Chapter
63**Hypertensive Urgencies and Emergencies***Ehud Grossman and Franz H. Messerli***Definition**

- A hypertensive crisis is defined as a severe elevation in blood pressure (BP), such as a diastolic BP above 120 to 130 mmHg, and is classified as either an emergency or urgency.

Clinical Implications

- Hypertensive emergencies are relatively rare and are said to be present only when BP elevation confers an immediate threat to the integrity of the cardiovascular system.
- In a hypertensive emergency, immediate reduction in BP is required to avoid further end-organ damage, generally by intravenous therapy in an intensive care setting, to lower the mean arterial pressure by 25% over the initial 2 to 4 hours with the most specific antihypertensive regimen. Fenoldopam, labetalol, nicardipine, and sodium nitroprusside are the most popular agents for treatment of hypertensive emergencies.
- Hypertensive urgencies are common and are said to be present when severe elevation in BP is not associated with end-organ injury.
- There is no scientific evidence that acute BP lowering is beneficial in hypertensive urgency. The appropriate approach is to lower BP gradually over 12 to 24 hours with oral antihypertensive agents. Any drug that lowers BP precipitously should be avoided.

Hypertensive crisis is defined as a severe elevation in blood pressure (BP), such as a diastolic BP above 120 to 130 mmHg; it can be subclassified as either emergent or urgent.^{1,2} Hypertensive emergency is relatively rare and defined as such only when there is an immediate threat to the integrity of the cardiovascular system (Box 63–1). Patients with a hypertensive emergency require an immediate reduction in BP to avoid serious end-organ damage, generally by means of intravenous therapy in an intensive care setting.²

Unlike patients with a hypertensive emergency, patients with severe elevation in BP who have no evidence of progressive end-organ injury are classified as having an urgent hypertensive crisis and require only a gradual reduction in BP over a period of 12 to 24 hours.²

It has been estimated that approximately 1% of patients with hypertension will develop a hypertensive crisis at some point during their lives.³ The incidence of hyper-

tensive crisis has increased over the past four decades. Hospital admissions for hypertensive emergency in the United States more than tripled between 1983 and 1990 from 23,000 to 73,000 per year.³ According to one study, the prevalence of hypertensive crisis in an emergency room in 1 year is 3% of total patients, but 27% of all medical urgency emergencies.⁴ Before it was possible to treat accelerated malignant hypertension, survival was 20% and 1%, for 1 and 5 years, respectively. During the last two decades survival improved, with a 10-year survival rate of 67% and mean survival of 18 years being reported.⁵ Therapy has dramatically reduced immediate deaths from hypertensive encephalopathy, acute renal failure, hemorrhagic strokes, and congestive heart failure.

ETIOLOGY AND PATHOGENESIS

Hypertensive emergency can develop *de novo* or can complicate underlying essential or secondary hypertension.³ Renal parenchymal diseases accounts for up to 80% of all secondary causes, with chronic pyelonephritis and glomerulonephritis being the most common diagnoses. The factors that lead to the severe and rapid BP elevation in patients with hypertensive emergency are poorly under-

Box 63–1**Definition of a Hypertensive Emergency**

Moderate to severe elevation of arterial pressure associated with:

1. Malignant hypertension^a
2. Intracranial hemorrhage
3. Atherothrombotic cerebral infarction
4. Acute congestive heart failure
5. Acute coronary insufficiency
6. Acute renal insufficiency
7. Acute aortic dissection
8. Adrenergic crisis (pheochromocytoma crisis, clonidine withdrawal, food and drug interactions with monoamine oxidase inhibitors, amphetamine overdose)
9. Eclampsia

^aMalignant or accelerated hypertension is a syndrome characterized by elevated blood pressure accompanied by encephalopathy or nephropathy or by papilledema and/or microangiopathic hemolytic anemia.

stood. The rapidity of onset suggests a triggering factor superimposed on preexisting hypertension. The release of humoral vasoconstrictor substances from the stressed vessel wall is thought to be responsible for the initiation and perpetuation of the hypertensive emergency. Mild to moderate increase in BP does not affect target-organ perfusion because of the autoregulatory mechanisms. However, severe BP elevation above the autoregulatory threshold leads to transmission of the pressure to small distal vessels, causing endothelial injury. The endothelial dysfunction leads to increased vascular wall permeability, cell proliferation, and activation of the coagulation cascade and platelets, resulting ultimately in fibrinoid necrosis of small blood vessels, release of vasoconstrictor substances, and tissue ischemia. The initial vascular damage leads to a vicious cycle of further vascular injury, tissue ischemia, and release of more vasoconstrictor substances. Renal ischemia causes activation of the renin-angiotensin system that plays a central role in the initiation and perpetuation of the vascular injury characteristic to hypertensive emergency. In addition to activation of the renin-angiotensin system, vasopressin, endothelin, and catecholamines are postulated to play important roles in the pathogenesis of hypertensive emergencies.⁶

EVALUATION OF PATIENTS WITH HYPERTENSIVE CRISIS

Early triage is critical in an effort to ensure the most appropriate therapy for each patient.⁷ A brief but thorough history should address duration as well as severity of hypertension, all current medications, including prescription and nonprescription drugs, and the use of recreational drugs. Direct questioning regarding the level of compliance with current antihypertensive medications may establish inadequacy of therapy. Information regarding neurologic, cardiovascular, and/or renal symptoms and specific manifestations, such as headache, seizures, chest pain, dyspnea, and edema is important for the correct diagnosis. A history of other comorbid conditions and prior cardiovascular or renal disease is critical for the initial evaluation.

Physical assessment should start with BP measurement in both arms, with an appropriate size cuff. A careful cardiovascular examination as well as a thorough neurological examination, including mental status, should be conducted. A careful funduscopic examination should be performed to detect hemorrhages, exudates, and/or papilledema.

Initial laboratory evaluation should include urinalysis with sediment examination, a stat chemistry profile, and an electrocardiogram. Laboratory results together with a complete history and thorough physical examination should enable a clinical assessment of the degree of target-organ involvement and should facilitate the selection of an appropriate antihypertensive agent for initial treatment.

Proteinuria, red blood cells, and/or cellular casts in the urine are suggestive of renal parenchymal disease. Electrolyte abnormalities and evidence of renal dysfunction may suggest secondary hypertension. The electrocardiogram should identify evidence of coronary ischemia and left ventricular hypertrophy, and pulse deficits should raise

the question of aortic dissection. A computed tomographic (CT) scan of the head should be considered when the clinical examination suggests cerebrovascular ischemia or hemorrhage, or in the comatose patient. The initial evaluation should help to decide whether to treat the patient with hypertensive crisis as emergency or urgency. The decision to treat as an emergency should prompt immediate admission to an intensive care unit for intravenous treatment and continuous BP monitoring.

GENERAL GUIDELINES FOR TREATMENT

The initial goal of the antihypertensive therapy is *not* to rapidly normalize BP but rather to prevent damage to target organs by gradually decreasing mean arterial pressure, while minimizing the risk of hypoperfusion.⁸ Before discussing drug therapy for patients with hypertensive crisis it is important to emphasize that outcome data attesting to benefits of acutely lowering BP are not available. Thus most interventions currently used to treat hypertensive crisis have never been vigorously scrutinized. Much of the therapy, therefore, is entirely empirical and based on an attempt to best match pathophysiologic findings with pharmacologic properties of antihypertensive agents.

Several pharmacologic agents are available in the management of hypertensive crisis.² Those agents can be divided by mechanism of action and route of administration (parenteral vs. oral or sublingual) (Table 63–1).

Drug selection should be based on the severity of the crisis and on the specific hypertensive case. Emergency situations should be aggressively treated typically using intravenous medication in units with monitoring facilities.⁹

PARENTERAL AGENTS

Several parenteral agents are available for the treatment of hypertensive emergencies (Table 63–2).

Sodium nitroprusside

Sodium nitroprusside is a short-acting direct vasodilator, requiring a constant intravenous infusion that can decrease BP in all patients irrespective of hypertension severity. The efficacy of sodium nitroprusside was compared with fenoldopam^{10,11} with diazoxide and hydralazine¹² and with urapidil^{13,14} in hypertensive crises, and was found to be effective in almost 100% of the cases.

The drug is light sensitive and should be shielded from light to prevent degradation. Sodium nitroprusside dilates both arteriolar resistance and venous capacitance vessels, thereby decreasing peripheral resistance without causing an increase in venous return.² The drug does not have any direct negative inotropic or chronotropic effects on the heart. By reducing the preload and afterload, sodium nitroprusside improves left ventricular function in patients with congestive heart failure and low cardiac output, and reduces myocardial oxygen demand in patients with ischemic heart disease.

The advantages of sodium nitroprusside in controlling hypertensive crisis in cardiac patients have been studied

DRUGS FOR TREATMENT OF HYPERTENSIVE CRISIS		
Drug	Mechanism of Action	Route of Administration
Sodium nitroprusside	Vasodilator	IV
Diazoxide	Vasodilator	IV
Hydralazine	Vasodilator	IV, IM
Nitroglycerin	Vasodilator	IV, SL
Nifedipine	CCB	PO
Nicardipine	CCB	IV, PO
Nimodipine	CCB	IV
Trimethaphan camsylate	Ganglionic blocker	IV
Phentolamine	α blocker	IV
Urapidil	α blocker with central serotonin-agonist activity	IV
Esmolol	β blocker	IV
Labetalol	α + β blocker	IV, PO
Captopril	ACE inhibitor	PO
Enalaprilat	ACE inhibitor	IV
Fenoldopam	Dopamine agonist	IV
Clonidine	α -2 agonist	PO
Furosemide	Loop diuretics	IV, PO

CCB, calcium channel blocker; IV, intravenous; IM, intramuscular; SL, sublingual; PO, oral.

Table 63–1. Drugs for Treatment of Hypertensive Crisis

extensively. Recently, Khot et al.¹⁵ reported their experience with nitroprusside in 25 normotensive patients with severe aortic stenosis and left ventricular dysfunction. Nitroprusside increased cardiac index that was associated with a significant increase in stroke volume and a significant fall in the systemic vascular resistance and pulmonary capillary wedge pressure. Nitroprusside was also well tolerated and improved renal function.

Several studies assessed the efficacy and safety of nitroprusside in ischemic heart disease. Kaplan and Jones¹⁶ compared the effects of sodium nitroprusside and intravenous nitroglycerin in 20 patients during elective coronary artery surgery. Both regimens were effective in reducing intraoperative BP. However, nitroglycerin improved electrocardiographic ST segment depression in 8 of 10 patients, whereas sodium nitroprusside made the ST segment depression more pronounced in 3 of 10 patients. Decreased coronary perfusion pressure and intracoronary steal syndrome may be involved in the worsening of ischemia seen in patients receiving sodium nitroprusside. Flaherty et al.¹⁷ found that sodium nitroprusside increased intrapulmonary shunting whereas nitroglycerin decreased it, thus making nitroglycerin more useful for managing patients with large intrapulmonary shunt or pulmonary hypertension.

Fremes et al.¹⁸ found that nitroglycerin caused a greater reduction in myocardial oxygen demand and consumption than sodium nitroprusside in hypertensive patients after elective coronary bypass surgery. Therefore, if perioperative myocardial ischemia in the setting of postoperative hypertension is suspected, nitroglycerin may be a better antihypertensive agent.

In spite of the fact that sodium nitroprusside can increase intracranial pressure,² the fall in systemic pressure seems to block the rise in cerebral blood flow. It is therefore still recommended for management of some patients with encephalopathy and cerebrovascular accidents.¹⁹ Despite its effectiveness as antihypertensive agent, sodium nitroprusside has not been used widely in pregnancy because of negative outcomes in animal experiments.²

Interaction of sodium nitroprusside with sulfhydryl groups in erythrocytes and tissues generates cyanide ions that are converted to thiocyanate by rhodanese in the liver, and then excreted by the kidney. However, with prolonged administration of sodium nitroprusside, or in patients with hepatic impairment, or renal insufficiency, free cyanide may accumulate, and interfere with aerobic metabolism, resulting in metabolic acidosis. Cyanide also interferes with the vasodilator action of sodium nitroprusside and may eventually lead to tachyphylaxis. Therefore, thiocyanate levels should be monitored periodically and maintained below 10 mg/100 mL in patients with hepatic impairment, renal insufficiency and in those receiving high dosages of sodium nitroprusside (3 μ g/kg/min) or a prolonged infusion (>24–48 hours). It should be noted that the development of thiocyanate accumulation can not be predicted and even a dose that is considered to be safe may be toxic.² Thiocyanate toxicity includes fatigue, nausea, headache, disorientation, psychotic behavior, skin rashes, anorexia, convulsions, unexplained cardiopulmonary arrest, coma, diffuse encephalopathy, and even death.² When cyanide toxicity is diagnosed, it can be treated by the administration of amyl nitrate, sodium nitrate, and sulphydryl compound

PARENTERAL AGENTS FOR TREATMENT OF HYPERTENSIVE EMERGENCIES				
Drug	Dosage	Onset of Action	Duration of Action	Adverse Effects
Sodium nitroprusside	0.25–10 µg/kg/min	Immediate	1–2 minutes after infusion stopped	Nausea, vomiting, hypotension, muscle twitching, thiocyanate and cyanide toxicity mainly in patients with azotemia
Nitroglycerin	5–100 µg/min	1–5 minutes	5–10 minutes	Headache, nausea, tachycardia, vomiting, tolerance with prolonged use, methemoglobinemia
Labetalol hydrochloride	20–80 mg every 10–15 minutes, or 0.5–2 mg/min	5–10 minutes	3–6 hours	Vomiting, nausea, scalp tingling, bronchospasm, bradycardia, heart block, orthostatic hypotension
Fenoldopam mesylate	0.1–0.3 µg/kg/min	<5 minutes	30–60 minutes	Tachycardia, headache, nausea, flushing
Nicardipine hydrochloride	5–15 mg/h	5–10 minutes	15–90 minutes	Tachycardia, headache, flushing, local phlebitis
Esmolol hydrochloride	250–500 µg/kg/min IV bolus, then 50–100 µg/kg/min by infusion; may repeat bolus after 5 minutes or increase infusion to 300 µg/minute	1–2 minutes	10–30 minutes	Hypotension, nausea, asthma, first-degree heart block, heart failure
Urapidil	12.5–25 mg bolus followed by infusion of 5–40 mg/h	3–5 minutes	4–6 hours	Hypotension, headache, dizziness
Enalaprilat	0.625–5 mg every 6 hours	15–30 minutes	6–12 hours	Hypotension, renal failure
Diazoxide	75–150 mg every 5 minutes, or 10–30 mg/min for 15–30 minutes	1–5 minutes	4–12 hours	Increased cardiac output and heart rate, precipitate ischemia, sodium retention, hyperglycemia, postural hypotension
Hydralazine	10–20 mg IV, or 10–50 mg IM; repeat every 4–6 hours	10–30 minutes	1–6 hours	Increased cardiac output and heart rate, headache, angina
Trimethaphan	1–15 mg/min	1–10 minutes	3–10 minutes after infusion stopped	Hypotension, tachyphylaxis, orthostatic effect, sympathetic blockade, respiratory arrest
Phentolamine	5–10 mg bolus	1–2 minutes	10–30 minutes	Tachycardia, flushing, headache, angina

Table 63–2. Parenteral Agents for Treatment of Hypertensive Emergencies

such as sodium thiosulphate. Thiosulphate can be used to prevent thiocyanate toxicity. It has also been demonstrated that hydroxocobalamin is safe and effective in preventing and treating cyanide toxicity associated with the use of nitroprusside.³ In case of failure to respond to such therapy, hyperbaric oxygen therapy, hemodialysis, or charcoal hemoperfusion may prove beneficial; however, there is limited experience with this modes of therapy.² Considering the potential for severe toxicity with nitroprusside, this drug should only be used when other intravenous antihypertensive agents are not available and then only in specific clinical circumstances and in patients with normal renal and hepatic function. The duration of treatment

should be as short as possible and the infusion rate should not exceed 2 µg/kg per minute.

Nitroglycerin

Nitroglycerin is an antianginal as well as antihypertensive agent that dilates peripheral capacitance and resistance vessels. At higher doses nitroglycerin dilates arteriolar smooth muscle, thereby reducing peripheral resistance and afterload. It causes hypotension and reflex tachycardia, which are exacerbated by the volume depletion characteristic of hypertensive emergencies. Nitroglycerin reduces BP by reducing preload and cardiac output, which are undesirable effects in patients with compromised

cerebral and renal perfusion. By diminishing preload, nitroglycerin decreases left ventricular end diastolic volume and pressure and myocardial wall tension, thus reducing myocardial oxygen consumption. These changes favor redistribution of coronary blood flow to the subendocardium, which is more vulnerable to ischemia. Nitroglycerin may dilate epicardial coronary vessels and their collaterals, and increase blood supply to ischemic regions. Continuous intravenous nitroglycerin is effective in decreasing the incidence of myocardial ischemia in patients with coronary artery disease undergoing cardiac and non-cardiac surgery. Nitroglycerin is a better vasodilator of coronary conductance arteries than sodium nitroprusside and for that reason is preferred in the management of hypertensive crisis associated with acute coronary insufficiency.¹⁹ Intravenous nitroglycerin infusion also has been used in controlling hypertensive crisis during pregnancy. Snyder et al.²⁰ reported the successful use of intravenous nitroglycerin in controlling hypertension during anesthesia for cesarean section, without neonatal depression or hypotension. The usual initial dose is 5 to 100 µg/min and can be titrated upward to a desired therapeutic endpoint. Doses as high as 200 to 300 µg/min may be required to achieve an adequate response. Onset of action is almost immediate with a very short duration of action of approximately 5 to 10 minutes.² Prolonged use of nitroglycerin is not associated with toxicity, but tolerance to its hemodynamic effects has been reported.² The main adverse effects are headache and tachycardia. The drug can also be used sublingually in selected patients.

Labetalol

Labetalol produces selective antagonism at the post-synaptic α -adrenoreceptors and nonselective antagonism at the β -adrenoreceptors. Labetalol reduces the systemic vascular resistance without reducing total peripheral blood flow. In addition, the cerebral, renal, and coronary blood flows are maintained. The drug can be given by repeated bolus of 20 to 80 mg every 10 to 15 minutes or by a continuous infusion of 0.5 to 2 mg/min. The average effective total dose is 200 mg. Labetalol is metabolized by the liver to form an inactive glucuronide conjugate. The hypotensive effect of labetalol begins within 5 to 10 minutes after its intravenous administration, reaching a peak at 5 to 15 minutes after administration and lasting for about 3 to 6 hours. The response rate in patients with hypertensive crisis is 80% to 93%.² The drug was found to be effective and safe in patients with myocardial infarction, in patients with acute postoperative hypertension after aortocoronary bypass surgery or surgery requiring general anesthesia, in neurovascular surgical patients, children with hypertensive crises, and hypertensive crisis complicating pregnancy.² The drug is contraindicated in patients with acute left ventricular failure, second- or third-degree atrioventricular block, and chronic obstructive pulmonary disease. Caution is needed to avoid postural hypotension if patients are allowed out of bed. Nausea, itching, tingling of the skin, and beta-blockade side effects may be noted. Transition to oral therapy with the same drug is not difficult.

Fenoldopam

Fenoldopam is a selective postsynaptic dopaminergic (DA_1) receptor agonist with weak α_2 antagonistic properties. Fenoldopam is a natriuretic agent that has potent vasodilator activity affecting primarily the renal vasculature.²¹ Fenoldopam is rapidly and extensively metabolized by conjugation in the liver, without the participation of cytochrome P450 enzymes. The onset of action is within 5 minutes with the maximal response being achieved by 15 minutes. The duration of action is between 30 to 60 minutes with the pressure gradually returning to pre-treatment values without rebound upon termination of the drug. Several clinical trials showed the effectiveness of intravenous fenoldopam in the treatment of severe hypertension and hypertensive crisis. At a dose of 0.2 to 0.5 µg/kg/min, fenoldopam decreases BP to desired levels within 5 to 40 minutes. Hemodynamically the drug induces a decrease in total peripheral resistance and in pulmonary vascular resistance with a slight elevation in heart rate. In another open, controlled, randomized, parallel trial, intravenous fenoldopam was compared to sodium nitroprusside in 18 patients with severe hypertension and mild renal failure.¹¹ Both antihypertensive agents successfully controlled BP in all patients. The rate of side effects was similar in both groups of patients. However, in two patients treated with sodium nitroprusside toxic levels of thiocyanate were detected. Thus fenoldopam may be superior to sodium nitroprusside for the control of hypertensive crisis in patients with decreased renal function.

In another comparative study, the electrocardiographic changes were recorded in 21 patients with hypertensive emergencies treated with either fenoldopam or sodium nitroprusside.¹⁰ Both drugs reduced BP significantly in all patients. New T-wave inversion occurred in two patients treated with fenoldopam, and in four patients treated with sodium nitroprusside. Side effects included headache, flushing, tachycardia, and dizziness. Overall, tachycardia has occasionally been noted, and a dose-related increase in intraocular pressure has been observed in normotensive and hypertensive patients. It seems that fenoldopam is comparable to sodium nitroprusside, and can be the drug of choice in severely hypertensive patients with impaired renal function.

Nicardipine

Nicardipine is a dihydropyridine calcium antagonist with high vascular selectivity that can be administered intravenously.²² The onset of action of intravenous nicardipine is between 5 and 10 minutes with duration of action of 15 to 90 minutes. It is an effective antihypertensive agent that decreases afterload by reducing total peripheral resistance without reducing cardiac output. Nicardipine improves left ventricular ejection fraction and pumping activity, both in normal and failing hearts.² The drug dilates more selectively the cerebral and coronary arteries than the remainder of the arterial tree, without changing heart rate. It may preserve tissue perfusion, and therefore may be advantageous in patients with ischemic disorders, such as coronary, cerebrovascular, and peripheral vascular disease. The drug is given as a continuous infusion at

a starting dose of 5 mg/hr followed by increments of 2.5 mg/hr every 5 minutes until either reaching a maximal dose of 30 mg/hr or achieving the desired reduction in BP. Nicardipine has been used for the treatment of postoperative hypertension. In a double-blind study, intravenous nicardipine was compared with placebo in 123 patients with BP over 213/126 mmHg.²³ Of 73 patients who were treated with nicardipine, 67 patients achieved the therapeutic goal. Several side effects were reported; 30 patients had headache, 7 patients had hypotension, and 7 patients experienced nausea. Halpern et al.²⁴ and David et al.²⁵ found that nicardipine was as effective as sodium nitroprusside in patients with severe postoperative hypertension. Patients receiving intravenous nicardipine can then be easily switched to oral medication.

Esmolol

Esmolol is an ultra-short-acting β_1 -selective adrenergic blocker. The onset of action of this agent is within 60 to 120 seconds and the duration of action is extremely short, about 10 to 30 minutes, because of its rapid metabolism by a specific plasma esterase. This characteristic provides a significant advantage because it is possible to titrate esmolol easily to the desired effect.² The drug can be administered either as a bolus injection or as a continuous intravenous infusion. The recommended loading dose is a bolus of 250 to 500 $\mu\text{g}/\text{kg}/\text{min}$ followed by an infusion of 50 to 100 $\mu\text{g}/\text{kg}/\text{min}$. Esmolol is frequently combined with direct vasodilators to provide a more desirable hemodynamic profile. The negative chronotropic effect produced by esmolol may be beneficial in patients with ischemic heart disease. Esmolol has been used successfully with sodium nitroprusside in a few cases of hypertensive crises.²

Urapidil

Urapidil is a selective post-synaptic α_1 adrenoreceptor antagonist with strong vasodilating properties. The fact that it also antagonizes the pre-synaptic 5HT_{1A} (hydroxytryptamine) receptors explains the lack of reflex tachycardia in response to peripheral vasodilatation. Urapidil has a rapid onset of action, with a response rate of 81% to 100% in hypertensive emergencies.²⁶ Urapidil is given as an intravenous bolus at a dose of 12.5 to 25 mg followed by a continuous infusion at a rate of 5 to 40 mg/hr. It has no effect on coronary sinus blood flow, myocardial oxygen consumption, and myocardial lactate extraction, and it does not increase intracranial pressure. Adverse effects occur in 2% of all patients, and include hypotension, headache, and dizziness. Urapidil is safe and efficient in intraoperative hypertensive crises. In one study, the drug was given to 42 patients with intraoperative hypertensive crises. A significant reduction in BP was observed within 10 minutes in 81% of the patients.²⁷ In two studies the safety and efficacy of urapidil were compared with sodium nitroprusside. Response to treatment was similar in both treatment groups. However, BP re-elevation during the follow-up period was more common with sodium nitroprusside. Moreover, major side effects were more common in patients treated with sodium nitroprusside.² Since

urapidil is equally effective compared to sodium nitroprusside with fewer adverse effects, urapidil is a reasonable alternative to sodium nitroprusside in the treatment of hypertensive emergency, especially in intraoperative hypertensive crises.

Enalaprilat

Enalaprilat is the only available angiotensin-converting enzyme (ACE) inhibitor that can be administered intravenously. Enalaprilat lowers BP within 15 to 30 minutes, but the BP response in hypertensive emergencies is unpredictable, in part because of variable degrees of plasma volume expansion. The initial recommended dose for enalaprilat is 0.625 to 1.25 mg administered over 5 minutes. The maximal single dose should not exceed 5 mg for patients receiving diuretics and 1.25 mg for patients with renal impairment.² The initial dose can be repeated after 1 hour if clinical response is inadequate. The total daily dose should not exceed 20 mg. In patients with severe renal insufficiency, the dose should be decreased because the compound is excreted primarily by the kidney.

Enalaprilat is more effective in patients with high-renin forms of hypertension, and may induce a dramatic fall in BP in patients who are volume depleted by previous dietary sodium restriction or diuretic use.² African Americans seem to respond poorly to enalaprilat, possibly because of their low renin levels. Because enalaprilat may induce severe hypotension in volume-depleted patients, it should be used with caution in patients who are at risk for cerebral hypotensive episode. In patients with hypertensive emergency, the response rate is about 65% and it is not dependent on the initial dose.² Thus a low dose of 0.625 mg may be adequate for initial treatment of hypertensive crisis.²⁸ In one study, enalaprilat was compared with intravenous urapidil and sublingual nifedipine in the management of hypertensive crisis. Only 70% of the patients in the enalaprilat group achieved goal BP (<180/95 mmHg within 45 minutes after start of treatment) versus 96% and 71% in the urapidil and nifedipine groups, respectively.²⁹

The most common adverse effect is hypotension. The risk for hypotension increases in patients with evidence of renal hypertension, volume-depleted patients, and patients with prior use of diuretics. Enalaprilat is contraindicated in patients with evidence of bilateral renal artery stenosis or in patients with unilateral stenosis of a single kidney.³⁰ Thus enalaprilat is particularly useful in hypertensive emergencies associated with congestive heart failure or high renin levels, and can be easily replaced by oral enalapril for long-term maintenance therapy.

Diazoxide

Diazoxide is a direct rapid-acting vasodilator that decreases total peripheral resistance with a reflex increase in heart rate and cardiac output. The compensatory increase in cardiac output and heart rate can be blocked by concomitant beta blocker therapy. Since it does not cross the blood brain barrier, diazoxide has no direct effects on cerebral circulation, but of course cerebral blood flow will

fall if systemic pressure is reduced below the lower limit of autoregulation. In the past, diazoxide was initially given as a rapid bolus of 300 mg. However, the standard rapid intravenous bolus administration may cause profound hypotension with subsequent myocardial ischemia and cerebrovascular insufficiency. The safer course is to give the drug either by smaller bolus doses of 75 to 150 mg intravenously, every 5 to 10 minutes or by a slow infusion of 10 to 30 mg/min for 15 to 30 minutes. These methods are equally effective and are associated with fewer adverse effects. The side effects of diazoxide include fluid retention, nausea, flushing, dizziness, and hyperglycemia. When using diazoxide, one must be aware of significant adverse effects such as postural hypotension, maternal and fetal hyperglycemia, and cessation of gestational labor that results from relaxation of the uterine smooth muscle. Diazoxide is contraindicated in patients with severe angina, acute myocardial infarction, dissecting aneurysm, and congestive heart failure. Because of potential side effects and the availability of new antihypertensive agents, the use of diazoxide in hypertensive emergencies decreased remarkably.²

Hydralazine

Hydralazine is a direct arteriolar vasodilator, with little effect on venous capacitance vessels, that produces a rapid BP decrease with diastolic pressure reduced more than systolic.³¹ Its administration results in activation of baroreceptor reflexes leading to increased heart rate, myocardial contractility, and cardiac output, and augmented renal blood flow. Hydralazine can be given intravenously or intramuscularly in an initial dose of 10 to 50 mg. The drug should not be diluted with solutions containing dextrose or other sugars, because of its ability to form potentially toxic hydrazones.³¹ The drug reduces systemic vascular resistance and BP in severe hypertension of pregnancy without a significant change in uteroplacental blood flow.²

Although hydralazine easily crosses the placenta, its relative safety and efficacy combined with extensive clinical experience have made it the most widely used antihypertensive agent in pregnancy-induced hypertension.³¹ The major drawbacks of hydralazine are its side effects that include reflex tachycardia, salt and water retention, intense flushing, headache, nausea, vomiting, myocardial ischemia, and increased intracranial pressure. Therefore, the use of intravenous hydralazine is limited to patients with preeclampsia or eclampsia.²

Trimethaphan camsylate

Trimethaphan camsylate is a ganglionic blocker agent that inhibits both sympathetic and parasympathetic autonomic activity. It has a rapid onset and brief duration of action, and must be administered by continuous intravenous infusion with constant monitoring of BP. The usual starting dose is 0.5 to 1 mg/min. The dose is then titrated to achieve the desired BP level up to a maximum 15 mg/min. It is important to titrate the drug carefully, and to elevate the head of the patient's bed during the infusion to avoid severe postural hypotension. Trimethaphan camsylate is

particularly useful in aortic dissection because it can be titrated carefully to permit smooth control of BP and because it decreases cardiac output and left ventricular ejection rate.

Tachyphylaxis develops frequently after 24 to 48 hours because of intravascular volume expansion, and this may be attenuated by the use of diuretics. Adverse effects include blurred vision, exacerbation of glaucoma, dry mouth, respiratory depression, nausea, constipation, fetal meconium ileus, paralytic ileus, impairment of renal blood flow with azotemia, and urinary retention. Because of the frequency and severity of side effects associated with this drug and the availability of more effective agents, it is now used only in patients with life-threatening disorders such as dissecting aortic aneurysm.^{2,8}

Phentolamine

Phentolamine is a parenteral nonspecific α -adrenergic blocking agent with rapid onset and short-lasting hypotensive effect. It is given intravenously in boluses of 5 to 10 mg as necessary. Adverse effects include tachycardia, vomiting, and headache. In patients with coronary artery disease, phentolamine may induce angina pectoris or myocardial infarction. It is specifically useful in treatment of catecholamine-mediated hypertensive crises.³⁰ However, it is not consistently effective in other types of hypertensive emergencies.

OTHER AGENTS

Nimodipine

Nimodipine is a potent cerebral vasodilator that has been approved for use in relieving the vasospasm accompanying subarachnoid hemorrhage. Nimodipine has improved the outcome of patients with aneurysmal subarachnoid hemorrhage.^{32,33} Its beneficial effect in aneurysmal subarachnoid hemorrhage seems to be unrelated to its hypotensive effect or to its cerebral vasodilator properties, and is perhaps related to preserving functioning neurons by preventing calcium influx to the ischemic cells. The drug is not recommended in hypertensive emergencies.²

Diuretics

In addition to an antihypertensive agent, a potent diuretic, usually furosemide, is given intravenously. The use of diuretics is somewhat controversial since most patients with hypertensive crisis are characterized by a contracted plasma volume. However, even if not given initially, a diuretic will likely be needed after other antihypertensives are used, since reactive renal sodium retention usually accompanies a fall in pressure and may blunt the efficacy of nondiuretic agents. Of note, if the patient is volume depleted, additional diuresis could be harmful.²

TREATMENT OF SPECIFIC HYPERTENSIVE EMERGENCIES

There is a multiplicity of disorders or diseases accompanying elevated BP that constitute a hypertensive crisis,

PREFERRED AGENTS FOR SPECIFIC HYPERTENSIVE EMERGENCY		
Emergency Condition	Preferred Agent	Comments
Hypertensive encephalopathy	Fenoldopam, labetalol, nicardipine or urapidil	Avoid methyldopa and diazoxide.
Cerebrovascular accident	Sodium nitroprusside, labetalol, urapidil, esmolol, nicardipine, nimodipine	Benefit from acute lowering of BP is uncertain.
Dissecting aortic aneurysm	Labetalol, or combination of nicardipine or fenoldopam or sodium nitroprusside with a β -blocker (metoprolol or esmolol), or trimethaphan	Titrate BP to the lowest possible level. Avoid hydralazine, diazoxide.
Acute left ventricular failure	Fenoldopam, or sodium nitroprusside with nitroglycerin, enalaprilat, urapidil, furosemide, morphine	Avoid labetalol, esmolol, diazoxide, hydralazine.
Coronary insufficiency	Nitroglycerin, labetalol, esmolol, nicardipine	BP should be reduced gradually. Avoid hydralazine, diazoxide.
Perioperative hypertension	Sodium nitroprusside, nitroglycerin, labetalol, urapidil, esmolol, nicardipine	Nitroglycerine is preferred in managing postcoronary bypass hypertension.
Eclampsia	Hydralazine, labetalol, urapidil, calcium antagonists	Avoid diuretics, trimethaphan, sodium nitroprusside, ACE inhibitor.
Catecholamine excess	Phentolamine, labetalol	Avoid diuretics, sodium nitroprusside.
Renal insufficiency	Fenoldopam, nicardipine, labetalol	Avoid β -blockers, sodium nitroprusside

BP, blood pressure.

Table 63–3. Preferred Agents for Specific Hypertensive Emergency

and there is broad spectrum of pharmacologic agents that may be selected for treatment of these cases. Some agents that are useful for one hypertensive emergency may actually be contraindicated for another.³⁴ The recommended therapeutic approaches for specific conditions are summarized in Table 63–3.

Hypertensive encephalopathy

When mean arterial pressure reaches a critical level (around 180 mmHg), the previously constricted vessels are unable to withstand the pressure, counterregulation fails, and generalized vasodilatation ensues. Such a breakthrough of cerebral blood flow (CBF) leads to hyperperfusing the brain under high pressure, and results in cerebral edema and the clinical syndrome of hypertensive encephalopathy.² It is possible that many patients labeled as having “hypertensive encephalopathy” essentially had cerebrovascular events or intra-cranial space-occupying lesions, as brain imaging was less advanced in the past when this diagnosis was commonly made.

This scenario occurs at a much higher BP in patients with chronic hypertension than in previously normotensive persons. If untreated, the clinical picture progressively worsens, culminating in coma and death. Hypertensive encephalopathy is often indistinguishable from other acute neurologic complications of hypertension, such as cerebral infarction, subarachnoidal bleeding, or intracerebral hemorrhage. The only definite criterion to confirm diagnosis of hypertensive encephalopathy is a prompt improvement in the patient’s condition in response to antihypertensive therapy.³⁵ First-choice drugs for this condition include intravenous fenoldopam, labetalol, nicardipine, or urapidil.

Cerebrovascular accidents

Intracerebral hemorrhage

As a result of intracerebral hemorrhage, intracerebral pressure rises and higher intra-arterial pressure is required to perfuse the brain adequately. In this condition, hypertension may be a result of increased intracerebral pressure and may resolve spontaneously within 48 hours.³⁵ Rapid reduction in BP may indeed prevent further bleeding, but at the risk of cerebral hypoperfusion.¹ One study compared the morbidity and mortality outcomes of patients with intracerebral hemorrhage according to their initial BP and the control of BP during the first 2 to 6 hours of presentation.³⁶ An improved outcome was observed in those who had an initial mean arterial pressure lower than 145 mmHg and in those who had their mean arterial pressure controlled below 125 mmHg. This retrospective study may suggest that markedly elevated BP may adversely affect the prognosis in hypertensive patients with intracerebral hemorrhage. Nevertheless, there is no consensus with regard to the advisability of reducing BP in these patients.¹⁹ In any event the reduction should not exceed 20% of pretreatment BP level.³⁷ If BP is extremely elevated (diastolic pressure greater than 140 mmHg) and lasts more than 20 minutes, intravenous treatment is recommended.³⁸ The first drugs of choice for this condition include intravenous sodium nitroprusside, labetalol urapidil, esmolol, or nicardipine.² In one study, it was reported that nimodipine has improved the outcome of patients with aneurysmal subarachnoid hemorrhage.³³

Acute ischemic stroke

Cerebral infarction causes impairment in autoregulation of CBF; thus elevated BP will accentuate perfusion through

the damage tissue, leading to edema and compression of normal brain tissue. This provides evidence for carefully reducing BP in hypertensive patients with stroke. Conversely, because of local vasoconstriction, high arterial BP is required to perfuse jeopardized brain tissue around the infarct area. This provides evidence against reducing BP in acute ischemic stroke. Moreover, chronic hypertension and cerebral vascular disease move the autoregulation curve of CBF to the right so that a decrease in CBF occurs at a higher BP levels than in normal individuals. Therefore, cerebral hypoperfusion may appear at levels of BP that are still above the upper limit of normal. Patients with acute ischemic stroke demonstrate elevated BP levels on admission to the hospital. However, a spontaneous decrease in BP usually observed within the first 4 days after the event.³⁹ Moreover, no beneficial effect has been demonstrated by acute lowering of BP in patients with acute ischemic stroke. To the contrary, it has been shown that in patients with multiple stenosis of cerebral arteries, elevation of BP may improve the neurologic condition.

No antihypertensive treatment is recommended if BP is less than 180/105 mmHg. If BP is higher than 230/120 mmHg and persists more than 20 minutes, intravenous treatment is recommended. The target BP should be 160 to 170/95 to 100 mmHg for previously normotensive patients and 180 to 185/105 to 110 mmHg for previously hypertensive patients. The benefits to be derived from acutely lowering BP in patients with acute stroke of any kind remain conjectural and unsupported by good clinical or experimental studies. Sodium nitroprusside, labetalol, urapidil, esmolol, and nicardipine are the agents of choice whenever BP is to be reduced for patients with acute ischemic stroke. Results with nimodipine in this condition are equivocal so far.

Acute aortic dissection

Most untreated patients with acute aortic dissection die within 1 year, and most of the deaths occur within 2 weeks. Once diagnosis is suspected, attempts should be made to decrease the shear stress to the aortic wall with suitable agents. BP should be reduced within 15 to 30 minutes to the lowest tolerated level that preserves adequate organ perfusion. It has to be kept in mind that the force and velocity of ventricular contractions and pulsatile flow determine shear stress on the aortic wall. Drugs such as diazoxide or hydralazine that reflexively stimulate sympathetic activity and increase the shear stress on the aortic wall are contraindicated. Initial treatment should consist of labetalol or a combination of intravenous nicardipine or fenoldopam or sodium nitroprusside with intravenous β -blocking agent, most commonly metoprolol or esmolol. Used alone, sodium nitroprusside increases the velocity of ventricular contraction so that simultaneous β -blockade is obligatory. Trimethaphan camsylate, a ganglionic blocker, is also an alternative treatment.^{2,30}

Acute left ventricular failure

Severe hypertension may precipitate acute left ventricular failure. Prompt reduction of BP decreases the work load of the failing myocardium and improves cardiac function.³⁵

Immediate decrease of afterload with balanced vasodilating agent such as fenoldopam or sodium nitroprusside in combination with nitroglycerine is indicated in this circumstance.² Nitroglycerin alone is a reasonable alternative that has less afterload reducing capability than sodium nitroprusside, but may increase myocardial blood flow to ischemic areas in patients with acute myocardial ischemia. As urapidil has no influence on heart rate and myocardial oxygen consumption, it is a potential alternative to sodium nitroprusside and nitroglycerin if BP is insufficiently reduced. Concomitant therapy with oxygen, diuretics, or opioids may enhance efficacy of antihypertensive agents. Although the ACE inhibitors may be useful in this situation, there is a paucity of clinical experience concerning the therapeutic response to ACE inhibition in patients with acute left ventricular failure.² Drugs causing reflex tachycardia (diazoxide, hydralazine) or decreasing myocardial contractility (labetalol) should be avoided in this setting.²

Ischemic heart disease

Reduction of systemic BP by intravenous nitroglycerin reduces cardiac work, wall tension, and oxygen demand, and therefore has become the drug of choice for this crisis.² Intravenous nitroglycerine shortly after the onset of myocardial infarction may limit infarct size and improve ventricular ejection fraction.⁴⁰ Intravenous vasodilators, mainly sodium nitroprusside and nitroglycerin, have been tested in 11 trials involving 2170 patients with acute myocardial infarction and have reduced mortality by 43%. Cautious treatment of hypertension in patients with acute myocardial infarction is likely to be beneficial. Conversely, unnecessary reduction in BP could compromise an already unstable situation,³⁵ and therefore BP should be reduced gradually until symptoms subside or until the diastolic BP is approximately 100 mmHg.² Rapid reduction of BP with any drug may cause electrocardiographic changes.¹⁰

Initial treatment of patients with angina pectoris and severe hypertension includes sublingual nitroglycerin and morphine, followed by intravenous nitroglycerin if treatment is not successful. Nifedipine should not be used in this crisis, as it causes reflex tachycardia, increases myocardial oxygen demand, and may aggravate myocardial ischemia.⁴¹

Perioperative hypertension

Most of the time, perioperative hypertension is not an emergency in the usual sense, but parenteral agents frequently have to be used to control BP because patients are unable to receive medications orally. Severe hypertension may occur in some patients in the postoperative period, especially after open heart and carotid artery surgery. The etiology of this severe hypertension is multifactorial, and includes withdrawal of antihypertensive drugs, pain, volume overload, and sympathetic activation.³⁵ In this setting, even moderate hypertension may jeopardize the integrity of the fresh vascular suture lines. Therapy should be individualized, and in some situations immediate lowering of the BP is warranted.³⁵ Hypoten-

sion is to be avoided in patients who have fresh vascular suture lines because of the danger of thrombosis.¹⁹ Sodium nitroprusside is usually the agent of choice, provided that the patient is in an intensive care environment. Nitroglycerine administered intravenously may be the drug of choice for managing postcoronary bypass hypertension.² Labetalol, urapidil, esmolol, and nicardipine can also be used.

Eclampsia

Preeclampsia occurring in pregnancy is the syndrome of hypertension edema and proteinuria. Some of these patients may progress to eclampsia, which is associated with seizures and end-organ damage (cerebral hemorrhage, renal failure, microangiopathic hemolytic anemia).⁴² The important part of safe treatment is to control hypertension, while keeping in mind the risk that reducing BP may further impair placental blood flow.

Hydralazine administered intravenously has been the drug of choice in recent years when diastolic BP is over 110 mmHg or when eclampsia supervenes; it is effective and does not decrease placental blood flow. Labetalol or calcium antagonists are possible alternative therapeutic approaches if hydralazine is ineffective.⁴² Diuretics, trimethaphan camsylate, sodium nitroprusside, and ACE inhibitors should be avoided. If convulsions are imminent or occur, magnesium sulfate should be administered parenterally.

Excessive circulating catecholamines

Catecholamine-induced crises are characterized by a sudden increase in predominantly α -adrenergic tone. Plasma catecholamine levels are elevated in pheochromocytoma, rebound hypertension following clonidine withdrawal, hypertension associated with ingestion of sympathomimetics (cocaine hydrochloride, amphetamines, phencyclidine hydrochloride, lysergic acid diethylamide, and diet pills), and drug interaction of monoamine oxidase inhibitors with tyramine-rich food (certain beers, cheese, wine, chicken liver).⁴³ When this condition is suspected, the α -adrenergic-blocking drug, phentolamine, should be given. An alternative to phentolamine would be labetalol or sodium nitroprusside with β -blockers. A β -blocking drug may be needed if the patient has concomitant tachycardia or ventricular ectopy. Administration of β -blocking agent should always be preceded by α -blockade to prevent unopposed α -mediated peripheral vasoconstriction.²

Renal insufficiency

Deterioration of renal function in the face of elevated BP is considered a hypertensive emergency and requires lowering the BP. Therapy should reduce systemic vascular resistance without compromising the renal blood flow or glomerular filtration.² Fenoldopam, nicardipine, and labetalol are effective and well tolerated in these patients, and therefore should be used as the drugs of choice. Sodium nitroprusside is effective in these patients, but because of the high risk of thiocyanate toxicity it should not be used. β -blockers reduce the renal plasma flow and the glomerular filtration rate, and should therefore be used with caution if at all in these patients.

ORAL AGENTS FOR HYPERTENSIVE URGENCIES

During the last 20 years, the treatment focus for hypertensive urgencies has moved toward the use of oral agents. The ideal oral drug to treat hypertensive crisis should be one that has a rapid and smooth onset of action, few adverse effects, does not cause excessive hypotension, is convenient to monitor, and can be easily converted to a maintenance therapy.⁴⁴ The use of oral agents should be limited to hypertensive urgency as clearly recommended in the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).⁹

Captopril

Captopril, an ACE inhibitor was initially studied for treatment of hypertensive crisis in a few small uncontrolled studies using a dose of 25 mg sublingually.^{45,46} Sublingual captopril is well tolerated and effective in reducing BP, the onset of action occurs within 5 to 10 minutes, and reaches a maximum within 30 minutes and lasts for at least 2 hours. Following oral administration of captopril on an empty stomach, maximal BP reduction is observed within 30 to 90 minutes.² Orally dissolved captopril seems to be more effective than captopril in standard oral administration. In one study,⁴⁷ sublingual administration of captopril reduced BP after 60 minutes from 196/112 to 154/90 mmHg with a response rate of 84%, whereas oral captopril reduced BP from 197/110 to only 182/99 mmHg with a response rate of 57%.

Patients with renal artery stenosis may suffer sudden severe deterioration of renal function. Undesirable effects are a rash and precipitous fall in BP in patients with suspected high renin levels.² In general, comparative trials have observed fewer side effects with captopril than with nifedipine administration. Most studies concluded that captopril should be considered as a first-line therapy in the acute management of hypertensive crisis.² However, as previously noted no outcome data are available that attest to benefits of captopril in this clinical situation.

Nifedipine

Nifedipine is a dihydropyridine calcium antagonist that lowers BP by peripheral vasodilatation with only mild negative inotropic and chronotropic effects. The advantages of nifedipine use are rapid onset of action and lack of central nervous system depression. Nifedipine is the most extensively studied agent for rapid control of BP, and until 1996 was used for acute BP lowering in hospitalized patients. After sublingual administration, the onset of action is within 1 to 5 minutes with a maximal effect at 20 to 30 minutes. The buccal absorption of nifedipine is minimal, and faster absorption and higher maximum concentrations were observed following the bite and swallow method when compared with other methods of dosing. The duration of action of a single dose of nifedipine is about 3 to 5 hours.² The most common adverse effect associated with nifedipine is reflex tachycardia secondary

to pronounced vasodilatation. Some patients may experience symptoms of hypotension and flushing. Despite some reports on its efficacy and safety, sublingual nifedipine was not approved by the U.S. Food and Drug Administration for use in hypertensive emergency because of lack of scientific validation of advantageous use in this situation.

Nifedipine also has been associated with some severe adverse effects, including retinal ischemia, cerebral vascular accident, and myocardial ischemia and infarction.⁴¹ Rapid uncontrolled pressure reduction may be harmful because it precipitates acute ischemic stroke or myocardial infarction. This has been emphasized with regard to short-acting nifedipine.⁴¹ Therefore, the use of nifedipine capsules for hypertensive crisis should be abandoned. Oral nifedipine, however, may be used in hypertensive urgencies.

Nicardipine

Nicardipine is a second-generation dihydropyridine calcium antagonist that unlike nifedipine causes little, if any, increase in heart rate.⁴¹ Nicardipine produces slower, and more prolonged decrease in BP than nifedipine, and therefore appears to be better tolerated. In a multicenter, randomized, double-blind, parallel placebo-controlled trial, 53 patients with hypertensive urgency were assigned to receive orally either 30 mg of nicardipine or placebo. Diastolic pressure decreased by 22.2 ± 11.7 (SD) mmHg in the nicardipine group and only by 8.5 ± 10.9 (SD) mmHg in the placebo group ($p < 0.0001$). Adequate BP response was observed in 65% of the 26 patients treated with 30 mg of nicardipine and only in 22% of the 27 patients given the placebo ($p = 0.002$). Of the 21 patients given the placebo who did not have an adequate BP response, 16 (76%) had adequate BP reduction after one open-label dose of 30 mg of nicardipine. Adverse events were reported in three patients given nicardipine and four patients given the placebo. Asymptomatic hypotension was noted in three patients, two in the nicardipine group, and one in the placebo group; one patient treated with nicardipine reported anxiety, headache, tachycardia, and chest pain.⁴⁸ During a 1-week follow-up, minor, well-tolerated adverse events were reported in the nicardipine group. Compared to nifedipine, it seems that oral nicardipine is safer and as effective a drug for the initial treatment of urgent hypertension.

Clonidine

Clonidine is a central-acting α_2 -adrenergic receptor agonist that reduces BP by decreasing cerebral sympathetic outflow. Its action begins 30 to 60 minutes after administration, and its maximal effect is achieved within 1 to 4 hours and lasts for 6 to 8 hours.² A well-accepted method of clonidine administration in hypertensive crisis is by an oral loading regimen of an initial dose of 0.1 to 0.2 mg that may be repeated as needed. However, doses higher than 0.4 mg have little additional benefit in nonresponders.² Most studies report an average response rate of approximately 80%.² The drug should not be used in patients with altered mental status, because of its

common adverse effect of drowsiness.² In addition, clonidine can cause a significant decrease in CBF. One case of death from a progressive cerebral infarct following the administration of a cumulative clonidine dose of 0.4 mg was reported. Other complications associated with clonidine include dry mouth, occasional dizziness, and development of hypertensive crisis upon abrupt discontinuation of therapy. Due to its unpleasant side effects and its pharmacokinetics, the popularity of this drug is declining.

Labetalol

Labetalol is a unique antihypertensive agent that competitively inhibits both alpha- and beta-adrenergic receptors.² The alpha-blocking properties dominate in the treatment of hypertensive crisis. Labetalol reduces systemic vascular resistance and BP without inducing reflex tachycardia or change in cardiac output. Gonzalez et al.⁴⁹ conducted a dose-response study with labetalol in 36 patients. The maximal BP-lowering effect was seen at 2 hours, and BP control was maintained for 4 hours. An oral dose of 200 mg of labetalol was the most appropriate to maximize efficacy and tolerability. However, several other investigators used doses as high as 500 to 1200 mg to achieve BP control.⁵⁰ The initial dose should be 200 mg followed by hourly 200-mg doses to a maximal dose of 1200 mg. The response rate in patients with hypertensive urgency is 80% to 94%.² Because of its pharmacology, labetalol should not be used in patients with chronic obstructive lung disease, congestive heart failure, atrioventricular block, or bradycardia. Adverse effects include hypotension, dizziness, headache, nausea, vomiting, and flushing.

Other oral agents

The efficacy of other oral agents including methyl dopa, phenoxybenzamine, losartan, valsartan, and direct-acting vasodilators, such as minoxidil and hydralazine, in treating hypertensive urgency has not been well studied. These drugs therefore have little if any role in the treatment of this condition.

TREATMENT OF HYPERTENSIVE URGENCIES

The most commonly seen hypertensive urgency is malignant-phase hypertension (MHT), which still occurs in the Third World and in clinical practices with a large migrant population.^{51,52} MHT is usually defined clinically as a raised BP in association with bilateral retinal linear or flame-shaped hemorrhages and/or cotton-wool exudates and/or hard exudates, with or without papilledema. Malignant hypertension may be accompanied by other organ damage such as heart failure, kidney failure, and hypertensive encephalopathy. MHT affects under 1% of people with essential hypertension, but could occur in any form of hypertension. Afro-Caribbean patients tend to do badly, possibly because of their higher BPs and greater renal impairment at presentation, and not their ethnicity *per se*.

In uncomplicated MHT, the target-organ damage, which is retinopathy, occurs over days or weeks rather than minutes, and hence may be classed as a hypertensive “urgency” for managing blood pressure. In the setting of coexisting hypertensive encephalopathy or aortic dissection, the management would be the same as for a “hypertensive emergency.”

The optimal approach in patients with a hypertensive urgency is to lower the BP gradually over 24 to 48 hours. This therapeutic approach requires a close follow-up of the patient in the first days after the acute event. When the cause of transient BP elevations is easily identified, such as pain or acute anxiety (as in panic disorders), the appropriate therapy is analgesic or anxiolytic medication. We have recently shown that antianxiety treatment with diazepam is as effective as sublingual captopril in patients with excessive hypertension.⁵³ When the cause of BP elevation is unknown, various oral antihypertensive agents are available. There are some reports attesting to the safety of intravenous drugs such as labetalol or urapidil in this setting, but this mode of treatment is not recommended. In the absence of any data comparing long-term outcome with the various agents, the choice of therapy should be based on efficacy and safety data.

The efficacy of the various oral antihypertensive agents seems to be similar, and it ranges in controlled trials between 96% to 98% for nifedipine, 79% to 100% for clonidine, 90% to 95% for captopril, 68% to 94% for labetalol, 65% to 91% for nicardipine, and 85% for nitroglycerine.² Acute lowering of BP may compromise cardiac and cerebral blood flow, especially in the elderly, and therefore may be associated with serious side effects. We have published a review of serious adverse effects following oral or sublingual administration of nifedipine capsule in hypertensive emergencies and pseudoemergencies.⁴¹ Given the potential seriousness of adverse events, and the lack of any clinical documentation attesting to a benefit of rapid BP lowering, nifedipine capsules and any drug that lowers BP acutely to unpredictable levels should be avoided in hypertensive crisis. Of note oral agents should be used only in hypertensive urgency, and not emergency, and in this condition a slower reduction of BP over a period of hours to several days is more appropriate.

One should be careful not to be too aggressive in lowering BP, and to use the right agent for the right condition. When considering the appropriate agent, the mechanism of action and the profile of adverse effects should be taken into consideration. Nifedipine and to lesser degree captopril tend to increase heart rate and clonidine and labetalol tend to decrease it. This is particularly important in patients with ischemic heart disease. Other limitations are the use of labetalol in patients with bronchospasm and bradycardia and second and third degree heart blocks. Clonidine should be avoided if mental acuity is desired. Captopril should not be used in patients with bilateral renal artery stenosis or unilateral renal artery stenosis of a solitary kidney. All agents should be used carefully in volume-depleted patients.

TREATMENT OF SPECIFIC POPULATIONS

Hypertension in childhood

Hypertensive emergencies are rare events during childhood. Most children with hypertensive crisis have an underlying secondary cause of hypertension that is usually renal or renovascular in origin.⁶ Extremely high BP may be seen in infants with autosomal recessive polycystic kidney disease. Extrarenal causes such as pheochromocytoma and neuroblastoma are less frequent. As in adults, the absolute BP values cannot be used as the only determinant of whether a child is experiencing a hypertensive emergency. In one study, as many as 24% of children presenting to the emergency room with hypertension required emergency management.¹² Of this group, 57 patients were treated with intravenous hydralazine or diazoxide to reduce BP within the first 12 to 24 hours. This management was associated with irreversible neurologic deficits in 4 out of the 57 patients. In a second subgroup of 53 patients, BP was reduced more gradually over 96 hours with either intravenous labetalol or sodium nitroprusside. In this subgroup no neurologic impairments were observed. Unfortunately, as in adults, a precise determination of what is safe for BP reduction has not been established. Intravenous treatment is often preferable due to greater ease in titrating BP.

In the absence of specific contraindications, a continuous infusion of nicardipine or sodium nitroprusside is preferable. Intravenous labetalol as a bolus injection followed by continuous infusion also may be used. Oral agents should be reserved for circumstances in which symptoms of end-organ toxicity are mild or absent.⁵⁴ Children have a more active renin-angiotensin system than adults, and a higher incidence of renal artery stenosis as a cause of severe hypertension. Therefore, the use of an ACE inhibitor should be withheld as long as the underlying cause for the hypertension is unknown.

Hypertension in the elderly

In general, older persons have a lower blood volume, lower plasma renin activity, and increased peripheral vascular resistance that affect the pharmacokinetics of some antihypertensive agents.² With age the decrease in glomerular filtration rate and blunted baroreceptor reflexes increase the risk of overdose and orthostatic hypotension. If supine hypertension is treated too vigorously, older patients may experience presyncope or actual syncope. The increase in systolic BP associated with age is actually atherosclerotic-related decrease in aortic distensibility. In this setting, small changes in stroke volume can result in greater changes in systolic BP. Rapid reduction of BP is especially dangerous in elderly patients, and can cause transient ischemic attacks, strokes, angina, myocardial infarction, and syncope; therefore, low doses of antihypertensive agents should be used.

SUMMARY

Hypertensive crisis is defined as a severe elevation in BP, such as a diastolic BP above 120 to 130 mmHg, and

can be subclassified into either emergency or urgency (Figure 63–1). Hypertensive emergencies are relatively rare, and are said to be present only when BP elevation confers an immediate threat to the integrity of the cardiovascular system. In this setting immediate reduction in BP is required, generally by intravenous therapy in an intensive care unit. Unlike emergencies, urgency is said to be present when severe elevation in BP is not associated with end-organ injury. Outcome data attesting to benefits of acutely lowering BP in this condition are not available.

Clearly, patients with hypertensive crises are not good candidates for prospective randomized trials. Therefore, the accepted approach for patients with hypertensive urgency is to lower the BP more gradually over 24 to 48 hours with oral antihypertensive agents. In many patients, panic or anxiety may be the precipitating factor for the BP elevation, and therefore anti-anxiety treatment may be initiated. If anxiety is not the cause, or an anti-anxiety agent does not lower the BP, then oral antihypertensive agent should be started. Any drug that lowers BP precipitously should be avoided. The efficacy of nifedipine, captopril, clonidine, labetalol, nicardipine, and nitroglycerin seems to be similar. Choice of the appropriate agent should be based on the underlying pathophysiologic and clinical findings, mechanism of action, and the potential adverse effects.

Renovascular Hypertension

Graham W. Lipkin, Puchimada Uthappa, and Jason Moore

Definition

- Renovascular hypertension (RVH) is a syndrome of arterial hypertension caused by reduced renal perfusion pressure secondary to a vascular lesion of the main renal artery or one of its branches.
- Atheromatous renovascular disease (ARVD) and fibromuscular dysplasia account for around 90% and 10% of renovascular hypertension, respectively.
- A significant renal artery stenosis is identified by a greater than 70% luminal area narrowing or 20-mmHg translesional pressure gradient. Lesser degrees of stenosis are unlikely to be causes of hypertension or chronic kidney disease.

Key Findings

- ARVD may present with RVH, ischemic nephropathy, flash pulmonary edema, and acute uremia following introduction of converting enzyme inhibitors or angiotensin receptor–blocking agents, or may be asymptomatic.
- ARVD, which is associated with widespread atheromatous disease, is progressive and portends a very high cardiovascular mortality.
- Magnetic resonance angiography (gadolinium contrasted) or computed tomographic angiography (in patients with normal renal function) are the investigations of choice for ARVD.

Clinical Implications

- In selected patients, percutaneous transluminal renal artery angioplasty (PTRA) is the treatment of choice for RVH caused by fibromuscular dysplasia. The use of stenting may successfully and durably correct ARVD, and may stabilize or improve chronic kidney disease and renovascular hypertension, as well as “flash” pulmonary edema secondary to ARVD.
- Controlled trials of PTRA (without stent) in RVH have shown little benefit in the control of blood pressure. Large multicenter randomized controlled trials of percutaneous renal artery endovascular stent insertion in patients with RVH and chronic kidney disease secondary to ARVD are underway.

5%), and is usually caused by atheromatous renovascular disease (ARVD) (>90%) or fibromuscular dysplasia (FMD). Less common causes include arteritis (Takayasu’s aortitis, giant cell arteritis and classical polyarteritis nodosa) thrombosis, embolism, dissection of the renal artery, neurofibromatosis and prior radiotherapy.¹ Where the lesion(s) subtend the entire renal mass, impaired renal function (ischemic nephropathy) may result. In patients aged over 50 years with chronic kidney disease, ARVD may contribute to renal damage in 14% to 25% of patients.² Correction of ARVD should ideally lead to the cure of hypertension and/or normalization of renal function. However, coexisting processes such as essential hypertension or renal parenchymal disease (such as diabetic, hypertensive, or atheroembolic nephropathy) frequently limit complete recovery in this patient group.³

It must be stressed that the finding of renovascular disease (RVD) in a patient with hypertension and/or impaired renal function does not necessarily indicate a causal relationship (see Figure 64–1). The prevalence of ARVD in a postmortem study was 5%, 18%, and 42% in those aged less than 64, 65 to 74, and 75 and older, respectively.⁴ “Incidental” ARVD is not uncommon and has been increasingly identified. The functional significance of renal artery stenosis should be explored when considering intervention.

Since the 1980s, major advances have occurred in the understanding of pathophysiology, diagnosis (particularly noninvasive contrast magnetic resonance angiography (MRA) and computed tomography angiography (CTA), medical and interventional treatment (percutaneous transluminal renal artery angioplasty [PTRA] plus endoluminal stent insertion) of RVH. As medical treatment of hypertension has improved, the focus of intervention has shifted from blood pressure control to the preservation of renal function in patients with ischemic nephropathy due to significant renal artery stenosis. Nevertheless, the evidence base in this field is severely limited, and many key questions surrounding patient investigation and patient selection for revascularization await the outcome of ongoing prospective randomized trials.

This chapter focuses on practical clinical approaches to the identification, investigation, and treatment of RVH in native kidneys in adults. The 2006 American College of Cardiology/American Heart Association recommendations have been summarized in boxes after each section so as to inform best current practice.¹

Renovascular hypertension (RVH) is a syndrome of arterial hypertension caused by reduced renal perfusion pressure secondary to a vascular lesion of the main renal artery or one of its branches. RVH is the most common cause of secondary, potentially remediable hypertension (1% to

ANATOMY AND PATHOLOGY

Fibromuscular dysplasia

Fibromuscular dysplasia (FMD) accounts for less than 10% of cases of renal artery stenosis and encompasses an important group of non-atherosclerotic, non-inflammatory vascular diseases pathologically sub-classified by the arterial layer in which the lesion predominates.⁵ The most frequent dysplastic pathology is medial fibroplasia, characterized by alternating aneurismal (intimal and medial thinning with loss of the internal elastic lamina) and stenotic (medial thickening and fibrosis) arterial segments. This leads to the classical “string of beads” appearance seen in angiography. In contrast to atheromatous disease, medial fibroplasia usually affects the mid and/or distal main renal artery (60% of cases) and less commonly intrarenal segmental branches (<10%). Bilateral renal artery involvement and involvement of extrarenal vascular beds, typically the extracranial carotid circulation, is seen in around one-third of cases. In the latter case, there is an association with intracranial aneurysm formation. Renal artery aneurysms may develop as the predominant clinical feature. Aneurysms larger than 2 cm are at risk of rupture, particularly in pregnancy. Intimal fibroplasia is identified as focal concentric stenoses at angiography. The differential diagnosis is of an arteritic process.⁵

The pathogenesis of FMD remains obscure, but mural ischemia, due to functional defects in the vasa vasorum during development, has been postulated. FMD of renal arteries is more common in younger women (second to fifth decade) and in those who smoke. A genetic component is suggested by the finding of FMD in increased frequency in first-degree family members and in people who carry certain angiotensin converting enzyme (ACE) gene polymorphisms.

Atherosclerotic renovascular disease

Atheromatous renovascular disease is the most common cause of renal artery stenosis. It can be considered primarily as a disease of the abdominal aorta, in which atheromatous plaques encroach on the ostia of the renal arteries. As such, over 80% of ARVD is ostial, and bilateral disease is found in 50% of cases.⁶ At angiography, ostial disease is defined as a stenosis of up to 1 cm from the aortic lumen, which reflects massive aortic wall thickening often seen in this setting. Widespread atheroma of other arterial territories is common, particularly in peripheral vascular disease.

Atheromatous renovascular disease is commonly associated with reduced glomerular filtration rate (GFR) related to parenchymal renal damage that may be unrelated to the stenosis.⁷ Typically, hypertensive nephropathy, atheroembolic damage, and diabetic glomerulonephropathy (where relevant) coexist. In the setting of critical narrowing, ischemic nephropathy or focal renal infarction can be superimposed. Unlike coronary artery stenosis, ARVD is usually characterized by slowly progressive stenoses. As such renal structure may be maintained by the development of collateral blood supply arising most commonly from adrenal and lumbar arteries even in the setting of renal artery occlusion. This should be considered in defining clinical management.⁸

Pathophysiology

It is important to emphasize that the finding of renal artery stenosis in a patient with hypertension and/or renal impairment may be incidental rather than causal, and therefore relief of stenosis may not be beneficial. Understanding the pathophysiology is essential to appropriate clinical management of this condition.

Animal models

Much of our understanding of the pathophysiologic mechanisms of renovascular hypertension stem from the seminal studies performed by Goldblatt of experimental renal artery clipping (stenosis) in dogs. The histology showed that there was a pattern of changes in the kidney with imposed narrowing including marked interstitial fibrosis and B- and T-cell infiltrate.

The two-kidney, one-clip (2K1C) model corresponds to unilateral renal artery stenosis. Renal hypoperfusion acutely activates the renin-angiotensin-aldosterone system resulting in angiotensin II-dependent hypertension. The mechanisms include vasoconstriction, sodium retention, aldosterone release, and augmentation of sympathetic nerve activation. This elevation of blood pressure (BP) results in a pressure natriuresis from the contralateral nonstenotic kidney preventing volume overload; however, systemic vasoconstriction persists. Although hypertension is sustained, plasma renin activity declines and raised BP may be subsequently maintained by alternative mechanisms such as enhanced oxidative stress, raised endothelin, and vasoconstrictor prostaglandin production together with vascular remodeling.⁹ In this model, GFR is preserved by angiotensin II-dependent constriction of postglomerular arterioles maintaining intraglomerular pressure. This may explain the loss of GFR in patients with renal artery stenosis to the entire functioning renal mass treated with ACE inhibitors or ARB drugs. The central role of angiotensin II is confirmed by observations that “knockout” mice deficient in ATII receptors or normal animals pre-treated with converting enzyme inhibitors do not become hypertensive despite unilateral renal artery clipping.

The one-kidney, one-clip (1K-1C) model more closely corresponds to tight bilateral renal artery stenosis or unilateral renal artery stenosis to a sole functioning kidney. Initially raised BP is secondary to activation of the renin-angiotensin-aldosterone system. With time, volume overload secondary to progressive sodium retention develops and tends to lead to reduction in plasma renin activity. This sodium-dependent model of hypertension can be converted to an angiotensin-dependent model by restricting salt intake or by administering diuretics.

Clinical studies

In the clinical setting of bilateral renal artery stenosis or unilateral renal artery stenosis to a single functioning kidney, ACE inhibitors or angiotensin-receptor blocking (ARB) drugs may induce acute renal failure by reducing BP and by relieving angiotensin II-dependent postglomerular vasoconstriction and, as a consequence reducing glomerular filtration. Acute uremia following these agents is an increasingly common presentation of renal artery stenosis.

Failure to tolerate ACE-inhibitor/ARB drugs represents an increasing indication for renal revascularization. The clinical situation is more complex than in experimental studies. It is now clear that most but not all patients with bilateral RVD do indeed tolerate cautiously monitored ACE-inhibitor/ARB drugs.¹⁰ Left ventricular hypertrophy, endothelial dysfunction, and renal interstitial fibrosis are striking features of renal artery stenosis and ischemic nephropathy. They appear to be in excess of that expected for BP and renal function when compared with essential hypertensive controls.^{11,12} Aldosterone released by angiotensin II is now recognized to participate in regulation of tissue fibrosis and left ventricular hypertrophy. It may be an important mediator of these effects in patients with RVH, suggesting a further important role for drugs that block the renin-angiotensin-aldosterone system.

What degree of renal artery stenosis is significant in humans?

Understanding the degree of arterial stenosis at which the kidney suffers ischemia is critical to interpretation of clinical data (Figure 64–1). In healthy people, the kidneys account for 0.5% of body weight, receive 20% of cardiac output, and less than 10% of oxygen delivery is required for metabolic purposes of the kidney. Furthermore, autoregulation maintains renal blood flow and glomerular filtration over a wide range of arterial perfusion pressure. It is therefore not surprising that substantial renal artery luminal stenosis is required before renal ischemia ensues. Difficulties in interpretation of clinical studies are further compounded by known interobserver variability in assessing the degree of renal artery stenosis at angiography, the current “gold standard.” In addition, there is inconsistent reporting of stenosis in clinical studies. Maximal luminal diameter or

luminal area narrowing are reported interchangeably (two-dimensional assessment only). In experimental studies, luminal area narrowing of more than 75% is required to significantly reduce renal blood flow. Renal blood flow, GFR, and perfusion pressure rapidly diminish with greater narrowing.¹³ Clinical studies demonstrate a clinically significant transstenotic peak pressure gradient to be greater than 20 mmHg (mean >10 mmHg). This corresponds to area stenosis of more than 75%, that is, greater than 50% reduction in renal artery diameter if the lesion is concentric.¹⁴ Renal blood flow reduction is thus a late phenomenon in progressive renal artery stenosis, and is manifested only by severe stenosis. This issue complicates interpretation of much of the clinical intervention literature. Studies that include patients with only 50% to 70% of renal artery diameter narrowing have probably incorporated patients without “significant” disease.¹⁵

The clinical situation is much more complex and heterogeneous, and the relevance of animal models is unclear. There is significant species variability in response to renal ischemia; the Goldblatt model is induced acutely in contrast to the slowly progressive clinical situation in ARVD, which allows collateral circulation to develop. In humans, there is frequent pre-existing essential hypertension and renal parenchymal damage due to small-vessel hypertensive damage, cholesterol emboli, and coexistent diabetic renal disease (Figure 64–2). Wright et al.^{7,16} demonstrated that in a group of patients with ARVD, there was no correlation between renal artery anatomy and baseline renal function or functional outcome following intervention. The same applies to studies comparing individual renal function and the severity of ARVD. Severe renal artery stenosis can lead to worsening renal interstitial fibrosis distal to a stenosis, but the mechanisms are incompletely understood.

Figure 64–1. Relationship between degree of renal artery stenosis and renal blood flow in a canine model of renovascular disease. (Redrawn from Schoenberg SOM, et al. *J Am Soc Nephrol* 2000;11:2190–198.)

CLINICAL PRESENTATION AND NATURAL HISTORY

Fibromuscular dysplasia

Fibromuscular dysplasia typically presents with hypertension in young women in the second to fifth decade of

Figure 64–2. Severe chronic parenchymal renal disease due to athero-embolism in a patient with moderate renal artery stenosis.

life. Screening of a population with resistant hypertension identified the cause to be FMD in 16% of cases (Figure 64-3). However, evidence from screening of kidney donors indicates that “incidental” asymptomatic FMD may be relatively common, being detected in 3% to 6% of normotensive individuals.¹⁷ The differential diagnosis includes atheromatous disease, arteritic processes, and rarely, connective tissue disorders Marfan’s and Ehlers-Danlos syndrome. It is not usually difficult to distinguish FMD from atherosclerotic disease clinically. Patients with symptomatic FMD are usually younger and have no other evidence of atherosclerotic disease. At angiography FMD affects the middle/distal renal artery rather than the renal artery origin. In contrast ARVD is almost invariably associated with aortic atheroma.² Arteritic diseases such as Takayasu’s aortitis

and giant cell arteritis are typically associated with systemic symptoms and elevated acute phase markers. The natural history of FMD is variable and not necessarily benign. Progression of angiographic disease (new lesions, increasing stenosis or aneurysm dilatation) occurs in over a third of cases and loss of renal mass (>0.5 cm bipolar length) may be seen in two-thirds of cases, although renal artery occlusion and progressive renal failure are rare unless severe hypertension causes contralateral renal damage.^{18,19}

Atheromatous renovascular disease

Atheromatous renovascular disease is relatively common but frequently asymptomatic and incidental to coexisting hypertension or chronic kidney disease⁹ (Figure 64-4). Hansen et al.²⁰ studied the prevalence of ARVD using renal

Figure 64-4. Catheter renal angiograms of a 55-year-old female with rapid worsening of hypertension on background of longstanding stable essential hypertension and mild chronic kidney disease. She suffered acute renal failure following introduction of converting enzyme inhibitor. Bilateral severe ostial atheromatous renal artery stenoses (**A**). Following successful bilateral percutaneous renal artery stent insertion. (**B**), renal function improved and antihypertensive drug therapy reduced. Twelve months later, serum creatinine and blood pressure rose. Repeat catheter angiography showing instant restenosis which was successfully treated with instant angioplasty (**C**).

artery duplex ultrasound in individuals aged over 65. Of 834 participants, the overall prevalence of significant ARVD (>60%) was 6.8%. It was more frequent in men (9.1%) than women (5.5%). Contrary to previous studies, the prevalence was equal in black and white subjects.

The typical patient with ARVD is older (aged over 55), often with a long-standing history of essential hypertension, features of the metabolic syndrome or type II diabetes mellitus, and a background of ischemic heart disease, peripheral vascular, and cerebrovascular disease. The patient frequently has associated mild chronic kidney disease (as assessed by estimated creatinine clearance), and it is not unusual for the patient to have already undergone revascularization in another arterial territory. The prevalence of ARVD seems to be increasing as mortality from asso-

ciated coronary artery and cerebrovascular disease is diminishing.⁹ Patients are living longer to be identified with more widespread manifestations of atheroma. It is also increasingly common to identify the lesion as the accuracy of screening tests has improved (MRI, CTA, and catheter aortography performed at the time of other indications such as peripheral vascular disease).

Clinically significant atheromatous renal artery stenosis (>75% stenosis or 20-mmHg translesional pressure drop) may present with one of the following clinical syndromes:

1. Renovascular hypertension
2. Ischemic nephropathy (chronic renal failure)
3. Acute renal failure following introduction of ACE inhibitor/ARB drugs
4. Resistant fluid retention/"flash" pulmonary edema

Box 64–1**Clinical Clues to Diagnosis of Renal Artery Stenosis: Recommendations of American College of Cardiology/American Heart Association, 2006****Class I**

The performance of diagnostic studies to identify clinically significant renal artery stenosis is indicated in patients with:

- The onset of hypertension before age 30 years (*Level of evidence: B*)
- The onset of severe hypertension (as defined in *The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure*, known as the JNC-7 report) after age 55 years (*Level of evidence: B*)
- The following characteristics: (a) accelerated hypertension, (b) resistant hypertension (defined as the failure to achieve goal blood pressure in patients who are adhering to full doses of an appropriate three-drug regimen that includes a diuretic), or (c) malignant hypertension (*Level of evidence: C*)
- New azotemia or worsening renal function after administration of an ACE inhibitor or an angiotensin-receptor blocking agent (*Level of evidence: B*)
- An unexplained atrophic kidney or a discrepancy in size between the two kidneys of greater than 1.5 cm (*Level of evidence: B*)
- Sudden unexplained pulmonary edema (especially in azotemic patients) (*Level of evidence: B*)

Renovascular hypertension

In patients with hypertension who are seen in specialist hypertension centers, renovascular hypertension is the underlying etiology in 0.5% to 4%.¹ Faced with a hypertensive patient, what features predict RVH?

Clinical markers for atheromatous renovascular hypertension

Kalra et al.²¹ recently examined a 5% sample of the Medicare population (>1 million subjects included). The incidence of a new diagnosis of renovascular hypertension was 3.7 per hundred patient years in those older than 67. As compared with the general population, the diagnosis of RVH was associated with increased relative risk (RR) of existing chronic kidney disease (RR=2.5), essential hypertension (RR=2.4), peripheral vascular disease (RR=2.0), and ischemic heart disease (RR=1.7). The key clinical challenge is to distinguish hypertensive patients, or those with hypertension in association with chronic kidney disease, who have incidental ARVD, from those where the renal artery narrowing is etiological. A subsequent diagnosis for disease in other vascular territories was also high. The incidence quoted per thousand patient-years was 304 for ischemic heart disease, 259 for peripheral vascular disease, 195 for congestive cardiac failure, 176 for cerebrovascular

disease, 29 for dialysis requirement, and 116 for subsequent patient death. The risk in each of these cases is three- to five-fold that of the general population.

Screening in patients undergoing catheter angiography for other indications highlights the association of ARVD with widespread atheromatous disease. Renal arterial disease was present in 30% of patients undergoing screening renal artery angiography at the time of cardiac catheterization. Lesions likely to be hemodynamically significant have been reported in 11% to 18% of this patient group. Likewise in patients undergoing catheter angiography for investigation of aorto-iliac or peripheral vascular disease, several reports indicate a prevalence of significant ARVD of between 22% and 49%.¹

Krijnen et al.²² reviewed the patient population who were screened for the Dutch Renal Artery Stenosis Intervention Cooperative (DRASTIC) study. These authors sought to identify factors that were predictive of renovascular hypertension as opposed to essential hypertension. In multivariable analysis, the following factors favored RVH over those with essential hypertension: increasing age (odds ratio [OR]=1.8), atherosclerotic vascular disease (OR=1.8), recent-onset hypertension (OR=1.9), smoking history (OR=1.6), abdominal bruit (OR=5.4), and impaired renal function (OR=1.4 per 10 $\mu\text{mol/L}$ increase). The clinical prediction appeared to be as sensitive and specific for ARVD as was the use of screening by captopril scintigraphy.

Renovascular hypertension and ischemic nephropathy

Detailed discussion of the management of ischemic chronic kidney disease is beyond the scope of this review. Nevertheless, it is important to recognize that chronic kidney disease is common in those patients with RVH due to ARVD. In patients over 50, ARVD is felt to be etiologic in 14% to 22% of patients with chronic kidney disease. One in eight patients entering dialysis programs has underlying severe ARVD.

Association with left ventricular hypertrophy

In a recent case-control series, Wright et al.¹¹ examined ambulatory BP and cardiac structure in patients with ARVD. Ninety-five percent of these patients had abnormal cardiac structure or function. As compared with matched patients with essential hypertension, those with ARVD have much greater left ventricular hypertrophy (79% vs. 46%). Those with bilateral renovascular disease had much greater LVH than those with unilateral disease. The cause of this excess LVH is unclear, but ambulatory BP monitoring identified the ARVD group to have less nocturnal fall in BP, and therefore the hypertensive load in the group with ARVD may be greater. In addition, activation of the renin-angiotensin system is well known to be associated with left ventricular re-modeling and growth. This excess LVH may explain in part some of the increased mortality in this patient group.

Mortality in patients with renovascular hypertension secondary to atheromatous renovascular disease

As ARVD is associated with widespread atherosclerotic disease, it is not altogether unsurprising that the mortality

rate in this population is particularly high. In a series of nearly 4000 patients undergoing screening at the time of cardiac catheterization, the 4-year survival rates for patients with and without ARVD was 57% and 89%, respectively. The mortality risk in this group is proportionate to the severity of renal artery narrowing. Four-year survival rates for individuals with ARVD of 50%, 75%, and 95% stenosis were 70%, 68%, and 48%, respectively. In those patients with bilateral ARVD, the 4-year survival was reportedly 47% as compared with 59% for those with unilateral disease. The severity of chronic kidney disease in those with renovascular hypertension due to atheroma also correlated with patient mortality. Three-year survival in this patient group with a creatinine of <1.4 mg/dL was 92%; for those with creatinine levels 1.5 to 1.9, it was 74%; and those with creatinine >2.0, it was only 51%.²³ Patients with RVH who progressed to end-stage renal failure had particularly high mortality rates. Mean life expectancy of individuals older than 65 with ARVD requiring dialysis was found to be only 2.7 years.²⁴ This compares with mean survival for patients with end-stage renal disease (ESRD) on dialysis secondary to malignant-phase hypertension and autosomal dominant polycystic kidney disease of around 6 and 11 years, respectively.

Natural history of atheromatous renovascular disease

The natural history of ARVD is one of progression. Early reports relied on retrospective analyses of serial angiograms performed in patients with either RVH or presumed ischemic nephropathy. Progression of renal artery stenosis occurred in 44% of 85 patients over a mean follow-up of 52 months and in 53% of 48 renal arteries over 7 years. High-grade stenosis (>75%) led to occlusion in 16% and 9%, respectively.^{25,26} These studies probably overestimated the degree of progression, as the decision to repeat angiography is likely to have been influenced by clinical deterioration. The Dutch DRASTIC study group prospectively repeated angiography in patients with RVH due to ARVD at 1 year. Progression of stenosis or subsequent occlusion occurred in 20% and 9% of patients, respectively.²⁷ Similarly, Caps et al.,²⁸ using prospective Doppler ultrasound assessment of ARVD, demonstrated progression to be 35% at 3 years, and 51% at 5 years. Only 3% of arteries progressed to occlusion. Factors that were significantly associated with the risk of renal artery disease progression during follow-up: systolic BP of 160 mmHg or higher, diabetes mellitus, and high-grade (>60% stenosis) disease in either the ipsilateral or contralateral renal artery.

There are relatively little clinical data on the natural history of BP and renal function in patients with RVH due to ARVD. Baboolal et al.²⁹ reported the natural history of a retrospective series of 51 hypertensive patients with severe bilateral ARVD. The rate of loss of renal function overall was 4 mL/min/annum (range 1 to 8). The mortality rate was 45% at 5 years, reducing the final number reaching ESRD to 12%. Those with more advanced uremia and rapid progression were more likely to require dialysis. It is possible that the current rate of progression of chronic kidney disease in this group may be slower than histori-

cally reported. Aggressive lipid and BP control, particularly the more widespread use ACE inhibition, may be relevant. This has significance in defining the best clinical management and in the power calculations underlying ongoing clinical trials in this area.

DIAGNOSTIC TECHNIQUES FOR DETECTION OF RENAL ARTERY STENOSIS

The ideal test for renovascular hypertension should be safe, noninvasive, and provide good anatomic detail of the stenosis in the main renal artery, accessory renal arteries, or branches, with a high degree of sensitivity and specificity. It should have the potential to demonstrate surrounding anatomic structures including details of the renal parenchyma, aorta, and adrenal glands. Most importantly, the test should demonstrate the functional significance of the renal artery stenosis, as well as predict the BP and renal functional response to revascularization (Box 64-2).

Numerous studies in the 1970s and 1980s examined markers of activation of the renin angiotensin system (RAAS) whether at rest or stimulated. These included selective renal vein renin measurements or plasma renin activity measured before or after the administration of captopril, an ACE inhibitor. Standardization of sodium balance and drug therapy were critical, and the diagnostic accuracy against catheter angiography was poor. The tests have largely been abandoned in current clinical practice.

Captopril scintigraphy

Captopril renography detects the angiotensin-II dependence of glomerular filtration rate employing dynamic MAG-3 renography performed before and after administration of a single dose of captopril. In a positive test, there is a delay in the uptake, reduced peak uptake, prolonged parenchymal transit, and slow excretion of tracer. The reported accuracy of captopril renography in identifying patients with renovascular disease has been variable with reported sensitivity around 85% (range 45% to 94%) and speci-

Box 64-2

Diagnostic Methods for Renal Artery Stenosis: Recommendations of American College of Cardiology/American Heart Association, 2006

Class I

The following are recommended as a screening test to establish a diagnosis of renal artery stenosis:

1. Duplex ultrasonography (*Level of evidence: B*)
2. Computed tomographic angiography (in individuals with normal renal function) (*Level of evidence: B*)
3. Magnetic resonance angiography (*Level of evidence: B*)
4. When the clinical index of suspicion is high and the results of noninvasive tests are inconclusive, catheter angiography (*Level of evidence: B*)

ficity of around 93% (range 81% to 100%).¹ When compared with catheter angiography in the clinical setting, the sensitivity and specificity was only 74% and 59%, respectively.³⁰ Furthermore, the predictive accuracy is greatly restricted in those patients with bilateral renal artery stenosis, stenosis to a single functioning kidney and in those with impaired renal function. Therefore, the use of captopril renography as a diagnostic test is limited, although it may have a useful role in predicting the BP benefit of revascularization where the functional significance is uncertain in patients with normal renal function.

Duplex (Doppler with B-mode) ultrasound

In experienced centers duplex ultrasound has a sensitivity of 84% to 98% and a specificity of 62% to 99% when compared with catheter angiography for detecting significant renal artery stenosis. Both direct interrogation of the main renal artery and the downstream intrarenal arteries has been examined. Direct peak systolic velocity higher than 180 to 200 cm/s and renal to aortic ratio greater than 3.5 have been correlated with a stenosis of over 60%. An end diastolic velocity of more than 150 cm/s predicts renal artery stenosis higher than 80%. Measurements of intrarenal Doppler signals to arrive at indirect indices, such as resistive index (RI), are frequently combined. The use of contrast enhancement of ultrasound was explored in a large study with a crossover-randomized design. Visualization of the renal arteries was improved, but the sensitivity and specificity for the diagnosis of renal artery stenosis was not improved.¹

In experienced hands, duplex Doppler ultrasound is an excellent technique to assess re-stenosis in renal arteries previously revascularized by metal stents (a major limitation of MRA in which the metal stent causes significant artifact). Intrarenal RI may also be of value in predicting the clinical outcome of revascularization by PTR.

The limitations of duplex Doppler are that it is time consuming, very operator dependent, and is technically unsuccessful in 20% of patients due to overlying bowel gas or obesity. The technique also frequently fails to identify accessory arteries.

In the last decade, CT angiography (CTA) and contrast-enhanced (gadolinium) MR angiography (MRA) has become the accepted standard for noninvasive imaging of renal arteries. A meta-analysis showed the superiority of both of these techniques over both captopril renography and ultrasonography.³¹

Computed tomographic angiography

CTA has a sensitivity and specificity for detecting significant renal artery stenosis of 59% to 96%, and 82% to 98%, respectively (Figure 64-5). The technology is rapidly advancing. The method is based on rapid volume acquisition capabilities of scans timed after intravenous contrast bolus. Thirty-two and 64 row and flat-panel scanners are in development. With more recent scanners, sensitivity and specificity in excess of 90% against catheter angiography have been reported. In addition, CTA has the advantage over MRA of being able to detect re-stenosis within previously stented renal arteries. Nevertheless, the main

Figure 64-5. Computed tomography angiography (CTA) three-dimensional reconstruction of a patient demonstrating nonostial, left renal artery stenosis.

limitation of CTA in those patients with impaired renal function (in particular, those suffering from diabetes) is the risk of contrast nephropathy (100- to 150-mL contrast is typically employed). As technology improves, the required iodinated contrast dose may be reduced.

Gadolinium-enhanced magnetic resonance angiography

The sensitivity and specificity of MRA for the detection of renal artery stenosis are around 90% to 100% and 76% to 94%, respectively³¹ (Figure 64-6). MRA has the major advantage that the contrast agent gadolinium is non-nephrotoxic in doses currently used. This facilitates its safe use in patients with impaired renal function. Three-dimensional image reconstructions greatly aid diagnosis and the planning of treatment for renal artery stenosis. In addition, newer technologies and improvements in acquisition speed and scanning technique continue to evolve. Contrast flow velocity and assessment of single-kidney GFR show early promise in investigating the functional significance of renal artery stenosis.

Some patients are unable to tolerate the claustrophobia induced by the more closed scanner designs. MRA may be less effective in the assessment of patients with FMD or with branch renal artery stenoses. Its other limitation is inability to re-image renal arteries that have previously undergone insertion of a stent (signal dropout artifact).

In due course, cross-sectional imaging may become the “gold standard” in assessment of the degree of luminal area narrowing, and replace catheter angiography, which is limited to two-dimensional assessment.

Selective renal artery catheter–contrast angiography

At present, selective renal artery catheter–contrast angiography remains the gold standard for the diagnosis of renal artery stenosis, which enables simultaneous percutaneous treatment of stenoses. It has now largely become

Figure 64–6. Gadolinium contrasted magnetic resonance angiography in a patient with severe hypertension and progressive chronic kidney disease demonstrating bilateral ostial renal artery stenosis (AP and coronal views).

a second-line investigation method used to guide percutaneous treatment after confirmation of the diagnosis by noninvasive screening tests. This is because of the higher risk of serious adverse outcomes in patients with impaired renal function and/or more advanced aortic and peripheral vascular atherosclerotic disease.

The risk of contrast-induced acute renal impairment in patients undergoing catheter renal angiography with chronic kidney disease is around 10% to 20%, and is even higher in individuals with concomitant diabetes, reaching between 20% and 50%.³² Contrast-induced allergic reactions and atheromatous renal and lower extremity embolization, as well as groin hematoma, bleeding, and pseudo-aneurysm are also well described. Another disadvantage of this technique includes significant interobserver error in assessing the degree of stenosis. The incidence of complications is greater for the axillary or brachial approaches as compared with the femoral artery approach, even with the use of smaller size-4 French-gauge catheters. Major complications occur in 0.5% to 2% of patients with a mortality risk of 0.02% to 0.05%. The risk of iodinated contrast nephropathy can be reduced by minimizing contrast dose and by prehydration with intravenous normal saline to establish a good urine output prior to and 6 hours following the angiogram. N-acetyl-cysteine given before the examination and after for 48 hours appears beneficial as shown in meta-analyses, although the results are not uniform. Recently the use of iso-osmolar contrast as compared with low osmolality–contrast media has been shown to be associated with a lower risk of contrast nephropathy. Furthermore, other studies have shown a beneficial effect of prehydration with intravenous sodium bicarbonate. Intravenous aminophylline may also be protective.³³

Alternative radiographic contrast media

Renal angiography employing carbon dioxide as a non-nephrotoxic contrast agent has been successfully used in patients undergoing renal arterial intervention studies.³⁴ Employing carbon dioxide as a contrast avoids nephrotoxicity but requires special equipment and is not widely available. Gadolinium (MRI contrast agent) is widely believed to be less nephrotoxic than iodinated contrast media. It is more expensive than other methods, and recent noncontrolled data suggest that it may not be without some risk of nephrotoxicity.³⁵ Gadolinium has recently been linked

to a severe condition of nephrogenic systemic fibrosis in patients with advanced renal failure, although this preliminary finding requires further confirmation.

Diagnosis/Imaging of fibromuscular dysplasia

At present spiral CT angiography and gadolinium-enhanced MRA cannot be relied on to adequately screen for FMD of the renal arteries. The current resolution of these techniques does not permit detailed review of branch renal artery lesions. In selected patients with a high clinical risk of FMD in whom intervention would be considered, it is advised to proceed directly to catheter angiography. In experienced centers, duplex sonography may have a role, as may captopril renography. Imaging technology is rapidly advancing, and as resolution improves these recommendations should be reviewed.¹

CLINICAL MANAGEMENT AND PROGNOSIS

Fibromuscular dysplasia

Fibromuscular dysplasia is the second most common cause of RVH, and is an important potentially remediable condition. The underlying renal parenchyma is usually normal in the absence of hypertensive damage. Patients with FMD rarely suffer renal failure, and those with hypertension will respond to antihypertensive therapy or where indicated, to balloon angioplasty typically without the need for renal artery stent insertion.²

In patients with FMD, percutaneous revascularization should be considered with (1) recent onset hypertension where relief of stenosis may achieve “cure” of raised BP, (2) resistant hypertension or that associated with multiple drug side effects, and (3) development of loss of renal mass/function related to ischemic nephropathy.⁵ The latter indicates the need for close follow-up of BP, renal function, and ultrasound-determined renal size and renal artery Doppler in this population.

There are no randomized trials comparing medical treatment alone against revascularization in patients with FMD. The outcome of 11 series of PTRAs performed for treatment of hypertension in 455 patients is shown in Table 64–1.^{5,36} The initial technical success rate of angioplasty is around 90% with stenosis rates at 2 years less than 10%. In this setting, renal artery stenting is reserved for “bailouts” (>50% residual stenosis after angioplasty or for complications). Cure (normotension without antihypertensive treatment) is achieved in around one-third of cases and a similar proportion showing improved BP control. Covered renal artery stents can be deployed where appropriate to exclude coexisting renal artery aneurysms from the circulation or, in rare cases, renal artery perforation or dissection. Surgery is reserved for cases not amenable to angioplasty/covered stenting, comprising a complex branch of arterial vessel disease requiring *ex vivo* reconstruction or aneurysm repair.³⁷ In experienced hands, the results are excellent.

REVIEW OF TRIALS OF PERCUTANEOUS RENAL ARTERY ANGIOPLASTY IN FIBROMUSCULAR DYSPLASIA (11 SERIES, 1983–2005)

Atherosclerotic renovascular disease

Medical therapy

Individuals with atherosclerotic disease and vascular disease should be treated according to recommendations in the Seventh report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure.^{37a} ARVD is associated with high cardiovascular mortality, and as such, aggressive cardiovascular protection measures should be offered to suitable patients including smoking cessation, cholesterol control with statin therapy, and antiplatelet treatment. Multiple studies demonstrate that calcium-channel blockers, thiazide diuretics, and beta blockers appear effective in BP reduction in patients with ARVD.² Widespread use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blocking (ARB) agents has impacted on both the diagnosis and indications for invasive treatment of ARVD (Box 64–3).

Converting enzyme inhibitors or angiotensin-receptor blockers in renovascular hypertension

Prior to the availability of ACE inhibitors or AR blockers, BP control could only be achieved in less than 50% of patients with RVH secondary to ARVD who were referred to specialist centers. With the use of ACE inhibitors as well

as the availability of new classes of antihypertensive agents in this population, 82% to 96% of patients achieve satisfactory BP control.³⁸

Patients suffering from vascular disease or impaired left ventricular dysfunction (both of which are common in this patient population) treated with ACE/ARBs reduces mortality, compared to other antihypertensive drug classes.¹⁰ Furthermore, ACE inhibitors/ARB drugs, compared to other antihypertensive agents, reduce the rate of progression of both diabetic and nondiabetic chronic kidney disease.³⁸ However, in patients with ARVD subtending the whole renal mass, there is a risk of acute uremia following treatment with these drugs. This occurs because glomerular filtration is preserved by angiotensin II–mediated post-glomerular vasoconstriction in these patients.

How much of a risk does this represent? Large clinical trials in populations at high risk of ARVD (congestive cardiac failure, ischemic heart disease) demonstrate a low rate of functional renal decline after ACE inhibition. Patient withdrawal as a result of acute renal failure or hyperkalemia from these trials is rare at 2% to 6%.³⁹ It should be recognized that a 20% rise in ACE inhibitor–induced creatinine may occur even in patients who do not suffer RVH. Hollenberg et al.³⁸ treated 136 patients with captopril, who were known to have ARVD in the entire renal mass. Only 6% developed a decline in renal function over 4 weeks, which was reversible on stopping treatment. In a randomized double-blind trial of enalapril versus a non-ACE inhibitor regime in patients with RVH, 20% in the ACE group developed a rise in creatinine.⁴⁰ Preliminary evidence suggests that these drugs may reduce mortality in the renovascular population. It appears that most patients with RVH can be safely treated with ACE inhibitors. Nevertheless, these drugs must be introduced with great caution in patients known to suffer, or be at high risk for ARVD. Caution must be taken to ensure that patients are not over-diuresed, and renal function must be checked 1 week prior to and 4 weeks after starting these agents or after drug dose escalation.

Increasingly, failure to tolerate ACE inhibition as a consequence of acute decline in renal function has become an important indication for investigation for ARVD. In suitable patients, an inability to tolerate ACE inhibitors due to acute uremia represents an important indication for intervention.^{10,38}

Medical Treatment of Renal Artery Stenosis: Recommendations of American College of Cardiology/American Heart Association, 2006

Class I

The following are effective medications for treatment of hypertension associated with unilateral renal artery stenosis:

- Angiotensin-converting enzyme inhibitors (*Level of evidence: A*)
- Angiotensin receptor blockers (*Level of evidence: B*)
- Calcium-channel blockers (*Level of evidence: A*)
- Beta-blockers (*Level of evidence: A*)

Revascularization for renovascular hypertension due to significant atheromatous disease

Procedural success and complication rate for angioplasty alone versus angioplasty and stent insertion

Over 75% of ARVD is ostial in origin (within 1 cm of the aortic lumen), and relates predominantly to aortic atheroma encroaching on the renal artery ostia. As such, balloon angioplasty alone is associated with a high immediate recoil rate and high likelihood of late re-stenosis. A single small randomized study ($n=85$) compared renal artery stent insertion with angioplasty for ostial renal artery stenosis associated with “critical” ARVD. Primary success rate (<50% residual stenosis) of angioplasty was 57% compared with 88% for stent (difference between groups was 31%, 95% confidence interval [CI]=12–50). At 6 months, the primary patency rate was 29% (12 patients) for PTRA, and 75% (30 patients) for PTRA plus stent (46%, CI=24–68). Restenosis after a successful primary procedure occurred in 48% of patients for PTRA and 14% for PTRA and stent (34%, CI=11–58).⁴¹ Leertouwer et al.⁴² performed a meta-analysis of published studies comprising 644 patients. Renal artery stent placement proved highly successful, with an initial adequate patency rate of 98% and a restenosis rate at 6- to -29 month-follow-up of 17%, compared to rates of 77% and 26%, respectively, for angioplasty alone. The “cure rate” for hypertension was higher (20% vs. 10%), but renal functional improvement was lower (30% vs. 38%) in those treated with stent placement versus angioplasty alone. The latter is unexplained, but may reflect

increased athero-emboli associated with stent placement. Renal angioplasty alone has a better procedural outcome in truncal disease, which is similar to the outcome in primary stenting (Boxes 64–4 and 64–5).

PTRA is not a benign procedure in this frail population group. Major complication rates are the same for both procedures at around 10%. These complications include renal failure (5%), segmental renal infarction (1%) perinephric hematoma (1%), renal artery thrombosis/occlusion (0.7%), and groin hematoma (5%). Patient mortality was around 1% (CI=0–2).

Randomized controlled trials of percutaneous transluminal angioplasty plus medical therapy versus medical therapy alone in patients with atheromatous renovascular disease

The evidence base on which to guide therapy is limited to three somewhat flawed, small randomized trials of PTRA versus medical treatment in patients with RVH and ARVD^{27,43,44} (see Table 64–2).

In the DRASTIC study, 106 patients with unilateral or bilateral ARVD of greater than 50%-diameter luminal narrowing were randomly allocated to PTRA (almost all angioplasty alone) or medical therapy with a follow-up of 12 months. Blood pressure did not differ between groups, although the defined daily dose (DDD) of antihypertensive drugs was reduced by one agent in the intervention group. Renal function was significantly better at 3 months in the angioplasty group, but no difference was found at 1 year. There are several shortcomings of this study. Forty-four

Box 64–4

Indications for Revascularization: Recommendations of American College of Cardiology/American Heart Association, 2006

Asymptomatic Stenosis

1. Percutaneous revascularization may be considered for treatment of an asymptomatic bilateral or solitary viable kidney with a hemodynamically significant renal artery stenosis. (*Level of evidence: C*)
2. The usefulness of percutaneous revascularization of an asymptomatic unilateral hemodynamically significant renal artery stenosis in a viable kidney is not well established and is presently clinically unproven. (*Level of evidence: C*)

Hypertension

1. Percutaneous revascularization is reasonable for patients with hemodynamically significant renal artery stenosis and accelerated hypertension, resistant hypertension, malignant hypertension, hypertension with an unexplained unilateral small kidney, and hypertension with intolerance to medication. (*Level of evidence: B*)

Preservation of Renal Function

1. Percutaneous revascularization is reasonable for patients with renal artery stenosis and progressive chronic kidney disease with bilateral renal artery stenosis or a renal artery stenosis to a solitary functioning kidney. (*Level of evidence: B*)
2. Percutaneous revascularization may be considered for patients with renal artery stenosis and chronic renal insufficiency with unilateral renal artery stenosis. (*Level of evidence: C*)

Impact of Renal Artery Stenosis on Congestive Heart Failure and Unstable Angina

1. Percutaneous revascularization is indicated for patients with hemodynamically significant renal artery stenosis and recurrent, unexplained congestive heart failure, or sudden, unexplained pulmonary edema. (*Level of evidence: B*)
2. Percutaneous revascularization is reasonable for patients with hemodynamically significant renal artery stenosis and unstable angina. (*Level of evidence: B*)

Box 64-5**Catheter-Based Interventions:
Recommendations of American
College of Cardiology/American Heart
Association, 2006**

1. Renal stent placement is indicated for ostial atherosclerotic renal artery stenosis lesions that meet the clinical criteria for intervention. (*Level of evidence: B*)
2. Balloon angioplasty with bailout stent placement if necessary is recommended for fibromuscular dysplasia lesions. (*Level of evidence: B*)

percent of patients initially allocated to drug treatment crossed over during the trial and received PTRAs due to presumed failure of medical treatment. As expected, renal artery patency achieved with angioplasty alone was poor at the end of the study with post-PTRA restenosis occurring in 48% of patients. Some patients with stenosis of around 50% were unlikely to have hemodynamically significant renal artery disease. The UK, Scottish and Newcastle Renal Artery Stenosis Collaborative Group (SNRASCG) randomized 44 of 135 eligible patients with presumed RVH and unilateral or bilateral ARVD of at least

50% to angioplasty (without stent) or medical treatment alone. After a follow-up of 3 to 54 months, systolic BP was lower in the PTRAs group. The benefit was confined to those with bilateral disease and no patient was cured. The same provisos apply to the significance of stenosis and long-term success of PTRAs. The French EMMA group randomized 40 patients with RVH in the setting of hemodynamically significant ARVD. After 6 months BP and renal function were the same in both groups although the DDD in the PTRAs group was lower. A quarter of patients crossed over from the medical to PTRAs for resistant hypertension.

Systematic review of randomized trials

A systematic Cochrane Library review of balloon angioplasty versus medical therapy for hypertensive patients with renal artery obstruction has recently been published. Meta-analysis of the above three randomized controlled trials included a total of 210 patients.⁴⁵ Those treated with balloon angioplasty required less antihypertensive drugs and were more likely to have patent renal arteries at 12 months (OR=4.2, CI=1.8–9.8). Cardiovascular and renovascular complications were also significantly less in the intervention group (OR=0.32, CI=0.15–0.7). There was no impact on renal function. A second meta-analysis that examined changes from baseline did in fact suggest that a small improvement in BP occurred; however, the improvement was of borderline significance with wide

RANDOMIZED CONTROLLED TRIALS OF PTA PLUS MEDICAL THERAPY VS. MEDICAL THERAPY ALONE IN PATIENTS WITH ATHEROMATOUS RENAL ARTERY STENOSIS

confidence intervals ($p=0.06$)(Figure 64–7).⁴⁶ Large randomized controlled studies in this area are required to define the true benefit and ideal patient selection for intervention.

Role of distal atheroembolic protection device at time of percutaneous transluminal renal artery angioplasty/stent

Manipulation of a guide wire and subsequent deployment of the angioplasty balloon and stent is associated with distal athero-emboli (mainly of cholesterol crystals) in coronary or carotid circulation. These emboli can adversely affect tissue microcirculation. Controlled trial evidence indicates that the deployment of distal protection devices at the time of angioplasty and/or stent in those areas captures cholesterol crystals and can lead to improved outcomes.⁴⁷ Clinical results following successful percutaneous renal artery revascularization in ARVD are variable. Stabilization or improvement of hypertension or renal impairment may result in some patients, while deterioration occurs in others. By extrapolation it is plausible that renal athero-emboli during PTRA may limit benefits in this setting. Indeed, recent preliminary evidence confirms generation of athero-emboli following PTRA, the magnitude of which can be limited by one distal protection device.⁴⁸ Technical improvement is required to adapt this treatment to the specific requirements for renal artery use. Importantly, the randomized CORAL study (Cardiovascular Outcomes with Renal Atherosclerotic Lesions) will examine whether these devices lead to better clinical outcomes when compared to renal stent placement alone.

Surgical management of atheromatous renovascular disease

The requirement for surgical intervention to accomplish renal revascularization in ARVD has diminished considerably

since the late 1990s. The technical success and long-term durability of percutaneous renal artery stenting has largely replaced the previous main indication for surgery, namely ostial ARVD.⁴⁹ Traditionally, aorto-renal bypass employing saphenous vein conduits were used for single-renal artery bypass while trans-aortic renal endarterectomy was employed in the case of multiple renal arteries, often in combination with aortic reconstruction. Subsequently, extra-anatomic bypass procedures employing disease-free splenic or hepatic arteries have become more popular.³⁸ Reported surgical perioperative mortality rates are 2% to 6% as compared with around 1% for percutaneous intervention. In a highly comorbid patient group with generalized arteriopathy, complication rates following aorto-renal surgery are also significant, including periprocedure myocardial infarction (2% to 9% vs. 0% to 3%, respectively) and cholesterol embolization syndrome. The reported risks of surgical renal artery revascularization failure at 5 years ranges from 6% to 18% in experienced hands.⁹ More recently, extra-anatomic bypass (splenic artery on the left and hepatic artery on the right) have gained acceptance. This approach avoids the need for surgery on a severely diseased aorta as well as the need for aortic cross-clamping in a group of patients with frequently compromised left ventricular function. Extra-anatomic bypass is associated with a lower mortality rate (2.9%) compared to aorto-renal bypass³⁷ (see Box 64–6).

A defined role for surgery remains in patients with ARVD requiring revascularization. Vascular surgical reconstruction is indicated for patients with a clinical indication for intervention who at the same time require aortic reconstruction, e.g., in the treatment of aortic aneurysm or severe aorto-iliac occlusive disease.⁴⁹ Combined surgery has increased mortality and morbidity rates as compared with aortic or renal artery surgery alone. Associated coronary and cerebrovascular diseases are common. Careful screening and, where possible, correction of critical disease

Figure 64–7. Meta-analysis of randomized controlled trials of angioplasty versus medical treatment in patients with renovascular hypertension due to atheromatous renal artery stenosis. Effect on diastolic blood pressure. (Redrawn from Ives N J, et al. *Nephrol Dial Transplant*, 2003. 18:298–304 with permission from Oxford University Press.)

Box 64–6**Surgery for Renal Artery Stenosis: Recommendations of American College of Cardiology/American Heart Association, 2006**

1. Vascular surgical reconstruction is indicated for patients with fibromuscular dysplastic renal artery stenosis with clinical indications for interventions (same as for PTRAs), especially those exhibiting complex disease that extends into the segmental arteries and those having macroaneurysms. (*Level of evidence: B*)
2. Vascular surgical reconstruction is indicated for patients with atherosclerotic renal artery stenosis and clinical indications for intervention, especially those with multiple small renal arteries or early primary branching of the main renal artery. (*Level of evidence: B*)
3. Vascular surgical reconstruction is indicated for patients with atherosclerotic renal artery stenosis in combination with pararenal aortic reconstructions (in treatment of aortic aneurysms or severe aortoiliac occlusive disease). (*Level of evidence: C*)

in these areas in advance of aorto-iliac surgery, may improve outcome or enable focused surgical selection; this issue remains controversial.⁵⁰ Surgery may also be indicated when there are stenoses in multiple small renal arteries or early primary branching of the main renal artery. Bilateral renal artery occlusion causing acute renal failure where the renal parenchyma is preserved by collateral blood supply remains a strong indication for surgical treatment.⁵¹

Comparison of surgery versus percutaneous transluminal renal artery angioplasty for revascularization

Weibull et al.⁵² performed the only randomized study comparing PTRAs (without stenting) with surgical revascularization in 58 patients with unilateral renovascular disease. The primary patency rate at 2 years was 75% and 96% in the PTRAs and surgical groups, respectively. The impact on BP or renal function was not significantly different, although 17% of the patients treated with PTRAs underwent subsequent surgical intervention. Major morbidity was reported in 34% of surgically treated patients as compared with 17% of those receiving angioplasty. It is difficult to generalize these results to current clinical practice. The primary patency rate quoted is much higher than in other series after angioplasty alone—the patients studied had unilateral disease only and were all non-diabetic. As such, the patients were not typical of current practice and represented a relatively low-risk group. A clinical trial comparing renal artery revascularization by PTRAs or surgery is now unlikely to be performed as the indications for the two procedures fall into different categories.

Predictors of intervention outcome in atheromatous renovascular disease

Both surgical renal revascularization and percutaneous renal artery stenting in selected patients durably correct renal arterial stenosis and improve BP control, and/or stabilize or improve renal function in selected patients with hemodynamically relevant renal artery stenosis. The clinical challenge is to identify individual patients who are likely to respond and then select them for intervention thereby sparing the remainder from the interventional risks. In surgical series, favorable response of BP and renal function to revascularization could be predicted by (1) serum creatinine <3 mg/dL, (2) preserved renal structure as defined by intraoperative histology, and (3) rapidly declining preoperative renal function.⁵³ In patients undergoing PTRAs, rapidly declining pre-intervention renal function was also predictive of a beneficial result. Radermacher et al.^{54,55} reported that a Doppler ultrasound-derived variable, intrarenal resistive index (RI) greater than 0.8, was a marker of poor outcome after PTRAs. A higher RI is associated with more extensive renal parenchymal disease. Nevertheless, this study has been criticized due to its retrospective nature and use of angioplasty without stenting. Furthermore, these data have been challenged recently by a prospective uncontrolled study of renal stent placement in 241 patients by Zeller et al.⁵⁶ Normal renal parenchymal thickness, high baseline BP, and female sex independently predicted a favorable fall in BP. Another multivariable logistic regression analysis demonstrated that bilateral ARVD and mean arterial pressure higher than 110 mmHg to predict a beneficial BP response to renal artery stenting in patients with RVH.⁵⁷ The evidence base is limited at present.

Revascularization in special situations**Flash pulmonary edema**

Pickering et al.⁵⁸ first described a syndrome of recurrent life-threatening pulmonary edema in patients with renal impairment who exhibit tight arterial stenosis to their whole renal mass (bilateral or unilateral to single functioning kidney). This was “cured” by surgical or percutaneous revascularization. Flash pulmonary edema is largely a diagnosis of exclusion, which is usually made after exclusion of other more common causes of pulmonary edema such as left ventricular systolic impairment or reversible myocardial ischemia. Alterations in circulatory homeostasis in these patients can provoke exacerbations of coronary ischemia and/or congestive cardiac failure (which frequently coexists,⁵⁹ due to peripheral vasoconstriction, direct effects of angiotensin II on the myocardium and/or volume overload).¹ Relief of renal artery stenosis may reduce angiotensin levels, increase GFR, enable natriuresis, and permit introduction of ACE inhibition. Furthermore, acute decline in renal function following introduction of a converting enzyme inhibitor in a patient with bilateral renal artery stenosis may limit optimal medical therapy of patients with impaired left ventricular systolic function, thereby predisposing them to decompensation and heart failure.

ONGOING RANDOMIZED CONTROLLED STUDIES OF PERCUTANEOUS TRANSLUMINAL RENAL ARTERY ANGIOPLASTY/STENTING FOR ATHEROMATOUS RENAL ARTERY STENOSIS						
Study (Recruitment Start/Projected End)	Target <i>n</i>	Stenosis (Site)	Renal Artery Intervention	Comparator Group	Primary Endpoint	Minimum Follow-up (Years)
ASTRAL (2000/07)	750	>50% (any)	Angioplasty ± stent	Medical (center specific)	Rate of chronic kidney disease progression	1
STAR (2000/06) ⁶¹	140	>50% (ostial)	Stent	Medical (defined)	20% fall in CrCl	1
NITER (2003/07) ⁶²	100	>70% (ostial)	Stent	Medical (defined)	Death/dialysis or >20% fall glomerular filtration rate	3
CORAL (2005/07) ⁶³	1060	>60% (or >20 mmHg pressure drop)	Stent	Medical (defined)	Death/dialysis or major adverse cardiovascular events	2

Table 64-3. Ongoing Randomized Controlled Studies of Percutaneous Transluminal Renal Artery Angioplasty/Stenting for Atheromatous Renal Artery Stenosis

Stable congestive cardiac failure and angina

Preliminary evidence suggests that percutaneous renal revascularization in selected patients with ARVD and ischemic heart disease may lead to improved severity of angina (Canadian Cardiovascular Society Angina score) and/or symptomatic heart failure.⁶⁰ In these studies, the benefits were sustained over 8 months. Patients underwent percutaneous stenting of both coronary and renal artery stenoses or of renal artery stenosis alone. Those who underwent renal artery stenting alone seemed to gain the same cardiac benefits as those patients who underwent both procedures. It must be stressed that these results require confirmation by ongoing prospective randomized studies.

