metabolism

Neuropeptide Y (NPY) is a 36-amino acid peptide extensively expressed in the paraventricular nucleus, ventro-

lateral medulla, nucleus of tractus solitari, presynaptic bulbospinal neurons of the brain stem, and sympathetic fibers innervating blood vessels.¹¹⁸ Four subtypes of NPY receptors have been identified in rat brains and five in mice (Y_1 , Y_2 , Y_4 , Y_5 , and Y_6 in mice),^{119,120} but Y_1 predominates.¹¹⁹ NPY receptors belong to the G-protein coupled-receptor family, and activation leads to inhibition of cAMP accumulation.¹²⁰

This neuropeptide is an important cardiovascular neuromodulator and exhibits opposing properties. It co-localizes in neural tissue with noradrenaline. NPY is released on sympathetic nerve stimulation across mammalian species,¹²¹ and in human disease, most notably heart failure.¹²² NPY actions include vasoconstriction,¹²³ vasodilatation,¹²⁴ inhibition of noradrenaline release,^{125,126} potentiation of other vasoconstrictors,¹²⁷ and stimulation of the mitogenesis of vascular SM cell growth¹²⁸ and angiogenesis.¹²⁹

The human NPY gene is located on chromosome 7p15.1.¹³⁰ Genetic studies have highlighted a thymidine-to-cytosine polymorphism (T1128C), which results in a substitution of leucine to proline in the signal part of the preproNPY coding region.¹³¹ A prospective study of 1032 hypertensive patients investigated T1128C polymorphism in the NPY gene and presentation of cardiac disease. The frequency of the NPYT1128C polymorphism was significantly higher in patients with a myocardial infarction or stroke, as compared to those who remained event-free (8.4% vs. 5.1%).¹³² In population studies, the frequency of heterozygotes for NPYT1128C polymorphism ranges from 0% to 15%, the highest prevalence in Finns.¹³³

Blood pressure regulation

The role of NPY in the regulation of BP needs to be evaluated in terms of its central and peripheral actions. Like other neurotransmitters, it is co-expressed with other neurohumoral factors and in the case of NPY, its activity is linked to the sympathetic nervous system. However, detailed investigation of the role of NPY in animal models has been limited due to the lack of specific NPY receptor agonists/antagonists.

In the brain, all NPY receptors are expressed, and thus specific activity against a particular receptor has not been identified. However, ICV infusion of NPY in normotensive rats results in hypotension and bradycardia,¹³⁴ and noncardiovascular features including increased feeding¹³⁵ and depressed spontaneous locomotor activity.¹³⁶ Similarly, in a transgenic rat model overexpressing NPY ameliorated L-NAME-induced hypertension, and ICV administration of a specific Y_1 receptor antagonist (BIBP3226) blocked this effect.¹²⁶

In peripheral resistant arteries, NPY nerve density is higher in the SHRSP than WKY rats, but no difference was found in cerebral arteries. Sympathectomy led to almost complete removal of NPY neuronal tissue in the peripheral vessels, but without an effect on the cerebral arteries.¹³⁷ Similarly, an increase in NPY is evident in the mesenteric vessels of SHRs, but in a rat model of hypertension induced by coarctation, there was no increase in mesenteric artery NPY content,¹³⁸ which suggests that this

neurotransmitter may be influential in “genetic” but not acquired hypertension.

B_2 -adrenergic receptor and neuropeptide Y are co-expressed in sympathetic neurons. The synergy between the sympathetic nervous system and NPY at a post-junctional nerve level allows NPY activity to increase noradrenaline-induced vasoconstriction.¹³⁹ In vessels such as the mesenteric artery, the direct constrictor action of NPY and the potentiation of noradrenaline are linked to Y_1 -receptor activation.¹²¹ Further studies have suggested that NPY exerts vasoconstrictive effects by activation of postjunctional Y_1 receptors and potentiation of tyramine and Ang II activity.¹⁴⁰

In addition, noradrenaline and NPY have prejunctional inhibitory actions on sympathetic neurotransmission, and can negatively regulate their own expression as well as the expression of each other. As an example, NPY controls B_2 -agonist-regulated lipolysis via sympathetic innervation of adipocytes¹⁴¹ affecting energy balance, lipid mobilization, and circulating lipids. In a study of patients with essential hypertension, elevated LDL cholesterol was associated with polymorphisms of the B_2 -adrenergic-receptor gene (Arg16Gly and Gln27Glu) and the NPY gene (Leu7Pro); however, all three polymorphisms were required for this relationship to exist.

In summary, NPY is expressed in the brain and with sympathetic neurons in peripheral blood vessels. In the brain, NPY activity results in hypotension, whereas its activity in peripheral resistance vessels is vasoconstrictor and has synergistic effects with noradrenaline. Genetic models of rat hypertension have increased mesenteric artery NPY content, but the exact role of NPY in the pathogenesis of hypertension is not clear.

PARATHORMONE AND PARATHORMONE-LIKE SUBSTANCES

Structure, genetics, and metabolism

Mammalian parathormone (PTH) is secreted by the parathyroid glands as a polypeptide containing 84 amino acids, and has a molecular weight of approximately 9.4 kDa. It is formed from preproparathyroid hormone (preproPTH), a 125-amino acid peptide encoded on chromosome 11.

PTH has a fundamental role in calcium and phosphorus metabolism. PTH regulates the conversion of 25-hydroxyvitamin D to the active metabolite 1,25(OH)₂D₃, and therefore stimulates and regulates bone remodeling, and influences the control of plasma calcium levels. In turn, 1,25(OH)₂D₃ causes marked suppression of both preproPTH mRNA and PTH secretion.¹⁴²

The amino terminal region of PTH, which regulates mineral ion homeostasis, shows high sequence conservation with PTH-related peptide (PTHrP), but less homology in the middle and carboxyl terminal regions.

The single G-protein-coupled receptor, now referred to as the common PTH/PTHrP receptor or PTHR1, mediates most of the actions of PTH in mineral ion regulation and is critical to its actions on bone and kidney.¹⁴³ The gene

encoding the PTHR1 is located on chromosome 3 in humans.¹⁴⁴ Activation of PTHR1 stimulates the production of intracellular cAMP and inositol 1,4,5-trisphosphate.¹⁴⁵ The carboxyl terminal PTH receptor may function as an antagonist of the actions of amino terminal PTH and PTHR1, but this is less well characterized.¹⁴⁴

Blood pressure regulation

In experimental rat and rabbit models, infused PTH is a vasodilator, lowers blood pressure,^{146–148} and attenuates noradrenaline and Ang II–induced BP increases in rats.^{146,148} This vasodilator action may result from PTH ability to elevate intracellular cAMP via activation of adenylate cyclase¹⁴⁹ and/or inhibit calcium entry into vascular SM cells.^{150,151}

However, chronic infusion of PTH into normal human subjects results in hypertension.¹⁵² PTH has been implicated in the development of hypertension in humans and animal models of genetic hypertension. There are several studies to support this. Hypertension occurs more frequently in humans with primary hyperparathyroidism compared to those with normal parathyroid function.¹⁵³ In addition, excluding primary hyperparathyroidism, higher serum PTH levels correlate to higher BP in young hypertensive men,¹⁵⁴ young untreated hypertensives,¹³⁴ and both hypertensive and normotensive elderly persons.^{155,156} However, the data are inconsistent in normotensive subjects: in younger study populations, one study demonstrated a positive correlation of serum PTH levels to clinic systolic BP and mean arterial pressure,¹⁵⁷ while another found no relationship.¹³⁴

Whereas primary hyperparathyroidism results in high serum calcium levels, secondary hyperparathyroidism might reflect a reduced dietary calcium intake, and hypertensive individuals are more likely than normotensive subjects to be consuming low-calcium diets.¹⁵⁸ This is fundamental given that calcium regulation influences vascular SM contraction. Studies investigating the relationship of serum calcium to BP are also inconsistent: lower serum ionized calcium concentrations¹⁵⁹ and lower serum 1,25(OH)₂-vitamin D concentrations¹⁶⁰ have been observed in hypertensive compared to normotensive subjects. But other studies have not identified any relationship,^{155,161} including a study of elderly subjects in which PTH levels, but not serum calcium and 1,25(OH)₂-vitamin D, correlated to ambulatory BP measurements.¹⁵⁵ A study of platelet intracellular calcium in primary hyperthyroid, hypertensive, and normotensive patients revealed that patients with essential hypertension had increased concentrations of platelet intracellular calcium and this correlated positively with BP level.¹⁶²