The ongoing ASTRAL (Angioplasty and Stent for Renal Artery Lesions) Trial (United Kingdom) and its heart and heart failure substudies, as well as the CORAL study, will hopefully answer these important questions.

SUMMARY

Many questions regarding the natural history, pathophysiology, and medical and surgical treatment of patients with renovascular hypertension remain unanswered. Despite this being a relatively common condition, the field is dogged by the lack of robust evidence on which to guide manage-

ment. It is clear from existing evidence that we have extremely good diagnostic tools to identify the disease as well as percutaneous intervention that durably restores renal artery patency, albeit at some risk. Fortunately, ongoing randomized controlled trials should help resolve at least some of the pertinent issues (Table 64–3).

Inclusion criteria for ASTRAL (>700 patients recruited, target 750) allow a wide range of stenosis severity. This study recruits predominantly from UK and Australasia. This will enable subsequent broad predefined subgroup analysis. Researchers have already recruited three times the number of patients included in all previous randomized studies in this area. Two substudies look at the impact of PTRAs on cardiac structure/function in those patients with preserved and impaired systolic function.

The North American CORAL study addresses whether medical therapy and stent placement for hemodynamically significant ARVD in patients with refractory systolic hypertension reduce the incidence of adverse cardiovascular and renal endpoints compared with medical therapy alone. The intervention subgroup also explores the important question of whether the deployment of a distal atheroembolic protection device at the time of stent placement improves outcomes compared with a stent alone.

Proteinuria

Chris Isles

Definition

- Microalbuminuria and proteinuria are common in hypertensive diseases. They predict progressive renal failure and also amplify the risk of vascular disease. The heavier the proteinuria the greater the risk of progressive renal failure, whereas even microalbuminuria can amplify the risk of vascular disease.
- 24 hour urine collections are no longer recommended for quantification of urine albumin or protein. Microalbuminuria can be detected by the albumin:creatinine ratio and proteinuria by the protein:creatinine ratio, on untimed specimens of urine.
- Microalbuminuria is defined as an albumin:creatinine ratio between around 3 and 30 mg/mmol creatinine, and proteinuria by a protein:creatinine ratio > 45 mg/mmol creatinine.

Clinical Implications

- Control of blood pressure and renin angiotensin system blockade can reduce both microalbuminuria and proteinuria, which in turn may lead to a reduction in the risk of vascular disease and in the rate of progression of renal disease.
- The target of blood pressure for patients with microalbuminuria and proteinuria is <130/80 mmHg, though this is not always possible to achieve even with several antihypertensive drugs taken in combination.
- ACE inhibitors and/or angiotensin receptor blockers have both antihypertensive and antiproteinuric properties. They are indicated for diabetics with microalbuminuria and for non diabetics with protein:creatinine ratio exceeding 50 mg/mmol.
- The antiproteinuric effect of these drugs is related to the intensity of renin angiotensin system blockade and may be increased when ACE inhibitors and angiotensin receptor blockers are given in combination.
- Adverse effects of renin angiotensin system blockade include hyperkalaemia and worsening renal function, which is more likely to occur in patients with vascular disease.
- Statins may also have antiproteinuric effects although evidence to date suggests that these are less than those of drugs that block the renin angiotensin system.

Hypertension may lead to renal failure and renal disease commonly causes hypertension. Elevated blood pressure is an independent risk factor for chronic kidney disease (CKD)¹ and may also be the main reason why renal function declines with age.^{2,3} Renal dysfunction is common among patients with diabetes or vascular disease, many of

whom are significantly hypertensive. The pathogenesis of the renal failure in this setting is likely to include contributions from large vessel renal disease (i.e., atherosclerotic renal vascular disease), small vessel renal disease (so called hypertensive nephrosclerosis) and cholesterol embolism.

Proteinuria, the hallmark of glomerular disease, is also common in the hypertensive renal diseases, and greater in patients with hypertensive renal diseases who have impaired renal function. For example, glomerular filtration rate (GFR) and proteinuria in the 1094 African Americans with hypertensive renal disease who participated in the AASK trial, ranged from 20 to 65 mL/min/1.73 m² and 20 to 2023 mg/24 h, respectively. Approximately two-thirds had microalbuminuria and one-third proteinuria, although none had nephrotic-range proteinuria (>3 g/24 h). Proteinuria greater than 1 g/24 h was seen almost exclusively in patients with GFR less than 40 mL/min.⁴

Proteinuria, when present in hypertensive renal diseases, may accelerate the decline of renal function^{4,5} and also amplify the risk of vascular disease.^{6,7} For these reasons, a working knowledge of the measurement, implications, and management of proteinuria in patients with hypertension is likely to be helpful to today's clinicians.

MEASUREMENT OF PROTEINURIA

The literature on measurement on proteinuria is not a particularly easy read. This is partly because measurements may be of urinary albumin or urinary total protein, and because of the different units of measurement used in the United States and United Kingdom. Against this background, normal urine protein excretion is less than 150 mg/24 h. This comprises up to 30 mg of albumin, the remainder consisting of low-molecular-weight proteins freely filtered by the glomerulus and Tamm-Horsfall proteins and β_2 -microglobulin that are secreted by the tubules. The relation between albumin and total protein excretion is nonlinear, such that albumin typically represents 50% of total urinary protein at 300 mg/L and 70% at 1 g/L.⁸ Tests for proteinuria range from the semiquantitative urinalysis strip to measurement of albumin:creatinine and protein:creatinine ratios on spot urine samples, and finally to quantitative assay for all forms of protein in a 24-hour urine collection.

Urinalysis for proteinuria is recommended as part of the initial assessment of patients with hypertension by the

British Hypertension Society,⁹ Scottish Intercollegiate Guidelines Network,¹⁰ and National Institute for Clinical Excellence,¹¹ because persistent proteinuria may indicate underlying CKD, and is also associated with an increased risk of cardiovascular disease (CVD). The simple dipstick urinalysis strip is a useful initial test for proteinuria provided the following four limitations are recognized. First, the test strip is more sensitive to albumin than to globulin and may not detect Bence Jones protein (BJP). Consequently, a negative urinalysis does not exclude significant urinary protein loss in the setting of myeloma. Second, dipstick proteinuria measures albumin concentration in excreted urine volume, not the rate of albumin excretion, and is therefore highly influenced by the concentration or dilution of the urine sample. Third, it is insufficiently sensitive to detect microalbuminuria (MA). Fourth, it is at best semiquantitative. As a general rule, 2+ proteinuria equates to a protein output of around 1 g/24 h, but for all urinalysis showing 1+ proteinuria or more, a quantitative assessment is recommended.

The gold standard for quantitative assessment, with some qualification, remains the laboratory analysis of a 24-hour urine collection, which detects both albumin and globulins. The qualification is that 24-hour urines are notoriously difficult to collect as many patients fail to understand that the collection begins by discarding the first specimen on the first day and is completed by including the first specimen in the second day. Some idea of the completeness of a 24-hour urine collection can be gained by measuring urine creatinine. Twenty-four-hour urine collections in which the ratio of measured creatinine (MC) to estimated creatinine (EC) is between 0.75 and 1.25 are likely to be accurate, where EC excretion is given by the following formula¹²:

$$\text{EC g/24 h} = (140 \text{ minus age}) \times \text{lean weight (kg)} \times 0.2 \\ (\times 0.85 \text{ if female})$$

Guidelines in the United States and United Kingdom suggest untimed “spot” urine samples should be used in preference to 24-hour urine collections to detect and monitor proteinuria, either by albumin:creatinine ratio or protein:creatinine ratio.^{13,14} Although a first-morning urine specimen has been recommended^{13,14} it is by no means clear that spot urines at other times of day are any less satisfactory. Three of eight studies in the National Kidney Foundation’s DOQI report¹³ evaluating urine protein:creatinine ratio concluded that a daytime sample was a better predictor of 24-hour urine protein than a first void. Two of the eight studies tested a daytime sample only, two reported little difference between first void and subsequent random urines, and one found that a first void was more accurate.¹³ Surprisingly, only one of these eight studies attempted to confirm the accuracy of the 24-hour urine protein (gold standard) by simultaneous measurement of urine creatinine, which may account for at least some of the deviations from the line of unity reported in these studies.¹³ The most recent contribution to the debate on timing of the spot urine sample has concluded that random urine samples through

the day are all satisfactory substitutes for 24-hour proteinuria.¹⁵

The normal range for albumin:creatinine ratio in the United Kingdom is given as less than 2.5 mg/mmol in men and less than 3.5 mg/mmol in women, reflecting the fact that women generally excrete less creatinine in their urine than men.¹⁶ MA, which is used primarily to identify people with diabetes who are at risk of developing nephropathy, and which is defined as an albumin excretion rate (AER) of 30 to 300 mg/24 h, can be inferred when the albumin:creatinine ratio is higher than 2.5 mg/mmol in men or higher than 3.5 mg/mmol in women and less than 30 mg/mmol in both sexes. For completeness, the American Diabetes Association expresses albumin:creatinine ratio as milligrams per gram. The Association’s normal range is less than 30 for both men and women.¹⁷ MA is defined as albumin:creatinine ratio of 30–300 (which corresponds rather conveniently with a urinary albumin excretion rate of 30–300 mg/24 h). Clinical proteinuria is suggested either by an albumin:creatinine ratio higher than 30 mg/mmol (United Kingdom) or 300 mg/g (United States), and is more appropriately assessed by the protein:creatinine ratio.¹² Table 65–1 presents thresholds for microalbuminuria and proteinuria by albumin and total urine protein excretion.

The normal range for total protein:creatinine ratio is less than 15 mg/mmol. MA is suggested by a protein:creatinine ratio of 15 to 44 mg/mmol, but is more appropriately assessed by the albumin:creatinine ratio (above). Protein:creatinine ratio >45 mg/mmol represents clinical proteinuria and is approximately equivalent to an AER >300 mg/24 h or to a total urinary protein excretion of 0.45 g/24 h.¹⁴ For completeness, the Americans express protein:creatinine ratio in grams per gram. To convert mmol of creatinine to grams of creatinine, divide by 8.84 or approximate (as is commonly done) by accepting that 10 mmol of creatinine is roughly equivalent to 1 g of creatinine.

A more precise estimate of urinary protein excretion can be obtained by calculating estimated protein output in grams per 24 hours using the formula given below. It is clear from this formula that estimated protein output will be the same as protein:creatinine ratio when the estimated creatinine excretion is 1 g/24 h, which it is for a 70-year-old man weighing 70 kg (see formula for estimated creatinine excretion). Estimated protein output therefore adds value to protein:creatinine ratio in very light or very heavy subjects whose estimated creatinine excretion is either much less or much greater than 1 g/24 h.¹⁸

$$\text{EPO g/24 h} = \text{protein/creatinine ratio} \times \text{estimated creatinine excretion}$$

RISKS OF PROTEINURIA

Renal risk of proteinuria

Much of the work on the pathophysiology of proteinuria and its relation to renal function comes from studies of diabetes in which the development of nephropathy typi-

THRESHOLDS FOR MICROALBUMINURIA AND PROTEINURIA BY ALBUMIN AND TOTAL URINE PROTEIN EXCRETION			
Albumin:Creatinine Ratio (ACR)	Albumin Excretion Rate (AER)	Protein:Creatinine Ratio (PCR)	Protein Excretion Rate (PER)
Normal			
<2.5 mg/mmol men	<30 mg/24 hours	<15 mg/mmol	<0.15 g/24 hours
<3.5 mg/mmol women			
<30 mg/g (U.S.)			
Microalbuminuria			
2.5–30 mg/mmol men	30–300 mg/24 hours	15–45 mg/mmol	0.15–0.45 g/24 hours
3.5–30 mg/mmol women			
30–300 mg/g (U.S.)			
But better assessed by ACR or AER			
Proteinuria			
> 30 mg/mmol	> 300 mg/24 hours	> 45 mg/mmol	>0.45 g/24 hours
> 300 mg/g (U.S.)			
But better assessed by PCR or PER			

Table 65–1. Thresholds for Microalbuminuria and Proteinuria by Albumin and Total Urine Protein Excretion

cally follows a biphasic pattern, which is characterized by MA and hyperfiltration initially before progressing to overt proteinuria with a fall in glomerular filtration.¹⁹ A similar biphasic response has recently been shown in nondiabetic subjects,²⁰ although the rate of progression to clinical proteinuria is lower than in people with diabetes. New proteinuria (more than 300 mg/24 h) in the HOPE Study was recorded in 20% of diabetics with microalbuminuria but in only 5% nondiabetics with microalbuminuria.²¹ It was not possible to judge whether this heralded future renal failure in nondiabetics, as there were very few cases of progressive failure during the 4 to 6 years of follow-up.²¹ Microalbuminuria has also been shown to predict a small fall in creatinine clearance during 7 years of follow-up in patients with essential hypertension, although no data were presented in this study to show whether this was associated with progression from microalbuminuria to overt proteinuria.²²

By contrast, overt proteinuria predicts renal outcome both in CKD^{5,23} and in population studies.^{24,25} The heavier the proteinuria the greater the risk (Figures 65–1 and 65–2). Relative risk of developing ESRD during 17 years of follow-up in a community-based program of 106,117 Japanese adults was 2.95 for men and 2.66 for women with ++ proteinuria (approximately 1 g/L). Similar findings have been reported from a population cohort of 8592 Dutch adults in whom urinary albumin excretion independently predicted the risk of developing a GFR of less than 60 mL/min.²⁵ Absolute risk of developing ESRD in these population studies was of course lower than that in the studies of CKD, because nearly all subjects in the population studies had normal renal function at the time of screening.^{24,25}

Cardiovascular risk of proteinuria

Microalbuminuria is also an independent risk factor for cardiovascular disease, in which setting it amplifies risk in patients who have vascular disease or are at high risk of

developing vascular disease. The best example of this is the Heart Outcomes Prevention Evaluation (HOPE) study where the presence of microalbuminuria was associated with substantially increased cardiovascular events in subjects with diabetes and also in those with pre-existing CHD, after adjusting for a number of competing risk factors including serum creatinine⁶ (Figure 65–3). Microalbuminuria has been shown to carry similar relative risks for cardiovascular events in general population studies,^{26–30} albeit with lower absolute risk than reported in HOPE.

Figure 65–1. Relation between decline of GFR in milliliters per minute per year and proteinuria in grams per 24 hours in three studies. Baseline GFR was 38 to 46 mL/min in the Ramipril Efficacy in Nephropathy (REIN) study, 25 to 55 mL/min in the Modification of Diet in Renal Disease (MDRD-A) study, and 13 to 24 mL/min in the MDRD-B study. The data shown are for the usual care groups.

Figure 65-2. Cumulative incidence of end-stage renal disease by baseline proteinuria during 17 years of follow-up in a community-based program of 106,177 Japanese adults. (Data from Iseki K, Ikemiya Y, Iseki C, Takishita S. *Kidney Int* 2003;63:1468–74.)

Figure 65-3. Influence of microalbuminuria on risk of MI, stroke or cardiovascular death in 4500 subjects in the HOPE placebo group who were followed for 4.5 years. Microalbuminuria was detected in 33% of those with diabetes and 15% of those with cardiovascular disease at baseline. (Data from Gerstein HC, Mann JF, Yi Q, et al. *JAMA* 2001;286:421–26.)

Several possible explanations for the association between microalbuminuria and cardiovascular risk have been proposed. It is unlikely that MA *per se* is the cause of the observed increase in risk. It is also unlikely simply to reflect the known higher prevalence of cardiovascular risk factors in MA, because MA continues to predict adverse outcomes after adjusting for the presence of these risk factors. It may, however, denote generalized endothelial dysfunction or abnormalities of coagulation and fibrinolysis, may be a marker of inflammation or may reflect a greater degree of end-organ damage in microalbuminuric subjects (reviewed by Sarnak et al.³¹).

BENEFITS OF TREATMENT

Blood pressure control

Most patients with proteinuric renal disease and raised serum creatinine have a clinical course characterized by relentless progression toward ESRD and dialysis. Control of hypertension is the single most effective intervention for those with proteinuria.³² Progression to ESRD is reduced when proteinuria is decreased with larger reductions in proteinuria leading to lower rates of decline in GFR.³³ The much quoted MDRD study supports a target blood pressure as low as 125/75 mmHg when patients pass more than 1 g of protein per day,⁵ although in other studies the benefits of such aggressive blood pressure control are not quite as convincing.^{34,35}

The guideline writers currently favor a target blood pressure of below 130/80 mmHg for patients with CKD, the definition of which includes subjects with proteinuria alone.^{36,37} They further recommend initiating treatment with an angiotensin converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB), while recognizing that in order to achieve a blood pressure goal of less than 130/80 combination therapy will usually be required; also that co-prescription of lipid-lowering and antiplatelet therapy should be considered to reduce cardiovascular risk.^{36,37} An integrated therapeutic intervention that includes anti-hypertensive drug therapy, statins, and aspirin has been tested with impressive benefits in patients with type 2 diabetes.³⁸

Can blood pressure be lowered too far in hypertensive patient with proteinuric renal disease? A meta-analysis of 11 randomized controlled trials of ACE inhibitor therapy in 1860 nondiabetic patients suggests that it can. For patients with protein excretion higher than 1 g/day, optimum systolic blood pressure (SBP) was 110 to 129 mmHg. Reduction of SBP to less than 110 mmHg involving use of an ACE inhibitor led to worse renal outcomes in patients with pre-existing renal disease. For reasons that are not entirely clear, this J-shaped relationship between risk of progression of kidney disease and SBP was a feature of patients with significant proteinuria only, and was not observed in those with protein excretion of less than 1 g/day.³⁹

Renin angiotensin system blockade

Notwithstanding the observations of Jafar et al.,³⁹ ACE inhibitors and ARBs have antiproteinuric properties that make them drugs of first choice in proteinuric patients.^{40,41} A systematic review of 43 trials comprising 7545 patients showed that these two classes of drug had equivalent effects on renal outcomes.⁴² Moreover, a recent study comparing the ACE inhibitor enalapril with the ARB telmisartan in type 2 diabetes and early nephropathy patients showed no significant differences between the effects of these two agents on a number of renal endpoints including change in glomerular filtration rate, serum creatinine level, urinary albumin excretion, and blood pressure.⁴³

For patients with diabetes, the renal benefits of these drugs appear to extend across the whole range of proteinuria from MA to nephrotic range,^{44–46} while for those with nondiabetic renal disease the threshold for benefit may

be higher.^{23,47,48} In a meta-analysis of 11 randomized trials of ACE inhibition in nondiabetic renal disease, patients with greater urine protein excretion at baseline benefited more from ACE inhibitor therapy, although the data were inconclusive as to whether benefit extended to those with baseline urine protein excretion of less than 0.5 g/24 h (protein:creatinine <50 mg/mmol)⁴¹ (Figure 65–4).

The benefits of renin:angiotensin system (RAS) blockade appear to be directly proportional to the degree of RAS inhibition. Thus, low-dose ramipril had no effect on cardiovascular and renal outcomes of patients with type 2 diabetes and microalbuminuria,⁴⁹ whereas extreme doses of candesartan were more effective than conventional doses.⁵⁰ Remission of nephrotic range proteinuria by ACE inhibition to a level less than 1 g/24 h occurred only in 15% to 20% of patients with type 1 diabetes who were enrolled in an early study involving the short-acting ACE inhibitor captopril.⁵¹ Incomplete inhibition of the RAS by ACE inhibitors and the fact that around 20% of treated patients still reach the combined endpoints of doubling serum creatinine or ESRD in randomized trials, has led to the hypothesis that better outcomes might be achieved by dual blockade of the RAS. This has since been tested in type 2 diabetes with microalbuminuria,⁵² type 1 diabetes with established nephropathy,⁵³ and in nondiabetics with heavy proteinuria and either normal renal function⁵⁴ or established renal failure.^{55,56} All have reported positive results.

The findings of Nakao et al.⁵⁶ are particularly relevant to current practice. Combination treatment with trandolapril and losartan was compared with trandolapril alone and losartan alone in 263 patients with nondiabetic renal disease whose baseline creatinine and protein output were 267 μ mol/L and 2.5 g/24 h, respectively. During an average 2.9 years follow-up, only 11% of the combination

group reached the combined primary endpoint of time to doubling serum creatinine or ESRD, compared to 23% in each of the other two treatment groups. Urinary protein excretion decreased significantly in all three groups, but to a significantly greater extent in patients receiving trandolapril and losartan. In subgroup analyses, benefits could be shown for patients with baseline proteinuria higher than 1 g/24 h, but less convincingly at lower rates of urinary protein excretion (Figure 65–5).

The clinical importance of the Nakao study is that the patients treated are precisely those for whom most clinicians would avoid dual RAS blockade for fear of provoking hyperkalemia or aggravating their renal failure. What it proves is that the kidney may benefit even in advanced renal failure provided that patients are selected carefully enough and monitored closely thereafter. An initial rise in serum creatinine is a normal hemodynamic response to blockade of RAS in patients with CKD, but is not a reason to withhold or suspend treatment unless the increase is greater than 30% above baseline or hyperkalemia develops.⁵⁷ A particular concern is the risk of life-threatening hyperkalemia and/or acute renal failure requiring dialysis when a patient taking an ACE inhibitor or ARB becomes dehydrated. This occurs not uncommonly during intercurrent illnesses characterized by blood volume depletion, and diarrhea and vomiting.^{58,59} Other circumstances in which renal function may be seriously compromised during RAS blockade include unsuspected bilateral renovascular disease⁶⁰ and co-prescription of a nonsteroidal anti-inflammatory drug.⁶¹

The possibility that the benefits of RAS blockade could be enhanced by drugs that lower blood pressure by other means has also been explored. The addition of felodipine to ramipril in patients with nondiabetic nephropathies gave no additional renoprotection despite further blood

Figure 65–4. Meta-analysis of 11 randomized trials of ACE inhibition in nondiabetic renal disease showing hazard ratios for ACE inhibition on a composite endpoint of doubling serum creatinine or end-stage renal disease at various levels of baseline urinary protein excretion (Data from Jafar TH, Schmit CH, Landa M, et al. *Ann Intern Med* 2001;135:73–87.)

Figure 65–5. Impact of losartan and trandolapril alone and together on proteinuria and the composite renal endpoint of doubling serum creatinine or end-stage renal disease in 263 patients with nondiabetic renal disease. (Data from Nakao N, Yoshimura A, Morita H, Takada M, Kayano T, Ideura T. *Lancet* 2003;361:117–24.)

pressure reductions of 5/0 mmHg⁶² and 4/3 mmHg.⁶³ Another recently published study in patients with type 2 diabetes and hypertension with normoalbuminuria, showed that the renoprotective effect of the ACE inhibitor trandolapril was not enhanced by the addition of the non-dihydropyridine calcium channel blocker, verapamil.⁶⁴

Statins

HMG-CoA reductase inhibitors or statins are now firmly established as the lipid-lowering treatment of choice in both primary and secondary prevention settings of coronary and vascular events. Patients in the statin trials who had moderate renal impairment (estimated GFR at 30 to 60 mL/min) had higher rates of vascular disease than those with eGFR higher than 60 mL/min, and also benefited from statins.⁶⁵ The role of statins in patients with more advanced CKD is less secure. An observational study of the U.S. Renal Data System information suggested that statin use was independently associated with lower all cause (relative risk [RR] 0.68, 95% confidence interval [CI] 0.54–0.87) and cardiovascular mortality (RR 0.64, 95% CI 0.45–0.91),⁶⁶ but a randomized comparison of atorvastatin and placebo in dialysis patients with type 2 diabetes showed no such benefits.⁶⁷ The ALERT (Assessment of Lescol in Renal Transplantation) study of fluvastatin in renal transplant patients showed a reduction in a secondary endpoint of fatal coronary heart (CHD) and nonfatal myocardial infarction, but not in cardiovascular or total mortality.⁶⁸ Against this background, the results of AURORA (A study to evaluate the Use of Rosuvastatin in subjects On Regular haemodialysis: an Assessment of survival and cardiovascular events) are awaited with interest.⁶⁹

The suggestion that statins might be good for the kidney as well as the heart is relatively new. Hyperlipidemia is thought to contribute to the progression of renal disease, either by a toxic effect on mesangial cells or by promoting intrarenal atherosclerosis.⁷⁰ Evidence is beginning to emerge that statins may have both antiproteinuric effects and benefits for renal function, although the mechanisms of benefit are as yet uncertain. A meta-analysis of 13 small randomized trials up to 1999 showed a slower rate of decline in GFR and a trend toward lower urinary protein excretion.⁷¹ Athyros et al.,⁷² in an analysis of the GREACE (Greek Atorvastatin and Coronary Heart Disease Evaluation) study reported that atorvastatin not only prevented decline but also improved renal function in patients who had established vascular disease and normal serum creatinine (less than 115 $\mu\text{mol/L}$) initially. Curiously, the authors did not provide details of urinary protein output in this analysis.

The most convincing evidence of renal benefit comes from a comparison of atorvastatin and placebo in 56 patients with CKD whose baseline

proteinuria and creatinine clearance were 2.2 g/24 h and 50 mL/min, respectively. During 1 year of treatment, patients who received atorvastatin experienced less proteinuria and a slower rate of GFR decline⁷³ (Figure 65–6). The benefits shown in this study were in addition to those of treatment with ACEIs and ARBs. Similar findings have been reported by others,^{74,75} although it has not been possible to show renal benefits for statins in patients with lesser degrees of proteinuria. In a randomized comparison of fosinopril and pravastatin in 864 mostly nondiabetic subjects with microalbuminuria and normal serum creatinine, fosinopril reduced urinary albumin excretion but pravastatin did not.⁷⁶

SUMMARY

The detection of protein in the urine of a patient with hypertension has major implications for both doctor and patient. The limitations of the dipstick test are now widely recognized. Urine collection for 24 hours is no longer recommended as a means of quantifying proteinuria. Instead, the albumin:creatinine ratio is firmly established as the method of choice for detecting and quantifying microalbuminuria, as is the protein:creatinine ratio for patients with overt proteinuria. Estimated protein output, derived by multiplying the protein:creatinine ratio by the estimated creatinine excretion, is the most accurate of measures based on a spot urine sample. On the rare occasions that a 24-hour urine collection is required, its accuracy can be determined by the ratio of measured to expected creatinine excretion with values lying between 0.75 and 1.25 suggesting that the collection is likely to be complete.

Proteinuria predicts subsequent loss of renal function. Relative risk is similar in the general population and in those with CKD, although absolute risks are much higher in patients with CKD, particularly in those with heavier proteinuria. Proteinuria also predicts cardiovascular disease, but in contrast to the renal risks of proteinuria, cardiovascular risk can be increased by microalbuminuria.

Figure 65–6. Creatinine clearance (milliliters per minute) and proteinuria (grams per 24 hours) in 56 patients with chronic kidney disease randomized to atorvastatin at 10 to 40 mg daily or placebo and followed for 1 year. Baseline creatinine clearance was 50.4 mL/min and baseline proteinuria 2.2 g/24 h. (Data from Bianchi S, Bigazzi R, Caiazza A, Campese VM. *Am J Kidney Dis* 2003;41:565–70.)

These observations may mean there are two types of proteinuria: “renal proteinuria,” in which the magnitude of the renal risk is directly related to the level of the proteinuria, and “cardiovascular proteinuria” (usually microalbuminuria), which probably arises as a result of endothelial dysfunction. Cardiovascular proteinuria does not generally lead to progressive renal failure, although it does indicate associated increase in risk of vascular events, particularly in patients who already have vascular disease.

Treatment options for proteinuria include blood pressure control to less than 130/80 mmHg and possibly to less than 125/75 mmHg if proteinuria exceeds 1 g/

24 h. ACE inhibitors and ARBs have additional anti-proteinuric properties with trial evidence of benefit for diabetics with microalbuminuria and nondiabetics with proteinuric nephropathy exceeding 0.5 g/24 h (50 mg of protein/mmol creatinine). Dual blockade of the renin:angiotensin system is associated with greater renal benefit than by ACE inhibitor or ARB alone. The use of statins in patients with proteinuria remains controversial. The antiproteinuric effect of statins is not only less than the ability of this class of drugs to reduce vascular events but it is also likely to be less than the antiproteinuric effects of RAS blockade.

Chapter
66Renin-Secreting Tumors and
Other Renin-Secreting States

Michel Azizi, Pierre-François Plouin, and Laurence Amar

Key Findings

- Juxtaglomerular cell (JGC) tumors (JGCT) are very rare renin-secreting tumors originating from the JG apparatus.
- JGCT diagnosis remains difficult, but JGCT should be suspected in young patients with severe hypertension and secondary hyperaldosteronism associated with the secretion of large amounts of renin, after the elimination of other much more frequent causes of secondary hyperaldosteronism.
- The tumor is localized by thin-slice computerized tomography (CT) scan showing a small isodense or hypodense tumor with no enhancement or slight enhancement on contrast and an isosignal intensity on magnetic resonance image (MRI). Renal arteriography is required to rule out other causes of renin-dependent hypertension especially a stenosis affecting the distal renal artery or intrarenal arterial branches, usually caused by fibromuscular dysplasia. It shows a small avascular radiolucent area at the external contour of the kidney.
- Microscopic study of the tumor reveals the presence of specialized vascular smooth muscle cells showing endocrine differentiation and containing secretory cytoplasmic granules. These cells are very similar to those of normal renin-producing cells, and are strongly immunohistochemically labeled by renin and prorenin antibodies, confirming the diagnosis of JGCT. They are frequently associated with histamine-secreting mast cells.
- Conservative surgery with elective tumor resection is the preferred procedure.

PRIMARY RENINISM DUE TO TUMOR
OF JUXTAGLOMERULAR APPARATUS

Renin may be produced by tumors of renal or extrarenal origin. This rare but severe form of secondary hypertension is usually referred to as primary reninism.¹ While very rare, this condition is of significance, as it may be confused with hyperaldosteronism and should attract specific management. Primary reninism is different from secondary reninism, which is caused by sodium depletion or by an abnormality of the extrarenal arteries or of the intrarenal arteries or arterioles, or other causes of excessive renin secretion by the kidney.

Juxtaglomerular cell (JGC) tumors (JGCT) are renin-secreting tumors that originate in the JG apparatus (Figure 66–1). The apparent prevalence (approximately 70 cases reported worldwide in the last review by Martin

et al.²) and incidence (eight cases of renin-secreting JGCT among 30,000 hypertensive patients treated at a single hypertension clinic in Paris over a 15-year period³) of this disease are very low, possibly due to underestimation of its frequency. Indeed, it remains difficult to diagnose primary reninism due to a JGCT because (1) there are no specific clinical symptoms or laboratory results associated with these tumors, and (2) these tumors remain difficult to visualize and to localize, and neither hyperaldosteronism nor hyperreninemia is routinely defined in the vast majority of hypertensive patients worldwide.

ANATOMY AND PATHOLOGY

JGCT are usually small, well-circumscribed encapsulated cortical renal masses of less than 4 cm in diameter.^{2,4} Larger JGCT, up to 8 or 9 cm in diameter, have been reported.^{2,5} Large tumors must be differentiated histologically from papillary renal cell carcinomas, because these cancers may be associated with hypertension and may include either tumoral or non-tumoral renin containing-cells (see below). The distinction between JGCT and papillary renal cell carcinomas is based on various histological characteristics and is generally straightforward.

The cut surface of the JGCT is yellow to tan/gray with areas of hemorrhage.^{2,4} The cell of origin of the JGCT is a modified smooth muscle cell from the vascular component of the JG apparatus. Light and electron microscopy studies reveal the presence of specialized vascular smooth muscle cells showing endocrine differentiation. JG cells are polygonal cells containing secretory cytoplasmic granules, myofilaments, and attachment bodies⁶ (see Martin et al.² for review). The ultrastructure of renin-secreting tumor cells is very similar to that of normal renin-producing cells, with the presence of secretory paracrystallin protogranules and round amorphous dense mature granules containing both prorenin and renin^{7,8} (Figure 66–2). These cells are strongly labeled with antibodies against renin and prorenin, confirming the diagnosis of JGCT (Figures 66–3 and 66–4). *In situ* hybridization, gives a signal with tumor cells, including those not stained by the renin antibody.⁹ Microscopy also shows that renin-secreting tumor cells are closely associated with capillaries and blood vessels and may occasionally show entrapped renal tubules. Histamine-secreting mast cells are frequent, accounting for up to 25% of all cells,^{6,10} even though no mast cells are found in the normal or pathologic JG apparatus. This suggests that JGCT may

Figure 66-1. The juxtaglomerular cell tumor is characterized by a homogeneous proliferation of regular round cells without any atypia or marked proliferation. (Courtesy of Patrick Bruveval, Hôpital Européen Georges Pompidou, Paris, France.)

release a factor attracting and favoring the growth of mast cells.

PATHOPHYSIOLOGY: AUTONOMY OF RENIN SECRETION

Human active renin is a 340–amino acid, aspartyl protease with a molecular weight of 40,000 Daltons and two N-glycosylation sites. It is secreted by the renal JG epithelioid cells, and synthesized in these cells as prorenin, which is activated by cleavage of an N-terminal 43-amino acid prosegment. Prorenin is also secreted into the blood. Total plasma renin concentration therefore corresponds to the concentration of both prorenin and active renin.

Active renin and prorenin originating from a JGCT or other tumor (see below) are the same molecules as physiologic renin and prorenin originating from normal kidneys, except for their secretion in excess, in an unregulated fashion.

In patients with JGCT, the renin response to various interventions known to inhibit or to stimulate renin is variable. Renin release from the JGCT usually responds to changes in posture and sodium intake, but this is not always so. Upright posture increases plasma renin activity (PRA) and/or plasma active renin concentration in about 70% of cases, whereas beta-blocker administration inhibits renin release, suggesting that beta-receptors may be present in these tumors.⁴

The demonstration that renin secretion by the tumor is autonomous is based on the inhibition of angiotensin II (Ang II) generation by angiotensin-converting enzyme (ACE) inhibitors or the blockade of angiotensin type 1 (AT1) receptors by Ang II receptor antagonists. Blockade of the renin-angiotensin system (RAS) consistently decreases

Figure 66-2. A tumor cell contains many renin granules exhibiting either an immature pattern with paracrystalline shape or a mature pattern with a round shape and a homogeneous matrix. Original magnification $\times 2500$. (Courtesy of Patrick Bruveval, Hôpital Européen Georges Pompidou, Paris, France.)

blood pressure (BP), demonstrating a direct role of Ang II in the maintenance of hypertension. In the absence of a renovascular disease or severe sodium depletion, a major decrease in BP in response to RAS blockade should lead to a search for renin-secreting JGCT. However, BP response to ACE inhibitors/AT1 receptor antagonists is

Figure 66-3. Tumor cells show a strong positivity for immunohistochemistry with renin antibody. Original magnification $\times 20$. (Courtesy of Patrick Bruveval, Hôpital Européen Georges Pompidou, Paris, France.)

Figure 66-4. The tumor is clearly separated from the adjacent nontumoral kidney tissue in which it is developed. Note that renin production is abolished in the adjacent glomerulus due to the huge local renin production by the tumor cells. Renin immunohistochemistry. Original magnification $\times 10$. (Courtesy of Patrick Bruveval, Hôpital Européen Georges Pompidou, Paris, France.)

not specific for JGCT, and may be observed in all cases of hypertension associated with RAS activation. Interestingly, blockade of the RAS frequently fails to increase circulating renin concentration, indicating that tumor renin secretion is autonomous. This autonomy may result from an absence of AT1 receptor expression in the tumors, leading to inactivation of the angiotensin-II negative feedback loop on renin secretion.¹¹

CLINICAL PRESENTATION

Robertson et al.¹² provided the first description of a case of primary reninism in 1967, and the first histologic description of a JGCT was provided by Kihara et al.¹³ JGCT generally occur in young male or female patients in their mid-20s, with a female/male ratio of approximately 1.9:1.^{2,14} However, these tumors have also been reported in children¹⁴ and older adults,⁵ and due to their rarity the age-stratified prevalence is not adequately defined.

There are no specific features of hypertension due to a renin-secreting tumor. Indeed, the patient may present hypertension for several years before the discovery of the JGCT. One case of normotensive JGCT has been reported,¹⁵ but in all other cases, hypertension has been severe, accelerated, or malignant with presence of thirst and polyuria.¹ Severe target-organ damage (e.g., alteration of optic fundi and left ventricular hypertrophy, proteinuria) and early complications (cerebrovascular accidents) may also be present. Hypertension may be resistant to conventional antihypertensive treatments, although this resistance is neither specific nor constant. As would be predicted, and unlike primary hyperaldosteronism, these tumors respond well to treatments blocking the RAS either by ACE inhibitors or AT1 receptor antagonists.

DIAGNOSTIC TECHNIQUES

Biological and hormonal parameters

The principal routine laboratory finding in almost all cases is severe hypokalemia at less than 3.0 mmol/L (occasionally as low as 1.9 mmol/L) due to secondary hyperaldosteronism associated with excess renin,^{1,2,4,6,14} but normal serum K^+ values have been reported in some cases.¹⁴ Mild hyponatremia may occur, due to the interaction of multiple factors.⁴ Renal function is generally not impaired, although proteinuria is common¹⁴ and/or plasma active renin concentration (PRA) is usually extremely high (more than five times the upper limit of the normal range), resulting in concomitantly high plasma Ang II and aldosterone concentrations. However, PRA levels may be only moderately high in some cases. There is no correlation between the tumor size and PRA.¹⁶ Prorenin (inactive form of renin) determinations by trypsin activation or direct radioimmunoassay may facilitate diagnosis, because some tumors may release more prorenin due to abnormal processing or storage in tumor cells.¹⁷

The diagnosis of a renin-secreting tumor should therefore be considered in young patients with severe hypertension and secondary hyperaldosteronism associated with the secretion of large amounts of renin, after elimination of the most frequent diagnoses associated with these non-specific clinical and biological conditions.

Tumor localization

JGCT localization takes place after the elimination of other much more frequent causes of severe hypertension with marked hyperreninism and hyperaldosteronism. The precise localization of the JGCT is a prerequisite for conservative surgery, limiting the extent of the surgical excision. Several methods may be used to localize the tumor.

Contrast-enhanced computerized tomography scans or magnetic resonance imaging

Thin-slice CT scan and MRI are the most reliable methods of tumor localization, and should be systematically performed whenever a renin-secreting JGCT is suspected, especially in patients with highly renin-dependent hypertension, a normal renal arteriogram, and two kidneys of similar size on renal ultrasound scans.

Noncontrast CT scan typically shows a small isodense or hypodense tumor at the external contour of the kidney, with no enhancement or slight enhancement after contrast injection^{4,6} (Figure 66-5). On MRI, the tumor displays isosignal intensity with the adjacent normal renal parenchyma in both T1- and T2-weighted images (Figure 66-6). Its visibility can be enhanced by using pre- and post-contrast fat-saturated T1-weighted images and pre- and post-contrast fat-saturated SPRG (spoiled gradient recalled acquisition in steady state) images.¹⁸

Renal ultrasound

Renal ultrasound cannot be recommended as a screening test for JGCT diagnosis, because of its low sensitivity and specificity for such tumors. Most JGCT are hyper-

Figure 66-5. Computed tomography scan of a juxtaloglomerular cell tumor in the left kidney.

echogenic, but some may be isoechogenic or hypoechogenic.¹⁹

Selective renal arteriography

Renal arteriography is required to rule out other causes of renin-dependent hypertension, especially a stenosis affecting the distal renal artery or intrarenal arterial branches that is usually caused by fibromuscular dysplasia. JGCT can be visualized on selective renal arteriograms with right and left anterior oblique views, as a small characteristic avascular radiolucent area at the external contour of the kidney. This image is highly suggestive of JGCT in the context of hypertension with reninism and hyperaldosteronism. However, it should be borne in mind that renal arteriography gives false negatives in as many as 60% of cases.¹⁴ Renal arteriography alone is therefore not sufficient for formal exclusion of the diagnosis of JGCT. This invasive procedure is complemented by CT scans or MRI. Finally, renal arteriography can also be used for precise analysis of the renal vasculature before conservative surgery.

Selective and segmental renin measurements in renal veins

Although this procedure is performed in most cases, a clear increase in PRA in a renal vein or one of its branches is not always observed.^{6,14} Negative lateralization of renal vein renin secretion was reported in 50% of the cases described by McVicar et al.¹⁴ In most cases, renin concentration is only slightly high on the affected side, probably because the tumor is frequently located at the surface of the kidney and most of the venous blood from the tumor is collected by the pericapsular veins rather than draining into the main renal vein. Selective catheterization of the branches of the renal vein is commonly used and may occasionally help localization of the tumor, but it is increasingly recognized that this technique may also give misleading results. Modern diagnosis usually involves CT or MRI scanning combined with angiography.

Figure 66-6. Magnetic resonance image of a juxtaloglomerular cell tumor in the left kidney.

PREOPERATIVE AND SURGICAL MANAGEMENT

Hypertension induced by renin-secreting JGCT is the best example of purely renin-dependent hypertension because hypertension should theoretically be cured by surgical removal of the tumor. If left undiagnosed and untreated, primary reninism can be lethal²⁰ or lead to severe complications due to severe hypertension.

Preoperative treatment aims to control hypertension control, with correction of hypovolemia in cases of malignant hyponatremic-hypertensive syndrome, and correction of hypokalemia. BP can be controlled by ACE inhibitors or AT1 receptor antagonists in association with other drugs, such as calcium channel blockers.¹⁴ RAS blockers also decrease the intensity of secondary hyperaldosteronism, thereby correcting hypokalemia. Spironolactone and amiloride can also be used to lower blood pressure and correct the hypokalemia.

Conservative surgery with elective tumor resection is the preferred procedure because JGCT are small (2–3 cm) and superficial and can be easily dissected from the adjacent kidney tissue.³ Careful palpation of the surface of the kidney usually reveals the presence of a superficial tumor, but perioperative ultrasound scans can also facilitate localization of the tumor.³ Larger tumors may require more extensive surgery, such as partial nephrectomy, after perioperative elimination of the histological diagnosis of renal carcinoma. It is difficult to obtain enough appropriate tissue for JGCT diagnosis and it is therefore important to make the best possible use of the excised tumor for molecular and cell culture studies.^{4,6,21}

PROGNOSIS

JGCT are technically benign in almost all cases although the consequences of uncontrolled hypertension and proteinuria clearly are not. Only one case of a very large (15 cm) malignant JGCT with pulmonary metastases has been reported.²² Following JGCT removal, both PRA and

BP rapidly decrease to normal levels. Some patients may have persistent mild hypertension, which is readily controlled by current antihypertensive treatments³ and may be caused by hypertension-induced vascular and/or kidney alterations.

HYPERENINEMIA AND SECONDARY HYPERALDOSTERONISM ASSOCIATED WITH RENAL TUMORS OTHER THAN THOSE OF JUXTAGLOMERULAR APPARATUS

Hypertension associated with reninism and secondary hyperaldosteronism are occasionally observed in patients with renal tumors other than JGCT. Almost 60% of cases of Wilms' tumor (nephroblastoma) in childhood are accompanied by hypertension.²³ These malignant tumors predominantly secrete prorenin, which is considered a tumor biomarker.²⁴ These tumors may secrete renin in infrequent cases, but hypertension may also be due to secondary reninism if the tumor compresses the kidney or the renal arteries.²³

In some rare cases of renal cell carcinomas, hypertension associated with high levels of renin secretion has been noted.^{25,26} Some of these carcinomas contain cells displaying positive staining for renin. These cases should be distinguished from cases of renin secretion occurring as a result of the compression of renal vessels by an expanding mass that synthesizes renin itself.

PRIMARY RENINISM ASSOCIATED WITH EXTRARENAL RENIN-SECRETING TUMORS

Excessive renin production may also occur in various other types of extra-renal tumor, but these tumors remain very rare in adults and are exceptional in children.⁴ Several cases of ectopic renin-secreting cancers have been reported: lung cancers,²⁷ cancers originating from the uterogonadal tract, ovarian and paraovarian tumors, adrenal carcinomas, oat cell carcinoma, epithelial liver hamartoma, orbital hemangiopericytoma, pancreatic cancer, angiolymphoid hyperplasia with eosinophilia, and other tumors (see reviews in Anderson et al.²⁸ and Balu et al.²⁹). All these cases presented severe hypertension with hypokalemia, with a higher frequency in women than in men. Interestingly, patients with extrarenal renin-secreting tumors present higher concentrations of prorenin, the inactive precursor of renin, than do patients suffering from renal tumors, with extremely high plasma levels of prorenin and normal-to-high plasma active renin concentrations.^{17,29,30} This may be due to (1) activation of the renin gene during cell multiplication, resulting in the synthesis of a large amount of prorenin, and (2) inefficient or incomplete processing of prorenin to generate active renin due to the absence of processing enzymes and specialized organelles in the neoplastic cells.²¹ As for JGCT, complete surgical removal of the tumor usually cures the hypertension, but the final prognosis depends on the nature and the aggressiveness of the primary tumor.

It remains likely that the prevalence of extrarenal renin-secreting cancers is underestimated. The development of hypertension and hypokalemia during the course of a malignant disease should systematically lead to consideration of this diagnosis and to the determination of plasma prorenin and active renin concentrations.

OTHER RENIN-ANGIOTENSIN-DEPENDENT FORMS OF HYPERTENSION

Essential hypertension

About one-sixth of patients with benign essential hypertension have high renin levels.³¹ Renin levels are also high in most patients with malignant hypertension. Renin concentration is very high in hyponatremic hypertensive syndrome, leading to hyperangiotensinemia with thirst, polyuria, and hyponatremia, and secondary aldosteronism with kaliuresis and systemic hypokalemia.³² Malignant hypertension may be primary or, as in 45% of cases, the consequence of an underlying renal or adrenal disease.

Renal artery stenosis

Renal ischemia associated with renal artery stenosis is the most frequent condition occurring with renin-angiotensin-dependent hypertension and has been considered in detail elsewhere. Uni- or bilateral renal artery stenoses may cause renovascular hypertension, a form of hypertension that is reversible on nephrectomy or renal revascularization. About two thirds of stenoses are due to atherosclerosis, usually in patients over the age of 50. One-third are due to fibromuscular dysplasia, mostly in young female patients. This diagnosis should be considered in patients with recent, progressive, severe and/or resistant hypertension, in young hypertensive women (fibromuscular dysplasia), in patients with angina or arteritis (atherosclerosis), or in hypertensive patients with ACE inhibitor-induced increases in plasma creatinine concentration. The gold standard procedure for diagnosing renal artery stenosis is catheter angiography. For screening purposes, this invasive procedure can be replaced by CT angiography, magnetic resonance angiography, or duplex Doppler ultrasound. These techniques have estimated the frequency of renal artery stenosis at 1% in unselected patients with hypertension, and 10% to 30% in drug-resistant hypertensive patients.³³

Other conditions with renal ischemia

A few conditions with chronic or acute intrarenal ischemia may also induce renin-dependent hypertension. These conditions include systemic diseases such as polyarteritis nodosa associated with widespread microaneurysms on renal angiogram and scleroderma in which BP and renal outcomes are greatly improved by ACE inhibitors, and segmental renal infarction.³⁴ Segmental renal infarction may result from renal embolism, renal artery thrombosis or dissection, or *in situ* thrombosis in cases of coagulation disorders. It usually presents as an abrupt onset of lumbar pain and hematuria followed by acute malignant

hypertension, polyuria, hypokalemia, hyponatremia, and extremely high renin concentrations. The condition may revert spontaneously to normotension because the ischemic renal tissue, which releases large amounts of renin, causing renin-angiotensin-dependent hypertension, may subsequently progress to a silent renal scar. Diagnosis is made either by CT angiography or magnetic resonance angiography.

A renin-dependent form of hypertension was recently described in two young patients with a nonstenotic elongated aberrant renal artery associated with a marked decrease in flow to the renal tissue, and thus with renal tissue ischemia.³⁵ Hypertension was cured by partial nephrectomy in one case.

Renal tumors and cysts

Some large non-renin-secreting cysts and tumors may present as renin-dependent hypertension, the mechanism of RAS stimulation being renal artery compression. In selected cases with lateralized renal vein renin ratio, cyst drainage or tumor resection may improve or cure hypertension.³⁶ Activation of the RAS also occurs in hypertensive patients with polycystic kidney disease, presumably because stretching of the intrarenal vessels around cysts causes areas of intrarenal ischemia.³⁷

Unilateral nonvascular small kidneys

Pyelonephritic scarring associated with urinary tract infection and bladder-ureter reflux can cause childhood hypertension and progressive degradation of renal function. PRA is often high and RAS activation has been implicated as a cause of hypertension.³⁸ High renin concentrations may also occur in cases of renal hypoplasia. In cases with a very small unilateral kidney and a lateralized renal vein renin ratio, unilateral nephrectomy may improve hypertension.

Non-renin-secreting extrarenal tumors

Pheochromocytoma is a catecholamine-secreting neoplasm of adrenal or extra-adrenal chromaffin tissue. Patients with pheochromocytoma usually have sustained or paroxysmal hypertension with headache, palpitations and excessive sweating. Diagnosis is based on the determination of plasma catecholamine levels or urinary excretion of catecholamine metabolites. The tumor is located by CT scan and metaiodobenzyl guanidine scintigraphy. The high BP levels associated with pheochromocytoma are caused by high plasma catecholamine levels both directly, through the stimulation of vascular adrenergic receptors, and indirectly, through RAS activation mediated by the adrenergic stimulation of JG cells and renal vasoconstriction.³⁹ Consequently, ACE inhibition may be used to control BP before surgery. In some very rare cases, pheochromocytoma may be associated with a renal artery stenosis (due to direct or indirect compression of the renal artery, or intense renal artery vasoconstriction

due to high levels of circulating catecholamines, or to the presence of an atherosclerotic disease), which may itself stimulate renin release.⁴⁰ Finally, malignant hypertension with RAS activation has been reported in patients with pheochromocytoma.⁴⁰

HYPERRENINEMIA WITH NORMAL BLOOD PRESSURE LEVELS

In most conditions with normal BP levels, hyperreninemia is a homeostatic response to reduced renal perfusion pressure or plasma flow. Conditions in which this is the case include dehydration, hemorrhage, adrenal insufficiency,⁴¹ cardiac failure, and reduced plasma volume due to hypoproteinemia in patients with nephrotic syndrome or kidney failure and liver cirrhosis. Two genetic disorders are also associated with hyperreninemia and normal BP. Bartter's syndrome, or inherited hypokalemic metabolic alkalosis, is an autosomal recessive disorder characterized by salt wasting, insensitivity to the vasoconstrictive effects of Ang II, and consequently high renin levels with normal BP, hyperaldosteronism, and hypokalemia. Gitelman's syndrome resembles Bartter's syndrome, but patients also display hypomagnesemia and hypocalciuria. Recent advances in the field of molecular genetics have demonstrated that these diseases are caused by genetically different abnormalities resulting from mutations in genes encoding renal electrolyte transporters and channels.^{42,43}

DRUG-INDUCED HYPERRENINEMIA

Independent of BP status, many drugs, especially those used to treat cardiovascular conditions, interfere with the RAS.⁴⁴ Diuretics, direct vasodilators (such as dihydralazine, minoxidil, phentolamine, prazosin, fenoldopam), ACE inhibitors, and AT1 receptor antagonists activate renin release and synthesis via different mechanisms (sodium depletion, reflex activation of the sympathetic system, and interruption of the Ang II–renin negative feedback loop, respectively). Hypokalemia, due in part to activation of the RAS, is also a hallmark of diuretic and laxative abuse. Nonselective β -agonists, such as isoproterenol and selective β_2 agonists can also stimulate renin release.⁴⁴

SUMMARY

Juxtaglomerular cell tumors are very rare renin-secreting tumors originating from the juxtaglomerular apparatus, and are benign in the vast majority of cases. Their diagnosis remains difficult, but these tumors should be suspected in young patients with severe hypertension and secondary hyperaldosteronism associated with secretion of large amounts of renin, after the elimination of other much more frequent causes of secondary hyperaldosteronism. Conservative surgery with elective tumor resection is the preferred procedure.

Chapter
67Primary Hyperaldosteronism
and Other Forms of
Mineralocorticoid Hypertension*Hari Krishnan Parthasarathy and Thomas M. MacDonald***Key Findings**

- Adrenal hypertension is the leading cause of secondary hypertension.
- Mineralocorticoid hypertension comprises a group of potentially curable syndromes.
- The genetic basis of several forms of mineralocorticoid hypertension has renewed interest in the role of steroid hormones in the control of blood pressure.
- Primary aldosteronism is the leading cause of mineralocorticoid excess.
- Unprovoked hypokalemia associated with hypertension strongly suggests mineralocorticoid hypertension.
- The use of the aldosterone:renin ratio as a screening test for aldosteronism has improved the rate of detection of the condition among hypertensives.
- Mineralocorticoid excess state can also be produced by an excess of other adrenal steroids apart from aldosterone, including deoxycorticosterone and cortisol.
- Rare inherited syndromes of mineralocorticoid excess include glucocorticoid-remediable aldosteronism, the syndrome of apparent mineralocorticoid excess, congenital adrenal hyperplasia, and Liddle syndrome.

Hypertension is the third most important cause of avoidable death worldwide and the second most important in developed countries.¹ In most cases, no underlying cause for a patient's raised blood pressure is apparent, and these cases are traditionally describe as "essential hypertension." Secondary causes of hypertension are uncommon; however, their importance is underlined by the fact that their recognition may in some cases lead to normalization of blood pressure. Importantly, several of these are associated with life-threatening complications and others are familial, stressing the need for careful family screening. It is, therefore, necessary to have a high index of suspicion to ensure that important rare endocrine causes of hypertension are not missed. In recent years, the genetic basis of several forms of mineralocorticoid hypertension has been elucidated, and this research has renewed interest in the role of steroid hormones in the control of blood pressure.

Mineralocorticoid hypertension comprises a fascinating group of potentially curable syndromes that lead to secondary hypertension (Box 67-1). Primary aldosteronism, which is comprised of various subsets, is the major syndrome in this group. Other rare but inherited syndromes

of mineralocorticoid excess include glucocorticoid-remediable aldosteronism (GRA), the syndrome of apparent mineralocorticoid excess (SAME), congenital adrenal hyperplasia (CAH), and Liddle syndrome.

PRIMARY ALDOSTERONISM

Primary aldosteronism is the leading cause of mineralocorticoid excess. It is characterized by autonomous hypersecretion of aldosterone from the adrenal cortex. It is either due to an adrenal adenoma or bilateral adrenal hyperplasia in more than 95% of cases. Adrenal carcinoma can be a rare cause of primary aldosteronism. Jerome Conn first characterized this syndrome in 1955.²

Much of the debate in the prevalence of primary aldosteronism is due to differences in the criteria used for defining the condition. Conn's syndrome of primary aldosteronism, which has been considered by many as a rare entity, was due to an aldosterone-producing adenoma (APA) that, if removed, may in many cases offer a potential cure for hypertension.² Therefore in earlier definitions, the syndrome was identified by the excessive autonomous secretion of aldosterone, leading to mineralocorticoid hypertension. This in turn is characterized by suppression of renin, expansion of body sodium content, expansion of plasma volume, and a tendency to hypokalemia. Using these criteria, the prevalence of aldosteronism was considered less than 1% in an unselected hypertensive population.^{3,4} However, not all adrenal glands in subjects with primary aldosteronism contain an APA. Some specimens are hyperplastic with varying degrees of nodularity. The term idiopathic hyperaldosteronism (IHA) was coined to describe this condition. The spectrum of primary aldosteronism includes APA and IHA, which are clinically indistinguishable from each other (biochemically they can be distinguished as IHA responds to AII—aldosterone is stimulated—but APA does not), although patients with APA may present with more severe hypertension and hypokalemia. However, the more recent introduction of a raised aldosterone-renin ratio (ARR) to define the condition has led to the emergence of primary aldosteronism as an important cause of secondary hypertension in about 5% to 15% of so-called essential hypertensives.⁵⁻⁹ There is an ongoing debate about whether this group of patients has true aldosteronism as first described by Conn. Moreover, in the majority of patients identified by a raised ARR, the real reason for the abnormality is the low level of renin rather than raised

Box 67–1**Causes of Mineralocorticoid Excess****Elevated Aldosterone****I. Primary Aldosteronism****Major Subtypes**

- Aldosterone-producing adenoma (APA): usual, angiotensin unresponsive
- Idiopathic hyperaldosteronism (IHA) or bilateral adrenal hyperplasia (BAH): angiotensin responsive

Rare Subtypes

- Angiotensin II–responsive adenoma: atypical
- Primary adrenal hyperplasia (PAH): morphologically like IHA, physiologically like APA
- Glucocorticoid-remediable hyperaldosteronism (GRA) or familial hyperaldosteronism type I (FH-I) (AD)
- Familial hyperaldosteronism type II (FH-II): probably heterogeneous
- Aldosterone-producing adrenal carcinoma
- Aldosterone-producing ovarian carcinoma

Suppressed or Normal Aldosterone**II. Secondary Aldosteronism****Deoxy Corticosterone (DOC) Excess**

- DOC-secreting adrenocortical carcinoma/adenoma
- Congenital adrenal hyperplasia (\uparrow ACTH)
11 β -Hydroxylase deficiency syndrome (AR)
17 α -Hydroxylase deficiency syndrome (AR)
- Primary cortisol resistance (AR/AD)

Cortisol Excess

- Deficiency of 11 β -hydroxysteroid dehydrogenase (HSD)
- The syndrome of apparent mineralocorticoid excess (SAME)
Inherited deficiency of HSD (AR)
Ingested glycyrrhetic acid (licorice and carbenoxolone) and \downarrow HSD
Other causes of cortisol excess exceeding the capacity of HSD: Cushing syndrome, exogenous steroids, neoplasms
Primary cortisol resistance (AR/AD)
- Defects in amiloride sensitive sodium channels (ASSC)
Liddle syndrome (mutations in β and γ subunits) (AD)

AD, autosomal dominant; AR, autosomal recessive.

aldosterone. In many patients, the level of aldosterone is within the normal range. It is uncertain how they differ from previously identified types of aldosteronism, and whether this phenomenon is synonymous with primary aldosteronism, as defined by earlier criteria.¹⁰

Anatomy and pathology**Aldosterone-producing adenoma**

About two-thirds of patients with classic aldosteronism (hypertension, hypokalemia, low renin) have a unilateral

solitary benign adenoma. This condition is more common among women and the most common age group is 30 to 40 years. The tumor is usually unilateral, less than 3 cm in diameter, encapsulated, well circumscribed, and solitary. It is usually solid with a golden-yellow to yellow-brown cut surface with no evidence of hemorrhage or necrosis. Histologically, in most adenomas the tumor cells resemble zona fasciculata cells more than glomerulosa cells due to numerous lipid-laden clear cells; however, occasionally these may appear pigmented due to lipofuscin or neuromelanin (“black adenoma”).¹¹ The adjacent adrenal cortex is nonatrophic (i.e., normal or hypertrophied, which is contrary to expectations), or may even demonstrate focal or diffuse hyperplasia. The presence of intracytoplasmic lipid is fairly specific for adrenal cortical adenomas, and this helps to differentiate these from other adrenal pathologies such as metastasis, hemorrhage, and other primary adrenal neoplasms.

An adrenal nodule in an individual with confirmed primary aldosteronism can be an APA, an incidental finding, or a macronodule of hyperplasia in an individual with bilateral adrenal hyperplasia (BAH).^{12,13} A nonsecretory adrenal mass can be incidentally discovered in 2% to 10% of all adults during imaging investigations of the abdomen.

Bilateral adrenal hyperplasia

Bilateral adrenal hyperplasia represents one-third of cases of classical primary aldosteronism. Some also use the term idiopathic hyperaldosteronism (IHA); the terms are often used interchangeably. It may be that the latter term is best reserved for those who have milder biochemical abnormalities and do not present with hypokalemia but who often do have adrenal hyperplasia. With the recent improved screening using aldosterone-renin ratio (ARR), BAH and IHA have been reported to constitute the most common forms of PA compared to APA.¹⁴ Adrenal hyperplasia is characterized by a non-neoplastic increase in adrenal cells. It can be diffuse (most common) or nodular. The nodular variety can be micro- or macro-nodular. The nodular variety of hyperplasia can often be misdiagnosed as APA. Similarly, hyperplasia adjacent to bilateral APAs can be misdiagnosed as BAH. Clinical correlation with dynamic adrenal testing usually helps to differentiate between these conditions.

Unilateral adrenal hyperplasia

Cases of unilateral hyperplasia leading to primary aldosteronism (<1%) have been reported.¹⁵

Adrenal carcinoma

Aldosterone-producing adrenal carcinomas are rare.¹⁶ Usually there is a global hypersecretion of all other adrenal hormones. Carcinoma is readily suspected by very high levels of aldosterone and its precursor steroids with loss of circadian rhythm. Hypokalemia is often profound. The tumors are usually large (200 g, 20 cm), and unencapsulated with a variegated cut surface due to hemorrhage, cysts, and necrosis. They often have soft, friable intratumoral nodules and often invade major veins.

Chemotherapeutic agents such as ketoconazole, aminoglutethimide, and mitotane are useful palliatively, but these are rarely curative. The prognosis is very poor (life expectancy of less than 6 months).¹⁷

Extra-adrenal tumors producing aldosterone

Aldosterone-producing tumors have been reported in the kidney and ovary.^{18,19}

PATHOPHYSIOLOGY

Adrenal corticosteroids are classified as mineralocorticoids or glucocorticoids. Both types of hormone are secreted from the adrenal cortex—glucocorticoids (in large amounts) from the zona fasciculata, and mineralocorticoids (in small amounts) from the zona glomerulosa. Aldosterone secretion is under control of the renin–angiotensin system (Figure 67–1).

However, aldosterone secretion is also determined by several other factors, notably serum potassium and adreno-cortico-trophic hormone (ACTH) as well as other hormones (Figure 67–2). Certain drugs can also modify its secretion.

Aldosterone was first discovered by Simpson and colleagues in 1953. Aldosterone is a steroid hormone produced by the adrenal cortex. It may also be synthesized locally in the heart, blood vessels, and brain, implying a paracrine function,^{20,21} although this is a contentious issue. Aldosterone has been conventionally associated with the control of fluid and electrolyte balance in epithelial tissues, and mainly in the kidney and distal colon. The best-known renal target sites for aldosterone are the cortical and outer medullary collecting tubules.^{22–24} At the cortical collecting tubule, the principal role of mineralocorticoids is to enhance Na^+ reabsorption and K^+ secretion, while in the outer medullary collecting tubules,

Figure 67–1. The renin–angiotensin–aldosterone axis. The common triggers for renin secretion are hypotension and hyponatremia.

Figure 67–2. Factors regulating aldosterone secretion. ACTH – adrenocorticotrophic hormone.

aldosterone stimulates H^+ secretion. There are three types of cells in these segments: principal cells, intercalated A cells, and intercalated B cells. Principal cells reabsorb Na^+ through apical sodium channels and basolateral $\text{Na}^+ - \text{K}^+$ ATPase. H^+ is excreted by intercalated B cells that have $\text{H}^+ - \text{ATPase}$ in the luminal membrane.²⁵ Aldosterone seems to have similar effects on Na^+ and K^+ transport in the colon.²⁶ The other epithelial targets for aldosterone are sweat glands, bile canalicula, and endolymphatic sac of the ear.^{27,28} The role of aldosterone in these target organs is unclear.

In addition to its classical epithelial effects, aldosterone has a variety of nonepithelial effects, including induction of inflammatory processes, collagen formation, fibrosis, and necrosis^{29,30} (Figure 67–3). Interest in these effects has recently resurfaced; the effects had been noted as early as in the 1940s, even prior to the actual discovery of the aldosterone molecule by Selye.³¹ In 1946, Selye reported on “a state of chronic stress” that developed in rats administered deoxycorticosterone acetate, an intermediate in the biosynthetic pathway of aldosterone with mineralocorticoid activity. This state resulted in an “adaptation syndrome,” leading to formation of perivascular granulomas visible in the coronary, renal, and systemic vasculature.

Mineralocorticoid receptors

Apart from renal sites, mineralocorticoid receptors have been detected in the colon, ureter, bladder, salivary glands, brain, heart, and arterial system.^{32–37} The mineralocorticoid receptor has been shown to be equally receptive to both mineralocorticoids and to glucocorticoids.³⁸ Relatively small amounts of aldosterone are able to bind to the mineralocorticoid receptor in preference to much higher concentrations of glucocorticoids (mainly cortisol). This selectivity is achieved through the expression of the enzyme 11β -hydroxysteroid dehydrogenase, which converts cortisol to cortisone (which does not bind to the receptor), but allows

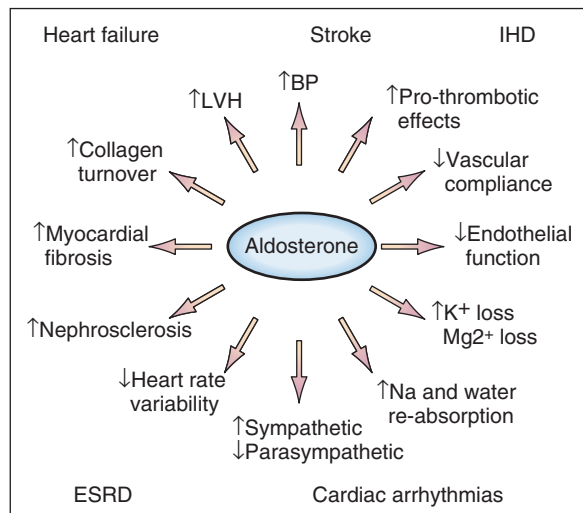

Figure 67-3. Deleterious effects of aldosterone. BP, blood pressure; ESRD, end-stage renal disease; IHD, ischemic heart disease; LVH, left ventricular hypertrophy.

aldosterone to occupy the mineralocorticoid receptor.^{39,40} Inhibition of this enzyme has the result that cortisol, usually classified as a glucocorticoid, acts as a potent mineralocorticoid.

Mineralocorticoid-based hypertension refers to hypertension caused by increased sodium and water retention by the kidney, and by expansion of the extracellular fluid compartment, which suppresses endogenous plasma renin activity.⁴¹ There is also renal potassium loss leading to hypokalemia. Hypokalemia leads to metabolic alkalosis (Figure 67-4). Unlike most cases of secondary aldosteronism, edema is not a feature of primary aldosteronism, probably because of “escape” from progressive sodium retention due to increases in renal perfusion pressure and a secondary atrial natriuretic factor.⁴² Nevertheless, in the short term, intravascular volume is reset at a higher volume, which leads to increased cardiac output and increased blood pressure. In the chronic state, hypervolemia cannot be consistently shown and other mechanisms including increase of vascular tone, vascular hypertrophy, activation of the sympathetic nervous system, and central effects of mineralocorticoids could potentially contribute to the hypertension.⁴³⁻⁴⁵

Hypokalemia

The presence of spontaneous or easily provoked hypokalemia ($K < 3.5$ mEq/L) in a patient with hypertension should provoke strong suspicion of primary aldosteronism. The classic case of primary aldosteronism presents with hypokalemia in association with metabolic alkalosis and low plasma renin activity. Of note, Conn first suggested that hypokalemia was a late manifestation of aldosteronism, and that many hypertensive patients may never reach this stage of the disease.^{3,46}

Many authors have nonetheless considered primary aldosteronism a rare cause of hypertension among patients with normal serum potassium concentrations.⁴⁷⁻⁴⁹ In recent years, evidence in support of Conn’s belief has

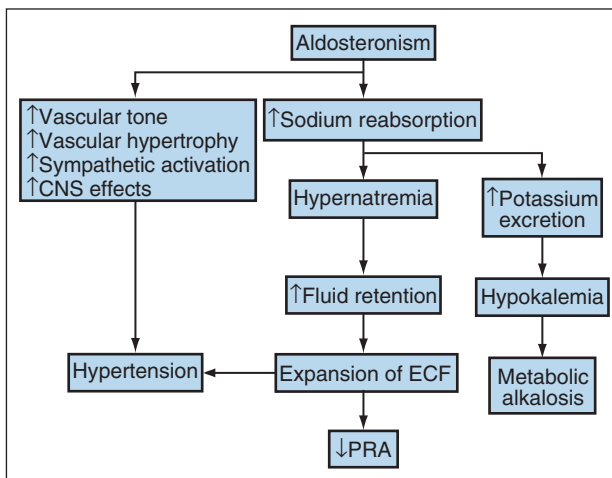

Figure 67-4. Pathophysiology of aldosteronism. ECF, extracellular fluid; PRA, plasma renin activity.

increased.⁵⁰ For example, Gordon and colleagues⁵ studied 199 normokalemic hypertensives and postulated a 10% incidence of aldosteronism in their clinic population. There have been numerous similar reports worldwide.^{14,51}

Hypokalemia leads to various clinical manifestations discussed in the following section. Other associated biochemical findings are suppressed plasma renin activity, hypernatremia, and hypomagnesemia.

CLINICAL PRESENTATIONS

Primary aldosteronism is commonly seen in the 30- to 50-year age group, and is more common in females. The clinical features of hyperaldosteronism are often nonspecific and variable.⁵² However, a majority of cases are associated with hypertension. The phenotype depends largely on the underlying cause and the severity of the aldosterone excess. The classic symptoms of primary aldosteronism can be divided into cardiovascular, neuromuscular, and renal (Box 67-2). In the majority of cases, however, only subtle clues of hyperaldosteronism exist, such as the presence of refractory hypertension.

Primary aldosteronism is a significant cause of resistant hypertension in both black and white subjects.⁵³ Importantly, these patients tend to suffer from more severe hypertension.^{54,55} Primary aldosteronism has been associated with malignant hypertension. However, in contrast to other causes of accelerated phase or “malignant” hypertension (who usually have high renin levels), the malignant phase of primary aldosteronism is associated with low renin levels.⁵⁶

Hypokalemia rarely leads to weakness, flaccid paralysis, paraesthesia, and tetany.⁵⁷ Even more rare are secondary myositis and rhabdomyolysis. Magnesium loss might partly contribute to some of these symptoms. Nephrogenic diabetes insipidus, caused by reversible hypokalemic tubular damage and renal tubule antidiuretic hormone resistance due to the hypokalemia, can cause nocturia, polyuria, and polydipsia. In severe cases of hypokalemia, cardiac arrhythmias occur and can be life threatening.

Box 67-2**Clinical Manifestations of Primary Aldosteronism**

Neuromuscular

- Paresthesia
- Tetany
- Flaccid paralysis
- Weakness

Cardiovascular

- Hypertension
- Left ventricular hypertrophy
- CCF
- Arrhythmias
- Retinopathy
- Headaches
- Renal
- Nephrogenic diabetes insipidus (polyuria, polydypsia, nocturia)

Patients with primary aldosteronism have a tendency to impaired glucose tolerance resulting from the inhibitory effect of hypokalemia on insulin action and secretion.⁵⁸ However, diabetes mellitus is rare.

DIAGNOSTIC TECHNIQUES

Clinical signs and symptoms of primary aldosteronism are nonspecific. Hence, diagnostic techniques form a vital part in the initial screening, confirmation, and subtype evaluation of primary aldosteronism (Figure 67-5).

Screening tests**Serum potassium**

Unprovoked hypokalemia associated with hypertension strongly suggests mineralocorticoid hypertension (Table 67-1). Hypokalemia provoked by diuretic use resistant

Figure 67-5. Three steps in the evaluation of primary aldosteronism.

to replacement should also raise a high index of suspicion. However, normokalemic hyperaldosteronism has been widely reported^{5,14,59,60} (Table 67-2). Therefore, hypokalemia is not a prerequisite for the diagnosis of hyperaldosteronism.

Other conditions requiring further screening tests for hyperaldosteronism are resistant hypertension, presence of an adrenal mass with hypertension, and evaluation of further causes for secondary hypertension.⁶¹

Aldosterone:renin ratio

Use of the ARR as a screening test for aldosteronism has improved the rate of detection of the condition among hypertensive patients (Figure 67-6). It has also enabled clinicians to overcome the shortcomings of using hypokalemia as a screening tool.

Units of measurement

Plasma aldosterone can be expressed in ng/dL (USA) and pmol/L SI units (in Europe, the conversion factor is 27.7). Plasma renin activity (PRA) is usually expressed as ng/mL Ang I/hr. However, a few investigators have used renin mass. Renin mass includes both active renin (contributing to PRA) and inactive renin. The relationship between renin mass and PRA is complex. The higher the renin mass, the greater the percentage of the renin that is active. For clarity, we will refer only to PRA. Most investigators consider the ARR level raised if it is higher than 25 when

STUDIES OF NORMOKALEMIC PRIMARY HYPERALDOSTERONISM					
Study	Number of Patients	Type of Patients	Incidence of Aldosteronism (%)	Normokalemia (%)	Confirmatory Tests

SCREENING TESTS FOR PRIMARY ALDOSTERONISM (OTHER THAN HYPOKALEMIA)			
Test	Procedure	Result	Comments
Serum potassium		Hypokalemia	Low sensitivity
Aldosterone:renin ratio	Plasma renin and aldosterone	Raised ratio	Ratio affected in low-renin hypertension and a variety of other factors
Captopril test	Sitting, plasma aldosterone before and 2 hours after oral captopril	Plasma aldosterone Unsuppressed in primary aldosteronism Suppressed in essential hypertension	Improves the specificity of aldosterone:renin ratio

Table 67–2. Screening Tests for Primary Aldosteronism (Other than Hypokalemia)

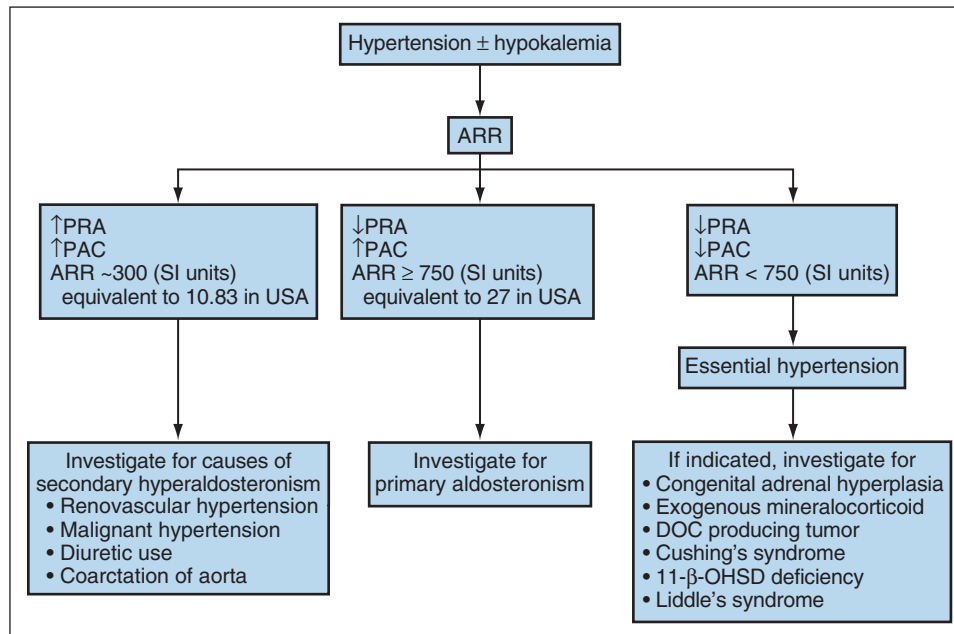

Figure 67–6. Using the ARR in hypertension. The ARR is the ratio between the PAC and PRA. (The PAC is expressed as pmol/L (SI units); in the United States the PAC is expressed as ng/dL. PRA is usually expressed as ng/mL/h.) ARR, aldosterone:renin ratio; PAC, plasma aldosterone concentration; PRA, plasma renin activity. (Modified from Young WF Jr. *Ann N Y Acad Sci* 2002;970:61–76, Blackwell Scientific.)

plasma aldosterone is expressed as ng/dL or greater than 750 when expressed as pmol/L.

Historical perspective on aldosterone:renin ratio

After the work of Hiramatsu and colleagues⁶² in 1981, ARR began to be used more often in clinical practice. These researchers measured serum sodium and potassium levels, PRA (ng/mL/hr), plasma aldosterone (pg/mL) concentration, and ARR in 348 patients with hypertension. Nine patients with substantially elevated ARR levels were selected and hospitalized for further study. All nine patients then underwent scintigraphy with labeled cholesterol, venography, and surgical excision, and all had proven APA or Conn's syndrome. The serum concentration of potassium was subnormal in only three of the nine patients with APA. In patients with APA, administration of diuretics and salt restriction significantly

elevated PRA. However, even with diurnal and day-to-day variation of plasma aldosterone concentrations, it was found that the ARR was always elevated inappropriately to more than 400 ng/dL (equivalent to 1108 when plasma aldosterone is expressed in pmol/L). In contrast, after administration of diuretics, both the PRA and aldosterone levels increased significantly in patients with essential hypertension, but the ARR was always less than 200 (equivalent to 554 when plasma aldosterone is expressed in pmol/L). Hiramatsu and colleagues suggested that an ARR higher than 400 was a useful screening tool for the prediction of APA among hypertensive patients.

In spite of concerns over the sensitivity, specificity, and validity of the ARR,⁶³ it is widely accepted as a useful screening tool in aldosteronism.¹⁴ A high ARR can be caused by a very low PRA and a normal aldosterone. Setting a lower limit for aldosterone (for example, 415 pmol/L)

increases the specificity of the test. This is explained below. Use of high aldosterone levels along with raised ARR increases the specificity of ARR. The need for plasma aldosterone to be above normal, along with suppressed renin is seen by many as an important distinction between aldosteronism and low-renin hypertension. This is because very low renin concentrations will always result in a high ARR, as it is similar to dividing by zero. For this reason, many investigators also impose other criteria such as a minimum plasma level of aldosterone, and do not rely on just the calculated ratio alone. It should also be noted that plasma renin activity can be low in older and black people apart from those patients with “low-renin” hypertension,^{64,65} and several hormonal and other factors can alter renin levels (Figure 67–7).

Moreover, the sensitivity and specificity of ARR depend on the cut-off values used. Most investigators would consider further evaluation for aldosteronism if the level of ARR is ≥ 25 when plasma aldosterone is expressed as ng/dL (or ≥ 750 when expressed as pmol/L) along with a raised plasma aldosterone concentration (PAC) of 15 ng/dL or more (equivalent to 415 in pmol/L).

Various factors that can cause false-positive or false-negative ARR are summarized in Table 67–3. In particular, many antihypertensive medications can affect the ARR, and therefore measurements should be undertaken if possible after stopping them for a duration that varies depending on the drug. Patients should be off spironolactone therapy for at least 6 weeks before evaluation of ARR. Beta-blockers should be stopped for at least a week because they suppress renin. However, there is some evidence to suggest that calcium channel blockers have no significant effect on the ARR while angiotensin-converting enzyme (ACE) inhibitors and ARBs probably enhance the diagnostic value of a high ARR because these drugs will serve to raise renin and reduce aldosterone via their action or the renin–angiotensin–aldosterone

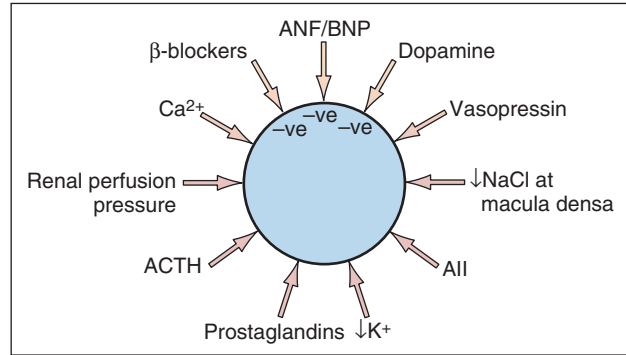

Figure 67–7. Regulation of renin secretion.

BNP – Brain natriuretic peptide.
ACTH – Adrenocorticotropic hormone.

system.^{66,67} This latter action is the basis of the captopril suppression test.

Captopril suppression test

Acute administration of an ACE inhibitor such as captopril blocks angiotensin II synthesis, and hence decreases aldosterone secretion. The post-captopril ARR has been used to improve the specificity of diagnosing primary aldosteronism.

In 1983, Lyons and colleagues⁶⁸ measured plasma aldosterone concentrations 2 hours after the administration of 25 mg of captopril in 9 normotensive subjects, 10 patients with essential hypertension, and 12 patients with primary aldosteronism on an unrestricted diet. The study showed that ARR was suppressed in essential hypertensives and normotensives but was not suppressed in primary aldosteronism. The presence of an ARR above 35 before and after 50 mg of captopril had been demonstrated to increase both the sensitivity and specificity of ARR.⁶⁹

CAUSES OF FALSE-POSITIVE AND FALSE-NEGATIVE ALDOSTERONE:RENIN RATIO	
Causes	Mechanisms
False-Positive Ratios	
β-blockers	↓ PRA
Very high-salt diet	↓ PRA
Renal impairment	Na retention, ↓ PRA
Nonsteroidal anti-inflammatory drugs	Na retention, ↓ PRA
Low-renin hypertension	↓ PRA
False-Negative Ratios	
Spironolactone	↑ PRA, ↑ Aldosterone (by feedback)
Angiotensin-converting enzyme inhibitors/angiotensin receptor blockers	↑ PRA, ↓ Aldosterone
Calcium channel blockers	↓ Aldosterone
Diuretics other than spironolactone	Volume depletion, ↑ PRA
Hypokalemia	↓ Aldosterone
PRA, plasma renin activity.	

Table 67–3. Causes of False-Positive and False-Negative Aldosterone:Renin Ratio

Confirmatory tests

The basic principle of confirmatory tests for primary aldosteronism (Table 67–4) is to demonstrate that the secretion of aldosterone is autonomous and nonsuppressible with expansion of extracellular fluid volume. Thus sodium loading with or without fludrocortisone plus potassium supplementation to correct or prevent hypokalemia is the basis of most definitive tests; in a positive test, aldosterone is not suppressed by such maneuvers.

Subtype determination

Both hormonal studies and radiologic evaluation help to determine the underlying pathology for aldosteronism.

Hormonal studies

Posture test

The posture test has traditionally been used in subtype evaluation of aldosteronism. The physiologic basis is that on upright posture plasma aldosterone increases if the renin angiotensin aldosterone system (RAAS) is intact as in essential hypertension, normal subjects, and in IHA. However, in APA, where the RAAS is suppressed, posture does not stimulate aldosterone production and levels may actually decline. The circulating aldosterone levels in patients with APA show a diurnal variation due to sensitivity to ACTH, and are relatively unaffected by changes in angiotensin II levels. In contrast, IHA is characterized by increased sensitivity to a small change in angiotensin II that occurs when standing. Samples of PRA and plasma aldosterone are collected along with cortisol levels after overnight recumbency and 2 to 4 hours of upright posture. A significant decline in plasma aldosterone levels on upright posture (>30%) is supportive of APA. A corresponding fall in cortisol is usually seen, which reflects the fall in ACTH levels. The predictive value of posture test in distinguishing APA from IHA is around 80% to 90%.

However, this study is not fully discriminative of the subtypes; for instance, studies have shown that some patients with APA are sensitive to angiotensin II, and some patients with IHA are responsive to ACTH and show diurnal variation in aldosterone secretion. Moreover, the posture test does not help in the lateralization of an adenoma.

Blood levels of 18-OH-corticosterone are usually greater than 100 ng/dL in APA, whereas patients with IHA have lower levels.⁷⁰ A posture-induced decrease in aldosterone levels is also seen in glucocorticoid-remediable hypertension (GRA) because aldosterone is solely regulated by ACTH in this variant of aldosteronism.

However, with the advent of high-resolution imaging techniques and centers proficient in adrenal vein sampling (AVS), these hormonal studies are less often used.

Radiologic investigations

An adrenal CT scan is useful in differentiating adenomas from adrenal hyperplasias.⁷¹ However, due to the spectrum of adrenal pathologies⁷² seen in primary aldosteronism, misdiagnosis can occur.⁷³ Adenomas can often be associated with adjacent adrenal hyperplasia. On the other hand, hyperplasia of the adrenal gland is often nodular. Consequently, dynamic and hormonal testing should always be used in conjunction with imaging techniques for subtype evaluation.

Adrenal magnetic resonance imaging has been shown to be more sensitive and has improved diagnostic accuracy compared to the CT scan.⁷⁴ Dexamethasone-suppressed selenium-75-Nor-cholesterol adrenal scintigraphy has been found to be useful in the presence of equivocal AVS results in ruling out aldosterone-producing adenomas.⁷⁵

Adrenal vein sampling

Adrenal vein catheterization was introduced about four decades ago for identification of the etiology of primary aldosteronism.⁷⁶ It forms the gold standard test to distin-

CONFIRMATORY TESTS FOR PRIMARY ALDOSTERONISM (DYNAMIC STUDIES)

Test	Procedure	Result	Comments
Saline infusion	2 L of normal saline over 4-hour period	Plasma aldosterone unsuppressed	Contraindicated in severe hypertension, CCF, MI, stroke Does not differentiate adenoma and hyperplasia
Oral salt loading	110 mEq of sodium/day for 3 to 5 days	Urinary aldosterone 1. Partially suppressed (hyperplasia) 2. Unsuppressed (adenoma) 3. Total suppression (essential hypertension)	“Gold standard test” Differentiates adenoma, hyperplasia, and essential hypertension
Response to DOC or fludrocortisone	DOC or 9 α -fludrocortisone for 2 to 3 days	Urinary aldosterone unsuppressed	Mineralocorticoid suppression tests provide little additional benefit over salt loading

Note: The basic principle of confirmatory tests for primary aldosteronism is to demonstrate that the secretion of aldosterone is autonomous and nonsuppressible to expansion of extracellular fluid volume.
CCF, congestive heart failure; DOC deoxycortisone; EH, essential hypertension; MI, myocardial infarction.

Table 67–4. Confirmatory Tests for Primary Aldosteronism (Dynamic Studies)

guish unilateral from bilateral disease. The success of adrenal vein catheterization depends on the operator's expertise. Bilateral adrenal venous sampling can be a challenging procedure. This is particularly true with catheterization of the right adrenal vein, because of its short limb and various anomalies.⁷⁷ Catheterization of the left adrenal vein, on the other hand, is usually simpler because of its longer trunk and uncommon anomalies. Adrenal veins are usually catheterized via the femoral approach using a Seldinger technique. Creating artificial gradients is avoided by keeping the patients supine before the AVS procedure. The time elapsing between catheterization of both adrenal veins should be kept to minimum. Blood should be drained by gravity or by gentle negative pressure when necessary. Samples of adrenal venous and infrarenal, inferior vena cava blood are collected for measurement of plasma aldosterone and cortisol. The selectivity of AVS on both sides is assessed with the ratio between cortisol levels in the right and left adrenal veins and the inferior vena cava plasma. In view of the risks of this invasive procedure, which include extravasation, adrenal vein thrombosis, and adrenal infarction, some authors advise that it should be used only if there is discordance among dynamic, hormonal, and imaging studies.⁷⁰ Young⁶¹ recommends using AVS for subtype evaluation in confirmed aldosteronism in the presence of a unilateral hypodense nodule of more than 1 cm in patients aged over 40 years, if associated with features of a high probability of APA, including severe hypertension, profound hypokalemia (<3.0 mEq/L), higher plasma (>25 ng/dL), and urinary (>30 µg/day) levels of aldosterone. Young further recommends unilateral adrenalectomy if solitary unilateral macroadenoma of more than 1 cm is present along with confirmed aldosteronism in a younger patient (<40 years). AVS is advised in cases of confirmed features of aldosteronism and a high probability of APA, where the CT scan reveals any of the following features: minimal, unilateral, adrenal limb thickening; unilateral microadenoma (≤1 cm); or bilateral macroadenomas. AVS in these instances helps in detecting the source. However, in some centers, AVS is routinely used in all patients with confirmed primary aldosteronism.⁷⁸ Our own practice has been to use AVS only where we are considering surgical therapy. This is usually confined to younger, low operative risk subjects in whom the diagnosis of APA is unclear. We also like to see blood pressure and biochemical abnormalities normalize with spironolactone, as this is the group most likely to attain a "cure" with surgery. Therefore, older and high-risk subjects are usually treated medically, and we would only consider AVS exceptionally in such subjects.

MANAGEMENT

The management of primary aldosteronism (PA) depends on the etiology. The aim is to correct the hypertension and hypokalemia associated with aldosterone excess and to reduce associated morbidity and mortality. In APA and in some cases of adrenal hyperplasia, surgery is a good treatment choice, and in some patients this may be curative. In

IHA and GRA and in subjects at high operative risk, medical management is indicated.

Surgical management

Cure rates (which might be defined as blood pressure <140/90 without medication, 6 months postsurgery) for APA and PAH postunilateral adrenalectomy range from 35% to 60%.^{61,79,80} However, nearly all patients (~95%) show improved blood pressure control if treated in addition with medications when necessary. Resolution of hypertension usually takes from 1 to 6 months. All patients should have hypokalemia corrected and hypertension controlled prior to surgery. The preoperative blood pressure response to spironolactone often predicts the blood pressure response to surgery in APA. Laparoscopic adrenalectomy, although technically more demanding than open adrenalectomy, has been shown to decrease the hospital stay and late incisional complications.⁸¹ In patients with APA who are reluctant to undergo surgery, super-selective, adrenal arterial embolization using high-concentration ethanol have been shown to be an option.⁸²

Medical treatment

Medical treatment is the therapy of choice in IHA and for subjects at high operative risk from surgery. It is also indicated before and in addition to surgical treatment of APA for control of hypertension and hypokalemia and also when surgery is not possible. Hypertension in IHA or PAH responds poorly to bilateral adrenalectomy, although potassium wasting is corrected.

Nonpharmacologic factors contributing to a successful medical therapy are dietary sodium restriction (<100 mEq/day), weight loss, alcohol restriction, and aerobic exercise where relevant. It is instructive to remember that a very low sodium diet can correct all biochemical and hemodynamic abnormalities seen in Conn's syndrome and that prior to the advent of mineralocorticoid antagonists, this was the mainstay of treatment.

Spironolactone has traditionally been the main stay in medical therapy. The range of doses used varies from 12.5 mg/day in milder cases to as much as 500 mg/day. Spironolactone is highly effective in the control of hypertension and hypokalemia. However, spironolactone has numerous metabolic, endocrine, gastrointestinal, hepatic, and renal side effects (Table 67-5). Spironolactone lacks specificity for mineralocorticoid receptors and binds to both progesterone and androgen receptors leading to various endocrine side effects. Gynecomastia can often be troublesome. However, in low doses (no more than 25 mg per day) spironolactone is tolerated well. A mistake often made is to up-titrate the dose too quickly, given that it can take up to 3 months for the full pharmacodynamic effects to be seen.

Eplerenone, a selective aldosterone receptor antagonist, is a derivative of spironolactone and has been shown to have a lower incidence of androgenic and progestogenic side effects. However, it is also a less-potent mineralocorticoid antagonist than spironolactone. Eplerenone selectively binds to mineralocorticoid receptors relative to

ADVERSE EFFECTS OF SPIRONOLACTONE	
System	Side Effects
Digestive	Gastric bleeding Ulceration Gastritis Diarrhea Cramping Nausea Vomiting
Metabolic/endocrine	Hyperkalemia Hyponatremia Gynecomastia Impotence Dysmenorrhea Amenorrhea Postmenopausal bleeding Deepening of voice Hirsutism Decreased libido Carcinoma of breast (reported but cause-effect not proved)
Hematologic	Agranulocytosis
Hypersensitivity	Fever Urticaria Rash Anaphylaxis Vasculitis
Nervous system/psychiatric	Mental confusion Ataxia Headache Drowsiness Lethargy
Hepatobiliary	Mixed cholestatic/hepatocellular toxicity; one reported fatality
Renal	Renal dysfunction/failure

Table 67–5. Adverse Effects of Spironolactone

its binding to glucocorticoid, progesterone, and androgen receptors. The efficacy and safety of eplerenone in hypertension have been assessed in numerous clinical trials, whether as monotherapy or concomitantly with other antihypertensive medications. Eplerenone was approved by the Food and Drug Administration in 2002 for the treatment of hypertension.⁸³ Weinberger and colleagues⁸⁴ randomized 417 patients with mild to moderate hypertension to eplerenone (in different doses), spironolactone, or placebo. The mean changes in both office systolic blood pressure (SBP) and diastolic blood pressure (DBP) and 24-hour ambulatory blood pressures were significantly greater for all doses of eplerenone compared to placebo. Furthermore, a dose-response effect was observed with eplerenone. On a molecular weight basis, however, eplerenone was only 50% to 75% as potent as spironolactone. There were no antiandrogenic or progestational side effects seen with eplerenone. However, at present there are no published data on its efficacy in aldosteronism; we are aware though of at least one unpublished study where subjects with aldosteronism were random-

ized to spironolactone or eplerenone. The antihypertensive effect of spironolactone was greater in this trial.

In some countries, a metabolite of spironolactone, potassium canrenoate, is available for oral administration. Its adverse effect profile is similar to spironolactone. However, some say that it has fewer endocrine side effects.⁸⁵ In animals, there have been reports of carcinogenicity. In 2-year studies in the rat, oral administration of potassium canrenoate was associated with myelocytic leukemia and hepatic, thyroid, testicular, and mammary tumors.⁸⁶

Amiloride and triamterene may be used as alternatives in those intolerant to spironolactone or eplerenone.^{87–89} These drugs have a direct effect on the renal tubule to impair sodium reabsorption in exchange for potassium and hydrogen.

Nifedipine has been tried in aldosteronism, and has been shown to decrease aldosterone secretion from APA.^{90,91} It seems to have both acute and chronic antihypertensive effects in aldosteronism.⁹² There are a few studies reported in literature to the effect that other calcium channel blockers including verapamil and diltiazem might be useful in treating primary aldosteronism.⁹³

OTHER SUBTYPES OF ALDOSTERONISM

Glucocorticoid-remediable aldosteronism

Glucocorticoid-remediable aldosteronism is also known as familial hyperaldosteronism type 1 (FH-1) or glucocorticoid-suppressible hyperaldosteronism (GSH). It is a rare inherited form of primary aldosteronism that was first described clinically by Sutherland and colleagues in 1966.⁹⁴ It is characterized by classic features of primary aldosteronism, but is completely reversible by exogenous glucocorticoid (hence, the name of glucocorticoid suppressible/remediable aldosteronism). The hormonal basis of GRA was first postulated by Ulick and colleagues.⁹⁵ They first identified increased levels of hybrid steroids including 18-oxo-cortisol and 18-hydroxy-cortisol,⁹⁶ and later postulated that the disorder might be due to defective acquisition of the aldosterone synthase enzymatic activity (methyl oxidase activity) by zona fasciculata.⁹⁵

Genetic basis

It was Lifton and colleagues who elucidated the genetic basis of GRA⁹⁷ (Figure 67–8). They identified a hybrid or chimeric gene arising from unequal crossing-over and fusing of regulatory sequences of steroid 11 beta-hydroxylase (CYP11β1) to coding sequences of aldosterone synthase (CYP11β2) genes by studying 12 kindreds with GRA.⁹⁸ This hybrid gene is regulated by ACTH (because the regulatory portion of CYP11β1 is ACTH sensitive) and produces aldosterone (due to the coding portion of CYP11β2, which is now without its usual regulatory portion sensitive to angiotensin II). This leads to aldosterone production that is then regulated by ACTH instead of angiotensin II.

Clinical features

GRA is an autosomal dominant disorder. The phenotype is extremely variable.^{99–101} Patients can present with mild

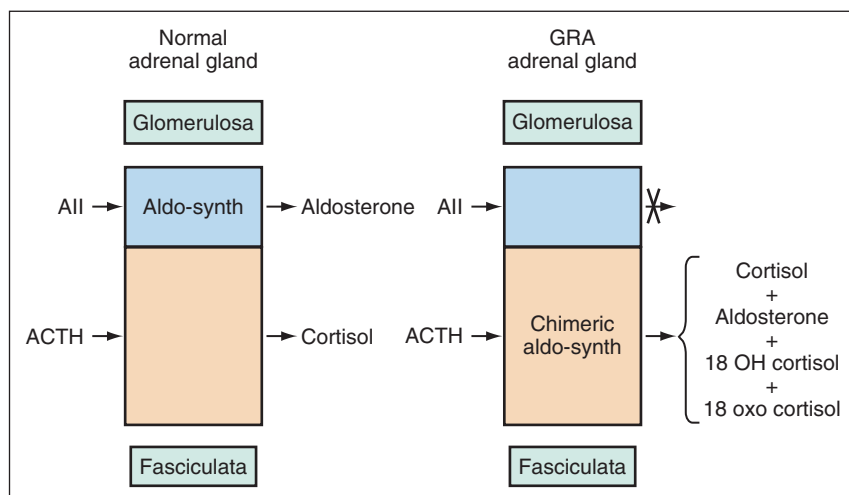

Figure 67–8. The genetic basis of glucocorticoid-remediable aldosteronism.

hypertension and normal biochemistry, and can be clinically indistinguishable from patients with essential hypertension, but it can also present with fatal hypertensive stroke in men aged 20 to 40 years.¹⁰² The disorder commonly begins during childhood.¹⁰³ Women who have GRA with chronic hypertension seem to be at increased risk for exacerbation of hypertension during pregnancy.¹⁰⁴ The most affected have normal potassium levels. Neither the differences in gene cross-over points nor plasma steroid levels seem to correlate with degrees of hypertension.¹⁰⁵

Jamieson and colleagues¹⁰⁵ observed that patients inheriting GRA from their mothers have higher blood pressure and plasma aldosterone concentration compared to those who inherited the syndrome from their fathers. Hence they postulated permanent programming of mineralocorticoid-dependent, blood-pressure regulatory mechanisms due to chronic intrauterine exposure to PA.¹⁰⁵ Dulhy and colleagues¹⁰⁶ observed reciprocal correlation of blood pressure with urinary kallikrein excretion, and postulated possible interaction of gene mutation with other blood-pressure regulatory mechanisms.

Diagnosis

Glucocorticoid-remediable aldosteronism can masquerade as essential hypertension because most affected subjects are normokalemic and their blood pressures can range from mildly to severely elevated.⁹⁹ Many patients are refractory to usual antihypertensive agents but may become hypokalemic if potassium-wasting diuretics (e.g., bendrofluzide at 2.5 mg) are administered.¹⁰⁷ GRA should be considered in a patient with hypertension of early onset or a history of early-onset hypertension in first-degree relatives, if there is a significant family history of early hemorrhagic stroke, precipitation of hypokalemia when treated with potassium-wasting diuretics, and the refractoriness of the blood pressure to standard treatments.^{102,107} A screening policy targeted at these individuals has been shown to be effective.¹⁰⁸

Patients with GRA have raised ARR (>30). PRA will be suppressed unless mineralocorticoid antagonists have been used as therapeutic agents. Therefore, nonsuppressed PRA levels in the absence of such therapies makes diagnosis of GRA unlikely. However, the presence of a suppressed PRA level is nonspecific. Aldosterone blood levels or urinary aldosterone excretion rates are usually normal or mildly elevated, but the levels may be inappropriate for the intake of sodium because production is solely regulated by ACTH.¹⁰⁹

The disorder is characterized by increased excretion of 18-oxo-cortisol and 18-hydroxy-cortisol in urine, and these provide a sensitive and highly specific test to confirm diagnosis of

GRA.^{96,109} However, their measurement necessitates 24-hour collection and the assay is not widely available. Dexamethasone suppression testing (DST) is also used to differentiate this disorder from other causes of primary aldosteronism. A fall in aldosterone to nearly undetectable levels after low-dose DST (0.5 mg of dexamethasone orally every 6 hours over 2 to 4 days) in GRA is expected, and reflects the sole control of aldosterone by ACTH in this disorder.¹⁰⁹ PA is measured before and after oral dexamethasone administration to determine the extent to which aldosterone is suppressed by the glucocorticoid. A post-DST aldosterone level of less than 4 ng/dL has been shown to demonstrate high sensitivity and specificity.¹¹⁰ A definitive diagnosis can only be reached by identification of the CYP11B1/ CYP11B2 chimeric gene in genomic DNA using either Southern blotting⁹⁸ or the long PCR technique.^{111,112}

Therapy

Glucocorticoid suppression

Dexamethasone suppression does not always result in normalization of blood pressure in GRA. This might be due to various causes, such as the duration of hypertension, end-organ injury, concomitant essential hypertension, and autonomous production of aldosterone in patients with longstanding GRA.¹⁰⁹ Great care should be taken due to side effects associated with excessive doses of suppressive glucocorticoids, especially in children. Iatrogenic Cushing's syndrome and impaired linear growth in children have resulted from such overdosing.¹⁰³ The smallest effective doses of shorter-acting agents such as prednisone or hydrocortisone are used. Target blood pressure in children should be guided by age-specific blood pressure percentiles, and linear growth should be monitored to detect any slowing as a result of overtreatment. The therapeutic goal should be normotension, and not normalization of biochemical markers such as urinary 18-oxosteroid or serum aldosterone levels, because these remain elevated in the majority of patients who normalize blood pressure. Titrating therapy to normalize laboratory values could unnecessarily increase the risk of Cushingoid side effects.¹⁰⁷

Antihypertensive medications

Mineralocorticoid antagonists, including spironolactone, amiloride, and triamterene, can be used as second-line agents to treat hypertension in GRA. Dihydropyridine calcium channel blockers have also been used in GRA.¹⁰⁹

Familial hyperaldosteronism type 2

Gordon and colleagues¹¹³ have described another familial variety of hyperaldosteronism (familial hyperaldosteronism type 2), which has been described as more common than FH-1. FH-2 does not involve inheritance of the hybrid gene and is not glucocorticoid-remediable; it was first described in 1991.^{114,115} About 32 Australian families (80 patients) with FH-2 have been identified thus far.¹¹³ Nine of the 32 families have demonstrated vertical transmission of phenotype between successive generations, consistent with autosomal dominant inheritance. The mode of inheritance in the remaining families remains unknown. FH-2 has been linked to the chromosome 7p22 region in some families. However, the syndrome is thought to be genetically heterogenous.¹¹³ The clinical, biochemical, and morphologic characteristics of patients with FH-2 are similar to those with classic primary aldosteronism.

CONDITIONS OF MINERALOCORTICOID EXCESS WITH SUPPRESSED OR NORMAL ALDOSTERONE

A mineralocorticoid excess state can also be produced by adrenal steroids other than aldosterone. These are due to either excess deoxy corticosterone (DOC) or cortisol. Other conditions of mineralocorticoid excess with normal or suppressed aldosterone are defects in the amiloride-sensitive sodium channels (Liddle syndrome) or defective mineralocorticoid receptors.

Deoxycorticosterone excess

Excessive DOC can lead to a mineralocorticoid excess state and hypertension. DOC excess can arise from adrenal tumors or congenital adrenal hyperplasia.

DOC-secreting tumors

Adrenal tumors producing excess DOC vary from benign adrenocortical adenomas to metastatic adrenocortical carcinomas.¹¹⁶ DOC-producing adrenal tumors are very rare. They can present with hypertension and hypokalemia.¹¹⁷

Congenital adrenal hyperplasia

The syndromes of congenital adrenal hyperplasia (CAH) associated with mineralocorticoid excess are 17 α -hydroxylase and 11 β -hydroxylase deficiencies.

17 α -hydroxylase deficiency

17 α -hydroxylase deficiency is a rare variety of CAH. Patients with 17 α -hydroxylase deficiency have alterations in their *CYP17* gene that encodes the P450C17 enzyme. This enzyme plays a central role in steroidogenesis, and is

essential for the production of cortisol and sex steroids (Figure 67–9).

The block in the production of cortisol and sex steroids stimulates ACTH via a feedback mechanism that in turn stimulates excess production of DOC and corticosterone. This leads to hypertension and hypokalemia and surprisingly low levels of aldosterone. It is believed to result from the feedback inhibition of the suppressed renin–angiotensin system in the presence of excess salt retention due to excess DOC. Deficiency in sex hormones leads to incomplete masculinization and pseudohermaphroditism in males and primary amenorrhea in women. Most affected 46XY males are phenotypically females. The characteristic steroid profile is marked elevation of deoxycorticosterone and corticosterone, slightly elevated pregnenolone and progesterone, and decreased aldosterone and cortisol. Treatment with glucocorticoid replacement corrects hypertension and hypokalemia.

11 β -hydroxylase deficiency

11 β -hydroxylase deficiency presents as hypertension, hypokalemia, and virilization in infants.¹¹⁸ This deficiency results from mutations in the *CYP11B1* gene.¹¹⁹ 11 β -hydroxylase deficiency leads to cortisol, corticosterone, and aldosterone production blocks. Activation of ACTH by feedback leads to stimulation of excess androgens. Excess DOC leads to signs of mineralocorticoid excess in the form of hypertension and hypokalemia. The typical steroid profile includes elevated 11-deoxycorticosterone and 11-deoxycortisol. Plasma androstenedione and testosterone are also elevated. PRA and aldosterone are suppressed. Recommended treatment consists of glucocorticoid replacement, which relieves hypertension and hypokalemia and helps normal development of the child.

CORTISOL EXCESS

Syndrome of apparent mineralocorticoid excess

The mineralocorticoid receptor (MR) is nonselective *in vitro*, and cannot distinguish between the glucocorticoid cortisol and its natural ligand, aldosterone. 11 β -hydroxysteroid dehydrogenase type 2 (11 β -HSD2) plays a crucial role in converting hormonally active cortisol to inactive cortisone, thereby conferring specificity on the mineralocorticoid receptor (MR).¹²⁰ Two isoforms of human 11 β -HSD have been described, but it is the NAD-dependent type 2 isoform (11 β -HSD2) that is expressed in the mineralocorticoid target tissues, kidney, and colon. Mutations in the gene encoding 11 β -HSD2 account for an autosomal recessive inherited form of hypertension, the syndrome of “apparent mineralocorticoid excess” (AME), in which cortisol induces hypertension and hypokalemia with suppression of plasma renin and aldosterone concentrations.^{121,122} It is caused by defective 11 β -HSD2, allowing cortisol, which has higher (100 to 1000 times) circulating levels than aldosterone, to bind to the MR and to act as a potent mineralocorticoid.

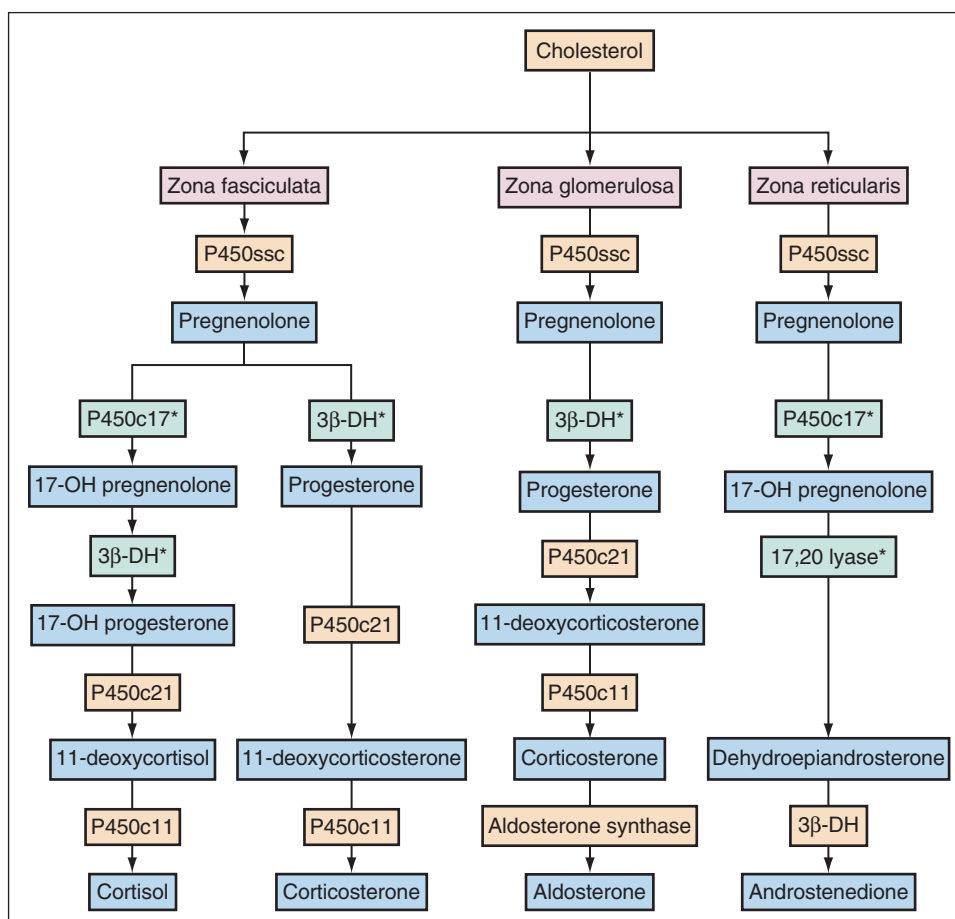

Figure 67–9. The pathways of steroid biosynthesis and the effect of spironolactone. P450ssc, P450-linked side-chain cleaving enzyme; P450c17, 17 α -hydroxylase; 3 β -DH, 3 β -dehydrogenase; P450c21, 21 β -hydroxylase; P450c11, 11 β -hydroxylase. 17,20 lyase is the same as 17,20 desmolase in the testis. Asterisks represent enzymes inhibited by spironolactone. (Adapted from King MW. On steroid hormones, May 2006. Available at: <http://web.indstate.edu/thcme/mwking/steroid-hormones.html>.)

Clinical features

The syndrome is salt sensitive and autosomal recessive inherited form of hypertension. SAME shows a close correlation between disease phenotype and genotype.¹²³ The *in vitro* enzymatic activity conferred by each mutation is strongly correlated with the ratio of cortisone to cortisol metabolites in the urine, with age of diagnosis, and with birth weight, suggesting that the biochemical and clinical phenotype of AME is largely determined by genotype. Patients with mutations resulting in little or no 11 β -HSD2 activity present in early life with a severe phenotype. On the other hand, patients presenting in late adolescence or early adulthood with mild forms of AME (also referred to as AME type 2) have been found to harbor mutations that result in a partially functional 11 β -HSD2 protein with attenuated activity.¹²⁴

This syndrome usually manifests in childhood with hypertension, hypokalemia, and low PRA. Other clinical features include moderate intrauterine growth retardation and postnatal failure to thrive. Complications of severe hypokalemia include nephrocalcinosis, rhabdomyolysis, and nephrogenic diabetes insipidus. Complications of

hypertension include cerebrovascular accidents and death during infancy or adolescence.

Diagnosis

An elevated ratio of cortisol to cortisone metabolites in the urine (tetrahydrocortisol plus allo tetrahydrocortisol to tetrahydrocortisone [(THF + aTHF)/THE]) is considered diagnostic.