Several reasons may account for the contradiction of a PTH-induced vasodilator response observed in experimental models and the finding of high PTH in hypertensive individuals. First, several studies have suggested PTH/PTHrP receptor adaptation (homologous desensitization or downregulation) to prolonged high concentrations of PTH.^{163,164} Second, a parathyroid hypertensive factor (PHF) has been identified in both humans and SHR.¹⁶⁵ PHF-like activity levels are elevated in hyper-

tensive individuals¹⁶⁶ and in normotensive rats; intravenous PHF induces a rise in BP.¹⁶⁷ Parathyroidectomy of hyperactive parathyroid glands in SHR and humans with essential hypertension leads to lowering of BP and decreases the activity of PHF.^{168–170} Interestingly, PHF, like PTH, is suppressed by high dietary calcium intake.¹⁶⁶

In summary, there is a predominance of evidence that PTH is positively correlated with high BP, but the exact contribution of PTH, its related peptide PHF, and calcium metabolism in the pathogenesis of hypertension has not been fully elucidated.

UROTENSIN

Structure, genetics, and metabolism

Urotensin II (U-II) isopeptides have a cyclical structure and are 11 to 15 amino acids in length. The C-terminus ring structure is preserved, but the N-terminus tail varies in content and length.^{171,172} Human U-II (hU-II) is an 11–amino acid peptide with its encoding gene, UTS2, located at 1p36. The spinal cord has the highest concentration of human prepro-U-II mRNA, but it has also been found in the brain, vascular and cardiac cells, kidney, liver, lung, pancreas, intestine, and other tissues.¹⁷³

The receptor for hU-II is a G-protein–coupled receptor 14 (GPR14).^{174,175} This receptor, now termed UT or sensory epithelia neuropeptide-like receptor, is a 389–amino acid, seven-transmembrane, G-protein–coupled receptor encoded on chromosome 17q25.3.¹⁷⁶ It shares 75% homology to rat GPR14, and is similar to the somatostatin receptor SST4 in structure.^{174,175} The highest density of the UT receptor has been identified in the brain and skeletal muscle; other tissues include the spinal cord, cardiac and vascular cells, renal cortex, adrenal gland, and thyroid.¹⁷³

Urotensin II is the most potent vasoconstrictor known,¹⁷⁴ mediated via UT. In addition to its vascular effects, U-II acts on the brain (stimulating prolactin and TSH release), kidney (increasing epithelial cell proliferation), and pancreas (inhibiting glucose-stimulated insulin secretion).¹⁷⁷

Blood pressure regulation

There are epidemiologic data to support a relationship between U-II and human essential hypertension. In a study of 62 individuals with hypertension and 62 age-matched normotensive controls, plasma U-II levels were significantly higher in the hypertensive group and correlated positively with the systolic blood pressure.¹⁷⁸ Although no differences in mean plasma or cerebrospinal fluid U-II were observed in another study comparing 10 patients receiving long-term treatment for essential hypertension and 10 age-matched normotensive subjects, a positive correlation was noted for levels of cerebrospinal fluid U-II and BP.¹⁷⁹ In addition, U-II excreted in urine was significantly higher in patients with essential hypertension than in normotensives, and in patients with hypertensive renal disease compared to normotensive patients with renal disease.¹⁸⁰

Urotensin II has predominantly peripheral vasculature effects and produces variable responses depending on species and vascular tissue.^{181–183} In rats, U-II increased tone in isolated thoracic aorta with 10-fold greater efficacy than in abdominal aorta, in part as a consequence of thoracic membrane preparations exhibiting a greater expression of UT receptors.¹⁸⁴ Similarly, UT receptor mRNA is evident in rat arterial, but not venous SM cells, and a vasoconstrictor response to U-II was only found in arteries.^{174,175} In humans, hU-II–induced vasoconstriction of coronary, mammary, and radial arteries is 50-fold more potent than endothelin-1 (ET-1). But a greater density of ET-1 receptors on coronary and mammary arteries results in a greater maximal response, as a third of these vessels exhibiting responses to ET-1 do not to respond U-II.¹⁸⁵