Treatment

A low-salt diet, potassium supplementation, and spironolactone have been the mainstay in treating SAME.¹²⁵ Therapy with spironolactone results in growth, weight gain, and blood pressure control. Triamterene inhibits the tubular sodium channel and has also been successfully used. Amiloride has similar effects, and is also effective therapy for AME. The dihydropyridine calcium-channel blocker, nifedipine, has been useful for hypertension in SAME. Angiotensin-converting enzyme inhibitors have been shown to enhance renal 11-HSD activity, and might be useful in patients with partial enzyme defects.¹²⁶

Ingested glycyrrhetic acid causing deficiency of 11 β -hydroxysteroid dehydrogenase

Both licorice and carbenoxolone contain glycyrrhetic acid. Excess consumption of licorice has been well known to produce hypokalemia and hypertension. Active components of licorice are glycyrrhetic acid and glycyrrhizic acid. Carbenoxolone is a hemisuccinate derivative of glycyrrhetic acid, which is used in the treatment of acid peptic disease. Carbenoxolone produces sodium retention, hypokalemia, and hypertension. A mechanism similar to SAME explains the mineralocorticoid excess state seen following the ingestion of these compounds containing glycyrrhetic acid. Glycyrrhetic acid is a potent inhibitor of 11 β -HSD.^{127,128}

The syndrome of primary cortisol resistance

The syndrome of primary cortisol resistance (SPCR) is a rare familial cause of cortisol and DOC excess due to a defect in the glucocorticoid receptor.¹²⁹ SPCR may be the outcome of mutations of the glucocorticoid receptor or the reduced number of receptors.^{130,131} ACTH is stimulated via feedback mechanisms, and there is overproduction of cortisol, mineralocorticoids, and androgens. In its severe form, hypertension and hypokalemic alkalosis are present, owing to increased secretion of the sodium-retaining mineralocorticoids. In subjects with a less-severe resistance to cortisol, there are no clinical abnormalities and the disease is revealed only by detailed examination of several parameters of cortisol metabolism. Excess androgens in women can result in acne, hirsutism, menstrual irregularities, anovulation, and infertility. In men, it may lead to infertility, and in children, to precocious puberty.¹³²

Other causes of cortisol excess

The most common causes of cortisol excess leading to hypertension (due to its mineralocorticoid activity), including Cushing syndrome and exogenous steroids, are dealt with in Chapter 69.

Liddle syndrome (Pseudohyperaldosteronism)

The amiloride-sensitive epithelial sodium channel (ENaC) is expressed in the distal part of the renal tubule where it constitutes the rate-limiting step of Na⁺ reabsorption, under the control of aldosterone. ENaC is composed of three subunits—alpha, beta, and gamma. Activating mutations of the C terminus of beta or gamma subunits of ENaC lead to a rare form of autosomal dominant hypertension described by Liddle in 1963, and is characterized by increased Na⁺ and water reabsorption which stimulates primary aldosteronism.¹³³ There could be a variety of mutations affecting the ENaC, the genes of which are located on chromosome 16p13-p12.^{134–136} Liddle's syndrome is an autosomal dominant form of salt-sensitive hypertension. The classic description of Liddle's syndrome includes early severe hypertension with hypokalemia, metabolic alkalosis, and suppressed PRA and aldosterone (hence the term “pseudohyperaldosteronism”). These abnormalities are not reversed by spironolactone. This syndrome has also been reported as sporadic cases due to *de novo* mutations without a family history.¹³⁷

Gain of function receptor mutations

Rarely, mutations can occur in the mineralocorticoid receptors¹³⁸ that result in gain of mineralocorticoid function.¹³⁸ Those subjects present with early onset hypertension that is often made worse by pregnancy. They have a suppressed PRA and aldosterone.

SUMMARY

Mineralocorticoid excess remains the leading cause of secondary hypertension. Mineralocorticoid hypertension comprises a group of potentially curable syndromes and a high index of suspicion is needed. Unprovoked hypokalemia associated with hypertension strongly suggests mineralocorticoid hypertension. The genetic basis of several rare forms of mineralocorticoid hypertension has provided insight into the pathophysiology of hypertension. Clearly there is more to discover about mineralocorticoid hypertension and further research is needed.

Glucocorticoid Hypertension

Steven Miller and John M. C. Connell

Definitions

- Glucocorticoid hypertension occurs in florid form in Cushing's syndrome.
- Cushing's syndrome can result from pharmacologic excess of glucocorticoid, a pituitary ACTH-secreting adenoma, adrenal adenoma or carcinoma, or ectopic secretion of ACTH.

Key Findings

- Excess glucocorticoid action leads to additional cardiovascular and metabolic risk factors including central obesity, glucose intolerance, and dyslipidemia.
- In the ectopic ACTH syndrome, the hypertension is characterized by activation of the mineralocorticoid receptor by cortisol, leading to hyporeninemic hypokalemia
- The mechanisms underlying glucocorticoid hypertension include sodium retention, central sympathetic activation and altered vascular endothelial function
- Patients with glucocorticoid hypertension do not have consistent abnormalities of the RAAS or sympathetic nervous system
- Patients with the metabolic syndrome share several features of Cushing's syndrome
- Recent evidence suggests that altered local regulation of glucocorticoid metabolism by the 11 α -HSD1 enzyme results in increased receptor activation in omental fat and liver in patients with metabolic syndrome

Clinical Implications

- Hypertension in patients with gross glucocorticoid excess can be resistant to antihypertensive agents; no one specific class of drug is best
- Novel agents to inhibit local cortisol regeneration by 11 α -HSD 1 may offer alternative strategies to manage features of glucocorticoid excess in the metabolic syndrome

Steroid hormones produced by the adrenal cortex are essential to health and homeostasis. The two principal adrenal steroids in man are cortisol, which is primarily a glucocorticoid, and aldosterone, which is classified as a mineralocorticoid. This distinction has become blurred in recent years, but still forms a useful means of identifying the key actions of the two hormones. When produced in excess, cortisol and aldosterone produce significant and contrasting syndromes, both of which include hyper-

tension. In this chapter the role of glucocorticoids in the genesis of high blood pressure will be considered in detail.

The importance of glucocorticoid production to cardiovascular health is illustrated by the circumstance of lack of cortisol production in patients with either primary or secondary adrenal failure. In these circumstances glucocorticoid deficiency results in a syndrome characterized by hypotension and a significant risk of premature death. In contrast, gross cortisol excess, in the form of Cushing's syndrome, if unrecognized can result in severe hypertension, and associated metabolic dysfunction, including hyperglycemia, dyslipidemia and a prothrombotic tendency. Indeed, in a careful reanalysis of the presenting features of Cushing's syndrome, Ross et al.¹ suggested that high blood pressure was an important and frequent accompaniment of this syndrome and helped distinguish it from "simple obesity." Thus, hypertension is a common accompaniment of glucocorticoid excess and that glucocorticoid-mediated hypertension is associated with several other cardiovascular risk factors

The morbidity associated with cortisol excess² is substantial, and the risk of death is largely accounted for by excess cardiovascular events, illustrating the importance of glucocorticoid action and regulation of vascular function. In this chapter we will address the mechanisms that underlie glucocorticoid hypertension, the clinical presentations that are characterized by glucocorticoid excess and the way in which steroid hormones may contribute to the wider occurrence of atherosclerosis and vascular occlusive disease in the population.

REGULATION OF CORTISOL PRODUCTION AND ACTION

Cortisol is produced in the zona fasciculata of the adrenal cortex in a series of biosynthetic reactions from the precursor cholesterol.³ These steps involve sequential hydroxylation reactions catalyzed by P450 enzymes that are encoded by distinct and separate genes (Figure 68-1). The key steps in cortisol production include the initial transport of cholesterol from the cell cytoplasm to within the mitochondrion by the steroid acute regulatory (STAR) protein. The initial step in cortisol synthesis involves cleavage of the side chain of cholesterol and production of the hormone pregnenolone. Subsequent steps include hydroxylations at the 17 and 21 positions, and the final hydroxylation at the 11 position. This last step, catalyzed by the enzyme 11 α -hydroxylase, is a key and rate-limiting

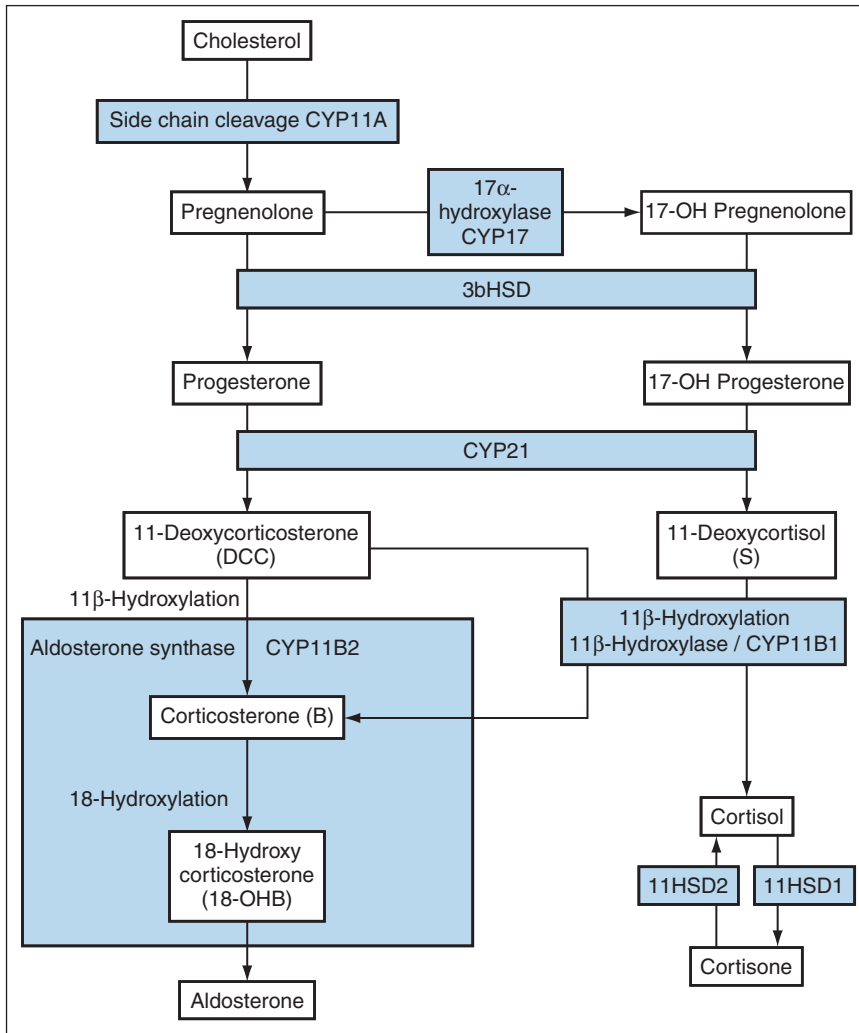

Figure 68–1. Schematic representation of adrenocorticoid synthesis and metabolism. Intermediate corticosteroid metabolites are in white, enzymes in grey. (3βHSD, 3β-hydroxysteroid dehydrogenase; CYP21, 21-hydroxylase; 11HSD1/11HSD2, 11α-hydroxylase. (Adapted from Connell JM, Fraser R, MacKenzie S, Davies E. *Hypertension* 2003;41:993–999.)

step within the pathway; the enzyme 11-hydroxylase is encoded by the gene CYP11B1. Expression of the genes involved in cortisol production and of the STAR protein is regulated by the pituitary hormone ACTH.⁴ Thus, ACTH deficiency leads to loss of expression of these key steroid hydroxylase genes and limits the ability of the adrenal gland to produce cortisol. In contrast, chronic ACTH excess leads to increased expression of these genes and, in addition, hyperplasia of adrenal cortical tissue. This, over time, leads to an increased capacity for production of cortisol from the adrenal glands.

Cortisol production by the adrenal cortex is controlled by the pituitary hormone ACTH. In turn, ACTH secretion is controlled through a negative feedback mechanism; in addition, pituitary ACTH production is regulated by input from the hypothalamus via corticotrophin-releasing hormone. ACTH (and cortisol) responds acutely to stress (hypoglycemia). There is a pronounced diurnal variation in ACTH (and thus of cortisol) so that levels are highest in the early morning and lowest in the late evening. In

subjects with pathologic syndromes of cortisol excess, this diurnal variation is lost. The complex feedback system described ensures that cortisol levels are regulated, normally within a well-defined range in day-to-day circumstances.⁵

The mineralocorticoid hormone, aldosterone, is produced by zona glomerulosa cells of the adrenal cortex. It is regulated, principally, by angiotensin-II and potassium,⁶ and has an important role in the control of sodium and potassium homeostasis by regulating the absorption and secretion, respectively, of these ions in the cortical-collecting duct of the kidney. The actions of aldosterone and the regulation of the hormone and its role in blood pressure will not be considered in detail here but are fully reviewed in Chapter 67.⁷

Steroid hormones exert their main effects through interaction with specific receptors that are located in the cell cytoplasm. On binding of ligand, these receptors translocate to the nucleus where they bind to particular receptor recognition sequences on the promoter regions of specific genes, leading to activation or repression of gene expression.^{8,9} Glucocorticoid receptors form part of a superfamily of nuclear hormone receptors that also includes the mineralocorticoid receptor, estrogen receptor, vitamin D receptor, and others. Glucocorticoid receptors are widely distributed in tissues leading to pleiotropic actions on

human physiology. Activation of the glucocorticoid receptor has effects on metabolic function, immune modulation, and growth and development.¹⁰

In addition to binding to the glucocorticoid receptor, cortisol binds with high affinity, *in vitro*, to the mineralocorticoid receptor that has, as its natural ligand, aldosterone.¹¹ Indeed, the affinity of this receptor for cortisol is at least equivalent to that of aldosterone. However, in normal circumstances this receptor is protected from binding by cortisol by the action of the enzyme 11α-hydroxy steroid dehydrogenase type 11 (HSD2). This enzyme acts as a dehydrogenase to convert cortisol to its inactive metabolite, cortisone, which does not have significant affinity for the glucocorticoid or mineralocorticoid receptor.¹² This enzyme is found in close proximity to the mineralocorticoid receptor (within the same cell) in the majority of tissues where the receptor has a key mineralocorticoid action (such as the distal renal tubule). In this circumstance, cortisol is unable to access the receptor, allowing aldosterone to act as the key activating ligand (see below).¹³

Altered glucocorticoid receptor function has been investigated as a possible explanation for some of the glucocorticoid-mediated effects that might contribute to essential hypertension. Thus, studies have suggested that increased sensitivity of the receptor to glucocorticoids might change vascular reactivity by demonstrating, for example, increased skin blanching in response to application of topical glucocorticoid.¹⁴ In other investigations, variation in the gene encoding the glucocorticoid receptor has been linked to the risk of inheriting hypertension. In an early study, Harrap et al.¹⁵ reported a restriction fragment–length polymorphism of the glucocorticoid receptor gene that was associated with an increased risk of developing high blood pressure in later life in a normotensive population. However, this has not been subsequently confirmed, although other studies have demonstrated the same variation is associated with a risk of morbid obesity.^{16,17} Thus, it is unlikely that major variation in glucocorticoid receptor sensitivity is a key factor that underlies the risk of developing glucocorticoid hypertension in patients with cortisol excess.

Glucocorticoid receptor activation is clearly central to the effects of glucocorticoid to alter blood pressure and regulate cardiovascular physiology. For example, in the kidney, activation of the glucocorticoid receptor will increase proximal sodium tubular reabsorption and, in addition, change the sensitivity of the renal tubule to the actions of vasopressin. Together, these actions will contribute to the effects of glucocorticoid on sodium and water homeostasis. Glucocorticoid receptors are also expressed in human vascular smooth muscle cells within blood vessels, and their activation will lead to a change in cell growth, and potentiation of response to a range of pressor hormones.¹⁸ Effects on the central nervous system will alter stress response and sympathetic outflow, the effects of which on the heart lead to a change in cardiac output. Specific effects of glucocorticoids on the endothelium regulate production of endothelial nitric oxide; glucocorticoid administration can be shown to reduce nitric oxide synthase (iNOS) expression, along with availability of its cofactor (tetra-hydro biopterin) and substrate (L-arginine).¹⁹ Taken together these actions will lead to altered circulating volume, cardiac output, and vascular responsiveness. It is easy to understand, therefore, how glucocorticoids can have an acute and chronic effect on blood pressure homeostasis.

Aldosterone binding to the mineralocorticoid receptor leads to a distinct set of events that include increased activity of the epithelial sodium transporter in the cortical-collecting duct of the kidney, resulting in net sodium reabsorption at that site. In addition, activation of this receptor has effects on other tissues that lead to increased cardiac collagen synthesis, altered vascular endothelial function, altered baroreceptor sensitivity, and an increase in central sympathetic outflow.^{20–22} As indicated above, cortisol normally does not activate this mineralocorticoid receptor in peripheral tissues. However, in situations of severe cortisol excess (e.g., in patients with the ectopic ACTH syndrome), grossly excessive levels of cortisol overwhelm the capacity of the enzyme HSD2, allowing

cortisol to access and activate mineralocorticoid receptor.²³ In these circumstances, cortisol action results in classic mineralocorticoid effects that include increased sodium reabsorption and potassium loss. The clinical presentation of this is discussed above. It has been proposed that the capacity of this enzyme (11 α -HSD2) might be reduced in some subgroups of patients with essential hypertension. Thus, it may be that polymorphic variation at this locus leads to altered sodium sensitivity, although definitive studies that prove this to be the case are lacking.

METABOLISM OF GLUCOCORTICOIDS AND CARDIOVASCULAR DYSFUNCTION

Cortisol is metabolized to the inactive hormone, cortisone, as described above by the enzyme 11HSD2. This enzyme is located in classic mineralocorticoid target tissues such as the kidney. The reverse reaction (predominantly a reductase) by which cortisone is converted to cortisol is catalyzed by the enzyme 11-hydroxylase steroid dehydrogenase type 1. This enzyme is present in a number of key glucocorticoid target tissues, including adipose and liver. By this means there is local regulation of cortisol generation close to the site of action. Thus, cortisol availability to the glucocorticoid receptor can be increased (by 11HSD type 1) or decreased (by 11HSD type 2). Cortisol metabolism is also carried out by reduction of the “A” ring of the molecule by 5 α -reductase, which generates tetrahydro cortisol. This alters bioavailability of the hormone. Thus, the net ability of cortisol to activate glucocorticoid receptors is determined not only by production rate within the adrenal cortex, but also by local generation and inactivation by the enzyme systems discussed above.³ This leads to a complex circumstance in normal physiology; the way in which local glucocorticoid action may be modulated in a subtle manner in central obesity and essential hypertension remains a subject of considerable debate. Nevertheless, syndromes of gross cortisol excess accounted for by increased production in the adrenal cortex provide clear examples of how glucocorticoid excess can lead to profoundly abnormal cardiovascular homeostasis.

Syndromes and experiments in which activity of these enzymes is either increased or decreased illustrate the way in which local regulation of cortisol availability can be important. Thus, patients who have lost the function of the enzyme 11HSD2 (which inactivates cortisol) have a syndrome characterized by increased cortisol availability to the mineralocorticoid receptor.²⁴ This is characterized by severe hypertension with low renin and hypokalemia. In contrast, where the enzyme 11HSD1 is deficient, an unusual syndrome develops in which patients have a relative inability to regenerate cortisol from cortisone.²⁵ This leads to a net increase in ACTH drive to the adrenal; consequently, cortisol levels in the circulation are not significantly abnormal. However, in this circumstance adrenal androgen production is increased; thus affected individuals can present with a syndrome resembling that of the polycystic ovary syndrome.²⁵ However, blood pressure levels in this circumstance are not reported to be consistently elevated.

In animal models in which 11HSD1 is knocked out, there is clear evidence of reduced glucocorticoid action in the liver, and improved insulin sensitivity and resistance to the development of obesity.^{26,27} In the converse circumstance, where the enzyme is specifically overexpressed in adipose tissue, regeneration of active glucocorticoid is enhanced. This produces a syndrome characterized by obesity, metabolic dysregulation, and hypertension.²⁸ This presentation has a remarkable similarity to the human metabolic syndrome, and it is tempting to speculate (see below) that local increased availability of cortisol within visceral fat and liver is a key contributor to metabolic dysfunction and risk of hypertension and diabetes. In contrast to animal data from knockout mice, there may be a paradox that blood pressure is not elevated in human 11HSD1 deficiency.

In summary, the regulation of cortisol production is complex and reflects both endocrine diurnal variation, classic negative feedback regulation, and local autocrine and paracrine mechanisms that lead to the ability to closely regulate the excess of glucocorticoids to the glucocorticoid and mineralocorticoid receptors. This complexity, coupled with the multiple sites of action and tissue-specific and varied effects of glucocorticoid, makes the understanding of glucocorticoid hypertension difficult. The experiments discussed above where specific enzyme systems are disrupted confirm, however, the key importance of glucocorticoid action in regulating cardiovascular function. In addition, the complex normal physiology of cortisol metabolism described identifies several mechanisms by which cortisol availability may be locally regulated and glucocorticoid action increased. How this contributes to obesity or hypertension within the general population remains the subject of considerable debate. Nevertheless, syndromes of gross cortisol excess, which are accounted for by increased production of the hormone by the adrenal cortex, provide clear examples of how glucocorticoid excess can lead to hypertension and altered metabolic homeostasis.

HOW DO GLUCOCORTICOIDS RAISE BLOOD PRESSURE?

The way in which glucocorticoid excess leads to hypertension has been the subject of a large number of studies in animal models and humans over the years. However, despite this intense effort, a full understanding of glucocorticoid hypertension remains elusive. There is no doubt that patients with gross cortisol excess have severe hypertension that is often resistant to therapy. These patients also have central obesity, dyslipidemia (mainly hypertriglyceridemia), and glucose intolerance, and have many features in common with the metabolic syndrome,^{29,30} although this is less so, if the new IDF definition of metabolic syndrome is used. Many of the actions of glucocorticoids that lead to these changes are easy to appreciate; activation of glucocorticoid receptors will, clearly, favor central weight gain. Increased hepatic glycogenolysis and increased fat deposition within the liver, resistance to the action of the hormone insulin, and disturbed lipid

metabolism leading to increased levels of LDL cholesterol, are also consequences of glucocorticoid excess. However, the way in which glucocorticoids specifically raise blood pressure is less evident.

Some of the effects of glucocorticoids on blood pressure may be very long-standing. For example, evidence suggests that early life exposure to glucocorticoids determines long-term cardiovascular function. Animals exposed to high doses of glucocorticoid *in utero* have an increased lifetime risk of developing glucose intolerance and high blood pressure.^{31,32} In human studies, it has been shown that there is an association between low birth weight and subsequent long-term regulation of the hypothalamic/pituitary/adrenal axis.³³ Thus, normotensive adults with low birth weight (who subsequently have a risk of becoming hypertensive in later life) have higher morning cortisol levels than subjects with normal birth weight.³⁴ The way in which this relationship develops and its importance in long-term development of hypertension remain unclear, but serve to illustrate the possible importance of glucocorticoids in the long-term regulation of cardiovascular function.

In addition to these very long-term “programming” mechanisms, several shorter-term mechanisms that may allow glucocorticoids to regulate cardiovascular function have been studied.

Sodium status and volume

The ability of cortisol to activate the mineralocorticoid receptor in circumstances of severe excess of the hormone has been discussed above. In such patients there is sodium retention, expansion of plasma volume and of total body exchangeable sodium (as reflected by suppression of renin), and potassium wasting. However, the majority of patients with glucocorticoid excess have normal levels of renin and do not have substantial expansion of body sodium content. Thus, although short-term administration of hydrocortisone to normal humans does lead to profound antinatriuresis, chronic cortisol excess appears not always to be associated with substantial volume expansion. Sodium restriction does not prevent the development of glucocorticoid-mediated hypertension in experimental circumstances.³⁵ Furthermore, administration of a mineralocorticoid receptor antagonist such as spironolactone does not prevent glucocorticoid-induced hypertension in human subjects or in animal models.³⁶

A rise in cardiac output (by administration)

Short-term administration of glucocorticoids can increase cardiac output. However, in experimental circumstances prevention of this rise in cardiac output (by the administration of beta-blockers) does not inhibit development of glucocorticoid hypertension, and a rise in cardiac output as a consequence of acute glucocorticoid administration is unlikely to be a primary pathogenic mechanism.

Central sympathetic activation

Steroid hormones have profound effects on central nervous system (CNS) function, so that administration of glucocorticoid leads to a rise in sympathetic activation.

For example, local administration of corticosterone within the ventricular system of the brain raises blood pressure acutely.³⁷ However, this is likely to be a consequence of direct mineralocorticoid receptor activation within the brain, and the influence of circulating glucocorticoids on the CNS in relation to blood pressure regulation is less well understood.

Pressor responsiveness

Administration of hydrocortisone to human subjects increases pressor responsiveness to agents such as phenylephrine.¹⁸ The mechanism of this remains unclear; in the long term this may reflect a change in vascular geometry so that responsiveness to any pressor agent is increased. However, in the short term it is likely that there is a change in α -receptor sensitivity or density in vascular smooth muscle cells. In addition, however, there is evidence that glucocorticoid receptor activation leads to a decrease in availability of endothelial nitric oxide.³⁸ Effects in relation to this appear to be specific. Thus, in animal studies the effects of glucocorticoid on NO availability are uncertain, whereas in human studies it seems clear that nitric oxide availability (as assessed by blood flow response to acetylcholine) is impaired in subjects given an acute short-term course of glucocorticoid.

In summary, there are a variety of potential mechanisms by which cortisol excess can raise blood pressure. Many of these can be shown to be present under short-term experimental circumstances when pharmacologic doses of glucocorticoids are administered. Thus, Brotman et al.³⁹ recently studied the effects of short-term dexamethasone administration in normal subjects, and showed a rise in blood pressure that was associated with a fall in heart rate and a change in a number of inflammatory markers. However, how this translates into long-term alteration on blood pressure regulation remains unclear. Evidence suggests that multiple pathways are involved in development of glucocorticoid hypertension. The one that dominates may in part be determined by the absolute level of glucocorticoid. Thus, in subjects with very marked overproduction of cortisol (as in the ectopic ACTH syndrome), the effect of cortisol on sodium and water metabolism may predominate, leading to a volume-dependent form of hypertension. In more subtle cortisol excess, long-term effects of glucocorticoid on vascular geometry and endothelial nitric oxide synthesis may become the dominant way in which blood pressure elevation is maintained.

CLINICAL PRESENTATIONS OF GLUCOCORTICOID-MEDIATED HYPERTENSION

Exogenous glucocorticoid excess

The commonest circumstance in which glucocorticoids cause hypertension relates to pharmacologic use in the treatment of patients with inflammatory and other disorders. Hypertension and altered vascular risk are important causes of morbidity and mortality in these patients. For example, in a survey of a large population within the

Tayside Region (Scotland) of patients given a range of glucocorticoids, Wei et al.⁴⁰ reported a marked excess of cardiovascular disease. A confounding factor in this study was, of course, the notion that patients prescribed glucocorticoids may have had increased cardiovascular risk due to underlying disorders (such as inflammatory arthritis), and the absolute impact of glucocorticoid prescription on hypertension and cardiovascular risk remains to be determined. Nevertheless, even when data in this study were corrected for other known confounding factors, vascular excess risk remained, and it seems likely that glucocorticoid prescription is associated with a potentially independent long-term effect to increase cardiovascular event rate in addition to an impact on blood pressure.

Endogenous glucocorticoid excess *Cushing's disease*

Cushing's disease remains the most common cause of endogenous cortisol excess. The disorder, due to increased ACTH secretion from the anterior pituitary, results in a syndrome characterized by overproduction of cortisol. Patients with untreated Cushing's disease have markedly increased 5-year mortality from cardiovascular disease, which is accounted for by hypertension, glucose intolerance, and dyslipidemia.^{2,41} Effective treatment of ACTH excess cures the condition. However, it is noteworthy that excess cardiovascular morbidity and mortality remain in patients following successful treatment of Cushing's disease,⁴² suggesting that glucocorticoid excess may confer increased long-term risk that is not relieved by normalizing cortisol levels.

Ectopic ACTH syndrome

The ectopic ACTH syndrome results in very severe cortisol excess. This can develop in patients with bronchial carcinoma, but is also seen in a variety of other circumstances, including bronchial carcinoid tumors. In the circumstance of gross cortisol hypersecretion, the capacity of the 11HSD2 enzyme to metabolize cortisol to cortisone is overwhelmed, allowing the hormone access to the mineralocorticoid receptor. Patients occasionally develop severe hypertension, associated with suppression of renin and hypokalemia. In this condition, the mechanism of hypertension is clearly due to mineralocorticoid receptor activation. However, this is a rare and unusual circumstance that does not reflect the general cardiovascular state of patients with less severe aspects of glucocorticoid excess.

Adrenal tumors

Adrenal tumors that release cortisol are most frequently benign. In patients with unilateral adrenal adenomas, hypertension and metabolic dysfunction resulting from cortisol excess is common. In such patients with marked excess of cortisol, the diagnosis is straightforward. However, it has become clear in recent years that a number of patients present with adrenal adenomas that produce cortisol at a much lower level; in many instances, circulating plasma cortisol is not increased in comparison with normal subjects. Such adrenal "incidentalomas" were

thought not to have any significant clinical syndrome associated with them. However, it is now clear that in a number of patients, cortisol production by the tumor does contribute to cardiovascular morbidity.⁴³ In particular, low-grade cortisol excess from apparent adrenal incidentalomas is associated with an increased risk of high blood pressure and other cardiovascular disturbance including glucose intolerance and hypercholesterolemia. For this reason it is important that careful studies are made of cortisol production and its suppressability in all patients with apparent nonfunctioning adrenal adenomas.

Although the majority of such adrenal tumors are benign, adrenal lesions that are malignant can also be associated with increased cortisol production. In this circumstance, mortality from the underlying adrenal lesion is high, and the response to chemotherapy and radiotherapy is disappointing.

While the majority of patients with unilateral cortisol-producing tumors show no evidence of excess production of other steroid hormones that might contribute to cardiovascular dysfunction, patients with adrenal carcinomas may present with a range of excess hormone production, including secretion of precursor hormones (such as deoxycorticosterone) that can have important mineralocorticoid actions. In addition, a small number of patients can present with increased production of both cortisol and aldosterone. In this circumstance, hypertension may occur as a result of both increased mineralocorticoid and glucocorticoid effects.

CONTRIBUTION OF GLUCOCORTICOIDS TO METABOLIC SYNDROME

The above instances illustrate how major pathophysiologic glucocorticoid excess presents with the clinical features of Cushing's syndrome. However, it has been observed that patients with the metabolic syndrome have several clinical features that resemble Cushing's syndrome, although cortisol levels are not significantly elevated in this circumstance. Thus, patients with the metabolic syndrome have central obesity, glucose intolerance, dyslipidemia, and hypertension.⁴⁴ In recent years, studies have focused on the notion that glucocorticoid excess might contribute to some of these manifestations. Additionally, there have been suggestions in the past that ACTH-dependent cortisol overproduction might contribute to the development of essential hypertension. For example, in the late 1980s, Whitworth et al.⁴⁵ demonstrated that dexamethasone treatment caused blood pressure to fall in patients with hypertension, and argued that this evidence of high blood pressure was a consequence of adrenal-derived steroids under the influence of ACTH. This concept has not been studied in detail by other investigators, although there is no clear evidence that there is a general overproduction of glucocorticoid in hypertensive patients.

The notion that the metabolic syndrome might represent a subtle form of increased glucocorticoid action has, however, been investigated.^{46,47} There is evidence of a small increase in cortisol metabolite excretion in subjects with obesity, although this is very much less than would

normally be found in patients with classic Cushing's syndrome.⁴⁸ Plasma cortisol levels, in contrast, are slightly lower than would be expected. These data have been interpreted as showing evidence of increased cortisol metabolic clearance (with a corresponding small increase in secretion rate) in obese patients. Cortisol is metabolized by several routes that are discussed above. Studies suggest that there is, in obesity, an increase in "A" ring reduction of cortisol that might account for the altered metabolic clearance noted.⁴⁹ The biological significance of this remains uncertain.

In addition to evidence of increased cortisol clearance, other studies have suggested that the activity of 11HSD1 is increased in the metabolic syndrome. Again, the significance of this remains unclear. Studies by Walker et al.⁵⁰ suggest that the expression of the enzyme in adipose tissue (particularly subcutaneous fat) is increased in obesity, while other studies⁵¹ have suggested that this is not the case in visceral adipose tissue, although visceral obesity is more commonly associated with most features of the metabolic syndrome, including hypertension. Nevertheless, it has been suggested that an increase in generation of cortisol from cortisone within omental fat results in enhanced cortisol delivery to the liver in obese patients. This would be expected to lead to a range of changes, including altered hepatic fat metabolism and, possibly, an increase in hepatic cytokine production. In turn, this might lead to a change in peripheral glucose disposal. In other circumstances increased secretion of cytokines (including IL6 and TNF α) from the liver has been shown to cause insulin resistance at the level of skeletal muscle and adipose tissue.⁵² If these data can be extrapolated to effects of increased local availability of cortisol, it is possible that altered regulation of cortisol metabolism within omental fat results in a change in whole body regulation of glucose disposal that favors the development of insulin resistance and, in some subjects, progression to diabetes mellitus. This notion is supported by studies in which the adipose HSD1 enzyme expression has been increased using a tissue-specific enhancer. In mice with this overexpression, central obesity develops as does hypertension and glucose intolerance.⁵³ In mice, in contrast, where the corresponding gene is knocked out in the liver, there is evidence of a resistance to obesity during high fat feeding.²⁷ Thus, it is possible that a local increase in cortisol delivery to the liver may set in process mechanisms that give rise to generalized insulin resistance with hypertension. The mechanism for the rise in blood pressure in this circumstance remains to be fully determined. However, there is an association between generalized insulin resistance and hypertension and some other circumstances⁵⁴ that may, in part, represent reduced vascular endothelial nitric oxide production,⁵⁵ although a cause-and-effect relationship between insulin resistance and hypertension remains unclear. However, in this circumstance, it is possible that the altered production of hepatic cytokines leads to a direct cytokine-mediated impairment of endothelial nitric oxide availability that alters, in the long term, blood vessel contractility and structure.

THERAPEUTIC ASPECTS

The uncertainty regarding the exact mechanisms for glucocorticoid-mediated hypertension means that specific treatment targeted to key pathways is unlikely to be successful. For example, although use of a mineralocorticoid receptor antagonist is of benefit in patients with aldosterone excess, this is unlikely to prove beneficial unless patients have cortisol excess to the extent that there is increased activation of the mineralocorticoid receptor (as in the ectopic ACTH syndrome). This is a rare circumstance. In other patients, the response to anti-hypertensive therapy can be variable. Patients often require a combination of treatment, and blood pressure can prove resistant. It is clear that the most important consideration is early action to normalize cortisol production. As noted above, however, there is evidence that significant cardiovascular morbidity remains in patients following successful treatment of Cushing's disease.

The implications of the role of cortisol regeneration in patients with the metabolic syndrome has led to therapeutic consideration of development of inhibitors of the HSD1 enzyme that might reduce cortisone to cortisol metabolism within omental fat. Such drugs might, in theory, prove valuable in treatment of the metabolic syndrome. It is less certain how effective they would be in

patients with gross glucocorticoid excess presenting as part of Cushing's syndrome.

SUMMARY

Patients with glucocorticoid excess suffer substantial cardiovascular morbidity and have increased mortality. Evidence from specific syndromes and from population studies of patients taking exogenous glucocorticoids indicate that there is, indeed, significant risk of hypertension in patients with glucocorticoid excess. The underlying mechanisms that give rise to this remain unclear; several potential pathways that may raise blood pressure have been implicated. At present it seems likely that glucocorticoids raise blood pressure through a range of different mechanisms that will include central activation of sympathetic outflow, alteration of vascular endothelial function (through change of availability of nitric oxide) and, potentially, increased activation of the mineralocorticoid receptor in specific circumstances. It is important to recognize that hypertension in this patient group is part of a cardiovascular syndrome that also includes glucose intolerance and dislipidemia. Thus, treatment of patients with glucocorticoid excess needs to focus not only on blood pressure-lowering but also on other aspects of metabolic management including treatment of hypercholesterolemia, and specific glucose-lowering strategies.

Chapter
69Cushing's Syndrome and
Human Glucocorticoid
Hypertension

Fernando Elijovich and Cheryl L. Laffer

Definition

- Cushing's syndrome is a cluster of clinical features produced by exaggerated action of glucocorticosteroids that are either stimulated by hypothalamo-pituitary or ectopic ACTH, hypersecreted by diseased adrenal glands, or given as therapeutic agents.

Clinical Implications

- Major manifestations include truncal obesity, hypertension, insulin resistance, overt diabetes, and dyslipidemia. These features, resembling the "metabolic syndrome," are associated with a large increase in cardiovascular morbidity and mortality.
- Stigmata of Cushing's syndrome may be absent; a high index of suspicion is required to establish the diagnosis when only isolated features are present (e.g., hypertension).
- Despite advances in definitive pituitary and adrenal surgeries, pharmacologic management to suppress synthesis or block the action of glucocorticoids may be required for severe disease, recurrences, or incurable etiology.

Cushing's syndrome has been considered an infrequent endocrinopathy (incidence 0.24 cases/100,000/year and prevalence of 1 to 4/100,000 in the general population,¹ or 5 cases/1000 hypertensive subjects in a referral tertiary care health center²), but nonetheless deserving of prompt identification and treatment because of its poor prognosis. Employing the World Health Organization–International Society of Hypertension classification, more than 80% of patients with Cushing's syndrome fall within high cardiovascular risk categories, and duration of disease is a major risk predictor, emphasizing the need for early recognition and therapy. Total and cardiovascular¹ mortalities are four- and five-fold higher than in the general population, respectively. In a study of 151,000 Scottish individuals without pre-existing cardiovascular disease (with 470,000 person-years follow-up), 46% of patients on chronic glucocorticoid therapy had 6.90 and 2.56/1000 person-year increases in absolute and relative covariate-adjusted risks for a cardiovascular event, respectively.³

Increasing use of computerized tomography and magnetic resonance imaging of the abdomen over the last two decades made it apparent that 5% of subjects have unsuspected, incidentally discovered adrenal masses.

Investigation of these "incidentalomas" showed that 5% to 20% of them are functional, secreting adrenal steroids autonomously and often producing clinically inapparent hypercortisolism with associated hypertension. Combined prevalence of clinical and subclinical forms of Cushing's syndrome is about 79/100,000. This is much higher than previously suspected, and suggests that undetected hypercortisolism may cause or contribute to blood pressure elevation in 150,000 to 600,000 subjects in the United States who carry a diagnosis of "essential" hypertension. Therefore, clinicians must seek subtle signs of Cushing's syndrome in all hypertensive patients and proceed with cost-effective screening if they are present. It has been argued that concomitant obesity, nonfamilial diabetes in both sexes and hirsutism in females, as well as otherwise unexplained menstrual irregularities, should prompt screening for hypercortisolism in hypertensive subjects.

In this chapter we will review the clinical features, diagnostic approach, and therapeutic options for the diverse forms of Cushing's syndrome. Also, we will discuss the complex and not fully understood mechanisms of hypertension and its treatment in states of glucocorticoid excess.

CLINICAL PRESENTATION**Clinical features**

A list of common and uncommon features of Cushing's syndrome is shown in Table 69–1. Frequencies represent a compilation from many literature sources.

Hypertension

Hypertension is present in 70% to 80% of pituitary and adrenal Cushing's syndrome,⁴ but less commonly (~20%) in chronic exogenous glucocorticoid therapy. It can be severe and refractory to therapy, and is usually salt resistant. Blood pressure correlates with age in Cushing's syndrome and fails to be normalized by successful therapy of hypercortisolism in about 30% of patients, suggesting that glucocorticoid hypertension may often be concomitant with or superimposed on essential hypertension.⁴

Circadian rhythm of blood pressure

Out of several forms of secondary hypertension in which the normal circadian rhythm of blood pressure is attenuated, abolished, or reversed, Cushing's syndrome is the one in which this abnormality (lack of nocturnal blood

FREQUENCY OF SYMPTOMS AND SIGNS OF CUSHING'S SYNDROME

Note: Based on composite data from several publications.

Table 69-1. Frequency of Symptoms and Signs of Cushing's Syndrome

pressure "dip") is most consistently observed, even in subjects without hypertension. The circadian rhythm of heart rate is preserved, indicating that the hypothalamo-pituitary-adrenal axis exerts specific control of blood pressure (not heart rate) variability. Nocturnal dipping is always absent in Cushing's syndrome of long duration, suggesting an interaction between hypertension itself and hypercortisolism in determining loss of the circadian rhythm of blood pressure. Glucocorticoid treatment of collagen vascular disorders or renal disease reduces nocturnal dipping as much as endogenous Cushing's syndrome, whereas this is not so in dexamethasone-induced hypertension in the rat,⁵ indicating that the effect is species-specific. Nocturnal dipping is more commonly normalized by surgical cure of adrenal than of pituitary Cushing's,⁶ and is restored to normal by cyproheptadine (inhibition of ACTH release⁷), suggesting that the effect of glucocorticoids on blood pressure variability is exerted in the central nervous system.

Lack of nocturnal dipping of blood pressure is a known risk factor for exaggerated hypertensive target-organ damage, and antihypertensive drugs of several families do not correct it in patients with Cushing's syndrome. Therefore, the need to quickly address definitive therapy of Cushing's syndrome cannot be overemphasized.

Obesity

Weight gain of Cushing's syndrome results in characteristic redistribution of subcutaneous fat leading to truncal obesity, moon facies, and supraclavicular and dorsal cervical ("buffalo hump") fat pads (see Figure 69-1). However, none of these features is specific for the obesity of glucocorticoid excess. Weight gain and growth retardation are prominent features of pediatric Cushing's syndrome, in which hypertension is not as prevalent as in adults (~50%).

Dermatologic features

Purple striae (Figure 69-1), dermal thinning, and easy bruising are common clinical signs, useful to alert the clinician regarding the possibility of hypercortisolism in patients who are being evaluated for obesity or hypertension. In contrast, hirsutism is more likely to be associated with primary obesity in hypertensive women.

Metabolic abnormalities

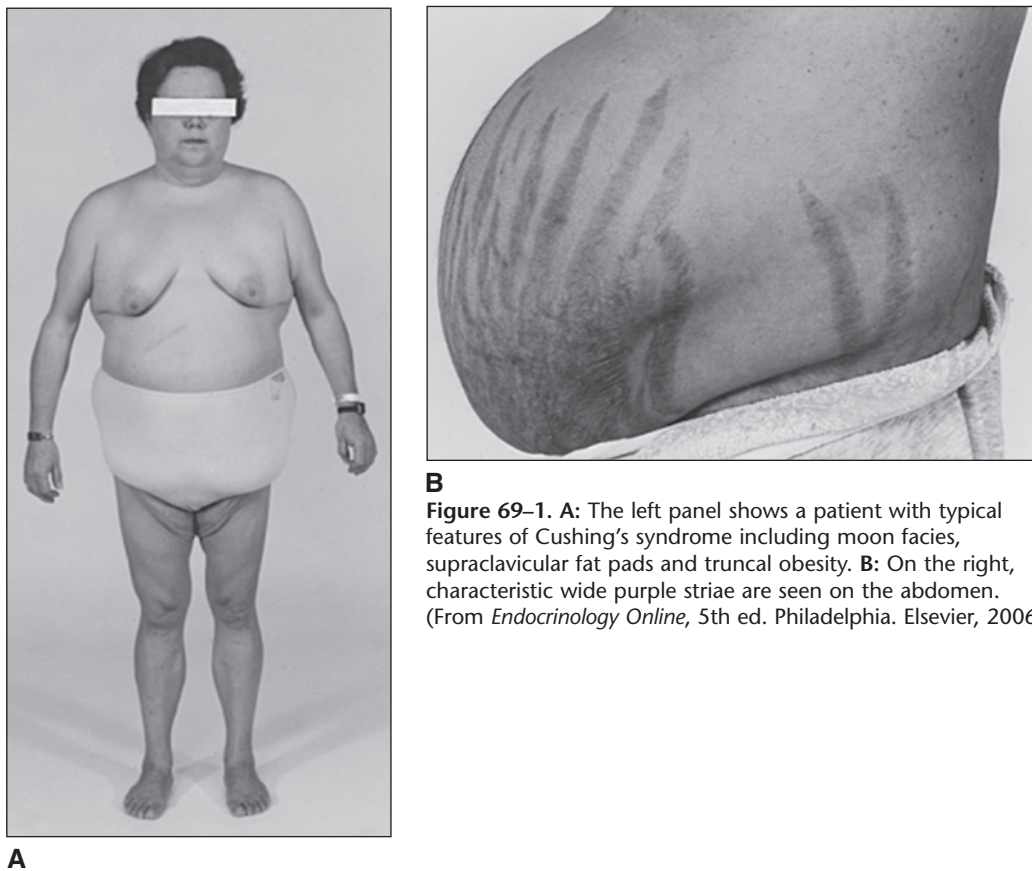

Diabetes mellitus type 2 and hyperlipidemia are present in approximately 40% of patients, but glucose intolerance is much more prevalent (~90%). These metabolic abnormalities are specific to the glucocorticoid excess because they regress after surgical therapy, improve with pharmacologic inhibition of glucocorticoid synthesis, are also produced by exogenous glucocorticoids, and can be reduced when the latter are given on alternate days. Metabolic factors account for the fact that cardiovascular damage of Cushing's syndrome can be observed in the absence of hypertension.⁴

Neuropsychiatric manifestations

Depression and cognitive impairment of Cushing's syndrome are associated with reduced brain volume and diminished cerebral glucose metabolism (measured with PET 18-fluorodeoxyglucose scanning⁸), which are somewhat reversible with therapy. In children, neuropsychiatric manifestations are frequent but subtle, often overlooked as behavioral problems.

Other

Severe osteoporosis in the young (even when an isolated manifestation), unexplained recurrent infections, myopathy (proximal muscle weakness), erectile dysfunction, and gynecomastia should prompt the search for subtle clinical stigmata of hypercortisolism. Nephrolithiasis, owing to

B

B: On the right, characteristic wide purple striae are seen on the abdomen. (From *Endocrinology Online*, 5th ed. Philadelphia. Elsevier, 2006.)

a combination of hypercalciuria, hyperuricosuria, hypercystinuria, hyperoxaluria, and diminished citrate excretion, occurs in 20% to 25% of Cushing's patients.

Complications and damage of target organs

Neuro-ophthalmologic complications and stroke

Rare neurologic complications include paralysis of oculomotor cranial nerves due to compression by large pituitary adenomas, and spinal epidural lipomatosis, an abnormal growth of epidural fat that produces compressive thoracolumbar myelopathy and radiculopathy. Epidural lipomatosis is more common in Cushing's syndrome caused by ectopic ACTH secretion and glucocorticoid therapy. It is often missed when symptoms are nonspecific, but can be easily detected by magnetic resonance imaging (MRI). Successful surgical decompression has been achieved in severe cases but a conservative approach is indicated if it is milder.⁹

Ischemic and hemorrhagic strokes occur in Cushing's syndrome, which are not unexpected in severe hypertension. Funduscopic changes may reflect hypertensive retinopathy or the effect of a large neighboring pituitary tumor. Glaucoma and exophthalmos are common with exogenous glucocorticoid therapy but rare in endogenous Cushing's syndrome. Proximal muscle weakness may be due to hypokalemia or to underlying malignancy in ectopic Cushing's syndrome.

Left ventricular hypertrophy

Left ventricular hypertrophy (LVH) was not more prominent in Cushing's syndrome than in essential hypertension, and less in these two groups than in primary hyperaldosteronism in one study.¹⁰ In contrast, others found severe LVH by electrocardiographic criteria and asymmetric LV septal hypertrophy (up to 32 mm) by echocardiogram in all patients. The latter was more prevalent in Cushing's syndrome than in essential hypertension or primary aldosteronism, suggesting a contribution of cortisol to LVH independent of blood pressure.¹¹ This is consistent with an observed relationship between LV mass and urine free cortisol in essential hypertension but not normal subjects.¹² However, echocardiographic relative wall thickness did not correlate with urine cortisol in another study of Cushing's syndrome.¹³ Regardless of their mechanisms, LVH and asymmetric septal hypertrophy normalized with successful surgical therapy in both studies.

Vascular complications

Delayed scar tissue formation by glucocorticoids may explain the increased risk for rupture of the LV free wall after myocardial infarction in patients on chronic therapy with these agents. A similar mechanism may account for the reported aortic and large conduit artery aneurysms and dissections in patients with Cushing's syndrome, although these are not more frequent than

expected in an illness characterized by atherosclerotic vascular disease.

Cushing's syndrome in pregnancy

Pregnancy in women with Cushing's syndrome is uncommon because glucocorticoids inhibit gonadotrophin-releasing hormone and stimulate androgens, resulting in ovulatory disturbance, amenorrhea, oligomenorrhea, infertility, and abortions. As opposed to the predominance of pituitary Cushing's in nonpregnant subjects, the cause in pregnant women is usually adrenal. Diagnosis is often delayed, assuming instead pre-eclampsia or gestational diabetes, to the point that adrenal adenomas have been accidentally discovered during Cesarean sections. Maternal (hypertension, diabetes, congestive heart failure, delayed wound healing, HELLP syndrome) and fetal (growth retardation, death in utero, prematurity) morbidities and mortalities are increased. Although normal births occur, the consensus is to intervene to reduce the risk of fetal loss. Multiple forms of therapy (pituitary and adrenal surgery, pharmacologic suppression of cortisol synthesis, and pituitary radiation) have been employed, with variable success.

Associated clinical conditions

Patients with Cushing's syndrome may present with the manifestations of the underlying illness responsible for ectopic secretion of ACTH (discussed later) or with those of associated conditions unrelated to the hypercortisolism. Some of them are authentic associations, whereas others are coincidental. Among the former are adrenal myelolipomas (benign tumors containing scattered islands of erythroblasts, myeloid and lymphocytic cells), sometimes found next to or combined with adrenal adenomas; and atrial myxomas that may or may not be part of Carney's syndrome. Concomitant pituitary corticotroph and lactotroph adenomas with hyperprolactinemia, and somatotroph adenomas with acromegaly have been reported.

Difficulties in clinical diagnosis

High blood pressure, weight gain, and glucose intolerance are most commonly produced by essential hypertension, primary obesity, and insulin resistance, three prevalent diseases that many times occur in combination (e.g., the metabolic syndrome). It is therefore very easy to overlook the diagnosis of Cushing's syndrome, which has a similar phenotype. This is particularly so when obesity is not clearly truncal or cutaneous stigmata are absent. Moreover, Cushing's syndrome may present with isolated features, be paucisymptomatic in the elderly, or subclinical in incidentalomas. The mean delay, from the retrospective assessment of the onset of symptoms to diagnosis, is about 3 years, with a range extending up to 8 years.¹⁴ However, improvement of laboratory and imaging techniques has increased physicians' awareness. Referrals of subjects who will have confirmed Cushing's syndrome in a specialized center have tripled since the late 1980s.¹⁵

CAUSES OF CUSHING'S SYNDROME: ANATOMY, PATHOLOGY, AND DIFFERENTIAL FEATURES

ACTH-dependent and ACTH-independent Cushing's syndrome

Figure 69–2 provides a schematic representation of the causes of Cushing's syndrome. The top panel represents the normal stimulation of pituitary ACTH release by hypothalamic corticotrophic releasing hormone (CRH), leading to normal cortisol secretion by the zona fasciculata of the adrenal cortex. The three orange lines depict the inhibitory feedback loops that fine-tune the system (ACTH on CRH and cortisol on both CRH and ACTH). Exaggerated release of ACTH by a pituitary adenoma (second panel) is designated as Cushing's disease (after its description by Harvey Cushing in 1919). There is feedback inhibition of CRH by ACTH (with a few exceptions to be discussed later), while that of ACTH by cortisol is diminished or absent. Adrenal adenomas, carcinomas, or hyperplasia produce ACTH-independent, autonomous secretion of cortisol (third panel). The latter inhibits both hypothalamic CRH and pituitary ACTH. The fourth and fifth panels depict ectopic production of ACTH or CRH (the former much more common) by a malignant tumor. Ectopic CRH stimulates pituitary ACTH, hence adrenal cortisol, with inhibition of hypothalamic CRH, whereas ectopic ACTH stimulates production of cortisol by the adrenal cortex, with feedback inhibition of CRH and pituitary ACTH. Finally, when Cushing's syndrome is secondary to exogenous administration of synthetic glucocorticoids (the most common cause now, due to use of high-dose steroids in oncology and immunology), the whole endogenous axis is inhibited, as shown in the bottom panel.

In the following sections we will describe the anatomy and differential clinical characteristics of the entities that produce ACTH-dependent and ACTH-independent Cushing's syndrome.

Pituitary adenomas

Ten to 15% of all pituitary adenomas secrete ACTH. They are the most common cause of endogenous hypercortisolism (70%), four to five times more frequent in women than men, and also the most common cause in the elderly, in whom increased prevalence of cancer does not lead to excess ectopic Cushing's syndrome. Only in pregnancy is adrenal Cushing's more common than Cushing's disease.

Most ACTH-producing tumors are single microadenomas (85%), the size of which is often below the limit of detection for current imaging modalities. Corticotrophs of ACTH-secreting adenomas are monoclonal, consistent with proliferation of a founder cell that developed a spontaneous somatic mutation. This is in contrast to the polyclonal corticotrophs stimulated by CRH of ectopic sources. Microscopically (Figure 69–3), ACTH adenomas show basophilic (rarely chromophobic) cells, strong PAS and lead-hematoxylin positivity, and a prominent Golgi

Figure 69-2. Schematic representation of the normal hypothalamo-pituitary-adrenal axis (*top panel*) and its alteration by the diverse causes of endogenous and exogenous glucocorticoid excess in humans. For description of each panel, see text. Normal function is depicted by blue organs, hyperfunction by green, and hypofunction by orange. Thick black lines and arrows and bolded letters signify excess stimulation, whereas thick orange lines indicate excess inhibition. Dashed thin black lines and *lightface italicized* letters indicate loss of normal stimulation. Dashed thin orange lines show loss of normal inhibition. ACTH, adrenocorticotropin; Cort, cortisol; CRH, corticotropin-releasing hormone; GC, tablet of therapeutic synthetic glucocorticoid; T, CRH- or ACTH-producing tumor.

apparatus harboring secretory granules that stain with immunoperoxidase (ACTH or other pro-opiomelanocortin-derived peptides). Large adenomas greater than 3 cm are seen only in 1% to 2% of cases, may invade surrounding tissues (60%), and have impaired secretory exocytosis

with lower ACTH levels and lesser prevalence of hypertension. Other causes of clinically inapparent Cushing's disease have been reported, including coincidental coexistence of mutations of adrenal 21-hydroxylase or dysfunction of 11- β -hydroxy-steroid dehydrogenase type

Figure 69-3. Photomicrograph of the histologic aspect of a pituitary adenoma. The monomorphic aspect of these cells, which usually stain positive with PAS, is accounted for by their monoclonal origin; see text. (From Kumar V, Abbas AK, Nelson F, eds. *Robbins and Cotran Pathologic Basis of Disease*, 7th ed. Philadelphia: Elsevier Saunders, 2005.)

1 (11bHSD1), reducing adrenal synthesis of cortisol or its tissue generation from cortisone, respectively.

As opposed to acromegaly, Cushing's disease is rarely due to multiple pituitary adenomas. When present, they may all secrete ACTH or be a combination of ACTH and prolactin- or growth-hormone-secreting tumors. Corticotrophs can also cluster into hyperplastic nodules, not adenomas, suggesting that hypothalamic stimulation by CRH may be the cause of hypercortisolism in these rare cases.

Extra-pituitary corticotroph adenomas are many times located in the cavernous sinus. They are often undetectable by imaging techniques and only found at autopsy. In one reported case, Cushing's disease was produced by leptomeningeal masses representing intracranial dissemination of a pituitary adenoma that was nonfunctional when resected years earlier.¹⁶

Adrenal adenomas

These benign tumors are responsible for 10% to 20% of all cases of endogenous Cushing's syndrome. The typical adrenal adenoma is a well-delimited yellowish-brown tumor that histologically resembles the normal gland (cords of clear and compact cells) (Figure 69-4), and rarely exceeds 25 to 35 g. Unusual variants include multiple adenomas in one or both adrenal glands, extra-adrenal location in the urinary tract, and so-called "black adenomas," which are larger, have higher than usual attenuation in a CT scan, and lack reduction of signal intensity in T1-MRI. They consist of polygonal cells with brown granules containing lipofuscin-like pigment and many lysosomes by electron microscopy. While traditional adenomas usually present with overt Cushing's syndrome, "black adenomas" may present only with hypertension.¹⁷

Analogous to carcinomas, cortisol-producing adenomas may have concomitant secretion of aldosterone, or lack of

Figure 69-4. Photomicrograph of the histologic aspect of an adrenal adenoma. The specimen contains a mixture of the two classical cell types observed in this entity: clear, lipid-containing (lightly stained on the picture), and compact, lipid-poor (darker stained) cells. (From Korobkin M, Giordano TJ, Brodeur FJ, et al. *Radiology* 1996;200:743-7.)

suppression of aldosterone by paradoxical hyperplasia of the zona glomerulosa, in which case they present with significant hypokalemia. They may also produce testosterone and other androgens, presenting with virilization and masked Cushing's syndrome.

Adrenal carcinoma

Adrenal carcinomas are the cause of ~5% of cases of Cushing's syndrome. They are large tumors, occasionally palpable, with all the macroscopic (necrosis, hemorrhage, capsular invasion, neovascularization) and microscopic (pleomorphic nuclei and prominent mitoses) pathologic characteristics of malignancy.

In addition to cortisol, adrenal carcinomas commonly secrete steroids with mineralocorticoid activity, such as combinations of 11-deoxycorticosterone, 11-deoxycortisol, and 17- α -hydroxyprogesterone, suggesting defective 11- β hydroxylation, isolated deoxycorticosterone, or aldosterone. Severe hypertension and hypokalemia may suggest primary hyperaldosteronism, but cortisol secretion is not suppressible. Androgenic steroids may also be secreted and produce clinical virilization. The steroid profiles of individual patients may be very different, but they remain constant during the course of the disease in each subject.

Adrenal hyperplasia

All forms of adrenal hyperplasia account for about 2% of endogenous Cushing's syndrome.

Micronodular hyperplasia

Several forms of adrenal hyperplasia can produce ACTH-independent secretion of cortisol with Cushing's syndrome. In the primary micronodular form, micronodules of clear cells, arranged in cords or acini, sometimes macroscopically, coexist with surrounding areas of diffuse

hyperplasia. In children, the disease may not be easily identified because the adrenal glands are not enlarged. Another variant without much enlargement of the adrenals is primary pigmented nodular adrenocortical hyperplasia (PPNAD), which is characterized by eosinophilic cells with dark lipofuscin pigment and areas of atrophy.

It has been argued that micronodular hyperplasia may be a form of “tertiary” Cushing’s syndrome, in which the hyperplastic adrenals acquired secretory autonomy after a period of ACTH stimulation, and also that it may represent hypersensitivity of the adrenal gland to normal ACTH levels.

Primary pigmented nodular adrenocortical hyperplasia can be secondary to mutations of the type-1 alpha-regulatory subunit of cAMP-dependent protein kinase A,¹⁸ and can also be a component of Carney’s syndrome (visceral and cutaneous myxomata, pituitary and testicular tumors, and spotty skin pigmentation).¹⁹ When not a part of this syndrome, PPNAD commonly presents with hypertension or severe osteopenia.

Macronodular hyperplasia

This rare form, also known as ACTH-independent massive bilateral adrenal disease (AIMBAD), derives its name from the fact that adrenal glands may reach weights up to 200 g with nodules up to 5 cm in diameter. The cortical macronodules have clear cells whereas the rest of the gland has disorganization of its structure.

A characteristic feature is that adrenocortical cells have abnormal expression of receptors for non-ACTH substances; hence, their agonists stimulate cortisol secretion. Examples include angiotensin II stimulation that can be prevented with the AT1 receptor blocker candesartan,²⁰ vasopressin stimulation via V1a and V1b receptors,²¹ and catecholamine stimulation prevented by propranolol in a case with adrenal binding sites with the properties of β -1 and β -2 adrenoceptors.²² Familial and nonfamilial forms of abnormal cortisol responsiveness to gastric inhibitory polypeptide (GIP), documented *in vitro* with tissue from resected adenomas, are characterized by food-induced Cushing’s syndrome that can be suppressed by octreotide, indicating that cells from the macronodules may have heterotopic receptors for GIP.²³

Patients with macronodular hyperplasia are older, with longer duration of disease and higher prevalence of hypertension than those with the micronodular form. There is frequent hypoandrogenism due to atrophy of the zona reticularis and occasional hypersecretion of DOC and 18-OH-DOC with significant hypokalemia. Lack of Nelson’s syndrome after bilateral adrenalectomy attests to ACTH independence. Treatment has included simultaneous bilateral laparoscopic adrenalectomy, although unilateral surgery (to avoid lifelong hormone replacement) and ketoconazole have also been used.

Unilateral nodular hyperplasia

This is an extremely rare condition first described in 1980. Patients present with severe hypertension and classic biochemical features of Cushing’s syndrome with imaging suggesting a unilateral adenoma but with gross, histologic,

and electron microscopy findings of nodular hyperplasia in one gland and suppression (lack of response to ACTH) in the contralateral one.²⁴ Suppression of cortisol by high-dose dexamethasone may lead to the mistaken diagnosis of Cushing’s disease. The nodules contain a mix of clear and compact cells that exhibit immunoreactivity for several enzymes involved in synthesis of steroids, and large mitochondria by electron microscopy, indicating exaggerated steroidogenesis.

Incidentalomas and Cushing’s syndrome

Incidentalomas are found in approximately 4% to 5% of the nearly half a million imaging studies of the abdomen carried out yearly in the United States for reasons other than adrenal disease. When the term was coined, the prevailing view was that these adrenal nodules were non-functioning and benign. Increased use of computed tomography (CT) scanning and MRI and accumulation of larger series of patients made it apparent that this interpretation was erroneous.

Low prevalence of adrenal carcinomas (0.25/1000 in the population and 3.2% in large series of incidentalomas²⁵) does not justify systematic exclusion workup.²⁶ CT-diagnosed adrenal cysts, myelolipomas, homogeneous masses with low attenuation, and nodules without change of size in 6 months may be considered benign.²⁶ Tumors greater than 6 cm are usually taken to surgery, whereas those less than 4 cm are managed conservatively, although size criteria are not extremely accurate. Percutaneous needle biopsy has been used, but it is not devoid of risk.

All patients with incidentalomas must have measurement of plasma or urine catecholamine metabolites. Although pheochromocytomas are at most 3.4% of all incidentalomas,²⁵ they may be silent (no hypertension) but fatal during anesthesia or surgery, when unsuspected and unprepared with alpha-blockers.

Excluding these two potentially fatal conditions, 80% to 90% of incidentalomas are nonfunctional.²⁵ Patients with hypertension must have measurements of serum potassium and aldosterone:renin ratio to exclude rare cases (0.9%²⁵) of unsuspected primary hyperaldosteronism that may have presented via accidental discovery of an adrenal nodule.

The remaining 5% to 20% incidentalomas have autonomous or excessive cortisol secretion that may be completely silent. This has led to the recommendation that all patients must undergo a 1-mg dexamethasone suppression test²⁶ for diagnosis and also to prevent post-operative adrenal crises. Subclinical Cushing’s syndrome is not actually that “silent.” The prevalences of hypertension, diabetes, obesity, and abnormal lipids in all incidentalomas exceed those in the general population, whereas in those with confirmed hypercortisolism, hypertension and diabetes may be present in 90% and 40%, respectively, not different from their prevalence in overt Cushing’s syndrome.²⁷ Metabolic risk factors such as increased fasting glucose and insulin, total cholesterol, triglycerides, fibrinogen, insulin-resistance index, and waist to hip ratio, as well as organ damage such as atherosclerotic plaques and increased carotid intima-media thickness are also more frequent in cortisol-producing than in non-

functioning incidentalomas. The causal relationship between the cortisol-producing adrenal incidentalomas and these clinical manifestations has been repeatedly confirmed by improvement of hypertension and metabolic abnormalities after surgical resection.²⁸

Biochemical screening for hypercortisolism in adrenal incidentalomas is somewhat different from overall testing for Cushing's syndrome. The early suggestion that reduced DHEA levels was a specific finding has not been confirmed.²⁵ In addition to dexamethasone suppression, midnight serum cortisol values greater than 5.4 µg/dL, suppressed responses to CRH, and excess uptake of iodomethylnorcholesterol are useful to identify functioning nodules. In contrast, urine free cortisol is not reliable because it is not elevated until Cushing's syndrome is fully established.

Normal results of screening have been observed in patients who nonetheless had tumors with immunoreactive evidence for increased steroidogenesis,²⁹ which may explain why some nodules deemed nonfunctional and managed conservatively develop hypercortisolism on follow-up. Although this may happen up to 10 years after initial diagnosis, the general consensus is that after 4 years without evidence for steroid secretion, no further follow-up is warranted.²⁶

Management of malignant or functioning incidentalomas with clinical repercussion (pheochromocytomas or Cushing's syndrome) is surgical, preferably with laparoscopy. In contrast, it remains controversial whether surgery is required for functioning nodules with negligible clinical repercussion, or with minimal clinical manifestations and high risk (e.g., patients older than 75 years).

Ectopic Cushing's syndrome

Ectopic Cushing's syndrome is a nonpituitary, nonadrenal hypercortisolism caused by ACTH secreted from malignant or neuroendocrine cells. It is responsible for 6% to 15% of all causes of endogenous Cushing's syndrome. Table 69–2 shows the tumors that produce it, grouped by organ system and relative frequencies (compiled from several series in the literature). The cause of ectopic ACTH production may be the loss of normal downregulated transcription of the pro-opiomelanocortin gene by malignant cells.³⁰ However, there are other causes such as secretion of CRH by pheochromocytomas, ganglioneuroblastomas, prostate carcinoma, bronchial carcinoids, and medullary thyroid carcinomas; local release of IL-6 by pheochromocytomas with stimulation of neighboring adrenal cortex; concomitant ACTH and CRH secretion by prostate carcinomas; concomitant production of catecholamines and cortisol by rare mixed adrenal corticomedullary adenomas; and ectopic production of cortisol by rare forms of ovarian cancer. Co-secretion of ACTH with insulin, gastrin, and glucagon (pancreatic islet cell carcinomas), PTH (small cell lung cancer), catecholamines (neuroendocrine tumors), calcitonin (thyroid medullary carcinoma) and endothelin, neuropeptide Y and ghrelin (carcinoids³¹) has been described but is usually clinically silent, except for the symptoms of a pheochromocytoma. ACTH immunoreactivity can be demonstrated in neuroendocrine and malignant cells, whereas some tumors (e.g., carcinoids) express a multiplicity of heterotopic receptors, including those for ghrelin, growth hormone secretagogue, vasopressin V3, CRH, and somatostatin. They may be linked to ACTH secretion, as demonstrated

Table 69–2. Tumors That Produce Ectopic Cushing's Syndrome

by the stimulatory effect of hexarelin, a growth hormone secretagogue,³¹ and their presence can be exploited for localization purposes (e.g., somatostatin receptor scintigraphy).³²

The course of ectopic Cushing's syndrome differs from that of ACTH-dependent pituitary disease in several aspects. First, its development is rapid, over the course of a few months, consistent with the pace of progression of malignant disease. Second, Cushing's stigmata may be absent because some (e.g., redistribution of adipose tissue) require a long time to be established. Third, levels of ACTH are higher than those in Cushing's disease and produce significant cutaneous and mucosal pigmentation. A similar situation is present in rare cases of pituitary carcinomas, which although not actually ectopic, have marked hyperpigmentation due to very high ACTH levels.³³ Fourth, severe hypercortisolism leads to hypokalemia (up to 57%³⁴) with muscle weakness, probably explained by saturation of 11 β HSD2, which allows activation of mineralocorticoid receptors by cortisol.³⁴ Fifth, hypertension is common (78%) and severe, requiring three or more drugs in almost half of the subjects.³⁴ Finally, there may be local (primary organ or metastasis) or systemic (anorexia, weight loss) symptoms of malignancy, as well as neuropsychiatric manifestations and rare forms with cyclical course.³¹

Mistaken diagnoses of pituitary Cushing's have been made when the cause of ectopic Cushing's evolves slowly, ACTH is suppressed by high-dose dexamethasone, and the source is not readily apparent (e.g., carcinoids). Also, when the initial finding is adrenal hyperplasia (secondary to ACTH stimulation), the diagnosis of ectopic Cushing's may not be suspected until after demonstration of ACTH dependency of the hypercortisolism.

Although treatment of ectopic Cushing's syndrome is that of the primary tumor, drugs that inhibit synthesis or actions of glucocorticoids may be required either temporarily for symptomatic management or permanently when the causative cancer is incurable.

DIAGNOSTIC TESTING

Laboratory tests

Screening

Screening for Cushing's syndrome is conducted with tests that assess hypersecretion of cortisol, autonomy of its secretion, and loss of its diurnal variation. No test is perfect, the choice depends on the clinical situation, and interpretation of results may be complex. It has been stated that, "Clinicians who have never missed the diagnosis of Cushing's syndrome or have never been fooled by attempting to establish its cause should refer their patients with suspected hypercortisolism to someone who has."³⁵

Secretion of cortisol in bursts leads to overlapping morning serum levels in normal individuals and patients with Cushing's syndrome, precluding their use for screening. Assessment of diurnal variation of cortisol is cumbersome and expensive, requiring hospitalization. Moreover,

diurnal variation is found in 30% of Cushing's patients and is absent in 20% of normal subjects. Midnight serum cortisol is a better discriminator (only 3% to 4% of Cushing's patients have normal levels), as is midnight salivary cortisol, which is highly correlated with serum cortisol and avoids hospitalization.

Overnight 1-mg dexamethasone suppression (serum cortisol 8 to 9 hours later less than 5 μ g/dL in normal subjects and more than 10 μ g/dL in Cushing's syndrome) is the most commonly used screening test. In populations with low prior probability (e.g., obese hypertensive subjects or all incidentalomas), the test is useful to exclude Cushing's syndrome. In contrast, when prior probability is high (i.e., overt clinical features), normal cortisol suppression does not exclude it because it can occur in a few subjects with mild hypercortisolism,³⁵ or with low clearance (i.e., high plasma levels) of dexamethasone, which misleadingly suppresses cortisol. Furthermore, "falsely positive" lack of cortisol suppression is observed in clinical situations designated as "Pseudocushing's." They include 30% to 40% of obese subjects (increased metabolic clearance rate for cortisol and urine free cortisol), 50% of patients with major depression (cortisol hypersecretion), and many chronic alcohol abusers (hypercortisolism attributed to the stress of repeated alcohol intoxication). Drugs that accelerate liver metabolism of dexamethasone, and the mere stress of hospitalization also produce falsely positive results.

Urine free cortisol excretion above the maximum normal (~100 μ g/day) may be enough to support the diagnosis in patients with clinically obvious Cushing's syndrome. A level greater than 300 μ g/day is required when clinical findings are equivocal, and repeated collections may be needed. Sensitivity of urine free cortisol as a screening test is very high, but there are documented false negatives owing to renal insufficiency or mild hypercortisolism.³⁵

Cushing's syndrome versus Pseudocushing's

Confirmation by a 2-day, low-dose (0.5 mg \times 4 doses per day) dexamethasone suppression test used to be the norm after a positive screening, but is now reserved for patients without definitive clinical features in whom free urine cortisol is between 100 and 300 μ g/day. The normal response is a serum cortisol less than 5 μ g/dL and urine free cortisol lower than 20 μ g/day. Because patients with Pseudocushing's may have false-positive results, a combination of the low-dose dexamethasone suppression test, followed by CRH stimulation is currently considered the best discriminator. Lesser suppression of cortisol by dexamethasone in Cushing's syndrome leads to exaggerated response to ensuing CRH, whereas the latter is blunted in Pseudocushing's patients.³⁵

ACTH-dependent versus ACTH-independent hypercortisolism

Once hypercortisolism is confirmed, determining whether it is ACTH-dependent or -independent has been simplified by the development of highly sensitive and specific immunoradiometric ACTH assays. Values less than 5 pg/mL indicate adrenal origin of Cushing's syndrome, a range

from high normal to 200 pg/mL is characteristic of pituitary Cushing's, while those more than 200 pg/mL are usually (but not always) observed in patients with ectopic ACTH-producing tumors. Few (~5%) cases of pituitary Cushing's may have levels less than 10 pg/mL on presentation, but they will exceed this value after a bolus injection of CRH, whereas this response will be absent in adrenal Cushing's. Lack of suppression of cortisol by either 8 mg overnight or 2-day high-dose dexamethasone was also used to establish diagnosis of adrenal Cushing's, but it has been rarely needed for this purpose since the advent of accurate ACTH assays.

Once adrenal hypercortisolism is confirmed, the next diagnostic steps are straightforward and include adrenal imaging to define the cause, and a search for unusual steroids if malignancy is suspected.

Pituitary versus ectopic Cushing's syndrome

In contrast, ACTH-dependent Cushing's syndrome requires further work up because 20% to 25% of patients with ectopic Cushing's will have ACTH levels in the 100 to 200 pg/mL range, that is, overlapping those of subjects with pituitary disease. Differential diagnosis cannot rely on imaging techniques because 30% to 50% of pituitary adenomas and one-third of bronchial carcinoids are below the detection size for pituitary MRI or chest CT. Furthermore, detecting an incidental pituitary tumor may be misleading in a patient who has ectopic Cushing's syndrome. High-dose dexamethasone (50% suppression of cortisol in pituitary Cushing's), although used, is not completely reliable because 10% to 30% of ectopic Cushing's patients may show a positive response, particularly those with bronchial carcinoids. Alternative tests include assessment of the ACTH responses to CRH and

metyrapone (11- β -hydroxylase inhibitor), which will be larger in pituitary than in ectopic Cushing's syndrome.

Inferior petrosal sinus sampling, a somewhat invasive test, is required in patients without an apparent tumor and equivocal ACTH levels. A petrosal sinus versus peripheral vein ACTH gradient of 2:1 or higher baseline, or 3:1 or higher after CRH stimulation establishes the diagnosis of pituitary Cushing's. An additional benefit of this test is that it provides the surgeon with information about the location of the pituitary adenoma, on the basis of lateralization of petrosal sinus ACTH values.

Radiology

Pituitary imaging

Detection of pituitary microadenomas (<1 cm) by MRI has improved with use of gadolinium contrast and rapid sequential imaging. The latter identifies 70% of microadenomas with a resolution of 5 mm. A positive MRI (such as those shown in Figure 69–5) allows for adenectomy in more than 80% of cases, whereas in the absence of an MRI finding, the surgeon identifies an adenoma in only half.³⁶ Doppler techniques and ACTH sampling from peripituitary veins have been employed intraoperatively to locate an adenoma, with variable results. Techniques that are still experimental include neurotransmitter-receptor ligand imaging by SPECT, using 123-I-IBZM for dopamine D2, or 111-In-DTPA-octreotide for somatostatin receptors.³⁷ In a few cases, the pituitary adenoma had uptake of 18-F-fluorodeoxyglucose by PET scanning.³⁸

Adrenal imaging

Arteriography and adrenal venous sampling for Cushing's syndrome are of historical interest. Contrast dye and purposeful injection of toxic substances led to remission

A

B

Figure 69–5. MRI films showing pituitary micro- and macro-adenomas (A and B, respectively), causing Cushing's disease. Tumors (arrows) appear hypodense, and the magnitude of displacement of the pituitary stalk is proportional to their size. While microadenomas are usually cured by surgery, macroadenomas that extend outside the sella turcica usually recur. (From Larsen PR, ed. *Williams Textbook of Endocrinology*, 10th ed. Philadelphia: Saunders, 2003.)

of disease in a few cases (sometimes with adrenal insufficiency), by necrosis of the adenoma. As opposed to its usefulness in primary hyperaldosteronism, adrenal venous sampling in Cushing's syndrome yielded overlapping results between different adrenal causes.

CT scan and MRI of the adrenal are now part of the routine evaluation and detect adrenal tumors with a resolution of 1 cm (see left panel of Figure 69–6). Presence of fat within a nodule suggests adenoma while necrosis, hemorrhage, and calcification are clues suggesting carcinoma. Although CT/MRI are not as accurate for imaging of adrenal hyperplasia, they may suggest primary pigmented nodular hyperplasia when normal-sized adrenals contain very small nodules with normal inter-nodal tissue, and ACTH-independent macronodular hyperplasia when there is extreme enlargement of the glands and nodules greater than 2 to 3 cm (Figure 69–6, right panel). MRI performs slightly better than CT for differentiation between adenomas and malignancies, owing to better tissue characterization and multiplanar visualization of blood vessels.³⁹ Ultrasonography has also been used successfully to locate and identify adrenal masses, but is very operator dependent.

The uptake of 6- β -(131-I)-iodomethyl-19-norcholesterol by cortisol-hypersecreting adrenal tissue correlates with the magnitude of the hyperfunction. Adrenal scintigraphies with this isotope and with selenium-75-6-seleno-methyl-cholesterol are better than CT/MRI for detection of bilateral adrenocortical hyperplasia,⁴⁰ for differentiating it from unilateral adenomas or carcinomas, and for recognition of functioning lesions located far from the adrenal glands.

Recent reports have described utility of 18-F-fluorodeoxyglucose PET scanning for differentiation between malignant and nonmalignant adrenal masses.⁴¹

Others have described uptake in adrenal hyperplasia. Positron emission tomography (PET) scanning with the 11- β -hydroxylase tracer (11)-C-metomidate distinguishes cortical from noncortical adrenal masses and Conn's syndrome from Cushing's adenomas. The latter distinction is due to preserved expression of 11- β -hydroxylase in the gland contralateral to the Conn's adenoma, versus its suppression in Cushing's syndrome. Further studies are needed to assess the clinical utility of this imaging modality.

Imaging of ectopic, ACTH-secreting tumors

The choice of radiologic technique to detect ACTH-secreting malignancies or neuroendocrine tumors depends on the organ of origin. In the absence of clues, the search should begin at the chest (x-rays and CT scan) because ~50% of these tumors are intrathoracic. Pancreatic tumors and pheochromocytoma may have to be investigated with abdominal CT, MRI, or scintigraphy. Thyroid nuclear scanning may also be required.

When ectopic Cushing's syndrome has been diagnosed by extremely high ACTH levels or by inferior petrosal sinus sampling but the tumor is not found, multiple selective venous catheterization and sampling throughout the body may be required to locate the source of ACTH secretion, particularly in slowly growing carcinoids that may not become radiologically detectable for years.

Alternative methods to identify carcinoid tumors include the use of radiolabeled octreotide-like compounds, which may be taken up when the tumor expresses somatostatin receptors, and more recently whole-body PET scanning with (11)-C-5-hydroxytryptophan, an isotope that is taken up by neuroendocrine cells, and may become the technique of choice for imaging of these tumors.⁴²

A

B

Figure 69–6. Classic examples of cortisol-secreting adrenal disorders. The *left* CT scan depicts a lipid-rich adenoma with obvious low attenuation. The *right* panel shows a large nodule (bars for size assessment) in a patient with enlarged adrenal glands due to nodular hyperplasia. (A, from Dunnick NR, Korobkin M. *Am J Roentgenol* 2002;179:559–68; B, From *Endocrinology Online*, 5th ed. Philadelphia: Elsevier, 2006.)

If a radiologic technique identifies a tumor, but its causative role is equivocal, percutaneous needle biopsy and detection of pro-opiomelanocortin secretory granules or mRNA in the tissue will provide the confirmation required to carry out a surgical excision.

PATHOPHYSIOLOGY OF HUMAN GLUCOCORTICOID HYPERTENSION

The basic biochemistry and physiology of steroidogenesis are extensively reviewed in Chapter 68. In this section, we will review the pathophysiologic mechanisms that are pertinent for the understanding of human glucocorticoid-induced hypertension.

The mechanisms of blood pressure elevation by glucocorticoids are not well known, but our understanding has been enhanced by the realization that in addition to glucocorticoid secretion rates and plasma levels, tissue levels and access to tissue receptors are major determinants of glucocorticoid action. In this regard, a major regulator is the 11- β -hydroxysteroid dehydrogenase (11bHSD) “shuttle,” composed of two enzymes that are distant congeners with conserved domains but different tissue distributions and actions. The type 2 isoform (11bHSD2), a dehydrogenase that converts cortisol into cortisone, is expressed in tissues in which the actions of aldosterone are physiologically important (e.g., kidney, gut epithelium, and regions of the central nervous system) and in vascular smooth muscle. Its main function is to “protect” against activation of the mineralocorticoid receptor by cortisol, which circulates in much higher concentrations compared to aldosterone, but binds with equal affinity to its receptor. Intracellular topology of 11bHSD2 (endoplasmic reticulum, facing the cytoplasm)⁴³ is consistent with its function as a regulator of mineralocorticoid receptor binding, a unique example of receptor specificity not due to protein structure, but to the actions of a neighboring enzyme. Failure of this “protection” (e.g., loss of function mutations of 11bHSD2 in the familial syndrome of apparent mineralocorticoid excess or inhibition of its action by licorice or carbenoxolone) leads to a clinical picture indistinguishable from that of primary hyperaldosteronism, in which the “mineralocorticoid” is cortisol.

The type 1 isoform (11bHSD1) is ubiquitous and can function bidirectionally, converting cortisol to cortisone as a dehydrogenase or cortisone to cortisol as a reductase. The latter function is more common, and is important for local tissue generation of cortisol in organs that regulate lipid and carbohydrate metabolism, such as liver hepatocytes and visceral fat adipocytes. Intracellular topology of 11bHSD1 (endoplasmic reticulum, facing the lumen)⁴³ is consistent with its function as a pre-receptor amplifier of glucocorticoid signals.

Glucocorticoids and long-term regulation of blood pressure (“programming”)

Animal studies have demonstrated that materno-fetal malnutrition with low birth weight leads to exaggerated rates of hypertension in the adult offspring, an effect that

is mimicked by administration of glucocorticoids during very defined, species-specific time windows in pregnancy.

Both malnutrition during pregnancy and glucocorticoid excess decrease the ability of placental 11bHSD2 to protect the placental glucocorticoid receptor and the fetus from abnormal exposure to maternal glucocorticoids. Malnutrition inhibits expression of placental 11bHSD2, whereas glucocorticoid excess saturates its catalytic activity. Inhibition of 11bHSD2 with carbenoxolone also enhances hypertension in the offspring, and its effects can be prevented by adrenalectomy, confirming the roles of the enzyme and glucocorticoids, respectively. Furthermore, offspring hypertension cannot be produced with other interventions that reduce birth weight, such as placental embolization. Finally, in rats and humans, normal levels of placental 11bHSD2 are highly variable and correlate with weight of neonates.

The mechanisms by which fetal glucocorticoid excess leads to adult hypertension are controversial. It has been suggested that even without fetal growth retardation, there is altered nephrogenesis with lower nephron numbers, tubular disruption and glomerulointerstitial fibrosis in the adult offspring, and that glomerulosclerosis is more important than reduction of nephron number. In contrast, data by others suggest that glucocorticoid-induced low birth weight is more important than effects on 11bHSD for development of hypertension, and that the latter is not clearly related to fetal renal abnormalities. Alternative explanations include altered expression of angiotensinogen and angiotensin receptors in the kidney and central nervous system of the offspring (although the circulating renin-angiotensin system is unaffected), vascular hypersensitivity to vasoconstrictors, increased expression of vascular smooth muscle contractile proteins, and controversial results on decreased expression of nitric oxide synthase.

Programming of metabolic abnormalities such as insulin resistance, and reduced insulin content of pancreatic beta cells by glucocorticoids may contribute to diabetes and the hypertension of the metabolic syndrome. These effects are gender specific and can be blocked by concomitant stimulation of 11bHSD by leptin, indicating regulation of the effects of fetal exposure to glucocorticoids by this peptide.⁴⁴

In humans, glucocorticoid programming may act via a permanently imprinted change in the adult pattern of expression of the glucocorticoid receptor via actions on its promoter,⁴⁵ although this effect is not present in other species. Regardless of its mechanism, low birth weight in humans is associated with higher blood pressure, glucose intolerance and higher rates of diabetes in childhood and adulthood, and also with higher plasma cortisol levels throughout adult life. Even when given prenatally, that is, late in pregnancy, glucocorticoids lead to higher systolic and diastolic blood pressures as early as age 14.⁴⁶

Glucocorticoids, essential hypertension, and the metabolic syndrome

Studies in rodent models for essential hypertension or the metabolic syndrome suggest that there may be a role for

glucocorticoids in these conditions in humans. The hypertension of SHR, a rat strain with increased expression of vascular endothelial glucocorticoid receptors,⁴⁷ is prevented by adrenalectomy and restored by glucocorticoids, not mineralocorticoids. In obese SHR, adrenalectomy prevents the hypertension and also the development of metabolic abnormalities and renal damage. Corticosterone increases blood pressure in lean Zucker rats, whereas mifepristone (glucocorticoid receptor antagonist) reduces it in obese rats of the strain, by effects unrelated to hyperinsulinemia or renin.

11bHSD2 mRNA and activity are reduced in DahlSS rats, a model for salt-sensitive essential hypertension, in which there is urinary excretion of inhibitors of 11bHSD2. This suggests that salt sensitivity of blood pressure may be mediated by glucocorticoid activation of mineralocorticoid receptors. Adipose tissue overexpression of 11bHSD1 in transgenic mice leads to abnormalities indistinguishable from those of the human metabolic syndrome, including insulin resistance, dyslipidemia, and salt-sensitive hypertension,⁴⁸ the latter associated with activation of the renin-angiotensin system and abnormalities of the renal distal tubular epithelium. Therefore, glucocorticoid effects on both isoforms of the 11bHSD shuttle may participate in salt-sensitive hypertension.

In humans with the metabolic syndrome, 11bHSD1 is overexpressed in adipocytes.⁴⁹ Transcriptional inhibition of this enzyme by PPAR- α agonists in the liver⁵⁰ and PPAR- γ agonists⁵¹ in adipose tissue may explain the improvement of metabolic abnormalities and modest antihypertensive effect of these agents. Consistent with this, metabolic abnormalities and early severe hypertension are present in rare patients with loss-of-function mutations of PPAR- γ .⁵² Also, a myocardial deficit of 11bHSD2, where this isoform is coexpressed with the mineralocorticoid receptor, may contribute to LV hypertrophy in essential hypertension, as suggested by the positive relationship between cortisol:cortisone ratios and LV mass in these patients.⁵³

Hypercortisolism (urine free cortisol:creatinine ratios greater than two standard deviations above those of normal subjects) may also play a role in 20% of essential hypertensive patients, who are usually salt sensitive with low PRA and serum aldosterone. This is supported by negative correlations between urine cortisol and both PRA and aldosterone in unselected hypertensive patients, suggesting that subtle hypercortisolism may play a role in the pathogenesis of low-renin essential hypertension.⁵⁴ Finally, increased affinity of glucocorticoid receptors for cortisol has been demonstrated with a dermal vasoconstriction assay in patients with essential hypertension and the metabolic syndrome.

Mineralocorticoid mechanisms in hypertension of glucocorticoid-excess states

Mineralocorticoid and glucocorticoid mechanisms are very different but the former may participate in diseases primarily characterized by glucocorticoid excess. Severe hypokalemia, metabolic alkalosis, or therapeutic responses

to spironolactone, which are not common in pure glucocorticoid hypertension, may become prominent clinical features if there is excess mineralocorticoid activity. The steroid responsible for the latter may actually be cortisol itself, when the catalytic capacity of 11bHSD2 (close to saturation at the physiologic range) is surpassed by very high cortisol levels, or when the activity of the enzyme is impaired.

Familial glucocorticoid resistance due to mutations in the ligand-binding domain of the glucocorticoid receptor,⁵⁵ is an example of the former situation. It leads to feedback stimulation of the hypothalamo-pituitary-adrenal axis and exaggerated secretion of cortisol. However, manifestations of glucocorticoid excess are absent because of the receptor abnormality. Symptoms relate to hypermineralocorticoidism produced by saturation of 11bHSD2 by high levels of cortisol and hyperandrogenism owing to ACTH stimulation of the adrenal gland.

Examples of impaired activity of 11bHSD2 include the syndrome of apparent mineralocorticoid excess (loss-of-function mutations of 11bHSD2), and inhibition of this enzyme by use of licorice or by therapy with carbenoxolone. These entities are best regarded as differential diagnoses of primary hyperaldosteronism, since the abnormality is entirely linked to aberrant activation of the mineralocorticoid receptor. In ectopic Cushing's syndrome, high levels of ACTH and cortisol are responsible for both the glucocorticoid and mineralocorticoid clinical features, via saturation of 11bHSD2, which is worsened by diminished A-ring reduction and turnover of cortisol. A negative correlation between cortisol:cortisone ratios and serum potassium proves that this mechanism is responsible for the hypokalemia of ectopic Cushing's syndrome.

It has been argued that the same mechanism plays a role, albeit of much lesser magnitude, in all forms of endogenous Cushing's disease because ACTH-stimulated cortisol:cortisone ratios in these patients are higher than in normal subjects. Whatever the mechanism for this subtle deficiency of 11bHSD2 activity, it is independent of ACTH, because it is observed in both Cushing's disease and adrenal Cushing's syndrome.

Mineralocorticoids such as aldosterone and 18-oxo steroids are usually not hypersecreted in pituitary Cushing's disease. However, there have been isolated reports of hypersecretion of desoxycorticosterone and of 18-oxo-cortisol with increased 18-oxo:cortisol and 18-oxo:aldosterone ratios, compared to normal subjects. The reason for the former is not clear. The latter may reflect increased cortisol supply to adrenal 18-hydroxylase.

In adrenal Cushing's syndrome, a whole host of different mineralocorticoids can be secreted, including 16- β -hydroxydehydroepiandrosterone, 19-nor-desoxycorticosterone, deoxycorticosterone, aldosterone, and combinations. In all cases but that of aldosterone, the secretion of this steroid is suppressed. Plasma renin activity is sometimes not inhibited, probably due to concomitant stimulation of liver angiotensinogen by cortisol.

Effects of glucocorticoids on ion pumps and transporters

Glucocorticoids affect the function of many cation transporters. Effects on vascular smooth muscle transport may modify vascular reactivity to vasoconstrictors. Those on renal transport of sodium may determine changes in systemic hemodynamics via changes in salt balance. We will review the relevance of these actions for changes in salt balance and hemodynamics in human glucocorticoid hypertension. A scheme of the major actions of glucocorticoids on transporters throughout the nephron is provided in Figure 69–7.

Renal tubular Na^+/H^+ exchanger

Glucocorticoids increase the rate of Na^+ -dependent H^+ efflux in acid-loaded proximal tubular cells and that of Na^+ entry in normal-pH, sodium-depleted isolated renal cells. Concomitant stimulation of the basolateral $\text{Na}^+/\text{CO}_3\text{H}^-$ transporter (NCB-1) contributes to the overall increase in proximal tubular bicarbonate reabsorption by glucocorticoids. Kinetic studies indicate that the effect on Na^+/H^+ exchange is mediated by increased number of exchangers (V_{max}) without change in affinity (K_m). Of the four known isoforms (NHE-1 to -4), glucocorticoids

stimulate the apical, amiloride-resistant NHE-3 (as opposed to aldosterone effects on NHE-2). Stimulation of basolateral amiloride-sensitive NHE-1 is controversial. Acute transport effects occur before increases in NHE-3 mRNA, indicating enhanced trafficking to the apical membrane,⁵⁶ or enhanced translational efficiency of NHE-3 mRNA. Increased trafficking is mediated by glucocorticoid-stimulated transcription of serum and glucocorticoid induced kinase-1 (SGK1), which after interaction with the regulatory protein NHERF2 phosphorylates a conserved Ser663 of NHE-3.^{57,58} Mutations of this site and use of a “dead” kinase abolish NHE-3 trafficking. Chronic stimulation of NHE-3 by glucocorticoids is due to enhanced transcription, mediated by an interaction between bound glucocorticoid receptors and cis-acting elements of the NHE-3 gene. Neither turnover rate of NHE-3 mRNA nor endocytic retrieval of the transporter from the membrane⁵⁶ is affected by glucocorticoids.

In whole animals, natriuresis may occur despite fourfold stimulation of cortical NHE-3 mRNA by glucocorticoids, as if systemic factors (e.g., renal hemodynamics) may be more important in determining overall sodium excretion. Also, ACTH inhibits NHE-3 expression, suggesting that Na^+/H^+ exchange of Cushing’s disease may be the net

Figure 69–7. Schematic representation of the effects of glucocorticoids on sodium transporters throughout the nephron. The transporters are color coded and their location in the basolateral or apical membrane is depicted. The major actions of glucocorticoids are described on the right. A detailed description of these effects appears in the text. CCD and MCD, cortical and medullary collecting ducts; DCT, distal convoluted tubule; ENaC, epithelial sodium channel; GR, glucocorticoid receptor; MR, mineralocorticoid receptor; mTAL, medullary thick ascending limb of Henle; Na⁺/K⁺/2Cl⁻, the mTAL cotransporter; NCB1, sodium bicarbonate transporter; Nedd4-2, a protein involved in ubiquitination steps for removal of ENaC from the membrane; NHE-1 and -3 designate isoforms of the proximal Na⁺/H⁺ exchanger; PCT and PCT(S1), proximal convoluted tubule and its S1 segment; ROMK-1, mTAL cellular potassium channel that recycles K⁺ to the lumen.

result of opposing effects of cortisol and ACTH. In normotensive humans, dexamethasone inhibits Na^+/H^+ exchange activity in lymphocytes, via activation of glucocorticoid receptors, whereas in patients with Cushing's disease and adrenal Cushing's syndrome, Na^+/H^+ activity is spontaneously increased in mononuclear leukocytes. Therefore, the role of Na^+/H^+ exchange in human glucocorticoid hypertension remains to be settled.

Renal tubular Na-K-ATPase

Glucocorticoids and mineralocorticoids stimulate the function of renal Na-K-ATPase—the major basolateral sodium transporter across all segments of the nephron—in isolated tubules and cultured tubular cells, that is, independent of hemodynamic effects or renal sodium load.

Transcriptional mechanisms had been suspected because specific receptor antagonists prevent hydrocortisone activation of Na-K-ATPase. They were confirmed by demonstration of an interaction between bound nuclear glucocorticoid receptors and specific oligonucleotide sequences in the genes for the two human subunit isoforms (alpha-1 and beta-1) that constitute the renal heterodimeric Na^+ pump. A combined mineralocorticoid and glucocorticoid receptor responsive element in these sequences has been confirmed by their ability to confer mineralocorticoid and glucocorticoid activation to heterologous promoters.

Nontranscriptional mechanisms had also been suspected because glucocorticoid-stimulated Na-K-ATPase activity does not correlate with abundance of mRNA subunits and is inhibited by blockers of protein synthesis. It is now known that glucocorticoids increase translation efficiency of rat mRNA for alpha (not beta) subunit isoforms, without intervention of the glucocorticoid receptor. In contrast, there is no effect of glucocorticoids on mRNA stability. Finally, concomitant with increased biosynthesis, glucocorticoids augment insertion of functional pumps in the basolateral membrane, independent of the presence of active Na^+ transport. Experiments in xenopus oocytes suggest that SGKs may be involved in this step, as they are in the trafficking of NHE-3.⁵⁹

Nephron-segment specificity for the stimulatory actions of mineralocorticoids and glucocorticoids on Na-K-ATPase has been shown in experiments with separate steroid replacement of adrenalectomized animals. Glucocorticoids stimulate activity of this enzyme in the S1 convoluted segment of the proximal tubule but not in the straight, S2, and S3 segments. Stimulatory effects of dexamethasone at the medullary thick ascending limb and the distal convoluted tubule are not blocked by spironolactone, whereas those on cortical and medullary collecting ducts are, as if in the latter segments dexamethasone activates the mineralocorticoid receptor.

In humans, erythrocyte ^{86}Rb uptake, a measure of Na-K-ATPase activity, is increased by ACTH and synthetic glucocorticoids. The latter also increase synthesis of alpha subunit mRNA (alpha-2) and total pump pool size in skeletal muscle.⁶⁰ In patients with Cushing's syndrome, Na-K-ATPase activity of erythrocyte ghosts is spontaneously increased, and greater than those in essential hypertension, renal disease, and primary hyperaldosteronism.

In contrast to its inhibitory effect on NHE-3, ACTH increases ouabain-sensitive Na^+ transport, similar to glucocorticoids.⁶¹ Despite this, and despite the potent stimulatory effect of synthetic or endogenous glucocorticoids on renal Na-K-ATPase, the baseline net proximal tubular reabsorption of Na^+ is not much increased by glucocorticoid excess. The effect of glucocorticoids may be much more important in potentiating the action of other substances that increase proximal tubular Na^+ reabsorption, such as angiotensin II,⁶² thus exerting an indirect effect on blood pressure regulation by this mechanism.

Loop of Henle, distal nephron, and the epithelial sodium channel

There are very few studies about effects of glucocorticoids on the Na-K-2Cl cotransporter of the medullary thick ascending limb of the loop of Henle. Dexamethasone increases its mRNA and protein contents in the rat, in a glucocorticoid receptor-dependent manner and concomitant with increased cotransport activity. This action may be more important for acid-base balance (NH_4^+ cotransport) than for net sodium reabsorption. Glucocorticoids also simulate activity of ROMK1, the K^+ channel that recycles luminal K^+ to the cells of the thick ascending limb, via the same interaction between SGK1 and NHERF2 that participates in stimulation of NHE-3.⁵⁷ Recycling of K^+ by ROMK1 is indispensable for the functioning of Na-K-2Cl. Therefore, stimulation of the latter by glucocorticoids may be due to the ROMK1 effect. Direct stimulation of Na-K-2Cl transport by dexamethasone has been shown in trabecular meshwork cells of the eye, an effect that may be linked to ophthalmologic complications of glucocorticoid therapy, such as glaucoma.

An additional effect of glucocorticoids in the distal nephron is to increase binding of (3H)-metolazone, that is, to increase the density of thiazide channels. This may contribute to enhanced sodium reabsorption in the distal convoluted tubule.

The most important distal Na^+ transporter is the epithelial sodium channel (ENaC), an amiloride-sensitive, heterotrimeric (alpha, beta, and gamma subunits) protein that is the major effector of aldosterone action in the kidney but is also expressed in many other epithelia. Activated glucocorticoid receptors augment transcription of the human alpha subunit chain by interacting with a glucocorticoid-responsive element in the 5'-flanking region of the gene.⁶³ In addition, transcriptional stimulation of SGK1 by glucocorticoids interferes with a ubiquitin ligase (Nedd4-2) that removes channels from the mouse collecting duct membranes for proteasome processing.⁶⁴ Hence, glucocorticoids also increase channel activity by increasing their number in the membrane.

In intestinal and airway/alveolar epithelia,⁶⁵ glucocorticoid-induced ENaC transport is associated with transcription of its inducible beta and gamma subunits, while the alpha chain is constitutively activated and less subject to regulation. ENaC is also regulated by glucocorticoids in ocular ciliary and semicircular canal duct epithelia, which may be important to explain some of their therapeutic actions.

In the kidney, glucocorticoid stimulation of ENaC is associated with increased transcription of the alpha subunit^{63,66} and post-translational mechanisms related to transcriptional stimulation of SGK1.⁶⁷ Most studies of transport activity have been conducted in tissues or cells representing the distal nephron, but there is also evidence for glucocorticoid-stimulation of a proximal tubular ENaC. As opposed to the studies on airway epithelium, conducted with human cells, there is no clear evidence that effects of glucocorticoids on renal ENaC play a role in the hypertension of Cushing's syndrome.

Glucocorticoids and transport abnormalities in vascular smooth muscle

Dexamethasone increases Ca^{2+} influx in isolated vascular smooth muscle cells and in aortic rings of rabbits made hypertensive by its *in vivo* administration. *In vitro* effects occur in minutes, are blocked by glucocorticoid but not mineralocorticoid receptor antagonists, and also by nifedipine. Binding experiments indicate that increased Ca^{2+} influx is mediated by the increased number of high-affinity, dihydropyridine-sensitive, membrane calcium channels. In contrast, Ca^{2+} efflux is halved by dexamethasone and aldosterone in aortic myocytes, the action of the former being 100-fold more potent. The effect is due to transcriptional inhibition of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger, with 90% reduction of its mRNA.

Dexamethasone doubles $^{22}\text{Na}^+$ incorporation into vascular smooth muscle cells, an action that is blocked by the competitive glucocorticoid receptor antagonist RU 486 and requires protein synthesis, suggesting a genomic mechanism. Transport may be via the Na^+/H^+ exchanger because hydrocortisone doubles the rate of recovery of smooth muscle intracellular pH following acidification, with increased V_{max} (but no change in K_{m}) for this exchanger. Smooth muscle synthesis of mRNA and protein is involved, as proved by blockade of the effect with actinomycin D and cycloheximide. Vascular smooth muscle Na-K-ATPase activity is also increased by glucocorticoids *in vitro*, that is, independent of blood pressure. The effect may be mediated by glucocorticoid-stimulated synthesis of mRNA and protein for alpha- and beta-subunit isoforms, as shown in skeletal muscle, where glucocorticoids increase tritiated ouabain binding.

In summary, exaggerated intracellular Ca^{2+} stores, via both increased Ca^{2+} influx and decreased Ca^{2+} efflux, and alterations in vascular smooth muscle Na^+ transport, may account for vascular hyperresponsiveness to vasoconstrictor stimuli in Cushing's syndrome, an issue that will be discussed further below.

Effects of ACTH and glucocorticoids on salt and water metabolism, plasma volume, and systemic and regional hemodynamics

Despite almost uniform stimulation of sodium reabsorption by nephron transporters, the effects of ACTH and glucocorticoids on salt balance in the whole animal are not straightforward. The synthetic glucocorticoids increase natriuresis and contract plasma volume in animals and

humans, an effect that has been exploited for the therapy of refractory edematous states (Figure 69–8, left). Natriuresis can be blocked by glucocorticoid but not mineralocorticoid receptor antagonists, and is associated with activation of the renal dopamine system and renal vasodilation.⁶⁸ Increases in single nephron plasma flow and glomerular filtration rate in methylprednisolone-hypertensive rats are pronounced enough to accelerate the progression of proteinuria and glomerular sclerosis in models of partial renal ablation.⁶⁹

ACTH increases water and salt intake in most species, including humans.⁷⁰ The mechanism does not involve the brain renin-angiotensin system. A mix of glucocorticoids and mineralocorticoids is required to reproduce the effect of ACTH, which is usually associated with hypernatremia.^{70,71} Hence, ACTH-induced mineralocorticoid activity seems to play a role.

Effects of ACTH on renal sodium handling are species dependent. Increased salt intake may contribute to ACTH-induced natriuresis despite stimulation of nephron sodium transporters. However, this does not explain why ACTH natriuresis is only observed in rats, rabbits, and dogs.⁷¹ The reason is the different magnitude of pressure natriuresis among species (Figure 69–8, right). In ACTH-hypertensive dogs, servo-controlling renal arterial pressure to keep it in the normal range leads to reversal of sodium losses and unmasking of ACTH-induced salt and water retention.⁷² Pressure natriuresis is such an important determinant of the renal action of ACTH that this peptide does not produce hypertension in the dog, unless salt excretion is impaired by other means.⁷¹

In contrast, ACTH produces sodium retention in sheep and humans.⁷⁰ In sheep, the effect is transient, whereas in humans it is sustained and reproduced by cortisol (albeit of lesser magnitude). Therefore, normotensive and hypertensive subjects develop plasma and extracellular fluid volume expansion,⁷³ and have increased total exchangeable sodium when given ACTH. These changes trigger release of atrial natriuretic peptide and inhibition of plasma renin activity, even during salt depletion. Moreover, plasma volume expansion is exaggerated by glucocorticoid-induced fluid shifts from the intra- to the extra-cellular compartment,⁷⁴ owing to increased Na-K-ATPase activity. However, plasma volume is increased in some⁷⁵ but not all patients⁷⁶ with Cushing's syndrome, perhaps due to differences in the severity of blood pressure elevation and consequent pressure natriuresis.

The hemodynamic pattern of glucocorticoid hypertension is similar in all species, consisting of increased cardiac output and normal total peripheral resistance. High cardiac output is initially caused by faster heart rate, but later by increased stroke volume. It precedes elevation of blood pressure, indicating transient compensatory vasodilation. When total peripheral resistance returns to normal, hypertension develops. Loss of the initial compensatory vasodilation can be prevented by pretreating ACTH-hypertensive sheep with either nisoldipine or minoxidil, indicating that recovery of vascular tone is not calcium dependent. If cardiac output is reduced to normal by atenolol or dietary potassium supplementation, blood

Figure 69-8. The figure illustrates differences in renal sodium handling, renal hemodynamics, and plasma volume produced by synthetic versus endogenous glucocorticoids and ACTH. The actions of the latter on the kidney are species specific, depending on the gain of the pressure–natriuresis mechanism (PNa). Despite these differences, the systemic hemodynamic pattern of the hypertension is common to all situations (high CO, and normal TPR). Question marks represent an unknown vascular bed that must sustain vasodilation to offset renal vasoconstriction in rat and humans, for maintenance of normal TPR. For a detailed explanation of these mechanisms, see text. BP, blood pressure; CO, cardiac output; E, epinephrine; MVR, mesenteric vascular resistance; P, capillary pressure; PNMT, phenylethanolamine N-methyltransferase; PV, plasma volume; RVR, renal vascular resistance; SNGFR, single nephron glomerular filtration rate; SNPFR, single nephron plasma flow rate; TPR, total peripheral resistance; UNaV, natriuresis.

pressure remains elevated. This indicates a shift to the hemodynamic pattern of normal cardiac output with high total peripheral resistance, suggesting resetting of blood pressure control to higher values. These observations explain why the hemodynamics of human glucocorticoid hypertension may vary from a pattern of increased cardiac output with normal total peripheral resistance⁷³ to exactly the opposite,⁷⁷ or a combined increase in cardiac output and vasoconstriction.⁷⁵

Although total peripheral resistance is normal, regional hemodynamic changes vary among species (Figure 69-8, right). In sheep, ACTH and combinations of steroids are renal and skeletal muscle vasodilators. Total peripheral resistance is unaltered because mesenteric vasoconstriction offsets these changes, contributing to the establishment of high cardiac output hypertension. In contrast, ACTH and cortisol are renal vasoconstrictors in rats and humans. In rats, cortisol participates in the physiologic

renal vasoconstrictor response to salt-depletion. Their renal vasoconstrictor response to ACTH is prevented by L-arginine and reversed by ramipril, indicating participation of the nitric oxide and renin-angiotensin systems. Reduction of cardiac output by atenolol and decreased total peripheral resistance by minoxidil do not fully restore blood pressure to normal, whereas normalization of renal (but not total) peripheral resistance by ramipril corrects the hypertension. This observation supports a major role for renal vasoconstriction in glucocorticoid-induced hypertension in rats. Increased renal vascular resistance and reduced renal blood flow also occur in normal humans given ACTH or cortisol, even if the renal vasculature is precontracted by salt depletion. Changes are more prominent in postglomerular vessels, with elevated glomerular filtration rate and filtration fraction. The vascular bed that offsets renal vasoconstriction and maintains normal total peripheral resistance in humans or rats is not known.

It can be concluded that ACTH and all glucocorticoids have the potential for the production of progressive glomerular dysfunction, either via glomerular hyperfiltration when they are renal vasodilators, or via glomerular hypertension when they are predominantly vasoconstrictors of the postglomerular vasculature.

Effects of glucocorticoids on vasoactive systems

A major reason by which the mechanisms of glucocorticoid-induced blood pressure elevation is not fully understood, is that the actions of these agents on vasoactive systems differ if studied in cells, tissues, whole animals, or humans. We will review the findings that are relevant for understanding of human glucocorticoid hypertension. Because of their complexity, an extensive but focused summary is provided in Table 69–3.

Renin-angiotensin system

Glucocorticoids increase synthesis of angiotensinogen. The effect is transcriptional, with increased mRNA in liver and other tissues,⁷⁸ can be inhibited by actinomycin D, and is mimicked by estrogens, but not by mineralocorticoids. Conversely, adrenalectomy reduces angiotensinogen mRNA and this can be prevented with a glucocorticoid receptor agonist.

In methylprednisolone-hypertensive rats, increased angiotensinogen leads to higher plasma renin concentration and activity, which account for blood pressure response to the angiotensin receptor blocker saralasin.⁷⁹ Once salt depleted, activation of the renin-angiotensin system is no longer different from that of normal salt-depleted rats and the blood pressure response to captopril is diminished. Because there is no change in circulating or tissue angiotensin-converting enzyme,⁸⁰ the data suggests a defect in non-angiotensin-mediated effects of the converting enzyme inhibitor during salt depletion. Lesions of the AV3V region prevent or improve blood pressure elevation and abolish the responses to saralasin and captopril,⁸¹ indicating a role for the central nervous system in the control of the renin-dependent component of the hypertension of this model.

Other prohypertensive effects of the renin-angiotensin system include ACTH downregulation of the vasodilatory angiotensin AT₂ receptor in arteries of sheep, dexamethasone-induction of angiotensin-converting enzyme in vascular smooth muscle cells, and increased AT₁ receptor number in vessels of SHR given a glucocorticoid agonist, but their role in glucocorticoid hypertension is not known.

In humans, glucocorticoid-induced synthesis of angiotensinogen is associated with protein heterogeneity that may affect the kinetics of the renin-substrate reaction.⁸² Increased angiotensin II in Cushing's syndrome, which correlates with serum cortisol, may be the result of this effect, because plasma renin activity is usually normal (although its response to salt depletion may be exaggerated). In the few cases in which plasma renin is suppressed, there is usually concomitant excess mineralocorticoid activity. The antihypertensive effect of saralasin has been used as a test of renin-dependency of the hyper-

tension of Cushing's syndrome and was found to be significant in some but not all patients.

Arginine vasopressin

Dexamethasone doubles the density of arginine vasopressin (AVP) V_{1a} receptors in vascular smooth muscle cells by increasing stability of its mRNA.⁸³ However, a vasopressor role for AVP in states of glucocorticoid excess is unlikely because these steroids actually blunt osmotic and nonosmotic release of AVP, inhibiting its mRNA expression in the parvocellular paraventricular nucleus. Methylprednisolone-induced hypertension is of the same magnitude in Brattleboro as in Wistar rats. Also, a non-peptide V_{1a} receptor antagonist fails to reduce blood pressure in rats with ACTH hypertension.⁸⁴ Both observations confirm lack of a vasoconstrictor role for AVP in glucocorticoid hypertension.

Stimulation of ACTH release by vasopressin is exerted via V_{1b} (also called V₃) receptors in corticotrophs. These receptors are overexpressed in ACTH-secreting pituitary adenomas and bronchial carcinoids.⁸⁵ Although it is not clear how much AVP contributes to secretion of ACTH by these tumors, there is great interest in the recent development of oxindole compounds that are specific blockers for V_{1b} receptors.⁸⁶ Direct stimulation of cortisol by AVP occurs in cases of ACTH-independent macronodular adrenal hyperplasia with "illicit" expression of V_{1a} receptors. It is now known that these receptors are expressed in normal adrenal cortex and overexpressed in compact cells of adrenal adenomas and less commonly carcinomas.⁸⁵ Therefore, V_{1a} receptor antagonists could attenuate hypercortisolism in these patients, as they do in macronodular adrenal hyperplasia.⁸⁷

Endothelin system

Glucocorticoids increase the pre-pro-endothelin-1 gene transcription rate in rat vessels and vascular smooth muscle cells, acting on their receptors. Release of endothelin-1 from vascular smooth muscle, not endothelium, is enhanced. Moreover, in the kidney, they downregulate expression of the natriuretic ET_b receptor. Although these are prohypertensive actions, glucocorticoids also decrease ET_a receptor mRNA and binding sites in vascular smooth muscle cells of normal rats and SHR.

In humans, the evidence is predominantly against a role for endothelin-1 in glucocorticoid hypertension. Increased production of this peptide by human endothelial cells exposed to glycyrrhizic acid (an inhibitor of 11 β HSD2) is most likely a mineralocorticoid effect of the corticosterone employed in these experiments.⁸⁸ In contrast, dexamethasone decreases release of endothelin-1 by human monocytes, baseline and cytokine-stimulated pre-pro-endothelin-1 mRNA expression in a pulmonary epithelial cell line, and the number of ET_a receptors in endothelium derived from human brain microvessels.

Consistent with the information above, ET_a receptor blockers prevent hypertension in glycyrrhizic acid-induced,⁸⁸ but not ACTH hypertension in the rat. There are no data on these receptor blockers in glucocorticoid hypertension in humans.

Table 69-3. Summary of Actions of Glucocorticoids on Vasoactive Systems

Prostaglandins and the kallikrein-kinin system

Glucocorticoids tonically inhibit expression of COX-2 by destabilizing its mRNA,⁸⁹ but it is not clear whether decreased availability of vasodilatory natriuretic prostaglandins participates in glucocorticoid hypertension. Renal prostacyclin is markedly inhibited by dexamethasone in rats and dogs, but glucocorticoids do not affect baseline levels of prostacyclin in vascular smooth muscle. These agents blunt the effect of some, but not all stimuli for prostacyclin synthesis in vascular smooth muscle, suggesting that their action is mediated by phospholipase A2, not inhibition of COX.

Glucocorticoids inhibit synthesis of PGE2 in renomedullary interstitial, tubular, and mesangial cells, but are paradoxically unable to normalize increased renal PGE2 produced by adrenalectomy, and increase its content in normal renal papillae. Urine excretion of PGE2 is unaltered in methylprednisolone-induced hypertension in rats but decreased in dexamethasone-treated dogs. In the latter, infusion of prostacyclin reduces blood pressure, whereas indomethacin does not worsen the hypertension, suggesting that inhibition of endogenous prostaglandins plays a major role. In contrast, infusion of prostacyclin does not improve ACTH hypertension in sheep, despite the fact that these animals have increased vascular sensitivity to prostaglandins—a compensatory, albeit ineffectual, mechanism to the hypertension.

Analogous results have been described for the kallikrein-kinin system. Glucocorticoids inhibit the action of bradykinin on its B1 receptor in isolated blood vessels, and decrease kallikrein excretion in Dahl rats and dogs. In the latter, infusion of bradykinin reduces blood pressure, whereas a bradykinin receptor antagonist does not worsen the hypertension, suggesting that inhibition of renal kallikrein by glucocorticoids plays a role in blood pressure elevation. However, the antihypertensive effect of trandolapril in human Cushing's disease is associated with paradoxical further reduction of urine kallikrein excretion.⁹⁰

Therefore, it is not clearly established that a deficiency in the action of these two vasodilatory natriuretic systems plays a major role in glucocorticoid hypertension.

Natriuretic peptides and ouabain

Replacement of glucocorticoids in adrenalectomized animals stimulates atrial synthesis, increases plasma levels, and restores impaired function (increased diuresis, natriuresis, and urinary cyclic GMP) of atrial natriuretic peptide (ANP) in response to water or salt loading. Glucocorticoid activation of ANP could be considered the positive limb of a feedback loop, because ANP inhibits adrenal production of glucocorticoids, not only aldosterone. In Addison's disease dexamethasone also restores impaired diuretic and natriuretic responses to infusion of human ANP.

However, in the absence of adrenal insufficiency, dexamethasone inhibits CGRP⁹¹ (a physiologic stimulus for ANP release), blunts the stimulation of cyclic GMP by ANP in vascular smooth muscle of normal rats by acting on glucocorticoid receptors, and upregulates neutral

endopeptidases that degrade ANP in vascular smooth muscle of normal humans in a dose-dependent, protein synthesis-dependent manner. The latter two effects may counter the actions of ANP, even if plasma levels in humans are increased by glucocorticoids as reported by others.⁹² Therefore, inhibition of the action of natriuretic peptides might be a pathogenetic mechanism in glucocorticoid hypertension.

Plasma ANP is decreased in glucocorticoid-induced hypertension in the rat and dog, but its hemodynamic actions are enhanced in ACTH-induced hypertension in sheep, perhaps because of concomitant plasma volume expansion. In human Cushing's disease,⁹³ and more so in patients on chronic high-dose prednisone therapy,⁹³ plasma levels of ANP are markedly elevated, but infusions of the peptide produce half the expected urine cyclic GMP response, with consequent decreases in diuresis and natriuresis.⁹⁴ Infusion of nesiritide could provide more information on the role of atrial natriuretic peptides in the hypertension of Cushing's syndrome, but this has not been explored to date.

Endogenous ouabain-like compounds are increased in systemic and adrenal vein plasma of patients with Cushing's syndrome, although lack of change with adrenalectomy suggests an extra-adrenal origin. In a patient with ectopic Cushing's syndrome and a 40-fold elevation in the levels of a compound indistinguishable from authentic ouabain (by chromatography and binding properties), there was a direct correlation of its plasma concentration with the magnitude of blood pressure elevation during the course of the disease and therapy.⁹⁵ This suggests a compensatory response to plasma volume expansion that contributed to vasoconstriction via inhibition of vascular smooth muscle Na-K-ATPase.

Nitric oxide and erythropoietin

Glucocorticoids downregulate eNOS in many organs,⁹⁶ prevent expression of iNOS in response to endotoxin or cytokines (explaining their therapeutic effect in septic shock), decrease L-arginine availability in endothelial cells by downregulating amino acid transporters and impairing regeneration from citrulline, and reduce synthesis of tetrahydrobiopterin, a necessary cofactor for the action of eNOS, by inhibiting the enzyme GTP-cyclohydrolase.⁹⁷ These actions on the nitric oxide system account for decreased plasma nitrite:nitrate ratios, attenuation of relaxation responses to acetylcholine, equipotent hypertensive effects of dexamethasone and eNOS inhibitors, and lack of development of glucocorticoid hypertension in eNOS knockout mice.^{96,98}

In ACTH and corticosterone hypertension of the rat, reduced kidney expression of iNOS and eNOS leads to increased renal vascular resistance and hypertension that can be prevented or ameliorated by L-arginine, lipopolysaccharide stimulation, or the NO donor isosorbide,⁹⁹ but not by tetrahydrobiopterin. The inhibitor N-nitro L-arginine blocks the beneficial effect of L-arginine. These data indicate a deficit in nitric oxide generation, not diminished L-arginine availability in these models. In contrast, in dexamethasone-induced hypertension in the

rat, L-arginine does not improve blood pressure, despite increasing plasma nitrite:nitrate ratio, suggesting differences in the participation of the NOS system in ACTH versus synthetic steroid hypertension.

In human endothelial cells, activated glucocorticoid receptors inhibit eNOS by decreasing binding of the transcription factor GATA to the eNOS gene promoter and by impairing mRNA stability, both leading to diminished eNOS mRNA and protein.⁹⁸ Consistent with this, cortisol-induced hypertension in normal humans is associated with reduced plasma nitrite:nitrate concentration (without changes in arginine cellular uptake, plasma levels, or stimulation of endogenous eNOS inhibitors), and with impaired forearm vasodilator responses to acetylcholine, indistinguishable from those to NOS antagonists. However, L-arginine does not prevent cortisol-induced reduction of nitrite:nitrate ratios or blood pressure elevation,¹⁰⁰ indicating that there may be additional defects that preclude the normal actions of nitric oxide.

It has been speculated that erythropoietin may be responsible because cortisol increases its levels in humans,¹⁰¹ and the vascular actions of erythropoietin are mediated by resistance to the actions of NO. However, data on ACTH hypertension in the rat do not support this speculation; in this model ACTH reduces erythropoietin levels, and the concentration of the renal hormone is inversely related to the magnitude of blood pressure elevation.¹⁰²

There is only one report about the nitric oxide system in a patient with Cushing's syndrome. Urinary excretions of nitrate and nitrite were reduced and could not be corrected by L-arginine.¹⁰³ Therefore, the hypertension of the naturally occurring disease may have mechanisms similar to that of normal volunteers given cortisol.

Oxidative stress

Increased generation of oxygen radicals may impair nitric oxide vasodilatation by scavenging of nitric oxide and formation of peroxynitrite. Glucocorticoids activate xanthine oxidase in renal cell preparations but decrease its serum levels in patients with rheumatoid arthritis.¹⁰⁴ Allopurinol, an inhibitor of xanthine oxidase, reduces blood pressure and muscle levels of this enzyme in dexamethasone hypertensive rats,¹⁰⁵ but does not affect blood pressure or plasma isoprostanes in ACTH hypertension, in which the source of superoxide is NADPH oxidase.¹⁰⁶

Actions of glucocorticoids on antioxidant enzymes are complex because they are tissue dependent. Renal tissue catalase, superoxide dismutase, glutathione peroxidase, and glutathione S-transferase are increased by glucocorticoids in rats, conferring protection against oxidative glomerular damage. In the heart *in vivo*, effects on antioxidant enzymes are opposite.¹⁰⁷ Effects on skeletal muscle superoxide dismutase and lymphoid tissue catalase depend on the organ studied. Moreover, in the same experiment in the liver, glucocorticoids concomitantly increase and decrease the contents of various antioxidant enzymes.¹⁰⁸ The superoxide dismutase mimetic tempol is able to prevent or ameliorate blood pressure in

dexamethasone and ACTH hypertension in rats, despite the various enzymes involved in generating oxygen radicals.^{109,110} However, improvement of hypertension is not associated with reduction of isoprostane concentrations, making it unclear whether the antihypertensive effect of tempol is due to reduced oxidative stress.

The issue is not less complex in humans. Glucocorticoids increase hydrogen peroxide and peroxynitrite by stimulation of both NADPH and xanthine oxidase in human endothelial cells,¹¹¹ but they decrease generation of superoxide anion in response to several stimuli in vascular smooth muscle, an action mediated by decreased expression of p22 phox, a major subunit of NADPH oxidase.¹¹² The pro-oxidative endothelial effect seems to predominate, as assessed by decreased forearm dilatory responses to hyperemia (reversible with vitamin C) in patients treated with glucocorticoids.¹¹¹ Finally, there is evidence for both anti- and pro-oxidant effects in humans receiving chronic glucocorticoid therapy. For example, markers of oxidative stress are increased in patients receiving fluocinonide cream for the treatment of psoriasis,¹¹³ whereas plasma isoprostanes and erythrocyte catalase decrease in those using glucocorticoid inhalers for the treatment of asthma.¹¹⁴ Exploring a role for oxidative stress in human glucocorticoid hypertension in direct fashion will have to wait for the development of specific and effective antioxidant agents for human use, an achievement that has been elusive to date.

Vascular endothelial growth factor

Vascular endothelial growth factor (VEGF), a cytokine best known for its angiogenic and endothelial mitogenic effects, is also a powerful activator of the nitric oxide system in vascular tissues. VEGF stimulates nitric oxide release by human endothelial cells and rabbit vessels and relaxes dog coronary arteries by a mechanism enhanced by L-arginine and attenuated or abolished by inhibitors of nitric oxide synthase. Exaggerated VEGF-induced aortic relaxation in SHR is consistent with a deficient nitric oxide system in this rat strain. In whole animals, the beneficial coronary vasodilation produced by VEGF is nonetheless accompanied by severe hypotension associated with decreased cardiac output and total peripheral resistance, both of which are prevented by nitric oxide synthase inhibitors.¹¹⁵

Glucocorticoids dose dependently inhibit VEGF expression (mRNA and protein) by a nontranscriptional increase in VEGF mRNA turnover.¹¹⁶ In nonvascular tissues, this effect decreases VEGF-induced vascular permeability, probably accounting for the beneficial effects of glucocorticoids in inflammatory cutaneous disorders,¹¹⁶ asthma, diabetic retinopathy, and the edema that accompanies several types of brain tumors.

It is thus conceivable that glucocorticoid hypertension involves a deficit in VEGF-dependent vasodilation. Paradoxically, however, plasma VEGF levels are increased in essential hypertensive patients, and more so in those with hypertension due to Cushing's syndrome.¹¹⁷ VEGF is expressed in normal adrenal fasciculata and glomerulosa cells and participates in terminal differentiation of the

endothelium into the fenestrated phenotype that is characteristic of endocrine glands.¹¹⁸ ACTH, in an action that is opposite to that of glucocorticoids, stimulates adrenal cell VEGF expression,¹¹⁹ thus modulating the tight balance between steroid-secreting cells and their capillary vessels. Because VEGF is overexpressed in adrenal tumor cells,¹²⁰ this could be the source for increased levels of the peptide in Cushing's syndrome. However, VEGF plasma levels are equally increased in ACTH-dependent and -independent human hypercortisolism, which does not support this interpretation.¹¹⁷ In adrenal carcinomas, the phenotype consists of overexpression of VEGF despite very low capillary density.¹²¹ Therefore, it is conceivable that increased VEGF in hypertension (whether essential or in Cushing's syndrome) is a compensatory response to rarefaction of the microvasculature. Regardless of the mechanism of its increased plasma levels, VEGF may participate in target-organ damage of Cushing's syndrome via remodeling of atherosclerotic plaques. This is supported by observations in a large number of essential hypertensive patients, in whom VEGF correlated with cardiovascular risk factors and could be decreased by their successful therapy.¹²²

Glucocorticoids and the autonomic nervous system

Glucocorticoids stimulate all major enzymes of the catecholamine biosynthetic pathway. Effects on adrenal medullary tyrosine hydroxylase include increased enzyme mRNA and activity, with augmented tissue and plasma concentrations of norepinephrine and epinephrine. The effect is transcriptional, via a glucocorticoid receptor responsive element in the tyrosine hydroxylase gene,¹²³ and functionally significant, as demonstrated by prevention of dexamethasone-induced hypertension by alpha-methyl-p-tyrosine.¹²⁴ Analogously, transcriptional stimulation of dopamine beta-hydroxylase mRNA by dexamethasone has been demonstrated in isolated cells. Stimulatory effects on cardiac phenylethanolamine N-methyltransferase (PNMT)—the enzyme that converts norepinephrine into epinephrine in adrenal and non-adrenal tissues—with consequent increased myocardial epinephrine, may explain increases in cardiac output despite plasma volume contraction in dexamethasone hypertension and play a role in hemodynamic responses to stress.¹²⁵

In contrast, modulatory effects of glucocorticoids on central nervous system control of the circulation are varied. For example, pressor responses elicited by corticosterone in the rostral ventrolateral medulla are glucocorticoid receptor dependent, whereas those produced by dexamethasone in the nucleus tractus solitarius are not.¹²⁶ Moreover, dexamethasone is depressor when given into the cerebral ventricles.¹²⁷ Clonidine fails to inhibit ACTH hypertension in sheep as if brainstem alpha-2-mediated sympathetic inhibition were impaired in this model, which is consistent with previously demonstrated alpha-2 adrenoceptor hyperactivity in glucocorticoid hypertension. Blunting of baroreflexes in rats and sheep could contribute to glucocorticoid-induced hypertension. However, renal denervation does not prevent ACTH hyper-

tension in sheep, making it doubtful that abnormalities in baroreflex control of heart rate or renal sympathetic nerves play a major role.

In normal humans, ACTH increases norepinephrine and epinephrine concentration in the adrenal vein, as if there were a role for the pituitary hormone in regulation of adrenal medullary function. However, hemodynamic responses to mental stress are not altered by dexamethasone, suggesting that glucocorticoids may not be major regulators of overall autonomic function in response to usual stimuli.¹²⁸ In Cushing's syndrome, epinephrine:norepinephrine ratios in adrenal vein blood (a marker of PNMT activity) and the metabolic clearance rate of epinephrine are normal, while plasma catecholamines and their response to glucagon are diminished, suggesting that the adrenal medulla does not play a role in the hypertension. Also, neuropeptide Y levels are not different from those in controls, indicating that the direct vasoconstrictor effect of this peptide and its ability to enhance vascular responses to norepinephrine are not involved in the hypertension of Cushing's disease. Finally, there are two major observations against a significant participation of the autonomic nervous system in the hypertension of Cushing's disease: the ganglionic blocker trimethaphan does not prevent cortisol-induced hypertension in normal volunteers;¹²⁹ and in Cushing's syndrome, there is a negative correlation between plasma norepinephrine levels and urine free cortisol excretion.¹³⁰

Glucocorticoids and vascular reactivity

Vascular smooth muscle glucocorticoid receptors mediate the transport actions discussed in a previous section and have also been implicated in vascular hypersensitivity to constrictor agents. For example, generation of inositol-triphosphate by angiotensin II and AVP in vascular smooth muscle cells is enhanced by dexamethasone, and prevented by glucocorticoid receptor blockers.

Whether there is vascular hyperreactivity in organ preparations or whole animals with glucocorticoid excess is less clear. Hypersensitivity to the constrictor action of endothelin-1 in sheep arteries⁸⁸ does not result in an endothelin pressor effect in ACTH hypertension. Increased pressor action of norepinephrine may be a mineralocorticoid effect of glucocorticoids, as suggested by experiments in 11bHSD2 knockout mice or humans given licorice or carbenoxolone. In methylprednisolone-induced hypertension in the rat, responses to exogenous angiotensin II depend on salt balance, that is, not on the steroid.^{79,80}

Results are equally controversial in humans. Forearm vascular resistance after glucocorticoids may be increased⁴ or unchanged.¹³¹ The cold pressor test (a measure of adrenergic responsiveness) is not modified by dexamethasone,¹³² whereas cutaneous vasoconstriction after topical cortisol or beclomethasone is increased in essential hypertensive patients.¹³³ In patients with Cushing's syndrome, hyperresponsiveness to exogenous norepinephrine infusion¹³⁴ and normal responses to phenylephrine¹³⁵ have both been reported. Angiotensin II infusions are equipressor in patients with Cushing's syndrome with normal plasma renin and in subjects with Conn's syndrome

and renin suppression. This implies hyperreactivity in the former, since responses to exogenous angiotensin II should be inversely related to the prevailing level of activation of the endogenous renin-angiotensin system.¹³⁶ Finally, methylprednisolone improves myocardial function in experimental heart failure by increasing beta-adrenergic receptor density, without effect on isoproterenol-stimulated adenylyl cyclase activity,¹³⁷ whereas in patients with Cushing's syndrome, enhanced hemodynamic responses to isoproterenol are unrelated to adrenoceptor numbers and remain unexplained.¹³⁸

TREATMENT OF CUSHING'S SYNDROME AND GLUCOCORTICOID HYPERTENSION

Pharmacologic therapy

Treatment of hypercortisolism

The primary treatment of Cushing's syndrome, discussed in the next section, is surgical. Therefore, medical therapy is reserved for incurable malignant disease, recurrences after transsphenoidal pituitary surgery, high surgical-risk patients, and transient management of severe hypertension or other manifestations of hypercortisolism to decrease surgical risk.

Hypercortisolism can be improved by blocking adrenal steroid synthesis, regulating release of ACTH by the pituitary gland, or targeting expression of aberrant receptors in tumors. Residual uncontrolled hypertension may require use of conventional antihypertensive agents.

Metyrapone and op'DDD, older inhibitors of steroid synthesis, are not much used any longer, although the former may still have a role in the management of ACTH-independent macronodular adrenal hyperplasia of the elderly.¹³⁹

Aminoglutethimide is an anticonvulsant that blocks CYP450 hydroxylation steps in the conversion of cholesterol to pregnenolone, with consequent inhibition of cortisol, aldosterone, and androgens. It has been used in all forms of hypercortisolism but is more effective in adrenal (including carcinoma) and ectopic Cushing's syndrome. In pituitary Cushing's disease, it produces further stimulation of ACTH, which overcomes its inhibitory action. Its use may be combined with metyrapone.

Ketoconazole, an antifungal imidazole, diminishes cortisol secretion and action via decreased synthesis of cholesterol, inhibition of 11- β -hydroxylase, and partial blockade of the glucocorticoid receptor. After a few weeks of therapy, its effects are sustained in Cushing's disease. Its major drawback is the potential for liver toxicity, which requires periodic monitoring of laboratory tests. It may lead to adrenal insufficiency, requiring dose adjustments.

Mitotane inhibits steroid synthesis via actions on mitochondrial hydroxylases but also induces microsomal hydroxylases that alter the metabolism of 17-OH compounds. In addition, its metabolites are toxic to mitochondria, producing cell necrosis of the zonae reticularis and fasciculata. There is relative sparing of the glomerulosa, which explains the lack of need for mineralocorticoid

replacement even when cortisol secretion becomes subnormal. Finally, mitotane inhibits ACTH production, preventing its secretion in response to cortisol suppression. It is effective, combined with pituitary radiation, after failure of transsphenoidal surgery or when patients cannot undergo surgery. The necrotizing effect of mitotane makes it useful for the treatment of adrenal carcinoma. It is currently given as adjuvant therapy immediately after the surgery for the primary tumor¹⁴⁰ because it is unclear that it prolongs survival once metastases have occurred.

Mifepristone (RU-486), a specific antagonist of glucocorticoid receptors, is a substituted 19-norsteroid that improves the clinical manifestations of Cushing's syndrome, usually without changing ACTH or cortisol levels. However, ACTH of pituitary tumors may occasionally overcome the receptor blockade. It is approved in the United States as an antiprogesterin agent to induce abortion. Experience in the treatment of Cushing's syndrome is limited, but it seems to be efficacious and devoid of major side effects.

Agents used to modulate release of ACTH in pituitary Cushing's disease include serotonin antagonists (cyproheptadine, ketanserin, and ritanserin), dopamine agonists (bromocriptine and cabergoline), the GABA agonist valproic acid, and somatostatin analogs of the octreotide family. In ACTH-independent adrenal macronodular hyperplasia, transient inhibition of cortisol secretion has been achieved with blockade of aberrant receptors for gastric inhibitory polypeptide (octreotide), catecholamines (propranolol), dopamine (cabergoline), LH (leuprolide), AVP (OPC-21268), and angiotensin II (candesartan). Finally, there is experimental evidence that retinoic acid¹⁴¹ and the PPAR-gamma agonist rosiglitazone¹⁴² inhibit ACTH secretion and have antiproliferative effects in cultured corticotrophs, but a role for these agents in the treatment of human disease is yet to be determined.

Antihypertensive agents

No systematic comparison of antihypertensive agents has been conducted in patients with Cushing's syndrome, probably because the focus is on the treatment of the primary disease. There are isolated reports on their use before surgery or for management of severe hypertension. Initially, central sympatholytic agents (e.g., clonidine) and beta-blockers were recommended. The latter were thought to have central nervous system actions because they reduced blood pressure in glucocorticoid hypertensive rats with excised renal medullae.¹⁴³ Use of diuretics was discouraged owing to their potential to increase the cardiovascular manifestations of adrenal insufficiency after correction of the hypercortisolism. More recently, it was shown that diuretics, calcium channel blockers, and angiotensin-converting enzyme inhibitors were equally effective in glucocorticoid hypertension. Failure to normalize blood pressure is usually due to unremitting hypercortisolism, not to the choice of antihypertensive agents, and can be overcome by pretreatment with or addition of ketoconazole.

Efficacy of the angiotensin-converting enzyme inhibitors captopril, benazepril,¹⁴⁴ and trandolapril,⁹⁰ and the angio-

tensin receptor blocker losartan is consistent with increased synthesis of angiotensinogen in animals and humans with glucocorticoid hypertension and with responses to captopril in methylprednisolone-induced hypertension in the rat.⁸⁰ In essential hypertension, the blood pressure effect of these agents correlates with their ability to decrease 11-oxycorticosteroids.¹⁴⁴ Hence, the latter effect may also participate in glucocorticoid hypertension. Plasma renin activity predicts the effect of blockade of the renin-angiotensin system in Cushing's syndrome. In the few cases in which mineralocorticoid activity is prominent and plasma renin suppressed, angiotensin-converting enzyme inhibitors will not be as effective.¹⁴⁵

Our review of pathophysiologic mechanisms in the hypertension of glucocorticoid excess predicts beneficial effects for agents that have not yet been tested in the hypertension of Cushing's syndrome or exogenous glucocorticoid excess. For example, tetrahydrobiopterin, L-arginine, and vitamin C supplementation are simple nutritional interventions that may improve nitric oxide synthase activity, endothelium-dependent relaxation, and blood pressure. Also, taking into consideration that activation of the endothelin system by glucocorticoids is more likely a mineralocorticoid effect, there is a rationale for the use of spironolactone and eplerenone, even in the absence of clinical evidence for excess mineralocorticoid activity. Effects of mineralocorticoid receptor blockers could be enhanced by their combined use with the ET(a) receptor blockers bosentan or darusentan,⁸⁸ a possibility that has not yet been tested.

Pituitary surgery

Adrenalectomy was used indiscriminately to eradicate excess cortisol before there was clear understanding of the multiple causes of Cushing's syndrome. It was complicated, when the origin was pituitary, by Nelson's syndrome (i.e., de-repression of ACTH secretion with tumor growth and hyperpigmentation). Currently, detection of the different causes of Cushing's syndrome with biochemical and imaging tests, and development of microsurgical techniques allow for cause-specific therapies.

The treatment of choice for Cushing's disease is transphenoidal pituitary surgery,³⁶ usually preceded by a few weeks of medical treatment to decrease surgical risk. Adenectomy is preferred, when the tumor is located by MRI or found by the surgeon. Hemihypophysectomy is carried out when the tumor is not located, but there was lateralization of ACTH secretion by inferior petrosal sinus sampling. Total hypophysectomy may be required otherwise, but is only conducted with the patient's full understanding of the problems of lifelong multihormone replacement. When fertility is an issue, adrenalectomy and medical therapy are better treatment choices. Successful adenectomy is currently achieved in 80% to 90% of cases, the mortality rate is negligible (~1-2%), but complications (pituitary insufficiency, diabetes insipidus, and cerebrospinal fluid leaks) may occur in 10% to 30% of procedures. The success rate is lower in macroadenomas that extend to the dura.

Abnormal corticotroph remnants may be inhibited for prolonged periods, but are the cause of late recurrences. Lack of postoperative hypocortisolism with need for replacement is a predictor of delayed recurrence.¹⁴⁶ Over a decade, success rates drop to ~50%. If a recurrence occurs early, diagnostic error needs to be considered. For example, failure to suppress ACTH after surgery may indicate an undiagnosed cause of CRH hypersecretion. Overall, when Cushing's disease persists after surgery, re-exploration, radiation, and adrenalectomy are possible alternatives.

Immediate postoperative glucocorticoid replacement is tapered rapidly, relying on cortisol measurements. Pseudotumor cerebri¹⁴⁷ may occur if replacement is insufficient. Testing for recovery of the pituitary-adrenal axis is usually begun after 6 to 12 months. If the need for chronic replacement is established, patients must receive instructions regarding titration of dosage in case of illness or stress. Evidence for other hormone deficiencies must also be sought out.

Pituitary radiation

High-voltage cobalt 60, the most common form of pituitary radiation, is used when surgery is not possible or has failed. The response rate is about 50%, with preservation of pituitary and adrenal function and no need for glucocorticoid replacement. Recurrences are rare, but medical therapy is required because it takes months for the effect of radiation to be established. A rare but severe delayed complication is radiation necrosis of the brain.

More powerful forms of radiation (proton beam, radioactive needle implant) are more effective but commonly lead to panhypopituitarism. The gamma knife (stereotactic radiosurgery) has been used for visible remnant adenomas and also in the primary therapy of Cushing's disease.

Adrenalectomy in pituitary Cushing's disease

Despite the major improvement in complication rates with laparoscopic, compared to open, adrenalectomy, bilateral adrenalectomy in Cushing's disease should be reserved for special circumstances, because it may lead to Nelson's syndrome and its complications, including local tumor invasion and a rare malignant course. Adrenalectomy is preferred over radiation to preserve fertility, but radiation may nonetheless be required if there are early skin or radiologic changes suggestive of Nelson's syndrome. Glucocorticoid and mineralocorticoid replacement will be required lifelong.

Surgical management of adrenal Cushing's syndrome

Laparoscopic adenectomy or unilateral adrenalectomy is the current treatment of choice for benign adrenal adenomas. Success rates approach 100%, even in large tumors,¹⁴⁸ although there have been recurrences in cases with bilateral adenomas or ectopic adrenal tissue. Patients require long-term (minimum of 6 months) glucocorticoid replacement until the normal function of the hypothalamo-pituitary-adrenal axis is restored, due to preexisting chronic suppression of the contralateral gland.

Bilateral adrenalectomy is the treatment for micro- and macro-nodular forms of adrenal hyperplasia, usually with good results. Choice of laparoscopy versus open adrenalectomy in the macronodular form depends on the size of the glands. Lifelong glucocorticoid and mineralocorticoid replacements are required.

Optimal management of adrenal carcinoma is controversial and prognosis is poor (<40% survival at 5 years), particularly when the primary tumor is large. Aggressive debulking surgery, including that of multiple metastases, does not improve outcomes significantly. Palliative radiation therapy and chemotherapy are not very useful. Use of mitotane has been discussed in the section on medical therapy, with dramatic responses in some cases, but controversial results in metastatic disease, for which survival is usually less than 1 year. Tumor embolization has been employed to produce necrosis of inoperable masses.

Treatment of ectopic Cushing's syndrome

Extensive review of the oncologic approach to the multiple diverse tumors producing ACTH (or rarely CRH) is beyond the scope of this chapter. It is of note, however, that nonmetastatic carcinoid tumors are those with the highest likelihood of cure by combined surgery and radiotherapy, provided that they can be located by radiologic means.

Medical therapy for nonresectable cancers in ectopic Cushing's syndrome has variable success, because blockade of synthesis of glucocorticoids and that of glucocorticoid receptors may be overcome by persistent ACTH hypersecretion, particularly when plasma levels are very high. In such situations, and also in patients who cannot tolerate the side effects of cortisol-suppressing therapy, bilateral adrenalectomy may be considered to control hypercortisolism. Obviously, the appropriateness of this surgery must be considered within the framework of expected survival; for instance, it may be indicated for slowly evolving carcinoids but not for rapidly growing cancers.

PROGNOSIS

Remission of hypertension and other clinical manifestations after successful treatment of hypercortisolism

Cure and recurrence rates for all forms of Cushing's syndrome have been discussed in the previous section. However, successful correction of hypercortisolism does not necessarily lead to complete resolution of clinical manifestations. Hypertension persists in 25% of patients with cured pituitary Cushing's disease¹⁴⁶ and in 10% to 30% of those with cured adrenal Cushing's syndrome,^{149,150} although medication requirements may decrease in some. One possible explanation, derived from the fact that these percentages are similar to the prevalence of essential hypertension in the general population, is that these patients had, while the Cushing's disease or syndrome was active, a combination of essential and glucocorticoid-induced hypertension.

However, many findings suggest that residual hypertension (historically called meta-glucocorticoid hypertension) may be caused by nonreversible, glucocorticoid-induced organ damage. For example, in children, hypertension of Cushing's syndrome resolves in almost all subjects 1 year after surgery. In adults, the predictors of lack of cure for hypertension (age,¹⁵¹ and duration or severity of glucocorticoid hypertension) are all determinants of target-organ damage. Finally, the rate at which blood pressure returns to normal after cure of Cushing's syndrome correlates negatively with the magnitude of renal damage assessed by biopsy.¹⁴⁹

Obesity (55%), menstrual abnormalities (41%), and diabetes (22%) may also persist after successful treatment of hypercortisolism, whereas hirsutism, neuropsychiatric manifestations, and myopathy are more likely to disappear.¹⁵⁰ Vascular damage established during Cushing's syndrome and lack of complete reversibility of hypertension and metabolic features probably account for the residual incidence of cardiovascular and cerebrovascular disease during long-term follow-up of subjects with cured hypercortisolism.¹⁵¹

Overall long-term prognosis

A recent study has shown that despite the cure of Cushing's disease, there may be long-term effects on quality of life, particularly if there is residual hypopituitarism with glucocorticoid dependency and requirements for other hormone replacements. Women and older patients are most commonly affected and nonspecific symptoms, such as fatigue, prevail.¹⁵²

Life expectancy of patients with Cushing's disease and benign adrenal Cushing's syndrome has sustained dramatic improvement due to the advances in therapy. Hence, in the early 1950s, 5-year mortality rates were about 50%. In contrast, a recent European epidemiologic study demonstrated that successful transsphenoidal surgery restores mortality to levels indistinguishable from those in the general population.¹⁵³ Although these results may appear inconsistent with the evidence for residual hypertension and metabolic abnormalities described above, it may simply mean that their impact is no longer different from that of similar prevalence rates for these disorders in the general population.

SUMMARY

Cushing's disease and syndrome, although endocrinopathies, are also cardiovascular diseases in terms of their major clinical manifestations and prognosis. Hypertension and the abnormalities in lipid and carbohydrate metabolism are the major determinants of morbidity and mortality. The mechanisms underlying the hypertension of glucocorticoid excess are varied, depending on the nature of the steroid (synthetic vs. endogenous), and the species studied. In humans, the renin-angiotensin system, exaggerated oxidative stress, and abnormalities in nitric oxide play a role in vasoconstriction. Arginine vasopressin regulation of ACTH and cortisol secretion by pituitary and adrenal adenomas may be amenable to therapy with V1b

blockers in development. The VEGF response to microvascular rarefaction may also be a therapeutic target for prevention of target-organ damage.

In contrast, some traditionally mentioned pathogenic mechanisms, such as abnormalities in the sympathetic nervous system, vascular hyperreactivity to vasoconstrictors, and deficient vasodilatory systems (e.g., ANP and prostaglandins), are of more questionable relevance and no clear therapeutic usefulness.

Studies on the pathophysiologic mechanisms of glucocorticoid hypertension have also revealed possible roles for glucocorticoids in the pathogenesis of essential hypertension. Moreover, a role has been established for the tissue 11 β HSD shuttle in the pathogenesis of the

metabolic syndrome, which provided impetus for further research on relationships among glucocorticoids, PPAR alpha and gamma nuclear receptors, and their therapeutic manipulation. Finally, knowledge about the role of prenatal glucocorticoids in the determination of long-term, adult arterial pressure will certainly have an impact on the management of obstetric maternal and fetal disorders.

These nonendocrine results of research on the hypertension of human glucocorticoid excess may turn out to be the most important, since progress in the reliable cure of Cushing's disease and syndrome continues, owing to improvements in biochemical diagnosis, imaging techniques, and microsurgery.

Oral Contraceptives, Hormone Replacement Therapy, and Hypertension

Talma Rosenthal and Suzanne Oparil

Key Findings

- Oral contraceptives provide the most reliable and convenient means of contraception and are safe for use in younger, healthy, normotensive women.
- Oral contraceptives are associated with increases in blood pressure that are usually minor and resolve quickly with cessation of use.
- High-risk women, including those with uncontrolled hypertension, established cardiovascular or thromboembolic disease, breast cancer, or smoking, should not use combined estrogen–progestin oral contraceptives.
- To minimize risks while preserving benefits, guidelines specify that combined oral contraceptives should contain low doses of estrogen (<35 or <50 µg of ethinyl estradiol) and the “lowest progestin dose.” Progestin-only contraceptives, delivered by oral, intramuscular, or intrauterine routes, provide safe alternatives to combined oral contraceptives for high-risk women.
- Medical management of oral contraceptive users with hypertension should include frequent monitoring of blood pressure and aggressive cardiovascular risk factor reduction, including smoking cessation.
- Estrogens, particularly 17β-estradiol, have anti-inflammatory, vasoprotective, and favorable hemodynamic effects when administered to healthy women in the early postmenopausal years. These benefits are not seen in older postmenopausal women for reasons that are not clearly understood.
- Menopausal hormones generally do not increase blood pressure but do increase risk of stroke, thromboembolic disease, and coronary heart disease events in older postmenopausal women.

Clinical Implications

- Menopausal hormones are not recommended for the prevention or treatment of cardiovascular disease in postmenopausal women.
- Combined estrogen–progestin menopausal hormones are indicated only for treatment of vasomotor symptoms and symptoms of vulvovaginal atrophy associated with menopause and for prevention of postmenopausal osteoporosis.
- Menopausal hormones should be administered in the lowest doses and for the shortest time period needed to achieve the desired clinical effect.

The introduction of the oral contraceptives (OCs) in the 1960s was met almost immediately with reports of severe hypertension in some users,^{1,2} and suspicions that OCs might evoke stroke.^{3,4} These reports led to a series of observational studies that found higher blood pressures among OC users than nonusers, although differences in cohort size and dosages and types of OCs resulted in variations in the magnitude of blood pressure differences between the two groups.^{4–13} The average difference in systolic and diastolic blood pressure between OC users and nonusers in these studies was, respectively, 5 to 7 mmHg and 1 to 3 mmHg for white American women. Blood pressure usually returned to pretreatment levels within 3 to 6 months when OC use was discontinued. The Nurses’ Health Study found that current users of OCs had a statistically significant increased risk of hypertension compared with never users that resolved quickly with cessation of OC use.¹³

Most of the studies conducted in the 1960s and 1970s on the cardiovascular effects of the OCs used formulations containing 80 or 100 µg estrogen, vastly different from the 30 to 35 µg estrogen in today’s agents.¹⁴ In addition, these earlier formulations contained high doses (>50 µg, often 100 µg) of ethinyl estradiol (EE), a synthetic estradiol that is activated in the liver, and was subsequently found to have deleterious side effects. One of the ways that OCs were made safer was reducing hormone content.¹⁵ The amount of EE in the “low-dose formulations” was reduced to 35 µg in the 1970s and to as low as 15 µg in some formulations today.¹⁶ Seibert et al.¹⁷ were unable to substantiate harmful cardiovascular effects of OCs containing less than 35 µg EE.

OCs have been reported in numerous studies to increase the risk of stroke.^{3,6,14} The original studies were carried out when OCs contained higher doses of estrogen (80 to 150 µg) and progesterone. When doses were reduced to 30 to 50 µg of estrogen, the results of studies varied, with some finding increased risk for stroke and others not.¹⁴ For example, the European arm of a WHO (World Health Organization) study found that women older than 35 years who used OCs containing less than 50 µg of estrogen did not have a higher risk for ischemic stroke than nonusers.¹⁷

Recommendations of the American College of Obstetrics and Gynecology (ACOG) and the WHO for use of combined estrogen–progestin OCs in women with characteristics that might increase the risk of adverse effects are summarized

in Table 70–1.^{18–20} A variety of concomitant conditions, including uncontrolled hypertension, smoking, established cardiovascular disease (CVD), breast cancer, and thromboembolic disease, are considered absolute contraindications to OC use due to unacceptable health risk. Medical management of OC users with hypertension should include frequent monitoring of blood pressure and aggressive CVD risk factor modification, including smoking cessation.

In contrast to OCs, menopausal hormones (hormone replacement therapy [HRT]) have not been shown to increase blood pressure in either normotensive or hypertensive postmenopausal women.^{21–26} These differences in blood pressure effect may be related to the dosage and molecular forms of estrogen used in menopausal HRT and in OC. Estrogens in HRT are usually natural estrogens, while

estrogens in OC are usually synthetic.^{5,27} The estrogenic component of HRT, particularly 17 β -estradiol, has been shown in some studies to lower both systolic and diastolic blood pressure, particularly nighttime blood pressure, in healthy normotensive, prehypertensive, and hypertensive postmenopausal women when administered in the first few years following cessation of menses.^{22,27,28} Further, both oral and transdermal estradiol have been shown to attenuate the age-related rise in blood pressure.²⁹

In older postmenopausal women, the effect of HRT on blood pressure appears to be minimal, but HRT regimens, particularly those that contain progestins, increase the risk of stroke, thromboembolic disease, and coronary heart disease events in this population.^{30,31} Accordingly, HRT is not recommended for the prevention of CVD in post-

RECOMMENDATIONS OF THE AMERICAN COLLEGE OF OBSTETRICS AND GYNECOLOGY AND WORLD HEALTH ORGANIZATION FOR USE OF COMBINED ESTROGEN-PROGESTIN ORAL CONTRACEPTIVES IN WOMEN WITH CHARACTERISTICS THAT MIGHT INCREASE RISK OF ADVERSE EFFECTS

Condition	Risk Status	Comment
Age		
Menarche to <40 years	No Restriction	
>40 years	Benefit>Risk	
Smoking		
Age <35 years	Benefit>Risk	OCP users who smoked were at increased risk of CVD, especially MI, compared with those who did not smoke. The risk of MI increased with increasing number of cigarettes smoked per day.
Age >35 years		
<15 cigarettes/day	Risk>Benefit	
>15 cigarettes/day	Risk Unacceptable	
Obesity: >30 kg/m ² body mass index	Benefit>Risk	Obese women who used OCPs were at increased risk of VTE compared with nonusers. The absolute risk of VTE remained small. Data are limited regarding the impact of obesity on COC effectiveness.
Multiple risk factors for CVD (older age, smoking, diabetes, and hypertension)	Risk>Benefit: May be Unacceptable	When a woman has multiple major risk factors, any of which alone would substantially increase the risk of CVD, use of COCs may increase her risk to an unacceptable level.
Hypertension		
History of hypertension, current BP unknown	Risk>Benefit	Women who did not have a BP check before COC use had increased risk of acute MI and stroke.
Adequately controlled hypertension	Risk>Benefit	Women adequately treated for hypertension are at reduced risk of acute MI and stroke as compared with untreated women. COC users with adequately controlled and monitored hypertension should be at reduced risk of acute MI and stroke compared with untreated hypertensive COC users.
Elevated BP levels		
Systolic 140–159 or diastolic 90–99	Risk>Benefit	Among women with hypertension, COC users were at increased risk of stroke, acute MI, and peripheral arterial disease compared with nonusers.
Systolic >160 or diastolic >100	Risk Unacceptable	
Vascular disease	Risk Unacceptable	
History of high BP during pregnancy (currently normotensive)	Benefit>Risk	Women who had history of high BP in pregnancy, who also used COCs, had an increased risk of MI and VTE, compared with COC users who did not have a history of high BP during pregnancy. The absolute risks of acute MI and VTE in this population are small.

RECOMMENDATIONS OF THE AMERICAN COLLEGE OF OBSTETRICS AND GYNECOLOGY AND WORLD HEALTH ORGANIZATION FOR USE OF COMBINED ESTROGEN-PROGESTIN ORAL CONTRACEPTIVES IN WOMEN WITH CHARACTERISTICS THAT MIGHT INCREASE RISK OF ADVERSE EFFECTS—cont'd		
Condition	Risk Status	Comment
DVT/PE		
History of or current DVT/PE	Risk Unacceptable	
Family history of DVT/PE (first-degree relatives)	Benefit>Risk	
<i>Major surgery</i>		
With prolonged immobilization	Risk Unacceptable	
Without prolonged immobilization	Benefit>Risk	
Minor surgery without immobilization	No Restriction	
Known thrombogenic mutations (e.g., factor V Leiden; prothrombin mutation; protein S, protein C, and antithrombin deficiencies)	Risk Unacceptable	Routine screening not appropriate because of the rarity of these conditions and high cost of screening. Among women with thrombogenic mutations, COC users had a 2- to 20-fold higher risk of thrombosis than nonusers.
Ischemic heart disease	Risk Unacceptable	
Stroke	Risk Unacceptable	
Hyperlipidemias		Routine screening inappropriate due to rarity of conditions and high cost. Base assessment on type, severity, and presence of other cardiovascular risk factors.
Headaches		
Nonmigrainous	No Restriction	Classification depends on accurate diagnosis of severe headaches that are migrainous and those that are not. Any new headaches or marked changes in headaches should be evaluated. Classification is for women without other risk factors for stroke. Stroke risk increases with age, hypertension, and smoking.
<i>Migraine without aura</i>		
Age <35	Benefit>Risk	Women who also had aura had a higher stroke risk than those without aura. COC users had a two- to four-fold increased risk of stroke versus nonusers.
Age >35	Risk>Benefit	
With aura, at any age	Risk Unacceptable	
Diabetes		
History of gestational disease	No Restriction	Patient should be assessed according to severity of condition.
Nonvascular disease		
Noninsulin dependent	Benefit>Risk	
Insulin dependent	Benefit> Risk	
Nephropathy/retinopathy/neuropathy	Risk>Benefit/Risk Unacceptable	
Other vascular disease or diabetes of >20 years duration	Risk>Benefit/Risk Unacceptable	Patient should be assessed according to severity of condition.

COC, combination oral contraceptive; CVD, cardiovascular disease; DVT, deep venous thrombosis; MI, myocardial infarct; OCP, oral contraceptive; PE, pulmonary embolism.

Table 70–1. Recommendations of the American College of Obstetrics and Gynecology and World Health Organization for Use of Combined Estrogen-Progestin Oral Contraceptives in Women with Characteristics that Might Increase Risk of Adverse Effects

menopausal women.³² Combined (estrogen plus progestin) HRT is indicated only for the treatment of vasomotor symptoms and symptoms of vulvovaginal atrophy associated with the menopause and for prevention of postmenopausal osteoporosis. Most guidelines suggest that HRT be administered in the lowest doses and for the shortest time period needed to achieve the desired clinical effect.³²

In this chapter we review the mechanisms by which estrogens and progestins alter blood pressure, and the

important clinical studies of the effects of OCs and HRT on blood pressure and related target-organ damage.

MECHANISMS

Estrogens

Estrogens reduce blood pressure, and thereby CVD risk, by multiple mechanisms, including modulation of nitric

oxide (NO)-mediated vascular responses,^{33–36} inhibition of sympathetic nervous system activity and vasoconstrictor responses to sympathetic stimulation,^{37,38} suppression of the renin–angiotensin system,^{39,40} inhibition of plasminogen-activator inhibitor type-1 (PAI-1) and endothelin,⁴¹ and enhanced production of natriuretic peptides⁴² and prostacyclin⁴³ (Figure 70–1).

NO-Mediated vascular responses

Estrogen acts on the endothelium to increase the production of the vasodilators NO and prostacyclin^{35,36} (Figure 70–1). Physiologic levels of estradiol potentiate endothelium-dependent, flow-mediated vasodilation in postmenopausal women, in part by modifying the synthesis/release/bioactivity of the powerful vasodilator NO.³³ It has been suggested that gender differences in vascular tone may be accounted for by the increased NO release from the endothelium in women compared to men. This gender difference tends to disappear in menopause when the circulating level of estrogen falls. Circulating levels of NO metabolites in postmenopausal women are generally less than 25 $\mu\text{mol/L}$, most likely because of estrogen deficiency, and treatment with oral or transdermal unopposed estrogen or tibolone has been shown, at least in the short term, to increase NO metabolites in these women.⁴⁴ Whether these endothelium-mediated effects on NO synthesis/release can be sustained over many years of menopausal hormone treatment is unknown.

Estrogen increases circulating NO/NO metabolite levels by a variety of mechanisms. It stimulates expression and activation of endothelial nitric oxide synthase (eNOS) via both genomic and nongenomic mechanisms, enhances Ca^{2+} -dependent NO release from endothelial cells, and modulates generation of reactive oxygen species and reduces oxidative stress by inhibiting NADPH oxidase. Thus, the effects of estrogen on the NO pathway are related to its antioxidant effects, which increase the bioavailability of NO.⁴⁵ These antioxidant/NO potentiating effects of estrogen inhibit the adhesion of activated monocytes to the

endothelium, the initiating phase of atherosclerosis, thus protecting the vasculature against plaque formation via a mechanism that is independent of blood pressure.⁴⁶

Sympathoinhibition

Estrogen supplementation in healthy perimenopausal women attenuates the pressor, glucocorticoid, and catecholamine responses to stress, suggesting that it inhibits sympathetic outflow from the central nervous system.³⁷ These effects may explain part of the apparently beneficial actions of estrogen on the acute symptoms of menopause and on long-term cardiovascular risk. Presynaptic modulation of norepinephrine release is another major way in which estrogen is thought to reduce the sympathetic response.³⁸ Further, estrogen therapy has been shown to improve baroreceptor sensitivity, thus lowering blood pressure and rate pressure product at rest and during physiologic challenge.⁴⁷ Perimenopausal women given estrogen supplementation show both an attenuated vasoconstrictor response to norepinephrine and diminished total body norepinephrine spillover, a measure of reduced sympathetic neural activity.⁴⁸ Estrogen blunts the vasoconstrictor response to norepinephrine and other sympathetic mediators by inhibiting Ca^{2+} entry into vascular smooth muscle cells, thus lowering intracellular free Ca^{2+} and attenuating the ability of the muscle to contract⁴⁹ (Figure 70–1). Thus, by mediating endothelium-dependent vasodilation and modulating sympathetically mediated vasoconstriction, estrogen may play an important role in regulating vascular tone and compliance and therefore blood pressure in women.⁵⁰ Mode of delivery seems to play a role here, since muscle sympathetic nerve activity and blood pressure in postmenopausal women are decreased by chronic transdermal estrogens but not oral estrogens.^{51,52} These differential effects of oral vs. transdermal estrogen treatment have been attributed to induction of insulin-like growth factor-1 (IGF-1) deficiency and increased adiposity/reduced lean body mass by oral estrogens.^{51,53–55} Sympathetic overactivity related to IGF-1 deficiency and/or increased adiposity opposes the direct inhibitory effect of estrogen on sympathetic nerve discharge, which is unopposed during transdermal estrogen treatment.

Aortic stiffness

Central arterial stiffness and wave reflections increase with advancing age and elevate systolic and pulse pressure.⁵⁶ Pulse wave analysis of 333 apparently healthy women in the Framingham Heart Study offspring cohort revealed a marked age-related increase in aortic stiffness, assessed by carotid-femoral pulse wave velocity. Augmentation of arterial stiffness with increasing age is more prominent in women than in men,⁵⁷ and appears to be further accelerated by occurrence of menopause.⁵⁸ A cross-sectional study of 3149 Japanese women undergoing annual health screening examination revealed that the relationship between age and the brachial-ankle pulse wave velocity, an index of central arterial stiffness, has the form of a quadratic curve with a slope that steepens after menopause.⁵⁹ Limitations of this study include its cross-sectional design, reliance on self-report for definition of menopausal status, and the

Figure 70–1. Mechanisms of estrogen-induced vasodilation. Estrogen relaxes vascular smooth muscle by increasing PGI₂ and NO levels; decreases vasoconstriction by acting as a calcium antagonist. (Redrawn with modification from *Heart Lung* 2001;30:401–426.)

lack of precision of brachial-ankle pulse wave velocity in assessing central arterial stiffness. Nevertheless, because of the large number of women examined, this study provides important evidence that menopause, and probably estrogen deficiency, has unfavorable effects on central arterial stiffness. To test the hypothesis that loss of hormonal modulation contributes to the rapid increase in arterial stiffness seen in the perimenopausal period, the effects of HRT and selective estrogen receptor modulators on arterial stiffness and blood pressure in perimenopausal women have been examined.^{60–63} HRT decreased pulse wave velocity and increased arterial compliance without major effects on blood pressure in these studies, indicating that ovarian hormones have favorable effects on central arterial stiffness that are independent of blood pressure. While the responsible cellular/molecular mechanisms have not been defined precisely, it is thought that impaired endothelial function and increased NO bioavailability play a major role.

Suppression of renin-angiotensin-aldosterone system

Estrogen modulates expression of several components of the renin-angiotensin-aldosterone cascade, including renin, angiotensinogen, angiotensin-converting enzyme (ACE), and the angiotensin AT₁ receptor^{39,40} (Figure 70–2). Renin levels are lower in women than in men, and in postmenopausal women receiving estrogen therapy than in those not receiving estrogen.^{39,64} Both endogenous estrogen and estrogen replacement therapy are associated with reduced plasma renin and prorenin concentrations, serum ACE activity and tissue ACE and AT₁ receptor expression in women and experimental animals.^{39,64–69} Additionally, estrogen induces production of the heptapeptide Ang 1–7, a potent vasodilator and inhibitor of smooth muscle cell growth,⁶⁸ and inhibits angiotensin-induced aldosterone secretion in ovariectomized animals.⁷⁰ This effect appears to be mediated by a posttranscriptional mechanism by which estradiol interferes with ribosomal efficiency for AT₁ receptor translation.⁷¹ In contrast, estrogen stimulates synthesis of angiotensinogen in liver and isolated hepatocytes, probably by binding to an estrogen response element in the angiotensinogen gene

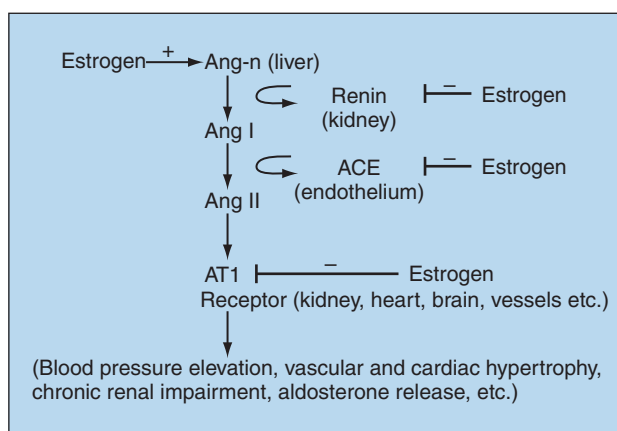

Figure 70–2. The influence of estrogen on the cascade leading to angiotensin II formation and subsequent receptor activation. (Redrawn from *Cardiovasc Res* 2002;53:672–77.)

promoter.^{72,73} This pro-hypertensive effect of estrogen on the initial step of the cascade opposes its inhibitory actions on downstream components. Thus, estrogen has a dichotomous effect on the renin-angiotensin-aldosterone system, whereby it increases the initial substrate (angiotensinogen) but inhibits the generation and biological action of the active hormones (angiotensin II and aldosterone), thus tending to reduce blood pressure and related target organ damage.

Renal effects

Postmenopausal women are more salt sensitive than premenopausal women, and salt sensitivity correlates inversely with levels of circulating ovarian hormones in the former group.^{74,75} Further, a strong sodium–blood pressure association that is independent of age has been identified in postmenopausal women, suggesting that postmenopausal salt sensitivity is related to hormonal changes rather than aging.⁷⁶ Estrogen protects against salt-induced increases in blood pressure, at least in part by increasing the sensitivity of the pressure–natriuresis relationship and augmenting renal excretion of sodium.⁷⁷ In young normotensive women, the pressure–natriuresis relationship is steep during all phases of the menstrual cycle and during oral contraceptive use, indicating insensitivity to salt. However, the pressure–natriuresis curve is shifted to the right in menopausal women, indicating that BP becomes salt-sensitive after the menopause (Figure 70–3).

To test directly the hypothesis that loss of ovarian hormones increases the salt sensitivity of blood pressure, blood pressure responses to intravenous saline and furosemide challenge were examined in healthy normotensive women immediately prior to and 4 months after surgical menopause.⁷⁸ The prevalence of salt sensitivity, defined as a decrease of more than 10 mmHg in systolic blood pressure between salt loading and salt depletion, doubled after surgical menopause, and nearly 40% of salt-resistant

Figure 70–3. Pressure–natriuresis relationship in normotensive women during the normal menstrual cycle, during use of oral contraceptives and after menopause. All women received randomly a diet low in sodium (40 mmol Na⁺/day) and high in sodium (250 mmol Na⁺/day) for 1 week. Blood pressure was measured over 24 hours using ambulatory blood pressure monitoring. (Redrawn from *Am J Hypertens* 2004;17:994–1001.)

women developed salt sensitivity without an associated increase in blood pressure during this period (Figure 70–4). Consistent with observations from epidemiologic studies that hypertension may not develop until 5 to 10 years after menopause, the investigators concluded that loss of ovarian hormones may unmask a population of women who, with aging, are at high risk for development of hypertension and CVD.

Progestins

The progestins generally antagonize the effects of estrogen on vascular tone. Native progesterone has minimal effects on endothelium-dependent and endothelium-independent relaxation of arteries *in vivo* and *in vitro*, but co-administration of progesterone with estrogen blunts both modes of vasodilator response to the latter hormone.^{79,80} The synthetic progestin medroxyprogesterone acetate (MPA) is a more potent antagonist of estrogen than native progesterone. In ovariectomized monkeys, MPA but not progesterone reduced or completely abolished endothelium-dependent vasorelaxation in response to administration of conjugated equine estrogen in doses comparable to those administered to humans.⁸¹ Likewise, in ovariectomized monkeys subjected to coronary vasospasm induced by direct stimulation, progesterone plus estradiol protected, while MPA plus estradiol failed, to protect against vasospasm.⁸²

Progesterone and MPA have differential effects on human umbilical vein endothelial cells *in vitro*: progesterone stimulates eNOS activity, does not alter stimulatory effects of estradiol on eNOS, and augments estradiol-induced ERK 1/2 phosphorylation and Akt phosphorylation, while MPA does not alter eNOS activity, blunts estradiol-induced increases in eNOS activity, and reduces estradiol-dependent ERK 1/2 phosphorylation.⁸³ Thus, progesterone and MPA are not equivalent, since they have distinct biological effects on vasoactive mediators and intracellular signaling pathways, as well as differential effects on the actions of estradiol.

Figure 70–4. Number of study participants with salt sensitivity (SS) and salt resistance (SR) just before (premenopausal) and 4 months after hysterectomy and ovariectomy (postmenopausal). *Significant increase in number of women with SS after surgical menopause ($p=0.01$). (Redrawn from *Hypertension* 2006;47:1168–74.)

Vascular remodeling

Native progesterone has a dose-dependent inhibitory effect on DNA synthesis and proliferation in rat aortic smooth muscle cells *in vitro*.⁸⁴ Progesterone appears to be vasoprotective, while MPA produces unfavorable effects on the vascular injury response by antagonizing the modulatory effects of estrogen on vascular remodeling in response to various stresses, including mechanical injury. In the setting of vascular injury, exogenous native progesterone, administered alone and with estradiol, has variable effects on neointima formation and does not alter the actions of co-administered estrogen. This may be related to variable partial conversion of progesterone to estrogen *in vivo*. In contrast, MPA has no independent biological effect, but blunts the antiproliferative and anti-inflammatory effects of estradiol in the balloon-injured carotid artery of the ovariectomized rat.^{85–87} MPA increases neointima formation in injured arteries of intact female rats and abolishes the anti-inflammatory and vasoprotective (inhibition of neointima formation) effects of estradiol in ovariectomized animals. The latter effect of MPA may be mediated by its demonstrated interference with nuclear factor- κ B suppression by estrogen.⁸³

Renin-angiotensin-aldosterone system

Progesterone may stimulate components of the renin-angiotensin-aldosterone system and may be a competitive inhibitor of mineralocorticoid receptors.^{88,89} In women undergoing ovarian stimulation for *in vitro* fertilization, there is a positive relationship between progesterone levels and plasma renin activity during and after ovulation and throughout pregnancy.⁸⁸ Progesterone increases plasma renin activity and aldosterone levels in Sprague-Dawley rats and increases baseline and angiotensin II-stimulated aldosterone production in isolated zona glomerulosa cells.⁹⁰ Thus, progesterone has complex and directionally opposite effects on components of the renin-angiotensin-aldosterone system that regulate both blood pressure and target organ damage.

Renal effects

Progesterone produces natriuresis in humans.^{91,92} This natriuretic effect results from mineralocorticoid-independent direct action on the distal nephron: progesterone increases Ca^{2+} reabsorption and Na^{+} excretion in the distal but not the proximal tubule of the rabbit kidney, and progesterone receptors are found in the distal nephron but not the proximal tubules.⁹³ Whether these effects can be extrapolated to other progestins (e.g., MPA) is unknown.

CLINICAL STUDIES

Menopausal hormone therapy

Endogenous estradiol tends to lower blood pressure.⁹⁴ Observational studies of blood pressure through the menstrual cycle have demonstrated that blood pressure is lower when estradiol levels peak during the luteal phase than when they are at their nadir during the follicular phase.^{95–97} The rise in blood pressure seen later in life in women has been related to menopause, in addition to aging *per se*, and been

attributed to estrogen withdrawal, overproduction of pituitary hormones, weight gain, or a combination of these and other yet undefined neurohumoral influences.^{5,98} The menopause is associated with a significant increase in blood pressure in cross-sectional studies.⁹⁹ Further, a prospective study of blood pressure in premenopausal, perimenopausal, and postmenopausal women demonstrated an age-dependent 4- to 5-mmHg increase in systolic blood pressure and a tripling in risk of developing hypertension in postmenopausal women over a 5-year follow-up period¹⁰⁰ (Figure 70-5).

Studies of the effects of HRT on blood pressure have reported somewhat inconsistent findings, including blood pressure-neutral,^{23,101} blood pressure-lowering,^{27-29,102-107} and blood pressure-elevating effects,¹⁰⁸⁻¹¹¹ likely due to differences in patient populations studied and in hormone preparations administered, as well as to methodologic differences in blood pressure measurement. In the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial, which enrolled 875 healthy normotensive early postmenopausal women, assignment to conjugated equine estrogen (CEE) (0.625 mg/day) plus or minus three progestin regimens did not impact systolic or diastolic blood pressure when compared with placebo controls.²³ Systolic blood pressure increased in all three treatment groups over the 3-year follow-up period, but there were no differences between treatments. Similarly, the Lipid Research Clinics Program follow-up study found no differences in systolic or diastolic blood pressures between HRT users and nonusers, although the latter had significantly higher body weight.¹⁰¹

In contrast, the Baltimore Longitudinal Study on Aging found that HRT has favorable effects on blood pressure in postmenopausal women.²⁹ This observational study followed

Figure 70-5. The cross-sectional association between the conventionally measured blood pressure and age. The relationship with age was studied cross-sectionally in 166 premenopausal (systolic blood pressure [SBP]=121.4±1.3 mmHg), 44 perimenopausal (SBP=122.0±1.8 mmHg), and 105 postmenopausal (126.5±1.7 mmHg) women and male controls. Values are regression slopes expressed in mmHg per 10 years (standard error), adjusted for body mass index and antihypertensive treatment. *p<0.05 slopes; †p=0.07. (Reprinted by permission from Macmillan Publishers Ltd: from *J Hum Hypertens* 1997;11:507-14.)

226 normotensive, postmenopausal women for an average of 5.7 years, 75 using both estrogen and progestin, and 149 using neither. There was a smaller increase in systolic blood pressure over time in women taking HRT than those not taking HRT, and the difference was greater at older ages (Figure 70-6). Diastolic blood pressure was not affected by HRT in this study. Similarly, the Framingham Heart Study reported that the average systolic blood pressure of HRT users was 139.4 mmHg (standard error [SE]=22.4 mmHg), compared with 142.1 mmHg (SE=23.4 mmHg) in nonusers.¹⁰² The Rancho Bernardo study also reported HRT users had systolic and diastolic blood pressures that

Figure 70-6. Results of a mixed-effects model predicting average changes in systolic blood pressure over time at different ages at first visit. The table below the graph shows the predicted average systolic blood pressure at first visit and the predicted average increase at different follow-up points (top). Predicted average increase in systolic blood pressure in hormone replacement therapy users (dotted line) and nonusers (solid line) over a mean follow-up of 10 years. Average predicted changes in systolic blood pressure are expressed as percentages to take into account the difference in starting systolic blood pressure at first visit in different age groups. The final model of the mixed-effects linear regression has been used to construct the figure (bottom). (Redrawn from *Ann Intern Med* 2001;135:229-38.)

were 2 to 4 mmHg lower than those of nonusers.¹⁰³ A follow-up study on a subset of these women¹⁰⁴ showed that those on combined estrogen/progestin had systolic blood pressures 5 mmHg lower than women on estrogen alone, and 7 mmHg lower than women who had never used hormones ($p < 0.01$).

A review of papers published since 1960 and listed in MEDLINE found that risk of developing hypertension during HRT was very low.²⁵ Indeed, blood pressure was often even lowered with HRT treatment: these authors' study of 1397 hypertensive postmenopausal women showed that various transdermal HRT regimens lowered blood pressure by an average of 7 (systolic)/9 (diastolic) mmHg. Remarkably, only 30 patients (0.22%) developed increased blood pressure. A recent study carried out in 161 postmenopausal women with hypertension showed that systolic blood pressure remained unaffected and diastolic blood pressure was reduced during HRT administration.²⁶ This was an extension of an earlier cohort of 75 hypertensive menopausal women, where the introduction of HRT did not adversely affect mean blood pressure, despite a small increase in mean weight.¹¹² However, few high-risk participants were enrolled in the study, and the authors cautioned that blood pressure should be monitored regularly in hypertensive postmenopausal women receiving HRT.

The Women's Health Initiative (WHI) collected data on risk factors for CVD, including blood pressure, from 98,705 women aged 50 to 79 years, the largest multiethnic, best-characterized cohort of postmenopausal women ever studied.¹⁰⁸ WHI found that current hormone use was associated with a 25% greater likelihood of having hypertension compared to past use or no prior use. The estrogen-plus-

progesterin clinical trial component of WHI, a placebo-controlled trial of HRT (CEE 0.625 mg/day plus MPA 2.5 mg/day) in 16,608 postmenopausal women, found a small (~1 mmHg) increase in systolic blood pressure in the active treatment group compared to the placebo control group.^{109,110} Importantly, the trial found significant increases in risk of CVD, including coronary heart disease, stroke, and venous thromboemboli, as well as increased risk of invasive breast cancer in the HRT group. Following publication of the WHI results, consensus panels recommended against use of HRT for chronic disease prevention in postmenopausal women, and promotion and prescribing of HRT fell drastically. Prescriptions for the fixed dose combination of CEE plus MPA declined by 66%, and those for unopposed CEE fell by 33%¹¹³⁻¹¹⁵ (Figure 70-7). Transdermal hormone preparations were less affected, and transvaginal and low-dose preparations gained in usage.

The Estrogen Replacement Trial (ERT) in the WHI randomized 5310 postmenopausal women who had undergone hysterectomy to CEE (0.625 mg/day) and an equal number to placebo.¹¹¹ In the CEE group, there was a 1.1-mmHg increase from baseline in systolic blood pressure at 1 year that persisted throughout the 6.8 years of follow-up and was not seen in the placebo group. There was no difference in diastolic blood pressure between treatment groups. In contrast, administration of transdermal estradiol in physiologic doses to healthy postmenopausal women has been shown to lower nocturnal systolic, diastolic, and mean blood pressure when compared to placebo in studies that employed ambulatory blood pressure monitoring.¹⁰⁵⁻¹⁰⁷ The selective benefits of transdermal estradiol over oral conjugated estrogen on blood pressure may relate to delivery

Figure 70-7. Number of and percentage change in U.S. prescriptions for hormone therapy, January-June 2002 to January-June 2003 by formulation. (Redrawn from *JAMA* 2004;291:47-53.)

of lower, more sustained levels of circulating estrogen without a potentially proinflammatory first-pass effect in the liver.¹¹⁶

A mechanistic study that compared 6 months of treatment with transdermal estradiol (0.05 mg/day) plus oral MPA (2.5 mg/day) to oral CEE (0.625 mg/day) plus the same progestin dose in healthy postmenopausal smokers, demonstrated more consistent and pronounced reductions in blood pressure, total peripheral resistance, and circulating norepinephrine levels, and increases in endothelium-dependent vasodilation and vascular β -adrenoreceptor responsiveness in the transdermal estradiol group¹¹⁷ (Figure 70–8). These relationships held during both resting and stress conditions. Importantly, serum estrogen (estradiol and estrone) concentrations were lower and

more reflective of premenopausal values during transdermal estrogen treatment compared to CEE.

Whether the improvements in endothelial function and other determinants of vascular integrity observed in this short-term study translate to vasoprotection and prevention of atherosclerosis with transdermal estradiol is being tested in the ongoing Kronos Early Estrogen Prevention Study (KEEPS).¹¹⁸ KEEPS is evaluating the effectiveness of CEE (0.45 mg/day) or transdermal estradiol (50 μ g/week) in combination with cyclic oral micronized progesterone and placebo in preventing the progression of vascular disease, as assessed by ultrasound measurement of carotid intimal-medial thickness and electron beam tomographic measurement of coronary artery calcification in women aged 42 to 56 years who are within 36 months of their final menstrual period. The placebo-controlled Early versus Late Intervention Trial with Estradiol (ELITE) is testing whether oral 17 β -estradiol (1 mg/day) can slow the progression of vascular disease assessed by surrogate endpoints in postmenopausal women.¹¹⁹ ELITE is randomizing women according to their number of years since menopause (<6 vs. \geq 10) to receive either oral 17 β -estradiol (1 mg/day) or placebo; women with a uterus also receive vaginal progesterone gel (or placebo gel) for the last 10 days of each month. Carotid artery thickness by ultrasound is the primary endpoint of the trial. Surrogate endpoints for vascular disease will be measured in both trials in lieu of morbid and mortal CVD events, which are rare in the perimenopausal age group.

Remarkably, and in contrast to the other outcome trials of menopausal hormone therapy, the ERT component of the WHI showed no significant effect of unopposed CEE on coronary heart disease risk.¹¹¹ There was even a statistically significant time trend in coronary heart disease occurrence that suggested a modest benefit with long-term use. Possible explanations for the discrepancy in effects of the two hormone regimens (CEE plus MPA vs. unopposed CEE) that were tested in WHI include the deleterious effects of the progestin MPA, which has been shown in preclinical studies to negate the anti-inflammatory and vasoprotective effects of 17 β -estradiol in the setting of acute vascular injury,^{85–87} as well as differences in study populations (with or without hysterectomy) and baseline risk factors, duration of intervention, and follow-up, and play of chance.^{113,120}

Another surprising finding of the ERT component of the WHI is that CEE appears to have more favorable effects in younger than older women.¹¹¹ Estimated hazard ratios for CEE for several outcomes, including coronary heart disease, were lower for women in their fifties than for older women (Figure 70–9). Although the differences in hazard ratios across age groups were not statistically significant, the results are consistent with the concept, supported by both human and animal studies, that aging and prolonged hormone deprivation may attenuate the hemodynamic, anti-inflammatory, neurohormonal, and vasoprotective effects of estrogen.^{121–124} For example, HRT has been shown to alter hemodynamics (blood pressure, heart rate, cardiac output, systemic vascular resistance, and plasma norepinephrine levels) under resting and behavioral stress conditions in women who were within 5 years after menopause but not in

Figure 70–8. Change from pretreatment levels (post-treatment–pretreatment) in total peripheral resistance during baseline rest and stressors in women randomly assigned to transdermal estrogen ($n=34$, $p<0.05$), oral conjugated equine estrogen ($n=33$), or placebo ($n=21$). Orange bar=transdermal ($n=31$); green bar=oral ($n=30$); blue bar=placebo ($n=21$). $p<0.05$, $p<0.01$, $p<0.001$ versus placebo (**top**). Change from pretreatment levels (post-treatment–pretreatment) in the dose of isoproterenol required to decrease vascular resistance by 40% in women randomly assigned to transdermal estrogen ($n=29$), oral conjugated equine estrogen ($n=29$), or placebo ($n=21$). Orange bar=transdermal ($n=29$); green bar=oral ($n=29$); blue bar=placebo ($n=21$). $p<0.05$ versus placebo (**bottom**). (Redrawn from *Obstet Gynecol* 2004;103:169–80.)

Figure 70–9. Selected clinical outcomes by participant age and randomization assignment. Data are plotted as hazard ratios with error bars showing 95% confidence intervals. CEE, conjugated equine estrogen; CI, confidence interval. (Redrawn with permission from *JAMA* 2004;291:1701–12.)

those more than 5 years postmenopausal¹²¹ (Figure 70–10). HRT was associated with a major reduction (–8.5 mmHg) in blood pressure in women at less than 5 years postmenopause, but had no depressor effect in those who were five or more years postmenopausal. Systemic vascular resistance and plasma norepinephrine also trended downward in response to HRT only in women who were less than 5 years postmenopausal.

The positive studies of HRT and ERT on blood pressure and vascular function discussed previously were carried out in healthy women in the early years postmenopause; the studies that showed harmful or neutral effects of HRT or estrogen on CVD outcomes were carried out in older women (average age ≥ 60 years) who were many years postmenopause.^{109–111} The KEEPS and ELITE studies are testing the hypothesis that HRT initiated at the time of menopause will delay the onset of subclinical CVD, ultimately providing cardiovascular benefit to women.

The selective estrogen receptor modulators (SERMs) are agents that bind to estrogen receptors and produce estrogen-agonist effects in some tissues and estrogen-antagonist effects in others. Raloxifene, the most widely used SERM,

has favorable effects on markers of cardiovascular risk, including LDL cholesterol and fibrinogen, and therefore its effects on coronary outcomes have been tested in women with or at increased risk for coronary heart disease.¹²⁴ The Raloxifene Use for Heart Disease (RUTH) trial tested the effects of raloxifene 60 mg/d compared to placebo on coronary events (death from coronary causes, myocardial infarction, or hospitalization for an acute coronary syndrome) and invasive breast cancer in 10,101 postmenopausal women (mean age 67.5 years) with coronary heart disease or multiple CVD risk factors over a median 5.6 years of follow-up. Raloxifene treatment had no significant effect on the risk of primary coronary events, all-cause mortality, or total stroke, but was associated with increases in fatal stroke and venous thromboembolism. The authors did not comment on blood pressure. Their main conclusion was that the benefits of raloxifene in reducing risks of invasive breast cancer and vertebral fracture, demonstrated in RUTH, should be weighed against the increased risks of venous thromboembolism and fatal stroke. There is no evidence that raloxifene or any other SERM has a role in blood pressure management or CVD prevention.

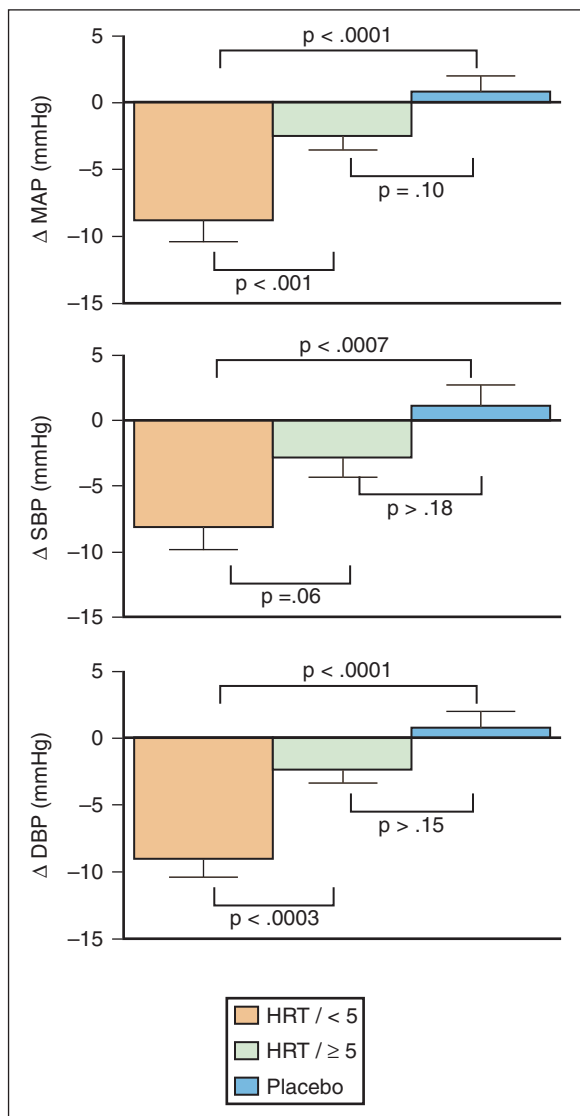

Figure 70–10. Change (Δ) in MAP, SBP, and DBP after 6 months of treatment in the three study groups (HRT-treated/postmenopausal <5 years; HRT-treated/postmenopausal \geq 5 years; placebo). Δ values are averaged across rest and task periods (cold pressor, active and passive speech, paper and computerized Stroop). The HRT/<5 group showed significantly greater decreases in MAP and DBP compared with the HRT/ \geq 5 group, which did not differ significantly from placebo. DBP, diastolic blood pressure; HRT, hormone replacement therapy; MAP, mean arterial pressure; SBP, systolic blood pressure. (Redrawn from *Am J Obstet Gynecol* 2004;190:1052–58.)

Recommendation

Pending the availability of data supporting the benefits of initiating HRT and/or ERT in the perimenopausal period in preventing CVD, caution is advised. Menopausal hormone treatment is not recommended for the prevention or treatment of CVD, and if administered for other indications, such as relief of hot flashes and vaginal dryness, use of the lowest effective dose for the shortest period of time needed to relieve menopausal symptoms is recommended. Unopposed estrogen treatment is recommended for women who have undergone hysterectomy; combined estrogen

plus low-dose progestin treatment is required for women with intact uteri to prevent unwanted uterine bleeding and endometrial carcinoma.

In relation to HRT use and BP management, we would suggest the following approach:

1. All clinicians should measure blood pressure before starting HRT.
2. In a normotensive postmenopausal woman, blood pressure should be measured annually following the start of HRT. One exception may be the use of Premarin, where a follow-up blood pressure measurement should be made at 3 months, due to a possible rare idiosyncratic rise in blood pressure.¹²⁵
3. In hypertensive menopausal women, blood pressure should at least be measured initially and thereafter at 6-month intervals, although if blood pressure is labile or difficult to control, three-month measurements should be done.
4. If a hypertensive woman on HRT demonstrates a rise in blood pressure, careful monitoring or observation and perhaps alteration or increase of antihypertensive treatment should be given.

Oral contraceptives

Combined estrogen–progestin oral contraceptives

Since the doses of estrogen and the types of progestin in combined oral contraceptive (COC) preparations have changed over time, published reports of the effects of COCs on blood pressure have been inconsistent and sometimes conflicting. However, the largest and most carefully conducted studies have concluded that use of COCs generally produces modest blood pressure elevation, with development of hypertension in a subgroup of women, and improvement of blood pressure upon withdrawal in most. Further, increases in blood pressure are major contributors to the adverse effects of COCs on the vasculature and to the increased prevalence of CVD, particularly stroke, among COC users.¹²⁶

A cross-sectional survey (Health Survey for England) of a sociodemographically representative sample of 3545 premenopausal English women, 892 of whom were current users of OCs (815 COCs and 77 progestin-only contraceptives [POCs]), revealed that mean blood pressures adjusted for age were significantly higher among COC users (125/70 mmHg) than among nonusers (123/68 mmHg, $p < 0.001$)¹²⁷ (Figure 70–11). Interestingly, blood pressures tended to be lower among POC users than among nonusers, although the numbers were small and the difference statistically nonsignificant. Blood pressure differences between users and nonusers tended to increase with age such that there was a 4-mmHg excess in systolic blood pressure in OC users aged 35 years and older, a number compatible with increased CVD risk at the population level. The results were not altered by adjustment for body mass index (lower among OC users), alcohol intake (higher among OC users), physical activity, and antihypertensive treatment.

The Health Survey for England did not collect detailed information about the formulations and durations of current and past OC use, making it impossible to assess the impact of estrogen dose on blood pressure. However, a contem-

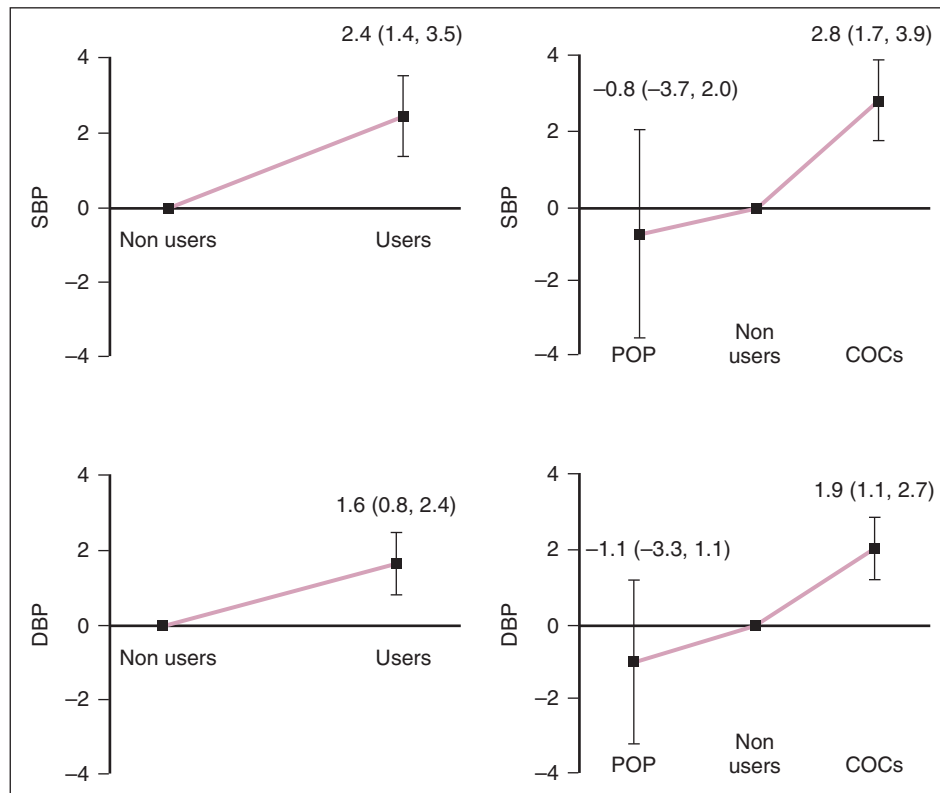

Figure 70-11. Differences in blood pressure (mmHg) between oral contraceptive users and nonusers, adjusted for age, body mass index, smoking, alcohol consumption, physical activity and treatment for hypertension. Confidence interval in parentheses. COCs, combined oral contraceptives; DBP, diastolic blood pressure; POP, progestogen-only pills; SBP, systolic blood pressure. (Redrawn from *J Hypertens* 1997;15:1063-68.)

poraneous study of OC use in the United Kingdom showed that more than 90% of users of COCs used products containing less than 35 μg of estrogen,¹²⁸ suggesting that the blood pressure effects observed in the Health Survey for England related mainly to low-dose estrogen contraceptives. The authors concluded that even low-dose COCs constitute a health risk, and recommend that women have their blood pressures checked before they receive COCs and that their blood pressures be monitored on a regular basis during COC use. For women with preexisting hypertension, POCs were recommended.

The Nurses' Health Study II (NHS II), a prospective cohort study of 68,297 premenopausal women free of CVD, documented the magnitude of the problem of OC-induced hypertension in the United States. The multivariate risk for the development of hypertension among current users of OCs compared with never-users was 1.8 (confidence interval [CI] 1.5-2.3).¹³ Absolute risk was small, however (only 41.5 cases of hypertension per 10,000 person-years could be attributed to OC use), and risk decreased quickly with cessation of OC use (past users had only a slightly increased [relative risk 1.2, CI=1.0-1.4] risk compared with never-users).

Importantly, however, there is evidence that prolonged use of OCs and continuation of OC treatment in women with established hypertension lead to increased prevalence and severity of hypertension and progressive difficulty in

blood pressure control.^{13,129} In a prospective cross-sectional study of 171 women who were referred to a specialized hypertension clinic, of whom 66 were current users of OCs, 26 were users of other contraceptive methods, and 79 were nonusers of contraception, OC use was associated with increased diastolic blood pressure and poor blood pressure control, independent of age, body mass index, and anti-hypertensive drug treatment. Diastolic blood pressure was significantly higher in OC users (100 ± 16 mmHg) than in those using other contraceptive methods (93 ± 15 mmHg) and in nonusers (93 ± 14 mmHg). Systolic blood pressure was also higher in OC users, although the difference was not statistically significant. Blood pressure control (<140/90 mmHg) was achieved in only 17% of OC users, versus 35% of users of alternate methods and 32% of nonusers ($p=0.046$ for trend), and a higher proportion of OC users had stage 2 or 3 hypertension according to JNC VI (Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, 6th report) criteria. These differences in blood pressure control could not be related to a lower intensity of antihypertensive treatment for OC users. Finally, there was a significant positive association between duration of OC use, adjusted for age, and levels of both systolic and diastolic blood pressure, supporting the findings of the Nurses' Health Study II, in which the cohort using OC for more than 6 years had an increased risk of developing hypertension (Hazard

ratio 2.1, CI=1.6–27).¹³ In this cross-sectional study, information about formulation of the OC used was available from 60% of participants: 62% of these used low-dose (≤ 30 μg estrogen) and 38%, high-dose (≥ 50 μg estrogen) OCs. Use of POCs was not reported. This study lends further support to the recommendation that POCs or alternative contraceptive methods be used rather than COCs in women with established hypertension.

COC use has been associated with increases in blood pressure, plasma renin activity, and aldosterone excretion, and these elevated blood pressure and hormone levels have been shown to normalize within weeks of COC withdrawal. In the absence of appropriate control data from COC users who did not develop hypertension, these findings suggest, but do not prove, that the hypertension-promoting effects of COCs are related to activation of the renin-angiotensin-aldosterone system and attendant alterations in intrarenal hemodynamics and salt and water handling.¹³⁰ Alternative mechanisms that have been adduced to explain the pressure effects of COCs include increases in sympathetic nervous system activity¹³¹ and insulin resistance,¹³² and alterations in hemodynamics¹³³ and adrenal cortical function.¹³⁴ Definitive evidence supporting these putative mechanisms is lacking, and mechanistic research in the area is hampered by the low prevalence of oral contraceptive-induced hypertension, the difficulty of carrying out controlled experiments in human subjects, and the unavailability of suitable animal models.

Progestin-only oral contraceptives

The finding of the Health Survey for England that POCs do not increase blood pressure confirmed the observations of previous investigators.^{135,136} Further, it has been shown that the type and dose of progestin included in COCs can influence the effect of the estrogenic component on blood pressure.^{137,138} A review of published literature (PUBMED and Cochrane database), which included three prospective controlled trials and one cross-sectional survey published in the period 1970–1994,^{127,135,136,139} revealed no significant association of high blood pressure with use of POCs (“minipills”) for up to 2 to 3 years of follow-up.¹⁴⁰ This neutral effect on blood pressure was seen with some POCs even among women who had developed blood pressure elevations while taking COCs.^{136,141} Further, the second-generation progestin norgestrel has been reported to reduce blood pressure in women with a history of hypertension, resulting in a recommendation that it be used in women with a history of blood pressure elevation with COC or long-acting progestin use, as well as women with preexisting hypertension.^{136,139,140} Importantly, there is no randomized controlled trial designed to examine the effect of POCs on blood pressure. Thus, the highest level of evidence on this important issue is lacking.

It is important to note that various progestins have differential effects on blood pressure and other CVD risk factors. For example, norethisterone, a first-generation progestin that was developed in the 1960s, has been shown to elevate blood pressure in women with a history of COC-induced hypertension¹³⁶ and levonorgestrel (Norplant) implants have been reported to elevate blood pressure and increase the risk of developing borderline hypertension (now referred

to as prehypertension).^{142–144} The third-generation progestins, including desogestrel, gestodene, and norgestimate, which came into use in Europe in the 1980s and in the United States in the 1990s, were developed to minimize the androgenic side effects of the earlier progestins, including acne, insulin resistance, sodium retention, and adverse effects on blood pressure and lipoproteins. They contain reduced doses and different types of progestins from earlier preparations.¹⁴⁵

Drospirenone, a novel fourth-generation progestin, contains a 17 α -spironolactone group that confers a mineralocorticoid antagonist effect similar to that described for progesterone.^{146–149} Drospirenone is eight times as potent a mineralocorticoid receptor antagonist as spironolactone, has antiandrogenic effects, and resembles natural progesterone more closely than conventional synthetic progestins.^{148,149} Thus, a 3-mg drospirenone dose is equivalent to 25 mg of spironolactone, the usual antihypertensive dose of the latter agent. Compared to placebo, drospirenone in a dose of 2 mg/day has been shown to effect a natriuresis and weight loss in normal menstruating young women.¹⁴⁶ A combination of 3 mg of drospirenone plus 30 μg EE, currently available as an oral contraceptive, reduces blood pressure and body weight and effects a negative sodium balance when compared to COC preparations containing 30 μg EE plus 150 μg levonorgestrel, a synthetic progestin that has no mineralocorticoid receptor antagonist activity.¹⁵⁰ Thus, drospirenone effectively counteracts the sodium-retaining and aldosterone-stimulating effects of EE, suggesting that it may be useful as an antihypertensive agent.^{149,150}

The combination of drospirenone plus 17 β -estradiol has been shown in randomized placebo-controlled trials to be effective in lowering blood pressure in hypertensive postmenopausal women.^{151–154} The 3 mg of drospirenone plus 1 mg of 17 β -estradiol combination reduced blood pressure by $\sim 9/5$ mmHg in postmenopausal women with stage 1 hypertension who were being treated with an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker for hypertension.^{151,152} Further, in a larger (213 participants) 12-week placebo-controlled study in postmenopausal women with stage 1 hypertension, treatment with 3 mg of drospirenone plus 1 mg of 17 β -estradiol reduced clinic blood pressure by 14/8 mmHg compared to 7/3 mmHg for the placebo ($p < 0.0001$).¹⁵³ In a subgroup of 43 women subjected to ambulatory blood pressure monitoring, 24-hour blood pressure fell by 9/4 mmHg (vs. 2/2 mmHg with placebo, $p = 0.002/0.07$). Potassium homeostasis was evaluated in this study because mineralocorticoid receptor blockade has been associated with significant increases in serum potassium.^{150,155} No significant changes from baseline in potassium levels or in the incidence of hyperkalemia were noted with drospirenone treatment.

Most recently, a rigorous dose-ranging study of the drospirenone–17 β -estradiol combination compared to estradiol alone and placebo has been carried out in 750 postmenopausal women with stage 1 to stage 2 hypertension using both ambulatory and clinic blood pressure monitoring.¹⁵⁴ Significant dose-dependent decreases in systolic and diastolic blood pressure in clinic and on 24-hour ambulatory recording were seen with the 2- and 3-mg doses of drospirenone plus 17 β -estradiol; the 1-mg dose, estradiol

alone, and placebo were ineffective (Figure 70–12). The treatment-induced blood pressure reductions persisted throughout the 24-hour dosing period and were similar in magnitude to those previously reported for the selective mineralocorticoid receptor antagonist eplerenone. There were no significant changes from baseline in potassium in any treatment group. Given the proven efficacy of the drospirenone–estradiol combination in treatment of vasomotor symptoms associated with menopause and prevention of endometrial bleeding/hyperplasia,¹⁵⁶ it appears to have advantages in the treatment of hypertensive postmenopausal women. A caveat in this regard is the possibility of precipi-

tating hyperkalemia, particularly in those with renal insufficiency and on concomitant angiotensin-converting enzyme inhibitor and/or angiotensin receptor blocker treatment. Longer-term safety studies will likely be needed to clarify this issue.¹⁴⁹

Recommendation

COCs have a favorable risk–benefit ratio for healthy women who are free of CVD and major CVD risk factors, including hypertension.¹⁸ Both the WHO and ACOG recommend use of COCs containing low doses of estrogen (<35 µg EE by WHO; <50 µg EE combined with the “lowest progestin

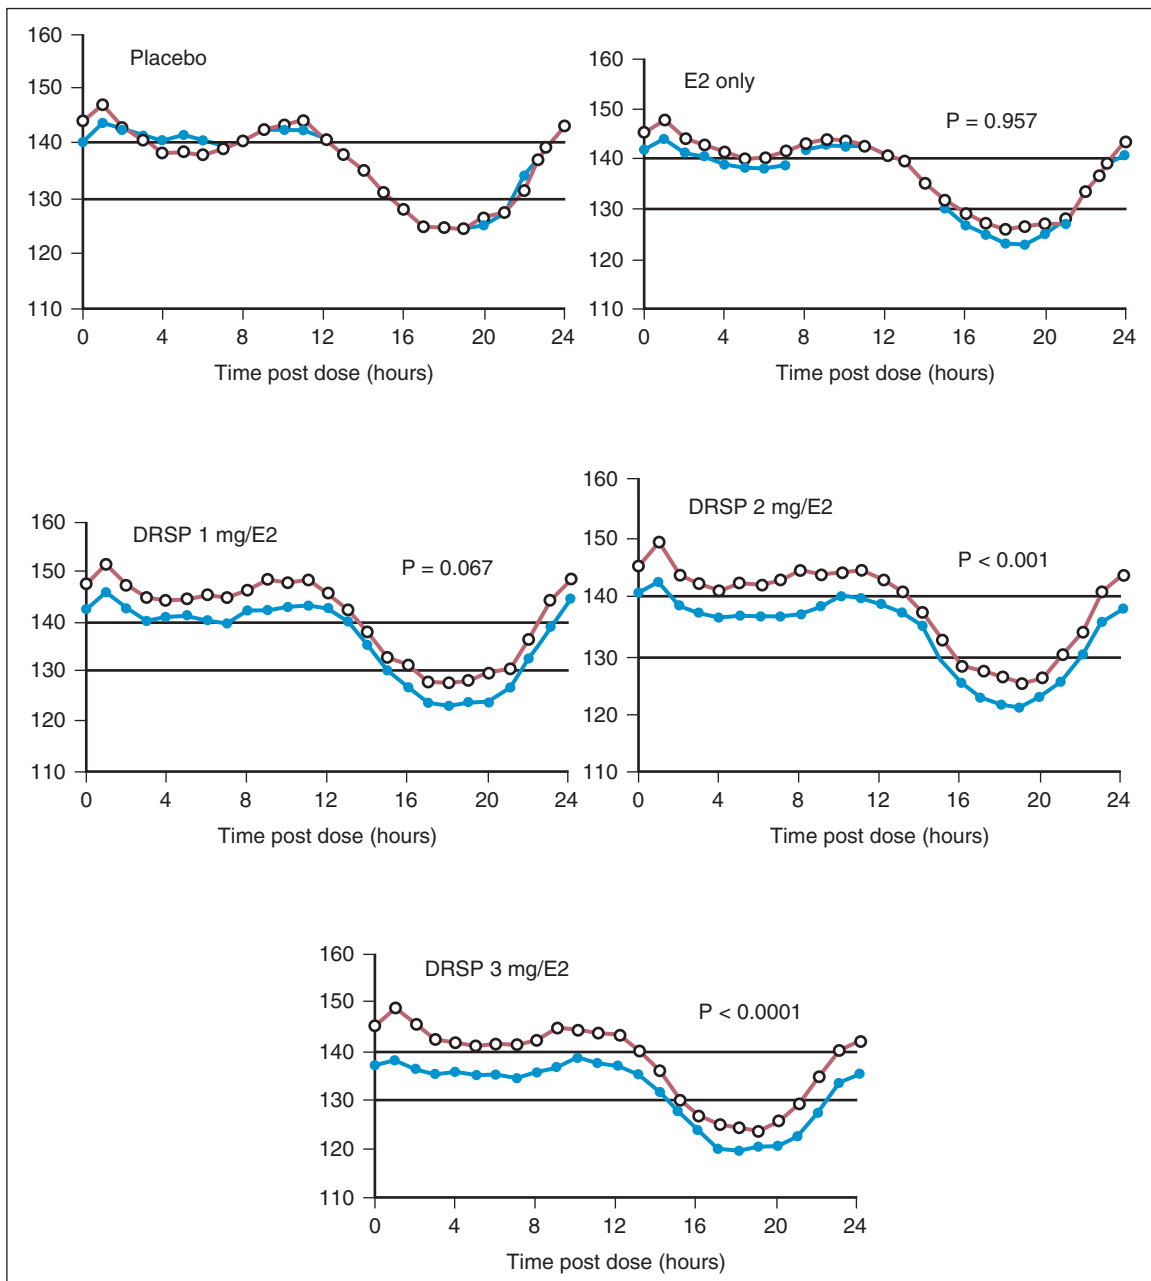

Figure 70–12. Effects of DRSP/E2 versus placebo on the coprimary endpoint of ambulatory systolic blood pressure over 24 hours at baseline and after 8 weeks of double-blind therapy that included placebo, E2 alone, 1-mg DRSP/E2, 2-mg DRSP/E2, and 3-mg DRSP/E2. Baseline period is the \circ — \circ , and treatment period is the \bullet — \bullet . (Redrawn from *Hypertension* 2006;48:246–53.)

dose” by ACOG) for these women.^{18,19,20,157} Progestin-only methods, including POCs, depot medroxyprogesterone acetate (MPA), and intrauterine devices are recommended as safer than COCs for women with established CVD, at high risk for CVD, migraine headaches with focal neurologic signs, or history of thromboembolic disease.¹⁹ Table 70–2 summarizes current WHO recommendations with comments on the evidence base for them.²⁰ ACOG recommendations are similar.¹⁹

CONCLUSIONS AND PERSPECTIVES

Ovarian hormones play an important role in women’s health, providing the most reliable and convenient means of contraception and of relieving menopausal symptoms. Hormone therapy also has other benefits, including the regulation of menstrual irregularities and relief of dysmenorrhea in menstruating women, and prevention of vulvovaginal atrophy and osteoporosis/fractures in postmenopausal women. Further, natural estrogens, principally 17 β -estradiol and natural progesterone (but not synthetic progestins), have biological effects that protect the vasculature from oxidative and inflammatory injury and prevent cardiovascular disease. These functions have been adduced by some to account for the 10- to 15-year delay in presentation of clinical cardiovascular disease and events in women compared to men.

Despite these impressive benefits, hormone therapy, both in the form of oral contraceptives and menopausal hormone treatment, poses substantial risks, particularly for women with preexisting cardiovascular disease or multiple cardiovascular risk factors. Principal among these conditions are history of ischemic heart disease, cerebrovascular, peripheral arterial and renal disease, deep-vein thrombosis/pulmonary embolism, hypertension, smoking, diabetes, and older age.

To minimize the risks of oral contraceptives, while at the same time preserving their benefits for the majority of younger, lower-risk women, guidelines specify that combined oral contraceptives should contain low doses of estrogen

(<35 or <50 μ g of ethinyl estradiol) and the “lowest progestin dose” (Table 70–1).^{19,20} Recommendations for use of combined oral contraceptives are then stratified according to the risk status of the woman. For example, ACOG guidelines comment that for healthy nonsmoking women, it is appropriate to continue use of combined oral contraceptives until age 50 to 55 years, after weighing the risks and benefits.¹⁹ Risk of venous thromboembolic disease and atherosclerotic cardiovascular disease with combined oral contraceptive use increases rapidly after age 35 to 40, particularly in the presence of multiple cardiovascular risk factors, and is unacceptable for some, such as smokers over age 35 years and those with stage 2 hypertension (blood pressure >160 mmHg systolic or >100 mmHg diastolic) (Table 70–1). Progestin-only oral contraceptives, depot MPA injections, or the levonogestrel intrauterine system provide safe alternatives to combined oral contraceptives for these high-risk women.

Despite evidence from observational studies that estrogen treatment is associated with reduced risk of coronary heart disease in postmenopausal women, menopausal hormone therapy has lost favor in recent years because of reports of increased stroke and coronary heart disease risk in randomized controlled trials. Guidelines recommend that menopausal hormone therapy not be used for the prevention of cardiovascular disease and, if used for the treatment of menopausal symptoms, that it be administered in the lowest doses and for the shortest time period needed to achieve the desired clinical effect.³² However, estrogens, particularly 17 β -estradiol, have been shown to have anti-inflammatory, vasoprotective, and favorable hemodynamic effects when administered to healthy women in the early postmenopausal years. Clinical trials are testing whether regimens of estrogen with or without natural progesterone are vasoprotective and effective in preventing atherosclerosis when administered to women within a few years postmenopause.^{118,119} The combination of drospirenone, a progestin with mineralocorticoid receptor antagonist effects plus 17 β -estradiol has been shown to lower blood pressure, and is being evaluated as menopausal hormone therapy in hypertensive women.^{146,154}

Drug-Induced Hypertension

Ehud Grossman and Franz H. Messerli

Key Findings

- A variety of therapeutic agents and chemical substances can induce transient or sustained hypertension, exacerbate well-controlled hypertension, or antagonize the effects of antihypertensive therapy.
- Careful evaluation of a patient's drug regimen and exposure to chemicals may identify chemically induced hypertension.
- Diagnosis of drug-induced hypertension may obviate the need for unnecessary, costly, and potentially dangerous evaluations, and prevent the need for lifelong antihypertensive therapy.
- When drug- or chemical-induced hypertension is identified, discontinuation of the causative agent should be recommended.
- When it is not possible to avoid chemical agents that cause hypertension, institution of appropriate antihypertensive treatment is indicated.

Most patients with hypertension have essential hypertension or well-known forms of secondary hypertension such as renal disease or renal artery stenosis or common endocrine diseases (hyperaldosteronism or pheochromocytoma). Physicians are less aware of rare and unusual forms of hypertension such as drug-induced hypertension. To secure a more complete diagnosis, an accurate and detailed medical history should include specific inquiries concerning foods, poisons, and medications that patients do not consider to be drugs, and therefore frequently omit from their history. Identification of the intake of these substances is important because their elimination can obviate the need for unnecessary, costly, and potentially dangerous evaluations, treatments, or both.^{1,2}

Hypertension related to drugs and other substances represents an important modifiable and often unnoticed source of secondary hypertension (Table 71-1). This chapter reviews therapeutic agents or chemical substances that may elevate blood pressure (BP) by different mechanisms of action.

STEROIDS

Hypertension occurs in about 20% of patients treated with high doses of synthetic corticosteroids. Oral cortisol increases BP in a dose-dependent fashion. At a dose of 80 to 200 mg/day, the peak increases in systolic pressure is

of the order of 15 mmHg. Increased BP is usually apparent within 24 hours.² Glucocorticoid-induced hypertension is more common in elderly patients, and in patients with a positive family history of essential hypertension. Hemodynamically, ACTH and adrenocortical steroids increase BP through increasing cardiac output, with little change in peripheral resistance.¹ The mechanism of glucocorticoid-induced hypertension remains uncertain and it seems to be multifactorial. The mechanisms of action of the various steroids are related to their glucocorticoid or mineralocorticoid effects, which include retention of salt and water (mineralocorticoid effect), redistribution of body fluid with increase in plasma volume and cardiac output (glucocorticoid effect), increased peripheral vascular responsiveness to vasoactive agents (mineralocorticoid and glucocorticoid effects), and activation of the central and peripheral nervous systems.¹ Of note, mineralocorticoid activity is not essential for steroids to induce an increase in BP. It has been shown that using synthetic steroids with glucocorticoid activity and little or no mineralocorticoid activity produced no effects on body weight, urinary sodium excretion, plasma volume and hematocrit, but increased BP significantly.³ Glucocorticoids modify multiple intracellular and extracellular biochemical processes but have limited direct effects on BP. In the proximal tubule, glucocorticoids do not induce a change in sodium transport directly but serve to enhance the activity of many existing pathways and transporters. Conversely, the distal tubule and collecting duct are responsive to glucocorticoids. Glucocorticoids are able to bind to mineralocorticoid receptors (MRs) and glucocorticoid receptors (GRs) and stimulate sodium reabsorption. Protein binding of the glucocorticoids in serum and the metabolic activity of local 11 β -hydroxysteroid dehydrogenase (11 β -HSD) limit access of these steroids to both MRs and GRs. Inhibition of 11 β -HSD with licorice or abnormality of this enzyme may enhance access of steroids to both MRs and GRs thereby causing BP elevation.⁴ Recent evidence suggests that the nitric oxide system also plays a key role in the hypertension produced by glucocorticoids. Glucocorticoid actions at various sites in the nitric oxide synthase (NOS) pathway may result in elevated BP. These include: alterations in L-arginine availability or transport, NOS2 and NOS3 downregulation, reduced cofactor bioavailability, NOS uncoupling, a concomitant elevation in reactive oxygen species and removal of nitric oxide (NO) from the vascular environment, alterations in whole body antioxidant status, and erythropoietin-induced resistance to NO.⁵ Inhaled corticosteroids during

LIST OF MEDICATIONS THAT MAY INCREASE BLOOD PRESSURE

Ingredient	Clinical Use	Notes
Glucocorticoid	Replacement therapy, rheumatic disease, collagen disease, dermatologic disease, allergic state, ophthalmic disease, inflammatory bowel disease, respiratory disease, hematologic and neoplastic disease, nephropathies	Dose-dependent, sustained increase mainly in systolic BP
Mineralocorticoid		Dose-dependent, sustained increase in BP characterized by hypokalemia, metabolic alkalosis, and suppressed plasma renin activity and aldosterone levels
Licorice	Flavoring and sweetening agent	
Carbenoxolone	Ulcer medication	
9-alpha fluoroprednisolone	Skin ointments, antihemorrhoid cream	
9-alpha fluorocortisol	Ophthalmic drops, and nasal sprays	
Ketoconazole	Antimycotic	
Sex Hormones		
Estrogen	Contraception, replacement therapy	Mild, sustained BP elevation, more common in premenopausal women. Severe hypertension has been reported.
Progesterone	Prostate cancer	
Androgens	Anabolic effect	
Danazol (semisynthetic androgen)	Endometriosis, hereditary angioedema	Mild dose-dependent, sustained increase in systolic BP
Anesthetics, Narcotics		
Ketamine hydrochloride	Anesthetic agent	Transient severe increase in BP has been reported
Fentanyl citrate	Narcotic analgesic and anesthetic agent	
Scopolamine	Preanesthetic medication, motion sickness	
Naloxone hydrochloride	Opioid overdose	Transient BP elevation
Drugs Affecting Sympathetic Nervous System		
Phenylephrine hydrochloride	Upper respiratory decongestant, ophthalmic drops	Dose-dependent, sustained increase in BP
Dipivalyl adrenaline hydrochloride	Ophthalmic drops	Severe HT has been reported
Epinephrine (with β blocker)	Local anesthetic, anaphylactic reaction bronchodilatation, decongestant antihemorrhoidal treatment	
Phenylpropanolamine	Anorectic, upper respiratory decongestant	
Pseudoephedrine hydrochloride	Upper respiratory decongestant	
Tetrahydrozoline hydrochloride	Ophthalmic vasoconstrictor drops	
Naphazoline hydrochloride	Ophthalmic vasoconstrictor and nasal decongestant drops	
Oxymetazoline hydrochloride	Upper respiratory decongestant drops	
Caffeine	Analgesia, vascular headache, beverages	Acute transient increase in BP
Herbal products	Complementary and alternative medicine	Mainly relate to dietary supplements that contain ephedra alkaloids
Cocaine	Local anesthetics	Transient severe increase in BP especially when used with β -blockers
Antiemetic Agents		
Metoclopramide	Antiemetic	Transient increase in BP in association with cancer
Alizapride	Antiemetic	
Prochlorperazine	Antiemetic	

LIST OF MEDICATIONS THAT MAY INCREASE BLOOD PRESSURE—cont'd		
Ingredient	Clinical Use	Notes
Other Agents		
Yohimbine hydrochloride	Impotence	Acute, dose-dependent increase in BP
Sibutramine	Weight loss	
Clozapine	Antipsychotic agent	
Glucagon	Prevent bowel spasm	Only in patients with pheochromocytoma
Physostigmine	Reverse anticholinergic syndrome	
Ritodrine hydrochloride	Inhibition of preterm labor	Hypertensive crisis has been reported
Antidepressant Agents		
MAOIs	Antidepressive agents	Mainly with sympathomimetic amines and with certain foods containing tyramine
Selegiline	Used mainly for Parkinson's disease	
Tricyclic antidepressants	Antidepressive agent	More common in patients with panic disorders
Buspirone	Anxiolytic agent	Mild dose-dependent increase in BP
Fluoxetine	Antidepressive agents	In combination with selegiline
Thioridazine hydrochloride	Psychotic and depressive disorders	Massive overdose may cause severe HT
Carbamazepine	Bipolar depression and seizures	
Lithium	Manic depressive illness	Acute intoxication can cause severe HT
Immunosuppressive Agents		
Cyclosporine A	Immunosuppressive agent, prophylaxis of organ rejection, autoimmune disease, dermatologic disorders	Dose-dependent mild to moderate increase in BP. Severe HT has been reported
Tacrolimus	Prophylaxis of organ rejection	Produces less hypertension than cyclosporine A
Rapamycin	Prophylaxis of organ rejection	Produces little BP increase
Antineoplastic Agents		
Alkylating agents	Antineoplastic agent	
Paclitaxel	Antineoplastic agent	
Cis-diamminedichloroplatinium	Antineoplastic agent	Only during intra-arterial administration
Recombinant human erythropoietin	Anemia of renal failure	Dose-related, mild increase in BP. Hypertensive crisis with encephalopathy has been reported
Alcohol	Beverage	Dose-dependent, sustained increase in BP
Disulfiram	Management of alcoholism	Slight increase in BP. Severe HT may occur in alcoholic-induced liver disease
NSAIDs	Rheumatic disease	Mild dose-dependent increase in BP
Heavy Metals		
Lead	Industry	
Cadmium	Industry	The association between cadmium exposure and hypertension is equivocal
Arsenic	Industry	
Bromocriptine mesylate	Suppression of lactation, and prolactin inhibition in prolactinoma	Severe HT with stroke has been reported following the use for suppression of lactation
Venoms	Sting of scorpion	
Amphotericin B	Fungal infections	
Protease inhibitor	Anti-HIV treatment	

BP, blood pressure; HT, hypertension.

Table 71–1. List of Medications That May Increase Blood Pressure

pregnancy do not increase the risk of pregnancy-induced hypertension or preeclampsia.⁶

Cessation of steroid therapy usually leads to normalization of BP. However, there is one report that reduction in steroid therapy in nine patients with steroid-requiring asthma was associated with a rise in BP. In these patients, BP elevations were resistant to diuretic therapy, but responded rapidly to angiotensin-converting enzyme inhibitor.¹

Certain exogenous compounds such as 9- α fluoroprednisolone and 9- α fluorocortisol have mineralocorticoid activity. Other compounds such as licorice and carbenoxolone have mineralocorticoid-like activity by inhibition of the 11 β -HSD enzyme. Excess consumption of these compounds may produce arterial hypertension characterized by increased exchangeable sodium and blood volume, hypokalemia with metabolic alkalosis, and suppressed plasma renin and aldosterone levels.¹ Prolonged use of high-dose ketoconazole may alter enzymatic degradation of steroids leading to mineralocorticoid-related hypertension.¹ Skin ointments, antihemorrhoidal preparations, ophthalmic drops, and nasal sprays may contain substances with mineralocorticoid activity (9- α fluoroprednisolone) and sympathetic amines. Their excessive use may even cause severe arterial hypertension.¹ Discontinuation of these substances is recommended to lower BP. However, when steroid treatment is mandatory, a diuretic is the drug of choice, since volume overload is the main mechanism by which steroids raise BP; careful monitoring of potassium is necessary.

SEX HORMONES

Oral contraceptives induce hypertension in approximately 5% of users of high-dose pills that contain at least 50 μ g of estrogen and 1 to 4 mg of progestin.² There is a two- to three-fold increased risk of hypertension in women taking oral contraceptives compared with age-matched controls using alternative methods of contraception.² This risk seems to correlate with the estrogen and progesterone dose, but even the newer generations of oral contraceptive drugs with lower doses of estrogen tend to increase the risk of hypertension.² The increased pressure is usually minimal; however, severe hypertensive episodes, including malignant hypertension, have been reported. Women with a history of high BP during pregnancy, those with a family history of hypertension, cigarette smokers, obese, black, or diabetic women, and those with renal diseases may respond with a greater increase in BP.¹ The risk of hypertension decreased quickly with cessation of oral contraceptives, and past users appeared to have only a slightly increased risk. Several mechanisms have been postulated to be involved in BP increase associated with oral contraceptive drugs, including activation of the renin-angiotensin-aldosterone system; the latter is activated by estrogens via amplified synthesis of angiotensinogen in the liver, thus resulting in increased intracellular volume and cardiac output, and as a consequence, hypertension.² The oral contraceptive effect probably relates to the exogenous administration of high levels of estrogens and/or progestones in women who already have “physiologically normal”

levels of these hormones, while in postmenopausal women, natural hormone levels are low, and (low-dose) hormone replacement therapy (HRT) merely restores the hormone levels to physiologic levels. The pressor effects of estrogens in oral contraceptives and in HRT are therefore likely to be different.²

Postmenopausal estrogen replacement therapy (ERT) has minimal effect on arterial pressure in normotensive women, and rare cases of estrogen-induced hypertension represent an idiosyncratic reaction to ERT.² Recently the use of ERT was associated with increased cardiovascular morbidity and mortality, and therefore it is not routinely recommended.^{7–10} Cessation of oral contraceptives is recommended when hypertension has developed.