In contrast, inconsistencies in human U-II biological activity have been highlighted by studies demonstrating a lack of response to hU-II in small muscular pulmonary arteries, abdominal resistance vessels, skeletal muscle resistance arteries, and small subcutaneous arteries and veins.^{186,187} Interestingly, U-II causes relaxation in rat isolated small mesenteric arteries.¹⁸⁸ There is some evidence that U-II upregulates human¹⁸⁹ and rat¹⁹⁰ eNOS, which would suggest a hypothesis that U-II can cause arterial vasodilatation via NO, but causes vasoconstriction in diseased vessels without an intact endothelium.

The UT receptor is expressed extensively in the glial cells within the brain stem, hypothalamus, and thalamus,¹⁹¹ and a central role for U-II has also been identified: ICV injections of U-II elicited a dose-dependent increase in blood pressure and heart rate in both SHR and normotensive WKY rats (greater in the SHR). Direct microinjection of U-II into the paraventricular nucleus of the hypothalamus and the arcuate nucleus also significantly increased BP and heart rate.¹⁹² This U-II activity could be prevented by ganglion blockade, suggesting that it was, in part, mediated by the autonomic nervous system.¹⁹³

In healthy sheep, an ICV infusion of U-II resulted in increased cardiac output and BP, but peripheral vasodilatation was noted in most vascular beds, suggesting that the increase in BP was dependent on the increased cardiac output,¹⁹⁴ rather than peripheral vasoconstriction.

In summary, U-II is a potent vasoconstrictor, but has some vasodilating properties in specific vascular beds, notably in nondiseased blood vessels via enhanced NO activity. The central action of U-II, in part mediated via the autonomic nervous system, leads to increased cardiac output and resultant higher BP.

VASOACTIVE INTESTINAL PEPTIDE

Structure, genetics, and metabolism

Vasoactive intestinal peptide (VIP) is a 28-residue peptide, derived by proteolytic cleavage from a 170–amino-acid precursor preproVIP¹⁹⁵ localized to chromosome 6.¹⁹⁶ This peptide is present in many tissues, including the brain, heart, intestine, lungs, thyroid, and kidney, and its actions include vasodilatation, bronchodilation, anti-inflammatory actions, immunosuppression, and SM relaxation. In the brain (cerebral cortex, hypothalamus, amygdala, hippocampus, corpus striatum, and medulla oblongata), VIP acts as a nonadrenergic, noncholinergic neurotransmitter.¹⁹⁷ In the heart, VIP immunoreactive nerve fibers are present in the epicardial coronary vessels, atria, ventricles, and conducting system (sinoatrial and atrioventricular nodes), and has 50 to 100 times more vasodilator potency than acetylcholine, with significant effects on coronary blood flow, cardiac contraction, and heart rate.¹⁹⁸

Blood pressure regulation

The role of VIP in the development of hypertension has been explored in rat models. VIP nerve density is higher in the superior mesenteric arteries and veins of 6-month or older SHR-SP compared to WKY rats, and lower in the cerebral arteries of SHRSP than WKY. Sympathectomy reduced the density of these nerves in all peripheral vessels, but had little effect on the cerebral arteries.¹³⁷ However, concentration and peripheral release of VIP were lower in SHRSP at 8 to 48 weeks of age compared to WKY.¹⁹⁹ It is not certain whether this has any significance for human hypertension pathogenesis.

SUMMARY

The role of neurotransmitters and other peptide systems in the pathogenesis of hypertension is unclear, with differences in plasma levels of these substances and the target organ levels of their cognate receptors reported between hypertensive patients and normotensive subjects. Some of the published data are contradictory. However, some of these discrepancies may be resolved with further investigation of the physiologic regulation of these peptide systems in humans, especially with the advent of specific pharmacologic agonists and antagonists and the availability of genetic knock-out animal models.