Men receiving estrogen for the treatment of prostate cancer may also exhibit an increase in BP.¹ Danazol, a semisynthetic androgen that is used in the treatment of endometriosis and hereditary angioedema, was reported to induce hypertension due to fluid retention.¹

ANESTHETICS AND NARCOTICS

Ketamine hydrochloride, widely used as an anesthetic in children, has been reported to severely increase arterial pressure.¹ A case of hypertension and pulmonary edema triggered by ketamine in a pregnant woman with a history of cocaine abuse has also been reported.¹ The mechanism by which ketamine hydrochloride increases BP is not completely understood. In one study,¹ clonidine—which suppresses sympathetic activity—was found to be effective in reducing the hypertensive response to ketamine.

High-dose fentanyl used as an anesthetic agent in valvular and coronary heart surgery may increase BP.¹ A case is reported in which hypertensive crisis occurred in a patient anesthetized with high-dose fentanyl-diazepam-oxygen.¹

Scopolamine, a belladonna alkaloid, has a central anticholinergic activity. A case is reported in which 0.1 mg of scopolamine intravenously administered during surgery induced marked hypertension in a patient with type 4 hereditary sensory and autonomic neuropathy.¹ The simultaneous use of vasoconstrictors (felypressin) with topical cocaine can result in severe hypertension.¹ Hypertensive responses to naloxone (opiate antagonist), especially during attempted reversal of narcotic-induced anesthesia in hypertensive patients, have also been reported. Naloxone seems to acutely reverse the antihypertensive effects of clonidine, and can thereby cause an acute hypertensive emergency.¹ Naloxone also partially ameliorates the hypotension associated with various forms of shock. Endogenous opioids appear to regulate BP in some hypertensive patients, and antagonizing their effect may increase BP.²

DRUGS AFFECTING THE SYMPATHETIC NERVOUS SYSTEM

Agents that directly activate the sympathetic nervous system

Phenylephrine, a sympathomimetic agent with a potent vasoconstrictor activity, has been reported to severely

increase arterial pressure following its administration in an ophthalmic solution.¹ The most important factor in the development of hypertension from topically applied phenylephrine is the total dose administered; it appears that infants, because of their immature degradation pathways, are more susceptible than adults.¹ Recently pulmonary edema was described in a child who developed severe hypertension after the inadvertent administration of a large dose of topical nasal phenylephrine, followed by the beta-adrenergic antagonist esmolol.¹¹ Dipivalyl adrenaline, an adrenaline prodrug used topically in the management of chronic simple glaucoma, can also increase BP in treated hypertensive patients.¹

The concomitant use of sympathomimetic agents and β -blockers can severely increase arterial pressure because of unopposed α -adrenergic vasoconstriction. Severe hypertensive crises were reported in a hypertensive patient treated with propranolol after subcutaneous epinephrine injection for anaphylactic reaction; after administering a local anesthetic containing epinephrine to a patient previously treated with propranolol, and after administration of levonordefrin during dental treatment to a patient receiving propranolol.¹ In diabetic hypertensive patients treated with both insulin and propranolol, hypoglycemic episodes may be accompanied by severe hypertension due to excessive vasoconstriction mediated by α -receptors and rising epinephrine levels.¹ If β -antagonists must be used in insulin-dependent diabetic patients, β_1 -selective antagonists appear to be the better choice. If hypertensive episodes occur, arterial pressure can be reduced by α -receptor antagonists.¹ In a prospective study, hypoglycemia was induced by insulin injection in diabetic patients who were previously treated with a placebo, atenolol, or propranolol.¹ Arterial pressure increased significantly in the group treated with propranolol, strengthening the concept that the β -receptor selectivity of these agents determines the change in arterial pressure.

Over-the-counter drugs

Most nonprescription anorectics contain combinations of an antihistamine and an adrenergic agonist (usually phenylpropanolamine [PPA], ephedrine, pseudoephedrine, or caffeine). All act by potentiating presynaptic norepinephrine release and by directly activating adrenergic receptors. Known toxic effects of these substances include hypertension, tachycardia, ventricular ectopy, agitation, psychosis, and seizure.¹ Alpha-adrenergic intoxication induced by nasal decongestant and cough medications containing massive doses of oxymetazoline hydrochloride, phenylephrine hydrochloride, and ephedrine hydrochloride has been reported to result in severe hypertension, cardiomegaly, and congestive heart failure in a 34-year-old man.¹ Severe hypertensive crisis was reported in a young man after ingestion of seven Trinalin tablets (120 mg of pseudoephedrine and 1 mg of azatadine sulfate per tablet). Labetalol given intravenously was very effective treatment.¹ PPA is the active ingredient in most diet aids and many decongestant agents, and is also used as a substitute for amphetamine. In a recent meta-analysis, Salerno et al.¹² showed that PPA caused a small, but significant increase in systolic BP.

The effect was more pronounced with shorter-term administration, higher doses of medication, and immediate-release formulations. Excessive doses may result in severe hypertension and, in rare instances, hypertensive encephalopathy, intracerebral hemorrhage, and death.¹ Of note, PPA was recently withdrawn from the market in the United States and is therefore no longer available.

Agents that indirectly activate the sympathetic nervous system

Caffeine

Caffeine can acutely and transiently increase BP by increasing peripheral resistance.¹ The reaction to caffeine is more pronounced in males, in those with a positive family history, and in African-American subjects.^{1,2,13} Several investigators showed by using ambulatory BP monitoring that caffeine may increase BP levels.^{13,14} Caffeine may cause persistent BP effects in persons who are regular consumers, even when daily intake is at moderately high levels.¹⁵ In a recent meta-analysis, Noordzij et al.¹⁶ found that regular caffeine intake increases BP; however, when ingested through coffee, the BP effect of caffeine is small. In one case report, intravenous caffeine, used to increase the length of seizure during electroconvulsive therapy, caused hypertension and tachycardia.¹ The effect of caffeine on the cardiovascular system is not homogenous. In a recent study, Sudano et al.¹⁷ showed that in nonhabitual coffee drinkers, coffee enhanced the cardiovascular response to mental stress with an additional increase in systolic BP, whereas in habitual drinkers, the response is blunted.¹⁷ It seems that strategies for encouraging reduced dietary levels of caffeine should be considered.¹⁸ Of note, concomitant medications, such as monoamine oxidase inhibitors (MAOIs), antihypertensive drugs, oral contraceptives, and nonsteroidal anti-inflammatory drugs seem to increase the risk of hypertension.¹

Herbal products

Herbal products that are popular have the potential to increase BP and to interfere with antihypertensive treatment.¹⁹⁻²⁸ The evidence is anecdotal, and therefore it is impossible to estimate the true incidence of these adverse effects. Several reports showed that dietary supplements that contain ephedra alkaloids can increase BP.^{22,26} Some herbs can have a significant influence on concurrently administered drugs.²⁸ Hypertension was reported after coadministration of ginkgo and a diuretic thiazide.²⁵

Cocaine

Cocaine intoxication and abuse is characterized by adrenergic overactivity associated with increased BP. Cocaine use is associated with acute but not chronic hypertension. Severe hypertension has been reported to occur in subjects treated with propranolol, because of unopposed peripheral α -stimulation.¹ Hypertensive encephalopathy secondary to cocaine abuse was reported in a 40-year-old woman who was treated successfully with nitroprusside and captopril.¹ Cocaine ingestion during pregnancy increases the risk of early placental abruption and BP elevation that are less responsive to conventional therapy than pregnancy-induced hypertension.¹

Antiemetic agents

Antiemetic agents such as metoclopramide, alizapride, and prochlorperazine, have been reported to increase BP transiently.¹ Metoclopramide—an antiemetic agent classified as an antagonist of central and peripheral dopamine receptors—has been reported to increase BP transiently in patients treated with cisplatin.¹ The exact mechanism responsible for the rise in BP is unclear. Two other antiemetics, alizapride and prochlorperazine, were found to have a similar effect on BP.¹

Yohimbine hydrochloride

Yohimbine hydrochloride—an α_2 -adrenoceptor antagonist that is approved for treatment of erectile dysfunction—may increase BP.^{1,2,29} In normal volunteers and in patients with panic disorders, oral administration at doses used clinically may slightly increase BP.¹ However, in hypertensive patients oral yohimbine was reported to induce a significant increase in mean arterial pressure.²⁹ The magnitude of the pressor response was related to baseline norepinephrine levels and to the yohimbine-induced increment in plasma norepinephrine levels.²⁹ Thus yohimbine increases BP by stimulation of the sympathetic nervous outflow, and the drug should be administered with caution to patients with evidence for increased basal sympathetic outflow or those undergoing concurrent treatment with tricyclic antidepressants or other drugs that interfere with neuronal uptake or metabolism of norepinephrine.

Sibutramine

Sibutramine, a novel serotonin and noradrenaline reuptake inhibitor, is an antiobesity drug. It reduces food intake by enhancing the physiologic response of postingestive satiety and increases energy expenditure. By activating the sympathetic nervous system, the drug may increase heart rate and BP.^{30–33} In obese hypertensive patients, the BP reduction achieved by weight loss may negate the potential BP increase related to the drug.^{34,35} In a recent combined analysis of two placebo-controlled trials, sibutramine treatment did not elicit a critical increase in BP even in hypertensive patients.³⁶ Nevertheless, obese patients being treated with sibutramine should be monitored periodically for changes in BP.

Clozapine

Clozapine is an antipsychotic agent that is used for schizophrenic symptoms in patients refractory to classical antipsychotics. This drug may raise BP by sympathetic activation.¹ Several case reports of pseudopheochromocytoma syndrome associated with clozapine have been described.^{1,37} Sympathetic overactivity and BP were normalized upon treatment discontinuation. It is not clear whether long-term use of clozapine may induce hypertension. Lund et al.³⁸ did not find an increased risk to develop hypertension, whereas Henderson et al.³⁹ showed increased rates of hypertension in patients treated with clozapine.

Nonspecific agents

Glucagon may produce a catecholamine-mediated rise in BP in patients with pheochromocytoma.⁴⁰ Blocking the

α -adrenoceptors by either intravenous phentolamin or oral agents such as phenoxybenzamine or doxazosin may prevent catastrophic cardiovascular events.

Administration of physostigmine, a centrally acting cholinergic agent, to patients with Alzheimer's disease was accompanied by a rise in BP, probably due to direct sympathetic activation.¹ A hypertensive crisis was reported in a pregnant woman who was treated with ritodrine hydrochloride for inhibition of preterm labor. This was related to its inherent pharmacology as a beta-mimetic drug.¹

ANTIDEPRESSANT AGENTS

Monoamine oxidase inhibitors (MAOIs) exert their effects by delaying the metabolism of sympathomimetic amines and 5-hydroxytryptophan, and by increasing the store of norepinephrine in postganglionic sympathetic neurons. MAOIs are used to treat psychiatric patients with depression. Hypertensive crisis, the most serious toxic effect of these agents, has been reported more frequently when MAOIs were taken concomitantly with exogenous sympathomimetic amines.¹

Certain foods containing tyramine, such as cheese (Parmigiano), beer, wine (Chianti), snails, chicken liver, yeast, coffee, citrus fruits, avocados, canned figs, broad beans, chocolate, and bananas, may interact with MAOIs to cause hypertensive crisis. A patient treated with isoniazid who ate Swiss cheese had recurrent episodes of severe hypertension.¹ There are some reports of MAOIs that cause severe hypertensive reaction even without use of concomitant medications.¹ Among the various MAOIs, tranylcypromine is the most hazardous because of its stimulant action, whereas moclobemide and brofaromine are the least likely to induce hypertensive reaction.¹ Selegiline, a type-B MAOI mainly used for Parkinson's disease, may also increase BP.⁴¹ A case of hypertensive crisis was reported when selegiline was coadministered with other anti-Parkinson's agents or dopamine.^{42,43}

Tricyclic antidepressants block the reuptake of the neurotransmitters in the synapse in the central nervous system. There are some reports that these agents increase BP, mainly in patients with panic disorders.¹

Buspirone, a serotonin receptor type 1 α -agonist, has also been reported to increase BP.¹ It is speculated that buspirone increases BP by its metabolite 1-2 pyrimidinyl piperazine, which is an α_2 -adrenoceptor antagonist, and therefore should not be used concomitantly with an MAOI. A small but sustained and dose-dependent increase in arterial pressure seems to occur with other serotonin agonists as well. Venlafaxine has a dose-dependent effect on BP that is clinically significant at high dosages.² Episodes of severe hypertension were described in patients treated with other antidepressant agents such as fluoxetine, fluoxetine plus selegiline, and thioridazine.¹

Carbamazepine used for bipolar depression and seizures may also induce hypertension.⁴⁴ In rare cases, lithium intoxication has been accompanied by severe hypertension. The exact mechanism for this phenomenon is not known.¹

IMMUNOSUPPRESSIVE AGENTS

Cyclosporine A (CyA) is a potent, orally active immunosuppressive drug used in human organ transplantation and in autoimmune diseases, such as psoriasis, primary biliary cirrhosis, rheumatoid arthritis, type 1 diabetes mellitus, myasthenia gravis, and uveitis. The major side effects of cyclosporine are nephrotoxicity and arterial hypertension.

The incidence of cyclosporine associated hypertension (CAH) varies with the patient population under evaluation. The greatest experience to date has been with patients undergoing organ transplantation with kidney recipients representing the largest single group.¹ In 212 cyclosporine-treated renal transplant recipients, the prevalence of arterial hypertension was as high as 81.6% at 1 year after transplantation.¹ The presence of hypertension before transplantation, a plasma creatinine level higher than 2 mg/dL at 1 year, and a maintenance therapy with corticosteroids were positively associated with CAH. In a large cohort of 1267 kidney transplant patients who received an immunosuppressive regimen based on CyA, usually in association with azathioprine and steroids, the rate of hypertension was 32.7% at 1 year of transplantation.⁴⁵

For patients undergoing bone marrow transplantation, the evidence of an excess incidence of hypertension due to cyclosporine appears to be more compelling. In recipients of bone marrow transplants, a 57% incidence of hypertension was reported in cyclosporine-treated patients, compared with a 4% incidence in methotrexate-treated patients.¹ The frequency of CAH in cardiac transplant recipients is approaching 100%, and virtually all patients develop hypertension soon after transplantation, independent of renal impairment and irrespective of conventional risk factors associated with CAH.¹

In liver transplant recipients, CAH is also frequent and occurred in more than 70% of the patients.¹ In liver transplant recipients with cyclosporine-related hypertension, conversion to a low dose of cyclosporine and azathioprine lowered the BP.¹ Using cyclosporine A microemulsion (CyA-ME) with C2 rather than C0 monitoring reduced the risk of developing hypertension to 42%, a rate that is similar to the rate with tacrolimus.⁴⁶ Substitution of CyA with mycophenolate mofetil may improve BP control.⁴⁷

CAH is also common in patients with autoimmune disease treated with cyclosporine. In one study, 11% of 321 patients with autoimmune disease treated with cyclosporine for up to 2 years developed new-onset hypertension.¹ Among 16 normotensive patients with idiopathic autoimmune uveitis who were treated with cyclosporine orally at an initial dosage of 5 mg/kg of body weight per day for at least 2 years, 81% developed hypertension.¹ Some investigators studied the effects of cyclosporine on BP after short- and long-term treatment for dermatologic disorders.^{1,48} In 21 psoriatic patients, cyclosporine at 14 mg/kg per day increased systolic BP by 10% and diastolic BP by 16% after 4 weeks of treatment.¹ There was a significant correlation between cyclosporine trough levels and diastolic BP. During a long-term follow-up, patients with psoriasis who were treated with cyclosporine exhibited a dose-related increase in the

mean diastolic BP, and 5 out of 10 patients who were treated with cyclosporine at more than 3 mg/kg per day became hypertensive.¹

Several potential mechanisms may contribute to the development of CAH. These include the nephrotoxic effects *per se*, and renal vasoconstriction, which has been documented in both animals and humans.^{1,49} The nephrotoxic effects can be mediated by one or more of several mechanisms, including stimulation of the renal sympathetic nervous system, imbalance in the production of renal vasoconstrictor eicosanoids and/or failure of vasodilatory prostaglandin synthesis, alteration of the renin-angiotensin-aldosterone system, and a direct vasoconstriction effect mediated by either stimulation of endothelin synthesis or interference with the production of endothelial-derived relaxation factor.¹ However, elevation of BP can also be observed without clinically detectable renal abnormalities. Thus nonrenal factors need to be considered in the pathogenesis of CAH.

Cyclosporine can cause direct vasoconstriction² and thereby increase BP. The role of the sympathetic nervous system in cyclosporine-induced vasoconstriction was suggested by some investigators.¹ Scherrer et al.⁵⁰ found a 2.7-fold higher rate of sympathetic-nerve firing in heart-transplant recipients receiving cyclosporine than those not receiving cyclosporine.

Increases in thromboxane production can also contribute to the vasoconstrictor effects of cyclosporine.²

The renin-angiotensin-aldosterone system has also been extensively investigated. Animal experiments indicated that cyclosporine stimulates plasma renin activity. However, subsequent studies in humans have consistently shown a suppressed renin-angiotensin system, extracellular volume expansion, and a sodium-avid state in transplant recipients with CAH.² Increased production of endothelin and reduced release of endothelial-derived relaxing factor may also contribute to the vasoconstrictive effects of cyclosporine.² Cyclosporine also causes increased vascular sensitivity to humoral and neurogenic stimuli.² Interference with intracellular calcium homeostasis could produce hypertension by direct action on resistance vessels.²

The occurrence of CAH is unrelated to age, sex, or race.² While most patients present with mild to moderate asymptomatic BP elevation, others may rapidly develop severe hypertension and encephalopathy. CAH is characterized by a disturbed circadian rhythm with the absence or reversal of the normal nocturnal fall in BP.⁴⁹ BP usually falls after the withdrawal or substitution of cyclosporine immunosuppression but may not remit completely. Furthermore, it is often not possible to discontinue therapy. Calcium antagonists have been used successfully to lower BP, but they can increase cyclosporine blood levels.⁵¹ Multidrug therapy is usually necessary to control CAH.

Tacrolimus, another immunosuppressive agent that inhibits calcineurin, may also induce hypertension. However, it produces less hypertension than cyclosporin A, and therefore conversion to tacrolimus may be considered in patients with CAH.^{52,53}

Rapamycin, a novel immunosuppressive agent, that does not inhibit calcineurin, produces little nephrotoxicity and hypertension.⁵⁴

ANTINEOPLASTIC AGENTS

Several alkylating agents can increase BP. In one series, 15 of 18 patients treated with multiple alkylating agents following autologous bone marrow transplantation developed hypertension.¹ The hypertension was unrelated to plasma renin activity, aldosterone, and catecholamines, but was related to digoxin-like immunoreactive factor. Hypertensive reactions associated with paclitaxel treatment has been reported.²

Cis-diamminedichloroplatinium (CDDP) is an organic platinum compound with an antineoplastic effect. It has been demonstrated in four of five patients that intra-arterial administration of CDDP produces sustained systemic hypertension. This complication has not been observed in patients receiving the drug by the intravenous route. The etiology of the hypertension remains obscure.²

RECOMBINANT HUMAN ERYTHROPOIETIN

Recombinant human erythropoietin (r-HuEPO) is effective in correcting the anemia of patients with end-stage renal failure, and patients with malignancies. r-HuEPO can lead to an increase in BP that appears to be dose related. Systemic hypertension has been reported to develop, or to worsen, in 20% to 30% of patients treated with r-HuEPO worldwide.⁵⁵ The greatest increases in BP affect daytime systolic and nighttime diastolic BP.^{1,2} Hypertension may develop in some patients as early as 2 weeks and in others as late as 4 months after the start of r-HuEPO treatment.^{1,2} Hypertension has not proved to be a serious general problem in the r-HuEPO treated patient; however, few cases of hypertensive crisis with encephalopathy have been reported.^{1,2}

Several risk factors for the development, or worsening, of hypertension after r-HuEPO therapy, have been identified. They include the presence of pre-existing hypertension, rapid increase in hematocrit, a low baseline hematocrit before r-HuEPO administration, high doses and intravenous route of administration, the presence of native kidneys, a genetic predisposition to hypertension, and possibly a younger age.^{1,2,56} There are several potential mechanisms by which r-HuEPO therapy may increase BP in hemodialysis patients. They include increased blood viscosity, the loss of hypoxic vasodilation, the activation of neurohumoral systems (catecholamines, the renin-angiotensin system), and especially a direct vascular effect. This last mechanism is supported by several data sets, and many factors may be involved in its pathogenesis (increased cell calcium uptake, imbalance in local vasoactive agents, with increased synthesis of ET-1, mitogenic effect, and a platelet-dependent mechanism).⁵⁷⁻⁶² Hemodynamically, r-HuEPO increases BP by a marked increase in peripheral resistance associated with only a mild decrease in cardiac output.¹ By optimizing dialysis treatment, paying close attention to volume regulation, giving r-HuEPO subcutaneously and in a fashion to increase hematocrit gradually, the occurrence of hypertension can be minimized.⁵⁶

The hypertension associated with r-HuEPO has not generally been too difficult to control. The BP can usually

be controlled with a combination of fluid removal with dialysis and conventional antihypertensive therapy. If these measures are unsuccessful, the dose of r-HuEPO should be lowered or therapy should be held for several weeks. Phlebotomy of 500 mL of blood may rapidly lower BP in refractory patients.

ALCOHOL

Excessive alcohol use has clearly been shown to raise BP and can also increase resistance to antihypertensive therapy. Small doses of ethanol slightly increase heart rate, cardiac output, and BP. The exact mechanisms mediating the acute effects are not yet clear; however, acute increases in plasma epinephrine and norepinephrine levels have been reported, reflecting an increase in sympathetic nervous activity.¹ Increased plasma renin levels in heavy drinkers, and increased plasma cortisol levels have been reported. In heavy drinkers, withdrawal from alcohol as well as drinking were found to increase BP, probably because of a hyperadrenergic state.¹

Apart from the acute effects of alcohol, an increased prevalence of hypertension has been shown in heavy drinkers.^{1,2} In the Australian Risk Factor Prevalence Study, 7% of the prevalence of hypertension was attributed to alcohol consumption, whereas in the Kaiser-Permanente Study, the rate for men was 11%.¹ It was found that the greater the quantity of alcohol consumption, the higher the prevalence of hypertension.

The BP effects of alcohol are independent of obesity, salt intake, cigarette smoking, and potassium intake, and there is a dose-response relationship for the hypertensive effects of alcohol. In a prospective cohort study of 3900 Japanese men, Yoshita et al.⁶³ found that annual systolic BP increase was greater in those who consumed 300 g/week or more of alcohol than nondrinkers. Baseline diastolic BP was associated with alcohol consumption and was significantly higher in drinkers consuming 200 g/week or more than nondrinkers. Therefore moderation of alcohol intake is recommended as an initial therapy for mild hypertension. A reasonable approach is to limit daily alcohol consumption to less than 200 g/week.

Disulfiram

Disulfiram is commonly used as a pharmacologic adjunct in the treatment of alcoholism. Administration of 500 mg per day of disulfiram for 2 to 3 weeks has been reported to increase BP slightly. A low dose of 125 mg per day of this agent may also increase BP. It seems that changes in peripheral or central noradrenergic activity are responsible for the increase in arterial pressure.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs (NSAIDs) can induce an increase in BP and interfere with antihypertensive treatment, nullifying its effect.¹ Two meta-analyses have demonstrated that, after pooling data drawn from published reports of randomized trials of younger adults, NSAID

use produces a clinically significant increment in mean BP of 5 mmHg.¹ Elderly patients, those with pre-existing hypertension, salt-sensitive patients, patients with renal failure and patients with renovascular hypertension are at a higher risk to develop severe hypertension when treated with NSAIDs.⁶⁴⁻⁶⁸ The mechanisms whereby NSAIDs raise BP are not fully understood. Inhibiting the synthesis of prostaglandins (PGs) from arachidonic acid via the two isoforms of cyclooxygenase (COX), COX-1 and COX-2, is probably the main mechanism of action.¹ Interference with both the control of vascular resistance and the regulation of extracellular volume homeostasis has been suggested, but several other putative mechanisms such as moderation of adrenergic activity or resetting of the baroreceptor response may also be involved.¹ NSAIDs may interact with some antihypertensive agents such as diuretics, beta-blockers, and ACE inhibitors, and do not interact with calcium antagonists and central-acting drugs (actions of these drugs are apparently unrelated to production of PGs).¹ NSAIDs vary considerably in their effect on BP.⁶⁹ Armstrong and Malone⁶⁹ found in a recent study that among the various NSAIDs, indomethacin, naproxen, and piroxicam were associated with the greatest increase in BP. They also showed that among the selective NSAIDs, rofecoxib is more likely than celecoxib to raise systolic BP.⁶⁹ In a recent meta-analysis, Aw et al.⁷⁰ showed that selective COX-2 inhibitors increase BP more than the nonselective agents. However, there is evidence that patients receiving celecoxib experience less increase in BP compared with those receiving rofecoxib. A recent study by Sowers et al.⁷¹ showed that at equally effective doses for osteoarthritis management, treatment with rofecoxib but not celecoxib or naproxen induced a significant increase in 24-hour systolic BP. Low-dose aspirin has no effect on BP control in hypertensive patients. It is wise to balance the risk of an increase in BP against the expected benefit of treatment with an NSAID. In patients who take NSAIDs, calcium antagonists would appear to be a preferred choice to other antihypertensive agents.⁷²

HEAVY METALS

Epidemiologic studies confirmed the high incidence of hypertension among patients exposed to lead.⁷³⁻⁷⁶ Even at low levels of exposure (40 µg/dL), blood lead level was positively associated with both systolic and diastolic BP and risks of hypertension among women aged 40 to 59 years. The relationship between blood lead level and hypertension was most pronounced in postmenopausal women.⁷⁷ History of lead exposure influences hypertension and elevated BP during pregnancy.⁷⁸ Lead exposure affects the renin angiotensin system, and induces sympathetic hyperactivity by acting on central and peripheral sympathetic junctions.¹ These results provide support for continued efforts to reduce lead levels in the general population, especially in women.

A retrospective study of 311 male workers in an alkaline battery factory indicated a possible relationship between exposure to cadmium oxide and the development of hypertension.¹ Several other studies also showed an association between cadmium exposure and hypertension.^{79,80} However,

other epidemiologic studies have failed to show such a relationship.^{1,81} In a recent study, environmental exposure to cadmium was not associated with higher conventional BP or 24-hour ambulatory BP measurements, or with increased risk for hypertension.⁸²

Some studies suggest that arsenic exposure also may induce hypertension in humans.^{83,84}

OTHER AGENTS

Bromocriptine

Bromocriptine mesylate is commonly used for prolactin inhibition and suppression of puerperal lactation. Although bromocriptine often has a hypotensive effect, severe hypertension with subsequent stroke has been reported in the postpartum period.¹ Patients with pregnancy-induced hypertension are at increased risk to develop hypertension. The suppression of lactation is no longer a Food and Drug Administration-approved use for bromocriptine.

Scorpions and black widow spiders

Venoms of scorpions (especially the South American species) and spiders (particularly the black widow spider, *Latrodectus mactans*) commonly produce a clinical picture of profuse perspiration, lacrimation, vomiting, convulsion, and cardiovascular collapse. However, occasionally hypertension and bradycardia occur. Hypertension is mediated by a massive discharge of catecholamines into the circulation produced by the venom, and therefore β- or α-blockade is effective in this condition.¹

Amphotericin B

Amphotericin B (AmB) is the mainstay of therapy for serious fungal infections. A few cases of severe hypertension associated with the use of AmB deoxycholate have been reported in the literature, and one case report of hypertension associated with a lipid-containing preparation of the medication have been described.¹

Anti-HIV treatment

One case report of severe hypertension and renal atrophy associated with the protease inhibitor indinavir has been described.⁸⁵ Hypertensive crisis secondary to phenylpropanolamine interacting with triple-drug therapy for HIV prophylaxis has also been reported.⁸⁶ In addition, potential drug interactions exist between antiretroviral medications, particularly the protease inhibitors and antihypertensive medications.

SUMMARY

A variety of therapeutic agents and chemical substances can increase blood pressure and even induce hypertension. These agents increase arterial pressure by either causing sodium retention and volume expansion or activate directly or indirectly the sympathetic nervous system. Some agents act directly on arteriolar smooth muscle.

For a few agents the mechanism is mixed or unknown. In general, these pressure increases are small and transient:

however, severe hypertension involving encephalopathy, stroke and irreversible renal failure have been reported. Careful evaluation of a patient's drug regimen may obviate the need for unnecessary, costly, and potentially dangerous evaluations and prevent the need for lifelong antihypertensive therapy.

Using these agents should be avoided in hypertensive patients and in subjects with pre-hypertension. When it is not possible to avoid chemical agents that cause hypertension, institution of appropriate antihypertensive treatment is indicated.

Catecholamines, Pheochromocytoma, and Hypertension: Genomic Insights

Fangwen Rao, Ryan Friese, Gen Wen, Lian Zhang, Yuqing Chen, Madhusudan Das, Kuixing Zhang, Bruce A. Hamilton, Nicholas J. Schork, Laurent Taupenot, Sushil K. Mahata, Michael G. Ziegler, and Daniel T. O'Connor

Key Findings

- Knowledge of catecholamine biosynthesis, vesicular storage, exocytotic release, and metabolism is crucial to the effective diagnosis and management of patients with pheochromocytoma.
- Discovery of naturally occurring common genetic variation in the catecholamine-storage vesicle protein chromogranin A opened the way to understanding interindividual differences in the storage and release process.
- Common genetic variation at the locus encoding the rate-limiting enzyme in catecholamine biosynthesis, tyrosine hydroxylase, seems to have pleiotropic effects on catecholamine production, stress physiology, and genetic risk of developing hypertension.
- Elucidation of the chromosomal positions of loci encoding the components of the sympathetic neuroeffector junction should assist in further studies of how allelic variation at such loci influences the development of hypertension.

The catecholamines (norepinephrine, epinephrine, and dopamine) are both neurotransmitters and circulating hormones.¹ Catecholamines possess a catechol (3,4-dihydroxyphenyl) modification of the aromatic phenyl ring. Norepinephrine is released from terminals of postganglionic axons of the sympathetic nervous system, as well as central nervous system noradrenergic axons. Adrenal medullary chromaffin cells store both epinephrine and norepinephrine in secretory vesicles.

Chromaffin cells arise embryologically from neuroectoderm. Adrenal precursor cells differentiate first in response to cortisol, and ultimately into sympathetic neurons in response to nerve growth factor. Such cells also migrate to form paraganglia, collections of chromaffin cells beside the aorta. The largest periaortic cluster, often found near the inferior mesenteric artery, is the organ of Zuckerkandl. Both chromaffin cells and postganglionic sympathetic axons are part of the effector limb of the sympathetic branch of the autonomic nervous system and

are innervated by thoracolumbar preganglionic axons emerging from the spinal cord.

Catecholamines are released from the adrenal medulla into the circulation through the adrenal vein. Norepinephrine from sympathetic neurons is released presynaptically, acting as a cell-to-cell neurotransmitter. Circulating plasma norepinephrine influences blood pressure and heart rate under extreme circumstances of sympathetic activation. Relatively selective adrenal catecholamine release occurs during syncope and insulin-evoked hypoglycemia, while dynamic exercise selectively stimulates sympathetic neuronal norepinephrine release.

CATECHOLAMINE BIOSYNTHESIS AND METABOLISM

Catecholamine biosynthesis starts with phenylalanine, which is converted to tyrosine by phenylalanine hydroxylase. Tyrosine is hydroxylated to dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase, the rate-limiting enzymatic step in catecholamine biosynthesis. DOPA decarboxylase then converts DOPA to dopamine, which is carried by the vesicular monoamine transporter from the cytosol into the catecholamine storage vesicle, where dopamine β -hydroxylase converts it to norepinephrine. In sympathetic axons and in ~15% to 20% of chromaffin cells, norepinephrine is the final catecholamine product. In ~80% to 85% of chromaffin cells, a further enzymatic step occurs: phenylethanolamine-N-methyltransferase, a cytosolic enzyme, catalyzes the N-methylation of norepinephrine to epinephrine.

Catecholamines in noradrenergic axons and chromaffin cells are sequestered in membrane-limited organelles called catecholamine storage vesicles (or chromaffin granules in chromaffin cells). Chromaffin granule cores contain not only catecholamines but also soluble proteins such as dopamine β -hydroxylase and chromogranin A (Figure 72-1).

The process of catecholamine discharge from chromaffin cells and sympathetic axons is “exocytosis,” wherein all soluble components of the granule are co-released and ultimately make their way to the circulation.

Neuronal uptake (or “reuptake”) is the major route of catecholamine removal from synaptic clefts and plasma

Figure 72-1. Localization of chromogranins within dense-core secretory granules of sympathoadrenal chromaffin cells. **A**, Resolution of bovine chromaffin-vesicle, soluble core proteins by two-dimensional SDS-PAGE gel electrophoresis, followed by Coomassie blue staining of separated proteins. **B**, Immunogold electron microscopy of bovine chromaffin cells. The electron-dense spherical or oblong structures are dense core secretory chromaffin granules. The 8- to 12-nm diameter black particles are immunogold labeling of CgA with rabbit anti-bovine CgA, indicating the presence of CgA in several secretory granules. **C**, Subcellular distribution of a human CgA-EGFP (enhanced green fluorescent protein) chimeric photoprotein in living sympathoadrenal PC12 cells. CgA-EGFP expressing PC12 cells were examined by three-dimensional (3D) deconvolution microscopy. Nuclei were visualized with (blue) Hoechst 33342 dye. Optical sections along the z axis were acquired with increments of 200 nm using 100 \times oil immersion objectives to generate 3D views of the photoprotein distribution. CgA-EGFP displays a bright, punctate/vesicular fluorescence signal, especially within the subplasmalemmal region, indicating storage of the chimera in chromaffin secretory granules. CgA, chromogranin A; CgB, chromogranin B; DBH, dopamine β -hydroxylase. (Åsa Thureson-Klein prepared the electron micrograph of immuno-localization of CgA in chromaffin granules of the bovine adrenal medulla. From Taupenot L, Harper KL, O'Connor DT. *N Engl J Med* 2003;348:1134-49.)

(Figure 72-2). Characteristics of this process are its location at the presynaptic axonal membrane, high affinity, stereoselectivity, saturability, dependence on extracellular sodium, and specific pharmacologic inhibition by agents such as tricyclic antidepressants (e.g., desipramine) and cocaine. Non-neuronal uptake may be mediated by the organic cation transporter (OCT) family, especially OCT3. After neuronal uptake, cytosolic catecholamines can be either retransported into storage vesicles or deaminated by the enzyme monoamine oxidase (MAO) to yield the unstable intermediate dihydroxyphenylglycolaldehyde, which is then metabolized to dihydroxyphenylglycol (DHPG) (Figure 72-2).² The enzyme catechol O-methyltransferase (COMT), which acts on both catecholamines and DHPG, is present mainly in the cytosol of liver and kidney cells, and also in chromaffin cells. COMT adds a methyl group to one of the hydroxyl oxygens on the catecholamines' dihydroxyphenyl rings to yield either metanephrine (i.e., methoxyepinephrine from epinephrine), normetanephrine (i.e., methoxynorepinephrine from norepinephrine), or methoxytyramine (from dopamine). The metanephrines can then be deaminated by MAO to yield vanillylmandelic acid (VMA), whereas deamination of methoxytyramine by MAO yields homovanillic acid. DHPG is also a substrate for COMT in the formation of MHPG. In the liver, alcohol dehydrogenase oxidizes MHPG to VMA. Thus complete enzymatic degradation of catecholamines to VMA (from epinephrine or norepinephrine) or homovanillic acid (from dopamine) involves the sequential action of two enzymes (MAO and COMT), either of which may initiate the process, followed by an alcohol dehydrogenase step in the liver. In the blood stream, catecholamines have a very short half-life, ~1 to 2 minutes. They are cleared from the circulation largely by neuronal uptake, but in addition are subject to direct renal excretion or sulfoconjugation of a ring hydroxyl group by SULT1A3 in the gastrointestinal tract.

CATECHOLAMINE ACTION

Catecholamine (adrenergic) G protein-coupled receptors are specific for particular ligands (agonists and antagonists) and thereby classified as subtypes of the α ($\alpha_{1a,b,c}$, $\alpha_{2a,b,c}$) and β ($\beta_{1,2,3}$) classes. The hemodynamic effects of circulating norepinephrine require extreme concentrations. Whereas plasma norepinephrine may vary normally over a range of 200 to 1000 pg/mL during physiologic stimulation of sympathetic neuronal activity, far higher concentrations of infused norepinephrine (in excess of 1000 to 2000 pg/mL) are required to substantially affect the blood pressure or heart rate. At β -receptors, norepinephrine is a strong agonist at β_1 (cardiac inotropic and chronotropic) sites, although a relatively weak agonist at β_2 (vascular, vasodilatory) sites. At α -receptors, norepinephrine is an effective agonist at both α_1 (vascular, vasoconstrictive) and α_2 (neuronal and vascular) sites. Infused norepinephrine acutely raises both systolic and diastolic

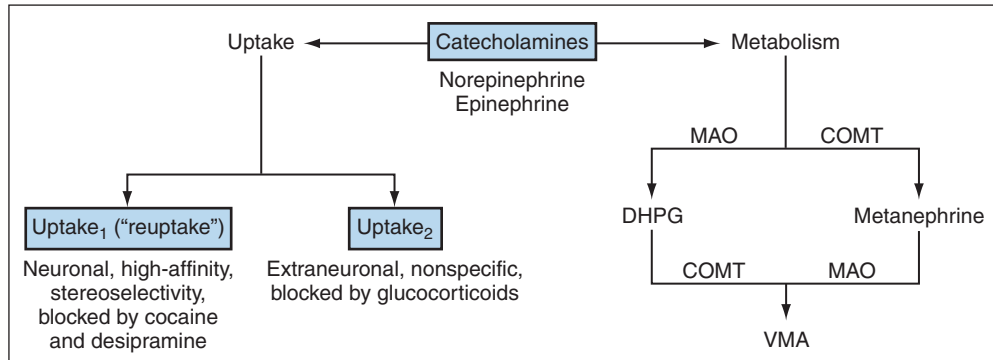

Figure 72-2. Catecholamine disposition and metabolism. COMT, catechol-O-methyltransferase; DHPG, dihydroxyphenylglycol; MAO, monoamine oxidase; VMA, vanillylmandelic acid. (From O'Connor DT. In: Bennett JC, Plum F, eds. *Cecil Textbook of Medicine*. 22nd ed. Philadelphia: WB Saunders, 2004:1419–24.)

blood pressure by actions on both β_1 - and α -adrenergic receptors, with vasoconstriction accompanied by reflex bradycardia. The hemodynamic effects of circulating epinephrine (50 to 500 pg/mL) differ from those of norepinephrine. At β -receptors, epinephrine is an agonist at both the β_1 - and β_2 -sites. It is also a more potent agonist than norepinephrine at both the α_1 - and α_2 -sites. During acute infusion, it increases systolic blood pressure, heart rate, and cardiac output, with a fall in diastolic blood pressure and systemic resistance, the latter effects resulting from actions at β_2 -adrenergic receptors.

With chronically elevated circulating catecholamines, the hemodynamic profile may change substantially, in part as a consequence of desensitization of catecholamine target organs resulting from adaptive changes in both receptor and postreceptor responses.

PHEOCHROMOCYTOMA

Introduction and location

Pheochromocytoma is a chromaffin cell neoplasm causing symptoms and signs of episodic catecholamine release, including paroxysmal hypertension.¹ The tumor is an unusual cause of hypertension and accounts for at most ~0.1% to 0.2% of cases of high blood pressure. In population-based cancer studies, its frequency was about two cases per million population. The diagnosis of pheochromocytoma is typically made in young to middle-aged adults, most commonly in the fourth or fifth decade of life; about 10% of diagnoses are made in children (usually male). Autopsy series indicate that the incidence of pheochromocytoma increases progressively with age. In adults, no gender difference is seen in the incidence of pheochromocytoma.

About 90% of pheochromocytomas exist as solitary, unilateral, encapsulated adrenal medullary tumors. About 10% are bilateral, more commonly seen in several members of a family, ~40% to 70% of whose members may

have bilateral tumors. The tumors are vascular, and large ones often contain internal hemorrhagic or cystic areas. Reported sizes have ranged from less than 1 g to several kilograms; the average is about 40 g. About 10% of tumors are extra-adrenal (paragangliomas), and 90% of these are intra-abdominal, most commonly arising from chromaffin cells near the aortic bifurcation in the organ of Zuckerkandl or near the kidney. Other sites include the paravertebral sympathetic ganglia, the urinary bladder, other autonomic ganglia (celiac, superior, or inferior mesenteric), the thorax (including the posterior mediastinum, the heart, and paracardiac regions), and the neck (in sympathetic ganglia, the carotid body, cranial nerves, or the glomus jugulare). Bilateral and extra-adrenal tumors are more common in children. Histologically, oval groups of cells, in clusters or “nests,” stain for chromogranin A; a less frequently used stain identifies neuron-specific enolase. Fewer than 10% of the tumors are malignant; malignancy occurs more frequently in extra-adrenal tumors and is diagnosed by local invasion or distant metastases, but cannot be judged reliably from the histologic appearance. Local invasion commonly involves adjacent vascular structures such as the inferior vena cava. Distant metastatic sites include bone, lung, lymph nodes, and liver. Bilateral adrenal medullary hyperplasia has been reported in gene carriers from kindreds with multiple endocrine neoplasia (MEN) type 2. This hyperplasia may be a precursor of pheochromocytoma.

The “rule of 10s” is useful to recall approximate frequencies of pheochromocytoma that vary from the usual: ~10% bilateral, ~10% extra-adrenal, ~10% malignant, ~10% familial, ~10% pediatric, and ~10% without blood pressure elevation.

Etiology, heredity, and familial forms

Familial pheochromocytomas constitute up to 10% of the total and are more frequently bilateral, although less commonly malignant. A careful family history is essential, and relatives of patients with the familial syndromes should

be screened for pheochromocytoma; biochemical screening is often not sufficient, and imaging studies are also recommended in this high-risk group.

Von Hippel-Lindau syndrome (VHLS) is an autosomal dominant disorder resulting from germline mutations at the VHL tumor suppressor locus on chromosome 3p25-p26. Its manifestations include pheochromocytoma (in about 14% of gene carriers), retinal angioma, cerebellar hemangioblastoma, renal cysts and carcinoma, pancreatic cysts, and epididymal cystadenoma.^{3,4} Accordingly, all patients with pheochromocytoma deserve careful fundoscopic examination. Pheochromocytoma occurs in type 2 VHLS, in which missense mutations (especially Arg238Trp or Arg238Gln) lie in a region of the VHL gene product that binds transcriptional elongation factors. Pheochromocytomas do not occur in type 1 VHLS, which is caused by deletion or premature termination (nonsense) VHL mutations.

MEN type 2A and type 2B (Sipple's syndrome) are autosomal dominant disorders arising from germline mutations on chromosome 10q11.2 in the RET proto-oncogene, which encodes a neurotrophin co-receptor tyrosine kinase. The features of MEN type 2A include pheochromocytoma (in about 40% of gene carriers), medullary thyroid carcinoma, and primary hyperparathyroidism (adenoma or hyperplasia). Because of this syndrome, it is wise to screen all pheochromocytoma patients for medullary thyroid carcinoma with serum calcitonin. MEN type 2B features include pheochromocytoma, medullary thyroid carcinoma, multiple mucosal neuromas (of the lips, tongue, buccal mucosa, eyelids, conjunctivae, corneas, and gastrointestinal tract), and a marfanoid body habitus (but without lens or aortic abnormalities). RET mutations in MEN 2A affect one of five Cys residues in the juxtamembrane extracellular domain, perhaps resulting in intermolecular disulfide formation and consequent constitutive activation of the kinase. The most common RET mutation in MEN 2B, Met981Thr, seems to alter the substrate specificity of the kinase.

The clinical presentation of pheochromocytoma may differ in MEN 2 versus VHLS: MEN 2 patients may be more symptomatic, have a higher incidence of hypertension, and higher plasma metanephrines, but lower plasma catecholamines than VHLS patients. Pheochromocytomas in VHLS patients exhibit a more noradrenergic phenotype characterized by selective increases in urinary and plasma normetanephrine and sometimes norepinephrine, whereas tumors in MEN 2 patients exhibit an adrenergic phenotype, characterized by additional and consistent increases in plasma and urinary metanephrine, sometimes associated with increases in epinephrine.

Hereditary neurofibromatosis (von Recklinghausen's disease), an autosomal dominant disorder resulting from mutations at the NF1 (neurofibromin) locus on chromosome 17q11.2, is manifested as neurofibromas and café au lait spots; about 1% of patients with neurofibromatosis have pheochromocytoma. Inactivating germline mutations at the SDHB (succinate dehydrogenase small subunit D) locus on chromosome 11q23 may also cause susceptibility to familial pheochromocytoma, as well as familial paragang-

glioma. Familial pheochromocytoma may also occur in isolation; whether such families represent disease processes etiologically distinct from von Hippel-Lindau syndrome or MEN is not clear.

In the 90% to 95% of pheochromocytomas that are sporadic, the cause of the neoplastic process remains obscure, although loss of heterozygosity on chromosomes 1p, 3p, 17p, and 22q suggests somatic cell deletion mutation of one autosomal allele at as-yet-uncharacterized tumor suppressor loci.

Because pheochromocytoma can be a curable form of hypertension, the diagnosis is important to consider in each new case of hypertension. However, because hypertension is so commonly encountered in clinical practice (>20% to 25% of the adult population) and pheochromocytoma is so distinctly unusual (<0.1% to 0.2% of patients with hypertension), laboratory evaluation should be selective, guided by the degree of clinical suspicion, and based on practical criteria outlined below (Box 72-1).

Clinical manifestations: symptoms and signs

Paroxysmal symptoms (such as the triad of episodic palpitations, diaphoresis, and headache) are the classic features of pheochromocytoma. These paroxysmal "attacks" characteristically begin abruptly, may last for minutes to hours, and subside gradually, with a frequency varying from many times daily to one or more per week (most commonly) or even every few months. Less common symptoms include apprehension or anxiety, tremulousness, pain in the chest or abdomen, weakness, or weight loss. In some series, more than 90% of patients have experienced paroxysmal symptoms of one or more of the classic triad. Autopsy series indicate that as many as 50% to 75% of pheochromocytomas may be undiagnosed during life, thus suggesting that many pheochromocytomas do not give rise to these classic symptomatic features. Patients older than 60 years with pheochromocytoma are especially likely to report minor or no symptoms.

Other features in the history may suggest pheochromocytoma. Affected patients may report an increase in blood pressure after receiving certain antihypertensive drugs, especially β -adrenergic antagonists and guanethidine, or they may experience a remarkable fall in blood pressure after receiving α_1 -adrenergic antagonists such as prazosin. Hypertension in such patients is relatively refractory to medical management. A history of extreme blood pressure lability during intubation, surgery, or induction of general anesthesia also suggests possible pheochromocytoma. A family history of pheochromocytoma, von Hippel-Lindau syndrome, or MEN 2 should prompt an evaluation for pheochromocytoma. Paroxysmal symptoms on micturition or bladder distention, or painless gross hematuria may suggest pheochromocytoma of the bladder; the diagnosis is confirmed by cystoscopy.

Hypertension (usually severe and refractory to anti-hypertensive medications) is the cardinal sign of pheochromocytoma, although it is nonspecific and may be insensitive. In about half of patients, hypertension is sustained, with intermittent blood pressure surges in half or more

Box 72-1**Practical Diagnostic Approach to Pheochromocytoma****Clinical Clues or “Tipoffs”**

- History
 - Paroxysmal symptoms (classic triad is headache, diaphoresis, palpitations)
 - History of extraordinarily labile or refractory hypertension
 - Family history of pheochromocytoma, von Hippel-Lindau syndrome, or multiple endocrine neoplasia (MEN)
 - Incidental adrenal abnormality on abdominal imaging test (rarely)
- Physical examination
 - Labile, refractory hypertension
 - Orthostatic hypotension
 - von Hippel-Lindau syndrome, or multiple endocrine neoplasia-associated findings (retinal angiomas, thyroid enlargement, mucosal neuromas)

Biochemical Confirmation (only after clue or tipoff; begin with urinary tests)

- Urinary catecholamines and metabolites (24-hour sample or 2-hour sample after a paroxysm; metanephrines, the initial screening test)
- Plasma catecholamines (if urinary values are equivocal; take care to obtain a basal, resting sample)
- Clonidine suppression test (if plasma catecholamines are in the equivocal 1000 to 2000 pg/mL range)
- Plasma chromogranin A (storage vesicle protein released with catecholamines; also elevated by renal failure)

Anatomic Localization (only after biochemical confirmation)

- By morphology (most sensitive, less specific)
 - Computed tomography (the imaging test most frequently obtained)
 - Magnetic resonance imaging (may have advantages for extra-adrenal tumors)
- By function (most specific, less sensitive)
 - Radiolabeled [¹³¹I]-MIBG scanning (accumulates in functioning chromaffin tissue)

From O'Connor DT. In: Bennett JC, Plum F, eds. *Cecil Textbook of Medicine*. 22nd ed. Philadelphia: WB Saunders, 2004:1419–24.

of these; in about 40%, hypertension is paroxysmal, with relatively normal blood pressure between surges. Hypertensive surges may be precipitated by abdominal manipulation, but generally no antecedent is noted. The heart rate is usually elevated during blood pressure surges but may decline as a result of physiologic reflex bradycardia. Orthostatic hypotension is variably observed. As many as 15% to 20% of patients may have cholesterol gallstones.

Laboratory diagnosis

Because hypertension is common and pheochromocytoma so rare, further biochemical evaluation for pheochromo-

cytoma in hypertensives should be selective and focused on subjects who display some relevant clue to pheochromocytoma on history, physical examination, or screening laboratory evaluation. If interpretation of urinary measurements is not clear-cut, evaluation should proceed to plasma measurements, which require more careful sampling technique. The number and diversity of biochemical tests obtained should parallel the clinical index of suspicion. If suspicion is low, a single screening test may suffice, usually 24-hour urinary metanephrine excretion. If suspicion is high, multiple tests, including urine and plasma, are in order. Because anatomic or imaging studies may detect nonspecific adrenal abnormalities in up to 2% of the population, such studies should not be undertaken unless biochemical tests are positive.

Routine/Screening tests

Results of routine screening tests obtained for other purposes (such as general health maintenance) may provide tip-offs. Hyperglycemia is common, and about half of patients with pheochromocytoma manifest carbohydrate intolerance; frank diabetes requiring insulin is unusual. Lactic acidosis occurs rarely, even without shock. Serum lactate dehydrogenase activity may be elevated from adrenal isoenzyme 3.⁵ Rarely, pheochromocytoma may be an incidental finding on computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen undertaken for other indications.

Urine biochemical tests

Widely available tests measure urinary free (unconjugated) catecholamines and catecholamine metabolites: the metanephrines and vanillylmandelic acid (VMA).⁶ A 24-hour urine sample is collected, and creatinine is measured in the same sample as an index of adequacy and completeness of collection. Of the available urinary tests, increased fractionated metanephrines (separately measured normetanephrine and metanephrine) have the highest diagnostic sensitivity for pheochromocytoma. Normal test results for urinary fractionated metanephrines are therefore useful for excluding pheochromocytoma. Inadequate specificity makes it difficult to reliably confirm pheochromocytoma from an increased test result. Testing of urinary VMA is less sensitive than testing of metanephrines. Urinary excretion of metanephrines and VMA remains normal until the very end stage of renal disease, so elevated levels validly diagnose pheochromocytoma.

False-positive assay results have been greatly minimized in recent years with the introduction of more specific assay methods based on separation of catecholamines and metabolites in urine by high-pressure liquid chromatography. False-positive increases in free catecholamines may result from exogenous sources, such as catecholamines (which may be administered surreptitiously), alpha-methyl dopa (but VMA excretion is characteristically normal), L-DOPA, labetalol, sympathomimetic amines (which release endogenous catecholamines from their stores), and fluorescent drugs such as tetracycline. Misleading elevations of endogenous catecholamines may occur as a consequence of the sympathoadrenal responses

to shock, hypoglycemia, physical exertion, increased intracranial pressure, or withdrawal of central α_2 -agonists such as clonidine. False-positive metanephrine elevations may result from excessive catecholamines (exogenous or endogenous) or the use of tricyclic antidepressants, MAO inhibitors, or propranolol (which interferes with the spectrophotometric assay). False-positive elevations in VMA may occur after ingesting carbidopa (a peripheral DOPA decarboxylase inhibitor) or MAO inhibitors.

Blood biochemical tests

Biochemical tests on blood samples offer the advantage of patient convenience but the disadvantage that even minor physical or mental stress can result in false-positive elevations. Plasma catecholamines are best sampled from a supine, resting patient in whom an indwelling antecubital venous cannula has been in place for at least 15 minutes. Plasma assay methods generally provide reliable results with the usual normal resting norepinephrine value being 200 to 400 pg/mL and the normal resting epinephrine value being 20 to 60 pg/mL. Most patients with pheochromocytoma have markedly elevated (>2000 pg/mL) resting plasma catecholamine (norepinephrine plus epinephrine) values; plasma concentrations elevated beyond this point strongly suggest pheochromocytoma. The upper limit of normal (norepinephrine plus epinephrine) is less than 1000 pg/mL. Values between 1000 and 2000 pg/mL are equivocal and may represent either pheochromocytoma or sympathoadrenal activation by physical or mental stress. In these subjects the clonidine suppression test discussed below is of particular value.

False-positive plasma catecholamine elevations may result from the same factors that produce false-positive urinary elevations but are a more severe problem because measurements are made at only one point. These factors include physical stress, such as trauma, surgery, upright posture, acute venipuncture, hypoglycemia, hypovolemia, hypotension, cold, and sodium depletion, or mental stress such as anxiety or pain. Drugs that increase plasma catecholamines include sympathomimetic amines, which release catecholamines from their stores; cocaine, which blocks catecholamine reuptake; and abrupt clonidine withdrawal. Illnesses known to elevate plasma catecholamines include both acute (e.g., myocardial infarction, diabetic ketoacidosis, or sepsis) and chronic conditions (e.g., congestive heart failure, anemia, respiratory failure, or hypothyroidism). Factors that diminish plasma catecholamines include drugs (clonidine, reserpine, and α -methylparatyrosine), autonomic neuropathy, and congenital deficiency of dopamine β -hydroxylase activity.

As with urine biochemical tests, plasma catecholamine sampling during a paroxysmal attack of hypertension is of value. A finding of normal plasma catecholamines when blood pressure is elevated is quite a useful negative result. Because only extreme elevations of plasma norepinephrine perturb blood pressure, the finding of normal plasma catecholamines while blood pressure is elevated argues strongly against pheochromocytoma as the cause.

Plasma metanephrine measurements are also highly sensitive and specific for diagnosis of pheochromo-

cytoma,² although the measurements are not as widely available as plasma catecholamines. Other components of the catecholamine storage vesicle core are released into the blood stream by pheochromocytomas. The plasma concentration of chromogranin A is elevated in patients with pheochromocytoma, with a diagnostic sensitivity of 83% and specificity of 96%.⁶ It is not substantially elevated by acute venipuncture, nor is it affected by drugs used in treatment or diagnosis of pheochromocytoma. Because chromogranin A is released by a variety of neuroendocrine secretory vesicles, its plasma concentration is also elevated in other neuroendocrine neoplasia.⁷ Chromogranin A values are also elevated in renal insufficiency because of retained immunoreactive fragments of the protein.⁸

Pharmacologic tests for pheochromocytoma are generally not necessary because the diagnosis can usually be confirmed by urine and plasma biochemical measurements at rest or during spontaneous blood pressure surges. The clonidine suppression test is of value if plasma catecholamine elevations in a patient with suspected pheochromocytoma are equivocal (i.e., from 1000 to 2000 pg/mL). The rationale for the test is that pheochromocytoma chromaffin cells, unlike normal adrenal medullary chromaffin cells, are not innervated; hence catecholamine release from pheochromocytoma chromaffin cells is autonomous and not susceptible to manipulation by drugs that decrease efferent sympathetic outflow, such as the central α_2 -agonist clonidine. Blood is obtained for plasma catecholamines before and 3 hours after a single oral dose of 0.3 mg clonidine. In a subject without pheochromocytoma, plasma norepinephrine should fall to less than 500 pg/mL after clonidine. A positive test (failure of catecholamines to decline after clonidine) is sensitive but may not be entirely specific for pheochromocytoma. Although catecholamine levels do not fall after clonidine administration in pheochromocytoma, the blood pressure fall is comparable to that seen in essential hypertensives. To prevent inordinate falls in blood pressure during the test, prior volume depletion should be avoided; the test is most safely done in subjects whose diastolic blood pressure before clonidine is 100 mmHg or higher. Because beta-blockers such as propranolol diminish circulating norepinephrine clearance (and hence plasma norepinephrine responses to clonidine), their use should be discontinued 48 hours before and during the test. The test remains valid during alpha-blockade.

Catecholamine provocative tests (such as the glucagon or tyramine tests) are used in only a few centers because of the potential hazard posed by inordinate catecholamine release.

Anatomical localization

Tumor localization allows for planning the proper surgical route. Ninety-five percent of pheochromocytomas are in the abdomen, and the great majority of these can be visualized by one of three modalities: CT, MRI, or [¹³¹I]-metaiodobenzylguanidine (MIBG) scintigraphy. CT and MRI are highly sensitive, although nonspecific because they visualize any mass lesion, not just pheochromocytomas.

[¹³¹I]-MIBG, a radiolabeled analogue of guanethidine, is transported into chromaffin cells by the reuptake cell membrane catecholamine carrier. Because it accumulates in chromaffin cells, an MIBG abnormality is extraordinarily specific (about 98%) for pheochromocytoma, although somewhat less sensitive (85% to 90%) than CT or MRI. [¹²³I]-MIBG is also used extensively outside the United States. MIBG imaging is especially useful for metastatic, recurrent, or extra-adrenal tumors. Abdominal ultrasonography is a safe imaging tool but is less sensitive than CT or MRI. Plain abdominal radiography, intravenous urography (pyelography), air insufflation retroperitoneal pneumography, arteriography, and venography are no longer done to localize pheochromocytoma. Indeed, arteriography or venography of the tumor may trigger hypertensive crises.

Differential diagnosis

Because many conditions can mimic the diagnostic features of pheochromocytoma, as many as 90% of patients who have some feature of the tumor turn out not to have one after diagnostic testing. Examples include certain drugs, such as surreptitiously self-administered epinephrine or isoproterenol. Abrupt withdrawal from clonidine can provoke a sympathoadrenal discharge with “rebound” blood pressure elevation. Subjects treated with MAO inhibitors for depression may have hypertensive crises if they inadvertently ingest foods rich in tyramine.

Disease states causing or simulating catecholamine excess and hypertension include thyrotoxicosis; acute intracranial disturbances such as subarachnoid hemorrhage or posterior fossa masses; hypertensive crisis of paraplegia, which can be initiated by visceral manipulation or bladder distention; and hypoglycemia, especially in the presence of beta-blockade. Damage to carotid sinus baroreceptors by surgery or tumor may result in baroreflex failure, with episodic blood pressure and plasma catecholamine surges; clonidine is the drug of choice.⁹ Episodic surges in plasma dopamine have been described in some patients with episodic blood pressure elevation but without pheochromocytoma; the mechanism has not been established.¹⁰ Some patients with symptomatic blood pressure surges have underlying unrecognized emotional trauma, which may respond to psychotherapy.

Pathophysiology and complications

Although circulating catecholamine excess is the ultimate cause of hypertension in pheochromocytoma, the correlation of blood pressure with plasma catecholamines is modest. Desensitization to catecholamine effects may contribute to underdiagnosis of the tumor in the elderly. In addition to catecholamines, pheochromocytomas also release a number of potentially vasoactive substances that may modify blood pressure. Hemodynamic studies suggest that elevations in systemic vascular resistance rather than cardiac output account for the blood pressure rise.

Acute norepinephrine infusion leads to plasma volume contraction, and a past mainstay of pheochromocytoma management has been an effort to re-expand plasma volume, either spontaneously after therapeutic α -blockade or with preoperative saline infusion. However, recent

careful measurements of plasma volume indicate that on average it is not as contracted as once believed. Orthostatic hypotension is variably observed in pheochromocytoma. It cannot be clearly attributed to plasma volume contraction and probably reflects catecholamine desensitization, the effects of vasodilator peptides and catecholamines and dysautonomia.

The major catecholamine secreted by most pheochromocytomas is norepinephrine. Small intra-adrenal tumors (especially early in the course of MEN type 2) may secrete predominantly epinephrine. Pure epinephrine secretion by pheochromocytomas is rare.

Cardiomyopathy (myocarditis) occurs in a minority of patients with pheochromocytoma, presumably as a consequence of catecholamine excess. This process is generally reversible after tumor removal, and congestive heart failure responds to preoperative α -adrenergic blockade. In most patients, however, the degree of myocardial left ventricular hypertrophy on cardiac ultrasonography is no different from that seen in essential hypertension.

MANAGEMENT

Preoperative preparation and drug treatment

After diagnosis of pheochromocytoma, the patient is prepared for surgery with adrenergic blockade for a period of 1 to 4 weeks. During α -blockade, any catecholamine-induced plasma volume contraction is allowed to correct itself. α -blockade is usually accomplished with oral phenoxybenzamine, an irreversible, noncompetitive antagonist that acts predominantly (although not exclusively) at α_1 -receptors. The drug is begun at 5 mg twice daily, and the dose is adjusted gradually upward by increments of 10 mg every 1 to 4 days to a maximum of 50 to 100 mg twice daily. The usual dose range required is 30 to 80 mg/day. Treatment goals are to normalize blood pressure (<160/<90 mmHg), prevent paroxysmal hypertension, and abolish tachyarrhythmias (ventricular extrasystoles, less than one to five per minute) without inducing intolerable orthostatic hypotension (i.e., orthostatic falls of >85/>45 mmHg). Side effects of an adequate phenoxybenzamine dosage include orthostatic hypotension, tachycardia, nasal congestion, dry mouth, diplopia, and ejaculatory dysfunction. In patients intolerant of phenoxybenzamine, one can use the α_1 -selective antagonists doxazosin (at 2 to 8 mg orally once daily) or prazosin (at 0.5 to 16 mg/day, orally two to four times daily). Some authorities advocate the initial use of the newer, more selective α_1 -selective antagonists (e.g., doxazosin) in preference to phenoxybenzamine, since phenoxybenzamine's alkylation of α -receptors may cause prolonged α -blockade contributing to postoperative hypotension, and its minor action on presynaptic α_2 -receptors may contribute to increased sympathetic neuronal norepinephrine release, causing undesirable chronotropic and inotropic effects in the heart.

If blood pressure or tachyarrhythmias, including sinus tachycardia, are not fully controlled by α -blockade, beta-

blockade is instituted with oral propranolol, 10 to 40 mg four times daily. Beta-blockade must not be undertaken before α -blockade has been instituted; after blockade of vasodilatory vascular β_2 -adrenergic receptors, catecholamines' continued access to vasoconstrictive α_1 -receptors, may induce unopposed vasoconstriction and exacerbation of hypertension. Beta-blockade may be especially useful for predominantly epinephrine-secreting tumors. The more β_1 -selective antagonists atenolol (50–100 mg/day) or metoprolol (50–200 mg/day), or the combined alpha/beta-antagonist labetalol (100–400 mg/day), are alternatives to propranolol, and are preferable in the view of some authorities. In subjects with contraindications to beta-blockade, lidocaine, or amiodarone can be used for tachyarrhythmias.

If combined management with α - plus β -adrenergic antagonists is not fully effective (especially in patients with widespread, unresectable malignant pheochromocytoma), the tyrosine hydroxylase inhibitor α -methyl-paratyrosine is added at an oral dose of 0.25 to 1.0 g four times daily. Its use may be complicated by sedation, fatigue, anxiety, diarrhea, or extrapyramidal reactions.

For acute management of severe hypertensive crises, intravenous nitroprusside is effective. Intravenous non-selective α_1/α_2 -blockade with phentolamine (1 to 2 mg bolus, then by further incremental doses or continuous infusion) is also useful. If a pressor response is accompanied by tachycardia, the combined α - and β -adrenergic antagonist labetalol (intravenous 5-mg incremental doses) may also be useful. Calcium channel blockade with sublingual nifedipine (10 mg broken under the tongue) has also been used.

Opiates (narcotic analgesics), narcotic antagonists (such as naloxone), histamine, adrenocorticotrophic hormone, saralasin, glucagon, or indirect sympathomimetic amines (such as phenylpropanolamine or tyramine) should be avoided. All of these agents may provoke hypertensive surges by releasing catecholamines from the tumor. Drugs that block catecholamine reuptake, such as tricyclic antidepressants (e.g., desipramine), cocaine, or guanethidine, may worsen hypertension. Beta-adrenergic antagonists, by blocking vasodilatory vascular β_2 -receptors, may cause unopposed α -mediated vasoconstriction by circulating catecholamines and thereby result in severe hypertension, unless α -blockade is first instituted beforehand. Dopaminergic antagonists (such as metoclopramide or sulpiride) may result in hypertension, and should be avoided.

Operative and perioperative management

Autopsy series indicate that even clinically unsuspected cases of pheochromocytoma can be lethal. At least 90% of pheochromocytomas are benign, and surgical resection provides a cure, although up to 25% of patients may retain some lesser degree of hypertension. Residual tumor may be diagnosed by urinary catecholamine measurement 1 to 2 weeks postoperatively. The operative mortality of pheochromocytoma resection should not exceed 2% to 3%. Patients should be followed for at least 10 years postoperatively, because of the small (~5%) risk of late tumor recurrence. Perioperative complications were more frequent in patients with higher blood pressures, higher catecholamine/metabolite excretion, recurrent/multiple surgical excisions, or prolonged anesthesia. In malignant pheochromocytoma, the individual course is highly vari-

Figure 72-3. Plasma concentrations of chromaffin granule transmitters (chromogranin A, norepinephrine, and epinephrine) in subjects with pheochromocytoma ($n=27$ patients) stratified by tumor behavior, benign ($n=13$) versus malignant ($n=14$). Individual values are shown from samples obtained prior to treatment. Normal ranges: chromogranin A, 48.0 (SE) ± 3.0 ng/mL; norepinephrine 200 ± 7.8 pg/mL; epinephrine 18.0 ± 1.5 pg/mL. The lower limit of detection for plasma epinephrine is 5 pg/mL. To convert chromogranin A from ng/mL to μ g/L, multiply by 1.0. To convert epinephrine from pg/mL to pmol/L, multiply by 5.458. To convert norepinephrine from pg/mL to nmol/L, multiply by 0.005911. (From Rao F, Keiser HR, O'Connor DT. *Hypertension* 2000;36:1045–52.)

Figure 72-4. Response of chromaffin granule transmitter concentrations to successful surgical resection of benign adrenal pheochromocytoma ($n=6$ patients). Postoperative nadir values were analyzed (samples obtained at 4.1 ± 2.0 , [range 0.7–13.5] months after resection). Normal ranges: chromogranin A, 48.0 ± 3.0 ng/mL; norepinephrine 200 ± 7.8 pg/mL; epinephrine 18.0 ± 1.5 pg/mL. Paired comparisons were made by the nonparametric Wilcoxon signed rank test. To convert chromogranin A from ng/mL to $\mu\text{g/L}$, multiply by 1.0. To convert epinephrine from pg/mL to pmol/L, multiply by 5.458. To convert norepinephrine from pg/mL to nmol/L, multiply by 0.005911. (From Rao F, Keiser HR, O'Connor DT. *Hypertension* 2000;36:1045–52.)

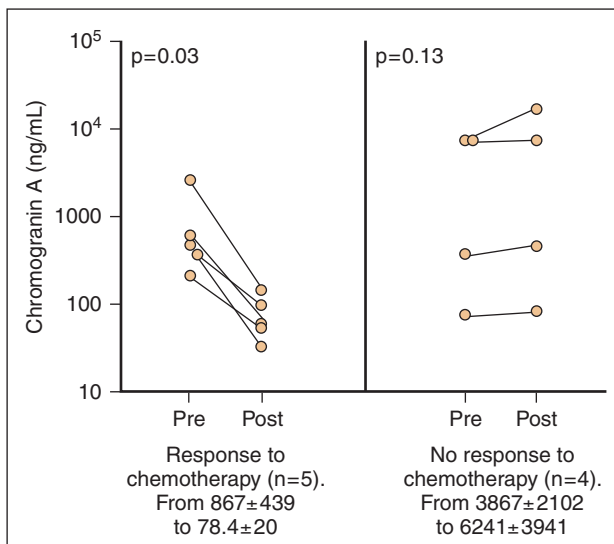

Figure 72-5. Changes in chromaffin granule transmitter (chromogranin A) concentrations in plasma after intravenous combination chemotherapy for malignant pheochromocytoma, stratified by response to chemotherapy: $n=5$ patients with response to chemotherapy versus $n=4$ patients with no response to chemotherapy. Postchemotherapy nadir values were analyzed (in the four nonresponders, samples obtained at 6.6 ± 1.1 [range 4–9] months after initiation of treatment; in the five responders, samples obtained at 13.2 ± 2.5 [range 6.5–22] months after initiation of treatment). Normal range: chromogranin A, 48.0 ± 3.0 ng/mL. (From Rao F, Keiser HR, O'Connor DT. *Hypertension* 2000;36:1045–52.)

able, but long-term 50% survival is less than 5 years.

Several surgical approaches are feasible, depending on the particular characteristics of the pheochromocytoma; the experience of the surgeon is crucial. Laparoscopic adrenalectomy is increasingly used and may result in faster postoperative recovery. The entire adrenal gland harboring a pheochromocytoma is usually excised, but during excision of bilateral pheochromocytomas, a section of cortex from one adrenal gland may be left in place, to prevent steroid dependency. Anesthetic management is guided by selection of agents that do not cause catecholamine release or potentiate its dysrhythmic effects.¹¹ Intravenous glucose replacement (5% dextrose in water or saline) should be given to prevent hypoglycemia, a frequent occurrence after tumor removal. Times at which hypertensive surges are likely to occur include anesthetic induction, intubation, tumor palpation, and ligation of tumor veins. If intraoperative hypotension occurs, the initial treatment should be saline infusion to expand intravascular volume. Norepinephrine infusion is appropriate only after plasma volume

expansion to euvolemia.

For intraoperative blood pressure surges, intravenous nitroprusside is often used. Alternatively, α -blockade can be accomplished with intravenous phentolamine (an α_1 - and α_2 -antagonist), starting with a 1- to 2-mg dose and proceeding to infusion. The calcium channel antagonist nicardipine has also been used.

In the postoperative period, the following problems occur with some frequency:

1. **Hypotension.** Most commonly, hypotension results from hypovolemia and responds to saline infusion; several liters may be required, often with the guidance of central pressure measurements. After volume repletion, norepinephrine can be infused if needed.
2. **Hypertension.** Plasma catecholamine levels may remain elevated for several days even after complete pheochromocytoma resection. Even 2 weeks postoperatively, up to one-fourth of patients still have hypertension. At this time the differential diagnosis includes residual unresected tumor, essential hypertension, or hypertension secondary to renal damage caused by prior hypertension. A urine collection for catecholamines, obtained at least 1 to 2 weeks after tumor resection, may clarify matters.
3. **Hypoglycemia.** After correction of catecholamine excess, insulin release may be increased and end-organ responsiveness to insulin augmented, resulting in hypoglycemia. Hypoglycemia may masquerade as refractory hypotension. Infusion of glucose (5% dextrose in water or saline) during the intraoperative and immediate postoperative period is useful.

Malignant pheochromocytoma

Although most pheochromocytomas are well-encapsulated, localized growths, approximately 5% to 10% are malignant. Malignancy is diagnosed by the biologic behavior of the tumor in the form of adjacent tissue invasion or distant metastatic spread. Extra-adrenal tumors are more likely to metastasize than are primary adrenal ones. Catecholamine biosynthesis tends to be especially deranged in malignant tumors, with secretion of substantial amounts of DOPA and dopamine (metabolized to homovanillic acid, which can be detected in the urine). Increased plasma DOPA in pheochromocytoma suggests malignancy. Extreme elevations in plasma norepinephrine or chromogranin A may suggest malignant pheochromocytoma; serial chromogranin A measurements can then be used to gauge tumor response to treatment.¹²

In patients with malignant pheochromocytoma, α - and β -adrenergic blockade with phenoxybenzamine and propranolol remains the mainstay of management of the symptoms and signs of catecholamine excess. If catecholamine effects are not controlled, the tyrosine hydroxylase inhibitor α -methylparatyrosine can be effective at 0.25 to 1.0 g four times daily.

Metastases tend to be slow-growing, and the natural history of malignant pheochromocytoma is variable; the

5-year survival rate is less than 50%. Common sites of metastasis are the retroperitoneum, skeleton (bone), lymph nodes, and liver. Periodic surgical debulking may help control symptoms. The response to chemotherapy has generally been disappointing, but the combination of vincristine, cyclophosphamide, and dacarbazine shows promise in many patients. Skeletal metastases show some response to irradiation, although the neoplasm is not particularly susceptible to radiation therapy. High-dose (~500 mCi cumulative dose) repeated radiation therapy with intravenous [¹³¹I]-MIBG remains experimental but is of value in some patients.

CHROMOGRANIN A IN PHEOCHROMOCYTOMA: DIAGNOSIS, TREATMENT, AND PROGNOSIS

Neurons and neuroendocrine cells contain membrane-delimited pools of peptide hormones, biogenic amines, and neurotransmitters with a characteristic electron-dense appearance on transmission electron microscopy (Figure 72–2). These vesicles, which are present throughout the neuroendocrine system and in a variety of neurons, store and release chromogranins and secretogranins (also known as “granins”), a unique group of acidic, soluble secretory

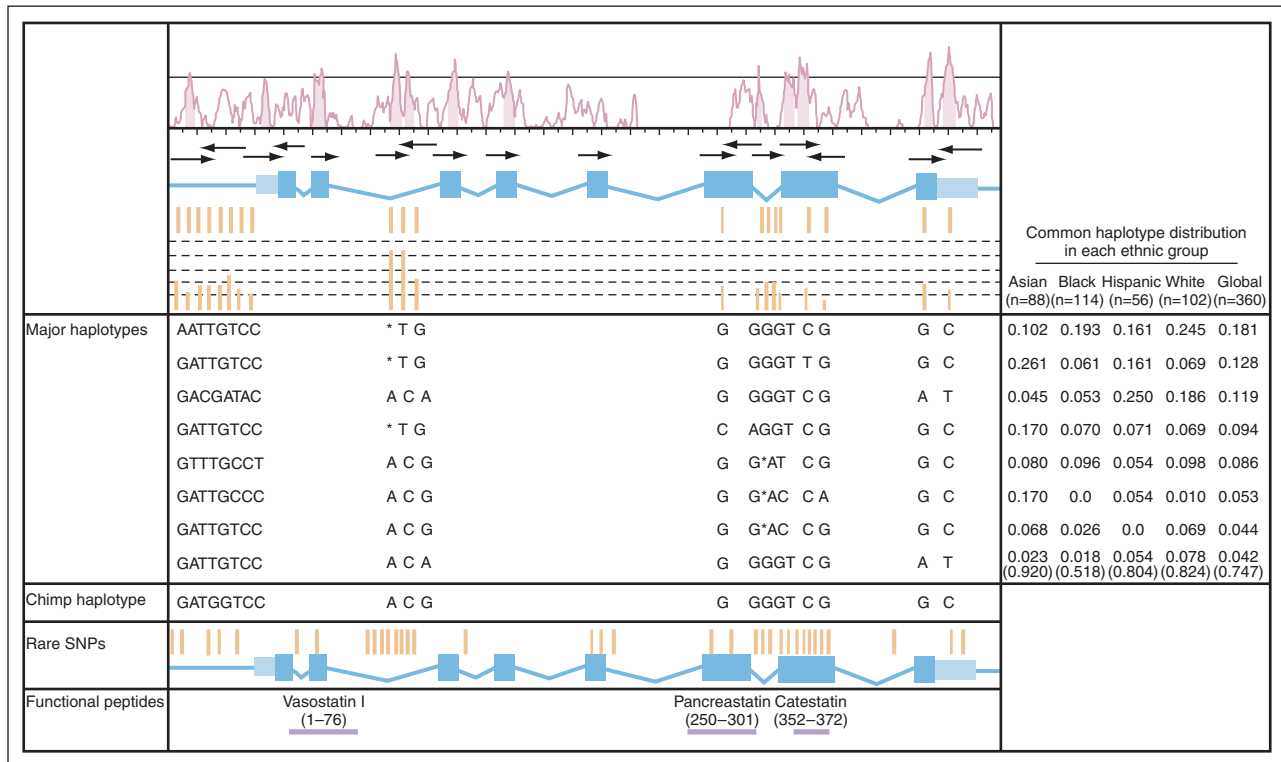

Figure 72–6. Resequencing strategy for the human chromogranin A gene, and identified variants. Conserved noncoding sequences between mouse and human chromogranin A were visualized with VISTA. Location of common (*upper*) and rare (*lower*) single nucleotide polymorphisms (SNPs) relative to exons and conserved noncoding sequences is indicated by position. *Red rods* represent nonsynonymous SNPs, and *black rods* represent synonymous SNPs. Nucleotides in red color in chimpanzee haplotype indicates the minor allele in the human sequence. Computationally reconstructed haplotypes are indicated along with their relative frequencies in ethnogeographic groups within our sample population. Nucleotide deletions in haplotype sequences are indicated by asterisk (*). (From Wen G, Mahata SK, Cadman PE, Mahata M, Ghosh S, Mahapatra NR, et al. *Am J Hum Genet* 2004;74:197–207.)

proteins.⁷ The three “classic” granins are chromogranin A (CgA), which was first isolated from chromaffin cells of the adrenal medulla; chromogranin B, initially characterized in a rat pheochromocytoma cell line; and secretogranin II (sometimes called chromogranin C), which was originally described in the anterior pituitary. Because of their ubiquitous distribution in neuroendocrine and nervous-system tissues and their co-secretion with resident peptide hormones and biogenic amines, granins are valuable indicators of sympathoadrenal activity and clinically useful markers of secretion from normal and neoplastic neuroendocrine cells. Indeed, numerous studies have documented the clinical value of detecting granins in tissues and measuring circulating levels of granins, particularly chromogranin A. In addition to providing information about the neuroendocrine character of various neoplasms, measurement of chromogranin A has yielded insights into the pathogenesis of essential hypertension.

Several circulating granins are sensitive biomarkers for pheochromocytoma. Elevation of plasma CgA is used diagnostically in suspected pheochromocytoma, and in familial syndromes such as von Hippel-Lindau syndrome,^{3,4} multiple endocrine neoplasia (MEN) type 2 (MEN2), and neurofibromatosis. In sporadic pheochromocytoma, elevation of plasma CgA concentration was 83% sensitive and 96% specific for the diagnosis, and CgA concentration correlated with tumor mass.⁶ Drugs commonly used to diagnose or treat pheochromocytoma, such as phentolamine, tyramine, clonidine, and metoprolol, do not significantly alter serum CgA levels. Furthermore, unlike plasma epinephrine and norepinephrine, plasma CgA levels can distinguish between malignant and benign pheochromocytoma. In one study, CgA levels of 188 ± 40.5 (SE) ng/mL signified benign disease while much higher levels of (2932 ± 960 ng/mL) suggested malignancy.¹² Serum CgA may not provide adequate diagnostic

Figure 72-7. Autocrine negative feedback regulation of nicotinic cholinergic processes by catestatin variants. The diagram illustrates nicotinic cholinergic receptor activation in chromaffin cells by the endogenous agonist, acetylcholine (ACh), with subsequent mobilization of signal transduction (initially ligand-gated extracellular Na⁺ entry); then Ca²⁺ entry through voltage-operated calcium channels. Farther downstream, activation of secretion and transcription (“stimulus transcription coupling”) is also illustrated. Agonist stimulation of nicotinic receptor activation (opening of the cation pore formed by the alpha and beta subunits), followed by receptor desensitization (closing of the cation pore) is depicted. Finally, the actions of catestatin, co-released by exocytosis with catecholamines, are shown on several nicotinic cholinergic processes: receptor activation, initial cationic signaling, subsequent signaling to secretion and transcription, and finally receptor desensitization. (From Mahata SK, Wen G, Mahapatra N, Mahata N, Hamilton BA, O’Connor DT. *Mol Pharmacol* 2004;66:1180–91.)

specificity for pheochromocytoma in patients with impaired renal function.^{8,13,14} However, this limitation can be overcome by evaluating renal function in the patient,^{8,13,14} and combining measurement of CgA with plasma catecholamines, which may provide lower diagnostic sensitivity, but improved specificity and positive predictive value.¹⁴ In factitious pheochromocytoma, normal plasma CgA may be a valuable clue to the diagnosis.¹⁵ Measurements of CgB and SgII may also be of diagnostic value in patients with suspected pheochromocytoma. Indeed, plasma CgB was elevated in 81% of patients,¹⁶ and an increase of four- to five-fold for plasma secretoneurin was observed.¹⁷

Rao et al.¹² studied plasma concentrations of chromaffin granule transmitters (chromogranin A, norepinephrine, and epinephrine) in patients with pheochromocytoma ($n=27$), both benign ($n=13$) and malignant ($n=14$). Patients with benign pheochromocytoma were studied before and after surgical removal ($n=6$), while patients with malignant pheochromocytoma were evaluated before and after chemotherapy cycles of cyclophosphamide/dacarbazine/vincristine (nonrandomized trial in $n=9$).

In the diagnosis of pheochromocytoma (benign or malignant), Rao et al.¹² found a progressive rise ($p<0.0001$) in plasma chromogranin A, from control subjects (48.0 ± 3.0 SE ng/mL) to benign pheochromocytoma (188 ± 40.5 SE ng/mL) to malignant pheochromocytoma (2932

± 960 SE ng/mL). Parallel changes were seen for plasma norepinephrine ($p<0.0001$). When stepwise linear regression was allowed to select the model, the independent variable best predicting the distinction of pheochromocytoma versus control was norepinephrine (multiple $R=0.417$, $R^2=0.174$, adjusted $R^2=0.149$, $T=2.67$, $F=7.14$, $p=0.011$).

Both plasma chromogranin A ($p=0.0003$) and norepinephrine ($p=0.0344$) were higher in malignant than benign pheochromocytoma (Figure 72–3), although plasma epinephrine was actually lower ($p=0.0182$) in malignant tumors. In a stepwise multivariate analysis, plasma chromogranin A elevation proved to be the most significant difference between benign and malignant tumors (adjusted $R^2=0.202$, $F=7.56$, $p=0.011$).

In the treatment of pheochromocytoma, Rao et al.¹² found that after surgical excision of benign pheochromocytomas, chromogranin A ($p=0.028$), norepinephrine ($p=0.047$), and epinephrine ($p=0.037$) all fell to values near normal (Figure 72–4). During chemotherapy of malignant pheochromocytoma ($n=9$) (Figure 72–5), plasma chromogranin A ($p=0.047$) and norepinephrine ($p=0.02$) fell, but not epinephrine. After chemotherapy, five clinical “responders” showed declines in chromogranin A (by $\sim 91\%$, $p=0.03$) and norepinephrine (also by $\sim 91\%$, $p=0.03$) but not epinephrine ($p=0.31$). By contrast,

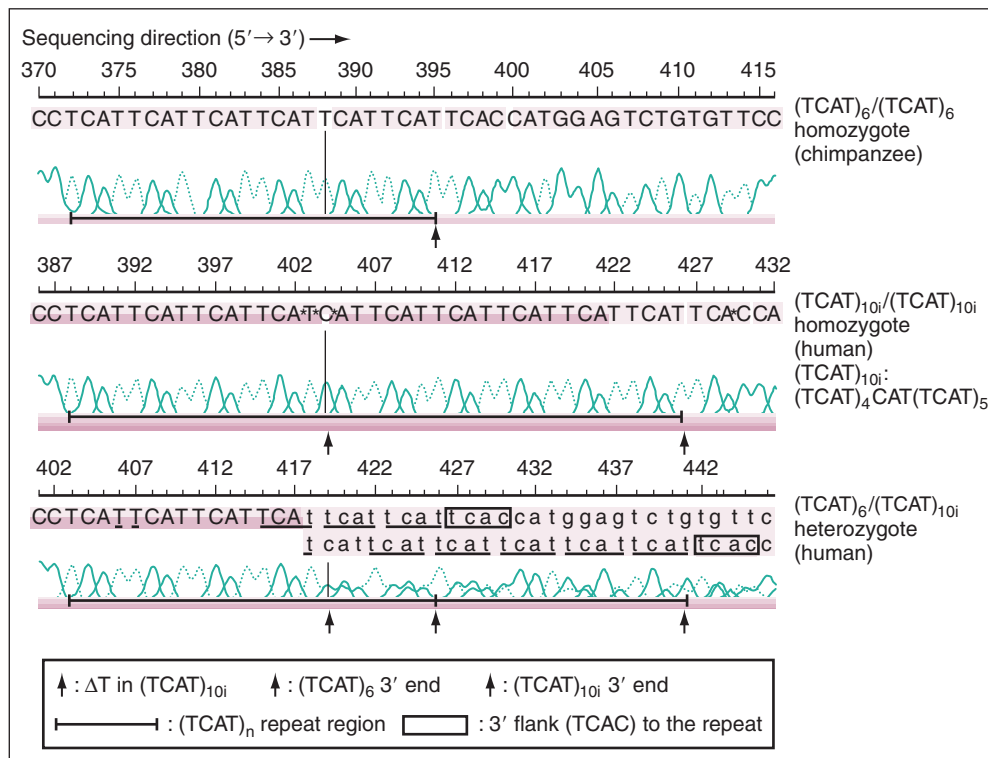

Figure 72–8. Determination of tyrosine hydroxylase ($TCAT$)_n genotype by resequencing a 475-bp amplicon in tyrosine hydroxylase intron A from human genomic DNA. The ABI-3100 sequence trace data display window from PolyPhred is shown, along with the direction of sense-strand sequencing ($5' \rightarrow 3'$). Results are shown for a $(TCAT)_6/(TCAT)_6$ homozygote, a $(TCAT)_{10i}/(TCAT)_{10i}$ heterozygote, and a $(TCAT)_6/(TCAT)_{10i}$ homozygote. $(TCAT)_{10i}$: $(TCAT)_4CAT(TCAT)_5$. Sequencing from the opposite (antisense) direction confirmed each genotype. (From Zhang L, Rao F, Wessel J, Kennedy BP, Rana BK, Taupenot L, et al. *Physiol Genomics* 2004;19:277–91. Used with permission.)

four “nonresponders” showed no significant decline in any of the transmitters (all $p=0.13$).

Rao et al.¹² concluded that plasma chromogranin A is an effective tool in the diagnosis of pheochromocytoma, and markedly elevated chromogranin A may point to malignant pheochromocytoma. During chemotherapy of malignant pheochromocytoma, chromogranin A can be used to gauge tumor response and relapse.

CATECHOLAMINE STORAGE AND RELEASE: COMMON HUMAN GENETIC VARIATION IN CHROMOGRANIN A

Chromogranin A (CgA) expression and activity have been proposed as “intermediate phenotypes” in human essential hypertension.¹⁸ Family studies have shown substantial heritability of hypertension, yet the specific genes leading to chronic, pathologic increases in blood pressure remain poorly understood. Genetic analyses of complex traits such as hypertension are complemented by the use of intermediate phenotypes—simpler, often monogenic traits with earlier penetrance than the ultimate disease phenotype.¹⁹ The CgA locus likely controls intermediate phenotypes that contribute to hypertension.¹⁸ CgA is overexpressed in chromaffin cells of genetic (SHR, spontaneously hypertensive rat)^{19,20} and acquired (renovas-

cular)²¹ rodent models of human essential hypertension, and twin studies have shown significant heritability of circulating CgA in humans.²² Furthermore, circulating levels of the CgA catestatin fragment, which inhibits nicotinic receptor-induced secretion of catecholamines,²³ are decreased in hypertensive patients as well as in normotensive patients at genetic risk (i.e., one or both parents have hypertension) of developing the disease.¹⁸

Wen et al.²⁴ studied the effect of sequence variation within the CgA gene to identify genetic variants that might quantitatively and/or qualitatively alter the protein and its bioactive peptide products. The investigators resequenced all eight exons and adjacent intronic regions, ~1.2 kilobases of the 5' promoter region, and two highly conserved intronic regions from 180 ethnically diverse human subjects living in urban southern California (San Diego). Wen et al.²⁴ identified 53 single nucleotide polymorphisms (SNPs) and 2 single-base insertion/deletions in the resequenced regions (Figure 72–6). Seventeen of the polymorphisms occurred in the coding region of the gene, while 11 of the 17 encoded amino acid substitutions. Three of these nonsynonymous coding SNPs—Gly364Ser, Pro370Leu, and Arg374Gln—were relatively uncommon (minor allele frequency 0.3% to 3.1%) variants of the catestatin region, where they appear the ability of the peptide to inhibit catecholamine secretion.

Figure 72–9. Tyrosine hydroxylase polymorphism: pleiotropy and phenotypic clusters. (TCAT)_{10i} joint predictions of biochemical (renal norepinephrine excretion) and physiologic (pulse interval) phenotypes in twins. Clusters are displayed as mean value plus or minus one standard error of the mean for each trait, by generalized estimator equations. Joint prediction of two traits by one genotype was tested by multivariate analysis of variance (MANOVA), wherein the model contains one independent variable (genotype) and two dependent variables (biochemical and physiological). MANOVA: Pillai's trace $F=3.30$, $p=0.012$; Wilks' lambda $F=3.38$, $p=0.011$. Hotelling's trace $F=3.46$, $p=0.009$; Roy's largest root $F=7.054$, $p=0.001$. (From Zhang L, Rao F, Wessel J, Kennedy BP, Rana BK, Taupenot L, et al. *Physiol Genomics* 2004;19:277–91. Used with permission.)

The functional significance of individual SNPs on the expression of CgA and its peptide products was examined. One-way analysis of variance with Bonferroni correction for multiple comparisons identified three SNPs in the promoter region that were significantly associated with plasma CgA concentrations. These three SNPs were in absolute linkage disequilibrium with each other, thus indicating possible haplotype-specific effects. The authors tested the functional significance of inferred promoter haplotypes by placing the haplotypes upstream of a luciferase reporter and assaying expression in PC12 rat chromaffin cells. The promoter SNPs resolved into 6 relatively common haplotypes, each differing in the ability to promote transcription and regulate gene expression.

To determine the functional significance of amino acid substitution SNPs occurring in the catestatin peptide, the authors synthesized wild-type and variant synthetic peptides and assayed their potency for inhibition of nicotinic cholinergic-stimulated catecholamine release from PC12 chromaffin cells.²⁵ The two SNPs resulted in greater than 10-fold differences in the ability of catestatin to inhibit catecholamine release. Figure 72–7 summarizes the role of the catecholamine release-inhibitory peptide catestatin in sympathochromaffin function.

Thus genetic variation within the chromogranin A locus can quantitatively and qualitatively affect the protein and its bioactive peptide products, further supporting the role of CgA as an important contributor to and intermediate phenotype for hypertension.

CATECHOLAMINE BIOSYNTHESIS: COMMON FUNCTIONAL HUMAN GENETIC VARIATION IN RATE-LIMITING ENZYME TYROSINE HYDROXYLASE

Tyrosine hydroxylase (TH) is the rate-limiting enzyme in catecholamine biosynthesis.²⁶ Zhang et al.²⁷ employed the classic twin study design to probe the influence of tyrosine hydroxylase polymorphisms on autonomic traits. Previous studies have shown associations between the microsatellite tetranucleotide repeat (TCAT)_n polymorphism within intron A of the human tyrosine hydroxylase gene, hypertension,²⁸ and blood pressure regulation. Zhang et al.²⁷ investigated the relationship between biochemical (catecholamine) and physiologic autonomic phenotypes, heritability estimates, and (TCAT)_n genotypes within the twin population. The twin study consisted of 103 monozygotic (MZ) and 45 dizygotic (DZ) twin pairs of European ancestry (white) from urban southern California (San Diego). Thirty subjects were hypertensive while the remaining individuals were normotensive.

Biochemical and physiologic autonomic phenotypes measured included plasma and urinary catecholamines (norepinephrine and epinephrine), basal blood pressure, pulse interval (R-R interval or heart period, in milliseconds per beat), and blood pressure and pulse interval responses to cold stress (i.e., the “cold pressor test”: immersion of one hand in ice water). Heritability for each of the autonomic phenotypes was determined and each subject was genotyped for the (TCAT)_n microsatellite. Sequencing

revealed six alleles of the (TCAT)_n microsatellite repeat, differing in number of consecutive TCAT repeats: (TCAT)₆, (TCAT)₇, (TCAT)₈, (TCAT)₉, (TCAT)₁₀, and the imperfect repeat (TCAT)₄CAT(TCAT)₅, also known as (TCAT)_{10i}. The two most common alleles observed were (TCAT)₆ and (TCAT)_{10i} (Figure 72–8).

Biochemical phenotypes showed substantial heritability (h^2): plasma norepinephrine (NE) $h^2=55.3 \pm 8.0\%$, $p<0.0001$; plasma epinephrine (EPI) $h^2=61.4 \pm 9.8\%$, $p=0.0460$; urinary NE $h^2=32.5 \pm 9.6\%$, $p=0.001$; urinary EPI $h^2=47.1 \pm 8.8\%$, $p<0.0001$. Basal heart rate and basal blood pressure also showed significant heritability, with heart rate ($h^2=61 \pm 6\%$, $p<0.0001$) showing substantially more heritability than either systolic blood pressure (SBP) ($h^2=26 \pm 8\%$, $p=0.0016$) or diastolic blood pressure (DBP) ($h^2=18 \pm 9\%$, $p=0.0359$). Cold stress-induced changes in heart rate (Δ HR $h^2=36 \pm 8\%$, $p<0.0001$) and blood pressure (Δ SBP $h^2=23 \pm 9\%$, $p=0.0098$; Δ DBP $h^2=32 \pm 8\%$) were also heritable. As positive controls, the heritability of weight ($h^2=87 \pm 2\%$, $p<0.0001$) and height ($h^2=93 \pm 1\%$, $p<0.0001$) were computed to verify the reliability of the heritability estimates.

Significant correlations between biochemical and physiologic traits with mechanistic implications for autonomic control of blood pressure were reported: (1) a positive correlation between renal NE excretion and resting SBP

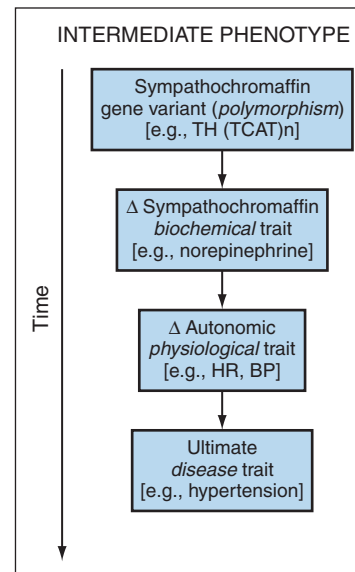

Figure 72–10. Tyrosine hydroxylase (TCAT)_n polymorphism and “intermediate phenotypes” in the autonomic system. In the “intermediate phenotype” schema,³⁶ biochemical traits are postulated to be determined earlier and more proximately by genotype than are physiologic traits. Δ , change; BP, blood pressure; HR, heart rate; TH, tyrosine hydroxylase. (From Zhang L, Rao F, Wessel J, Kennedy BP, Rana BK, Taupenot L, et al. *Physiol Genomics* 2004; 19:277–91. Used with permission.)

(Pearson $R=0.48$, $R^2=0.23$, $n=111$, $p<10^{-7}$), and (2) a positive correlation between renal NE excretion and SBP increase in response to cold stress ($R=0.30$, $R^2=0.09$, $n=112$, $p=0.001$).

Zhang et al.²⁷ used a variance components method to determine the effect of variation of individual $(TCAT)_n$ microsatellite alleles on autonomic trait heritability. To maximize statistical power, the variance components analysis focused only on the most common alleles: $(TCAT)_6$ and $(TCAT)_{10i}$. An increase in $(TCAT)_6$ copy number (from 0 to 1 to 2 alleles) was associated with increased basal pulse interval ($p=0.007$), as well as basal ($p=0.0003$) and post-cold-stress ($p=0.0001$) heart rate. In contrast, an increase in $(TCAT)_{10i}$ copy number was associated with decreased pulse interval ($p=0.0349$), increased plasma epinephrine ($p=0.0133$), and increased renal NE excretion ($p=0.0309$). The $(TCAT)_6$ and $(TCAT)_{10i}$ alleles exerted directionally opposite effects on pulse interval.

The $(TCAT)_6/(TCAT)_6$ homozygous, $(TCAT)_6/(TCAT)_{10i}$ heterozygous, and $(TCAT)_{10i}/(TCAT)_{10i}$ homozygous diploid genotypes also exerted effects on autonomic

phenotypes, specifically basal and post-stress heart rate. Within the diploid genotypes, the $(TCAT)_6$ allele exerted a dose-dependent direct effect on basal pulse interval and inverse effect on pre- and post-stress heart rate. Conversely, the $(TCAT)_{10i}$ allele displayed a dose-dependent inverse effect on basal pulse interval, and a direct effect on pre- and post-stress heart rate. Finally, Zhang et al.²⁷ suggested that the $(TCAT)_n$ polymorphisms of tyrosine hydroxylase exhibit pleiotropy (i.e., one gene influences multiple phenotypes), since $(TCAT)_{10i}$ allele copy number predicted both pulse interval (inverse relationship) and renal norepinephrine excretion (direct relationship) in a dose-dependent fashion (multivariate analysis of variance: Pillai $F=3.30$, $p=0.012$) (Figure 72–9).

$TCAT$ allele frequencies also differed in subjects stratified by genetic risk of hypertension. Thus the catecholamine and stress physiologic traits may represent “intermediate phenotypes” in the pathway whereby common human genetic variation influences ultimate disease traits, such as hypertension (Figure 72–10).

Figure 72–11. Pre- and post-synaptic locations, within the sympathetic neuroeffector junction, of proteins encoded by loci examined. The schematic neuron is illustrative of the functions of an efferent postganglionic sympathetic axon, innervating such cardiovascular targets as vascular smooth myocytes or cardiac myocytes. Note that the biosynthesis and vesicular uptake of catecholamines (although not soluble peptides) can take place throughout the neuron, even in the terminus. By contrast, vesicular soluble peptides (e.g., chromogranin A and neuropeptide Y) can only enter the vesicle as it buds off the Golgi apparatus in the cell soma. (From Chitbangonsyn SW, Mahboubi P, Walker D, Rana BK, Diggle KL, Timberlake DS, et al. *J Hum Hypertens* 2003;17:319–24.)

Figure 72-12. Chromosomal clusters of adrenergic candidate loci observed during radiation hybrid (RH) mapping: human chromosome 5q. The map units are cR3000, where one cR3000 corresponds to ~270 kbp. Chromosome 5q cluster in a region linked to systolic blood pressure. The microsatellite marker linked to systolic blood pressure variation in sibling pairs is D5S1471, while the microsatellite associated with systolic blood pressure variation is D5S2093. A neuroeffector candidate locus newly mapped by the RH technique to chromosome 5q is ADRA1B. Other locus positions are already in the public domain (www.ncbi.nlm.nih.gov/genome/guide/human). ADRA1B, alpha₁-adrenergic receptor; ADRB2, β₂-adrenergic receptor; DRD1, dopamine receptor isoform 1; GPRK6, G protein-coupled, receptor kinase isoform 6; NPY6R, neuropeptide Y receptor isoform 6 (pseudogene). (From Chitbangonsyn SW, Mahboubi P, Walker D, Rana BK, Diggle KL, Timberlake DS, et al. *J Hum Hypertens* 2003;17:319–24.)

Zhang et al.²⁷ thus presented compelling evidence for the role of allelic variation at the tyrosine hydroxylase locus in regulation of biochemical and physiologic autonomic phenotypes, with mechanistic implications for regulation of blood pressure and, ultimately, the development of hypertension.

SYMPATHETIC NEUROEFFECTOR JUNCTION GENOMICS

Allelic variation at multiple genetic loci may contribute to hypertension. Since autonomic or sympathetic dysfunction may play an early, pathogenic, heritable role in hypertension, we evaluated candidate loci likely to contribute

to such dysfunction, including the components of the sympathetic neuroeffector junction (Figure 72-11): catecholamine biosynthetic enzymes, catecholamine transporters, neuropeptides, and adrenergic receptors.²⁹ Since chromosomal locations and physical map positions of many of these loci had not yet been identified, we used the GeneBridge4 human/hamster radiation (somatic cell) hybrid library panel (resolution ~1 to ~1.5 Mb), along with specifically designed oligonucleotide primers and PCR (200–400 bp products) to position these loci in the human genome. Primers were designed from sequences outside the coding regions (3'-flanking or intronic segments) to avoid cross-species (hamster) amplification. Chromosomal positions were assigned in cR (centi-Ray) units (~270 kbp/cR3000 for GeneBridge 4). A total of 13 loci were newly assigned chromosomal positions; of particular interest was a cluster of adrenergic candidate loci on chromosome 5q (including ADRB2, ADRA1A, DRD1, GPRK6, and the NPY6R pseudogene), a region harboring linkage peaks for blood pressure (Figure 72-12). Such physical map positions will enable more precise selection of polymorphic microsatellite and single nucleotide polymorphism markers at these loci, to aid in linkage and association studies of autonomic-sympathetic dysfunction in human hypertension.

SUMMARY

In the “postgenomic era,” information on interindividual DNA sequence variation will become more readily available, and applicable to complex human traits such as systemic hypertension and other catecholaminergic disorders. Careful human phenotyping may be essential to understanding the consequences of genetic variants in the catecholaminergic pathway for autonomic function. Such study designs as the classical twin method²⁷ present many advantages for the elucidation of the hereditary basis of common human phenotypic variation. Coupling of such human study designs with increasingly powerful and rapid advances in genome technology²⁹ may ultimately provide a comprehensive picture of the role of the genome in determination of sympathochromaffin activity.

Chapter
73Nonadrenal Endocrine
Hypertension

J. Enrique Silva

Key Findings

- Thyroid dysfunction, hyperparathyroidism, and acromegaly are frequently associated with changes in systemic arterial blood pressure or overt hypertension.
- Thyroid hormone increases cardiac contractility and reduces systemic vascular resistance, which leads to increased cardiac output and pulse pressure. Hyperthyroidism is associated with increases in pulmonary arterial pressure, while there is little effect on mean systemic blood pressure.
- Hypothyroidism is frequently associated with increased mean blood pressure and reduced amplitude of pulse pressure.
- Primary hyperparathyroidism is frequently associated with increases in blood pressure. Elevated serum calcium, changes in intracellular calcium, increased 1,25-di-OH vitamin D, and the so-called parathyroid hypertensive factor are likely contributors.
- Given acutely, parathyroid hormone reduces blood pressure, but chronically leads to functional abnormalities, and with time, to vascular remodeling.
- Hypertension is frequently found in acromegaly, and cardiovascular disease is the main cause of mortality in these patients.
- Because of the progression from functional abnormalities to tissue remodeling, particularly in primary hyperparathyroidism and acromegaly, these conditions should be diagnosed early and treated promptly.

Systemic arterial hypertension is a central manifestation of endocrine diseases involving hypersecretion of the adrenal cortex, adrenal medulla, or extra-adrenal chromaffin tissues. These conditions are discussed in other chapters in Section 3 of this volume. However, hormones from other glands have important hemodynamic effects or may affect vascular biology; hence, diseases disrupting their hormones frequently have an impact on hemodynamics and blood pressure (BP). Among these conditions, thyroid dysfunction, hyperparathyroidism, and acromegaly are frequently associated with changes in systemic arterial BP or overt hypertension.

HYPERTENSION AND THYROID DYSFUNCTION

The biological effects of thyroidal secretion, called thyroid hormone (TH) here (calcitonin is not included in this

discussion), are for the most part mediated by triiodothyronine (T_3), although the major product of thyroidal secretion is thyroxine (T_4). T_3 is about 10 times more active than T_4 and more than 80% of T_3 is produced outside the thyroid in humans from 5' deiodination of T_4 .¹ The effects of TH are largely the result of modifying the transcription of specific genes by T_3 , which is mediated by nuclear TH receptors (TRs). These are ligand-activated transcription factors that, upon binding T_3 (or T_4 , or a suitable analog), will recruit to the regulatory elements of those genes other transcription factors that will ultimately modify their transcription by RNA polymerase II (see Bassett et al.² for review). TRs are the product of two genes, $TR\alpha$ and $TR\beta$, which generate various products by alternate splicing or from the use of diverse promoters. Only $TR\alpha 1$, $TR\beta 1$, $TR\beta 2$, and $TR\beta 3$ are *bona fide* receptors in that they can both bind TH and mediate effects of TH on the transcription of specific genes.² TRs are ubiquitously distributed, indicating that most tissues are, or can be, directly affected by TH. Given the ubiquitous presence of TRs, TH can affect tissues directly as well as indirectly, that is, as a consequence of its effects in other tissues or as part of homeostatic responses to effects in the body. Thus, TH increases oxygen consumption in all tissues (except the brain, spleen, and testes³), resulting in augmented oxygen demands and more heat production, thereby creating the need to increase cardiac output and heat dissipation.

Thyroid hormone effects on cardiovascular system and hemodynamics

The cardiovascular effects of TH are quite prominent and dramatic, and have been recognized by clinicians since the early descriptions of thyrotoxicosis by Parry et al. in the 19th century (see Kahaly and Dillmann⁴ and references). It has long been known that myocardial contractility is increased by TH continuously from the hypothyroid to hyperthyroid state.⁵ Such effect is the result of the modified expression of several genes. Among others, TH stimulates the expression of myosin heavy-chain alpha ($MHC\alpha$), while it inhibits the expression of $MHC\beta$, and also stimulates the expression of sarco-endoplasmic reticulum, calcium-dependent ATPase 2 (SERCA2). These changes largely account for the increased velocity and force of contraction and accelerated relaxation seen in response to TH. Thus, $MHC\alpha$ is catalytically more efficient than $MHC\beta$, which explains faster contraction, whereas the increase in SERCA2 explains a greater release of sarcoplasmic calcium

during systole, increasing the force of contraction and a faster reuptake during diastole that accelerates relaxation.⁴ These effects may be enhanced by a concomitant decrease in the expression of phospholamban and increase in ryanodine channels, causing less inhibition of SERCA2 and increased calcium flux into the cytosol during systole, respectively. TH also has a direct chronotropic effect, as well as increasing the rates of depolarization and repolarization, and shortening the duration of the action potential in the sinoatrial node. These effects are mediated by T₃-dependent acceleration of the ion currents in the sinoatrial node and the conduction system, and result from increases in Na⁺ pump density and enhancement of Na⁺ and K⁺ permeability, as well as stimulation of the ID L-type Ca channels, which also serve important pacemaker functions.⁶

All of these effects are believed to result from the direct action of T₃ on the expression of specific genes, which are independent from effects on sympathetic activity and responsiveness (discussed below). TRs are present in the heart⁷ and in blood vessels.^{8,9} Both TR α and TR β are expressed in the heart, with TR α 1 being the predominant receptor.¹⁰ Mice with deletion of this receptor have lower heart rates, yet the rate responds normally to adrenergic stimulation,^{11,12} whereas the role of TR β is less well characterized but evidenced by the fact that mice devoid of both receptor isoforms have an even lower heart rate than the TR α -deficient model.¹³ However compelling the evidence that TH directly affect genes concerned with heart contractility, TH response elements (TREs) have been so far identified and characterized only in the MHC α and β genes and the SERCA2 gene (reviewed by Kahaly and Dillmann⁴).

In addition to its direct effects on the heart, TH affects myocardial function via increasing its responsiveness to adrenergic stimulation. The density of β -adrenergic receptors (β -AR) in the heart is increased in the hyperthyroid state,¹⁴ which is known now to reflect an increase in β ₁-AR gene transcription mediated by a TRE.¹⁵ However, it is very likely that the increased β ₁-AR receptor density is not the main factor in the enhanced responsiveness. Indeed, TH also stimulates the adrenergic pathways at post-receptor levels, increasing Gs protein and reducing Gi α and β ,¹⁶ enhancing the cAMP responses to a much higher level than expected from about double of the β ₁-AR number.

Altogether, the direct effects of TH on the myocardium and the TH-mediated increase in responsiveness to catecholamines converge to increase cardiac output and circulatory velocity. The more rapid and energetic contraction causes the systolic BP to increase faster and to higher levels. In addition, TH markedly reduces systemic vascular resistance (SVR) and increases blood volume.¹⁷ SVR is three to four times lower in the hyperthyroid than in the hypothyroid state, with intermediate values in the euthyroid condition, and together with the expanded blood volume, the reduced SVR importantly contributes to the augmented cardiac output of hyperthyroid states. The reduced SVR also causes a rapid reduction in intra-arterial pressure after the systolic peak and this is usually associated with reduced diastolic BP. Typically, hyperthyroid patients have modestly elevated systolic pressure (140 to 150 mmHg)

with reduced diastolic pressure (50 to 70 mmHg), and greater amplitude of pulse pressure even at high heart rates.

It is not entirely clear how TH causes a reduction in SVR. A major factor could be enhanced responsiveness of vascular smooth muscle to β ₂-AR-mediated effects of catecholamines. This is supported by the marked increase in SVR caused by propranolol, a nonselective β ₁- β ₂-AR blocker,¹⁸ compared with the modest effect of the selective β ₁-AR agent, bisoprolol.¹⁹ In addition, T₃ can directly relax vascular smooth muscle *in vitro*,²⁰ although the physiologic significance of this mechanism is to be demonstrated. Yet another possible contributing mechanism is augmented production of nitric oxide,²¹ but again, the significance of this finding in human physiology and disease has not been established.

Clinically, the hyperdynamic state of thyrotoxicosis is characterized, subjectively, by palpitations, felt as forceful, rapid “pounding” on the chest, and objectively, by tachycardia, hyperdynamic precordium, increased pulse pressure, and usually modestly elevated systolic pressure with normal or modestly reduced diastolic BP, and normal or modestly increased mean arterial blood pressure. The skin is warm and well perfused, with rapid capillary filling. In otherwise normal individuals, the thyrotoxic hyperdynamic state is usually of no consequence. The judicious use of β -AR blockers ameliorates the clinical translation of this state and is objectively associated with a significant reduction of heart rate and less so of systolic BP, while diastolic blood pressure may increase modestly and pulse amplitude is reduced. Except in individuals with pre-existing hypertension, in whom BP may become harder to control, arterial hypertension is generally not a clinical problem in hyperthyroid patients. Systolic BP rarely surpasses 150 mmHg, and generally can be reduced, along with the hyperdynamic circulation, by modest doses of β -AR blocking agents. No additional treatment is necessary. In patients with pre-existing hypertension, this may worsen, which is caused by the hyperdynamic state and the reduced effectiveness of antihypertensive drugs owing to stimulation by TH of drug clearance, angiotensinogen-converting enzyme and sympathetic activity. However, it is rarely necessary to adjust the treatment, sufficing to give, or increase the dose of, β -AR antagonists and treat rapidly the thyrotoxic state (Figure 73–1A).

Pulmonary hypertension has been reported in hyperthyroidism with increasing frequency^{22–24} (Figure 73–1B). It seems to be more frequent in women than in men. It is likely that the pulmonary vascular bed is less compliant than the systemic arterial bed, and cannot accommodate the increased cardiac output as the systemic bed does. Indeed, experimental hyperthyroidism is associated with greater right than left ventricular hypertrophy.²⁵ The frequency of pulmonary hypertension is likely underestimated, and will be better appreciated as more Doppler studies are done. In one study, 9 of 17 untreated patients with Graves disease had elevated pulmonary arterial pressure, with an average or mean of 29 mmHg,²² whereas another study found 41% of patients with systolic pulmonary pressures higher than 35 mmHg.²³ The thyrotoxic

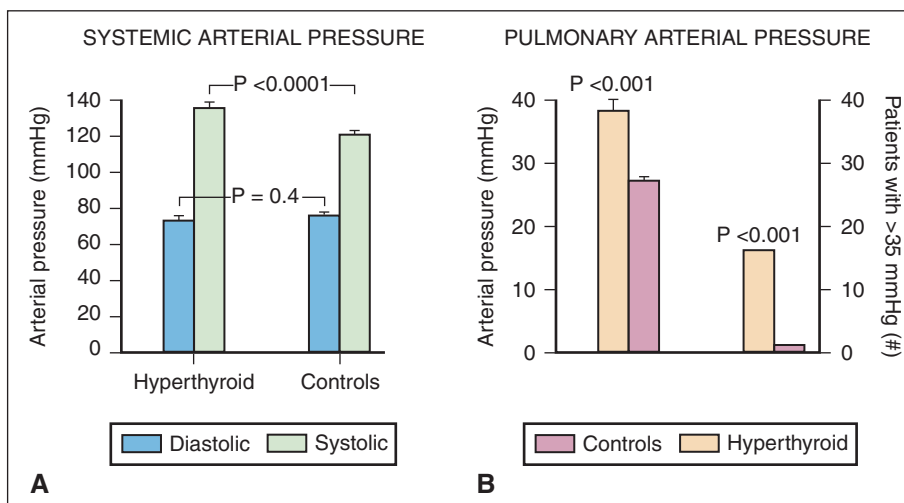

Figure 73-1. Changes in systemic and pulmonary arterial pressures in patients with thyrotoxicosis. Values are means (\pm standard error of the mean) of 39 cases and 39 matched euthyroid controls. **A**, Systolic and diastolic systemic blood pressures. In this study, diastolic blood pressure was not significantly reduced in the hyperthyroid patients. **B**, Systolic pulmonary hypertension in the same cohort of patients. The right axis shows the number of cases with systolic blood pressures greater than 35 mmHg, which included 16 in the hyperthyroid group and only 1 among the controls. (Data from Merce J, Ferras S, Oltra C, Sanz E, Vendrell J, Simon I, et al. *Am J Med* 2005;118:126–31.)

pulmonary hypertension is reversible with treatment, especially since it is related to the thyroid status, specifically the thyrotoxic state^{22–24}; however, its clinical impact is to be defined. It is expected that patients with pre-existing secondary or primary pulmonary hypertension have a significant worsening of their condition if they become thyrotoxic, possibly with development of overt right-sided congestive heart failure, requiring aggressive treatment of the hyperthyroid state.

Effects of hypothyroidism on sympathetic activity, vascular physiology, and blood pressure

The hemodynamic effects of hypothyroidism are essentially the opposite of those described for hyperthyroidism. Myocardial contraction is slower and less energetic, and diastolic relaxation is delayed. Cardiac output is reduced and SVR is increased as much as 70%.^{4,17} Clinical findings include bradycardia and reduced skin perfusion and pulse amplitude. Frequently, hypothyroidism is considered a cause of hypertension, but the reported prevalence of hypertension among hypothyroid patients is highly variable.^{26–29} Nonetheless, the majority of longitudinal studies of patients with chronic hypothyroidism show modest increases in systolic and, more consistently, in diastolic BP that disappear upon treatment with T_4 (see Fletcher and Weetman²⁶). Hypothyroid patients sometimes have unequivocal hypertension that reverts with correction of the hypothyroid status.^{28,30,31} Interestingly, among nearly 700 patients with newly diagnosed hypertension, 3.6% had previously unrecognized hypothyroidism.²⁸

The mechanisms leading to hypertension in hypothyroidism are probably multiple. The increase in SVR plays

a central role, and whether it leads to frank hypertension may depend on the magnitude of the increase and the participation of other factors and mechanisms. Increased SVR is caused by the lack of TH both locally at the blood vessel level, and indirectly by the enhancing effect on sympathetic activity due to hormone absence. In addition, the lack of TH could conceivably result in changes in the concentration or activity of other factors regulating the tone and lumen of resistance vessels. Chronic hypothyroidism is associated with increased circulating levels of norepinephrine.^{32–34} Furthermore, sympathetic activity in muscle is increased,³⁵ and its vascular bed is a major determinant of SVR. Enhanced sympathetic stimulation, however, is not the only factor. The number and proportion of β -AR and α -AR in the vasculature seem also to play a significant role. The number of β_2 -AR, which are involved in vasodilatation in important vascular beds, such as muscle, is reduced, whereas that of α_1 -AR is increased.³⁶ Interestingly, the pressor response to exogenous norepinephrine is reduced in muscle,³⁷ which is possibly due to desensitization caused by the tonic increase in sympathetic activity. The presence of TRs in vascular smooth muscle cells²⁰ is an indication that these cells have at least the potential to respond directly to TH. Little is known, however, as to what genes are affected by TH. It has been recently found that T_3 reduces the expression of type-1 angiotensin II receptors in vascular muscle cells³⁸ at the transcriptional and post-transcriptional level. T_3 also induces relaxation of vascular smooth muscle cells *in vitro*, which is believed to be a nongenomic effect of TH.²⁰ Additional evidence indicating a direct effect of TH in blood vessels is the presence in vascular smooth muscle cells of type-2 T_4 5'-deiodinase (D2), which catalyzes the conversion of T_4 into the 10-fold more active T_3 .^{39,40}

The experimental observations mentioned here suggest that vascular tone and BP are more sensitive to TH than one would anticipate from past observations in individuals with overt, long-term hypothyroidism. Indeed, relationships between BP and TH homeostasis are demonstrable even in euthyroid individuals as well as in short-term hypothyroidism. Thus, in hypertensive individuals, the serum-free T_4 index and TSH are lower and higher, respectively, than in appropriately matched controls.⁴¹ Moreover, serum FT_4I is inversely correlated to the sensitivity of BP to salt, and both TSH and FT_4I are directly and inversely related, respectively, to renal vascular resistance.⁴¹ In a study of short-term hypothyroidism, normotensive subjects with stage 1 of differentiated thyroid cancer maintained on L- T_4 were studied 6 weeks after withdrawal of the hormone (in preparation for whole-body scanning with ^{131}I) and then 2 months after resuming treatment. There was a modest but significant increase of both systolic and diastolic pressures during the hypothyroid phase. This was associated with a nearly twofold increase of norepinephrine and epinephrine, and the daytime diastolic BP was inversely related to the T_3 levels during the replacement with L- T_4 .⁴²

Altogether, these studies suggest that vascular tone is highly dependent on TH via direct as well as indirect effects such as increased sympathetic tone. Such influences are reversible but, if prolonged and severe, they may lead to irreversible remodeling of the vasculature. Such conceptualization is supported by more recent and detailed studies. One such study reports increased SVR and aortic stiffness in patients with hypothyroidism, which were significantly greater in those who were also hypertensive.³⁰ In about 50% of the hypothyroid patients with hypertension, the treatment with LT_4 was associated with a normalization of BP and a significant reduction of SVR and aortic stiffness, whereas these latter changes did not occur or were less pronounced in the other half with persistent hypertension after euthyroidism was achieved.³⁰ When all patients were pooled, the reduction in systolic BP was significantly correlated to the reduction in aortic stiffness ($r=0.83$, $p<0.001$).³⁰ Reasons for the normalization of BP with LT_4 treatment in only half of the hypothyroid patients are not clear, but certainly the difference was not due to the degree of hypothyroidism because there were no differences in TSH, FT_4 , or FT_3 between responders and nonresponders. The nonresponsive group had greater SVR and aortic stiffness, suggesting a more pronounced change in vasculature, but whether this was related to duration of the hypothyroidism or the presence of other factors is not readily evident.³⁰

Systemic arterial hypertension is rarely a clinical challenge in hypothyroidism. Besides, with the availability of inexpensive and accurate TSH assays, severe, protracted hypothyroidism is currently less frequently seen. From a practical point of view, hypothyroidism should be considered in a patient with newly diagnosed hypertension, whereas hypothyroid patients with hypertension, particularly if moderate, should not be rushed into extensive investigation or treatment without correcting the hypothyroidism.

HYPERTENSION IN PRIMARY HYPERPARATHYROIDISM

Numerous studies show that systemic arterial hypertension is more frequent in patients with primary hyperparathyroidism (PHP) than in the appropriately matched general population.⁴³⁻⁴⁶ A number of vascular abnormalities have been reported in patients with PHP, some of which may play a pathogenic role while others may be consequence of vascular stress. PHP patients have endothelial dysfunction as revealed by impaired flow-mediated dilation of medium-size arteries,⁴⁷ which is reversible after successful parathyroidectomy.⁴⁸ However, the mechanical properties of the arteries such as isobaric distensibility, pulse wave velocity, and intima media thickness, were not altered by recent-onset PHP, nor were they modified by parathyroidectomy in patients with PHP without hypertension or kidney involvement or any other known vascular risk factor such as diabetes or hypercholesterolemia.⁴⁹

More recently, a study showed increased arterial stiffness in mild PHP.⁵⁰ The authors used the augmentation index (AI) as a measure of stiffness. The AI basically represents the increase in systolic pressure due to the reflection of the initial pressure wave caused by the ventricular ejection, the timing and magnitude of which are functions of artery compliance. When corrected by all confounding variables, PHP was a stronger predictor of elevated AI than age, gender, smoking, hypertension, hyperlipidemia, or diabetes, and AI correlated significantly with the levels of PTH and inversely with radius mineral density, used in the study as a cumulative effect of PTH.⁵⁰ The discrepancy between these two reports^{49,50} is probably explained by age and length of the disease, as in the latter⁵⁰ patients were significantly older and had been hyperparathyroid for longer time periods than in the aforementioned study.⁴⁹ Altogether, these results suggest that PHP is associated with functional abnormalities of blood vessels that lead to hypertension, but vascular remodeling takes time and probably requires the contribution of other factors. Compensatory mechanisms may be one such factor and a source of variability in the timing and magnitude of the elevation of blood pressure in PHP. For example, patients with PHP have higher levels of adrenomedullin, a vasodilator, and while mean levels are higher among those that are hypertensive, not all hypertensive patients with PHP have high adrenomedullin.⁵¹

The mechanisms leading to vascular changes and hypertension in PHP have been only partially identified and are not yet well characterized. Acute injections of parathyroid hormone (PTH) itself cause hypotension in a dose-dependent manner in several species, but most prominently in dogs.⁵² PTH-related peptide (PTHrP), acting on the same receptors, also has a clear vasodilating effect.⁵³ Furthermore, these hormones cause substantial reduction of intracellular calcium in vascular smooth muscle,^{54,55} although in some instances a transient increase has been reported.⁵⁶ PTH receptors have been identified in endothelial cells.^{57,58} Another potential mechanism mediating an acute vasodilating response is a reduction of endothelin-1, because this is sensitive to inhibition by PTHrP acting presumably via the PTH receptor.⁵⁹

How then to explain the higher frequency of hypertension in patients with PHP? As mentioned above, in spite of the acute vasodilating effects of PTH, there is an impaired dilation response to increase flow that is reversible with parathyroidectomy.^{47,48} There are several possible mechanisms to explain the hypertension and impaired dilation responses. One is obviously hypercalcemia, whether general or limited to a vascular territory (i.e., forearm), has been associated with impaired endothelial vasodilatory function, and when systemic, with a significant increase in blood pressure.⁶⁰ It has been found that intracellular calcium is increased in platelets of patients with PHP, in proportion to the increase in serum Ca and PTH. Interestingly, platelet Ca is increased and more than in PHP in patients with essential hypertension, which lends support to the use of platelets as surrogates for vascular smooth muscle. In PHP, platelet Ca normalized promptly following parathyroidectomy.⁶¹ Another interesting factor is that hypercalcemic states, PHP included, are associated with increased levels of norepinephrine and, most importantly, increased pressor response to exogenous norepinephrine.⁶²

In addition to the effects of PTH on blood vessels, several lines of evidence point to effects on myocardial contractility. One study showed no effect of acutely injected PTH on myocardial contractility, but in patients with PHP there were changes suggesting increased heart sympathetic activity such as shortening of the relaxation and loss of circadian variation of heart rate.⁶³ Two other studies showed increased ejection fraction (EF) and cardiac output in patients with PHP that were at least partially reversible with parathyroidectomy.^{64,65} Finally, other investigations have shown left ventricular hypertrophy, above and beyond the expected from the hypertension.^{66,67} Thus, it appears that increased cardiac output, which is, at least in part, adrenergically mediated, could contribute to the hypertension seen in patients with PHP.

Finally, parathyroid hypertensive factor (PHF) is also a contributing factor. PHF was discovered in the circulation of spontaneously hypertensive rats (SHR). Injected into normotensive rats, PHF causes a delayed (60 to 90 min) increase in arterial BP (see Pang et al.⁶⁸ for a review). Subsequent studies in animals and then in isolated parathyroid cells or tissues showed that the source of this factor was the parathyroid glands.^{69,70} The chemical structure has not yet been completely defined, but is believed to be a peptide linked to a phospholipid.^{69,71,72} About 30% to 40% of patients with hypertension have elevated PHF, most notably those exhibiting a low-renin, salt-sensitive form of hypertension, in whom PHF correlates well with BP.⁷³ The PHF mechanism of action was shown to rely mainly on the opening of L-type calcium channels in vascular smooth muscle cells with an increase in intracellular Ca^{2+} and possibly sensitization to norepinephrine and perhaps other hypertensive factors.⁷⁴ It is possible that PHF is responsible for the hypertension in a substantial portion of patients with PHP. In 9 of 10 of these patients with hypertension, PHF was elevated and its elevation predicted a BP reduction following parathyroidectomy.⁷⁵

It is also very interesting that circulating Ca^{2+} regulates PHF, and its secretion can be reduced by substances acting on the parathyroid calcium sensor receptor,⁷⁶ whereas 1,25-di-OH vitamin D3 stimulates its secretion, and more in SHR than in their normotensive cognates.⁷⁷ These are interesting observations that have the potential to explain clinical observations such as the beneficial effect of calcium supplementation in the management of hypertension.⁷⁸ Elevation of PTH in hyperparathyroidism might contribute to hypertension via increasing the synthesis of 1,25-di-OH vitamin D3 by the kidney, which will in turn increase the secretion of PHF.

Although several studies have reported BP normalization in significant fractions of the PHP cohorts studied,⁴⁴⁻⁴⁶ others have failed to document a significant reduction in BP following successful surgical treatment of the PHP.⁷⁹⁻⁸¹ It is likely that discrepancies derive from differences in the populations studied and in the endpoints of the studies. In two of these studies, the hypertensive patients had more severe disease with greater kidney damage^{80,81} than the normotensive patients, suggesting that they had moved into a phase of irreversibility due to end-organ damage. The third study compared blood pressure longtime after the surgery (15 years) with that existing prior to parathyroidectomy in a cohort with a mean age of 58, and during this period many patients became hypertensive, regardless of treatment and calcium status.⁷⁹ In general, these three studies⁷⁹⁻⁸¹ aimed at assessing the long-term cardiovascular risk of not surgically treating the primary hyperparathyroidism. However, in another large cohort study in Denmark that compared patients surgically treated with those kept under observation, the authors observed no difference in the prevalence of hypertension, but mortality during the follow-up occurred in 31% of surgically treated patients compared to 37% of conservatively treated patients (Figure 73-2).⁸² There are limits to this study. First, the overall frequency of hypertension in both groups was very low, 4% to 5%, but more important was the bias that

Figure 73-2. Kaplan-Meier plot of survival in surgically and conservatively treated patients with primary hyperparathyroidism. Death during follow-up occurred in 591 (31%) surgically treated patients and 474 (37%) conservatively treated patients. (Redrawn from Vestergaard P, Mosekilde L. *BMJ* 2003;327:530-34.)

patients undergoing surgery are generally those with more severe hyperparathyroidism and more end-organ damage.

From a practical viewpoint, it is reasonable to accept the potential of PHP to cause hypertension or enhance essential or secondary pre-existing hypertension. If PHP is not prolonged, and there is no evidence of arterial and kidney damage, parathyroidectomy is likely to result in reduction of BP or in making pre-existing hypertension more manageable.

HYPERTENSION IN ACROMEGALY

Hypertension is frequently found in at least one-third of patients with acromegaly.^{83,84} In a recent study, systolic BP descended from 132 to 121 mmHg in 15 of 30 patients considered “cured” after treatment of acromegaly ($p < 0.003$), whereas in the same patients diastolic BP decreased from 88 to 80 mmHg ($p = 0.09$).⁸⁵ In another study, mean arterial BP was significantly higher in patients with acromegaly, and failed to decrease overnight as it did in normotensive controls.⁸⁶ Together with insulin resistance, dyslipidemia, and probably direct effects of growth hormone (GH) and insulin-like growth factor I (IGF-I) on the heart, hypertension contributes to increased mortality due to cardiovascular events in patients with acromegaly. The rate of cardiovascular events in patients with acromegaly is three to four times that of the appropriately matched general population, and ranks as the major cause of death in patients with this disease.⁸³ As in the case of hyperparathyroidism, discussed previously, the mechanisms leading to hypertension in acromegaly have not been totally defined, and they seem to be multiple and of variable importance depending on individual backgrounds, severity, and duration of the disease.

Of the multiple abnormalities observed in the heart of patients with acromegaly,^{83,87} increased cardiac output and stroke volume^{84,87} may be early contributing factors to the increase in systolic BP. Globally, vascular peripheral resistance is reduced,⁸⁴ which may explain why diastolic BP is not as elevated as systolic pressure. On the other hand, diastolic dysfunction is common (particularly during exercise) in acromegalic patients,^{85,87} and is associated with a progressive reduction in EF.⁸⁸ Diastolic dysfunction is the result of the trophic effects of GH and IGF-I on cardiomyocytes as well as increased interstitial collagen accumulation, all of which leads to myocardial stiffness.⁸⁹ As the heart starts to fail, it ceases to play any role in the hypertension, which is now maintained by changes in the arteries and kidney. Heart failure in acromegaly is due to a combination of muscle hypertrophy and stiffness (note that acromegaly *per se* is not usually associated with dilated cardiomyopathy).

There are acute and long-term systemic and vascular effects of acromegaly that are likely to contribute significantly to the hypertension observed in these patients. Most important among these are fluid and sodium retention, endothelial dysfunction, and arterial remodeling. More speculative and perhaps less important are the roles of insulin resistance and the sympathetic nervous system.

That GH promotes fluid and sodium retention, as it has been shown in individuals with deficiency and excess of this hormone, as well as in adults treated with GH.⁹⁰ The consensus is that this effect is ultimately mediated by IGF-I, as this can nicely mimic these effects of GH.^{91,92} Probably central to the fluid retaining effect is the stimulation of the renin-angiotensin-aldosterone system (RAAS), because its blockade cancels the volume expansion induced by GH or IGF-I.⁹³ The injection of GH to normal volunteers is associated with fluid and sodium retention concomitantly with an increase in renin and a seven-fold increase in circulating aldosterone, without changes in plasma osmolality or antidiuretic hormone concentration.⁹⁴ An important factor in the activation of RAAS is the potential inhibition of atrial natriuretic factor (ANF) by GH-IGF-I, derepressing RAAS.⁹² The importance of these mechanisms in maintaining hypertension in the long term remains unclear, because population studies do not show a clear correlation of hypertension with levels of renin, aldosterone, or responses of the RAAS to standard challenges.⁹⁵ It is reasonable to think that somehow elevated GH can ultimately increase the responsiveness of target cells to angiotensin or aldosterone, or both.

Even though studies on endothelial function in acromegaly are scarce and at times difficult to reconcile, the notion that endothelial dysfunction occurs in this condition is widely accepted.⁸³ In spite of reduced global vascular peripheral resistance, Chanson et al.⁸⁴ found decreased brachial artery blood flow with significantly higher forearm vascular resistance in acromegalic patients compared with matched controls. Since other studies have demonstrated increased renal blood flow, glomerular hyperfiltration,⁹⁶ and increased functional liver plasma flow,⁹⁷ it is well accepted that the chronic excess of GH differentially affects various vascular beds, causing heterogeneity in the distribution of cardiac output in acromegaly.⁹⁸ Defective artery dilation in response to increased blood flow is considered a marker of endothelial dysfunction, and may explain the failure of the brachial arterial territory to accommodate increased flow pressure. Recently, Maison et al.⁹⁹ reported impaired endothelium-dependent vasodilatation in acromegalic patients together with exaggerated sympathetic-mediated vasoconstrictor response. Flow-mediated dilatation of the brachial artery was significantly lower in acromegalic patients than in healthy and risk-factor-matched controls (by 64% and 47%, respectively).¹⁰⁰ The contributions of insulin resistance of acromegaly and of high levels of GH or IGF-I to endothelial dysfunction are unclear.

In addition to functional abnormalities, several investigators have reported arterial remodeling with increased intima media thickness (IMT), and narrowing of the arterial lumens together with hypertrophic remodeling of small arteries.^{85,101,102} These changes probably require a long time to take effect, and to some extent they may regress with treatment.¹⁰² It is most interesting that such changes are also seen in transgenic mice overexpressing bovine GH.¹⁰³ These mice have higher BP than wild-type genotype controls, and their blood vessels show increased IMT and other changes seen in patients with acromegaly. Notably, BP in these mice is not salt-sensitive and the

arteries do not respond to manipulations of vasomotor tone such as norepinephrine, sodium nitroprusside, and acetylcholine. Since these mice have been chronically exposed to GH (i.e., congenitally), such results support the notion that chronic exposure to GH causes blood vessel remodeling, making the hypertension difficult or impossible to control. In addition, IGF-I elevation in acromegaly seemingly stimulates vascular growth factors, such as angiogenin and endostatin, the concentrations of which correlates with IGF-I levels.¹⁰⁴

These observations together suggest that, as occurs in hyperparathyroidism, functional abnormalities lead somehow to arteriolar remodeling, which in turn makes hypertension irreversible or less responsive to successful treatment of the acromegaly. Only longitudinal studies could confirm this hypothesis (difficult to implement because of ethical considerations). But even if this sequence remains hypothetical, the studies mentioned here provide support to the idea of promptly correcting the high GH/IGF-I levels to reduce the risk of morbidity and mortality due to cardiovascular events.

SUMMARY

Except for endocrine diseases associated with hypersecretion of the adrenal cortex, adrenal medulla, or chromaffin

tissue, hypertension is not a central manifestation of most endocrine diseases. Thyroid dysfunction, primary hyperparathyroidism, and acromegaly are frequently associated with significant hemodynamic changes and increases in arterial BP. These are, of course, of more clinical significance in previously hypertensive individuals. In spite of the dramatic effects of thyrotoxicosis on the heart and vasculature, hypertension is rarely of clinical significance. Hypothyroidism may more frequently associate with hypertension and its correction, particularly when severe, is followed by a reduction in arterial pressure. Primary hyperparathyroidism and acromegaly are frequently associated with elevations of BP, and cardiovascular disease is the leading cause of death in protracted acromegaly. In both conditions, factors leading to elevation in BP are multiple. Likewise, in both conditions abnormalities are initially functional and reversible, but with time lead to vascular remodeling and irreversibility, adding support to the tendency of diagnosing and treating these conditions early and radically, that is, eliminating the source of the hormonal excess.

Coarctation of the Aorta

Richard A. Krasuski and Fetnat Fouad-Tarazi

Definition

- Coarctation of the aorta (CoA) is an important cause of secondary hypertension with the potential to serve as a model for the understanding of essential hypertension.
- CoA is a very common defect, accounting for ~8% of all congenital heart defects. Approximately 50% to 85% of patients with CoA also have a bicuspid aortic valve.

Clinical Implications

- Symptomatic patients with a peak gradient over 30 mmHg on invasive measurement or a similar gradient in asymptomatic patients with upper extremity hypertension that becomes severe with exercise or is associated with left ventricular hypertrophy should have intervention.
- Other evolving indications for treatment include the presence of concurrent aortic aneurysms and symptomatic aneurysms of the circle of Willis. Young women who wish to bear children are also at risk.
- Surgery has remained the mainstay approach to native CoA, although percutaneous intervention is an alternative.
- Despite intervention, hypertension is more prevalent in these patients, developing at a far younger age than would normally be expected.

Coarctation of the aorta (CoA) is an important cause of secondary hypertension with the potential to serve as a model for the understanding of essential hypertension. This chapter reviews the prevalence, pathophysiology, presenting features, invasive and noninvasive assessment, treatment and long-term clinical outcome of this congenital anomaly.

DEFINITION AND PREVALENCE

Coarctation of the aorta (CoA) refers to a narrowing in the descending aorta (Figure 74–1), typically in the location of the takeoff of the left subclavian artery and the ligamentum arteriosum (ductus arteriosus). Anatomically it can occur just before the ductus, at the ductus, or just after the ductus. In its rarest form, CoA can involve the abdominal segment of the aorta (<2% of all cases).¹ Adults with a previously undiagnosed CoA will almost always have postductal lesions. The lesion itself is either a localized narrowing or a hypoplastic segment of the aorta, with the former lesion being much more common.

CoA is a very common defect, accounting for an estimated 8% of all congenital heart defects.² Although distributed fairly evenly between genders among infants, older patients have a male predominance. Approximately 50% to 85% of patients with CoA also have a bicuspid aortic valve.³ If there are no other anatomic abnormalities (with the exception of the bicuspid valve), the lesion is referred to as a “simple coarctation.”⁴ If accompanied by other cardiac anomalies it is referred to as a “complex coarctation.”

Patients with complex CoA typically are diagnosed early in childhood, while simple CoA may not be recognized until adulthood. It is estimated that CoA may account for up to 0.2% of all adults with hypertension, and is therefore a lesion with which hypertension specialists should become familiar.⁵

ANATOMY AND DEVELOPMENT

There are two main hypotheses that have been proposed to explain CoA formation.¹ In the hemodynamic theory, there is an abnormal angle between the ductus arteriosus and the aorta leading to abnormal blood flow and subsequently reduced growth of the descending aorta. By the time the ductus closes, this segment of aorta is hypoplastic and results in partial obstruction. Supporting this theory is the high incidence of CoA in congenital heart disease patients with decreased aortic flow *in utero*, and the absence of CoA in patients with right heart obstructive disease. The “ectopic ductal tissue” hypothesis proposes that tissue from the ductus arteriosus abnormally extends into the descending aorta, and this ectopic ductal tissue then constricts during ductal closure. While compelling, the latter theory does not easily explain the common occurrence of hypoplasia of the aortic arch and isthmus seen with CoA.

In addition to bicuspid aortic valves, other pathologic abnormalities have been described in patients with both simple and complex CoA. This includes the above mentioned hypoplasia of the transverse aortic arch (region between the left common carotid artery and left subclavian artery) and aortic isthmus (region between the left subclavian artery and ductus arteriosus).⁶ Dilatation of descending aorta just beyond the CoA, often referred to as “poststenotic dilatation,” is typically present as well.⁷ There may also be an inherent structural weakness of the ascending aorta in a so-called “cystic medial necrosis” pattern, usually seen in patients with concurrent bicuspid aortic valve. This abnormality appears to

Figure 74-1. Coarctation of the aorta.

increase the risk of aortic dissection.⁸ Similarly, the presence of Berry aneurysms in the cerebral circulation (found in up to 10% of patients with CoA) appears to increase the risk of intracranial hemorrhage.^{9,10}

PATHOPHYSIOLOGY AND PRESENTATION

Presentation during infancy is most common among patients with complex CoA. Heart failure resulting from significant hemodynamic compromise can necessitate early repair. For simple CoA, the lesion is most often discovered during childhood or early adolescence by the recognition of otherwise unexplained hypertension or by the presence of a loud systolic murmur. The most common presentation in adults is the fortuitous discovery during secondary work-up for systemic hypertension.¹¹ Although early theories focused solely on the role of mechanical obstruction of aorta as the source of blood pressure elevation, a better understanding of the humoral pathways of blood pressure regulation has provided a stronger explanation for hypertension in CoA. Renal hypoperfusion secondary to the CoA generally leads to a state of activation of the renin-angiotensin-aldosterone system and subsequent increased production of angiotensin and aldosterone. Plasma renin and aldosterone levels typically return to nearly normal levels after arterial pressure increases and renal perfusion is restored toward normal. Activation of the central sympathetic nervous system has also been suggested to play an additional role in the development of hypertension.

In most children and adults with significant CoA, there is upper extremity hypertension and the development of collateral vessels around the coarctation to the lower extremity. These collateral channels often create a continuous murmur heard over the back, and involvement of the intercostal arteries leads to the familiar rib notching seen on chest radiography (Figure 74-2). Lower extremity hypoperfusion can also lead to symptoms of leg fatigue during exercise in up to half of patients.¹²

PHYSICAL EXAMINATION

The examination of a patient with suspected CoA requires careful diligence on the part of the practitioner, as the physical findings can be subtle and often overlooked. In addition to upper extremity hypertension, the fundoscopic examination will generally show the classic retinopathic changes of long-standing hypertension including pulsatile, U-shaped, corkscrew arterioles.¹³ An essential aspect of the examination in patients with suspected CoA is careful palpation of pulses in all four extremities as well as the simultaneous palpation of the femoral and brachial pulses. A significant delay or decrement in the femoral pulse should lead one to suspect CoA, particularly in the absence of known peripheral vascular disease. Blood pressures can be taken in the arm and leg, and a decrement of 20 mmHg or greater in the systolic blood pressure in the legs is suggestive of CoA. Of note, diastolic blood pressure generally does not differ. Simultaneous palpation of the brachial pulses is also helpful, particularly to differentiate a pre-ductal coarctation where the left pulse will be diminished and possibly delayed from the right pulse.

DIAGNOSTIC WORK-UP

The electrocardiogram of the patient with CoA often demonstrates the voltage abnormalities of left ventricular

Figure 74-2. Chest x-ray of coarctation. A chest x-ray that demonstrates the classic findings in an adult patient with unrepaired coarctation of the aorta. Short arrows point out the "number 3" sign resulting from the focal narrowing. Rib notching (long arrows) is seen on the inferior portion of the posterior ribs (third to ninth) and results from pressure erosion caused by dilated intercostal arteries that serve as collateral blood flow between the internal mammary arteries and the descending aorta. (Photo courtesy of Richard White, MD.)

hypertrophy, while the presence of prominent, coved ST segment depressions and deeply inverted T waves are more suggestive of concurrent bicuspid aortic valve.¹ The chest x-ray in CoA can range from essentially normal to pathognomonic. The most classic finding is the presence of rib notching that signifies the presence of collateral flow through dilated posterior intercostal arteries (Figure 74–2). This finding is very important, because it helps to differentiate CoA from pseudocoarctation (Figure 74–3). The latter lesion is an unusual anomaly associated with buckling or kinking of the aorta in the region of the ligamentum arteriosum.¹ This is often related to long-standing hypertension and is associated with elongation, tortuosity, and dilatation of the descending aorta. Although this lesion is by no means benign, it is called “pseudo” because of the lack of true obstruction to flow (no evident gradient).

Echocardiography with a focus on the descending aorta is an excellent noninvasive manner in which to make the clinical diagnosis of CoA in patients with suspicious clinical findings.¹⁴ A resting peak systolic velocity of 3.2 or more meters per second or a diastolic velocity of 1.0 or more meters per second suggests a significant coarctation. Echocardiography also allows interrogation of the aortic valve and the assessment of the ascending aortic root.

Magnetic resonance imaging has now become the choice imaging modality preoperatively to size the aorta and the coarctation region (Figure 74–4) and postoperatively to follow patients.^{15,16} In the event of a contraindication (pace-maker or severe claustrophobia) or lack of availability, computer tomography is a reasonable alternative.

INDICATIONS FOR INTERVENTION

Symptomatic patients with a peak gradient over 30 mmHg on invasive measurement or a similar gradient in asymptomatic patients with upper extremity hypertension that becomes severe with exercise or is associated with left ventricular hypertrophy should be considered for intervention. Other evolving indications for treatment include

Figure 74–3. Chest x-ray of pseudocoarctation. A chest x-ray that demonstrates the classic findings of unrepaired pseudocoarctation of the aorta. The arrows mark the “double-left aortic arch sign,” which can appear very similar to the “number 3” sign of coarctation. Because there is no physiologic obstruction, there is an absence of collateral vessel development and subsequent rib notching. (Photo courtesy of Richard White, MD.)

Figure 74–4. Magnetic resonance image of a patient with unrepaired coarctation of the aorta. Magnetic resonance angiogram of the heart and great vessels in a patient with unrepaired coarctation of the aorta. There are prominent collateral vessels which drain into the descending aorta below the coarcted segment (*arrow*) and maintain lower extremity perfusion. AAo, ascending aorta; DAo, descending aorta; LV, left ventricle. (Photo courtesy of Janine Arruda, MD.)

the presence of concurrent aortic aneurysms and symptomatic aneurysms of the circle of Willis. Young women who wish to bear children are also at risk, as placental flow may be inadequate should they become pregnant.¹⁷

THERAPEUTIC MODALITIES

Surgery

Surgery has remained the mainstay approach to native CoA since its first description in 1945.¹⁸ Several different techniques have been developed over time with the most notable options being resection and end-to-end anastomosis, prosthetic patch aortoplasty, interposition (tube bypass) grafting, and subclavian to aortic bypass (Figure 74–5). The procedural choice is often dictated by the unique anatomy of the coarctation, including the need for significant mobilization of the aorta and the presence of extensive collateral vessels. Resection with end-to-end anastomosis remains the most popular surgical option, and has the advantage of limiting the use of prosthetic material. This may reduce the degree of inflammation at the anastomosis site, and therefore reduces the risk of recoarctation. In one large series, the risk of re-operation in extended follow-up was the lowest (<2%) using this technique.¹⁹

Several large surgical series describing CoA repair have been published with a large range of perioperative and long-term morbidity and mortality reported.²⁰ Complications during the procedure are most common with the

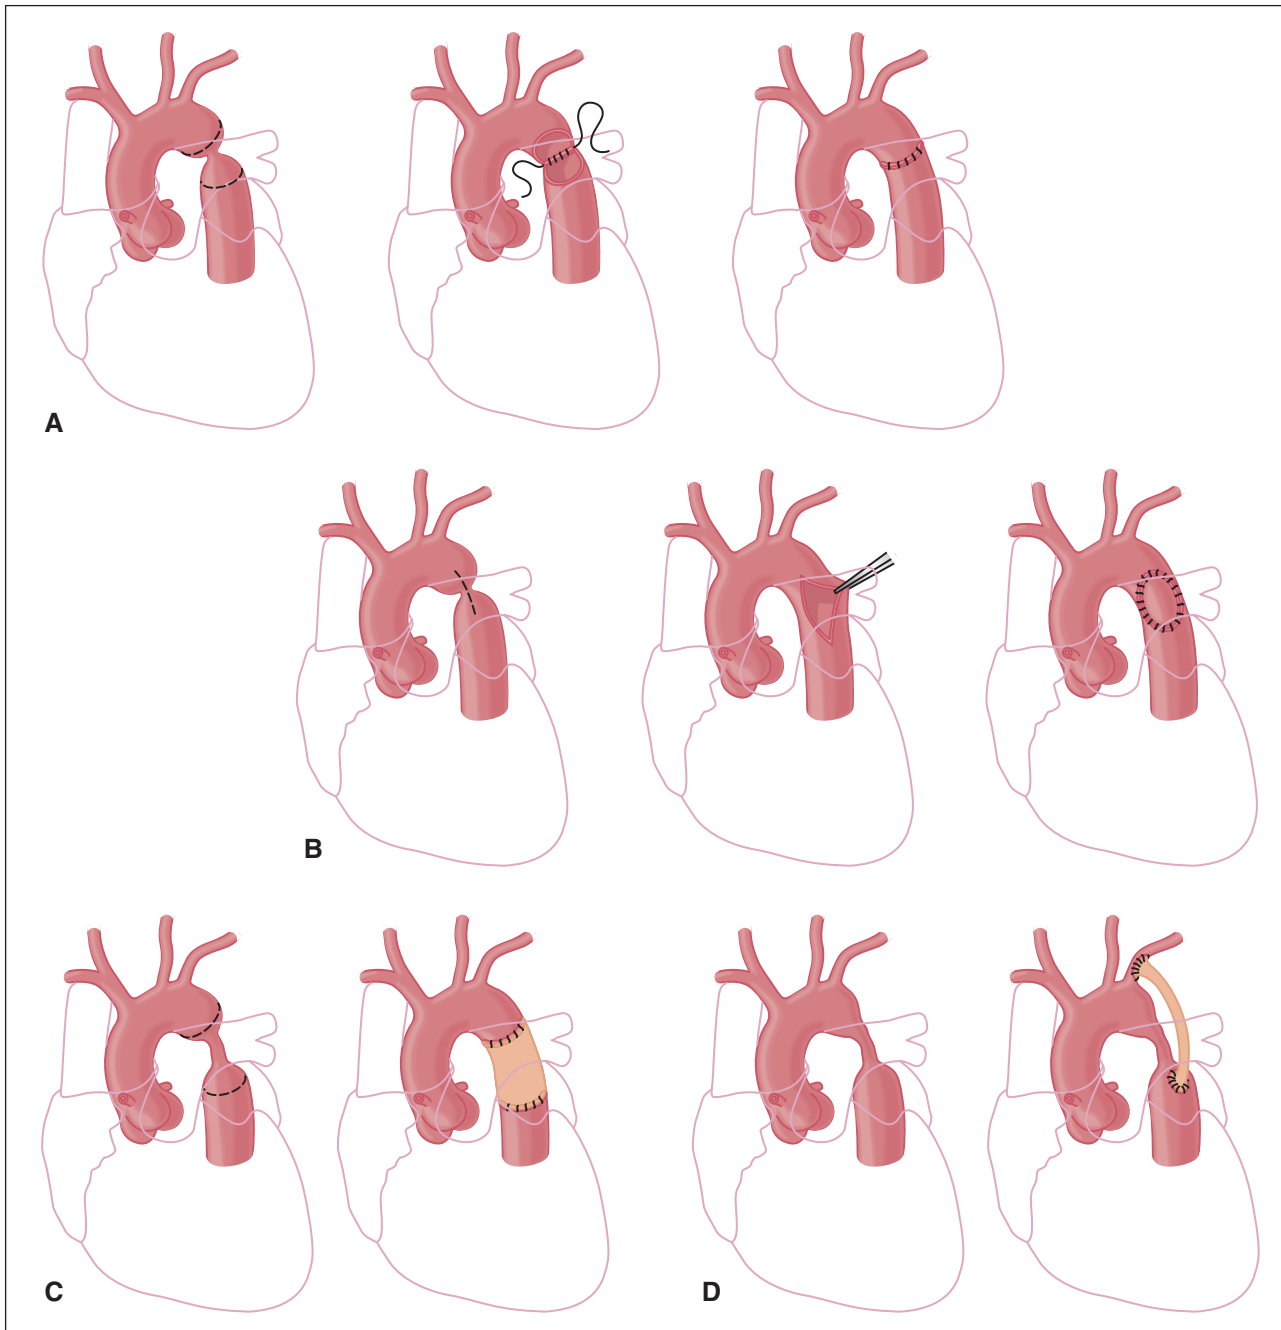

Figure 74-5. Surgical approaches to coarctation repair. The most commonly used techniques to repair aortic coarctation over the years include resection and end-to-end anastomosis (A), prosthetic patch aortoplasty (B), tube interposition bypass grafting (C), and subclavian to aortic bypass (D).

repair of complex coarctation, while operative mortality may be less than 1% for simple coarctation.⁴ Unique perioperative complications include chylothorax, damage to the recurrent laryngeal or phrenic nerves, ischemic bowel, parenchymal lung injury, and spinal chord ischemia and paraplegia.¹⁹ There is a long-term risk of pseudoaneurysm formation, particularly in patients receiving a patch aortoplasty, as well as a risk for recoarctation.²¹ Patients also remain at a substantially higher risk of developing hypertension (see below) despite proper repair, but are even more likely to be hypertensive if residual coarctation is present.²² The optimal timing for repair appears to be in

the range of 2 to 5 years where the risk of long-term complications appears to be the lowest.⁴

Percutaneous intervention

Recently some success has been achieved with percutaneous intervention in young patients with native coarctation.²³ Older patients, however, should still be considered for surgery if they are viable candidates. Percutaneous angioplasty has been performed since 1982,²⁴ and the availability of stents has recently led to improved outcomes, to the extent that percutaneous intervention is now considered the procedure of choice in patients with

recoarctation following surgery.²⁵ Stents are particularly effective in preventing complications from recoil of the aorta following angioplasty. The size of the stent should never be larger than the native aorta. Intravascular ultrasound has been very useful in ensuring that there is adequate apposition of the stent against the aortic wall.

Several large series of angioplasty/stent patients suggest success rates of 65% to 100% with a complication rate of ~10%. Problems to watch for include recoarctation and aneurysm formation at the site of intervention, blood pressure problems including hypo- and hypertension, and paraplegia. Endocarditis prophylaxis remains important, even if the residual gradient is minimal (Figure 74–6). Postcoarctation aneurysm formation occurred commonly when angioplasty alone was used to treat native coarctation, but appears to be less of a concern with the wider use of stents.²⁵

LONG-TERM CLINICAL OUTCOMES

The natural history of CoA prior to the modern era of surgical and percutaneous repair was unfortunately quite poor with one large series showing a mortality rate of 25% by age 20, 50% by age 32, 75% by age 46, and 92% by age 60.²⁶ Although surgical and percutaneous interventions have greatly mitigated this risk, epidemiologic studies still suggest that premature morbidity and mortality remain common in this patient population. In fact, two long-term studies found the mean age of death to be under 40.^{27,28} Later problems after coarctation may be due to recoarctation or aneurysm formation at the anastomotic site.¹⁵ Or they may be secondary to associated lesions such as Berry aneurysms of the brain or a bicuspid aortic valve. In at least 5% of patients, re-operation for the aortic valve will be necessary at some point in the future. Also associated with the bicuspid valve is a strong

Figure 74–6. The presence of endarteritis in a patient with prior percutaneous balloon angioplasty. A transesophageal echocardiographic view of a linear strand (arrow) emanating from the aortic wall just distal to the site of prior percutaneous intervention to a coarcted segment of the descending aorta. This patient had blood cultures positive for *Staphylococcus aureus* and the lesion was later confirmed to be a vegetation. He was successfully treated with surgery and prolonged intravenous antibiotics.

predilection for aortic dilatation and the potential for aortic dissection. Finally, there is evidence that hypertension is substantially more prevalent in these patients, developing at a far younger age than would normally be expected. Hypertension is likely an important mediator of the accelerated atherogenesis reported in patients with CoA. Of late deaths in CoA, up to one-third are related to acute myocardial infarction, so the importance of cardiovascular risk reduction in these patients should not be overlooked.

HYPERTENSION IN THE COARCTATION PATIENT

Probably the best recognized complication resulting from CoA is hypertension. It is thought to directly contribute to the poor prognosis associated with unrepaired coarctation by increasing the risk of myocardial infarction, intracranial hemorrhage, aortic dissection, and congestive heart failure. In one early series, 25% of unrepaired patients died before age 20, 50% before age 32, 75% before age 46, and 90% before age 58. It was previously hoped that relieving the obstruction would cure the hypertension and return normal life expectancy. Although advancements in both surgical and percutaneous repairs have greatly impacted on the morbidity and mortality of this disorder, the longevity of patients with CoA still appears significantly reduced compared to patients without CoA.

The hypertension in patients with CoA prior to repair is unique, as it affects only the upper extremities. Thus, vascular beds above the CoA are subjected to hypertensive changes while vascular beds below the CoA are generally normotensive or even occasionally hypotensive. Several mechanisms have been proposed to explain the genesis of hypertension in CoA patients.²⁹ The first is that the stenosis leads to high mechanical resistance to cardiac output that subsequently increases pressure. The second is increased activation of the renin-angiotensin-aldosterone system through underperfusion of the kidneys, the so-called “Goldblatt phenomenon.” Finally, the neural hypothesis proposes that baroreceptors in the aorta above the obstruction are reset to facilitate blood flow to the lower parts of the body. It is quite likely that all three mechanisms work in concert in CoA patients to increase blood pressure.

After coarctation repair, blood pressure returns to normal in the upper extremity in the majority of patients, particularly in the young. The development of systemic hypertension following CoA repair should prompt a thorough evaluation to exclude restenosis at the site of surgical or percutaneous repair. In such case, re-intervention may be warranted, which can relieve obstruction and lead to a reduction in upper extremity blood pressure.

The incidence of so called “late hypertension” in repaired CoA patients still far exceeds the incidence of essential hypertension in the general population, suggesting that long-standing perturbations of normal homeostatic mechanisms are present in CoA patients. Previous studies have used fairly conservative definitions for hypertension (including systolic blood pressure higher than 160 and

diastolic blood pressure higher than 90 or 95 mmHg) and have been limited by relatively short follow-up periods, and therefore underestimate the true prevalence of hypertension in patients with repaired CoA. In general, the older the patient is at the time of repair, the greater the likelihood of developing long-standing hypertension. One short-duration follow-up series (median 7.5 years) showed that in the absence of recoarctation, no patients operated on prior to age 4 weeks developed hypertension, while over a quarter of patients operated on after 1 year of age developed hypertension.³⁰ The optimal timing of repair, however, has been greatly debated over the years, and it now appears that performing surgery at age 5 to 6 years (prior to entering primary school) best limits the risk of stenosis and improves long-term clinical outcome.⁴

While surgery is most effective in the younger patient, it is important to recognize that repair of the adult with CoA can still result in a significant systolic blood pressure reduction and reduce the need for antihypertensive therapy^{31,32}; similar results may also be seen with percutaneous interventions. The hypertension that eventually develops despite coarctation repair is almost indistinguishable from essential hypertension, and has led to the study of coarctation patients and animal models of coarctation to gain greater insight into essential hypertension. The primary mechanism is believed to be increased activity of the renin-angiotensin-aldosterone system and volume retention. At the heart of this may be the presence of a small residual gradient at the site of coarctation repair. In a study of 73 patients with repaired coarctation with residual gradients of less than 20 mmHg, the ratio between the diameter of the aorta at the repair site to the diameter at the diaphragmatic aorta was among the strongest independent predictors of elevated ambulatory blood pressure and carotid intimal-medial thickness.²² Subtle gradients may become particularly more pronounced during exercise when the cardiac output increases significantly.^{33,34}

Another mechanism likely to be involved is a reduction in cardiopulmonary baroreceptor sensitivity. The proximal thoracic aorta in CoA has been shown to be stiffer³⁵ and more fibrotic,³⁶ which may result in less stretch and activation in response to elevated blood pressure.³⁷ Such a diminished response remains present more than 10 years after corrective surgery.³⁸

Aside from affecting the baroreflex, a stiff, fibrotic ascending aorta may be part of a generalized defect in arterial elasticity and/or reactivity that may result in abnormal vascular function and subsequently hypertension.²⁹ Several studies have demonstrated abnormal vascular reactivity to various interventions including intra-arterial norepinephrine,³⁹ reactive hyperemia,⁴⁰ and nitrates.⁴¹ It remains unknown, however, whether these vascular abnormalities are a cause or merely a consequence of hypertension.

MEDICAL THERAPY FOR LATE HYPERTENSION

It is generally accepted that antihypertensive therapy should be initiated for any coarctation patient with a

resting blood pressure higher than 140/90 mmHg, once the presence of a significant gradient has been properly excluded. Similar to essential hypertension target organ damage such as left ventricular hypertrophy is readily found in hypertensive patients with CoA,^{42,43} and therapy may help to prevent these complications. As in patients with essential hypertension, therapy should be initiated and lower goals targeted in the presence of high-risk features such as diabetes and renal insufficiency. Although inhibitors of the renin-angiotensin system are often mentioned as the preferred therapeutic agents for patients with CoA,⁴⁴ no long-term efficacy studies exist to confirm the benefits of this strategy.

Up to a third of repaired CoA patients are normotensive at rest but develop a profound hypertensive response to exercise.⁴⁵⁻⁴⁷ Although there are studies suggesting that normal individuals with a hypertensive response to exercise have a higher risk of developing hypertension or experiencing a cardiovascular event,⁴⁸⁻⁵⁰ no such evidence exists for CoA patients, and treatment for such patients can therefore not be recommended at this time.⁵¹

SUMMARY

Coarctation of the aorta is an important cause of secondary hypertension. It is estimated that coarctation accounts for approximately 0.2% of all adults with hypertension. Patients with complex coarctation typically are diagnosed early in childhood, while simple coarctation may not be recognized until adulthood. Coarctation may be associated with other anatomic changes such as bicuspid aortic valve, hypoplasia of the transverse aortic arch and aortic isthmus, poststenotic dilatation of the descending aorta, and cystic medial necrosis of the ascending aorta. The clinical diagnosis of coarctation is suggested by the presence of hypertension in the upper extremities with significantly lower blood pressure in the lower extremities, by the presence of collateral channels manifested as rib notching on the chest x-ray, and by EKG evidence of left ventricular hypertrophy. Echocardiography is an excellent noninvasive tool for diagnosing coarctation of the aorta in patients with suspicious clinical findings. Magnetic resonance imaging has now become the choice imaging modality preoperatively to size the aorta and the coarctation lesion, and is very useful in postoperative follow-up. In the event of a contraindication to MRI or lack of availability, computer tomography scanning is a reasonable alternative.

Interventional therapy for coarctation of the aorta is indicated in the presence of a peak gradient over 30 mmHg, a significant hypertensive response to exercise testing or with concurrent aortic aneurysm or symptomatic aneurysm of the circle of Willis. Surgery remains the mainstay in the treatment of native coarctation of the aorta, although some success has recently been achieved with percutaneous intervention in younger patients. Percutaneous intervention appears particularly effective in the treatment of recoarctation. Postinterventional “late hypertension” is well recognized, and suggests long-standing perturbations of normal homeostatic mechanisms in coarctation patients. Re-coarctation or aneurysm formation at the anastomotic

site may also occur. Consequently, follow-up after surgical treatment is a necessity. Medical therapy is indicated for “late hypertension.” Overall, the hypertension in coarctation and “late hypertension” carries at least the same cardiovascular risk as hypertension in the general popu-

lation, including accelerated atherogenesis, and increased risk of myocardial infarction and stroke. Consequently, the importance of cardiovascular risk reduction in these patients should not be overlooked.

Chapter
75**Hypertension Due to Central Nervous System Dysfunction***J. David Spence***Definition and Key Features**

- Conditions affecting the central nervous system that may cause severe paroxysmal hypertension include stroke and brainstem lesions, carotid endarterectomy, general anesthesia, epilepsy, electroconvulsive therapy, and quadriplegia.
- The principal differential diagnosis is pheochromocytoma.

Therapy

- Management of hypertension in acute stroke must avoid sudden hypotension, which may aggravate ischemia. Labetalol is effective.
- In the management of hypertension in quadriplegic patients, it is important to avoid bladder distension. A beta-adrenergic antagonist in combination with a competitive alpha-blocker is effective.
- During electroconvulsive therapy ganglionic blockade may be achieved with trimethaphan camsylate.
- Epilepsy-related hypertension may be managed with administration of trimethaphan or phenoxybenzamine.

Short-term blood pressure is regulated by the autonomic nervous system (see Chapters 17 and 18). This reflex regulation of blood pressure from beat to beat depends on several key structures: the anterior hypothalamus and brainstem nuclei including the nucleus of the tractus solitarius, baroreceptors in the carotid artery, aorta and heart, stretch receptors in the bowel, bladder, ureters and kidneys, and the intermediolateral cell column, which represents in a sense the “lower motor neurons” of the autonomic system (Figure 75–1).

When these structures are damaged, or their function is disrupted by lesions or events in the central nervous system, severe hypertension can result. Failure of the peripheral autonomic nerves, as in diabetes or amyloidosis (including amyloidosis secondary to “benign” monoclonal gammopathy), causes severe postural hypotension because reflex control of blood pressure is lost. Although hypertension secondary to dysfunction of the central nervous system is uncommon, the syndromes are instructive. Effective management of such events requires an understanding of the mechanisms. For those reasons, this chapter will discuss several examples of hypertension due to disorders of the central nervous system.

ANATOMY AND PATHOLOGY

The hypothalamus has been called the head ganglion of the autonomic nervous system. It has extensive connections with the limbic system, and with the brainstem, so that in addition to influencing the body through pituitary secretions, the hypothalamus is involved in blood pressure regulation via central nervous system control. Nuclei in the brainstem receive inputs from baroreceptors in the heart, aorta, and carotid arteries via the hypoglossal (IXth cranial) nerve. The nucleus of the tractus solitarius, present bilaterally in the lower medial medulla (Figure 75–2), is involved in integrating blood pressure as sensed by the baroreceptors, and sends inputs down the spinal cord to the intermediolateral column (Figure 75–3). These inputs may be inhibitory or excitatory. From the intermediolateral cell column impulses go via cholinergic fibers to sympathetic ganglia, where a multiplier effect occurs: for every one preganglionic fiber approximately 100 postganglionic adrenergic fibers travel to structures including peripheral veins and arteries. Excitatory impulses from the brainstem result in vasoconstriction, whereas inhibitory impulses result in vasodilation. Thus within seconds an elevation of blood pressure is sensed by the baroreceptors, integrated in the brainstem, and vasodilation results from downward inhibitory traffic; a reciprocal sequence results from a drop in blood pressure. This mechanism can be thought of as reflex control of blood pressure through a reflex loop that has its afferent limb in the baroreceptors, integration in the brainstem, descending traffic to the spinal cord, and its efferent limb in preganglionic nerves.

PATHOPHYSIOLOGY

Central nervous system regulation of blood pressure can become disordered at several levels: the hypothalamus, brainstem, baroreceptors, and spinal cord.

Lesions of the hypothalamus may cause severe hypertension either as the result of damage such as infarction, or may be paroxysmally be activated leading to severe hypertension in the setting of epilepsy.

Lesions of the brainstem, including infarction, tumor and compression by vascular loops, may lead to severe hypertension because baroreceptor reflex integration is disturbed by damage to the nucleus of the solitary tract.

Disruption of baroreceptor nerves during carotid endarterectomy or neck dissection for cancer disrupts reflex control of blood pressure by eliminating the afferent limb of the reflex.

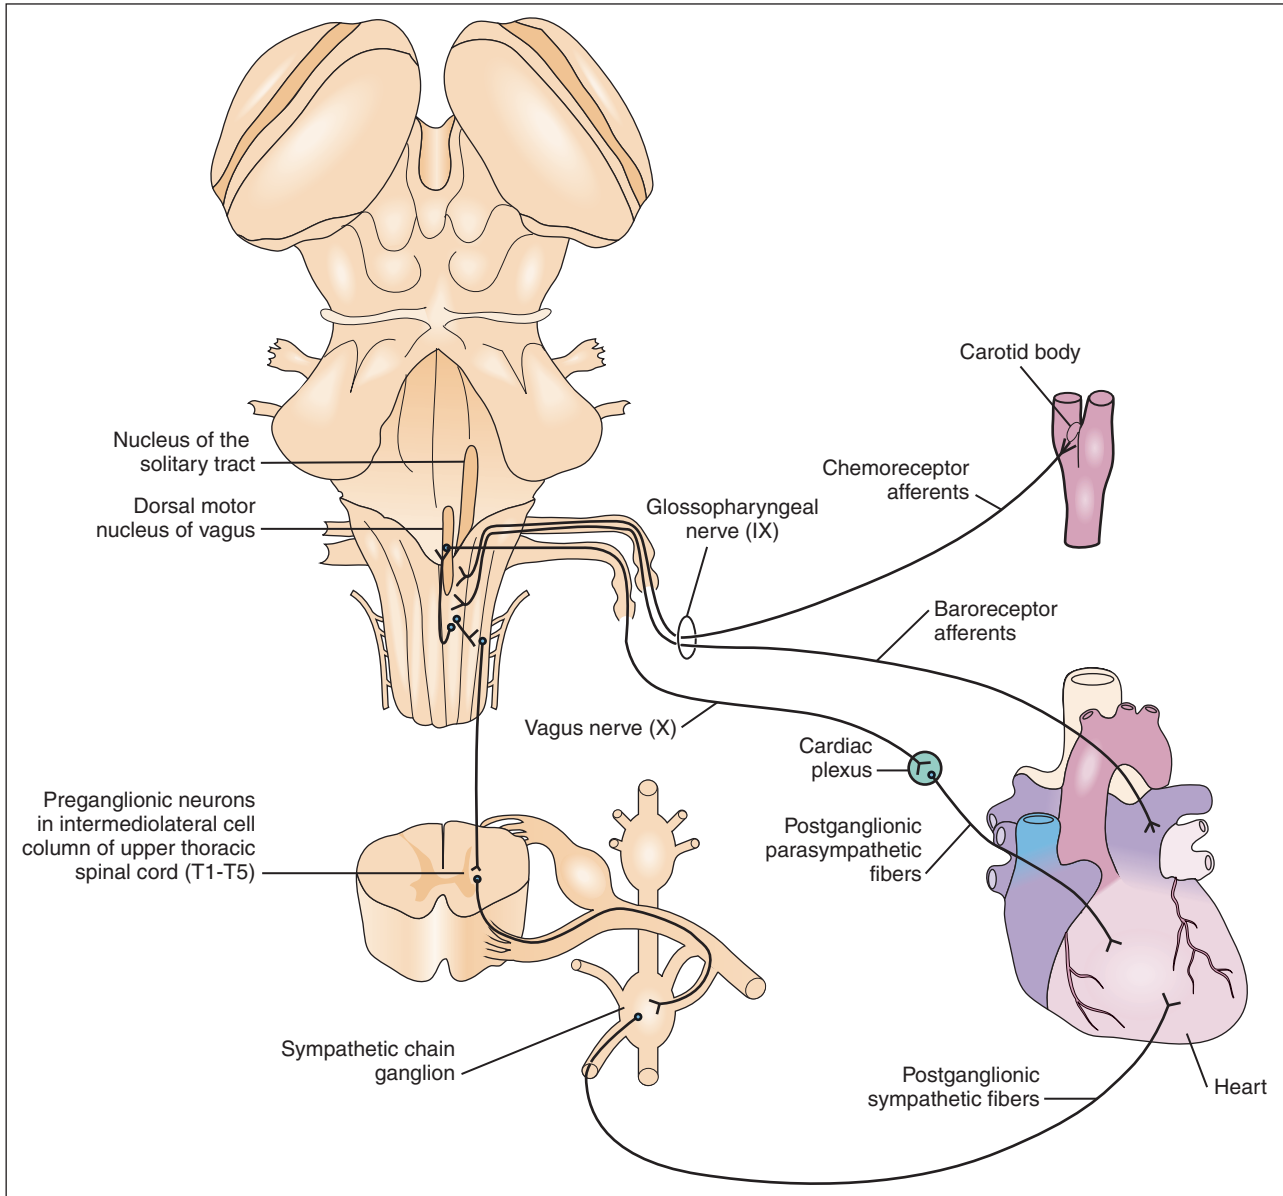

Figure 75-1. Reflex integration of blood pressure. Afferents from baroreceptors in the heart, aorta, and carotid artery ascend via the glossopharyngeal (IXth cranial) nerve to the nucleus of the solitary tract. Descending inputs go via the vagus to the heart and down to the intermediolateral cell column of the spinal cord (T₁-T₅). (Redrawn from Purves D, Augustine GJ, Fitzpatrick D, et al. *Neuroscience*. 2nd ed. Sunderland, MA: Sinauer Associates, Inc., 2001, Figure 21.7.)

In quadriplegic patients, damage to the cervical cord interrupts the connections between the brainstem and the intermediolateral cell column (which is located in the thoracic cord). Distension of viscera including the ureter, kidneys, bladder, or bowel causes afferent traffic to the spinal cord, which leads to reflex activation of sympathetic nerves in the intermediolateral cell column and a rise in blood pressure that can no longer be corrected by the brainstem in response to baroreceptor input. The result is severe hypertension with bradycardia, because the vagus is intact.

In patients under deep general anesthesia the reflex control of blood pressure may be impaired, with the potential for severe hypertension related to visceral distension

or traction. In patients who undergo carotid endarterectomy or neck dissection for cancer, the baroreceptor nerves may be damaged, so that the afferent loop of the reflex is lost.

CLINICAL PRESENTATIONS

Several cases are presented below to illustrate the various presentations of hypertension attributable to central nervous system dysfunction.

Hypertension as consequence of stroke and brainstem lesions

In 1974, Mazey¹ described a syndrome resembling pheochromocytoma following a stroke. Two years later, the author

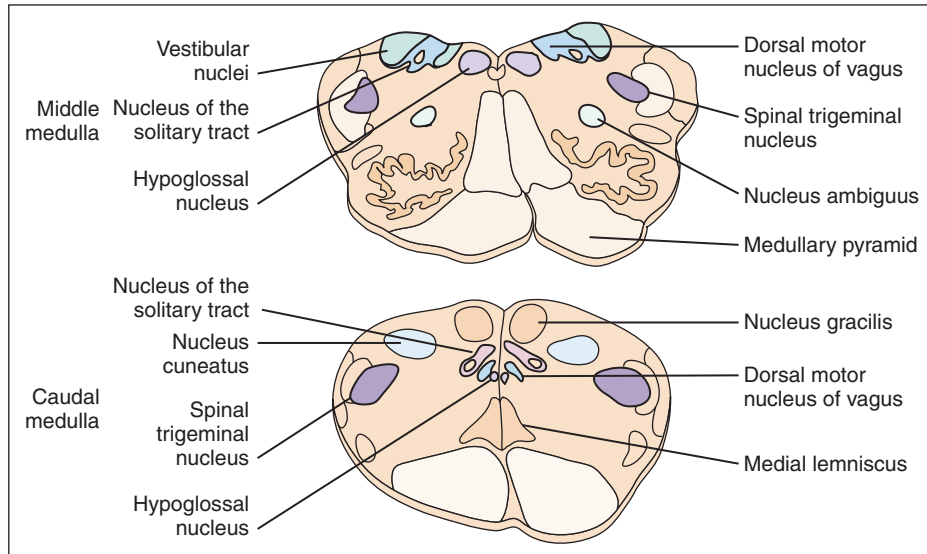

Figure 75-2. The dorsal motor nucleus of the vagus, and the nucleus of the solitary tract, in the lower medulla. (Redrawn from Purves D, Augustine GJ, Fitzpatrick D, et al. *Neuroscience*. 2nd ed. Sunderland, MA: Sinauer Associates, Inc., 2001.)

admitted a 36-year-old woman with no previous history of hypertension, who presented with a brainstem infarction and severe labile hypertension, ranging from 200/100 to 230/130, with a heart rate of 70 to 80 per minute. She was shaky and sweaty, raising the possibility of pheochromocytoma. Most of her findings were consistent with lateral

medullary syndrome, but she had some pontine involvement, and some features of medial medullary syndrome. Her cerebral angiogram showed bilateral lesions at the C1-2 level typical of chiropractic injury, and upon questioning she reported that she had undergone chiropractic manipulation with rotation of the neck the day before her stroke. Plasma catecholamines were initially moderately elevated, with a plasma norepinephrine that was three times the upper limit of normal for the author's laboratory. She was managed initially with phenoxybenzamine and propranolol, but over the course of 3 weeks her blood pressure settled down and these medications were gradually stopped. She made a good recovery from her brainstem infarction.

Such patients present a "chicken-and-egg" problem; often it is assumed that the hypertension caused the stroke, rather than the reverse. It seems that in this case the severe hypertension was due to interruption of baroreceptor reflexes by damage to the nucleus of the tractus solitarius (NTS); this problem is more common with brainstem infarctions than with carotid territory ischemia, but Nathan and Reis^{2,3} showed that severe hypertension with 100-fold elevations of plasma renin and elevated catecholamines could be produced in rats with lesions of either the NTS or of the anterior hypothalamus. Thus a large infarction with carotid occlusion affecting the hypothalamus might also present in this way. Reis and Doba⁴ also presented a case of hypertension secondary to a mass lesion of the brainstem. Tumors of the fourth ventricle can also cause hypertension, presumably by irritating or compressing structures in the floor of the ventricle, and basilar artery aneurysm has been described with a syndrome resembling pheochromocytoma.⁵

Jannetta⁶ showed that several paroxysmal cranial nerve syndromes such as tic douloureux, hemifacial spasm, vertigo, and glossopharyngeal neuralgia may be due to pulsatile compression of the involved cranial nerves by vascular

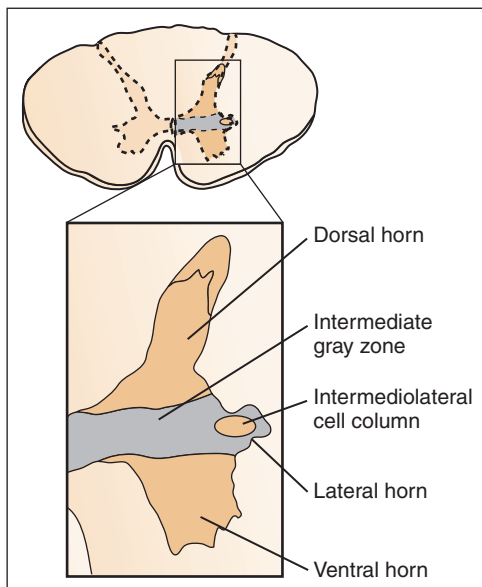

Figure 75-3. Intermediolateral cell column. In the thoracic cord (T_1 - T_3), the intermediolateral cell column represents the equivalent of the "lower motor neurons" of the sympathetic nervous system. Their axons terminate on the sympathetic ganglia. (Redrawn from Purves D, Augustine GJ, Fitzpatrick D, et al. *Neuroscience*. 2nd ed. Sunderland, MA: Sinauer Associates, Inc., 2001, Figure 21.2.)

loops, and that surgical decompression is an effective treatment in many such cases. Similarly, Levy et al.⁷ have proposed that paroxysmal hypertension, and even sustained hypertension, may be due to medullary compression by vascular loops, and relieved by surgical decompression.

Cushing reflex

A 32-year-old auto mechanic presented to the emergency room after a witnessed generalized tonic-clonic seizure. He was comatose, with right hemiplegia, bilateral papilledema, and a blood pressure of 236/130 mmHg. The house staff admitted him with a diagnosis of hypertensive encephalopathy, but his examination the next morning was more consistent with a left hemisphere lesion. Computerized tomography showed a large brain tumor, with a 2-cm midline shift. On biopsy, the lesion was a high-grade glioma. He died several weeks later. It seems likely that his markedly elevated blood pressure was due to a Cushing reflex, with elevation of blood pressure secondary to raised intracranial pressure.

Hypertension in patients with quadriplegia

A 23-year-old quadriplegic man presented to the neurosurgery service with a C5–6 lesion sustained a month earlier by diving into a quarry and striking his head on a rock. He was being taught to empty his bladder with a tap maneuver, and during this session he became very pale and diaphoretic, and developed a severe headache. His blood pressure was 230/130 mmHg, and he was developing acute pulmonary edema. With catheterization and emptying of the bladder, the entire syndrome abated immediately.

Several years later I was consulted about a similar event with severe hypertension and an intracerebral hemorrhage triggered by bladder distension in a young man with quadriplegia. Such patients with quadriplegia and severe hypertension during bladder distension had high plasma catecholamines during bladder distension in the course of a cystometrogram, and the elevation of plasma catecholamines during bladder distension could be blunted by treatment with phenoxybenzamine. This syndrome has been described by several authors.^{8–10} Severe paroxysms of hypertension have also been described in quadriplegia during lithotripsy.¹¹

Hypertension during general anesthesia

During surgery for treatment of a cerebral aneurysm, hypotension often is induced to reduce the risk of catastrophic hemorrhage in the event of rupture of the aneurysm during clipping. I report here one case where, despite efforts to achieve hypotension with trimethaphan camsylate, the patient's blood pressure did not fall, and she was not producing urine despite having been given 500 mL of mannitol to slacken her brain. It was found that her urinary catheter was kinked, and once the kink was removed, her blood pressure decreased dramatically. It appears that the general anesthetic had interfered with reflex control of blood pressure, so that the stimulus from bladder distension had caused hypertension. Reflex

activation of blood pressure by bladder distension, and termination of that activation by bladder emptying probably account also for micturition syncope and the hypotension sometimes seen after catheterization of old men with prostatic obstruction.

A related phenomenon is the severe hypertension that sometimes occurs after removal of a pheochromocytoma. During the surgery, the general anesthetic inactivates the autonomic system; but in the recovery room when the patient begins to shiver and experience piloerection, severe hypertension may develop even though the tumor has been successfully removed, because catecholamine stored in the sympathetic nerve boutons requires about a week to be exhausted. (Approximately 80% of discharged norepinephrine is taken back up into the bouton after discharge, so it is recycled and takes some time to be depleted.) It is therefore advisable to leave a phentolamine infusion hanging for some time after removal of a pheochromocytoma in case it is needed. (A missed pheochromocytoma in the case of multiple pheochromocytomas is another possible cause of this phenomenon. It is for that reason that abdominal exploration during removal of a pheochromocytoma is advocated, rather than posterior removal of the single recognized pheochromocytoma.)

Hypertension in patients undergoing carotid endarterectomy

A 67-year-old woman underwent right carotid endarterectomy because of severe symptomatic stenosis. A left carotid endarterectomy had been performed 3 years earlier because of symptomatic severe stenosis. Preoperatively she was mildly hypertensive, with pressures around 150/90, and was being treated with propranolol. Immediately postoperatively, she became extremely hypertensive, with a blood pressure of 250/150 mmHg, with shaking, diaphoresis, and pallor that raised the possibility of pheochromocytoma. She was treated with phentolamine and phenoxybenzamine; indeed over the next 2 days she exhausted the entire supply of phenoxybenzamine in the city, and an emergency supply had to be flown in. Her plasma catecholamines were elevated to around four times the upper limit of normal, but extensive investigation including computerized tomography and nuclear medicine scanning with metaiodobenzylguanidine ruled out pheochromocytoma. Her blood pressure stabilized over the course of a month. Rebound hypertension from propranolol withdrawal was a consideration, but a virtually identical experience several years later with a patient who underwent bilateral neck dissection with cancer suggests that interruption of baroreceptor reflexes by the neck dissection was a more likely cause.

This problem is distinctly unusual and no case was reported among the 1108 patients randomized to endarterectomy in the North American Carotid Endarterectomy trial.¹² However, it has been suggested that the problem is more common than is recognized.^{13,14} There does not appear to be a long-term effect of carotid endarterectomy on blood pressure.¹⁵

A more common problem is moderate hypertension following endarterectomy, with a syndrome resembling unilateral hypertensive encephalopathy. This syndrome of

cerebral hyperperfusion¹⁶ appears to be due to hypertension (possibly related to the neck dissection^{17,18}) with sudden increased perfusion pressure after a severe stenosis is alleviated. Breakthrough of cerebral autoregulation in this circumstance probably results from high pressure entering a circulatory bed that was previously under low pressure, with the consequent loss of hypertensive remodeling of the resistance vessels.

Hypertension in epilepsy

Rarely, epilepsy may present with a syndrome resembling pheochromocytoma.¹⁹ Seizures originating in the diencephalon,¹⁹ hypothalamus,²⁰ or temporal lobe²¹ can elevate blood pressure and plasma catecholamines, presumably by activating hypothalamic, limbic, and insular structures relating to autonomic function. In addition to elevation of plasma norepinephrine, hypothalamic seizures have been shown to elevate levels of prolactin and adrenocorticotropic hormone.²⁰

Hypertension in patients undergoing electroconvulsive therapy

Some patients have severe hypertension, in the range of 250/150 mmHg, immediately after electroconvulsive (ECT) therapy. Extensive investigation ruled out pheochromocytoma in both cases. It is suspected that this syndrome, which may be more common with bilateral than with unilateral ECT, is pathophysiologically similar to the severe hypertension that may occur with epilepsy.

DIAGNOSTIC TECHNIQUES

In these conditions the diagnosis is made by recognizing and understanding the pathophysiology as described in this chapter, and by exclusion of pheochromocytoma and other causes that may be contributing. For example, in addition to cervical spinal cord transection, obstruction to outflow of urine by a kinked catheter or by prostatic disease may be the immediate cause of the hypertension; catheterization, or suprapubic drainage may be needed in emergency circumstances with severe hypertension and pulmonary edema.

The principal differential diagnosis is that of pheochromocytoma, and the association of bladder distension with paroxysms of hypertension, diaphoresis, and pallor will raise the specter of a pheochromocytoma related to the bladder. A second competing problem of the chicken-and-egg variety is that seizures may complicate severe hypertension from other causes, so that it may be thought that the epilepsy was the cause of the hypertension, rather than the result of the hypertension. This has been described with renovascular hypertension²² and pheochromocytoma.²³ In my experience, it is much more common for the seizures to be secondary to the hypertension, rather than the epilepsy being the cause of the hypertension.

The differentiation of pheochromocytoma from quadriplegic hypertensive crises requires careful and thoughtful investigation.^{10,24} Plasma catecholamines will be elevated to several times above the lab reference range in many of these cases, but seldom are extremes of catecholamine

elevation seen as with pheochromocytoma. A 24-hour urine collection for metanephrine will be more abnormal in pheochromocytoma, and in most of these circumstances such as pseudopheochromocytoma following stroke, the syndrome settles down over several weeks. In the meantime if blood pressure is very difficult to control, it may be necessary to go on to imaging studies, including computed tomography, MRI, or nuclear medicine imaging with metaiodobenzylguanidine, which can identify pheochromocytomas anywhere from the bladder to the base of the skull.

MANAGEMENT

Management of hypertension in acute stroke

In the past, many experts recommended that the elevation of blood pressure during acute stroke should remain untreated, since abrupt lowering of blood pressure to levels that are too low may exacerbate brain ischemia. However, that recommendation is too simplistic, as sometimes the blood pressure must be treated.²⁵ For example, in a patient whose stroke is caused by aortic dissection that occludes a carotid artery and at the same time occludes a renal artery, the severe hypertension from the renal artery occlusion must be treated. Similarly, a patient with severe hypertension who is in pulmonary edema with a recent myocardial infarction that has caused an embolic stroke must have the hypertension treated on account of the pulmonary edema and myocardial ischemia. Recently the Acute Candesartan Cilexetil in Stroke Survivors (ACCESS) trial²⁶ showed that treatment with candesartan in acute stroke was associated with improved outcomes; however, to conclude that the improvement was due to blood pressure reduction is problematic; benefits may have been related to protective effects of angiotensin receptor blockade.²⁷

The real issue is not whether to treat hypertension in acute stroke; it is how to treat it. The principal concern is to avoid sudden hypotension that may aggravate ischemia; for this reason sublingual nifedipine should never be used in acute stroke.²⁸ Intravenous drugs such as labetalol are probably best for this purpose, but before initiating treatment with a beta blocker it is important to draw blood for plasma renin and aldosterone, so that the underlying cause of the severe hypertension can be identified and treated specifically after the crisis has resolved.^{29,30}

This topic is discussed in detail in Chapter 48 and is also touched on in Chapter 71.

Management of hypertension in quadriplegic patients

Attention to avoidance of bladder distension is part of management, but I have found that phenoxybenzamine was successful in a number of cases. Unfortunately this drug (a noncompetitive blocker of alpha receptors, and therefore better suited to paroxysmal hypertension such as with pheochromocytoma) is increasingly difficult to obtain, so it may be more practical to use beta-adrenergic antagonists in combination with the less satisfactory competi-

tive alpha-blocker such as doxazosin (which is longer acting than terazosin or prazosin). Phentolamine infusion may be used in short-term settings in hospital. Stimulation with transcutaneous electrical nerve stimulation has been described as a treatment for paroxysmal hypertension during colonic distension in quadriplegic rats,³¹ so this may offer an alternative in some cases. Clonidine has been used to treat this condition,³² but because of my experience with severe rebound hypertension from clonidine withdrawal, I avoid using this drug.

Electroconvulsive therapy

A good approach to the management of severe hypertension during electroconvulsive therapy was described by Petrides et al.³³ using intravenous trimethaphan camsylate (Arfonad). They found that a bolus of 15 mg was more effective than lower doses. This treatment is physiologically sound, as it represents ganglionic blockade. It is also practical, as anesthetists are commonly involved in the care of patients during electroconvulsive therapy, which is a brief scheduled event. Nicardipine and labetalol in combination have been used to treat this problem,^{34,35} but because these drugs are competitive antagonists, they are less logical, and in my view less likely to be effective than ganglionic blockade.

Epilepsy

By analogy with hypertension during electroconvulsive therapy, it seems likely that trimethaphan may also be useful therapy during hypertensive emergencies caused by diencephalic epilepsy; however, for preventing hypertension during seizures that occur outside the hospital setting, phenoxybenzamine would be the most effective therapy if available.

Here an explanation is in order for the need for a non-competitive alpha receptor antagonist. Paroxysmal hypertension due to discharge of catecholamines from sympathetic nerve boutons is best treated with phenoxybenzamine because it is a noncompetitive antagonist. It binds covalently to alpha receptors, so that when a norepinephrine molecule arrives the receptor is already occupied (Figure 75–4). Because the paroxysm releases such a flood of catecholamines, it is not possible to treat this effectively with competitive alpha-blockers: in order to have enough antagonist on board to deal with the paroxysm when it happens, the blood pressure while standing would be so low between paroxysms that the patient would not be able to walk around. This principle applies equally to the management of pheochromocytoma and to that of disorders of reflex control of blood pressure in which severe hypertension results from paroxysmal sympathetic discharge.

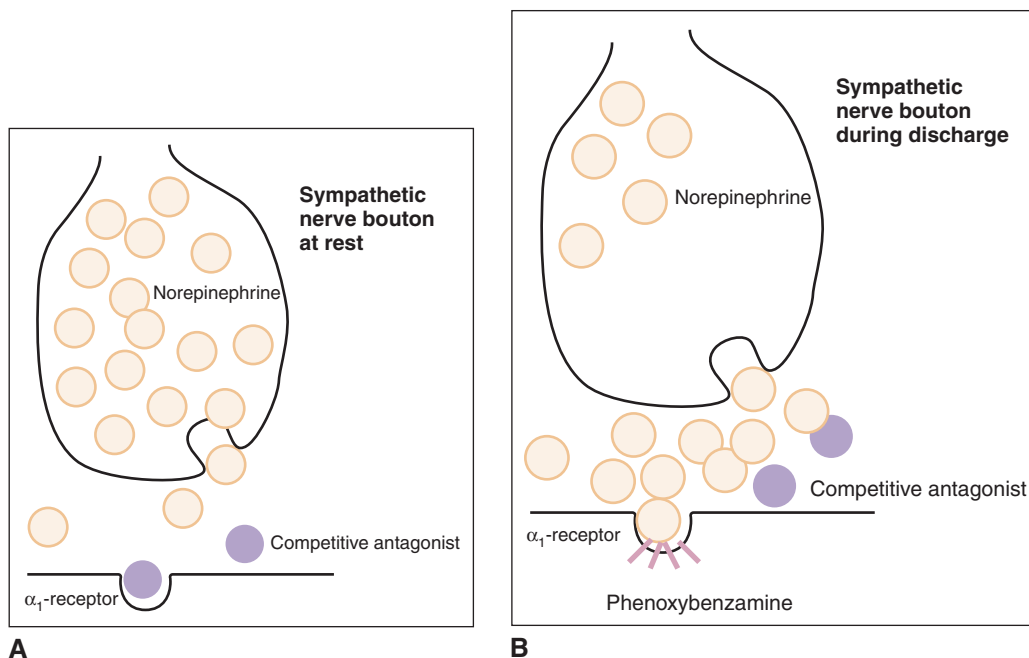

Figure 75–4. Noncompetitive α -receptor antagonism with phenoxybenzamine. Norepinephrine (white circles) is released from a sympathetic nerve bouton, stimulating the postsynaptic α_1 -receptor. Competitive antagonists such as phentolamine or doxazosin (purple circles) block the stimulation by competing for the receptor. This is successful at reasonable doses of antagonist while the sympathetic nerves are quiescent (*left above*), but when a paroxysmal discharge floods the synaptic space with excess norepinephrine (*right above*), the effect of the competitive antagonist is overcome by norepinephrine's competition for the receptor. Phenoxybenzamine (purple bars) binds covalently to the receptor, so that no matter how much norepinephrine is present in the synaptic space, the receptor cannot respond. This principle is the reason that phenoxybenzamine is the preferred α -blocker for severe paroxysmal hypertension due to adrenergic agonism, such as in pheochromocytoma, or in hypertension due to central nervous system disorders that cause loss of reflex control of blood pressure.

PROGNOSIS

The prognosis of hypertension secondary to lesions of the central nervous system depends on how high the pressure goes, how well and how quickly it is controlled, and in part on the premorbid state of the vasculature. Patients who previously had low blood pressure will be at greater risk from a sudden severe rise in pressure because they will not have adaptive hypertrophy of their resistance vessels, and they will therefore be more likely to sustain a brain hemorrhage or hypertensive encephalopathy. In the longer term, the severe hypertension due to loss of reflex blood pressure control generally abates over several weeks with acute lesions such as stroke or carotid dissection. Surgical removal of the brainstem compression generally resolves the problem within days. The prognosis in epileptic cases depends on control of the epilepsy, and in this regard it is worth considering surgical treatment of the epilepsy if there is an accessible lesion, as surgical treatment of epilepsy is much more effective than medical therapy in resistant cases.^{36,37} Hypertension during electroconvulsive therapy can usually be managed, and because it occurs during a planned procedure, the management is usually successful.

The principal exception is the syndrome of hypertension during bladder distension due to cervical cord transection, which may continue for years.

SUMMARY

Lesions of the central nervous system can cause acute severe hypertension due to loss of reflex control of blood pressure. The principal differential diagnosis is pheochromocytoma. When bladder distension is the trigger for the hypertensive crisis, emptying the bladder will usually solve the immediate crisis, but longer-term management will usually be required to prevent recurrence. For severe hypertension due to electroconvulsive therapy, because it is a brief scheduled event, the ganglionic blocker trimethaphan camsylate is a practical therapy. However, for most of these conditions more long-term therapy is required, and phenoxybenzamine, because it binds covalently to alpha-receptors, is the treatment of choice.

It is therefore a problem, not only for the management of pheochromocytoma but also for the management of reflex disorders of blood pressure regulation such as the conditions described in this chapter, that phenoxybenzamine is now so difficult to obtain. It is hoped that regulatory authorities and the pharmaceutical industry will address it. Development of an alternative noncompetitive antagonist might be an alternative to making phenoxybenzamine more readily available, but the market is so small that such a product should probably be regarded as an orphan drug.

Sleep Apnea and Hypertension

Peter Y. Hahn and Virend K. Somers

Key Findings

- Obstructive sleep apnea (OSA) is a common disorder affecting 5% to 25% percent of men and women worldwide.
- OSA is characterized by repetitive partial or total collapse of the pharyngeal airway resulting in arousals and sleep fragmentation.
- Risk factors for OSA include age, male sex, obesity, and retrognathia.
- OSA is diagnosed using polysomnography and is defined by a respiratory disturbance index (RDI) of more than five per hour.
- OSA patients are at increased risk of developing cardiovascular diseases, including hypertension (HTN).
- Disordered sympathetic activation, endothelial dysfunction, inflammation, and insulin resistance may play a role in the development of HTN in OSA.
- Positive airway pressure (PAP) treats OSA by acting as a pneumatic splint, thereby preventing the pharyngeal airway from collapse.
- PAP reduces both nocturnal and daytime blood pressure in OSA patients with HTN.

Obstructive sleep apnea (OSA) is a common disorder affecting 5% to 25% of men and women worldwide.¹ The prevalence of OSA has been reported to be equivalent to that of diabetes. Patients with OSA have a high prevalence of cardiovascular disease, including hypertension, ischemic heart disease, heart failure, and stroke. Epidemiologic studies show that OSA is an important risk factor for the development of systemic hypertension.^{2,3} There appears to be direct linear relationship between incidence of hypertension and the severity of OSA.³ The seventh report by the Joint National Committee on the Detection, Prevention, Evaluation and Treatment of High Blood Pressure (JNC-7) lists OSA as first on the list of causes of secondary hypertension.⁴ Although the mechanisms linking OSA and hypertension remain incompletely understood, disordered sympathetic activation, endothelial dysfunction, and inflammation are thought to play important roles. To date, several studies have demonstrated that treatment of OSA has beneficial effects on the treatment and control of systemic hypertension.^{5,6} OSA patients already on anti-hypertensive treatment appear to derive particular benefit, suggesting that OSA as a cause of resistant hypertension. Recognizing and diagnosing sleep apnea in patients with

hypertension is important considering the potential effective treatments currently available for OSA.

ANATOMY AND PATHOLOGY

The human upper airway is a compliant structure that is susceptible to collapse during inspiration. Obesity is an important risk factor for OSA. Obesity can result in increased fat deposition around the neck resulting in an increased positive pressure outside the airway thereby predisposing to collapse. Any reduction in cross-sectional area of the pharynx and in particular reduced lateral dimensions of the pharynx increases the risk of upper airway collapse. Concordantly, large tonsils, long prominent soft palate, macroglossia, or posterior displacement of the mandible (retrognathia) have all been shown to increase the risk of OSA (Figure 76–1).

Although anatomic predisposition is important, decreased pharyngeal dilator muscle function during sleep also plays an equally important role in the development of upper airway collapse characteristic of obstructive sleep apnea. During the awake state, neuromuscular input to the pharyngeal dilator muscles (e.g., glossopharyngeal) actively keeps the airway patent. Neuromuscular input to the pharyngeal muscles consists of a complex interplay of innervation of over 20 different upper airway muscles (Figure 76–2). This complex system consists of an underlying tonic activation and intermittent phasic activation of the muscles. The phasic activation is a reflex mechanism counteracting the pulses of increased negative intrathoracic pressure generated during inspiration. Both phasic and tonic activation are increased during wakefulness in patients with OSA compared to controls. This is thought to be due to the increased activity required to keep the anatomically compromised airway open. With sleep onset, however, neuromuscular input to the dilator muscles is decreased. The loss of this input puts the airway at increased risk of collapse in individuals with anatomic predisposition leading to obstructive breathing events (Figure 76–3).

PATHOPHYSIOLOGY

Normal sleep is characterized by a state of cardiovascular “relaxation.” Blood pressure, both systolic and diastolic, decrease with sleep onset (stages 1 and 2) and with deepening levels of NREM sleep (stages 3 and 4). Heart rate and cardiac output also decrease during NREM sleep. These changes

Figure 76-1. Prominent soft palate and uvula.

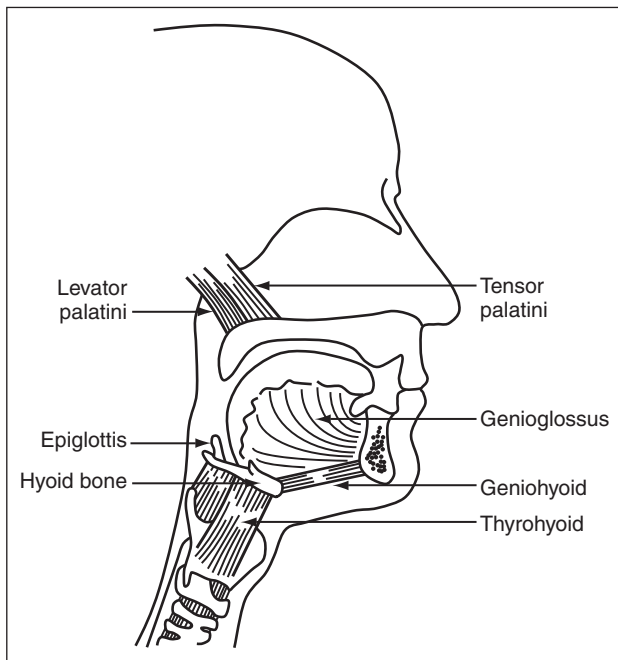

Figure 76-2. Schematic representation of muscles important in the maintenance of upper airway patency.

are likely due to the reduction in sympathetic nervous activity and the progressive rise in parasympathetic activity. During REM sleep, there is increased variability in blood pressure and heart rate with levels approaching those of relaxed wakefulness. Sympathetic nervous activity has been found to be increased during REM sleep, which likely accounts for these findings. Obstructive sleep apnea, however, results in acute hemodynamic effects that disrupt cardiovascular relaxation during sleep.

During obstructive apneas, hypoxemia and hypercapnia stimulate peripheral and central chemoreceptors leading to an increase in sympathetic activity.⁷ A progressive rise in sympathetic activity is noted during apneas followed by a peak with arousal and resumption of breathing. Increased SNA results in increased peripheral vascular resistance. Concordantly, blood pressure increases progressively during the apnea and also peaks with arousal (Figure 76-4). Although heart rate and cardiac output decrease during obstructive apneas, both increase dramatically with arousal and resumption of breathing. This increase in cardiac output in the face of continuing severe peripheral vasoconstriction contributes to the large increase in blood pressure observed with arousals.

While much is known regarding the acute hemodynamic effects of OSA, the mechanisms underlying the association of OSA and systemic hypertension remain incompletely understood. Disordered sympathetic activity, however, may play an important role in the development of hypertension in these patients. Patients with OSA have evidence of a heightened sympathetic drive that is present even during wakefulness. This heightened sympathetic drive in patients with OSA is associated with faster heart rates, decreased heart rate variability, and increased blood pressure variability.⁸ Previous studies have demonstrated that individuals with decreased heart rate variability are at increased risk of developing future hypertension, while increased blood pressure variability results in target-organ damage.⁹

Abnormal relaxation of the endothelium is thought to represent a nascent form of atherosclerosis and may lead to the development of hypertension and other cardiovascular disorders. Studies have demonstrated that OSA is an independent risk factor for the development of endothelial dysfunction. Patients with OSA who are free of overt cardiovascular or vascular disease have been shown to have

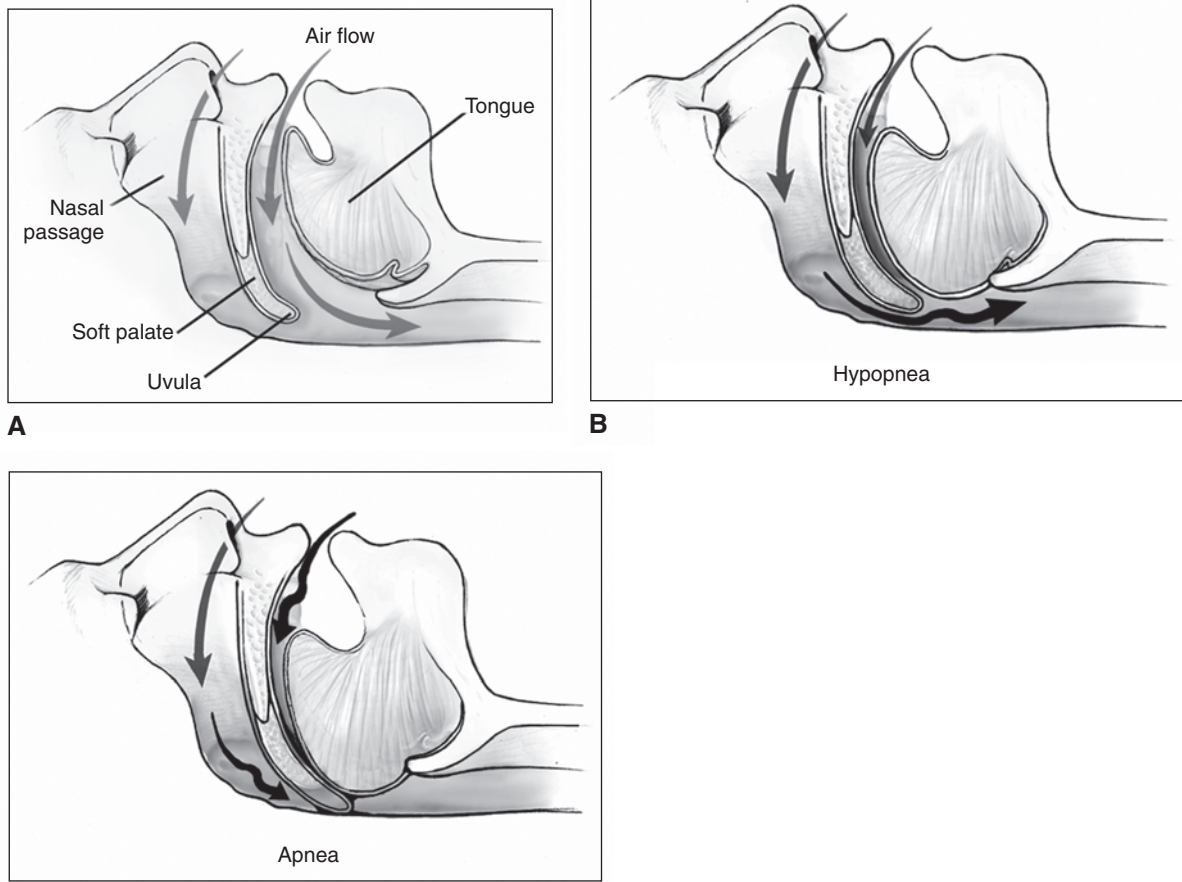

Figure 76-3. Schematic representation of a patent upper airway. Obstructed breathing manifesting as a hypopnea and apnea are illustrated.

Figure 76-4. Sympathetic nerve activity rises progressively during an apnea followed by a decrease after arousal and resumption of breathing. Blood pressure gradually rises during the apnea and peaks with arousal.

impaired resistance vessel endothelial function.^{2,10} Whether conduit vessel (brachial artery) endothelial function is also impaired is controversial. Disordered sympathetic nervous activity (SNA) may play a role in the development of endothelial dysfunction in patients with OSA, as may inflammation, disordered coagulation, and metabolic dysfunction.

The adhesion of leukocytes to the endothelium can result in impaired endothelial function by interfering with endothelial cell-derived, nitric oxide-dependent vasodilation. Several studies have shown that adhesion molecule expression (ICAMs, VCAMs) is increased in OSA, which suggests that the endothelium is “primed” for leukocyte binding.¹¹ Furthermore, monocytes isolated from patients with OSA have been shown to have increased expression of adhesion molecules and to have increased *in vitro* binding to cultured endothelial cells. Several studies have also found decreased levels of NO breakdown products in OSA further suggesting impaired synthesis. Levels of inflammatory markers C-reactive protein (CRP) and serum amyloid A (SAA) as well as various cytokines (TNF- α , IL-6,

IL-8) are elevated in patients with OSA also suggesting a state of heightened inflammatory response.^{12,13} CRP may directly damage the endothelium, as may reactive oxygen species (ROS), which have also been shown to be increased in patients with OSA.¹⁴ ROS, which can be produced during hypoxia-reoxygenation episodes, may also stimulate leukocyte production of cytokines and upregulation of adhesion molecules on the endothelium.

Other hormonal factors may play a role in the development of hypertension in OSA. Endothelin-1, a potent vasoconstrictor, may be elevated in patients with OSA,¹⁵ and may play a role in the development of hypertension. Dysregulation of leptin, an adipocyte-derived hormone that suppresses appetite and promotes satiety, may also be involved. Leptin is elevated in obese patients, but even further elevated in patients with OSA, suggesting a state of leptin insensitivity. Administration of leptin in an animal model resulted in increases in blood pressure.¹⁶ VEGF, an angiogenesis factor important for normal blood vessel growth is also elevated in OSA, which suggests activation of a protective response to endothelial dysfunction. It remains unclear, however, whether it is the repetitive apneas, arousals, or hypoxemia that is the primary mechanism responsible for these findings.

There is also accumulating evidence linking OSA with glucose intolerance and insulin resistance. Patients with OSA have increased levels of fasting blood glucose, insulin, and glycosylated hemoglobin.^{17,18} Furthermore, the severity of OSA appears to correlate with the degree of insulin resistance. The risk of overt diabetes may be increased in patients with severe OSA. The mechanisms underlying this relationship are unclear, but likely are associated with sympathetic activation and sleep deprivation. Glucose intolerance and other metabolic disturbances in OSA may potentially play a role in the development of hypertension in these patients.

CLINICAL PRESENTATIONS

The predominant risk factor for OSA is obesity (body mass index [BMI] >25), and specifically the android pattern of obesity with fat deposition in the neck and trunk.¹⁹ Male sex, increasing age, African-American race, and family history of OSA have also been shown to be risk factors. Postmenopausal status in women is also a risk factor thought to be due to the loss of the protective effects of female hormones.²⁰ Some studies suggest that hormone replacement therapy (HRT) decreases the prevalence of OSA in postmenopausal women.²¹ Although less well defined, smoking and a history of chronic nasal congestion are also considered to be risk factors for OSA.

Patients with OSA may present with both nocturnal symptoms and daytime complaints (Box 76–1). Common nocturnal symptoms include snoring, witnessed apneic pauses, awakenings with choking/gasping or dyspnea, and snort-arousals. Restless sleep, nocturia, and diaphoresis are also common complaints. Most patients with OSA do not complain about difficulty falling asleep. However, studies have suggested that sleep-onset insomnia is not an uncommon complaint. Bruxism, or teeth grinding, has also been

- Poor concentration
- Cognitive dysfunction
- Personality changes
- Mood disturbance
- Erectile dysfunction
- Lower extremity edema

Nocturnal Symptoms

- Snoring
- Snorts, gasping, choking spells
- Restless sleep
- Frequent arousals
- Nocturia
- Diaphoresis
- Insomnia
- Bruxism
- Palpitations

shown to be a frequently cited complaint. Patients often will present to the physician primarily due to bed partner complaints or concerns regarding these symptoms.

Common daytime symptoms of OSA include excessive daytime sleepiness (EDS), tiredness and fatigue, cognitive difficulties, and changes in mood. Excessive daytime sleepiness is a common presenting symptom of patients with OSA and can be present with any severity level of OSA. EDS, however, does not correlate directly with OSA severity as measured by the apnea-hypopnea index (AHI), and patients with severe OSA may have no daytime complaints of sleepiness. Sleepiness is often mild and may present predominantly during inactive situations such as during reading, watching TV, while riding as a passenger in a car, and while sitting quietly after lunch. Patients with more severe sleepiness, however, may fall asleep during active situations such as eating, during conversations, and while driving. A commonly used clinical tool to measure the degree of self-reported sleepiness is the Epworth Sleepiness Scale. Many patients, however, complain more of tiredness, fatigue, and lack of energy as opposed to daytime sleepiness.

It is important to note that studies have shown that men and women often have very different clinical presentations. Women report less snoring and witnessed apneas and more daytime fatigue, morning headaches, and complaints of mood disturbance.²² One study found that women were twice as likely as men to be treated for depression before their OSA diagnosis was established.

On physical examination, increased neck size, retroposition of the mandible or maxilla, large soft palate, and lateral narrowing of the pharyngeal walls have all been shown to be good predictors of OSA.²³ Increased neck circumference (>40 cm) in particular has been shown to be

a better predictor of OSA than BMI.²⁴ Reduced mandibular body length can be manifested by retrognathia (small chin) or overjet (upper teeth resting anteriorly to lower teeth). The relationship between OSA and retroposition of the maxilla is most striking in young patients with craniofacial abnormalities such as Down's syndrome. Obesity itself is associated with increased fat deposition in the tongue, soft palate, uvula, and parapharyngeal fat pads, all of which can compromise upper airway space. Lateral narrowing of the pharyngeal walls may be an important anatomic predictor of OSA.

DIAGNOSTIC TECHNIQUES

Obstructive sleep apnea is diagnosed using overnight polysomnography. Polysomnography (PSG) consists of continuous measurement of nasal pressure, oxygen saturation, electroencephalogram, electro-oculogram, chin and lower extremity electromyography, electrocardiogram, and chest and abdomen plethysmography (Figure 76–5). PSG is performed in the setting of a sleep laboratory and the patient is monitored continuously via video by certified sleep technicians. Important indices determined during PSG include the overall AHI, AHI according to sleep stage and position, and the arousal index (AI). An apnea is defined as the absence of airflow for 10 seconds in the setting of continued respiratory effort (Figure 76–6). A hypopnea is considered to be a decrease in airflow greater than 50% for 10 seconds associated with a 4% drop in saturation and arousal (Figure 76–7). Although there is no universally accepted definition of a respiratory effort–related arousal (RERA) or “snort arousals,” they are generally accepted to consist of a transient decrease in air flow followed by an

arousal and normalization of airflow. Crescendo snoring prior to the arousal and mild desaturation of less than 4% after is commonly observed. Simply put, RERAs describe events that do not meet definitions for apneas or hypopneas.

Obstructive sleep apnea has been defined as an AHI of more than five per hour. OSA can be purely positional with obstructive events only occurring during supine sleep. OSA occurring only during REM sleep is also not uncommonly observed. The obstructive sleep apnea syndrome (OSAS) is OSA associated with symptoms of excessive daytime sleepiness, mood disturbance, or impaired cognition. Upper airway resistance syndrome (UARS) was described in 1998 and has been considered to represent a mild form of OSA, where RERAs result in sleep disruption and symptoms of excessive daytime sleepiness.²⁵ The recently published International Classification of Sleep Disorders-2 (ICSD2), however, defines OSA as more than five respiratory events (apneas, hypopneas, or RERAs) per hour with symptoms, or more than 15 without symptoms. The new ICSD incorporates UARS as part of OSA, given the essentially identical underlying pathophysiology. Generally accepted is the concept that OSA lies on a spectrum that includes severe OSA with cor pulmonale on one end of the spectrum and simple snoring on the other.

MANAGEMENT

Several treatment options exist for OSA, including positional therapy, weight loss, continuous positive airway pressure (CPAP), oral appliances, and surgery. A subset of patients has position-dependent OSA. Positional therapy utilizing tennis balls sewn into the back of a nightshirt is often effective in the treatment of these patients. Weight

loss should be recommended in most OSA patients. Loss of 10% of body weight results in an approximately 20% reduction in AHI.²⁶

The primary treatment for obstructive sleep apnea is positive airway pressure in the form of nasal CPAP. CPAP

effectively provides a constant pressure to the pharyngeal airway, and thereby acts as pneumatic splint preventing airway collapse²⁷ (Figure 76-8). The optimal pressure of CPAP is largely a function of sleep stage and position, with the highest pressures usually being required during supine

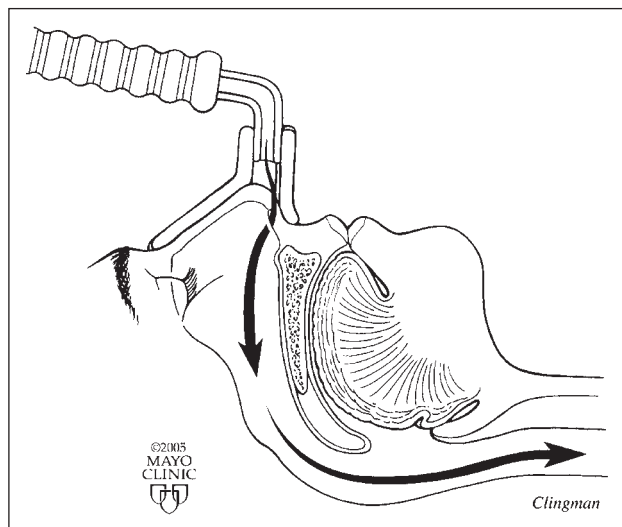

Figure 76-8. CPAP provides positive pressure to the pharyngeal airway thereby preventing collapse.

REM sleep. Pressures between 5 and 15 cm H₂O are commonly used. The optimal CPAP for any given patient is determined during polysomnography. A split-night protocol using both a diagnostic study and CPAP titration over the course of one night is increasingly being used. Although autotitrating CPAP (auto-CPAP) devices are available, they are not currently recommended for use in determining optimal CPAP pressure in the unattended home setting.

Numerous studies have demonstrated the beneficial effects of CPAP on the daytime and nocturnal symptoms of OSA. However, compliance with CPAP can be a problem in some patients. Depending on the type of surveillance used (e.g., surreptitious) and definition of compliance, overall CPAP compliance is reported to be between 50% and 80%. Rhinorrhea, nasal congestion, headache, and claustrophobic symptoms are common complaints. The degree of sleepiness prior to treatment appears to predict favorable compliance. Interestingly, higher CPAP pressure levels are not associated with decreased compliance. A heated humidifier as part of the CPAP unit and close follow-up 1 month post-CPAP initiation may increase compliance. Compliance is certainly an important issue given that only 46% of patients in one study were reported to use CPAP at least 4 hours for 70% of nights. It is generally accepted that at least 4 hours of usage is required for adequate treatment of daytime symptoms. Despite hope that auto-CPAP or bi-level PAP (bi-PAP) might be better tolerated due to lower mean pressure, studies suggest these may not lead to increased compliance. Other treatments for OSA include oral appliances and surgery. Oral appliances reposition the mandible in a forward position during sleep thereby, increasing upper airway space, and have been shown to be effective in patients with mild to moderate OSA. This therapy is contraindicated in patients with temporal mandibular joint problems or edentulous patients. Current surgical options include uvulopalatopharyngoplasty (UPPP) and maxillomandibular advancement (MMA). Gastric bypass procedures can also result in indirect treatment of

OSA through their effects on weight loss. The most commonly performed surgical procedure for OSA, UPPP, is unfortunately effective in only about 50% of cases, with effectiveness being measured as at least a 50% decrease in AHI.²⁸ Many patients will require further treatment of OSA, including CPAP. Patients with milder OSA and those with more pronounced retropalatal obstruction (as opposed to retroglossal) may have more benefit. MMA usually consists of forward advancement of the mandible and maxilla utilizing titanium plates. MMA can be very effective for OSA, with studies documenting approximately a 90% to 95% success rate. Patients with retrognathia may derive particular benefit. Tracheostomy, which allows complete bypass of the collapsible upper airway, was the routine treatment for OSA before the era of CPAP. Although highly effective, it is currently uncommonly used except in severe cases unresponsive to other therapy modalities.

PROGNOSIS

Several studies have demonstrated beneficial effects of CPAP on blood pressure. There has been general agreement on the beneficial effects of CPAP on nocturnal blood pressure. Early studies demonstrated that CPAP restores the normal nocturnal dip in blood pressure (BP) in patients with OSA.⁷ The effects on daytime blood pressure, however, have been more controversial, perhaps because early studies were small and observational. Recently, however, several randomized controlled studies have been reported using subtherapeutic or “sham” CPAP.^{5,29} Becker et al.⁶ reported the largest decrease in blood pressure with CPAP. In a study using noninvasive continuous BP monitoring, OSA patients treated with therapeutic CPAP for 9 weeks had a 10-mmHg decline in daytime systolic and diastolic BP. Patients in this study had at least moderate to severe OSA with a mean AHI of 63, which fell to 3 with CPAP. Interestingly, the subtherapeutic CPAP group did not have a significant change in daytime BP despite having a noticeable reduction in AHI from 65 to 33. Another study by Peperell et al.⁵ also showed reduction in daytime BP, albeit a smaller one, in OSA patients treated with CPAP versus sham CPAP. There was an overall reduction in mean BP of 3.4 mmHg. Although they used the oxygen desaturation index (ODI) as opposed to AHI, there appeared to be a greater reduction in daytime mean BP in patients with severe OSA (ODI >33) and patients on antihypertensive medications. CPAP may also have beneficial effects on complications of systemic hypertension including congestive heart failure, atrial fibrillation, and ischemic heart disease.³⁰⁻³²

The mechanisms by which CPAP decreases nocturnal and daytime blood pressure are likely multiple. By eliminating obstructive breathing (apneas, hypopneas, RERAs), repetitive arousals, and the resulting large swings in intrathoracic pressure, CPAP has obvious beneficial acute physiologic effects on the heart. Disordered sympathetic activity and endothelial function appear to be normalized.³³ CPAP has also been shown to result in decreased inflammatory markers, cytokines, and endothelin-1, as well as improving glucose metabolism in patients with OSA.³⁴

SUMMARY

Obstructive sleep apnea is a common condition. It is characterized by recurrent partial or total collapse of the upper airway, resulting in intermittent hypoxia and hypercapnia, sleep fragmentation, and daytime sequelae. There is compelling evidence that OSA may be an important risk factor for the development of cardiovascular disease, especially systemic hypertension. Even mild OSA appears to place individuals at a higher risk of developing systemic hypertension. Although the exact mechanisms for this

association are incompletely understood, increased sympathetic activity, endothelial dysfunction, inflammation, and disordered metabolism may play important roles. Effective treatments for OSA include positional therapy and weight loss, CPAP, oral appliances, and surgery. Recent studies suggest that CPAP therapy for OSA results in a decrease in both nighttime and daytime blood pressure. Patients already using antihypertensive medications may derive particular benefit, suggesting that OSA may be a cause of resistant hypertension.

Diuretics

John F. Setaro and Marvin Moser

Key Findings

- Most hypertension patients will require a diuretic in some form to achieve adequate blood pressure (BP) regulation and a reduction in cardiovascular (CV) events.
- Low-dose diuretics may be given in combination with beta blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, calcium channel blockers, or other drugs with excellent BP-reducing effects.
- Black and elderly patients, who are characteristically more sensitive to sodium, exhibit a greater response to diuretics than younger or white individuals.
- Despite questions concerning the metabolic effects of thiazide diuretics, newer trials and guidelines have reaffirmed their safety and effectiveness in initial management of high BP and as an element of combination therapy in more complex cases.
- Diuretic-associated hypokalemia is dose related and can be minimized by using combination agents such as spironolactone/thiazide or an angiotensin-converting enzyme inhibitor or angiotensin-2 receptor-blocker with thiazide.
- Contemporary strict BP treatment goals will require that diuretics continue to play a major role in hypertension therapy.

INTRODUCTION

Diuretics, in particular thiazide compounds, were the earliest forms of practical and well-tolerated antihypertensive drugs introduced in the modern therapeutic era. Numerous large randomized clinical trials have demonstrated the value of these agents in reducing morbidity and mortality in the hypertensive patient. Despite questions raised concerning the metabolic effects of thiazide diuretics, newer trials and guidelines have reaffirmed their primacy in the safe and effective initial management of high BP and as an element of combination therapy in more complex or difficult cases. Contemporary strict BP treatment goals will require that diuretics continue to play a major role in hypertension therapy.

HISTORICAL BACKGROUND

Thiazide diuretics were introduced initially in 1957 and were quickly accepted as therapy for hypertension because they were effective, inexpensive, and well tolerated and

because they could be used once daily in contrast to existing agents.¹ Large randomized clinical trials in hypertensive patients subsequently proved their effectiveness in reducing morbidity and mortality. This chapter surveys the physiology and pharmacology of diuretics, examines early trial evidence, assesses the metabolic implications of diuretic use, and discusses recent trials and management guidelines that confirm the key role of diuretics in hypertensive patients.

PHYSIOLOGY AND PHARMACOLOGY OF DIURETIC COMPOUNDS

There are four classes of diuretics. *Thiazide-type diuretics* (including hydrochlorothiazide, chlorthalidone, bendroflumethiazide, methyclothiazide, and metolazone) inhibit the reabsorption of sodium in the early distal renal tubule (Figure 77–1).² These are most effective in patients who have normal serum creatinine values (< 1.5 mg/dl), although metolazone may also be effective despite some renal impairment. *Indoline derivatives* (including indapamide) may also interfere with calcium influx into vascular smooth muscle cells.³ *Loop diuretics* (furosemide, bumetanide, torsemide, and ethacrynic acid) are compounds that act more rapidly in the proximal region, inhibiting sodium reabsorption in the loop of Henle. These are ideally suited for patients with evidence of renal impairment.

Potassium-sparing diuretics (amiloride, triamterene, spironolactone, and eplerenone) are active in the distal tubule and inhibit the exchange of sodium for potassium. Amiloride and triamterene inhibit potassium secretion directly and thus can help maintain potassium homeostasis. Both of these agents are weak diuretics, however, and are most effective in combination with hydrochlorothiazide. Spironolactone and eplerenone inhibit aldosterone by competitive or direct blockade of the aldosterone receptor, respectively. Both are potassium-sparing as well as antihypertensive agents. Eplerenone may be particularly useful in male patients because as a direct inhibitor it is free of anti-androgenic effects (mastodynia, gynecomastia, sexual dysfunction) in contrast to spironolactone.

Initially, when diuretics are given plasma volume decreases—lowering cardiac output and arterial BP. Later, volume rises toward normal and cardiac output normalizes. However, BP remains low, with reduced peripheral vascular resistance.⁴ This effect is attributable to direct arterial relaxation via alterations in ion flux across vascular smooth muscle cells, which likely occurs as an autoregulatory

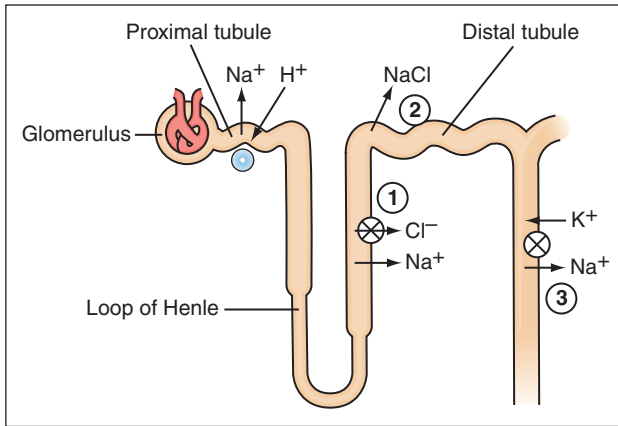

Figure 77-1. Diuretics: sites of action. (1) Loop agents, (2) thiazide diuretics, and (3) potassium-sparing diuretics. (Redrawn from Moser M. *Clinical Management of Hypertension, Seventh Edition*. Caddo, OK: Professional Communications 2004, with permission.)

response to reduced BP (Figure 77-2).⁵ High dosages were used in the past, such as 50 to 200 mg of hydrochlorothiazide, although it is now recognized that 12.5 to 25 mg are effective doses in most patients. The Systolic Hypertension in the Elderly Program (SHEP) employed low-dose chlorthalidone (12.5 mg) to attain goal BP values in nearly half of the subjects.⁶

Low-dose hydrochlorothiazide (12.5 mg) reduces BP in up to two-thirds of diuretic-responsive patients, with an additional 15% responding to 25 mg. Up to 90% may respond to 50 mg daily, but above this dosage side effects may become troublesome. Diuretics lower BP by 10-15/5-10 mmHg compared to a placebo effect, with a greater effect on systolic BP. This is of importance in the treatment of older patients who have isolated systolic hypertension.⁶ Black and elderly patients, who are characteristically more sensitive to sodium, exhibit a greater response to diuretics than younger or white individuals.⁷

Low-dose diuretics may be given in combination with beta blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, calcium channel blockers, or other drugs with excellent BP-reducing effects (Figure 77-2). Such combinations may permit a return to normotensive BP levels in 80% of patients.⁸ The reduction in plasma volume with a diuretic stimulates the renin-angiotensin-aldosterone system. Consequently, additional BP lowering occurs when agents such as beta blockers, angiotensin-converting enzyme inhibitors, or angiotensin receptor blockers that inhibit the system are added to a diuretic.

EARLY EVIDENCE FROM RANDOMIZED CLINICAL TRIALS

Diuretics and beta blockers were used in the majority of randomized trials conducted before 1995, with the optional addition of vasodilators or centrally acting agents when initial therapies were insufficient to achieve BP targets. A pooled analysis of 17 placebo-controlled trials

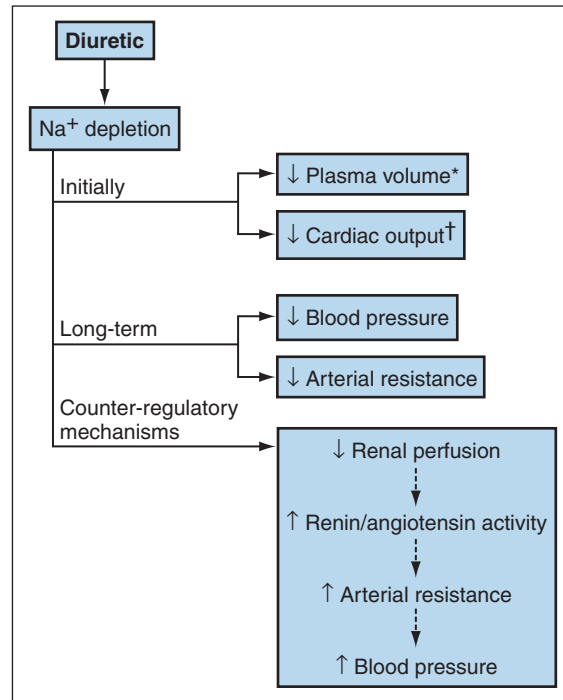

Figure 77-2. Physiology of diuretic action. Plasma volume and cardiac output decrease (a,b), returning to normal after several weeks, with long-term reduction in vascular resistance and blood pressure. Although consequent stimulation of the renin-angiotensin system does not lead to a rise in blood pressure, this counter-regulatory mechanism can be addressed to attain further improvements in blood pressure control by adding an angiotensin-converting enzyme inhibitor, angiotensin receptor blocker, or beta blocker. (Redrawn from Moser M. *Clinical Management of Hypertension, Seventh Edition*. Caddo, OK: Professional Communications 2004, with permission.)

revealed that subjects treated with these medications experienced a 52% lower incidence of congestive heart failure, 38% reduction in stroke morbidity and mortality, 35% less left ventricular hypertrophy, 21% less vascular mortality, and a 16% lower incidence of coronary events.⁹ Active therapy also prevented progression to more severe stages of hypertension.⁹ Another meta-analysis of 18 trials of antihypertensive therapy confirmed stroke reduction with active therapy, with a lesser beneficial effect on coronary heart disease events.¹⁰

Studies that used diuretics as part of a treatment regimen included the Veterans Administration Study, which reported significant stroke reduction in subjects who had severe and moderately severe hypertension—with a beneficial trend in regard to coronary outcomes.¹¹ The Hypertension Detection and Follow-up Program (HDFP), where diuretics were administered as first-step therapy in subjects with less severe hypertension, demonstrated a 45% reduction in stroke mortality and a 20% reduction in coronary event mortality in the more intensively treated subjects.¹²

The SHEP, using diuretics (and beta blockers, if necessary), reported a 54% reduction in heart failure, 30% reduction in myocardial infarctions, 37% reduction in

stroke, and 25% fewer transient ischemic neurologic attacks.⁶ Based on these findings, as well as on data from more recent trials, all of the Joint National Committee (JNC) Reports on the Detection, Evaluation, and Treatment of High Blood Pressure (from the first in 1977 and including the 2003 JNC 7 Report) have recommended diuretics as one of the preferred agents for the initiation of antihypertensive therapy in most patients.^{13,14}

METABOLIC ISSUES IN DIURETIC USE

Diuretic compounds are generally well tolerated, and two large prospective controlled series reported only a 3% withdrawal rate for adverse effects in subjects randomized to diuretic therapy.^{15,16} However, questions have been raised by the observation that BP-lowering therapy in large clinical trials has significantly reduced pressure-related complications (stroke, congestive heart failure, renal impairment, and left ventricular hypertrophy). Although there were improvements in coronary heart disease outcomes (angina, fatal and nonfatal myocardial infarction),^{6,12} these were somewhat less than predicted by epidemiologic data. Some investigators believe that metabolic changes from diuretics may account for this shortfall. Several explanations have been advanced to account for this phenomenon.

First, atherosclerotic coronary heart disease is a long-term multifactorial process whose outcome may not be affected by short-term manipulation of a single risk factor such as high BP. It is possible that the short duration of the diuretic-based treatment trials compared to the longer duration of epidemiologic follow-up explains an apparent shortfall in coronary heart disease benefit. For instance, a 12/4–5 mmHg reduction in BP predicts a decrease of approximately 20 to 25% in coronary heart disease events over 10+ years.

In the three- to five-year clinical trials, a decrease in BP of this magnitude led to only 16% fewer coronary events. Newer studies, however, indicate that longer-term BP reduction improves coronary event rates to a greater degree than that seen in shorter-term trials. In the ALLHAT (Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial) study, for example—which compared a diuretic, angiotensin-converting enzyme inhibitor, and calcium channel blocker—thiazide diuretics reduced coronary events to the same extent as competing agents.¹⁷

The metabolic side effects of thiazide diuretics (electrolyte, lipid, and glucose changes) were originally advanced as reasons for the less than dramatic reduction of CHD events in the early studies. The claim was that these may negate some of the advantages of BP lowering. These questions have been addressed elsewhere.^{9,18} Specific components of the “metabolic debate” are reviewed in material following. In general, the results of recent trials such as ALLHAT have negated these speculations.

Electrolytes

Diuretic-associated hypokalemia is dose related. Up to one-third of patients show a decrease in serum potassium, ranging from 0.5 to 0.8 mEq/L when given high doses of

hydrochlorothiazide (50 to 100 mg daily). The use of an intermediate dose of 25 mg hydrochlorothiazide results in a decrease in potassium of 0.3 to 0.4 mEq/L, with minimal effects seen at 12.5 or 6.25 mg daily. Potassium-sparing diuretics may be advisable in patients who are especially sensitive to hypokalemia—particularly in older individuals, those taking digitalis preparations, or diabetic patients whose insulin utilization may be affected by hypokalemia.

Hypokalemia can also be minimized by using combination agents such as spironolactone/thiazide or an angiotensin-converting enzyme inhibitor or angiotensin-2 receptor blocker with thiazide. The potassium-conserving tendencies of the former medications serve to offset potassium loss caused by the latter. However, diuretic-induced hypokalemia with presently recommended doses is not infrequently of clinical significance.

One report argued that thiazide-related hypokalemia could provoke increased ventricular ectopy, including ventricular tachycardia and sudden death.¹⁹ In the Multiple Risk Factor Intervention Trial (MRFIT), subjects with abnormal electrocardiograms in the special care higher-dose diuretic group had a higher coronary heart disease mortality compared to usual care patients who received lower doses of diuretics. This finding, however, was likely a statistical anomaly.^{20,21} Retrospective non-randomized case-control studies questioned the increased incidence of sudden death in diuretic-treated patients, yet comparative groups were not adequately matched in these series.^{22,23}

Anecdotal reports of hypokalemia in cardiac arrest victims who had received thiazide diuretics aroused some concern. However, 24- and 48-hour Holter monitoring studies with prospective controlled trials of high-dose thiazide-treated subjects showed no significant increase in simple or complex ventricular ectopy—whether in the presence or absence of left ventricular hypertrophy despite the presence of some hypokalemia.^{6,16,24} The use of diuretics results in regression of left ventricular hypertrophy, itself an independent risk factor for ventricular rhythm disturbances.²⁵ Finally (and perhaps most importantly), recent large studies employing diuretics compared to placebo, angiotensin-converting enzyme inhibitors, or calcium channel blockers failed to report any increase in sudden cardiac death in groups receiving diuretics.^{6,18,26} Thus, hypokalemia is less of an issue with low doses of diuretics—especially when these agents are used with other medications in attempts to lower BP to attain present BP goals.^{27–30}

Lipid changes

Over the course of the first year of treatment, thiazide diuretics may increase total and low-density lipoprotein cholesterol by 5 to 7%, without changes in high-density lipoprotein cholesterol concentration. Two small studies suggested that thiazide agents increase serum lipid concentrations significantly,^{30–32} whereas large long-term clinical trials using diuretics show no change or even a decline in total cholesterol in diuretic-assigned cohorts.³³ Trials that demonstrated no lipid effects include the Medical Research Council Study (MRC), the Medical Research

Council Study in the Elderly (MRC-Elderly), the Metoprolol Atherosclerosis Prevention in Hypertension Study (MAPHY), and the Heart Attack Primary Prevention in Hypertension Study (HAPPHY).^{34–37}

Other series report improved lipid levels the diuretic treatment study arms. For example, a decrease in total cholesterol was noted in subjects in the HDFP of 232 to 223 mg/dl in the active diuretic treatment (special care) group,³⁸ and similar results have been noted in other diuretic-assigned subjects in multiple large prospective studies. These investigations include the Multiple Risk factor Intervention Trial (MRFIT), the European Working Party on High Blood Pressure in the Elderly Study (EWPHE), the Treatment of Mild Hypertension Study (TOMHS), the Verapamil in Hypertension Atherosclerosis Study (VHAS), and ALLHAT.

The data in ALLHAT are confounded by the significant number of subjects who were taking statin agents at the trial's conclusion.^{16,18,20,39,40} Despite slightly higher mean cholesterol levels in the diuretic compared to the lisinopril or amlodipine arms at the conclusion of ALLHAT, coronary heart disease rates were similar among study groups.¹⁸ In SHEP and HDFP, CV morbidity and mortality were decreased with the use of diuretics, regardless of baseline lipid values.^{6,38} Based on these findings, it would appear that thiazide diuretics can be used safely irrespective of the lipid status of an individual.

Glucose and insulin metabolism

Although thiazide diuretics may adversely affect insulin sensitivity and glucose utilization, unfavorable clinical outcomes with these medications have not been reported in large prospective trials. Significant vascular risks arise from insulin resistance and abnormal glucose tolerance in an increasingly obese and diabetic population. Yet in large studies employing thiazide diuretics only minimal changes in fasting glucose are observed, and newly

incident diabetes (NOD) is increased by only 0.6% more than placebo.^{6,34,36,38,39,41}

Given that typical older hypertensive patients may have been minimally insulin resistant upon study entry, a higher rate of diuretic-induced progression to overt diabetes would be expected if indeed diuretics caused diabetes. Although hypertensive individuals show a greater tendency toward development of diabetes than normotensive patients, people who have received diuretics have not required antidiabetic medication any more frequently than those given other antihypertensive compounds.⁴²

Comparative data in new onset of diabetes

The ALLHAT investigators noted a small increase in serum glucose and an absolute increase of 3.5% in new-onset diabetes in the thiazide- compared to lisinopril-treated patients (11.6 versus 8.1%), yet there was a similar frequency of CV events in the diuretic therapy group in this five-year study.¹⁸ Diabetic subjects in ALLHAT who received diuretics had coronary heart disease outcomes equal to diabetic subjects who received lisinopril or amlodipine, and experienced fewer strokes or episodes of heart failure compared with lisinopril.

Heart failure was less frequent in diabetic or non-diabetic thiazide-treated patients compared with the amlodipine cohort.¹⁸ In the Controlled Onset Verapamil Investigation of Cardiovascular End Points (CONVINCE) trial, diabetic individuals had equal CV outcomes whether they were assigned to verapamil, diuretic, or beta blocker.⁴³ Potential metabolic changes associated with diuretic use are summarized in Table 77–1. Of some interest is the theory that hypokalemia itself may mediate the development of diabetes, given the tendency of drugs that raise potassium levels to have the lowest rates of new-onset diabetes (angiotensin-converting enzyme inhibitors and angiotensin receptor blockers).⁴⁴

THIAZIDE DIURETICS: POTENTIAL METABOLIC ALTERATIONS	
Metabolic Change	Comments
Hypokalemia	Can be minimized by using lower dosages. Avoid if possible, especially in diabetics and patients taking digitalis. Replace as appropriate.
Hyperlipidemia	Short term: total cholesterol and low-density lipoproteins increased 5 to 7% (effect may be less with lower dosages). No effect on high-density lipoproteins. Long term: few measurable effects. Same degree of reduction in cardiovascular events in subjects with hyperlipidemia or normal cholesterol levels.
Increased insulin	Insulin resistance increased, but only small average rise in blood glucose levels in long-term resistance trials in diuretic-treated versus placebo subjects. Some difference in new-onset diabetes when compared with other medications. Overall cardiovascular mortality reduced to same or greater extent in diabetics versus non-diabetics.
Hyperuricemia	Gout in fewer than 3% of patients. If diuretic is essential, allopurinol can be used.
Hypercalcemia	May be advantageous in treatment of osteoporosis and prevention of fractures.

Table 77–1 Thiazide Diuretics: Potential Metabolic Alterations

Another perspective on this question arises from the observation that in most studies diabetic patients receiving diuretics experienced fewer adverse CV outcomes than non-diabetics on diuretics, reflecting the safety and usefulness of diuretics in diabetic hypertensive persons.⁴⁵ The SHEP trial results illustrate this point (Figure 77-3).⁶ The importance of BP reduction using effective and well-tolerated agents was again confirmed in the United Kingdom Prospective Diabetes Study Group (UKPDS) trial, in which tighter versus less strict BP control (a difference of $-10/-5$ mmHg) led to better outcomes with respect to both macrovascular and microvascular events. There was no difference in outcomes between angiotensin-converting enzyme inhibitor versus diuretic/beta-blocker combination groups.⁴⁶

In diabetic patients, angiotensin receptor blockers can delay or reverse the progression of nephropathy and prevent the occurrence of end-stage renal disease. They are thus indicated for this patient group.⁴⁷⁻⁴⁹ To attain the new BP goal of 130/80 mmHg in diabetic patients (JNC 7 2003), thiazide diuretics may have to be added to a multi-drug program—particularly because diabetic patients tend to be sodium sensitive with consequent volume expansion.^{14,50} Overall, most large hypertension trials conducted in the last several decades have employed thiazide diuretics as a component of a multi-drug regimen.

The prospect of preventing diabetes in at-risk patients has stimulated interest with the publication of at least three trials that report the prevention of new-onset type 2 diabetes by using inhibitors of the renin-angiotensin-aldosterone system. Agents studied include captopril in the Captopril Prevention Project (CAPP), ramipril in the Heart Outcomes Prevention Evaluation study (HOPE), and losartan in the Losartan Intervention for Endpoint

reduction in hypertension study (LIFE).⁵¹⁻⁵³ In a significant number of subjects in these and most of the trials, diuretic therapy was necessary to reach BP goals.

Although the mechanism by which diabetes is possibly prevented by inhibitors of the renin-angiotensin system is unclear, it has been proposed that these agents defend potassium balance.⁴⁴ For example, in the Valsartan Anti-hypertensive Long-term Use Evaluation (VALUE) trial the incidence of new-onset diabetes was 3.3% less in the group treated with the angiotensin receptor blocker valsartan compared with the calcium channel blocker amlodipine.⁵⁴ An equal number of subjects in both arms received thiazide diuretics as well, with hypokalemia more common in the amlodipine group.

The fewer cases of NOD in the Valsartan group are presumably based on this drug's tendency to elevate potassium, which has been theorized to play a role in diabetes prevention.^{44,54} It is therefore reasonable to initiate therapy using a combination of a diuretic and an angiotensin-converting enzyme inhibitor or diuretic and angiotensin receptor blocker in hypertensive patients who are obese, have a family history of diabetes, or have personal criteria for the diagnosis of metabolic syndrome. This is especially true in patients with stage 2 hypertension.

RECENT STUDIES AND PRESENT RECOMMENDATIONS

Recent studies have underscored the role of diuretics as initial therapy for patients who have high BP.¹⁴ For other patients (including those with resistant hypertension, diabetes, or renal impairment), diuretics should form the essential core of a multi-drug regimen.^{14,27,50,55}

Figure 77-3. Effect of treatment in reducing morbidity and mortality in the Systolic Hypertension in the Elderly Program (SHEP) study using low-dose thiazide diuretic (with beta blocker added as needed) versus placebo. CABG, coronary artery bypass surgery; MI, myocardial infarction; SCD, sudden cardiac death. Open bars: diabetic cohort receiving active treatment ($n = 283$) versus placebo ($n = 300$). Filled bars: non-diabetic cohort receiving active treatment ($n = 2080$) versus placebo ($n = 2069$). (Redrawn from Moser M. *Clinical Management of Hypertension, Seventh Edition*. Caddo, OK: Professional Communications 2004, with permission.)

Role of aldosterone inhibitors

Recently, published data have led to a renewed appreciation for the role of aldosterone-inhibiting diuretics in hypertension management—especially when hypertension is drug resistant.⁵⁶ In resistant hypertension patients, it has been reported that there is a relatively high prevalence of primary aldosteronism⁵⁷ and that there may be an overlap between essential hypertension and subtle forms of hyperaldosteronism. This typically occurs in the form of bilateral adrenal hyperplasia rather than discrete adenoma. If essential hypertension and mild aldosteronism were part of a continuum, it would explain the excellent response to spironolactone across a broad spectrum of hypertension patients.

Obesity may be a factor that amplifies the hypertensive and vascular risks of aldosterone.⁵⁸ A published analysis from the Framingham Heart Study shows that initially normotensive individuals who have higher baseline serum aldosterone concentrations are more likely to develop hypertension later in contrast to those with lower baseline concentrations.⁵⁹ In one study, when the mineralocorticoid receptor inhibitor spironolactone was added to the multi-drug programs of resistant hypertension patients (which included other diuretics and inhibitors of the renin-angiotensin system) mean BP over six months decreased 25/12 mmHg.⁶⁰ This suggests that mineralocorticoid receptor-inhibiting diuretics can play an important role in managing difficult-to-treat hypertensive patients, and raises the prospect that dual diuretic programs may be safe and effective.

Hypertension trials employing diuretics

In several recent controlled prospective trials, the principal role of diuretics has been validated. In diabetic hypertensive patients, a combined regimen of beta blockers and diuretics with tight BP control produced favorable CV outcomes over a nine-year study (UKPDS).⁴⁶ In the CONVINCE trial, a calcium channel blocker verapamil was not proved superior to either a beta blocker or a thiazide diuretic in preventing unfavorable CV events.⁴³ In the PROGRESS (Perindopril Protection Against Recurrent Stroke Study) investigation, the angiotensin-converting enzyme inhibitor perindopril required the addition of the diuretic indapamide before significant benefit could be observed in regard to reduction of stroke and transient ischemic neurologic attacks in hypertensive patients who had previously suffered a CVA.⁶¹

In the INCLUSIVE (Irbesartan/HCTZ Blood Pressure Reductions in Diverse Patient Populations) study, 77% of patients achieved a systolic BP goal and 83% achieved a diastolic BP goal when given a combination of hydrochlorothiazide and an angiotensin receptor blocker.⁸ The MIDAS (Multicentre Isradipine Diuretic Atherosclerosis Study) evaluated a short-acting dihydropyridine calcium channel blocker and a diuretic and reported fewer CV events in the diuretic group.⁶² In the VHAS, long-acting verapamil possessed no advantage in preventing CV events over diuretic therapy.⁴⁰

The INSIGHT (International Nifedipine GITS Study: Intervention as a Goal in Hypertension Treatment) inves-

tigation assessed long-acting nifedipine compared to a diuretic in combination with a potassium-sparing component, showing no difference between the two groups in overall CV outcomes.⁶³ The NORDIL trial comparing diltiazem to a beta-blocker/diuretic reported no overall event difference.²⁶ The Swedish Trial in Old Patients with Hypertension-2 (STOP-2) reported no difference in outcomes among older hypertension patients treated with diuretics, calcium channel blockers, or angiotensin-converting enzyme inhibitors.⁶⁴ In each instance, diuretic compounds were equivalent to or better than newer, more expensive agents.

ALLHAT

ALLHAT analyzed 33,000 high-risk hypertensive patients over a five-year period.¹⁸ The trial sought to determine outcome differences among patients randomized to a diuretic (low-dose chlorthalidone), a calcium channel blocker (amlodipine), or an angiotensin-converting enzyme inhibitor (lisinopril). An earlier alpha-adrenergic blocker arm of the study (doxazosin) was terminated when investigators reported a significant excess in congestive heart failure events in the doxazosin group compared to the diuretic group.

To reach goal BP in ALLHAT, beta blockers, reserpine, clonidine, and hydralazine were permitted as second- or third-step agents. Study participants represented a high-risk group for adverse hypertensive CV outcomes: average age was 67 years, 35% were black, and 36% were diabetic.¹⁸ Results showed fewest overall CV events in the diuretic-assigned patients, but there was no difference among the groups in the primary outcome of fatal or non-fatal coronary events. Compared with lisinopril-treated patients, patients on diuretics had fewer strokes and heart failure events (particularly in blacks). Compared with amlodipine-treated patients, the diuretic group had fewer severe heart failure events causing death or hospitalization.

Some differences among treatment groups may reflect overall BP differences. Systolic BP was 0.8 mmHg higher in the amlodipine compared to chlorthalidone groups, a significant difference in a trial with very large numbers of participants. The ALLHAT authors reported a 4-mmHg lower average systolic BP in blacks and a 3-mmHg lower average in subjects older than 65 years of age treated with chlorthalidone compared to the angiotensin-converting enzyme inhibitor. Previous clinical and investigative experience affirms that elderly and black individuals respond better to diuretic agents. If other compounds are used, they probably should be used with diuretics to lower BP more effectively. Such a combination, however, was not permitted by the ALLHAT protocol—perhaps accounting for the lesser effectiveness of therapy in the non-diuretic-treated patients.⁶⁵

In a similar fashion, the inability to use diuretics as initial therapy may have biased the results of the ASCOT (Anglo-Scandinavian Cardiac Outcomes Trial—Blood Pressure Lowering Arm) trial.⁶⁶ In this study, subjects received a calcium channel blocker (amlodipine) or a beta blocker (atenolol) as initial therapy. As a second drug, an

angiotensin-converting enzyme inhibitor (perindopril) could be added to amlodipine, and a thiazide diuretic (bendroflumethiazide) could be added to atenolol.

Overall CV outcomes were more favorable in the amlodipine/perindopril group compared to the atenolol/bendroflumethiazide group, a finding perhaps linked to the 2.7/1.9-mmHg BP difference favoring amlodipine/perindopril at the study conclusion.⁶⁶ The primary outcome of CHD events, however, was similar in the two groups. This study was conducted in predominantly older Caucasian males. The findings therefore may not apply to a non-European, younger, or female population. Moreover, it is interesting to speculate whether results may have been different if diuretics had been given first (with beta blockers added later) in light of the overall excellent record of using diuretics in this age group.

Recommendations

As previously mentioned, the equivalent primary outcome results and the more favorable secondary CV endpoint results for the diuretic-treated group in ALLHAT contradict arguments that the possible metabolic changes as a result of diuretics detract from their protective potential.⁶⁷ More than half of the ALLHAT study participants were not fully controlled on monotherapy, multi-drug treatment being required. Based on ALLHAT and many other trials, JNC 7 continued to advocate diuretics as first-step therapy in most cases—acknowledging that many (if not a majority of) patients will need a multi-drug program.¹⁴

Compelling reasons for starting with other agents (such as angiotensin-converting enzyme inhibitors or angiotensin receptor blockers) include heart failure, diabetes, diabetic nephropathy, or a desire to prevent diabetes in individuals at risk. Additional studies have confirmed the protective role of inhibitors of the renin-angiotensin system. In the Australian National Blood Pressure-2 trial, there was a marginally significant benefit in CV event reduction favoring a program based on an angiotensin-converting enzyme compared to a diuretic-based program⁶⁸ (but only in men). Less than two-thirds of subjects continued the study drug throughout the protocol, and the demographics of the study were different from those of ALLHAT (more Caucasians, few blacks)—factors that may limit the application of these findings to other populations.

SUMMARY AND PERSPECTIVES

Most hypertension patients will require a diuretic in some form to achieve adequate BP regulation and a reduction in CV events. These agents have been widely used for nearly five decades, with an unequalled record of safety and effectiveness across diverse populations. Current recommendations favor initiating therapy with diuretics. Perhaps more important than the question of how one begins therapy is the question of how one ends it. For most hypertension patients, this will consist of a multi-drug program including diuretics to attain BP targets that duplicate benefits observed in clinical trials.

Beta Blockers in Hypertension

Gurusher S. Panjra and Franz H. Messerli

Key Findings

- Beta blockers (β -blockers) are used widely as antihypertensive agents.
- Evidence regarding primary prevention of cardiovascular morbidity and mortality is lacking.
- Multiple randomized controlled trials (RCTs) have shown β -blockers to be blood-pressure-lowering drugs.
- β -blockers should *only* be used in combination with other drug classes for controlling hypertension.
- Selection of β -blocker should be done based on patient profile and other co-morbid conditions.
- β -blockers are indicated in patients with chronic heart failure (CHF), arrhythmias (e.g., atrial fibrillation), or post myocardial infarction (MI).
- Until further evidence is available, β -blockers are not suitable as first-line agents for uncomplicated hypertension.

INTRODUCTION

Since the first description of the use of propranolol in 1964 in the treatment of hypertension,¹ β -blockers have become a popular choice for controlling hypertension. β -blockers have traditionally played a widespread role in hypertension therapy and are recommended as first-line agents along with other classes of antihypertensive drugs per the *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNCVII)* guidelines.^{2,3} Other cardiovascular disorders (such as angina pectoris, post-MI, and arrhythmias) are also indications for β -blockers.

MECHANISM OF ACTION

β -blockers are competitive antagonists and are classified based on their selectivity for β_1 or β_2 receptors. Further characterization is based on the presence of partial β -agonist activity [otherwise known as intrinsic sympathomimetic activity (ISA)], on lipid solubility, and on combined alpha- and beta-blocking activity. The common characteristic required for their role in lowering blood pressure is β -receptor antagonism.

The beta receptor and selectivity

The β -adrenoreceptor is a polypeptide with a molecular weight of 67,000. Catecholamines (agonists) and β -blockers

(antagonist) serve as first messengers on the β -receptor, which is present on the surface of target cells. Catecholamines form a complex with the receptor that usually activates adenylyl cyclase (via the Gs protein), resulting in formation of intracellular cyclic adenosine monophosphate (cyclic AMP).⁴ Subsequently, metabolic or physiologic events are stimulated or inhibited by cyclic AMP. Whereas some of the cyclic AMP is metabolized by phosphodiesterase (PDE), some activates protein kinase via dissociation of 'R' and catalytic subunits. Phosphorylation of catalytic subunits results in the final effects.

Beta-adrenoreceptors vary in their distribution (Table 78–1) among organ systems.⁵ A significant inter-species and inter-individual variance exists in their distribution.^{6,7} β_1 -adrenoreceptors are predominantly found in cardiac and adipose tissues, whereas β_2 -adrenoreceptors are present in tissues such as bronchi and vasculature.⁸ The β_1 -receptor mediates renin release and the effects of catecholamines and sympathetic activity on the cardiac tissue. Effect of β -blockers on either receptor depends on receptor selectivity and drug concentration. Selectivity is lost with increasing doses of the drug.

At lower concentrations of drug action is preferential to specific receptors. For example, low plasma concentrations of a selective β_2 agonist will favorably bind β_2 receptors. As plasma concentrations of the β_2 agonist increase, binding becomes less selective.

Blood pressure lowering

The mechanism of blood pressure lowering by β -blockers may be multifactorial. Four possible modes are described in the following material (Figure 78–1). The first possibility is diminished sympathetic outflow mediated by effects on the central nervous system (CNS). Hydrophilic agents such as practolol and sotalol do not decrease peripheral sympathetic activity while lowering blood pressure.⁸ Thus, although the effects on the CNS may contribute to the mechanism of blood pressure lowering for certain drugs it may be difficult to use this to explain the efficacy of β -blockers (which lack the capacity to cross the blood/brain barrier).

The second possibility is that diminished cardiac output may contribute to lowering blood pressure. There is a drop in cardiac output in response to β -blockers, accompanied by increased peripheral resistance.⁹ Continued therapy results in a decrease in peripheral resistance (although above pre-treatment levels) and thus may not alone explain the mechanism of blood pressure lowering.¹⁰

DISTRIBUTION OF α - AND β -RECEPTORS AND MEDIATED EFFECTS		
Receptor Subtype	Organ System	Effect
α	Blood vessel	↑ Constriction
	Uterus	↑ Contraction
	Pancreas	↓ Insulin secretion
β 1	Heart	↑ Heart rate
	Kidneys	↑ Contractility
	Adipose tissue	↑ Conduction
	Parathyroid glands	↑ Excitation
		↑ Automaticity
		↑ Renin secretion
		↑ Lipolysis
β 2		↑ Secretion
	Heart	↑ Heart rate
	Blood vessels	↑ Contractility
	Skeletal muscle	↑ Conduction
	Liver	↑ Excitation
	Lungs	↑ Automaticity
	Pancreas	↑ Vasodilation
	Uterus	↑ Vasodilation
	Urinary bladder	↑ Glycogenolysis
	Gastrointestinal	↑ Contractility
	Gall bladder and ducts	↑ Potassium uptake
	Nerve terminals	↑ Glycogenolysis
	Thyroid	↑ Bronchodilation
	Parathyroid glands	↑ Insulin and glucagon secretion
		↑ Relaxation
	↑ Adrenaline release	
	↑ T4-T3 conversion	
	↑ Secretion	

Table 78-1. Distribution of α - and β -receptors and Mediated Effects

A third possibility is inhibition of renin secretion from the kidneys and a subsequent decrease in plasma angiotensin II.¹¹ Although studies have shown a correlation between reduction in blood pressure with β -blocker use and decreased plasma renin levels,¹² this may not fully explain the action of all members of this class.¹³ Plasma renin levels were found to increase with β -blockers in combination with an ISA such as pindolol, with blood pressure reduction achieved.¹⁰ Furthermore, techniques such as concomitant diuretic use or upright posture helped overcome the inhibitory effect of β -blockers on renin release while maintaining blood pressure control.

A fourth possibility is the uptake and accumulation of adrenaline in sympathetic nerve terminals and their stimulation of pre-synaptic β 2 receptor release of noradrenaline and elevation of blood pressure.¹⁴ Inhibitory effects upon stimulation of pre-synaptic β 2 adrenergic receptors by adrenaline have also been suggested to explain the reduction in arterial pressure.¹⁰ Nonselective blockers (e.g., propranolol) inhibit noradrenaline, whereas β 1 selective agents (e.g., atenolol) do not inhibit β 2 receptors but are still good blood-pressure-lowering agents.¹⁵ In addition, β 2 selective agents are not blood-pressure-lowering agents *per se* (undermining the importance of this mechanism).¹⁶

Structure/Activity relationships

Most β -blocking agents vary widely in their chemical structure but contain a common aminopropanol moiety linked to an aromatic system.¹⁷ They are commonly prepared as racemic mixtures and consist of pairs of optical isomers.¹⁸⁻²⁰ Most of the β -blocking effect, which is useful in treating hypertension, is attributed to the negative levorotatory (l) stereoisomer. The dextrorotatory (d) form may not have many clinical benefits other than in d-sotalol and nebivolol, where it has antiarrhythmic and vasodilatory properties.^{21,22} Membrane-stabilizing activity is a function of both forms (d and l).

PHARMACOKINETICS OF BETA BLOCKERS

Wide variances exist in the pharmacokinetics of this class of drugs (Tables 78-2 and 78-3). Despite similarities in their chemical structures, a number of differences arise in their pharmacokinetics (which are attributed to variations in aromatic ring).¹⁹ Drugs in this class can be divided into aryloethanolamines (e.g., sotalol) and aryloxypropanolamines (e.g., propranolol, atenolol, and pindolol). β -blocking drugs can be further characterized on the basis of absorption in the gut, lipid solubility, first-pass metabolism,

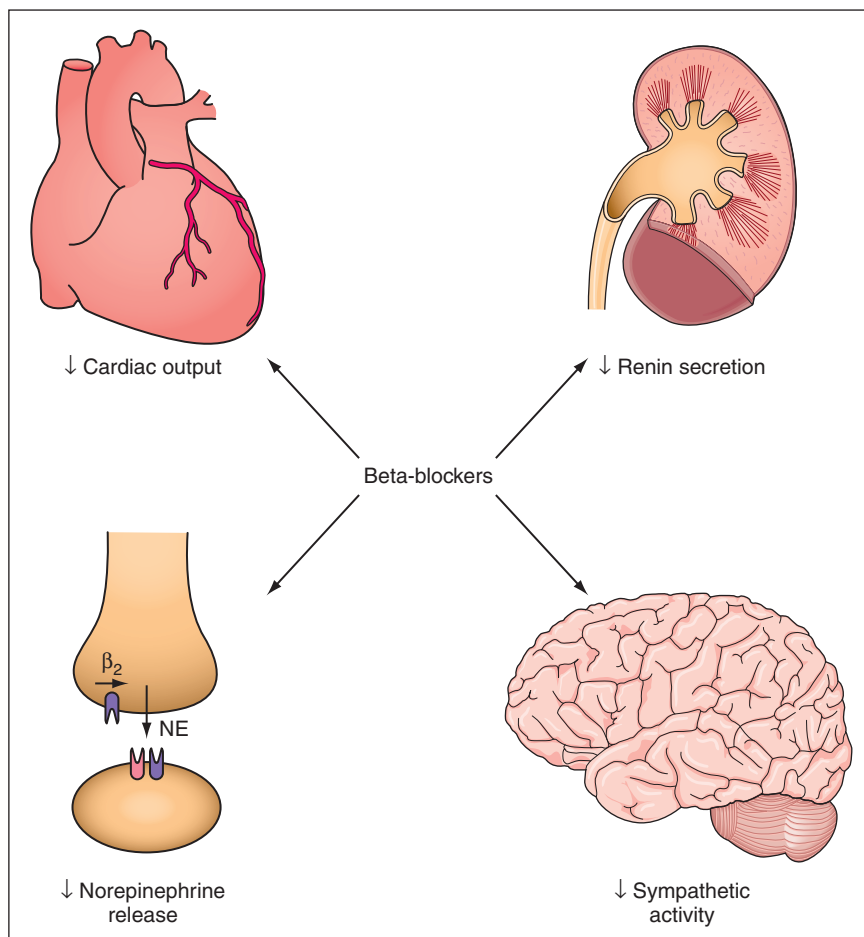

Figure 78–1. Mechanism of action for blood pressure lowering by β -blockers. Several modes of action have been proposed for the blood-pressure-lowering effect. The four most probable modes are depicted in this figure. No single mechanism can explain the effect for all agents in this class of drug.

blood/brain barrier crossing ability, concentration within cardiac tissue, biotransformation, and renal clearance.

Absorption from the gut among this class of drugs remains fairly constant, with few exceptions.²³ Bioavailability of these drugs is variable. Whereas some of them are metabolized in the liver and thus have a shorter half-life, others are largely excreted by the kidneys unchanged and thus have a longer average half-life.

Absorption

Generally, β -blockers are absorbed from the gastrointestinal tract via passive diffusion. The majority of the β -blockers are well absorbed in the small intestine. Exceptions (e.g., nadolol and atenolol) are not well absorbed from the gut.²⁴ Rates of absorption ranges vary from 30% for nadolol to more than 90% for the majority of the other agents in this class. Where absorption tends to be rapid for the short-acting lipid-soluble drugs, water-soluble drugs take longer. Other factors that interfere with absorption of drugs in the gastric tract include gastric emptying time and the presence of food.

Lipid solubility

Absorption of lipid-soluble drugs from the gastrointestinal tract is rapid and complete. These drugs have a relatively

low and variable oral bioavailability because they are metabolized in the wall of the gastrointestinal tract and in the liver. Lipid-soluble drugs show unpredictable absorption levels in patients receiving drugs that alter metabolism and hepatic blood flow. They also show unpredictable absorption levels under other low-flow conditions, with decreased hepatic circulation in the elderly and in patients with congestive heart failure and liver cirrhosis.^{25,26}

In contrast, hydrophilic agents have relatively poorer absorption from the gut, are excreted from the kidneys relatively unchanged, and have poor transport across the blood/brain barrier. These drugs tend to have a longer half-life, which is further increased under conditions of reduced glomerular filtration rate (renal insufficiency and in the elderly).²⁷ These drugs show minimal interaction with other liver-metabolized drugs.

Relationships among dose, plasma concentration, and clinical effect

Lipid-soluble drugs of predominantly hepatic metabolism have wide variations in plasma concentrations.^{28,29} In contrast, drugs with renal clearance have lower variations in plasma

levels because they are excreted essentially unchanged. No clear relationship exists between β -blocker plasma concentrations and their clinical effects.³⁰ Wide variability exists among patients in regard to the relationship between plasma concentration and effect achieved.²⁸ A number of explanations have been offered in regard to this variation. One explanation posits that differences in sympathetic tone result in, for example, a higher concentration of drugs being required by individuals with increased sympathetic tone.

Body fat distribution (especially in regard to lipid-soluble drugs) and flat dose-response curves are among the other mechanisms suggested. A flat dose-response curve may result in minor changes in clinical effects despite variations in plasma concentrations. In addition, plasma concentrations of pharmacologically active metabolites of certain drugs (such as propranolol and acebutolol) that may not be detectable on standard plasma assays have been suggested as causes of this discordance.

Intrinsic sympathetic activity

Certain β -blockers possess partial agonist properties.³¹ ISA caused by a beta-adrenoceptor-blocking drug results in a number of different pharmacologic properties. Most profound are the central hemodynamic effects. β -blockers

Abbreviations: ISA, intrinsic sympathetic activity; MSA, membrane-stabilizing activity.

Table 78–3. Pharmacodynamic Properties of Beta-blocking Agents

with a significant degree of ISA interact with both binding and activation sites on the beta receptor. Although these drugs attach avidly to the binding sites, they tend to have low affinity for the activation site. The overall effect depends on the sympathetic state. Conditions with low sympathetic tone (e.g., during rest/sleep) are associated with a sufficient degree of ISA and a resultant decreased reduction in heart rate and cardiac output. If the drug possesses β_2 ISA, stimulation of β_2 vasodilator receptors may result in less of a decrease in peripheral blood flow.

In contrast, during conditions of high sympathetic tone (e.g., exercise)—and if full dosages of the drugs are used— β -blockade predominates and a β -blocking drug with ISA produces less of an increase in heart rate. In asthmatic subjects, the modest β -stimulant action on bronchial smooth muscle is not important, as these patients are potentially sensitive to any receptor blockade. Down-regulation of β -receptors by β -blocking drugs with ISA prevents post-beta-blocking drug hypersensitivity upon withdrawal of the agent. In contrast, β -blockade with drugs without ISA results in up-regulation of β -receptors. Upon discontinuing the drug, rebound phenomena resulting from uninhibited stimulation by catecholamines characterized by palpitations and anxiety are seen.³² Patients with ischemic disease are at risk of cardiovascular events (including myocardial infarction and death) following abrupt β -blocker withdrawal.

Membrane-stabilizing activity

Membrane-stabilizing activity refers to the ability of certain drugs to exert a quinidine-like effect by reducing the rate of rise of intra-cardiac action potential or by reducing local anesthetic activity. β -blockers interact with sodium channels to produce this effect, although such actions appear to occur only at doses much higher than those required to produce effective β -blockade. Not all β -blockers possess this characteristic. Certain β -blockers (such as metoprolol and pindolol) have weak effects, whereas drugs such as atenolol have none. Membrane-stabilizing activity does not contribute to the lowering of blood pressure.

DRUG INTERACTIONS

Interactions with other drugs can be understood using an example of propranolol, which traditionally represents this class.³³ The bioavailability of propranolol (a liver-metabolized drug) is decreased by agents (e.g., alcohol, phenytoin, rifampin, Phenobarbital, and smoking) that induce hepatic biotransformation enzymes. These agents decrease the plasma concentration and half-lives of lipophilic β -blockers. In contrast, drugs (e.g., cimetidine, hydralazine, and so on) that inhibit hepatic enzymes can increase lipophilic β -blocker bioavailability.³⁴ Concomitant use of antiarrhythmic drugs and calcium antagonists may cause sinus nodes or conduction anomalies.

Nonsteroidal anti-inflammatory drugs (NSAIDs) may have an antagonistic effect on the antihypertensive effect of β -blockers.³⁵ Elderly blacks are at the greatest risk. The mechanism of the hypertensive effects of NSAIDs seems primarily related to their ability to block the cyclooxygenase pathway of arachidonic acid metabolism, with

a resultant decrease in prostaglandin formation. Co-administration of clonidine and β -blocker can result in elevated blood pressure,³⁶ and stopping clonidine in the presence of propranolol has been shown to result in cerebral hemorrhage.³⁷

ADVERSE EFFECTS

The adverse effects of β -blockers are usually due to blockade of β_2 -receptor-mediated functions such as bronchodilation, vasodilation, and mobilization of glucose and free fatty acids. β -blockers can result in a wide range of side effects, depending on the dose and population (Box 78–1). Usage should be determined based on risk/benefit comparison in a particular clinical scenario. Although it is necessary to observe caution regarding side effects, it is important to remember the utility of β -blockers in patients with peripheral vascular disease, coronary artery disease, and diabetes (especially post-MI or involving CHF).

Cardiovascular

By virtue of their chronotropic effects, β -blockers reduce heart rate, reduce the firing rate of ectopic pacemakers, decrease conduction, and increase the refractory time of the AV node (resulting in bradycardia and atrioventricular (AV) block). These effects are predominantly observed in patients with sinus nodes or conduction abnormalities. Caution should be exercised when prescribing other negative chronotropes such as diltiazem, verapamil, or digoxin. β -blockers may worsen symptoms of peripheral vascular disease by producing cold extremities and Raynaud's phenomenon. β -blockers with vasodilatory effects result, and β_1 -selective agents may produce lesser effects on peripheral vasculature.

As mentioned previously, β -blockade with a nonselective blocker results in up-regulation of β -receptors. Suddenly

Box 78–1

Adverse Effects Related to Beta-blocker Use

General: Arthralgias, asthenia, fatigue, diaphoresis, edema, myalgia, pharyngitis, urinary retention

CNS: Depression, dizziness, hallucinations, headache, insomnia, nightmares, paresthesias

Eye: Lacrimation, ocular irritation, xerosis

Cardiovascular: Orthostatic hypotension, peripheral vasoconstriction, peripheral edema, QT prolongation, sinus bradycardia, syncope, torsade de pointes, ventricular tachycardia, angina, AV block, cardiac arrest

Respiratory: Bronchospasm, wheezing, dyspnea

Gastrointestinal: Jaundice, diarrhea, dyspepsia, hepatic necrosis, nausea, vomiting, constipation, flatulence, hypoglycemia, elevated liver function tests

Sexual: Ejaculation dysfunction, impotence, libido decrease, orgasmic dysfunction in women

Skin: Skin hyperpigmentation, alopecia, exfoliative dermatitis, pruritis

Metabolic: Weight gain, increased cholesterol and triglycerides, increased insulin resistance

discontinuing the drug exposes the up-regulated receptors to uninhibited catecholamines, resulting in symptoms such as hypertension, arrhythmias, anxiety, and increased risk of myocardial ischemia in susceptible patients.^{38,39}

Metabolic

Nonselective β -blockers in insulin-dependent diabetes mellitus may mask warning symptoms of hypoglycemia, including tremor and tachycardia. Other symptoms (such as sweating) persist. Selective β -blockers are preferable in insulin-dependent diabetics.⁴⁰ Data on the effects of β -blockers on serum lipoproteins is conflicting. β -blockers have been shown to increase triglyceride levels and decrease high-density lipoprotein (HDL) levels.^{41–43}

β -blockers with ISA have a smaller effect on serum lipoproteins compared to those lacking it. A review of 474 studies demonstrated that increase in triglyceride levels and effect on HDL was diminished with cardio-selective agents.⁴⁴ β -blocker use is often associated with an increase in body weight.⁴⁵ Thus, its use in uncomplicated obese hypertensives is further affected by unwanted weight gain.

Pulmonary

Use of β -blockers in patients with asthma or significant reactive airway disease can lead to increased airway resistance and even to life-threatening bronchospasm. Although the threat of worsening airway disease exists, certain patients with chronic obstructive pulmonary disease may benefit from β -blockade.⁴⁶ Chronic obstructive pulmonary disease in the absence of any significant reactive component is not a contraindication to the use of β -blockers.

Sexual dysfunction

Certain patients may experience worsening impotence or loss of libido. Higher rates of impotence were seen in a propranolol group compared to placebo in the MRC mild hypertension study.^{47,48} Ejaculation dysfunction is another side effect associated with β -blocker use.

Central effects

As mentioned previously, central effects are more common with lipophilic agents compared to hydrophilic agents.⁴⁹ Central effects include fatigue, headache, sleep disturbance, insomnia, vivid dreams, nightmares, and depression.

CLINICAL USE AND INDICATIONS

Hypertension

β -adrenoreceptor-blocking drugs are recommended, along with thiazides, as one of the first-line drugs in initial treatment of hypertension. Although all of these first-line agents have a near equal ability to lower blood pressure in large clinical studies, their efficacy may differ depending on demographic groups and other co-morbid conditions. When considering the initial class of drug, age, race, metabolic side effects, cardiovascular disease, and concomitant disease states should be taken into account. Guidelines recommend blood pressure reduction to levels based on risk profile. A greater reduction should be achieved in high-risk patients.

While maintaining adequate blood pressure control, it is quintessential that the antihypertensive agent should reduce cardiovascular morbidity and mortality. β -blockers as a class have failed to show any role in primary prevention in uncomplicated hypertension. Hence, they should not be recommended as first-line agents in uncomplicated hypertension.

Based on recent trial evidence, β -blockers were removed as first-, second-, and third-line agents by the guidelines of the British Hypertension Society. However, not all agree with this position. In 2003, the *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)* still considered β -blockers as appropriate drugs for primary prevention in uncomplicated hypertension. We may select a β -blocker for hypertensive patients who are symptomatic from excessive sympathetic activity, although there is no outcome evidence in this regard.

β -blockers that have traditionally been recommended for the initial treatment of hypertension include propranolol, metoprolol, and atenolol. All β -blocker are similar in efficacy to control blood pressure regardless of whether they are cardio-selective (β_1 -specific) or nonselective (β_1 and β_2), possess ISA, or are lipid/water soluble. However, they differ in their metabolic effects and ability to reduce cardiovascular morbidity and mortality, especially in hypertensives without risk factors.⁵⁰ Box 78–2 compares the differential effect of newer and traditional agents on the hemodynamic profile of patients.

Beta blockers and ethnic differences

Ethnic differences exist in responses to β -blockers in patient populations.⁵¹ The reason for this difference is not clear, but results suggest differences in hepatic metabolism may be an important contributory factor. For example, propranolol is least responsive in blacks.⁵² In contrast, Chinese patients have been shown to be more sensitive to beta-blockade effect in comparison to white patients.⁵³

β -blockers also tend to be less effective as monotherapy in black/Afro-Caribbean populations, possibly due to the low renin state in this ethnic group (especially in older subjects).

Box 78–2

Unfavorable Hemodynamic and Metabolic Effects of Beta Blockers

- Decrease in cardiac output and heart rate; increase in vascular resistance
- Low efficacy in reducing LV hypertrophy
- Reduced renal blood flow and glomerular infiltrate rate
- Minimal effect on arterial stiffness
- Increased risk of new-onset diabetes, triglycerides
- Decrease in high-density lipoproteins
- Decrease in exercise tolerance

This can largely be overcome by co-administration of a diuretic.

Beta blockers in chronic heart failure

Recent clinical trials have demonstrated the beneficial effects of β -blocker therapy on survival in CHF due to systole dysfunction. Based on data from these trials, β -blocker therapy has become part of standard therapy for patients with CHF, in addition to angiotensin-converting enzyme inhibitors and diuretics. Whether clinical effects of certain β -blockers are the result of properties such as antioxidant effects or of enhanced nitric oxide production is not certain. β -blockers (particularly those with vasodilatory properties) have beneficial hemodynamic, metabolic, and renal responses. These drugs have been effective in the reduction of long-term cardiovascular morbidity and mortality in patients with CHF and in survivors of acute MI.

In a recently reported COMET (Carvedilol or Metoprolol European Trial) report,⁵⁴ effects of carvedilol and metoprolol were compared in patients with CHF due to left ventricular (LV) systolic dysfunction. Patients with ejection fractions (EF) <35% (N = 1,151) were randomized to equivalent β -blocking doses of either drug. Carvedilol treatment was associated with a significant 17% greater reduction in all-cause mortality ($P = 0.0017$) and a 20% greater reduction in cardiovascular mortality ($P = 0.0004$) compared to metoprolol therapy.

Beta blockers in post myocardial infarction patients

The use of β -blockers in post-MI has been shown to reduce cardiovascular mortality. Noteworthy trials demonstrating the role of beta blockade in MI are the β -blocker Heart Attack Trial (BHAT)⁵⁵, the Norwegian Multicenter Study of Timolol after Myocardial Infarction,⁵⁶ and the Carvedilol Post-Infarct Survival Control in LV Dysfunction (CAPRICORN) trial.⁵⁷

The BHAT compared the incidence of coronary incidence defined as recurrent nonfatal definite reinfarction plus fatal coronary heart disease in 3,837 patients receiving propranolol or placebo. Patients were followed up for an average of 25 months and the trial was terminated early on evidence of clear differences in reduction of coronary incidence in the propranolol group. An incidence of 10% was observed in the propranolol group compared with 13% in the placebo group, which was a reduction of 23%. The incidence of definite nonfatal reinfarction was lower (by 15.6%), and that of definite or probable nonfatal reinfarction was also lower (by 14.7%).^{55,58}

Similarly, timolol was compared to placebo in the Norwegian timolol study in 1,884 patients followed for 12 to 33 months. One hundred fifty-two patients in the placebo group and 98 in the timolol group died. The life-table cumulative probability of total death was 21.9% in the placebo group and 13.3% in the timolol group, corresponding to a relative reduction of 39.4% ($P = 0.0003$). One hundred thirty-one nonfatal reinfarctions were confirmed in the placebo group and 90 were confirmed in the timolol group, including events among withdrawn patients. The life-table probability rate of reinfarction was

16.4% in the placebo and 11.8% in the timolol group ($P = 0.001$). It was concluded that chronic treatment with timolol in survivors of acute MI who can tolerate beta-adrenergic blockade is effective in reducing both total mortality and reinfarction over 33 months.⁵⁶

The CAPRICORN trial compared the effect of carvedilol and placebo on cardiovascular end points in 1,959 survivors of acute MI with reduced EFs. Carvedilol-treated patients experienced a significant 23% greater reduction in all-cause mortality ($P = 0.031$), a 25% greater reduction in cardiovascular death ($P = 0.024$), and a 41% greater reduction in nonfatal recurrent MI ($P = 0.014$) compared with placebo-treated patients. Another trial comparing carvedilol and atenolol in MI survivors with normal EF found carvedilol to significantly lower a composite score of cardiovascular events better than atenolol.⁵³

Blacks, patients 80 years old or older, and those with a LV EF below 20%, serum creatinine concentration greater than 1.4 mg per deciliter, or diabetes mellitus had a lower percentage of reduction in mortality. However, given the higher mortality rates in these subgroups the absolute reduction in mortality was similar to or greater than that among patients with no specific risk factors. After MI, patients with conditions often considered contraindications to beta-blockade (such as pulmonary disease and older age) and those with nontransmural infarction benefit from β -blocker therapy.⁵⁹ Controlled trials in patients who are post-MI with normal or close to normal LV function are needed to assess use of β -blockers in this subgroup.⁶⁰

Beta blockers in acute coronary syndromes

Role of β -blockers in acute settings have been primarily based on results from two major trials conducted in the 1980s: metoprolol in acute myocardial infarction (MIAMI)^{61,62} and first international study of infarct survival (ISIS-1).⁶³ Results from ISIS-1 show non-significant reduction of early in-hospital events described as nonfatal cardiac arrests and reinfarctions with the use of atenolol compared to placebo. Subsequent necropsy of patients with complications in the ISIS-1 study failed to reveal any considerable role of mechanisms such as limitation of infarct size or prevention of reinfarction or cardiac arrest.

The extent of thrombolytic use in these studies is also not clear. In the absence of data pertaining to concomitant use of thrombolytics in these patients, added benefits of β -blockers in acute events is still debatable. The recently reported Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT/CCS-2)⁶⁴ showed that early use of β -blockers in acute MI was associated with increased risk of cardiogenic shock. Results from this study of more than 45,000 patients suggest avoiding intravenous use of β -blocker and use of β -blockers in general within 12 hours of acute MI.

Beta blockers in diabetes mellitus

As previously mentioned, β -blockers were relatively contraindicated in diabetes until recently. Nonselective β -blockers can prevent normalization of blood sugar after an episode of hypoglycemia in patients on insulin. This is

accompanied by a rise in blood pressure and reflex bradycardia. The risk of developing diabetes is high in nondiabetic hypertensives on treatment with β -blocking agents.^{65–68} Similarly, the efficacy of β -blockers in reducing cardiovascular and all-cause mortality in diabetics is not impressive. The Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) trial⁶⁹ showed that atenolol was less effective than the angiotensin receptor blocker (losartan) in reducing cardiovascular events and all-cause mortality in mainly elderly hypertensives with diabetes.

The United Kingdom Prospective (UKPDS) study showed a non-significant difference between β -blockers (atenolol) and ACE inhibitors (captopril) in type 2 diabetics with hypertension in preventing all primary macrovascular and microvascular endpoints.⁷⁰ Captopril and atenolol were equally effective in reducing the risk of macrovascular endpoints. Similar proportions of patients in the two groups showed deterioration in retinopathy by two grades after nine years (31% in the captopril group and 37% in the atenolol group) and developed clinical-grade albuminuria at 300 mg/L (5 and 9%, respectively). Data from this trial showed that young, middle aged diabetics witnessed the most reduction in cardiovascular endpoints. This difference in outcomes was attributed to β -blockade in a relatively higher sympathetic state in the younger age group, and to subsequent stimulation of normally functioning beta-1 receptors.⁷¹ β -blockers utilized in the type 2 diabetic patients resulted in an even greater decrease in cardiac events than in the nondiabetic patients.

Recent evidence shows that benefits of β -blocker reign over the risks in high-risk patients, such as patients post-MI.⁷² The COMET showed that use of carvedilol resulted in a decrease in new onset of diabetes in patients with heart failure.⁵⁴ The Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GEMINI) trial⁷³ compared carvedilol and metoprolol (third- and second-generation β -blockers, respectively) in patients with hypertension and type 2 diabetes. Both treatment groups had similar blood pressure lowering. Mean HbA1c increased with metoprolol (0.15% [0.04%]; $P < .001$) but not carvedilol (0.02% [0.04%]; $P = 0.65$). Insulin sensitivity improved with carvedilol (–9.1%; $P = 0.004$) but not metoprolol (–2.0%; $P = 0.48$). Progression to microalbuminuria was less frequent with carvedilol than with metoprolol (6.4 versus 10.3%; odds ratio, 0.60; 95% CI, 0.36 to 0.97; $P = 0.04$). More participants withdrew due to worsening glycemic control in the metoprolol group.

Unfortunately, traditional β -blockers are associated with the worsening of insulin resistance, deterioration of glycemic control, peripheral vasoconstriction, potentially worsening peripheral vascular disease, and more frequent and severe hypoglycemia. The newer β -blockers have unique properties, including alpha1-blockade, and they lower insulin resistance, improve glycemic control, and vasodilate resistance arterioles.

Beta blockers in the elderly and those with left ventricular hypertrophy

The JNC 7 guidelines made the recommendation that systolic blood pressure be the primary target for the diagnosis and

care of older persons with hypertension.³ Multiple studies have provided evidence that increased large artery thickening and stiffness⁷⁴ and endothelial dysfunction in healthy elderly persons, which were earlier considered to be part of normal aging process, along with the resulting increase in systolic and pulse pressure may be related to a greater risk of manifestation of hypertension, to atherosclerosis, and to other associated cardiovascular events.⁷⁵

Hypertension, especially in the elderly, is marked by reduced cardiac output and increased peripheral vascular resistance.^{76,77} In addition, there is a decrease in renal blood flow and glomerular filtration rate and an increase in proteinuria.^{78–83} Unlike the other classes of antihypertensive agents that reduce blood pressure by lowering peripheral vascular resistance while preserving cardiac output, traditional β -blockers lower blood pressure by reducing cardiac output through their negative inotropic effect and induce a compensatory increase in vascular tone mediated through α_1 vascular receptors (Box 78–2). In addition, nonselective β -blockers can also promote vasoconstriction by blocking vasodilatory β_2 vascular receptors.⁸⁴

Long-term β -blocker therapy produces homeostatic regulatory adjustments that can improve cardiac output but still be depressed compared to original state. These adjustments may decrease vascular resistance to some degree, but cardiac output will remain distinctly elevated (often above pretreatment levels).^{85,86} Traditional β -blockers further decrease renal blood flow and glomerular filtration rate and have no effect on proteinuria.^{81,82,87,88} Similarly, older agents have no effect on arterial stiffness or hypertrophy.^{89,90} Cardioselective β -blockers with low lipid solubility have a preferable side-effect profile in older persons.

β -blockers that are lipophilic cross the blood/brain barrier, possibly causing more sedation, depression, and sexual dysfunction in older patients.²² Particularly in older patients, β -blockers as a class can cause bradycardia, conduction abnormalities, and development of heart failure if started too aggressively in patients with preexisting LV dysfunction.^{6,22,23} β -blockers should be tapered before discontinuation to minimize the risk of reflex tachycardia.

A meta-analysis of 10 placebo-controlled hypertension trials of more than 16,000 elderly patients (= 60 years) found that although traditional β -blockers significantly lowered blood pressure they were ineffective in preventing coronary heart disease (defined as fatal or nonfatal MI and sudden cardiac death, cardiovascular mortality, and all-cause mortality).⁹¹ In addition, a meta-analysis of 80 double-blind randomized controlled trials with 3,767 hypertensive patients found that β -blockers were the least effective in reducing LV mass compared with ARBs, calcium channel antagonists (CCAs), and ACE inhibitors despite similar blood pressure reduction among these antihypertensive drug classes ($P = 0.004$).⁹²

The lesser effectiveness of β -blockers, compared with angiotensin II receptor antagonists, on LV mass reduction is in accordance with the results of one of the largest trials on antihypertensive treatment in patients with LV hypertrophy [the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) study]. In that study, losartan was more effective in reducing electrocardiographically

determined LV hypertrophy than was atenolol. The beneficial effects on LV hypertrophy were partly responsible for the better cardiovascular outcome in patients treated with losartan.

A randomized study with 42 elderly patients with hypertension concluded that the β -blocker atenolol failed to reduce LV mass compared to the CCA verapamil after six months of treatment despite comparable blood pressure lowering.⁹³ In a randomized double-blind study of 19 untreated hypertensive patients treated with the ARB losartan or atenolol treatment, atenolol-treated patients failed to demonstrate a reduction in LV mass despite comparable blood pressure reduction in both groups.⁹⁴ In addition, a meta-analysis of 80 double-blind randomized controlled trials with 3,767 hypertensive patients found that β -blockers were the least effective in reducing LV mass compared with ARBs, CCAs, and ACE inhibitors despite similar blood pressure reduction among these antihypertensive drug classes ($P = 0.004$).⁹²

A randomized study with 42 elderly patients with hypertension concluded that atenolol failed to reduce LV mass compared to verapamil after six months of treatment despite comparable blood pressure lowering.⁹³ In a randomized double-blind study of 19 untreated hypertensive patients treated with losartan or atenolol treatment, atenolol-treated patients failed to demonstrate a reduction in LV mass despite comparable blood pressure reduction in both groups.⁹⁴

The poor efficacy of β -blockers in the elderly may be attributed to unfavorable effects on the hemodynamics in the vasculature and end organs and to metabolism. Table 78–4 summarizes the effect of traditional β -blockers on the hemodynamic profile. Newer agents with peripheral vasodilating properties have a more favorable profile. Based on results from trials and inherent properties of β -blockers that result in a less than favorable effect, β -blocking drugs are not suitable as first-line agents in the elderly without other co-morbid conditions such as CHF or MI.⁹⁵

Beta blockers and cardiac arrhythmias

Hypertensive patients are prone to both supraventricular and ventricular arrhythmias. The most common sustained cardiac rhythm disorder is atrial fibrillation, and the β -

blockers have a role for rate control in permanent AF.⁹⁶ In paroxysmal AF, β -blockers may also be useful for the suppression of paroxysms and maintenance of sinus rhythm, as well as the facilitation of cardioversion in persistent AF.

BETA BLOCKERS AND PRIMARY PREVENTION

Hypertension is a well-recognized risk factor for the development of serious cardiovascular disease. Multiple prospective observational studies have documented a strong, continuous, graded, and independent association between blood pressure and mortality risk due to stroke, coronary artery disease (CAD), or other vascular causes.⁹⁷ Hypertension also doubles the risk of developing congestive heart failure, which is augmented by the presence of CAD.^{98,99} Hypertension also similarly increases the risk of developing end-stage renal disease.¹⁰⁰

Using a variety of antihypertensive agents to lower elevated blood pressure to <140/90 mmHg has consistently decreased cardiovascular events. Systematic overviews of multiple trials show that reducing diastolic blood pressure by as little as 7.5 mmHg results in 46% and 29% relative risk reductions in stroke and CAD, respectively.¹⁰¹ Even reducing systolic blood pressure by as little as 2 mmHg can lower the risk of stroke by 10% and CAD mortality by 7%.⁹⁷ The largest single randomized controlled blood pressure trial, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),¹⁰² reported that lowering blood pressure with a diuretic, an ACE inhibitor, or a CCA significantly improved cardiovascular endpoints. Unfortunately, however, β -blockers were not directly studied in this landmark trial.

In a recent review of clinical hypertension trials, although β -blockers significantly lowered blood pressure there was no convincing evidence to support their effectiveness in reducing cardiovascular morbidity and mortality, including fatal and nonfatal stroke and MI. A meta-analysis of 10 placebo-controlled hypertension trials of more than 16,000 elderly patients (> 60 years) similarly found that although traditional β -blockers significantly lowered blood pressure they were ineffective in preventing coronary heart disease, defined as fatal or nonfatal MI and sudden cardiac death,

COMPARISON OF TRADITIONAL AND NEWER BETA-BLOCKING AGENTS ^a			
Function	Ideal Drug	Traditional Beta Blockers	Carvedilol
Mean arterial blood pressure	Decrease	Decrease	Decrease
Total peripheral resistance	Decrease	Increase	Decrease
Cardiac output	None	Decrease	None
Heart rate	None/decrease	Decrease	None/decrease
Activation of sympathetic nervous system	Decrease	Decrease	Decrease
Renin-angiotensin-aldosterone system	Decrease	Decrease	Decrease
Lipid metabolism	None/positive	Negative	None
Glucose metabolism	None/positive	Negative	None

a. Newer agents have a more beneficial metabolic and hemodynamic profile.

Table 78–4. Comparison of Traditional and Newer Beta-blocking Agents^a

cardiovascular mortality, and all-cause mortality.⁹¹ Another recent meta-analysis showed that although atenolol reduced blood pressure greater than placebo and comparably to other antihypertensive agents there was no difference in mortality or MI compared to placebo and there was an increased risk of mortality and stroke compared with other antihypertensives. However, the risk of stroke with atenolol was lower compared to placebo.¹⁰³

NEWER AGENTS

Nonselective β -blockers (such as propranolol, and the β_1 -selective blockers atenolol and metoprolol) have traditionally played a role in the treatment of hypertension. β -blockers successfully lower elevated blood pressure but are less effective in reducing the risk of morbidity and mortality associated with hypertension-related cardiovascular diseases (including stroke and CAD) compared with other antihypertensive agents such as diuretics, ACE inhibitors, and CCAs. The mechanisms by which traditional β -blockers lower blood pressure differ significantly from those of other antihypertensive agents. β -blockers lower cardiac output and induce a compensatory increase in peripheral vascular resistance. This reflex increase in α_1 -adrenergic activity may in turn lead to metabolic consequences that can promote CAD, decrease insulin sensitivity and glucose utilization, increase triglyceride levels, and decrease HDL cholesterol levels.

The availability of vasodilating β -blockers represents a significant change from the hemodynamic, renal, and metabolic responses associated with traditional β -blocker therapy (Table 78-4). Newer agents with a combined alpha and beta effect maintain cardiac output, have a lower effect on heart rate, and decrease blood pressure by decreasing systemic vascular resistance.⁵⁰ These newer agents thus have a more preferential hemodynamic profile. Carvedilol increases plasma flow to the kidneys as opposed to the decreased glomerular filtration rate seen with traditional β -blockers. These properties are an advantage, especially in the elderly (in whom the cardiac output is low and systemic vascular resistance elevated).

Figure 78-2. Algorithm for β -blocker use. Beta-blocking agents should not be used for management of hypertension in patients with no other co-morbid conditions. In patients with hypertension and congestive heart failure, post-MI, or diabetes, beta-blocking agents should be a first-line agent.

The beneficial effect of carvedilol on systemic resistance is similar to ACE inhibitors and calcium channel blockers. Carvedilol was found superior to traditional β -blockers on many levels in addition to its hemodynamic properties. One aspect is the lower rate of new-onset diabetes compared to traditional β -blockers, owing to its effect on increase of glucose utilization, in turn decreasing circulating insulin levels and hence improving insulin sensitivity. Carvedilol seems to have fewer metabolic adverse effects than traditional β -blockers. Furthermore, carvedilol has a beneficial effect on lipid profile or a neutral effect on atherogenicity. This may be of particular importance in younger patients, who will be exposed to these drugs for a longer duration.

FUTURE POSSIBILITIES

β -blockers have been popular antihypertensive agents in clinical practice. However, the efficacy of β -blockers has been poorly documented. Guidelines relating to β -blocker use need to be readdressed (Figure 78-2). Further outcome trials on the role of newer β -blockers in the primary prevention of cardiovascular events and mortality in uncomplicated hypertension and the elderly are warranted.

Calcium Antagonists

*Stefano Taddei, Lorenzo Ghiadoni, Agostino Virdis,
and Antonio Salvetti*

Key Findings

- Non-dihydropyridine calcium antagonists are less potent vasodilators, but also show chronotropic, dromotropic, and inotropic effect.
- Calcium antagonists have potent antioxidant effects that are relevant to the restoration of endothelial function.
- Calcium antagonists lower blood pressure in primary and secondary hypertension and in special populations, including elderly and black individuals.
- Calcium antagonists effectively reduce left ventricular mass and prevent atherosclerosis, as well as reduce the occurrence of stroke.

INTRODUCTION

After the pioneering observation by Fleckenstein in 1967 that reduction of calcium movement into cardiac myocytes determined a negative inotropic effect, calcium antagonist drugs were developed for the treatment of several disorders (mainly of the cardiovascular apparatus)—including high blood pressure, angina pectoris, supraventricular tacharrhythmia, Raynaud's phenomenon, hypertrophic cardiomyopathy, pulmonary hypertension, migraine, and esophageal spasm. However, despite this large variety of clinical indications treatment of hypertension remains the main indication for the utilization of this drug class throughout the world because calcium antagonists represent one of the cornerstones for the therapy of this disease.

The term *calcium antagonist* was coined by Fleckenstein to convey the fact that these agents produced *in vitro* effects similar to those exerted by specific antagonists. Later, the International Union of Basic and Clinical Pharmacology proposed the term *calcium channel blocker* (CCB). Finally, in addition to this more common term these drugs are also designated as *calcium entry blockers*, *calcium blockers*, *calcium channel antagonists*, and *calcium channel inhibitors*. All of these terms have the same meaning.

Recent years have seen the emergence of the need for stricter blood pressure control in the general population. Utilization of this drug class in cardiovascular medicine has thus gained new relevance. This is due to the undisputed efficacy of these compounds in reducing blood pressure values independently of the characteristics of the

patients (age, race, sodium repletion, pathogenesis of hypertension), their notable flexibility for use in combination therapy, and the extensive availability of clinical intervention trials demonstrating the effectiveness of this drug class on target organ damage and cardiovascular events (including a high safety profile).

MECHANISMS OF ACTION

Calcium in its ionized form (Ca^{2+}) is generally considered the ubiquitous second messenger, and Ca channels regulate the entry of Ca^{2+} into the cytoplasm. Thus, cells utilize Ca from two different sources: Ca^{2+} entering from the outside or Ca^{2+} released from internal stores. Ca^{2+} enters the cell through a variety of plasmalemmal ion channels such as voltage-operated channels, receptor-operated channels, store-operated channels, and non-selective channels. Voltage-operated channels have been divided into at least three subtypes based on their conductance and voltage sensitivity. The channels best characterized are the L (long-lasting), T (transient), and N (neuronal) subtypes. The main effect of calcium antagonists is blockade of calcium entry into cells by acting on the L subtype and changing the opening mode for these channels to a preponderance of short-lived rather than long-acting channels and switching them to long-lived closed state.^{1,2}

From the clinical point of view, calcium antagonists are divided into different classes according to their chemical structure. The three main classes are (1) phenylalkylamines (prototype is verapamil), (2) benzothiazepines (prototype is diltiazem), and (3) dihydropyridines (prototype is nifedipine). Less specific agents are categorized as diphenylpiperazines (cinnarizine, flunarizine) and diarylaminoethylamines (bepridil).

It must be stressed that each of the calcium antagonists of cardiovascular interest (namely, verapamil, diltiazem, nifedipine, and all other dihydropyridines) has a completely different molecular structure, and as a consequence different receptor sites on Ca channels (although receptors for verapamil and diltiazem have some overlapping sites). This concept is important in explaining the various hemodynamic properties of these compounds.

After the first generation of calcium antagonists, characterized by rapid onset of action and very short half-life, second- and third-generation drugs were developed with compounds characterized by a longer duration of action attributable to pharmacokinetic properties or extended-

release mechanisms (Box 79–1). Second- and third-generation drugs are therefore associated with slower onset and longer duration of action, with lower reflex sympathetic nervous system activation and fewer side effects.³

The cardiovascular activity of the three classes of calcium antagonists shows important differences: verapamil has more significant effects on cardiac performance (determining a negative chronotropic, dromotropic, and inotropic effect), while causing modest vasodilation; dihydropyridines are potent and almost pure vasodilators (with some slight difference between nifedipine and the other dihydropyridines); and diltiazem has intermediate effects between verapamil and dihydropyridines. Among the various dihydropyridines, nifedipine shows a modest negative inotropic effect that has no clinical relevance in patients with preserved left ventricular function (such as the majority of patients with essential hypertension). Newer dihydropyridines are characterized by more pronounced vascular selectivity caused by an increased lipophilicity.²

The pharmacokinetics of calcium antagonists are characterized by nearly complete absorption after oral administration, associated with marked reduction in bioavailability because of first-pass hepatic metabolism. The effect of the prototypes is evident within 30 to 60 minutes after the oral dose, but it is obviously delayed with the extended-release formulation or longer-acting agents (Box 79–1). These agents are all bound to plasma proteins to a significant extent (70 to 90%), and their elimination half-lives vary widely, ranging from 1.3 to 64 hours. During repeated oral administration, bioavailability and half-life may increase because of saturation of hepatic metabolism. In patients with hepatic cirrhosis, the bioavailability and half-life of calcium antagonists may be increased and dosage should be decreased accordingly. On the other hand, no dose adjustment is required in patients with renal failure.

The main mechanism through which calcium antagonists lower blood pressure values is the reduction in peripheral vascular resistances (Figure 79–1). This effect is the consequence of several properties of this drug class. Basically, through the reduction in cytosolic free calcium concentrations calcium antagonists are potent vasodilators, an effect mainly observed at the level of resistance arteries. In addition, these drugs can interfere with several vasocon-

strictors acting through intracellular calcium mobilization, including alpha-adrenergic agonists (norepinephrine, phenylephrine) or angiotensin II. Finally, calcium antagonists also induce mild natriuresis, thereby averting volume retention, a negative effect usually common to direct vasodilators (Figure 79–1). Compared to dihydropyridines, verapamil and diltiazem prove to be less potent as vasodilating agents, although their negative chronotropic, dromotropic, and inotropic effects can contribute to antihypertensive activity (Figure 79–1).⁴

The clinical efficacy of calcium antagonists as single agents is well documented not only in patients with mild to moderate or severe essential hypertension but in special populations, including patients with primary aldosteronism or pheochromocytoma, hypertensive emergency, cyclosporine-induced hypertension, and hypertension (in elderly and black patients). It is worth noting that nifedipine is considered the first-choice drug in pregnancy-induced hypertension.⁵

Calcium antagonists can be effectively combined with all other antihypertensive drug classes, apart from diuretics. Although the association between calcium antagonists and diuretics has been employed in intervention clinical trials, it has no mechanistic rationale because (as previously stated) calcium antagonists themselves have a natriuretic activity and several studies have documented that these two drug classes show no antihypertensive additive effect. The only exception concerns patients with renal failure, who often require both calcium antagonists and loop diuretics to obtain adequate blood pressure control.⁵

Another limitation to therapy with calcium antagonists is the combination of verapamil or diltiazem with beta blockers because of prolongation of atrioventricular conduction time as well as an additive negative inotropic effect.¹ In contrast, the combination of dihydropyridines

Classification of Calcium Antagonists

- *First generation:* verapamil, diltiazem, nifedipine, felodipine, isradipine, nifedipine, nitrendipine
- *Second generation:* verapamil SR, diltiazem CD, nifedipine XL, nifedipine GITS, felodipine ER, isradipine CR
- *Third generation:*
 - Long plasma half-life: amlodipine
 - Long receptor half-life: barnedipine, lercanidipine, lacidipine, manidipine

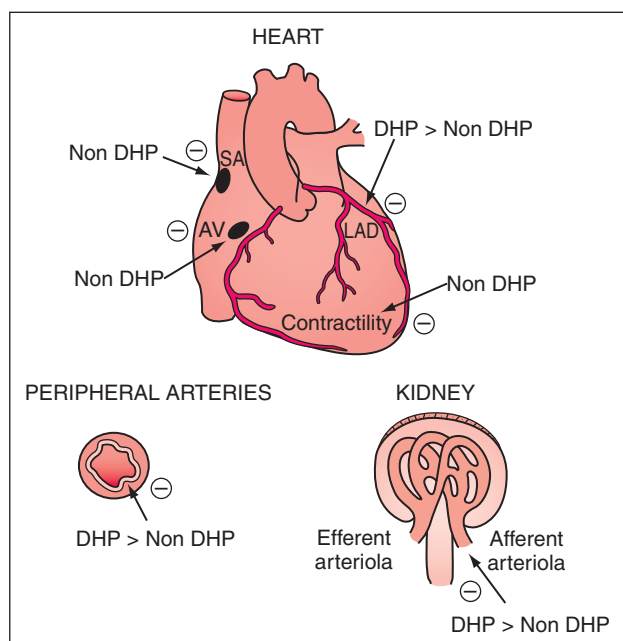

Figure 79–1. Mechanisms of action of calcium antagonists (DHP, dihydropyridines).

and beta blocker is an ideal and effective combination in the treatment of essential hypertension.

Metabolic effects are considered of primary relevance in the treatment of hypertensive patients because of the need to reduce the global cardiovascular risk. Calcium antagonists show a neutral effect on lipid and glucose profile. However, prospective randomized trials have clearly documented that treatment using this drug class is associated with a reduced incidence of new cases of diabetes mellitus compared to diuretic and beta-blocker-based treatment.

ANTIATHEROSCLEROTIC EFFECT

One of the relevant characteristics of calcium antagonists that could be clinically important in the prevention of cardiovascular disease is the antiatherosclerotic effect. Some aspects of the pathogenesis of atherosclerosis depend on calcium-regulated cell processes such as chemotaxis, cell migration and adhesion, proliferation, lipid uptake, and endothelial necrosis. In experimental models, most of these processes are inhibited by calcium chelating agents and calcium antagonists.⁶ In addition, a large body of evidence indicates that an early event in the atherosclerotic disease process is endothelial dysfunction, which promotes a constellation of processes that contribute to plaque development (including vasoconstriction, thrombosis, inflammation, oxidation, and proliferation). In the healthy endothelium, nitric oxide (NO) protects the vessel wall not only by inducing vasodilation but through various anti-inflammatory benefits (including scavenging of superoxide, inhibition of platelet aggregation, reduced hyperadhesiveness of leukocytes, and interference with platelet aggregation). Essential hypertension is causally associated with endothelial dysfunction, which results in reduced NO availability because of the production of oxidative stress.

These alterations lead to increased vessel wall permeability to atherogenic lipids and inflammatory cells such as monocytes and T lymphocytes. Consequently, it is believed that the cascade of events leading to the formation of atherosclerotic plaques includes the penetration of damaged vessel walls by monocytes/macrophages and their development into cholesterol-rich foam cells (mediated by oxidized low density lipoprotein (LDL)) and the proliferation of vascular smooth muscle cells followed by their migration toward the vascular lumen. This view is increasingly supported by mounting evidence demonstrating the association of endothelial dysfunction with carotid and coronary atherosclerosis, both in patients with essential hypertension and those with atherosclerotic disease. Finally, the presence of endothelial dysfunction has been associated with the occurrence of cardiovascular events in several longitudinal studies, especially in patients with coronary atherosclerosis.

Calcium antagonists are powerful compounds that interfere with the cascade of events leading to the development of atherosclerosis. Such effects are mediated not only by the interaction with intracellular calcium but by the strong antioxidant activity that characterizes this drug class. A positive effect of calcium antagonists (mainly of

the dihydropyridine type) on endothelial function in different vascular beds has been documented in essential hypertension and coronary artery disease. Thus, one-year treatment with nifedipine gastro-intestinal therapeutic system (GITS) (but not the β -blocker atenolol) improved relaxation to acetylcholine in gluteal subcutaneous resistance-size small arteries of essential hypertensive patients.⁷

This beneficial effect of calcium antagonists on endothelial function was confirmed in the coronary vascular bed by the demonstration that intracoronary infusion of two different calcium antagonists, the dihydropyridine nifedipine and the benzothiazepine-like diltiazem, improved endothelium-dependent dynamic exercise-induced vasomotion in stenotic epicardial vessels of normotensive subjects and in normal and stenotic epicardial vessels of essential hypertensive patients.⁸ In addition, the ENCORE study⁹ showed that treatment with nifedipine GITS resulted in a significantly greater improvement of response to acetylcholine as compared to the placebo group in epicardial arteries of patients with coronary artery disease. Finally, several positive studies are also available in the forearm microcirculation of essential hypertensive patients.¹⁰

In particular, extensive evidence indicates that different dihydropyridine calcium antagonists (including lacidipine,^{11,12} nifedipine GITS,¹³ isradipine,¹⁴ and lercanidipine¹⁵) significantly increase the forearm vasodilation to acetylcholine or bradykinin. The potential mechanism by which calcium antagonists could exert their beneficial activity on endothelial dysfunction is very likely to be an antioxidant activity.¹⁶ This hypothesis is reinforced by evidence that calcium antagonists can restore NO availability and decrease oxidative stress in essential hypertensive patients (Figure 79–2).^{12,13,15}

As discussed later in the chapter, this specific effect of calcium antagonists on endothelial dysfunction could account for the well-documented effect of preventing atherosclerosis in the coronary and carotid arteries exerted by these compounds. It is also conceivable that the restoration of endothelial dysfunction might play a role in long-term reduction of cardiovascular events.

INDICATIONS

Calcium antagonists are first-choice drugs for the treatment of essential hypertension. As stated previously, they can be used in all essential hypertensive patients. However, to better understand the specific beneficial effects that can derive from this drug class it is necessary to examine the available clinical evidence on target organ damage and clinical events (Box 79–2).

EFFECTS OF CALCIUM ANTAGONISTS ON TARGET ORGAN DAMAGE

Left ventricular hypertrophy (LVH)

Although several studies have assessed the effects of various antihypertensive drugs on LVH by echocardiographic determination of left ventricular mass (LVM), only

Figure 79–2. Graphs show a study performed in essential hypertensive patients documenting that calcium antagonists can restore endothelial function by improving NO availability through an antioxidant effect. At baseline, in essential hypertensive patients vasodilation (measured by strain-gauge venous plethysmography) induced by intrabrachial infusion of acetylcholine is resistant to L-NMMA, indicating the presence of impaired NO availability. When the agonist is repeated in presence of the intrabrachial infusion of vitamin C (an antioxidant), the vasodilation to acetylcholine is increased and the ability of L-NMMA to inhibit the relaxing effect of the endothelial agonist is restored, demonstrating the presence of oxidative stress-induced impairment in NO availability. After three months of nifedipine GITS administration, the response to acetylcholine is increased compared to baseline (whereas L-NMMA clearly blunts the vasodilation induced by the agonist). It is worth noting that after nifedipine treatment the facilitating effect of vitamin C is prevented. Thus, calcium antagonists can restore NO-dependent relaxation by an antioxidant mechanism. (Modified from Taddei S, Virdis A, Ghiadoni L, et al. Restoration of nitric oxide availability after calcium antagonist treatment in essential hypertension. *Hypertension* 2001;37:943.)

a few studies have followed sufficiently strict criteria to provide reliable information.⁵ Consequently, meta-analyses cannot provide indisputable evidence. However, as reviewed elsewhere¹⁷ angiotensin converting enzyme (ACE) inhibitors and calcium antagonists seem to be more efficient than other antihypertensive drugs in reducing LVM. A more recent meta-analysis of 80 trials, also including patients treated with angiotensin II receptor blockers (ARB), indicated that ARBs, ACE inhibitors, and calcium antagonists similarly reduce LVM by approximately 10 to 13%. This effect was marginally greater than that of diuretics (–8%) and significantly greater than that of β -blockers (–6%).¹⁸

It is relevant to specifically quote three studies^{19–21}, performed with the application of strict methodological criteria to evaluate the effect of antihypertensive drugs on LVM changes. The ELVERA trial, a study in elderly newly diagnosed hypertensive patients, showed that monotherapy with nifedipine or lisinopril while similarly reducing clinic blood pressure caused a similar and significant decrease in LVM at one-year and even more at two-year follow-up.¹⁹

The PRESERVE trial, a randomised, double-blind study in essential hypertensive patients with LVH, demonstrated that amlodipine- and enalapril-based treatment (in combination with hydrochlorothiazide and atenolol) similarly reduced clinic blood pressure and LVM at one-year follow-up.²⁰ Finally, in a large group of essential hypertensive patients participating in the ELSA study lacidipine- and atenolol-based treatments significantly and similarly

reduced clinic and ambulatory blood pressure and the LVM index at one- and four-year follow-up (Figure 79–3).²¹

Interestingly, in this study changes in LVM were significantly associated with mean 24-hour systolic blood pressure changes. A similar correlation, although less consistent, was found with clinic blood pressure in the ELVERA¹⁹ and PRESERVE studies.²⁰ It can be concluded from these studies that in hypertensive patients treatments with dihydropyridine calcium antagonists, ACE inhibitors, and β -blockers are equally effective in reducing LVM when blood pressure values are similarly lowered. Such a finding supports the primary role of hemodynamic load lowering to achieve LVM reduction.

Atherosclerosis of carotid arteries

Several randomized trials have compared the long-term effects of calcium antagonists on carotid intima-media thickness (IMT). In the PREVENT study,²² performed in patients with angiographic evidence of coronary artery disease, amlodipine significantly reduced the progression of mean maximal (M-max) IMT in three-year follow-up compared to placebo.

The MIDAS study²³ compared the effect of isradipine and hydrochlorothiazide on the rate of change of IMT in hypertensive patients and indicated that the rate of progression of M-max IMT did not significantly differ between the two treatment groups over three years. However, six months after randomization M-max increased significantly more in the diuretic group (a difference that

persisted over the entire three-year duration of the study). As a consequence, at the end of the study the average difference in M-max IMT change from baseline was significantly lower in the isradipine group despite a greater reduction in systolic blood pressure in the diuretic group.

Figure 79-3. Estimated treatment effect of lacidipine versus atenolol on mean maximum intima media thickness (IMT) of the four far walls in the distal common carotids and carotid bifurcations bilaterally (CBM_{max}), common carotid (CC), and carotid bifurcation (CB) IMT changes using repeated measurements model analysis. Mean changes over the treatment period (approximately four years; circles) and their 95% confidence intervals are illustrated by the bars. Values to the left of the 0 line indicate less progression with lacidipine. The intention-to-treat population consisted of all patients randomized to double-blind medication who had the baseline ultrasound scan and at least one follow-up scan, including scans performed after withdrawal (mean follow-up 3.75 years). The completer population was made up of patients who actually completed the four years of the study under randomized medication. (Modified from Agabiti-Rosei E, Trimarco B, Muiesan ML, et al. Cardiac structural and functional changes during long-term antihypertensive treatment with lacidipine and atenolol in the European Lacidipine Study on Atherosclerosis (ELSA). *J Hypertens* 2005;23:1091.)

Moreover, this significant difference was detectable in diseased segments, indicating that the calcium antagonist is more efficient than the diuretic in slowing down the progression of carotid lesions.

The VHAS²⁴ trial, which compared the effect of verapamil slow-release and chlorthalidone on IMT changes in hypertensive patients, indicated that at four-year follow-up the rate of change in carotid artery IMT (although tending to be smaller in the verapamil group) did not significantly differ compared to the chlorthalidone group. However, because in carotid arteries with M-max > 1.2 mm the rate of IMT progression during long-term treatment was dependent on baseline value, the slope of the regression rate of M-max changes related to initial M-max was significantly steeper in the verapamil compared to the chlorthalidone group. This finding indicated a greater effectiveness of the calcium antagonist in inducing a structural regression in the carotid wall, despite a blood pressure reduction similar to that observed with the diuretic.

In a subgroup of the INSIGHT study, common carotid artery IMT progressed significantly in patients treated with Co-Amilozide but not in those on nifedipine GITS for a follow-up ranging from two to four years.²⁵ Finally, the ELSA study (the largest available randomized double-blind long-term study) compared the effect of lacidipine and atenolol (associated with hydrochlorothiazide in about 35% of patients) on IMT and plaque of common carotid artery and carotid bifurcation of essential hypertensive

patients during four-year follow-up.²⁶ Treatment with lacidipine significantly reduced the four-year progression of IMT compared to atenolol treatment.

Moreover, patients with plaque progression were significantly less common (and patients with plaque regression significantly more common) in the lacidipine group. It is worth noting that although clinic blood pressure was similarly reduced by both treatments 24-hour ambulatory blood pressure was greatly reduced in the atenolol group. Therefore, this study was able to show a greater effect of lacidipine not only in slowing the progression of IMT but in plaque progression and regression (despite a smaller ambulatory blood pressure reduction). Such a finding supports the antiatherosclerotic action of lacidipine independently of its antihypertensive action. In conclusion, overall data from the previously described studies show uniform evidence of the beneficial action of calcium antagonists on atherosclerotic carotid lesions, with a superiority of these drugs over diuretic and β -blocker therapy.

Atherosclerosis of coronary arteries

Placebo-controlled studies, in which coronary atherosclerosis was assessed by coronary angiography, have given contrasting results. The INTACT study showed that nifedipine reduced the incidence of new lesions by 28% in a follow-up of one year,²⁷ and the Montreal study indicated that nifedipine reduced the progression of minimal lesions in patients with 5 to 7.5% stenosis in at least four coronary artery segments at two-year follow-up.²⁸ By contrast, in the PREVENT study treatment with amlodipine had no effect on angiographic progression of coronary atherosclerosis.²²

However, in a substudy of CAMELOT²⁹ (a double-blind randomized trial comparing amlodipine or enalapril with placebo in patients with angiographically documented coronary artery disease) the progression of arteriosclerosis was evaluated by intravascular ultrasound at baseline and after 24 months. The results showed a trend toward a lesser progression of atheroma volume in the amlodipine group versus placebo, with significantly less progression in the subgroup with systolic blood pressure greater than the mean. In the coronary calcification substudy of the INSIGHT trial,³⁰ total calcium score (measured by double-helical computed tomography) was significantly lower in the nifedipine-GITS-treated group than in the Co-Amilozide recipients during the first and third years (a finding that suggests that nifedipine GITS can slow the progression of coronary calcification). Thus, available data indicate that treatment with calcium antagonists exerts a modest or no effect on coronary atherosclerosis.

Finally, with regard to the REGRESS trial (a randomized placebo-controlled study aimed at evaluating the effect of two-year treatment with the statin pravastatin on progression/regression of angiographically documented atherosclerosis of patients with normal to moderately raised serum cholesterol), revision of the results indicated that the addition of various dihydropyridine and non-dihydropyridine calcium antagonists had a synergistic effect with pravastatin in retarding the progression of coronary atherosclerosis.³¹

Renal protection

Dihydropyridine calcium antagonists, and probably to a lesser extent non-dihydropyridine calcium antagonists, induce renal vasodilation and increase glomerular filtration rate (GFR) by relaxing the afferent arteriole. However, in hypertensive patients with preserved renal function this effect can impair renal autoregulation with no effect on (or even increase of) intra-glomerular pressure. In addition, calcium antagonists do not improve glomerular membrane permeability and selectivity, and thus lack any direct effect on proteinuria (as shown by drugs blocking the renin-angiotensin system). Therefore, the capacity of calcium antagonists to protect the kidney in hypertensive patients and in patients with diabetic and nondiabetic nephropathy may depend on the mere capacity of these drugs to reduce systemic blood pressure.^{32,33}

This possibility is clearly demonstrated by several controlled clinical studies that indicate that blood pressure reduction induced by calcium antagonists is a major mechanism leading to renal protection. A post hoc analysis of the SYST-EUR trial in older patients with isolated systolic hypertension indicates that blood pressure lowering with nitrendipine significantly reduced the risk of proteinuria (especially in diabetic patients) and the risk of mild renal dysfunction, with a slight but significant decrease in serum creatinine concentrations in patients with proteinuria at entry.³⁴ In addition, it is worth noting that after a mean follow-up of five years very strict and similar blood pressure control by enalapril or nitrendipine attained a similar degree of renal protection.^{35,36}

Post hoc analysis from the ALLHAT study indicates that in high-risk hypertensive patients with reduced GFR but with well-controlled blood pressure values (about 135 to 75 mmHg) the risk of end-stage renal disease (ESRD) (or = 50% GFR reduction) was similar in the total study population and diabetic subgroup independent of the treatment (chlorthalidone, amlodipine, or lisinopril).³⁷ However, the data on renal outcome from ALLHAT, which apparently contradict available evidence indicating the specific ability of drugs blocking the RAS to protect the kidney beyond blood pressure reduction,³⁸ should be cautiously evaluated due to the several limitations of this study—such as selection bias (patients with nephropathies treated with ACE inhibitors not enrolled), lack of acknowledgement of the underlying kidney disease, no data on proteinuria, and the great prevalence of cardiovascular events (which could have masked renal outcomes).³⁷

Moreover, these results contrast with other studies comparing calcium antagonists with diuretics in hypertensive patients. The INSIGHT trial showed that in spite of similar blood pressure control both the rate of decline in creatinine clearance and the occurrence of renal insufficiency were significantly lower in patients treated with nifedipine GITS compared to those receiving the diuretic combination hydrochlorothiazide and amiloride.³⁹ These data suggest that antihypertensive treatment based on a long-acting dihydropyridine calcium antagonist may offer better renoprotection than therapy based on diuretics.

This hypothesis is further supported by the results of SYST-EUR, which indicated that serum creatinine did

not change in patients on nitrendipine monotherapy but increased in patients treated with hydrochlorothiazide.³⁴ It is also supported by the NICS-EH study, which reported that abnormally elevated serum urea nitrogen was observed less frequently in patients treated with sustained-release nifedipine compared to those receiving a thiazide diuretic.⁴⁰ Finally, available evidence indicates that calcium antagonists can improve renal function in cyclosporine-treated patients.^{41,42}

Diabetic nephropathy

Primary prevention of the occurrence of incipient nephropathy does not seem to occur with calcium antagonists. The BENEDICT study demonstrated that verapamil does not prevent or delay the occurrence of microalbuminuria and does not enhance the beneficial effect of the ACE inhibitor trandolapril on prevention of diabetic nephropathy in type 2 diabetic patients with hypertension.⁴³

With regard to the progression of incipient to overt nephropathy, although calcium antagonists have no effect in type 1 diabetic patients with incipient nephropathy³² results in type 2 diabetics are more controversial. Available evidence indicates that dihydropyridine calcium antagonists, in reducing blood pressure, can reduce the urinary albumin excretion (UAE) rate³² and prevent the progression to overt nephropathy. It is worth noting that if blood pressure is strictly controlled^{35,36} or greatly reduced⁴⁴ this effect is basically the same as that observed with ACE inhibitors.

However, in type 2 diabetic patients when blood pressure is reduced but not perfectly controlled (as in the MARVAL study) valsartan (an AT-1 receptor antagonist) significantly reduced the UAE rate whereas amlodipine had no significant effect. In addition, valsartan induced regression to normoalbuminuria in a significantly greater proportion of patients than the calcium antagonist. This study therefore reinforces the view that blockade of the renin-angiotensin system adds a specific beneficial effect to blood pressure control as a means of reducing the UAE rate and thereby slowing down the progression to overt nephropathy and increasing regression to normoalbuminuria in type 2 diabetic patients with microalbuminuria.^{45,46}

As far as the prevention of progression to overt nephropathy is concerned, several studies performed in a small number of type 1 and type 2 diabetic patients with overt nephropathy indicated that calcium antagonists decrease or do not change either proteinuria or GFR in a relatively short-term follow-up.³² A four-year prospective study in a small number of hypertensive type 1 diabetic patients with overt nephropathy indicated that nisoldipine and lisinopril, although similarly reducing blood pressure, had a similar effect on the rate of decline in GFR (although only lisinopril significantly reduced proteinuria).⁴⁷ Moreover, a 4.5-year follow-up open study in a small number of hypertensive African Americans with type 2 diabetes indicated that verapamil sustained release significantly reduced the rate of decline in creatinine clearance and of creatinemia doubling compared to atenolol.⁴⁸

However, the IDNT study comparing irbesartan with amlodipine and placebo in a large number of hyper-

tensive type 2 diabetic patients indicated that given similar blood pressure reduction the AT-1 receptor antagonist was superior to the dihydropyridine calcium antagonist in reducing the doubling of serum creatinine and marginally the occurrence of ESRD. In addition, these endpoints did not differ between the amlodipine and placebo groups.⁴⁹

These results suggest that calcium antagonists do not exert a specific renal protective action beyond blood pressure reduction in hypertensive type 2 diabetic patients with overt nephropathy. However, as shown by the results of the RENAAL study dihydropyridine calcium antagonists are decisive in providing adequate blood pressure reduction without reducing the efficacy of the AT-1 receptor antagonist losartan on hard renal endpoints (including ESRD).⁵⁰ Thus, calcium antagonists can be effective and safely used in combination therapy, which is very often needed to control blood pressure in diabetic patients with nephropathy.

The results appear to be similar in patients with non-diabetic nephropathy. The AASK study,⁵¹ performed in African Americans with hypertensive renal disease, showed that ramipril was superior to amlodipine (despite a similar blood pressure control) in determining a significant reduction of GFR decline (the primary endpoint) as well as the rate of secondary endpoints, including GFR decline >50% or by 25 mL/min per 1.73 m² and ESRD. In addition, proteinuria increased in the amlodipine group but declined in the ramipril group during the first six months of treatment and thereafter tended to rise in both groups, although with a significantly greater increase in the amlodipine group. However, the superiority of the ACE inhibitor was detectable only in patients with baseline proteinuria, without a significant difference in non-proteinuric patients.⁵¹

Moreover, in the same study the rate of decline in GFR was slower for amlodipine than metoprolol in non-proteinuric patients, but faster for amlodipine than metoprolol in proteinuric patients. Finally, only in patients with proteinuria was the risk for ESRD or death significantly lower in the metoprolol group compared to the amlodipine group.⁵² Taken together, these results indicate that treatment with an ACE inhibitor, and to a lesser extent with a β -blocker, is superior to treatment with a dihydropyridine calcium antagonist in slowing the progression of proteinuria in hypertensive patients with nephroangiosclerosis. However, in non-proteinuric patients the calcium antagonist seems to have the same efficacy as the other two treatments.

Two other studies have confirmed the superiority of an ACE inhibitor compared to a dihydropyridine calcium antagonist in hypertensive patients with mild proteinuria and nondiabetic nephropathies. In a randomized double-blind study, at one-year follow-up enalapril (which greatly reduced blood pressure) significantly reduced proteinuria, whereas the latter was unmodified by manidipine (the rate and slope of creatinine clearance was similar with both treatments).⁵³ In addition, the ESPIRAL study demonstrated that fosinopril greatly reduced blood pressure values compared to nifedipine GITS, and significantly improved renal survival as evaluated by time to serum

creatinine doubling or dialysis while reducing proteinuria (which was unchanged by the calcium antagonist).⁵⁴ Finally, another controlled study in hypertensive patients with primary glomerulonephritis and heavy proteinuria demonstrated that only trandolapril, in monotherapy or even better if combined with verapamil, significantly reduced proteinuria (which was unchanged by verapamil and atenolol treatment).⁵⁵

It is therefore possible to conclude from the available information that hypertensive patients with diabetic or nondiabetic nephropathy, especially with microalbuminuria or proteinuria, should receive a compound blocking the renin-angiotensin system as a first-line therapy.⁵⁶ However, calcium antagonists must be considered part of a combination therapy that will be required in most patients to reach target blood pressure control.

EFFECTS OF CALCIUM ANTAGONISTS ON CLINICAL EVENTS

Placebo-controlled studies indicate that calcium-antagonist-based therapy reduces major cardiovascular events and cardiovascular death, as well as the total rate of stroke and all cardiac endpoints in elderly hypertensive patients.³ As shown in Table 79–1, results from meta-analyses of placebo-controlled trials indicate that conventional therapy based on diuretics and β -blockers,⁵⁷ ACE inhibitors,⁵⁸ and calcium antagonists⁵⁸ similarly reduced cardiovascular outcomes. Furthermore, a recent meta-analysis of placebo-controlled trials in diabetic patients indicates that calcium antagonists reduce the risk of stroke by 53%, coronary artery disease by 40%, major cardiovascular events by 28%, cardiovascular deaths by 46%, and total mortality by 17%.⁵⁹

The benefit achieved in these placebo-controlled studies was related to the degree of blood pressure reduction.^{57,58} In addition, greater risk reductions were produced by regimens targeted to reach lower blood pressure goals.⁵⁸ Taken together, these results indicate that blood pressure lowering is the major component of the benefit of anti-hypertensive drug treatment, including that with calcium antagonists.^{5,60} However, the results of these meta-

analyses indicate that calcium antagonists do not reduce (or even tend to increase) the risk of heart failure, whose incidence was independent of blood pressure reduction.^{58,59} However, the lack of protective action of calcium antagonists on heart failure (despite blood pressure reduction) is apparently contradicted by the results of the ACTION trial, which aimed to investigate the effect of long-acting nifedipine GITS in patients with stable angina receiving antianginal drugs (including β -blockers in about 80% of patients).⁶¹

This study showed that at 4.9-year follow-up nifedipine GITS, although reducing blood pressure by 5/3 mmHg, did not change fatal and nonfatal coronary events and total mortality but achieved a significant 29% reduction in new overt heart failure (a component of primary combined endpoint) as well as an 18% reduction in coronary angiography and a 21% reduction in coronary bypass surgery (two secondary endpoints).⁶¹ Moreover, a predefined subgroup analysis of hypertensive patients (baseline blood pressure values $\geq 140/90$ mmHg) indicated that nifedipine GITS significantly reduced new overt heart failure by 38%, any stroke or transient ischemic attacks (TIA) by 28%, and debilitating stroke by 33%—without affecting the rate of all-cause death, cardiovascular death, and myocardial infarction.⁶²

Therefore, in agreement with the results of other placebo-controlled studies in patients with stable coronary artery disease^{22,29,63,64} long-acting dihydropyridine calcium antagonists appear to be safe, do not increase the risk of hard coronary outcomes, and offer the additional advantage of reducing angina-related events such as hospitalization for unstable angina^{22,29} and revascularization procedures.^{22,29,63,64} Although the direct effect of calcium antagonists on heart failure (tested in placebo-controlled trials) is still an open question,⁵⁸ results from studies designed to provide drug class comparison indicate that calcium antagonists provide less protection from heart failure compared to conventional therapy or ACE inhibitors.⁵⁸

On the question of the clinical efficacy of calcium antagonists compared to other drug classes, seven large long-term controlled clinical trials based on cardiovascular outcomes allow a comparison of calcium antagonists

PERCENT RISK REDUCTION IN CARDIOVASCULAR EVENTS INDUCED BY ACTIVE TREATMENT WITH CONVENTIONAL THERAPY ACE INHIBITORS AND CALCIUM ANTAGONISTS VERSUS PLACEBO			
Outcome	Conventional Therapy ^{a,57}	ACE Inhibitors ⁵⁸	Calcium Antagonists ⁵⁸
Stroke	–38	–28	–38
Coronary heart disease	–16	–20	–22
Heart failure	Not assessed	–18	+21 ^b
Major cardiovascular events	Not assessed	–22	–18
Cardiovascular deaths	–21	–20	–22
Total mortality	–12	–12	–11 ^b

a. Conventional therapy is based principally on diuretics and beta blockers.
b. Not significant.

Table 79–1. Percent Risk Reduction in Cardiovascular Events Induced by Active Treatment with Conventional Therapy ACE Inhibitors and Calcium Antagonists Versus Placebo

versus conventional therapy,⁶⁵⁻⁶⁸ ACE inhibitors,^{65,69,70} and ARB.⁷¹ Data obtained so far show no difference in primary endpoints between calcium antagonists and other drug classes (Table 79–2). However, a differential effect of calcium antagonists compared to the other drug classes can be observed on different cardiovascular outcomes.

A recent prospectively designed meta-analysis, and therefore not biased by *a posteriori* selection of trials, including nine studies comparing calcium antagonists with conventional therapy and six studies comparing calcium antagonists with ACE inhibitors showed that the risk of major cardiovascular events and cardiovascular and total mortality was similar when calcium-antagonist-treated groups were compared to those on conventional therapy or ACE inhibitors.⁵⁸ Moreover, another randomized controlled study (INVEST, not included in the meta-analysis) compared outcomes in older hypertensive patients with coronary artery disease treated with a verapamil- or atenolol-based strategy (both treatments being mainly associated with an ACE inhibitor and a thiazide diuretic).

The results of this study showed that the rate of cardiovascular and total mortality did not differ between the two treated groups.⁷⁰ Finally, the VALUE trial (a randomized double-blind study performed in hypertensive patients at high cardiovascular risk) was designed to test the hypothesis that with the same blood pressure control an ARB (valsartan) would reduce cardiac mortality and morbidity more than a dihydropyridine calcium antagonist (amlodipine). The results at a 4.2-year follow-up showed that although blood pressure was greatly reduced in the amlodipine arm cardiovascular and total mortality did not differ between the treated groups.⁷¹

Overall, these data indicate that Ca-antagonist-based treatment exerts an effect on cardiovascular and total

mortality similar to that exerted by treatments based on conventional therapy, ACE inhibitors, and ARBs. The data on coronary artery disease (CAD) events are even more interesting, considering the past controversy on the possible adverse effect of calcium antagonists on this outcome.⁷²

The result from the previously quoted meta-analysis⁵⁸ indicates that the risk of coronary artery disease events in calcium-antagonist-treated patients did not differ from that of patients receiving conventional therapy or ACE inhibitors, a finding in agreement with the more recent INVEST⁷⁰ study (not included in the meta-analysis). Moreover, a post hoc analysis from the ALLHAT study showed that given similar blood pressure control the primary outcome of fatal CAD and nonfatal myocardial infarction did not differ between amlodipine and lisinopril in essential hypertensive patients with CAD at baseline.

However, a very recent meta-analysis—including 14 placebo-controlled studies (six with calcium antagonists and eight with ACE inhibitors) and 18 studies comparing conventional therapy versus calcium antagonists (13 studies) or ACE inhibitors (5 studies) and modeling the risk of coronary artery disease on group difference in achieved systolic blood pressure—indicated that (1) the risk of coronary artery disease was not significantly different between regimens based on calcium antagonists and conventional therapy, (2) the risk of coronary artery disease decreased by 15% per 10 mmHg reduction in systolic blood pressure, and (3) independently of blood pressure difference ACE inhibitors were superior to calcium antagonists in the prevention of coronary artery disease.⁷³

In the VALUE trial, the risk of myocardial infarction was significantly greater in the valsartan-treated patients compared to those receiving amlodipine.⁷¹ This difference was partially but not fully explained by differences in blood pressure control.⁷⁴

CONTROLLED CLINICAL TRIALS OF CARDIOVASCULAR OUTCOMES COMPARING CALCIUM ANTAGONISTS WITH OTHER DRUG CLASSES IN HYPERTENSIVE PATIENTS			
Study	Drugs	Primary Endpoint	Relative Risk (95% CI)
STOP-2 ⁶⁵	Felodipine, isradipine vs D/βB	Fatal stroke, MI, and other CV deaths	0.97 (0.80–1.17)
STOP-2 ⁶⁵	Enalapril, lisinopril, vs D/βB	Fatal stroke, MI, and other CV deaths	1.01 (0.84–1.22)
NORDIL ⁶⁶	Diltiazem vs D/βB	Fatal stroke, MI, and other CV deaths	1.00 (0.87–1.15)
CONVINCE ⁶⁸	Verapamil vs atenolol/HCTZ	First occurrence of stroke and MI, CV mortality	1.02 (0.88–1.18)
INVEST ⁷⁰	Verapamil vs atenolol	CHD morbidity and mortality	1.02 (0.92–1.15)
INSIGHT ⁶⁷	Nifedipine vs HCTZ/amiloride	CV mortality, MI, HF, stroke	1.10 (0.91–1.34)
ALLHAT ⁶⁹	Chlorthalidone vs amlodipine	CHD morbidity and mortality	0.99 (0.91–1.08)
ALLHAT ⁶⁹	Lisinopril vs amlodipine	CHD morbidity and mortality	1.01 (0.91–1.11)
VALUE ⁷¹	Valsartan vs amlodipine	CHD morbidity and mortality	1.04 (0.94–1.15)

Abbreviations: CI, confidence intervals; MI, myocardial infarction; CV, cardiovascular; CHD, coronary heart disease; HF, heart failure; D, diuretics; βB, beta-blockers; HCTZ, hydrochlorothiazide; and ACE-I, angiotensin-converting enzyme.

Table 79–2. Controlled Clinical Trials of Cardiovascular Outcomes Comparing Calcium Antagonists with Other Drug Classes in Hypertensive Patients

Finally, the MOSES study was a randomized open trial in a relatively small number of hypertensive patients with a history of documented cerebrovascular disease. The study compared an ARB (eprosartan) with nitrendipine, which showed at four-year follow-up that cardiovascular events (mainly including acute coronary syndrome and heart failure) were significantly lower in the eprosartan compared to the nitrendipine arm.⁷⁵ It can therefore be concluded that long-acting calcium antagonists are as effective as other drug treatments for prevention of coronary artery disease in hypertensive patients, a finding that strongly contradicts the hypothesis of a possible negative effect of these drugs on coronary artery disease events. However, the possibility exists that beyond blood pressure reduction treatment with ACE inhibitors is superior to that with calcium antagonists in preventing coronary artery disease events.

With regard to the prevention of cerebrovascular disease, meta-analyses indicate a marginally lower risk of stroke in calcium-antagonist-treated patients compared to those receiving conventional therapy^{58,76} and ACE inhibitors.⁵⁸ A more recent meta-analysis, including 13 studies comparing calcium antagonists with other antihypertensive treatments, showed a 10% significant reduction in the risk of stroke in patients treated with calcium antagonists. This beneficial effect was unrelated to the degree of systolic blood pressure reduction.⁷⁷ The superiority of calcium antagonists compared to conventional therapy and ACE inhibitors in reduction of the risk of stroke is further confirmed by the previously quoted meta-analysis.⁷³

In the VALUE trial, the risk of fatal and nonfatal stroke was marginally lower in the amlodipine than in the valsartan group⁷¹—a difference that can be explained by differences in blood pressure control.⁷⁴ However, in the MOSES study given the same blood pressure reduction total cerebrovascular events (including recurrent events, but not first cerebrovascular events) were significantly lower in the eprosartan compared to the nitrendipine arm.⁷⁵ One may therefore conclude that calcium antagonists seem to be more effective compared to conventional therapy and ACE inhibitors in stroke prevention, whereas comparative data with AT-1 receptor antagonists are too scanty to draw definitive conclusions.

Decisive demonstration of the effectiveness of calcium-antagonist-based treatment derives from the ASCOT-BPLA trial, which compared amlodipine-based treatment (plus perindopril in about 50% of patients) with atenolol-based treatment (plus bendroflumethiazide in about 55% of patients) in hypertensive patients with moderately high cardiovascular risk.⁷⁸ This study, which was stopped prematurely after 5.5 years of median follow-up owing to a significant difference in mortality in the two treatment arms, showed that amlodipine-based treatment [although not significantly reducing (10%) the primary endpoint of nonfatal myocardial infarction plus fatal coronary artery disease] significantly decreased secondary endpoints, including nonfatal myocardial infarction (excluding silent myocardial infarction) plus fatal coronary artery disease (–13%), total coronary events (–13%), total cardiovascular events and procedures (–16%), all-cause mortality

(–11%), and cardiovascular mortality (–24%) and fatal and nonfatal stroke (–23%). It also decreased tertiary endpoints, such as unstable angina (–32%), peripheral arterial disease (–35%), development of diabetes (–30%), and renal impairment (–15%).

Therefore, the ASCOT-BPLA study shows the superiority of an antihypertensive regimen based on a dihydropyridine calcium antagonist (with the combination of an ACE inhibitor when necessary) compared to a beta-blocker-based treatment with the eventual addition of a thiazide diuretic for the prevention of most cardiovascular events associated with hypertension.⁷⁸ It is worth noting that the beneficial effect of the calcium antagonist is partially but not fully explained by the different effect not only on blood pressure but on other cardiovascular risk factors, including high density lipoprotein (HDL) cholesterol, triglycerides, glucose, potassium, and body weight.⁷⁹

COMPLICATIONS

Calcium antagonists are generally well-tolerated compounds. Among possible side effects caused by this drug class, the most common manifestations are related to vasodilation (observed particularly with the dihydropyridines). These main side effects include headache, flushing, and reflex tachycardia.⁴ They are usually benign, appear with the first dosing, and spontaneously disappear in a few days. From a clinical point of view, a more troublesome adverse effect of dihydropyridine calcium antagonists is ankle edema.

Usually, this side effect appears after several weeks of treatment and is specifically related to arteriolar vasodilation. It is dose dependent, and available evidence suggests that it is less evident with newer calcium antagonists (including lacidipine, lercanidipine, and possibly barnedipine). Although ankle edema is not dangerous for the patient, it can determine some discomfort or cause esthetic problems. If the patient tolerates this side effect, treatment can be continued. However, another possibility is to add an ACE inhibitor or an AT-1 receptor antagonist (which can reduce the severity of ankle edema). It is also important to note that given the mechanistic cause of the ankle edema the association of diuretic treatment is totally ineffective. Finally, although diltiazem treatment sometimes induces ankle edema (although with a lesser incidence compared with dihydropyridine calcium antagonists) such an effect is only very rarely observed with verapamil.

Non-dihydropyridine calcium antagonists may have side effects related to the specific cardiac mechanism of action.¹ Verapamil and diltiazem can lead to bradycardia, atrioventricular block, and worsening of congestive heart failure. It is therefore important to assess heart rate and P-R interval on EKG before administering one of these compounds. In addition, if the patient has clinical symptoms that could be related to heart failure it is crucial to evaluate left ventricular function by echocardiography. As well as these expected side effects, verapamil treatment can also induce constipation, which is usually not seen with diltiazem or dihydropyridines. However, this characteristic of verapamil can be useful when treating patients with chronic diarrhea.

Another side effect specifically related to calcium antagonist treatment is gingival hypertrophy. This effect is not frequent, but it occurs both with dihydropyridines and non-dihydropyridines. It is reversible by withdrawal of treatment. Other less common side effects may include digital dysesthesia, nausea, and occasionally minor elevation of the liver function test.

A special comment is needed concerning massive utilization of sublingual nifedipine in hypertensive emergencies. This treatment is extremely dangerous because the rapid and powerful vasodilating effect can frequently cause cerebrovascular or coronary ischemia, and in any case there is little or no absorption of the drug from the buccal mucosa. Because in most cases the urgent reduction of blood pressure values is overestimated the utilization of sublingual nifedipine should be avoided in common clinical practice and reserved as a procedure for selected and monitored patients in emergency care units.

Finally, it is necessary to consider some harmful drug interactions. Earlier, attention was drawn to the dangerous combination between verapamil or diltiazem and beta blockers, which can sum their effects of heart rate, A-V conduction, and left ventricular contractility. In addition, verapamil (and sometimes other calcium antagonists) can cause an increase in plasma digoxin concentrations, although toxicity from the cardiac glycoside rarely develops.

In conclusion, calcium antagonists are well-tolerated compounds with very few side effects. It is also important to observe that although some of the side effects may cause discomfort for the patients none of these effects is life-threatening, and the physician has the possibility of adjusting the treatment without serious and/or permanent damage to patients.

SUMMARY

Calcium antagonists are very effective antihypertensive drugs. These compounds can be divided into dihydropyridine and non-dihydropyridine calcium antagonists. Dihydropyridines are pure vasodilators, whereas non-dihydropyridines (verapamil and diltiazem) are associated with a lesser ability to vasodilate (with a chronotropic,

dromotropic, and inotropic effect). However, all calcium antagonists induce a significant dose-dependent reduction in blood pressure values (with few and non-life-threatening side effects). The main adverse reaction caused by these compounds is ankle edema, which although discomforting is not dangerous to patients.

Usually, no specific indication exists for the utilization of calcium antagonists because these compounds are effective in any form of hypertension—including secondary hypertension, sodium repleted hypertension, black and elderly patients, and pregnancy-induced hypertension (although in this case the evidence is limited to nifedipine). Dihydropyridine calcium antagonists are effective as combination therapy with all the other antihypertensive drug classes, with the exclusion of diuretics (except in patients with heart failure). In contrast, non-dihydropyridine calcium antagonists cannot be associated with beta blockers, to avoid the sum of the cardiac effects.

The clinical relevance of these compounds is supported by the evidence that calcium antagonists are as effective as ACE inhibitors and AT-1 receptor antagonists in reversing left ventricular hypertrophy. In addition, they show antiatherosclerotic properties, probably related to their antioxidant properties and the consequent restoration of endothelial function. Evidence from clinical trials indicates that these compounds are effective in reducing the occurrence of stroke and myocardial infarction, whereas discordant results are available on the prevention of heart failure. Calcium antagonists have no specific effects in protecting renal function, as observed with drugs blocking the renin angiotensin system, but they can be useful in treating patients with diabetic and nondiabetic nephropathy because of their ability to lower blood pressure values.

In the future it will be necessary to investigate whether some specific characteristic of calcium antagonists, including their antiatherosclerotic activity, might be clinically relevant. However, only results from large numbers of patients and especially a more prolonged period of observation will give further information on the possible clinical implications of calcium antagonist treatment.

Chapter
80Angiotensin-Converting Enzyme
Inhibitors

Alan H. Gradman and Darren Traub

Key Findings

- Angiotensin-converting enzyme inhibitors (ACE inhibitors) inhibit the conversion of the inactive decapeptide angiotensin I to the active vasopressor angiotensin II. ACE inhibitors also prevent the breakdown of bradykinin, a potent endothelium-dependent vasodilator.
- Although the 12 currently available ACE inhibitors differ in their pharmacokinetics and pharmacodynamics, all ACE inhibitors are capable of producing a clinically effective blood pressure (BP) response when dosed appropriately.
- ACE inhibitors effectively reduce BP and cardiovascular endpoints in unselected patients with hypertension.
- Currently, ACE inhibitors are the only drug class recommended for all of the “compelling indications” in the recent JNC-7 hypertension guidelines.
- Experimental models and clinical trials have shown that ACE inhibitors effectively reduce target organ pathology, including regression of left ventricular hypertrophy and fibrosis, reversal of vascular hypertrophy, reduction of proteinuria, and the development of end-stage renal disease.
- ACE inhibitors are recognized as preferred treatment for patients with hypertension complicated by heart failure; coronary artery disease or history of myocardial infarction (MI); diabetes; or chronic kidney disease. It is also used for recurrent stroke prevention (JNC-7).
- The maximum BP response to ACE inhibitors is achieved in approximately four to six weeks.
- By activating the renin-angiotensin system, low-dose diuretics combined with ACE inhibitors produce additive BP reduction and improve responder rates to ACE inhibition.
- In patients with renal insufficiency, an initial rise in serum creatinine (SCr) of up to 30% above baseline levels can be expected with initiation of ACE inhibitor therapy. This elevation of SCr usually stabilizes within two to three weeks and represents a hemodynamic (not a toxic) effect.
- ACE inhibitors are well tolerated by a broad population of hypertensive patients. The most common side effect is a persistent nonproductive cough, reported in 0.5 to 20% of patients.

INTRODUCTION

The first ACE inhibitor, teprotide, was derived from the venom of the Brazilian arrowhead viper (*Bothrops jararaca*).¹ When it became available for clinical testing in

1973, the role of the renin-angiotensin system (RAS) as an endocrine system involved in the regulation of BP and volume status had been established for almost a century.² Activation of the RAS induced by experimental renal artery stenosis had been shown to produce marked hypertension, and it was originally postulated that inhibiting the RAS would be beneficial primarily in treating renovascular hypertension. The wider therapeutic potential of inhibiting ACE became apparent following the observation that teprotide effectively lowered BP in patients with essential hypertension.

Almost 25 years after their introduction, the role of ACE inhibitors in cardiovascular medicine continues to expand as new beneficial effects are discovered, tested in animal models, and evaluated in clinical trials. ACE inhibitors have been shown to reduce BP and cardiovascular endpoints in unselected patients with hypertension. They are among the most effective category of anti-hypertensive drugs. In the recent JNC-7 report, ACE inhibitors are the only drug class recommended for all of the six categories of “compelling indications” for which directed drug therapy is advised.³

ACE inhibitors have been shown to improve symptoms and survival in patients with heart failure, decrease proteinuria and the progression of both diabetic and non-diabetic renal disease, reduce myocardial infarction (MI) and post-infarction ventricular remodeling in patients with coronary artery disease, decrease the incidence of new-onset diabetes, reduce the progression of diabetic retinopathy, and in conjunction with diuretics attenuate the risk of stroke and transient ischemic attacks in patients with symptomatic cerebrovascular disease. Importantly, these achievements are obtained with a favorable side effect profile that allows ACE inhibitors to be well tolerated by the vast majority of treatment-eligible patients.^{4–12}

The importance of angiotensin II in the pathogenesis of atherosclerosis, left ventricular hypertrophy, vascular/ventricular remodeling, and glomerulosclerosis has placed the RAS and drugs that block its effects at the center of investigation of virtually all aspects of hypertensive disease and its complications.¹³ Evidence that the RAS plays a critical role in the development of the structural precursors of cardiovascular complications in the hypertensive population has led to interest in the ability of ACE inhibitors to produce therapeutic benefits beyond those achieved through BP reduction alone.

It is now generally accepted that the effectiveness of ACE inhibitors in slowing the progression of renal disease

is due to a combination of antihypertensive and organ-specific effects. Likewise, their ability to confer protection against the occurrence of MI in high-risk populations is apparently due to direct effects on the vasculature in addition to BP reduction. Further delineation of the direct organ protective effects of ACE inhibitors remains an area of active investigation.¹³

MECHANISM OF ACTION

ACE inhibitors competitively inhibit ACE, thus preventing the conversion of the inactive decapeptide angiotensin I to the active octapeptide vasopressor angiotensin II. ACE inhibitors also prevent the breakdown of the endothelium-dependent vasodilator bradykinin (Figure 80–1).

Pharmacodynamics

Humoral effects

ACE inhibitors inhibit the conversion of the inactive decapeptide angiotensin I to the active octapeptide angiotensin II. Following ACE inhibitor administration, the pressor response to intravenous infusion of angiotensin I (but not angiotensin II) is blocked. Short-term administration of ACE inhibitors causes a reduction in plasma and tissue angiotensin II levels. Plasma aldosterone levels are also reduced.^{14–16} These changes, along with increases in circulating bradykinin, account for the immediate hemodynamic effects of ACE inhibitors.¹⁷

Over a period of days to a few weeks, loss of negative feedback inhibition by angiotensin II results in an increase in plasma renin activity (PRA) and circulating levels of angiotensin I, the ACE substrate. Driven by increased substrate availability and elaboration via non-ACE enzymatic pathways such as chymase, angiotensin II reaccumulates in the plasma during chronic dosing. Circulating levels of angiotensin II and aldosterone often return to pre-therapeutic levels, particularly at trough drug concentrations.^{14,16,18,19} Despite this phenomenon of “ACE escape,” BP reduction and other favorable hemodynamic alterations are maintained with chronic therapy, indicating that suppression of circulating angiotensin II does

not fully explain the antihypertensive effect of ACE inhibitors.^{14–16,19}

Role of bradykinin

ACE, also referred to as kininase II, is the principal enzyme responsible for the metabolism of bradykinin (a potent endothelium-dependent vasodilator). Bradykinin induces vasodilation by stimulating production of nitric oxide, the arachidonic acid metabolites prostacyclin (PGI-2) and PGE-2, and endothelium-derived hyperpolarizing factor. The brief duration of action and rapid degradation of bradykinin (plasma half-life of 15 to 30 seconds) has made it difficult to investigate its role in ACE inhibitor therapy.^{14,20–22} Development of bradykinin receptor antagonists has helped clarify the important contribution of bradykinin to the acute and chronic actions of ACE inhibitors.¹⁴ In normotensive and hypertensive salt-depleted subjects, addition of the selective BK₂ receptor antagonist icatibant (HOE 140) significantly reduced the acute hypotensive effect of captopril.¹⁷

Small studies in heart failure patients demonstrate blunting of the vasodilatory effects of chronic ACE inhibition following infusion of bradykinin receptor antagonists.^{20,22} In dog models of heart failure induced by right ventricular pacing, animals receiving a bradykinin receptor antagonist in conjunction with enalapril developed increased cardiac fibrosis (types I and III collagen deposition) and increased left ventricular filling pressures compared to dogs receiving enalapril alone.²³ Animal models also suggest that bradykinin has anti-fibrotic effects in the renal interstitium.²⁴ Increased bradykinin levels may contribute to the anti-thrombotic properties of ACE inhibitors by increasing endothelial tPA release.^{25,26} Bradykinin is thought to be responsible for ACE-inhibitor-induced cough and for the infrequent but clinically serious adverse reaction of angioedema.²⁷

Hemodynamic effects

The acute hemodynamic effects of ACE inhibitors are the result of inhibition of angiotensin II formation and prevention of bradykinin degradation.^{14,17,28} Vasoconstriction is reduced in both small and large arteries, with resultant decline in systemic vascular resistance. Venous capacitance is increased through venodilation.^{28,29} In contrast to direct-acting vasodilators, ACE inhibitors do not provoke reflex tachycardia or increases in cardiac contractility. Baroreceptor function and cardiovascular reflexes are maintained, and responses to postural changes and exercise are virtually unimpaired. Vasodilation (without a compensatory increase in cardiac output) leads to a reduction in systolic, diastolic, and mean arterial BP.^{28,30}

The magnitude of the initial BP reduction correlates positively with pre-treatment PRA and angiotensin II levels. Patients with a highly activated renin-angiotensin system caused by salt and water depletion or other conditions demonstrate an exaggerated acute hypotensive response to ACE inhibitors.^{14,28,31} With chronic administration, BP continues to decline for a period of four to six weeks. In contrast to the acute effects, BP reduction with chronic administration is independent of pretreatment PRA.^{14,16,28,32,33}

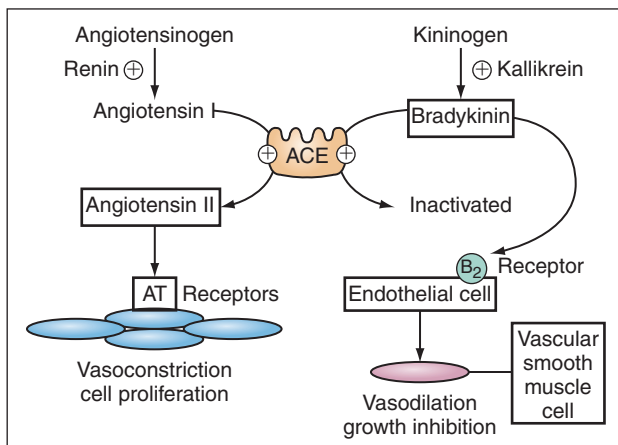

Figure 80–1. Mode of action of ACE inhibition.

Structure activity relationships

ACE inhibitors are structurally heterogeneous molecules, of which 12 chemical entities are currently available in the United States and/or the European Union (EU). All ACE inhibitors reduce ACE activity by competitive inhibition, achieved by binding to the zinc ion on the active site of the ACE molecule. The agents can be divided into three classes according to the functional group that serves as the ligand for ACE: sulfhydryl-, carboxyl-, and phosphinyl-containing groups. Captopril, the first available ACE inhibitor, and zofenopril are the only approved agents with a sulfhydryl group serving as a ligand for the ACE molecule. Fosinopril is the only agent with a phosphinyl group. All other ACE inhibitors use a carboxyl group to bind to ACE.

The potency of an ACE inhibitor is determined by the zinc ligand as well as the number and chemical structure of auxiliary binding sites, which further enhance the ACE/drug interaction. Although the strength of binding between the sulfhydryl group and the zinc ion is greater than that for the carboxyl group, enalapril and other carboxyl analogues are actually more potent than captopril because of their additional binding sites. Differences in potency, however, are of little clinical relevance. A similar degree of ACE inhibition can be achieved by adjusting drug dosage.^{34–37} Captopril's sulfhydryl moiety appears to be responsible for the side effects of dysgeusia and maculopapular skin rash seen with this agent.³⁸

Pharmacokinetics

ACE inhibitors differ in their absorption, bioavailability, time to onset of action, duration of action, lipophilicity, and mode of elimination (see Table 80–1). The lipophilicity of an ACE inhibitor may influence the degree of tissue penetration and distribution.^{16,34,35} With the exception of captopril and lisinopril, all ACE inhibitors are administered as ester-containing pro-drugs. In general, these pro-drugs have greater oral bioavailability compared to their active metabolites. They remain biologically inactive until hydrolyzed in the liver or the gastrointestinal mucosa by first-pass metabolism into their active diacid form. The active form is designated by the suffix *at* (e.g., enalaprilat).

Patients with severe hepatic dysfunction may not be able to adequately activate the pro-drug or may have a significant delay in activation. This problem has not been reported in patients with stable modest liver dysfunction. Although neither captopril nor lisinopril require hepatic activation, only lisinopril has almost exclusive renal elimination and may provide the most predictable pharmacokinetics in cirrhotic patients.^{34,35}

Differences in bioavailability exist among ACE inhibitors. This has limited clinical significance if appropriate doses of an agent are used. Captopril and moexipril have potential drug/food interactions. A 50% decrease in the rate, but not necessarily the extent, of absorption may occur with either agent. These drugs should be administered one hour before meals.³⁵

All ACE inhibitors are capable of producing clinically relevant BP reduction. The dose-response curve for ACE

inhibitors is relatively steep at lower doses and flattens considerably as the plateau is approached. There is no convincing evidence for greater maximum BP-reducing potency of one ACE inhibitor versus another provided each drug is administered at a dose that reaches the plateau of the dose-response curve.^{16,34,39}

The duration of clinically significant BP reduction differs among ACE inhibitors. Results of 24-hour BP monitoring studies indicate that fosinopril, lisinopril, perindopril, ramipril, andtrandolapril can be administered once daily. Captopril, enalapril, benazepril, quinapril, and moexipril often require twice-daily dosing to achieve sustained BP reduction over a 24-hour period.^{34,35,40} At higher doses, further up-titrating the dose of an ACE inhibitor will produce little incremental effect in peak BP reduction but may favorably extend the duration of BP response. By taking advantage of this dose-response relationship, shorter-acting drugs such as enalapril or benazepril can be used as once-a-day medications provided high-enough doses are given.^{39,32}

Most ACE inhibitors have dual routes of elimination via the renal and hepatobiliary systems. ACE inhibitors are predominantly excreted as active compounds. The molecular size and lipophilicity of an ACE inhibitor influence the route of elimination. Larger molecular size and higher lipophilicity increase biliary excretion. When one route of elimination is compromised, accumulation of active drug may occur. Fosinopril is the only ACE inhibitor in which there is a compensatory increase in hepatobiliary elimination in the setting of renal insufficiency. Thus, total body clearance of fosinopril does not appreciably differ with any degree of renal insufficiency, permitting the use of the usual dosage in patients with any degree of renal impairment. All other ACE inhibitors require an initial dosage reduction, usually by one-half, when administered to patients with moderate to severe renal insufficiency. Plasma clearance oftrandolapril is reduced in patients with either renal or hepatic insufficiency, requiring a lower starting dose.^{33,35}

Organ-specific effects of ACE inhibitors

Renal

The effects of ACE inhibitors on renal hemodynamics are a consequence of blocking angiotensin II formation. Experimental evidence indicates that a significant contribution to the renal effects is accounted for by local ACE inhibition in the renal parenchyma.⁴¹ ACE inhibitors reduce mesangial cell contractility, thereby increasing glomerular capillary area.⁴² Renal vascular resistance is decreased and renal blood flow increases in many patients. ACE inhibitors dilate postglomerular efferent arterioles to a greater degree than the preglomerular afferent arterioles.

This discrepancy in vasodilation results in a net reduction in glomerular capillary hydrostatic pressure. As a consequence, GFR remains the same or falls despite the overall increase in renal plasma flow. The reduction in glomerular filtration rate (GFR) may lead to an increase in serum creatinine concentration, usually less than 10 to 20%. This reflects the renal hemodynamic effects of ACE

PHARMACOKINETICS OF ACE INHIBITORS									
Drug	Hypertension	Heart Failure/ LV Dysfunction	Labeled Indications Diabetic Nephropathy	Risk Prevention*	Duration of Action (h)	Serum Half-life (h)	Dosing for Hypertension	Elimination	
Sulphydryl-containing Captopril	✓	✓, ✓ ¹	✓		6 – 10 ³	<2	25–50 mg bid - tid	renal	
Zofenopril	✓				24	5–6	7.5–30 mg in 1–2 doses	renal + hepatic	
Carboxyl-containing Benazepril	✓				24 ³	11	10–40 mg in 1–2 doses	primarily renal	
Cilazapril	✓				24	9	2.5–10 mg once daily	renal	
Enalapril	✓	✓, ✓ ²			12–24 ³	11	5–40 mg in 1–2 doses	renal	
Lisinopril	✓	✓			24	11–12	10–40 mg once daily	renal	
Moexipril	✓				24	2–9	7.5–30 mg in 1–2 doses	hepatic > renal	
Perindopril	✓			✓	24	3–10	2–8 mg once daily	renal	
Quinapril	✓	✓			24	2	10–80 mg in 1–2 doses	renal	
Ramipril	✓	✓ ¹		✓	24	13–17	2.5–20 mg in 1–2 doses	renal > hepatic	
Trandolapril	✓	✓ ¹			24	10	1–4 mg once daily	renal > hepatic	
Phosphinyl-containing Fosinopril	✓	✓			24	12	10–80 mg once daily	renal = hepatic ⁴	

* = Reduce risk of MI, stroke, and death from cardiovascular causes.

1 = Post-myocardial infarction.

2 = Asymptomatic LV dysfunction.

3 = Dose related.

4 = Compensatory hepatobiliary excretion in the setting of renal insufficiency.

Table 80–1. Pharmacokinetics of ACE Inhibitors and labeled indications

inhibition (not renal toxicity). ACE inhibitors promote natriuresis by decreasing proximal tubular and collecting-duct Na⁺ reabsorption and by blocking activation of adrenal AT₁ receptors by angiotensin II. The resulting reduction in aldosterone release leads to decreased sodium reabsorption and potassium excretion in the collecting ducts.⁴³

Reduction of intraglomerular hypertension is of paramount importance to the renal protective action of ACE inhibitors. Elevated intraglomerular pressure caused by hyperfiltrating states such as diabetes or a reduction in nephron mass impairs the size-selective function of the glomerular permeability barrier and causes protein ultrafiltration. The excessive protein traffic activates tubular epithelium, leading to elaboration of inflammatory and pro-fibrotic cytokines. The net effect is fibroblast proliferation, increased synthesis, and decreased breakdown of extracellular matrix proteins in the mesangium and interstitium (leading to glomerulosclerosis and interstitial fibrosis).⁵

Control of systemic hypertension does not necessarily translate into reduction of intraglomerular hypertension. Animal models of two-thirds nephrectomy have demonstrated that control of systemic BP with vasodilators and a diuretic, both of which elevate plasma renin levels, leads to angiotensin-II-mediated efferent arteriolar vasoconstriction and continued intraglomerular hypertension. When ACE inhibitors were administered at doses producing an equivalent reduction in systemic BP, glomerular capillary pressure returned to near-normal values. In this model, ACE inhibition prevented proteinuria and the development of glomerulosclerosis. Triple antihypertensive therapy without ACE inhibition led to proteinuria and glomerulosclerosis similar to untreated controls.⁴⁴ Animal models and human studies have demonstrated that the renal protection afforded by ACE inhibitors is associated with a reduction in the expression of both plasminogen activator inhibitor (PAI-1) and the growth factor TGF- β .⁴⁵⁻⁴⁷

Left ventricular hypertrophy and fibrosis

In spontaneously hypertensive (SHR) rats, early administration of ACE inhibitors to young animals who do not yet exhibit hypertension prevents the development of left ventricular hypertrophy (LVH). ACE inhibitors produce LVH regression in older animals with established hypertension (a result not seen when similar degrees of BP reduction are induced by direct-acting vasodilators such as hydralazine or with diuretics). Rats with LVH produced by abdominal aortic banding exhibit a decrease in left ventricular mass when treated with ramipril at doses too low to reduce BP, indicating a direct myocardial effect.⁴⁸ Reduction of interstitial collagen content and restructuring of the myocardial extracellular matrix with ACE inhibition contributes to LVH mass regression, improves diastolic dysfunction, and reduces the tendency to arrhythmogenesis.⁴⁹

In humans, reduction of left ventricular mass has been documented after eight weeks of ACE inhibitor therapy.⁵⁰ Early meta-analyses suggested that for equal reductions in

BP ACE inhibitors had a greater effect on LVH regression.^{51,52} More recent meta-analyses and head-to-head comparisons with dihydropyridine calcium antagonists suggest that ACE inhibitors, angiotensin receptor blockers (ARBs), and calcium channel blockers exert similar effects.⁵³ A recent meta-analysis of 80 trials and 3,767 patients found that when adjusted for the decrease in diastolic BP and treatment duration ARBs (13%) produced the greatest reduction in left ventricular mass index, followed closely by calcium antagonists (11%) and ACE inhibitors (10%). There was no statistical difference among these three drug classes. All three classes were superior to beta blockers and diuretics.⁵³

The LVH associated with hypertension consists of perivascular and myocardial fibrosis, medial thickening of intramyocardial coronary arteries, and myocyte hypertrophy. In one elegant study, the effect of ACE inhibition on myocardial fibrosis in hypertensive patients was studied directly. Thirty-five patients with hypertension and normal coronary angiograms received either lisinopril (n = 18) or hydrochlorothiazide (n = 17) for a six-month period. Left ventricular biopsies were performed at baseline and at the end of the treatment period. Myocardial fibrosis, measured by left ventricular collagen volume fraction and hydroxyproline concentration, decreased significantly with lisinopril compared to hydrochlorothiazide (HCTZ) (which showed no change to a small increase in both parameters). Diastolic function as determined by echocardiography improved with lisinopril but not with HCTZ.⁵⁴

Vascular hypertrophy

Remodeling of small resistance arteries represents one of the earliest manifestations of target organ damage and is characterized by an increase in the media thickness to lumen ratio. Animal models and human studies document the ability of ACE inhibitors to prevent or reverse vascular hypertrophy, remodeling, and fibrosis. In SHR, initiation of perindopril from age 4 to 24 weeks results in a dose-dependent reduction of BP and media-to-lumen ratio of small resistance arteries leading to an increase in lumen diameter. Interestingly, BP in treated animals remained below controls even at 36 weeks (12 weeks after cessation of the ACE inhibitor).

This study and others performed in young SHR indicate that at least in this animal model of genetically determined hypertension short-term administration of ACE inhibitors at a critical period of growth can have lasting effects on cardiovascular structure and the development of hypertension.^{55,56} ACE inhibitor administration in older SHR induces regression of both vascular and cardiac hypertrophy. Administration of the direct-acting vasodilator hydralazine and beta blockers, however, does not produce equivalent hypertrophy regression when given at doses that produce comparable BP reduction.³²

In humans, investigators have utilized subcutaneous gluteal specimens to study the effects of various antihypertensive agents on the structure and function of resistance vessels. In one study, previously untreated males with essential hypertension were treated with cilazapril versus atenolol for a two-year period. BP reduc-

tion was similar for both groups throughout the study. Gluteal biopsies were obtained after one and two years of treatment. After one year, the media-to-lumen ratio of the cilazapril-treated group was significantly reduced (whereas that of atenolol-treated patients remained unchanged). At year 2 of therapy, the media-to-lumen ratio of the cilazapril-treated group demonstrated continued regression and was statistically no different from arteries derived from normotensive control subjects. Cilazapril was also found to improve endothelial dysfunction. At baseline, patients with hypertension demonstrated reduced vasodilation in response to acetylcholine infusion. After two years of treatment, the response to acetylcholine was similar in cilazapril-treated patients and normotensive controls.⁵⁷⁻⁵⁹

Improving vascular compliance is emerging as an important therapeutic objective in the management of hypertension.^{60,61} Antihypertensive therapy can reduce aortic stiffness passively by reducing mean arterial BP. Animal models and *in vitro* study of human smooth muscle cells also suggest that chronic ACE inhibitor therapy may generate pharmacologic remodeling of the arterial wall, leading to BP-independent reduction in large arterial stiffness. When human aortic smooth muscle cells were incubated with ramiprilat for 10 weeks, staining for collagen was reduced by >50%, whereas staining for elastin and fibrillin-1 increased by more than three- and fourfold, respectively. The elastin/collagen ratio increased sevenfold.⁶² In older SHR, treatment with perindopril decreased aortic stiffness by reducing BP and caused regression of medial hypertrophy and a decrease in the collagen content of the aortic wall.⁶³

Based on studies of arterial wave reflections, ACE inhibitors appear to be quite effective in reducing larger-artery stiffness in humans. In a study of 2,187 patients with essential hypertension, treatment with perindopril reduced pulse pressure and pulse wave velocity after two months of therapy. Continued improvement in these parameters was noted after six months of treatment.⁶⁴ In patients with peripheral arterial disease, six months of treatment with ramipril significantly increased arterial compliance and reduced pulse wave velocity and augmentation index.⁶² As the structure and composition of the larger arteries cannot be directly assessed in humans, it is difficult to demonstrate conclusively that favorable hemodynamic alterations are the result of structural remodeling and changes in arterial composition.

Atherosclerosis

Atherosclerosis is the anatomical substrate for the majority of cardiovascular endpoints in hypertensive patients. It is a complex multifactorial process that begins with endothelial dysfunction and involves vascular inflammation, lipid accumulation, and smooth muscle cell growth and migration. Angiotensin II and ACE are intimately involved in every stage of atherosclerotic lesion development and in the events that lead to vascular complications.^{65,66} A significant body of evidence indicates that ACE inhibitors exert salutary effects on the complications of atherosclerosis. Whether these effects are in

part independent of BP reduction is a subject of continuing controversy.

ACE inhibitors improve endothelial vasodilator function and appear to do so better than other available classes of antihypertensive agents. By blocking angiotensin-II-induced reactive oxygen species (ROS) formation, ACE inhibitors prevent nitric oxide (NO) degradation and increase NO release. In healthy volunteers, quinaprilat enhanced radial artery diameter during reactive hyperemia. Vasodilation was abolished by the bradykinin receptor antagonist HOE 140, suggesting that this effect is bradykinin mediated.²¹ Several studies comparing ACE inhibitors to other commonly used antihypertensive drugs have been performed. In a prospective study of 168 hypertensive patients comparing the ACE inhibitor perindopril to other antihypertensive treatments (including beta blockers, calcium channel blockers, and an angiotensin receptor blocker), perindopril alone improved vasodilation during reactive hyperemia.⁶⁷ In a similar trial of 296 hypertensive patients performed in Japan comparing the effects of various antihypertensive drug classes, ACE-inhibitor-treated patients had significantly greater vasodilatation following forearm occlusion compared to patients taking calcium channel blockers, beta blockers, and thiazide diuretics.⁶⁸

The Trial on Reversing Endothelial Dysfunction (TREND) study demonstrated that chronic administration of an ACE inhibitor can improve abnormal endothelial function in atherosclerotic coronary arteries. Patients with coronary artery disease who demonstrated reduced vasodilator or a vasoconstrictor response to intracoronary acetylcholine infusion were randomized to receive quinapril or placebo for a six-month period. A target arterial segment at the site of a noncritical (<40%) stenosis was studied at baseline and again at the end of the blinded treatment period. Whereas the placebo group demonstrated no change in vascular response to acetylcholine infusion, the target arteries of quinapril-treated patients showed a marked (statistically significant) improvement in endothelial-mediated dilatation. A significant number of quinapril-treated patients had complete resolution of abnormal vasoconstriction seen at baseline.⁶⁹

ACE inhibitors retard the development of atherosclerotic lesions in multiple animal models of hyperlipidemia, including the rabbit, hamster, mini-pig, cynomolgus monkey, and apolipoprotein E-deficient mice.⁷⁰ Without correcting hyperlipidemia, delapril (in a dose-dependent fashion) inhibited the development of atherosclerosis (expressed as aortic area covered by lesions) in cholesterol-fed rabbits.⁷¹ Captopril reduced aortic atherosclerosis in the normotensive Watanabe hyperlipidemic rabbit model and in the cynomolgus monkey.^{70,72} In apo E-deficient mice, fosinopril given at a dose insufficient to produce a hypotensive effect reduced atherosclerotic lesion size and increased the resistance of LDL to oxidation.^{70,73} This property of ACE inhibitors is independent of bradykinin.⁷⁴

Human studies on prevention and regression of atherosclerosis with ACE inhibitors have yielded inconsistent results. Two large studies have been performed to assess

the ability of ACE inhibitors to inhibit carotid atherosclerosis and two studies have evaluated coronary atherosclerosis. In the Prevention of Atherosclerosis with Ramipril-2 (PART-2) study, patients with a history of cardiovascular events were assigned to ramipril or placebo. After four years of follow-up, neither carotid artery wall thickness nor carotid plaque burden differed between the two groups.⁷⁵ Ramipril reduced progression of carotid atherosclerosis by 0.008 mm/year compared to placebo in the Study to Evaluate Carotid Ultrasound Changes in Patients Treated with Ramipril and Vitamin E (SECURE), a sub-study of the Heart Outcomes Prevention Evaluation (HOPE) study. Several studies have failed to demonstrate any effect of ACE inhibitors on the progression of coronary artery disease.⁷⁶ Therapy with ACE inhibitors has also been unsuccessful in preventing restenosis following coronary angioplasty or stent placement.⁷⁷

CLINICAL INDICATIONS

Hypertension

All available ACE inhibitors are approved for the treatment of hypertension. Based on outcome data, the *Seventh Report of the Joint National Committee on the Prevention, Detection, Evaluation and Treatment of High Blood Pressure* (JNC-7), the World Health Organization/International Society of Hypertension, and the European Society of Hypertension/European Society of Cardiology recognize ACE inhibitors as an option for first-line therapy in patients with essential hypertension. ACE inhibitors are recognized as preferred treatment for patients with hypertension complicated by heart failure, coronary artery disease (CAD) or history of MI, diabetes, or chronic kidney disease (as well as for recurrent stroke prevention).³

The magnitude of BP reduction seen after ACE inhibitor administration depends on a number of factors, including the degree of elevation in baseline BP, intravascular volume status, and demographic characteristics of the population studied. White subjects have the most consistent response to ACE inhibitors. Sodium restriction, which activates the RAS, increases the magnitude of BP reduction after ACE inhibitor administration. For these reasons, the reported response rate (usually defined as diastolic BP reduction of ≥ 10 mmHg or BP normalization) to ACE inhibitor monotherapy is quite variable (ranging from 20 to 70%).⁷⁸

There is no convincing evidence for greater hemodynamic efficacy of one ACE inhibitor compared to another, provided that each drug is titrated to its effective dose. ACE inhibitors generally reduce BP within several hours of oral administration. The maximum response to an administered dose is achieved after approximately four to six weeks. Patients with a highly activated RAS and very high PRA, as occurs in renal artery stenosis, may show an immediate and profound hypotensive response to ACE inhibitors. There is little relationship, however, between pretreatment PRA and the magnitude of long-term BP reduction.^{14,16,32}

Concomitant aspirin administration (ASA) does not seem to affect the BP response to ACE inhibitors. BP was

not altered when ASA 81 or 325 mg was administered to patients receiving chronic stable dosing with enalapril. Subgroup analysis from the Hypertension Optimal Treatment (HOT) trial revealed no interaction between low-dose (75 mg daily) ASA with the BP-lowering effect of antihypertensive agents, including combinations that included ACE inhibitors.⁷⁹⁻⁸¹

Demographic subgroups

African Americans

Although individual responses vary, BP reduction and responder rates after ACE inhibitor administration are less in African Americans compared to Caucasians. The magnitude of mean diastolic BP reduction in most studies is approximately one-half to two-thirds that seen in white patients. This has been attributed to the tendency of African Americans toward low-renin, volume-expanded, salt-sensitive hypertension.^{14,82} The abolition of racial differences in response to ACE inhibitors when diuretics are coadministered lends credence to this theory. However, there may be inherent mechanistic differences mediating BP response in whites and African Americans. In a study using trandolapril, white and black hypertensive patients were given 1-mg, 2-mg, or 4-mg doses of this agent.

A 1-mg dose of trandolapril resulted in a 6.1-mmHg mean decrease in baseline sitting diastolic pressure for whites. Black patients required 4 mg of trandolapril to achieve the same BP response. Despite the robust differences in BP response, a similar reduction in serum ACE activity was achieved for each dose of trandolapril in both populations. There were also no racial differences in the trandolapril concentrations required to achieve a given level of serum ACE inhibition.⁸³ In general, African Americans require a higher dose of ACE inhibitor to achieve therapeutic BP reductions. However, the maximum response cannot be equalized regardless of dose. Despite these differences in BP response, in black patients with renal disease, diabetes, and heart failure ACE inhibitors appear to produce endpoint reductions comparable to those of whites (indicating a dissociation between hemodynamic and tissue protective effects).^{84,85}

The elderly

More than two-thirds of patients over age 65 have hypertension and are candidates for antihypertensive drug therapy. With aging, there is progressive loss of distensibility of the aorta and large conduit arteries. Diastolic BP remains the same or decreases, whereas systolic BP rises.⁵⁸ Low PRA is seen in the elderly, but unlike African Americans it is the result of age-related changes in the RAS axis and not a consequence of volume expansion. Although this might theoretically render elderly individuals less responsive to ACE inhibitors, BP reduction and responder rates are equivalent in studies comparing younger and older individuals.⁸⁶⁻⁸⁸

ACE inhibitors are generally well tolerated in older patients. These agents do not interfere with (and may even improve) baroreceptor sensitivity in elderly hypertensive individuals. With the exception of occasional first-dose

hypotension, orthostatic hypotension is quite rare and occurs less often than with diuretics and most other vasodilating agents. Cerebral blood flow is well maintained and improvement has been documented in the BP range in which effective cerebral autoregulation is maintained. Cognitive function is unaffected by ACE inhibitors. When prescribing ACE inhibitors to the elderly, age-related decline in renal function must be taken into account. Drug elimination may be slower. Dosage and dosing intervals often need to be adjusted. First-dose hypotension can be avoided by starting elderly patients at lower doses and gradually increasing the dose over days to weeks.⁸⁶⁻⁸⁸

Rational use of ACE inhibitors in combination

It is estimated that approximately 75% of patients with hypertension require two or more drugs to achieve the BP goals specified in JNC-7. Devising effective drug combinations is therefore an essential element of antihypertensive therapy. The goal is to combine drugs with complementary pharmacologic mechanisms of action in order to produce additive BP reduction. For ACE inhibitors, diuretics and calcium channel blockers constitute the preferred combination partners.^{89,90}

The combination of an ACE inhibitor and a low-dose thiazide diuretic constitutes one of the most successful approaches to contemporary combination therapy. From an evolutionary perspective, the primary purpose of the RAS is to protect the organism from salt and water depletion. Because the pharmacologic action of diuretics is to increase urinary sodium excretion and reduce intravascular volume, their administration results in renin release and increased angiotensin II production. Coadministration of an ACE inhibitor blocks this activation and leads to additive BP reduction. In addition, the hypokalemia associated with diuretic therapy is often blunted or abolished by ACE inhibitors (which tend to promote potassium retention by reducing the availability of aldosterone).⁹⁰

Dihydropyridine calcium channel blockers are also effective in combination with ACE inhibitors. When combined with ACE inhibitors, additive BP reduction is achieved. Addition of an ACE inhibitor has the added benefit of partially neutralizing the lower extremity edema, which is the most frequent dose-limiting side effect of calcium channel blockers. The edema seen with these agents is not the result of sodium retention but is due to a selective reduction in arteriolar resistance and an increase in capillary hydrostatic pressure. ACE inhibitors, by lowering post-capillary resistance, decrease the pressure gradient and the stimulus to fluid extravasation. In a study of 707 patients randomized to receive enalapril, felodipine, and their combination, the incidence of edema was reduced from 10.8% with felodipine monotherapy to only 4.1% in patients receiving the combination.^{29,90}

In patients requiring three antihypertensive agents, the combination of an ACE inhibitor, diuretic, and calcium channel blocker offers an excellent combination of complementary pharmacology, additivity of BP reduction, and proven effectiveness in achieving endpoint protection.

ENDPOINT TRIALS

The Captopril Prevention Project (CAPPP) compared the effects of ACE inhibition to conventional therapy (beta blockers and/or diuretics) on cardiovascular morbidity and mortality in 10,985 hypertensive patients.⁹¹ Captopril was prescribed in a dose of up to 100 mg/day given once or twice daily. At a mean follow-up of 6.1 years, there was no difference in the primary endpoint (a composite of MI, stroke, and cardiovascular death). There was a trend in favor of lower cardiovascular mortality in the captopril arm (relative risk 0.77). The rate of MI was similar, but stroke was more common with captopril (relative risk 1.25, $p = 0.004$). The incidence of newly diagnosed diabetes was significantly lower with captopril therapy (relative risk 0.79, $p = 0.007$), a finding replicated in later trials with ACE inhibitors.

The dosing regimen for captopril in CAPPP was unconventional. Captopril has a known duration of action of 6 to 10 hours. Nonetheless, 48% of captopril-treated patients received the drug once daily (raising the possibility that 24-hour BP control was inadequate). Target diastolic BP was more rapidly achieved with conventional treatment, and both systolic and diastolic BPs were on average 2 mmHg higher in the captopril arm throughout the trial. Stroke is an endpoint that is exquisitely sensitive to BP and the 2-mmHg difference could account for up to a 15% difference in the cerebrovascular accident (CVA) event rate.

In the smaller diabetic arm, equal BP reduction was obtained throughout the trial. The rate of CVA was the same among diabetics in both arms and the combined primary endpoint was significantly lower with captopril treatment (relative risk 0.59, $p = 0.019$). The CAPPP trial showed that even with slightly less BP control ACE inhibitor therapy was at least equivalent to conventional beta blocker and diuretic therapy in preventing cardiovascular complications.

The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) is the largest hypertension trial conducted to date.⁹² It involved 42,416 patients over age 55 with hypertension and at least one additional coronary heart disease (CHD) risk factor. The study compared chlorthalidone, amlodipine, lisinopril, and doxazosin as first-line therapy. The doxazosin arm was terminated early due to an increased event rate compared to chlorthalidone. At a mean follow-up of 4.9 years, there was no difference among the three remaining treatment groups in the primary endpoint of fatal CHD or nonfatal MI. The occurrence of new-onset heart failure and stroke was higher in the lisinopril arm.

Some have interpreted ALLHAT as showing an advantage of diuretic-based therapy compared to ACE inhibitors. However, as in CAPPP on-treatment BPs were higher in the ACE inhibitor group throughout the trial (2 mmHg), with the difference being greatest in the first two years of therapy (4 mmHg). The increased stroke rate with lisinopril was entirely driven by the 35% of the population who were African American (relative risk 1.40). In this subgroup, BP remained an average of 4 mmHg higher with lisinopril compared to chlorthalidone throughout the trial.

In ALLHAT, combination of the ACE inhibitor with its two preferred combination partners (diuretics and calcium channel blockers) was not permitted. Atenolol, clonidine, and hydralazine were the designated step 2 drugs, and most patients received atenolol as add-on therapy. Because ACE inhibitors and beta blockers when combined do not produce additive BP reduction, this artificial treatment regimen may well account for the higher BPs observed in the lisinopril arm. In ALLHAT, as in CAPP, the ACE inhibitor achieved equality with regard to the primary endpoint despite a disadvantage in terms of BP control.

The Second Australian National Blood Pressure Study (ANBP2) compared outcomes with an ACE inhibitor (enalapril recommended) or a diuretic-based regimen (hydrochlorothiazide recommended) in a relatively healthy hypertensive population.⁹³ BP reductions were similar throughout the five-year study duration. There was a statistically significant 11% lower incidence for the primary endpoint of all cardiovascular events or death from any cause favoring the ACE-inhibitor-based regimen. The difference in outcomes was driven mainly by a reduction in MI in the ACE inhibitor group. There was no difference in stroke rate.

In the Second Swedish Trial in Old Patients with Hypertension (STOP-2), 6,614 elderly patients (ages 70 to 84) with a systolic BP >180 and/or diastolic BP >105 were randomly assigned to one of three treatment groups: conventional therapy with beta blockers and/or diuretics, the ACE inhibitor enalapril or lisinopril, or the calcium antagonist felodipine or isradipine.⁹⁴ Similar BP control was obtained throughout the trial. At 4.5 years follow-up, the combined endpoint of fatal stroke, fatal MI, and other fatal cardiovascular disease was the same in the three groups. There were significantly fewer MIs and episodes of congestive heart failure in patients treated with ACE inhibitors compared to those receiving calcium channel blockers.

Taken together, the major outcome trials indicate that ACE inhibitors are excellent first-line agents in hypertensive patients of any age. A meta-analysis performed by the Blood Pressure Lowering Treatment Trialists' Collaboration concluded that there is no reliable evidence of a difference between ACE-inhibitor-based regimens and conventional beta-blocker/diuretic-based regimens for preventing major cardiovascular events. There was also no reliable evidence of a difference between ACE-inhibitor-based regimens and calcium-antagonist-based regimens (with the exception of a lower incidence of heart failure with ACE inhibitor therapy).⁹⁵

Renal protection

Therapeutic goals in the treatment of patients with hypertension and kidney disease are to normalize BP, reduce proteinuria, and slow or arrest the deterioration in renal function. Effective BP control *per se* delays the progression of renal dysfunction. JNC-7 recommends a BP goal of <130/80 mmHg for patients with chronic kidney disease defined by either a GFR <60 mL/min per 1.73 m² or the presence of albuminuria >300 mg/day, regardless of GFR. Compelling evidence that reduction in protein

excretion by at least 30% below baseline is associated with a marked decrease in renal disease progression has led the National Kidney Foundation to recommend that therapies used to treat BP also target proteinuria reduction.

In patients with renal disease, specifically those with proteinuria, blockade of the renin-angiotensin system affords end-organ protection clearly superior to that obtained with other classes of antihypertensive agents. This appears to be the case in normotensive as well as hypertensive individuals, and the treatment effect is greater than can be accounted for on the basis of BP reduction alone. The renal protection afforded by ACE inhibitors is intricately linked to producing a decline in protein excretion. This applies to both diabetic and non-diabetic kidney disease.

In patients with diabetic nephropathy, ACE inhibitors have been more extensively studied in patients with type I diabetes. The benefits of ACE inhibition can be demonstrated early in the course of the disease. Administration of captopril to normotensive type I diabetics with microalbuminuria significantly reduced both the albumin excretion rate and the fraction of patients who progressed to clinical proteinuria, the hallmark of the rapidly progressive phase of diabetic nephropathy.⁹⁶ In a landmark study, 409 type I diabetics with urinary protein excretion >500 mg/day and serum creatinine concentration <2.5 mg/dL were randomized to receive captopril 25 mg three times daily or placebo.^{97,98} After a median follow-up of three years, captopril reduced the risk of doubling of serum creatinine by 48% and the combined endpoint of death, dialysis, and transplantation by 50% (Figure 80–2).

The data for renal protection with ACE inhibitors in type II diabetes are somewhat less robust, but are consistent with the view that ACE inhibitors provide renal protection in this population and are approximately equivalent in their efficacy to ARBs. In normotensive and

Figure 80–2. Captopril in diabetic nephropathy: end-stage renal disease (ESRD) or death. In patients with renal disease, specifically those with proteinuria, ACE inhibitors afford end-organ protection clearly superior to that obtained with other classes of antihypertensive agents. (Redrawn from Lewis EJ, Hunsicker LG, Bain RP, Rohde RD. The effect of angiotensin-converting-enzyme inhibition on diabetic nephropathy: The Collaborative Study Group. *N Engl J Med* 1993;329:1456–62.)

hypertensive type II diabetics, enalapril has been shown to reduce the progression from microalbuminuria to proteinuria and to protect against decline in GFR.^{99,100} In the recently published Diabetics Exposed to Telmisartan and Enalapril (DETAIL) study, enalapril 20 mg/day was compared to the ARB telmisartan (at a dose of 80 mg/day) in 250 patients with early diabetic nephropathy and a serum creatinine level <1.6. After five years of treatment, GFR declined by 17.9 mL/min per 1.73 m² in the telmisartan group and 14.9 mL/min per 1.73 m² in enalapril-treated patients. This trend in favor of the ACE inhibitor was not statistically significant.¹⁰¹

In hypertensive patients with type II diabetes, the progression from normal urinary albumin excretion to microalbuminuria can be delayed by treatment with an ACE inhibitor. This protective effect was demonstrated in the Bergamo Nephrologic Diabetes Complications (BENEDICT) trial. Treatment with the ACE inhibitor trandolapril or the combination of trandolapril plus verapamil delayed the onset of microalbuminuria compared to placebo or verapamil treatment alone. The results of this study further support the value of treating hypertensive type II diabetics with an ACE inhibitor.¹⁰²

A number of well-conducted studies have confirmed that ACE inhibitors also confer renal protection in patients with non-diabetic nephropathy. In the Ramipril Efficacy in Nephropathy (REIN) study, patients were classified into two groups based on degree of proteinuria (stratum 1, of 1 to 3 g/24 h, and stratum 2 of >3 g/24 h) and randomized to receive ramipril or placebo. BPs in the two arms were almost identical throughout the study. Urinary protein excretion decreased significantly at one month in the ramipril group and remained lower than baseline throughout the study period. After 16 months, the study was prematurely terminated in stratum 2 patients (baseline protein excretion of >3 g/day) because of a highly significant reduction in the rate of GFR decline (0.53 versus 0.88 mL/min per month ramipril versus placebo). Risk reduction was correlated with the percentage decrease from baseline in urinary protein excretion.¹⁰³

Analysis of stratum 1 patients (1 to 3 g/24 h protein excretion) revealed that ramipril significantly benefited those with a basal GFR of less than 45 mL/min and proteinuria of at least 1.5 g/day. Patients with the most severe renal dysfunction (basal GFR of 10 to 30 mL/min per 1.73 m²) experienced a 22% reduction in decline in GFR and a 33% reduction in progression to end-stage renal disease (ESRD) without increased risk of major adverse events. These findings are important because many physicians are reluctant to start ACE inhibitors in patients with more severe renal dysfunction. Such patients may actually derive the greatest benefit from ACE inhibition.¹⁰⁴

Although ACE inhibitors are less effective as BP-reducing agents in African Americans, renal protective effects are preserved. In the African American Study of Kidney Disease and Hypertension (AASK) trial, ramipril was more effective than amlodipine or metoprolol in slowing the progression of hypertensive nephrosclerosis.⁸⁵

A significant decrease in proteinuria was seen with ramipril, whereas patients treated with amlodipine had an increase in proteinuria. In concordance with previous trials, the treatment effect was greater in the patient subgroup with baseline proteinuria UP/Cr >0.22 (approximately 300 mg/day).

A meta-analysis of 1,860 patients with non-diabetic renal disease concluded that ACE inhibitors reduce the risk for doubling of serum creatinine or progression to end-stage renal disease by 30% compared to other antihypertensive regimens. Patients with greater baseline urinary protein excretion benefit the most from ACE inhibitor therapy. The data were inconclusive for patients with baseline urinary excretion less than 0.5 g/day.^{105,106}

Combining an ACE inhibitor with an ARB has theoretical advantages for renal protection. There is emerging evidence that in some patient populations this combination provides superior reduction in proteinuria and renal protection than either agent alone. In the combination treatment of angiotensin-II receptor blocker and angiotensin-converting-enzyme inhibitor in non-diabetic renal disease (COOPERATE) trial, 263 Japanese patients with non-diabetic nephropathy were randomized to receive trandolapril, losartan, or their combination. The dose of trandolapril was selected as that dose beyond which further proteinuria reduction could not be achieved. The combination therapy group demonstrated further reduction in proteinuria and improvement in renal survival despite equality of on-treatment BPs in the three treatment groups.¹⁰⁷

When initiating ACE inhibitor therapy in patients with decreased renal function, a few caveats should be kept in mind. There may be an initial elevation in serum creatinine level of up to 30% from baseline. This usually occurs within the first two weeks of therapy, stabilizes within two to four weeks, and is often transient. When a more significant elevation in serum creatinine occurs, an explanation should be sought. Common causes include renal artery stenosis, volume depletion from concomitant diuretic use, and the use of non-steroidal anti-inflammatory drugs (NSAIDs). Review of trial data indicates that acute limited increases in serum creatinine of up to 30% correlate with slower rates of long-term decline in renal function. Careful monitoring of electrolytes upon initiation or up-titration of ACE inhibitors is recommended for patients with more severe renal dysfunction.^{43,108}

Cardiac protection

In the context of antihypertensive therapy, cardiac protection refers to the ability of a drug to protect the heart from (1) MI, (2) progressive deterioration in ventricular function after MI or other processes initiating ventricular dysfunction, and (3) mortality related to cardiac events. With regard to cardiac protection, JNC-7 delineates three categories of “compelling indications” (i.e., subgroups of patients in whom certain drug classes are preferred). These include those with heart failure due to systolic dysfunction or prior/recent MI and patients at high risk for clinical coronary events. ACE inhibitors are designated as a preferred therapy in each of these patient groups.

The Survival and Ventricular Enlargement (SAVE) trial was the first study to show cardiac protection by ACE inhibitors in patients with recent MI¹⁰⁹ (Figure 80–3). It was undertaken after animal models showed that ACE inhibitors could reduce ventricular dysfunction and improve survival following experimental MI. The study randomized 2,231 patients with LVEF <40% and no overt signs of heart failure to treatment with captopril or placebo. After an average 3.5 years, the captopril group demonstrated a reduction in all-cause mortality (19%) and the number of patients developing clinical heart failure. An unexpected finding was a 25% reduction in the risk of recurrent MI.

The post-MI trials validated the results of SAVE. The Acute Infarction Ramipril Efficacy (AIRE) trial included 2,006 patients with clinically overt heart failure symptoms after MI randomized to receive ramipril at a dose of 5 mg bid.¹¹⁰ Follow-up averaged 15 months. The primary endpoint of all-cause mortality was 27% lower in the ramipril arm. The secondary endpoint of progression to severe heart failure, re-infarction, or stroke was reduced by 19%. The reduction in MI was statistically significant. In the Trandolapril Cardiac Evaluation (TRACE) study, post-MI patients with left ventricular dysfunction after MI were studied.¹¹¹ Mortality and progression to severe heart failure were reduced in patients randomized to trandolapril. A non-significant reduction in MI risk was observed. The six-year follow-up of TRACE patients documented that median life expectancy was prolonged by 15.3 months in trandolapril-treated patients.¹¹²

SAVE, AIRE, and TRACE firmly established ACE inhibitors as first-line therapy for patients with asymptomatic left ventricular dysfunction following acute MI. A meta-analysis of the three trials revealed a reduction in

mortality from 29.1% in placebo to 23.4% with ACE inhibitor treatment, at an average follow-up of 2.6 years.¹¹³ It was estimated that to avoid one death about 15 patients required therapy for 2.5 years. Cumulative reduction in the development of chronic heart failure was also observed. The reduction in re-infarction apparent in these trials laid the groundwork for evaluating the vascular protective effect of ACE inhibitors in broader high-risk populations with normal left ventricular function.¹¹³

The HOPE trial evaluated whether ramipril at a dose of 10 mg daily could reduce the composite endpoint of MI, stroke, or death from cardiovascular causes in a population at high risk for cardiovascular events.¹¹⁴ More than 9,000 patients, age 55 years or older, with a history of known vascular disease or diabetes plus at least one other cardiovascular risk factor were randomized to ramipril 10 mg/day or placebo. Patients were excluded if they had heart failure or were known to have an ejection fraction below 40%. The mean BP at entry was 139/79 mmHg in both groups.

The study was not designed as a hypertension trial, and patients with hypertension required ongoing BP treatment in order to be eligible for participation. The BP of patients in the ramipril arm was reduced by a mean of 3/2 mmHg compared to placebo. The primary composite endpoint of MI, stroke, or cardiovascular mortality was 22% lower in the ramipril group. Each of the components of the composite endpoint was reduced with ramipril: cardiovascular death by 26%, MI by 20%, and stroke by 32%. The benefits were consistent across all subgroups of patients, including diabetics with no previously documented vascular disease.

It has been debated whether the cardiovascular protection afforded by ramipril was the result of BP reduction or was in part related to non-BP related effects. It is clear that endpoint reduction exceeded what would be predicted by the relatively small difference in mean BP between the placebo and treatment groups. However, subsequent analysis of 38 patients with peripheral arterial disease in whom ambulatory BP monitoring was performed revealed a larger difference in 24-hour BP (10/4 mmHg), mainly caused by a pronounced BP lowering effect at night (17/8 mmHg). It is difficult, however, to derive far-reaching conclusions from such a small subgroup.¹¹⁵ Regardless of the BP effect, the overall trial result validated the cardiovascular protective effects of ACE inhibitor therapy in a population not previously thought to require either anti-hypertensive therapy or to be candidates for ACE inhibition.

Further evidence for cardiac protection by ACE inhibitors came from the European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease (the EUROPA study).¹¹⁶ In EUROPA, 13,655 patients with stable coronary artery

Figure 80–3. Prevention of myocardial infarction with ACE inhibitors. Reduction in the incidence of myocardial infarction compared to placebo in studies of patients who are post-MI and/or at high-risk for cardiovascular events.

disease and without clinical evidence of heart failure were randomized to perindopril 8 mg/day or placebo. The baseline BP was 137/82 in both groups. After randomization, BP in the perindopril group was reduced by an average of 5/2 mmHg compared to placebo. Perindopril treatment was associated with a significant reduction in the primary endpoint of cardiovascular mortality, non-fatal MI, and resuscitated cardiac arrest (relative risk reduction 20%). The risk of MI was reduced by 24%. In a post hoc analysis of the EUROPA data, no relationship was noted between either baseline BP or BP reduction during blinded treatment and endpoint reduction.

The results of the Prevention of Events with Angiotensin Converting Enzyme Inhibition (PEACE) trial, comparing trandolapril with placebo in a population with stable coronary artery disease, are at variance with HOPE and EUROPA.¹¹⁷ There was no reduction in the incidence of the primary endpoint of death from cardiovascular causes, MI, or coronary revascularization. This negative result may be due to the fact that the study was statistically underpowered, to the relatively low dose of trandolapril utilized, to the low adherence to treatment noted in the study, or to the fact that the population studied exhibited a very low cardiovascular mortality in the placebo group (0.8%/year). Meta-analysis of data from HOPE, EUROPA, and PEACE combined demonstrate an overall reduction in mortality.¹¹⁸

Reduction in diabetes

ACE inhibitors (and ARBs) consistently reduce the risk of diabetes development compared to placebo or other antihypertensive agents (Table 80–2). The first study to report a decrease in the incidence of new-onset diabetes with ACE inhibition was the CAPP study, which compared captopril to beta blocker and diuretic therapy in patients with diastolic hypertension.⁹¹ The incidence of new onset diabetes mellitus (DM) was 21% lower in captopril-treated patients. In the HOPE study, a 34% relative risk reduction for development of new-onset diabetes with ramipril was noted. A small sub-study of the

HOPE trial found that fasting glucose increased more with placebo than with ramipril.^{114,119–121}

In ALLHAT, the incidence of new-onset DM was highest in the chlorthalidone group (11.6%) and lowest in the lisinopril-treated patients, lisinopril versus chlorthalidone 30% risk reduction (8.1%). The incidence in the amlodipine (9.8%) arm was intermediate.⁹² In ANBP-2, there was a 31% lower incidence of new-onset diabetes with enalapril compared to hydrochlorothiazide.⁹³

Cerebrovascular disease

The Perindopril Protection Against Recurrent Stroke Study (PROGRESS) randomized 6,105 patients with a history of a stroke or transient ischemic attack (TIA) within five years to receive perindopril ± indapamide or placebo irrespective of BP. Administration of indapamide was at the discretion of the investigator. There were no BP criteria mandating combination therapy.⁹ Fifty percent of patients were already receiving antihypertensive therapy. BP at baseline averaged 147/86 mmHg in both treatment arms and was reduced by a mean of 9/4 mmHg in the active therapy compared to the placebo group. The results demonstrated a highly significant 28% risk reduction for stroke after four years of follow-up. Normotensive patients as well as hypertensives experienced significant stroke risk reduction.¹²²

Post hoc analysis indicated that patients receiving perindopril monotherapy showed no benefit, whereas patients receiving both drugs showed a 43% risk reduction for stroke. It is noteworthy that PROGRESS was designed as a combination therapy trial and was not powered to detect statistical differences between the monotherapy and combination arms. Because of its unusual study design, the PROGRESS data are subject to several interpretations: (1) that BP reduction *per se* regardless of baseline BP is valuable in reducing recurrent cerebrovascular events, (2) that ACE inhibition improves prognosis in this patient population, and (3) that a diuretic or a diuretic in combination with an ACE inhibitor improves prognosis. Recognizing these uncertainties,

ACE INHIBITORS: ROLE IN THE PREVENTION OF DIABETES			
Trial	Population	Intervention	Diabetes
HOPE	High-risk CVD	Ramipril vs. placebo	↓34%
CAPP	HTN	Captopril vs. beta blockers/ diuretics	↓21%
SOLVD sub-study	Heart failure	Enalapril vs. placebo	↓21%
ANBP-2	HTN	Enalapril vs. HCTZ	↓31%
ALLHAT	High-risk HTN	Lisinopril vs. chlorthalidone	↓30%
ALLHAT	High-risk HTN	Lisinopril vs. amlodipine	↓17%

ACE inhibitors consistently reduce the incidence of new-onset diabetes compared to placebo or other antihypertensive agents. The mechanism for the apparent improvement in glucose tolerance with ACE inhibition remains to be delineated. Data from Yusuf S, et al. *JAMA* 2001; 286:1882–85; Hansson L, et al. *Lancet* 1999;353:611–16; Vermees E, et al. *Circulation* 2003; 107:1291–96; Wing LMH, et al. *N Engl J Med* 2003;348:583–92; and ALLHAT. *JAMA* 2002; 288:2981–97.

Table 80–2. ACE Inhibitors: Role in the Prevention of Diabetes

JNC-7 recommends the combination of an ACE inhibitor and a diuretic for secondary prevention in patients who have sustained a stroke or transient ischemic attack.^{3,122}

ADVERSE EVENTS AND COMPLICATIONS

ACE inhibitors are well tolerated in most patients. They do not cause excessive fatigue or other central nervous system symptoms. As with all classes of antihypertensive medications, symptomatic hypotension can occur. This is more likely to happen in patients who are sodium or volume depleted and in whom the RAS is activated, making BP more angiotensin dependent. Hypotension can be minimized by starting with a low dose of ACE inhibitor and gradually titrating upward or by withholding diuretic therapy for a few days prior to starting ACE inhibitors. Patients who become hypotensive after receiving ACE inhibitors while volume depleted will often tolerate them without difficulty in a volume-repleted state.¹²³

Hyperkalemia resulting from the anti-aldosterone effect of ACE inhibitors is a recognized side effect of therapy. In patients with normal renal function, a small and clinically insignificant rise in serum potassium routinely occurs. Hyperkalemia (defined as serum potassium >5.1) occurred in 11% of patients who had received prescriptions for ACE inhibitors in an outpatient Veterans Affairs medical center. The strongest predictor of hyperkalemia was a serum creatinine level >1.6 mg/dL.¹²⁴ Patients with baseline low aldosterone levels (as occurs in diabetics and the elderly) are predisposed to developing hyperkalemia. Concomitant use of NSAIDs, potassium supplements, and potassium-sparing diuretics also increase the risk for hyperkalemia.

Alternatively, use of thiazide and loop diuretics can prevent hyperkalemia. When prescribing an ACE inhibitor to a patient with risk factors for hyperkalemia, it is advisable to start at a low dose and check serum potassium concentrations one week after drug initiation and after any increase in dose.¹²⁵

When renal function declines with chronic ACE inhibitor therapy, an explanation should be sought. Common reasons include hypoperfusion secondary to reduced cardiac output, volume depletion from excessive diuretic use, the presence of renal artery stenosis or the use of NSAIDs. In these settings, ACE inhibitors interfere with the kidney's compensatory mechanism for maintaining GFR. The ACE inhibitor should be temporarily discontinued while precipitating factors are corrected. Once renal function has stabilized, therapy can be resumed in some patients.^{43,108}

The most common side effect of ACE inhibitors and the most frequent reason for drug discontinuation in clinical trials is a persistent nonproductive cough reported in 0.5 to 20% of patients.¹²⁶ The etiology of the cough is incompletely understood. It likely results from the accumulation of substances normally metabolized by ACE, including bradykinin and tachykinins (such as substance P). Increased synthesis of NO in the pulmonary epithelium and enhanced production of prostaglandins may

be contributory factors.¹²⁷ The cough is reported more frequently by women than by men. An increased prevalence of ACE-inhibitor-associated cough has been reported in Asian populations, with rates up to 53%.¹²⁸

The cough is generally characterized as troublesome or annoying, rather than disabling, and does not result in pulmonary dysfunction. It usually begins within one week of starting therapy. In some cases it may have a delayed onset of up to six months. Once the drug is stopped, the cough usually disappears within one to seven days. However, it can take as long as four weeks to subside. Upon re-challenge with the same or another ACE inhibitor the cough will almost always recur. The cough appears to be dose independent, but its frequency may be reduced with a decrease in dosage. Failure of a clinician to consider ACE inhibitor therapy as a possible etiology for cough can lead to unnecessary evaluations and treatment. A simple four- to seven-day trial of drug withdrawal is an easy way of making the diagnosis. If the cough is mild and tolerable, the ACE inhibitor can be continued. Alternatively, substitution with an AT₁ receptor blocker is well tolerated.¹²⁶⁻¹²⁹

Angioneurotic edema is a rare but potentially fatal side effect of ACE inhibitors requiring immediate medical attention. Clinical manifestations include well-demarcated non-pitting edema of the tongue, lips, eyelids, or other parts of the face. Edema of the mucous membranes of the mouth, throat, and nose may also occur. Edema of the gastrointestinal tract has also been reported. Dysphagia can be a presenting symptom. Involvement of the upper respiratory tract can result in life-threatening airway compromise.¹²⁶⁻¹³⁰ The incidence of angioedema associated with ACE inhibitor use is approximately 0.1 to 1.2%. In the Omapatrilat Cardiovascular Treatment vs. Enalapril (OCTAVE) trial, angioedema occurred in 86 of 12,557 (0.68%) patients treated with enalapril. The occurrence of angioedema does not appear to be influenced by dosage, age, or gender. African Americans are predisposed to ACE-inhibitor-associated angioedema with relative risks of 3 to 4.5 times that of white patients.^{130,131}

The pathogenesis of angioedema is thought to be the same as that of ACE inhibitor-induced cough; namely, increased activity of bradykinin. Interestingly, cough and angioneurotic edema generally occur independently. The risk of angioedema is greatest within the first eight weeks of initiating therapy and declines thereafter. It can, however, occur within a few hours or be delayed for up to five years. In a retrospective analysis of 82 patients with documented angioedema while using ACE inhibitors, the risk of a recurrent episode was 10 times higher if ACE inhibitor therapy was reinstated. The mean time between recurrent episodes was 11 months (range 0.6 to 34 months). The variable temporal relationship between ACE inhibitor administration and the occurrence of angioedema may contribute to a failure to recognize the association and discontinuation of the drug. Patients who develop angioedema while taking ACE inhibitors should not be re-challenged with any agent of this class.¹²⁶⁻¹³¹

A few idiosyncratic side effects appear to be unique to captopril, including a maculopapular skin rash, taste disturbances, membranous glomerulopathy, and leukope-

nia. Leukopenia is particularly rare and occurs more frequently in patients with collagen vascular disease. These undesirable effects were much more common when captopril was used in excessively high doses (600 to 1,200 mg/day) and are rarely encountered with current dosing regimens.³⁸ Finally, ACE inhibitors are embryopathic. Use in the second and third trimester of pregnancy can cause renal dysgenesis, oligohydramnios, pulmonary hypoplasia, and neonatal death. All ACE inhibitors carry an FDA “black box” warning against use during the second and third trimesters of pregnancy.^{123,132}

CONCLUSIONS

ACE inhibitors are among the most commonly prescribed and well-studied class of antihypertensive agents. They are effective in lowering BP in all patient populations, although the magnitude of the BP response is decreased in individuals of African descent. Despite the lack of long-term suppression in plasma angiotensin II levels, they maintain their BP-lowering effect without the development of tolerance. Their tolerability profile is generally benign and common side effects are limited to nonproductive cough and to increases in serum creatinine and potassium in susceptible individuals, primarily those with volume depletion, renal insufficiency, or heart failure. Importantly, ACE inhibitors do not interfere with cognitive function or cardiovascular reflexes.

Angiotensin II Receptor Blockers

Hans R. Brunner

Key Findings

- Renin via angiotensin II induces cardiovascular risk independent of blood pressure (BP).
- Blockade of the renin-angiotensin system reduces risk beyond BP reduction.
- Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor antagonists (ARBs) act similarly and mainly by blocking the renin-angiotensin system.
- ARBs have an antihypertensive efficacy comparable to that of other classes of antihypertensive agents.
- In patients with congestive heart failure, ARBs alone or in addition to ACEIs improve cardiac function and reduce cardiac death.
- In patients with type 2 diabetic nephropathy ARBs have been shown to provide clear renal protection, but optimal BP control is imperative.
- In many trials, so far ARBs have been shown to reduce the risk of new-onset diabetes.
- So far ARBs are the only class of antihypertensive agents available that exhibit a side effect profile comparable to placebo. Consequently, high doses of ARBs can and should be administered to obtain maximal therapeutic benefit. Whether the combination of maximal doses of ACEIs and ARBs can exert additive effects remains doubtful.

There is a continuous and independent relationship between BP and risk of cardiovascular disease events, including myocardial infarction, heart failure, stroke, and renal disease.^{1,2} Consequently, the primary goal in the treatment of hypertensive patients is to achieve the maximum reduction in the long-term total risk of cardiovascular and renal morbidity and mortality.^{1,3} The importance of lowering BP in reducing the risk of cardiovascular events has been demonstrated in various controlled clinical trials.^{4,5} In addition to the lowering of BP per se, successful realization of the primary goal of treatment also requires consideration and appropriate management of co-morbidities, such as diabetes or preexisting cardiovascular disease.^{1,6}

The renin-angiotensin system (RAS) plays an important physiologic role in the preservation of hemodynamic stability and the pathogenesis of many cardiovascular disease states, including hypertension, heart failure, nephropathy, atherosclerosis, and myocardial infarction.^{7,8} The RAS is present in the systemic circulation, as well as in a variety of tissue types, including brain, heart, blood

vessel, adrenal gland, and kidney tissue.^{9,10} The maladaptive effects of the RAS are mediated by the actions of angiotensin II, which is the major RAS effector peptide.^{7,8,11} As well as controlling cardiovascular homeostasis, angiotensin II contributes to cellular growth and replication, and is involved with inflammation and oxidative stress.^{12–15} Consequently, RAS activity contributes to the pathophysiology of hypertension, renal disease, atherosclerosis, diabetes, and heart failure.¹² Inhibition of the RAS has been shown to play an important role in lowering BP and in reducing the risk of development or progression of the conditions associated with hypertension.

Angiotensin II receptor blockers (ARBs) are the newest class of approved antihypertensive agents. These imidazole derivatives were developed with a specific and unique purpose: to block angiotensin II receptor binding. This chapter provides an overview of ARBs, focusing on their efficacy and tolerability in reducing BP patients with hypertension. The chapter also examines the evidence from some key clinical trials relating to their efficacy in treating related conditions and co-morbidities.

The RAS and evolution of ARBs

Angiotensin II is central to many of the pathologic changes that occur in hypertension and cardiovascular disease, and thus agents that interrupt the RAS are prime candidates for reducing BP and preventing or ameliorating disease processes.¹⁶ Pharmacologic inhibition of the RAS has indeed proven to be a successful therapeutic strategy, and has helped to define the contribution of the system to BP control and the pathogenesis of diseases such as hypertension, congestive heart failure, and chronic renal failure.¹⁷ The first major breakthrough in this regard was development of the angiotensin-converting enzyme (ACE) inhibitors, which are now recognized as an important therapeutic class in the control of hypertension.^{1,17} Clinical studies have also shown that ACE inhibitors are able to reduce morbidity and mortality in a wide range of patients, including those with ischemic heart disease, heart failure, diabetic nephropathy, and stroke.^{1,18–24}

Angiotensin II, which is converted from angiotensin I by angiotensin-converting enzyme (ACE), is the major end product of the RAS cascade—a series of reactions that starts with the cleavage of angiotensinogen by renin (Figure 81–1). From the RAS cascade, it can be seen that ACE is not an ideal target for RAS blockade.¹⁷ One reason is that ACE is not specific for angiotensin I, and this lack of specificity (leading to accumulation of kinins and other

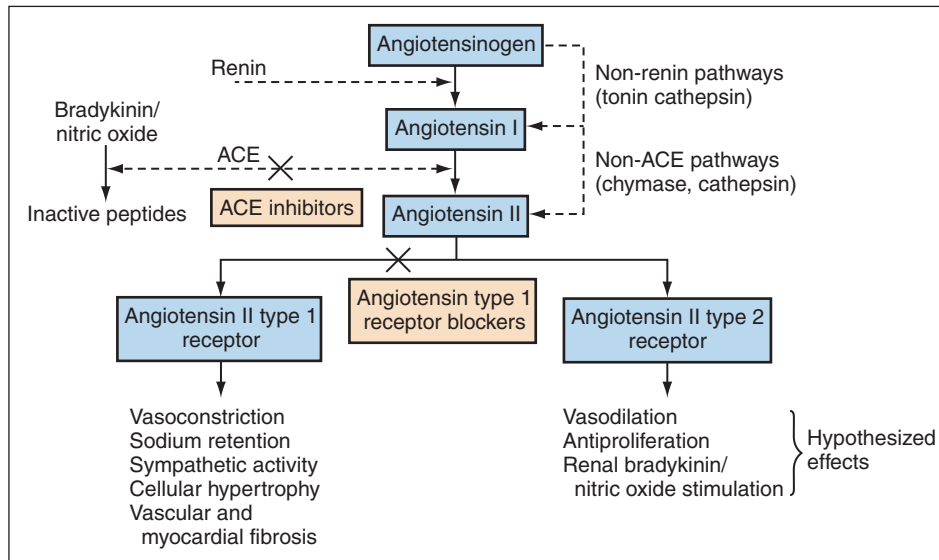

Figure 81-1. Schematic of the renin-angiotensin system and its inhibitors.

peptides) is the source of some of the most common side effects of ACE inhibitors, including cough and angioedema.^{25,26} Another potential drawback is that non-ACE-dependent pathways exist for conversion of angiotensin I, which may contribute to incomplete or temporary suppression of angiotensin II production associated with ACE inhibitors.¹⁷

There is also the issue of the effects ACE inhibition may exert on the different types of angiotensin II receptor. At least four types of receptor for angiotensin II are known (AT1, AT2, AT3, and AT4).²⁷ The AT1 and AT2 subtypes are the most well characterized, but the role of the AT2 receptor remains to be fully defined. The physiologic effects of angiotensin II mediated by the AT1 receptor include vasoconstriction, stimulation of renal sodium reabsorption, increased collagen deposition, and cellular proliferation.²⁸ It has been proposed that the AT2 receptor antagonizes the vasoactive effects of the AT1 receptor, but experimental findings are inconsistent²⁹⁻³¹ and the function of the AT2 receptor remains controversial.³² Thus, it is not clear whether inhibition of AT2 receptor function (as

would be expected with ACE inhibition) is clinically beneficial or detrimental.

In principle, blockade of the RAS at the rate-limiting step between renin and angiotensinogen would provide specific blockade of the system. However, the development of suitable candidate molecules for renin inhibition has been slow.¹⁷ Such agents may soon become available,³³ and their introduction is awaited with interest. Blockade of the RAS at the level of the AT1 receptor (which would provide specific blockade, obviate angiotensin escape, and allow continued activation of the AT2 receptor) is an attractive option. Compared with ACE inhibition, it was hypothesized that inhibition of angiotensin II at the level of the AT1 receptor should result in at least equal antihypertensive efficacy with a reduced incidence of side effects.

Several orally active ARBs have now been successfully developed (Table 81-1). Losartan was the first orally active ARB available on the market (approved for use in 1995), and olmesartan is the most recent ARB to have been successfully launched for the treatment of hyper-

PHARMACOKINETICS AND RECOMMENDED DOSAGE OF CURRENTLY AVAILABLE ANGIOTENSIN RECEPTOR BLOCKERS FOR THE TREATMENT OF HYPERTENSION

Drug Name	Bioavailability (%)	Terminal Half-life (h)	Protein Binding (%)	Conversion to Active Metabolite	Dosing	Starting/Maximum Recommended Dose (mg/day)
Losartan (Cozaar)	~30	6-9	99.8	Yes	OD	50/100
Candesartan (Amias)	15	5-9	>99	Yes	OD	16/32
Irbesartan (Aprovel)	60-80	11-15	(90-92)*	No	OD	150/300
Valsartan (Diovan)	25	6-9	94-97	No	OD	80/320

tension (approved for use in 2002). ARBs have the same mechanism of action, exhibiting high-affinity competitive AT1 receptor binding with almost no affinity for the AT2 receptor.³⁴ Structural differences between the ARBs contribute to variable degrees of “insurmountable” AT1 blockade. These range from classic competitive antagonism of the receptor with losartan to very slow dissociation from the receptor and almost complete insurmountable blockade with candesartan and olmesartan.^{35,36} Surmountable antagonists are those that produce parallel rightward shifts of agonist dose-response curves *in vitro* with no alteration of the maximal response, whereas insurmountable antagonists also depress the maximal response. Insurmountable antagonism, which is due to slow dissociation of the antagonist from the receptor, should help to ensure sustained activity when concentrations of angiotensin II increase in response to an interrupted negative feedback loop—with no rebound effect upon ARB withdrawal.³⁴ Insurmountable blockade is, however, difficult to achieve at doses used clinically.³⁴

ARBs also have different pharmacokinetic profiles.³⁴ The bioavailability of ARBs ranges from 13% for eprosartan to about 60% for irbesartan and telmisartan. The terminal half-lives of losartan, eprosartan, valsartan, and possibly candesartan are relatively short (<10 hours). Irbesartan and olmesartan have longer half-lives (11 to 15 hours), and telmisartan has the longest half-life of all

ARBs (approximately 24 hours). Once-daily oral dosing is claimed to be sufficient to provide effective antihypertensive treatment with all of the commercially available agents. Analyses of clinical studies comparing the efficacy of olmesartan with losartan, valsartan, and irbesartan appear to support this (Table 81–2).^{37,38} Olmesartan produced the greatest decreases in BP, but BP levels were reduced from baseline during the last 2 and 4 hours of the dosing interval with all of the ARBs studied.³⁸ A recent analysis of a comparison between olmesartan and candesartan showed that both agents produced substantial reductions from baseline during the last 2 and 4 hours of the dosing interval, with olmesartan again providing better BP control over 24 hours.³⁹

Blood-pressure-lowering efficacy and tolerability of ARBs

The hypothesis behind the rational pharmacologic development of ARBs has been confirmed: a number of clinical trials have now shown ARBs to be at least as effective as other classes of antihypertensive drugs (ACE inhibitors, β -blockers, calcium channel antagonists, and diuretics), with an excellent tolerability profile.⁴⁰

Comparative efficacy

A comprehensive meta-analysis of 43 randomized placebo-controlled trials involving losartan, valsartan, irbesartan,

Table 81–2. Least Squares Mean Reductions from Baseline in Systolic Blood Pressure (SBP) and Diastolic Blood Pressure (DBP) as Assessed by Ambulatory BP Monitoring After 8 Weeks of Treatment with Losartan (50 mg/day), Valsartan (80 mg/day), Irbesartan (150 mg/day), or Olmesartan (20 mg/day) in a Randomized Double-blind Study^{37,38}

and candesartan suggested that agents within the ARB class of drugs have comparable antihypertensive efficacy.⁴¹ However, studies that have directly compared the effects of ARBs are beginning to reveal some differences among agents.^{37,38,42-44} These differences among ARBs seem to be mainly related to selected dose and duration of action of drug, with longer-acting ARBs such as irbesartan, telmisartan, and olmesartan providing more effective 24-hour control of BP than shorter-acting agents such as losartan and valsartan, particularly over the latter stages of the dosing interval.

In addition to assessing the efficacy of an antihypertensive agent over an entire dosing interval, 24-hour ambulatory BP monitoring (ABPM) values may provide a more accurate assessment of a patient's risk for cardiovascular events than cuff BP values.^{45,46} Several head-to-head trials of ARBs have used ABPM as an indication of comparative antihypertensive efficacy. A 6-week double-blind randomized placebo-controlled study that involved more than 200 patients with mild to moderate essential hypertension compared the antihypertensive efficacy of telmisartan 40 or 80 mg/day with losartan 50 mg/day. Analysis of ABPM results revealed both doses of telmisartan to be significantly more effective than losartan in reducing mean 24-hour diastolic and systolic BP (DBP and SBP) (Figure 81-2).⁴⁴ Compared with losartan, telmisartan

80 mg produced significantly greater reductions in DBP and SBP during all monitored periods (day, night, and morning), whereas telmisartan 40 mg produced significantly greater reductions in DBP and SBP during the nighttime period and DBP during the morning period.

Olmesartan is another ARB with a longer half-life that has been assessed using ABPM. An 8-week double-blind randomized trial involving more than 500 patients with mild to moderate essential hypertension compared olmesartan (20 mg/day) with losartan (50 mg/day), valsartan (80 mg/day), and irbesartan (150 mg/day). The dosages of ARBs used in this study were the recommended starting doses for these agents at the time the study was carried out. The results of this comparison showed that reductions in mean 24-hour day, night, and morning DBP and SBP with olmesartan were generally significantly greater than those obtained with losartan and valsartan and equivalent to reductions obtained with irbesartan (Table 81-2).^{37,38} A similar study comparing olmesartan (20 mg/day) with candesartan (8 mg/day) also showed significantly greater reductions in mean 24-hour day, night, and morning DBP and SBP with olmesartan.⁴³

Tolerability

The adverse event profile of ARBs is similar to that of placebo.^{47,48} Moreover, unlike other antihypertensive drug

Figure 81-2. Mean reductions from baseline in mean systolic blood pressure (SBP) and diastolic blood pressure (DBP) for daytime (0600 to 2200 hours), nighttime (2201 to 0559 hours) and morning (0600 to 1159 hours) as measured by 24-hour ambulatory blood pressure monitoring after 6 weeks of therapy with telmisartan 40 or 80 mg/day, losartan 50 mg/day, or placebo in a randomized double-blind study. (Redrawn from Mallion J, Siche J, Lacourciere Y. ABPM comparison of the antihypertensive profiles of the selective angiotensin II receptor antagonists telmisartan and losartan in patients with mild-to-moderate hypertension. Reprinted by permission from Macmillan Publishers Ltd: *J Hum Hypertens* 1999;13(10):657-64, with permission.)

classes no clear class-specific adverse effects have been attributed to ARBs (Table 81–3).^{48,49} The cough frequently encountered with ACE inhibitors is not an issue with ARBs, which makes them excellent alternatives for patients intolerant to ACE inhibitors.^{50,51} Angio-oedema is another side effect of ACE inhibitors that seems to be related to the accumulation of bradykinin, although this may not be the only mechanism of action.²⁶ Some cases of angio-oedema have also been reported with losartan, but it is not clear that these cases are really linked to the drug.^{17,48} The relative freedom of ARBs from adverse effects that limit compliance has contributed to enhanced patient adherence and low discontinuation rates associated with their use in clinical studies.^{52–54} Patients also appear to be more likely to persist with long-term treatment when an ARB is prescribed as the initial agent.⁵⁴ ARBs also have no clinically important interactions with other agents commonly used in patients with hypertension,⁴⁸ indicating that they can be safely combined with other classes of antihypertensive agents.⁵⁵ The chronic nature of hypertension means that treatments are likely to be prescribed to patients for many years. In this regard, the excellent tolerability profile of ARBs is an important feature.

Dose and dosing intervals

ARBs have been shown to dose-dependently inhibit the pressor effects of exogenous angiotensin II.³⁴ However, dose recommendations for clinical use (Table 81–1) are based on antihypertensive efficacy, and ARBs are considered to have a rather flat BP dose-response curve.⁴⁰ Almost all ARBs have been shown to lower BP over 24 hours when given once per day in patients with mild to moderate hypertension.⁴⁰ However, although full blockade of angiotensin II around the clock is a clear therapeutic goal ARBs may not necessarily achieve this goal when administered according to prescribed doses as monotherapy.^{56,57}

Blockade of the RAS for the duration of 24 hours can be achieved by combining relatively low ARB doses with an ACE inhibitor.⁵⁸ However, this strategy is limited by the side effects of ACE inhibition. It has also been shown that twice-daily administration of ARBs with a relatively short duration of action or an increase in dose for ARBs with longer durations of action can produce as much blockade of the RAS as adding an ACE inhibitor to currently recommended clinical doses.^{59,60} Forclaz et al. demonstrated that when losartan 100 mg was given twice daily to normotensive subjects it produced a high degree of 24-hour RAS inhibition (77% blockade of SBP response to exogenous angiotensin I at trough). This was comparable to that achieved with losartan 100 mg once daily plus lisinopril 20 mg/day (76%), and approximately double the inhibition achieved with once-daily administration of losartan 100 mg (35%).⁵⁹ Possibly because of its longer half-life, a similar effect was not seen with twice-daily administration of telmisartan 80 mg.⁵⁹

These results have been confirmed by the more recent findings of Hasler et al., who compared olmesartan with lisinopril in a similar context. They showed that olmesartan 20 mg/day produced a similar degree of 24-hour RAS inhibition to lisinopril 20 mg/day (58% of SBP response to angiotensin at trough for both). The combination of lisinopril 20 mg/day plus olmesartan 20 mg/day produced a higher degree of inhibition (80%), which was comparable to that produced by olmesartan 80 mg/day (76%).⁶⁰ Thus, in terms of blocking the vascular effects of angiotensin higher doses of longer-acting ARBs such as olmesartan are as effective as lower doses of the same compounds combined with an ACE inhibitor. Findings such as these provide a rationale for the use of higher doses of ARBs. Because ARBs do not exhibit any dose-dependent adverse effects, it is unlikely that there will be any safety concerns associated with increased dosing.^{59,60}

ADVERSE EFFECT PROFILES OF ANTIHYPERTENSIVE DRUG CLASSES					
Adverse Effect	ARBs	ACE Inhibitors	Diuretics	β -blockers	CCBs

ARBs = angiotensin II receptor blockers, ACE = angiotensin-converting enzyme, CCBs = calcium channel blockers.

Table 81–3. Adverse Effect Profiles of Antihypertensive Drug Classes

Outcome studies involving ARBs

The benefits of lowering BP are undisputed. However, because hypertension increases the risk of cardiovascular disease and other conditions a full range of outcomes are necessary to evaluate the efficacy of antihypertensive medication.⁶¹ The best source of clinical evidence upon which physicians should base decisions about the treatment of patients is generally regarded as “hard endpoints” obtained from large randomized clinical trials with antihypertensive agents.⁶² These include all-cause mortality, cardiovascular disease-specific mortality, and morbidity. Intervention trials are usually limited to a duration of =5 years, and thus it is often only when patients with high absolute cardiovascular risk are studied that differences in hard endpoint outcomes among antihypertensive drug classes are seen.⁶³ Consequently, many important outcome trials involving ARBs have been conducted in a range of patients at relatively high risk of morbidity and mortality from conditions such as cardiovascular disease and stroke (Table 81–4).

Studies in high-risk patients with hypertension

Various trials have been conducted with ARBs in hypertension, but there are three major cardiovascular outcome trials of ARBs in high-risk patients with hypertension that merit particular interest. These are the Losartan Intervention for Endpoint (LIFE) study,⁶⁴ the Study on Cognition and Prognosis in the Elderly (SCOPE),⁶⁵ and the Valsartan Antihypertensive Long-term Use Evaluation (VALUE) study.⁵⁵ Add-on treatment with diuretics and other antihypertensive drugs were permitted as required to lower BP to goal in all of these trials. Composite outcome endpoints, major cardiovascular outcome endpoints, and BP results from these three trials are outlined in Table 81–5.

LIFE

The LIFE study⁶⁴ provided some of the first evidence that ARBs may have possible cardiovascular protective effects beyond the powerful independent effects of lowering BP. In this large study, 9193 patients with primary hypertension and electrocardiographic evidence of left ventricular hypertrophy were randomly assigned to at least 4 years’

treatment with losartan or the β -blocker atenolol at equal doses (50 to 100 mg). The primary composite endpoint of cardiovascular mortality, stroke, and myocardial infarction was reached at a rate of 23.8 per 1000 patient-years of follow-up in the losartan group versus 27.9 with atenolol. This resulted in a significant 13% reduction of relative risk of the composite endpoint in the losartan-based treatment group compared to the atenolol-based regimen. The difference was due mainly to a highly significant 25% reduction in the relative risk of fatal or nonfatal stroke. Rates of myocardial infarction and cardiovascular mortality were not significantly different between the treatment groups. The losartan-based regimen produced substantial BP reductions that were similar to those obtained with the atenolol-based regimen. However, at the end of follow-up the reduction in sitting SBP was 1 mmHg greater with losartan than with atenolol.

Diabetes is a major independent indicator risk factor for cardiovascular disease, and patients with diabetes have at least a twofold higher risk of cardiovascular disease than nondiabetic individuals.⁶⁶ Diabetes is also closely associated with hypertension, and hypertension is approximately twice as common in patients with diabetes compared with nondiabetic patients.⁶⁷ Moreover, in patients who are already at high risk because of hypertension diabetes mellitus approximately doubles the risk of cardiovascular disease.⁶⁸ As expected, the incidences of cardiovascular morbidity and mortality in the subgroup of patients with diabetes who participated in the LIFE study were higher than in the overall population. The relative risk of the primary endpoint in the subgroup of patients with diabetes (n=1195) was significantly reduced by 24% with losartan versus atenolol ($p<0.05$), and the relative risk of death from cardiovascular disease was also significantly reduced (relative risk 0.63; $p<0.5$).⁶⁹ Adjustment for SBP had little effect on these results. Notably, in the lower-risk category of patients without vascular disease or diabetes the relative risk of the primary endpoint also significantly favored losartan (relative risk 0.82; $p<0.05$).

The overall LIFE trial results have led some to comment that a treatment strategy based on combining an ARB with a low dose of hydrochlorothiazide provides cardio-protection at least equal to that provided by β -blockers, greater protection from stroke (despite almost equal

BP control), and the benefit of fewer adverse effects.⁶³ There is, however, still room for improvement in terms of outcome. It has been hypothesized that because once-daily administration of losartan 100 mg cannot provide sustained high RAS blockade over 24 hours higher doses of losartan administered twice daily might enhance the differences in outcome between losartan and atenolol.⁶³ This again underlines the issue of dosing with ARBs and the need for clinical trials to assess the efficacy of using doses higher than those currently prescribed.

SCOPE

A significant ARB-associated reduction in the risk of stroke has been observed versus placebo in SCOPE, the first large-scale clinical trial to determine the effects of an ARB on cardiovascular outcomes in elderly patients.⁶⁵ A total of 4964 hypertensive elderly patients (mean age 76 years) were randomized to 3 to 5 years' treatment with candesartan 8 to 16 mg/day or placebo. However, it

should be noted that 84% of patients in the control group received active antihypertensive agents to control BP. A 10.9% risk reduction for candesartan versus placebo in the composite primary endpoint of major cardiovascular events (cardiovascular death, nonfatal myocardial infarction, and nonfatal stroke) was not statistically significant. The SCOPE researchers remarked that when compared with the control group the reductions in event rate seen in SCOPE were of similar magnitude to those observed in the losartan group versus atenolol in LIFE. As in the LIFE study, the effect of the ARB was driven by the reduction in stroke, with the risk of nonfatal stroke being significantly reduced by 28% in the candesartan treatment group. There were no significant differences between the treatment groups with regard to fatal, nonfatal, or total myocardial infarction; fatal stroke; cardiovascular mortality; or total mortality. A 3.2/1.6-mmHg greater reduction in BP was observed in favor of the candesartan group in the SCOPE study, which probably explains most of the reduc-

tion in nonfatal stroke observed with the ARB. Evidence from meta-regression analysis shows that even relatively small reductions in BP are important in terms of stroke reduction.⁷⁰

VALUE

The aim of the VALUE study was to test the hypothesis that valsartan would be more effective than the calcium channel blocker amlodipine in preventing cardiac morbidity and mortality for the same degree of BP lowering.⁷¹ In the VALUE study, 15,245 hypertensive patients at high cardiovascular risk were randomized to 4 to 6 years' treatment with antihypertensive regimens based on valsartan 80 to 160 mg/day or amlodipine 5 to 10 mg/day. There was no difference in the primary composite endpoint of cardiac morbidity and mortality between the two treatment groups. Stroke was less common in the amlodipine group, but the difference between the treatment groups did not reach statistical significance. Myocardial infarction was significantly more frequent in the valsartan group. Unfortunately for the interpretation of the trial results, patients treated with amlodipine-based therapy had significantly greater reductions in BP than patients treated with the valsartan-based regimen.

The differences in BP control in favor of amlodipine were sufficiently large to have major endpoint effects. These confounded the ability to test the primary hypothesis of VALUE, which was dependent on there being similar BP control between the two treatment groups.⁷² One of the most interesting aspects of the VALUE data relates to the speed of onset of antihypertensive efficacy. After 1 month of treatment, BP control in the amlodipine group was substantially lower in the valsartan group (4.0/2.1 mmHg). This BP difference between the two groups had decreased to 2.1/1.6 mmHg by 6 months, and remained stable thereafter. For all endpoints, the highest odds ratios in favor of amlodipine were observed during the first 6 months of the trial (when BP differences between the treatment groups were greatest) (Figure 81-3). In the following months, when the difference in BP was relatively low, odds ratios were attenuated. In an attempt to overcome inequal-

ities in BP, serial median matching at 6 months was used to create 5006 valsartan-amlodipine patient pairs matched for SBP (mean 139.9 mmHg) and other variables. In this analysis, most outcomes (including the primary endpoint) were similar for the two regimens.⁷²

During the latter stages of the VALUE trial, there was a persistent trend toward fewer admissions for heart failure in the valsartan group. However, the overall difference (which resulted in an 11% relative risk reduction) did not reach statistical significance.⁷¹ In the post-hoc analysis of results, using serial median matching at 6 months the heart failure endpoint was significantly less likely with valsartan than with amlodipine ($p < 0.05$).⁷² The steady trend for a benefit of valsartan with regard to reduction of heart failure was consistent with the original VALUE study hypothesis and is also consistent with other research suggesting that a reduction in heart failure is seen with drugs that block the RAS.⁷⁰

When data for both the valsartan and amlodipine treatment groups were pooled, immediate responders (patients who when switched from previous treatment to study drug had not increased in BP by 1 month, or those previously untreated who had an initial decrease in SBP of ≥ 10 mmHg) had significant advantages in relation to combined cardiac events, stroke, and all-cause death during the remainder of the study.⁷² Such findings indicate that prompt control of BP, independent of drug type, was the main determinant of event rates in the VALUE study.

The results of the VALUE trial emphasize the importance of prompt BP lowering. Consequently, it has been recommended that instead of treatment initiation involving immediate rollover to a low dose of study drug (as occurred with valsartan in VALUE) more stringent initial control of BP should be an ethical requirement for clinical trials involving patients with hypertension.⁷² It is, for example, important to adequately and rapidly titrate ARBs, and the addition of a low-dose thiazide diuretic at the first treatment step should be considered in high-risk hypertensive patients.¹⁻⁶ When the VALUE study was designed, the usual clinical dose range for valsartan was 80 to 160 mg/day. It has subsequently been shown that higher doses are

Figure 81-3. Differences in blood pressure between treatment groups, and odds ratios for the primary endpoint, secondary endpoints, and all-cause death during consecutive time periods in the VALUE study. Bars show 95% confidence intervals. (Redrawn from Julius S, Kjeldsen SE, Weber M, et al. Outcomes in hypertensive patients at high cardiovascular risk treated with regimens based on valsartan or amlodipine: The VALUE randomised trial. *Lancet* 2004;363(9426):2022-31, with permission from Elsevier.)

required for full angiotensin II blockade,⁵⁷ and a 160- to 320-mg/day dose range has now been approved. It should be noted that speed of onset of antihypertensive action is not an issue for ARBs, and that studies have shown substantial BP reduction with ARBs such as olmesartan and candesartan after a single week of treatment.⁴³

Patients with isolated systolic hypertension

With increasing age, a gradual stiffening of the large arteries occurs, typically resulting in loss of elasticity and compliance and a consequent continuous elevation of SBP. Isolated systolic hypertension (ISH) is the most common form of hypertension in the elderly and a major risk factor for cardiovascular disease. Angiotensin II is believed to contribute to the development of endothelial dysfunction and vascular remodeling associated with hypertension, and it has been hypothesized that ARBs may be particularly useful in patients with ISH.⁷³

The ISH substudy of LIFE involved 1326 patients with ISH (SBP between 160 and 200 mmHg and DBP <90 mmHg). This substudy demonstrated that compared to atenolol the adjusted relative risk of cardiovascular mortality was reduced by 46% with losartan ($p=0.01$), and the risk of stroke decreased by 40% ($p<0.05$).⁷⁴ BP was reduced by 28/9 mmHg in both arms of the study. These results are consistent with those reported in a subgroup analysis of outcome results in SCOPE patients with ISH (1518 patients had SBP >160 mmHg and DBP <90 mmHg) in which a reduction of 42% in the relative risk of stroke was observed for candesartan versus control.⁷⁵ BP reduction was slightly better with the candesartan-based regimen (2.0/1.2 mmHg advantage). It is possible that this small difference could account for part of the observed benefit with regard to stroke, but it was calculated that it should only account for a 15% difference between the treatment groups, suggesting that the beneficial effect of AT1 receptor blockade on stroke was not a result of BP reduction alone.⁷⁵

Preventing new-onset diabetes mellitus

Several studies have suggested that blockade of the RAS may protect against the development of new-onset type 2 diabetes.⁷⁶ During the VALUE trial, the incidence of new-onset diabetes was significantly lower with valsartan-based than with amlodipine-based regimens (32 versus 41 cases per 1000 patient-years), resulting in a 23% relative risk reduction ($p<0.0001$).⁷¹ There was a 25% risk reduction in the incidence of new-onset diabetes in the losartan treatment group relative to the atenolol treatment group during the LIFE trial ($p=0.001$).⁶⁴ During the SCOPE study, new-onset diabetes was reported in 4.3% of patients in the candesartan treatment group and 5.3% in the control group, but the difference did not reach statistical significance ($p=0.09$).⁶⁵ The SCOPE researchers commented that the lower rate of new-onset diabetes in the candesartan group versus the control group was similar in size to that observed in the LIFE study.

The VALUE results are particularly interesting because the calcium channel blocker comparison group is considered to be metabolically neutral, suggesting that AT1 recep-

tor blockade had a positive effect on long-term glucose metabolism.⁷¹ β -blockade, however, may decrease insulin sensitivity and increase the risk for the development of diabetes. Thus, a detrimental effect of atenolol may have contributed to the difference between losartan and atenolol with regard to new-onset diabetes in the LIFE study.^{63,77,78} The SCOPE researchers also commented that a likely contribution to the reduced incidence of diabetes for patients receiving the ARB in their trial was that the use of diuretics and/or β -blockers reduced insulin sensitivity in the control group.⁶⁵

It is well known that diabetes increases the cardiovascular consequences of hypertension. However, the duration of the VALUE trial was not long enough for cardiovascular complications of new-onset diabetes to emerge. Longer-term trials would be required to ascertain the true extent of benefits of ARBs on morbidity and mortality due to cardiovascular and renal disease in patients with hypertension.⁷⁹

Patients with heart failure or acute myocardial infarction

The value of ACE inhibitors in reducing mortality rates and major nonfatal cardiovascular events in patients with chronic heart failure caused by left ventricular systolic dysfunction and in those with acute myocardial infarction is well established.⁸⁰ Evidence from clinical trials now suggests that when used at appropriate clinically effective doses ARB regimens lead to reductions in the risk of death and cardiovascular events in patients with heart failure and left ventricular systolic dysfunction or a high-risk acute myocardial infarction. The extent of these effects is comparable to that seen with ACE inhibitors, and additive benefits may be produced in patients with chronic heart failure when ARBs and ACE inhibitors are used in combination.^{50,81-83}

Head-to-head comparisons of ARBs and ACE inhibitors

The 48-week Evaluation of Losartan in the Elderly (ELITE) study involved 722 ACE-inhibitor-naïve elderly patients with symptomatic heart failure. ELITE was designed to determine whether ARB blockade with losartan 50 mg once daily offered safety and efficacy advantages over ACE inhibition with captopril 50 mg three times daily.⁸⁴ As expected, losartan was generally better tolerated than captopril. However, unexpectedly a 46% risk reduction for all-cause mortality was seen with losartan compared to captopril ($p<0.05$). However, the ELITE II trial ($n=3152$), which was subsequently designed as a superiority trial to prospectively compare the two treatments on all-cause mortality, failed to find a significant difference between the treatment groups over a mean 1.5 years of follow-up (hazard ratio of 1.13 for total mortality in the losartan versus the captopril treatment group).⁸⁵ The once-daily 50-mg dose of losartan used in the ELITE trials was certainly too low to be optimally effective and provide reliable results. This led to the initiation of a heart failure outcome trial in which losartan 50 mg is being compared to 150 mg/day.⁸⁶

In the Optimal Therapy in Myocardial Infarction with the Angiotensin II Antagonist Losartan (OPTIMAAL) trial,⁸³ 5477 patients with acute myocardial infarction and signs or symptoms of heart failure during the acute phase were randomized to the same losartan/captopril regimens used in the ELITE studies and followed for a mean 2.7 years. A nonsignificant difference in the primary total mortality outcome was seen in favor of captopril (relative risk 1.13, $p=0.07$), and non-inferiority of losartan could not be proved.

Subsequently, in the Valsartan in Acute Myocardial infarction (VALIANT) trial⁸⁷ valsartan 160 mg once daily was found to be as effective as captopril 50 mg twice daily in reducing the risk of major cardiovascular events in patients after acute myocardial infarction. In the VALIANT trial, 14,703 patients with acute myocardial infarction complicated by heart failure, left ventricular dysfunction, or both were randomized to one of three treatment arms: valsartan 160 mg bid, captopril 50 mg tid, or a combination of valsartan 80 mg bid + captopril 50 mg tid and followed for a median of 25 months. The risks of mortality from any cause and from cardiovascular mortality were similar in the three treatment groups. In an imputed placebo analysis, valsartan was shown to preserve 99.6% of the mortality benefit of captopril. The rate of the secondary endpoint of death from cardiovascular causes, recurrent myocardial infarction, or hospitalization for heart failure was also similar in the three groups.

Combining an ARB and an ACE inhibitor

The Valsartan Heart Failure Trial (Val-HeFT)⁸¹ and the Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM)-Added trial⁸² found that addition of an ARB to standard therapy involving ACE inhibitors provided additive clinical benefits in patients with chronic heart failure. This is in apparent contrast to the results of the VALIANT trial, which indicated no such benefits of combining an ARB with ACE inhibitor therapy in high-risk acute myocardial infarction patients.⁸⁷ However, it should be noted that the results of Val-HeFT were driven by the small subgroup (7%) of patients who did not receive an ACE inhibitor because of intolerance.

In the Val-HeFT trial, patients ($n=5010$) were randomized to placebo or valsartan 160 mg twice daily, which were added to standard treatment (this included an ACE inhibitor in 93% of patients) and followed for a mean of 23 months. Although there was no reduction in mortality (relative risk 1.02), valsartan significantly reduced the risk of the composite co-primary endpoint (mortality, cardiac arrest with resuscitation, hospitalization for heart failure, or administration of inotropic or vasodilator drugs for ≥ 4 hours without hospitalization) by 13.2% ($p<0.01$). This was mainly driven by a 27.5% reduction in the risk of hospitalization for heart failure ($p<0.001$).

In CHARM-Added, patients taking an ACE inhibitor ($n=2548$) were randomized to either placebo or a target dose of candesartan 32 mg once daily and followed for a mean of 41 months. Candesartan significantly reduced the risk of the primary outcome (cardiovascular death or

hospitalization for worsening heart failure) by 15%, and the risk of both primary endpoint components was also significantly reduced from 16 to 17% ($p<0.05$ for all outcomes). It has been suggested that the cardiovascular mortality benefit associated with the ARB in the CHARM-Added study may have been due to the fact that these patients had more advanced disease over a longer follow-up than patients in Val-HeFT.^{86,88}

In CHARM, many patients with chronic heart failure remained symptomatic despite treatment with an ACE inhibitor. One consequence of this is that “ACE escape” could have occurred in such patients, resulting over time in increased levels of angiotensin II.⁸⁶ In contrast, only 14% of the VALIANT patients had previous chronic heart failure and many may have had relatively short-lived activation of the RAS, in which environment an ARB and ACE inhibitor were started simultaneously. In addition, different ARB inhibitor doses used in the VALIANT, CHARM-Added, and Val-HeFT trials may have affected outcomes, and this appears to be a much more likely explanation. In the VALIANT combination arm, the dose of valsartan was half that used in both the monotherapy arm and Val-HeFT study. Thus, it was unlikely that the relatively low dose of valsartan was equivalent to the dose of candesartan used in CHARM-Added.

An ARB as an alternative to an ACE inhibitor

The CHARM-Alternative trial⁵⁰ was the first randomized trial to evaluate an ARB in ACE inhibitor-intolerant patients with chronic heart failure. Patients ($n=2028$), most of whom were unable to take ACE inhibitors because of cough (72%), were randomized to placebo or a target dose of candesartan 32 mg once daily and followed for a median duration of 33.7 months. The risk of death from a cardiovascular cause or hospitalization for heart failure was significantly reduced by 23% with candesartan ($p<0.001$). The researchers noted that this result was similar in magnitude to reductions in these outcomes previously seen with ACE inhibitors in other trials. Risk reduction for the primary endpoint was mainly driven by a 32% relative risk reduction of hospital admission for heart failure ($p<0.0001$). Reduction in the risk of cardiovascular death in patients receiving valsartan (hazard ratio of 0.85) was not statistically significant, but did reach significance in a covariate-adjusted analysis (hazard ratio 0.80; $p<0.05$). Candesartan was almost as well tolerated as placebo in the CHARM-Alternative ACE-inhibitor intolerant group of patients.

Renal protection in patients with type 2 diabetes

In general, chronic renal disease can be a cause or consequence of hypertension. The majority of patients with chronic renal disease have hypertension, and without intervention this can result in a vicious cycle of worsening renal function and hypertension.^{89,90} Diabetic renal disease is consequently closely linked with cardiovascular disease, and there are many similarities between renal and cardiovascular disease regarding the role of endothelial dysfunction and angiotensin-II-mediated cellular proliferation.⁹¹

Trials such as the Irbesartan MicroAlbuminuria Type 2 Diabetes Mellitus (IRMA 2),⁹² Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL),⁹³ and the Irbesartan Diabetic Nephropathy Trial (IDNT)⁹⁴ suggested that ARBs may have renoprotective effects that are independent of BP-lowering effects in patients with diabetes. Also worthy of mention is the more recent Angiotensin-Receptor Blockade Versus Converting-Enzyme Inhibition in Type 2 Diabetes and Nephropathy (DETAIL) study. This demonstrated that antihypertensive treatment based on the ARB telmisartan was equivalent to therapy based on the ACE inhibitor enalapril in providing renoprotection, as assessed by change in glomerular filtration rate in hypertensive patients with type 2 diabetes and early nephropathy.⁹⁵

Patients with microalbuminuria

One of the earliest markers of nephropathy is microalbuminuria, a persistent increased urinary albumin excretion (UAE) rate of 20 to 200 $\mu\text{g}/\text{min}$ or an albumin-to-creatinine ratio of 30/300 mg/g.⁹⁶ Microalbuminuria is more prevalent in diabetic and hypertensive populations,⁹⁷ and is a known risk factor for progression to further stages of nephropathy as well as for cardiovascular risk in patients with hypertension.^{1,3} Clinical studies with ARBs have shown that they can reduce the rate of progression of diabetic nephropathy.

A total of 590 hypertensive patients with type 2 diabetes and persistent microalbuminuria were enrolled in the IRMA 2 trial, a randomized placebo-controlled 2-year trial of irbesartan at a dose of either 150 mg/day or 300 mg/day.⁹² Over the course of the study, irbesartan reduced the rate of progression to clinical macroalbuminuria (a more advanced and clinically overt stage of nephropathy). After adjustment for the baseline level of microalbuminuria and the BP level achieved during the study, the relative risk of diabetic nephropathy was reduced by 44% for irbesartan 150 mg compared with placebo ($p=0.05$) and by 68% in the 300-mg group ($p<0.001$). This again highlights the importance of complete blockade of the RAS, independent of BP control.

The DETAIL study randomly assigned 250 patients with type 2 diabetes and early nephropathy (approximately 82% of whom had microalbuminuria) to receive telmisartan 80 mg/day or enalapril 20 mg/day.⁹⁵ After 5 years, the difference between the treatment groups in mean change in glomerular filtration was $-3.0 \text{ ml}/\text{min}/1.73\text{m}^2$ (95% confidence interval -7.6 to $1.6 \text{ ml}/\text{min}/1.73\text{m}^2$). The lower 95% confidence interval boundary of $-7.6 \text{ ml}/\text{min}/1.73\text{m}^2$ was greater than $-10 \text{ ml}/\text{min}/1.73\text{m}^2$, which was the predefined level for a clinically significant difference between the groups—indicating that telmisartan was not inferior to enalapril. The study authors commented that with respect to renoprotection the results of the DETAIL study were consistent with those of the IRMA 2 trial.

Patients with macroalbuminuria

ARBs delayed progression from macroalbuminuria toward end-stage renal disease in the IDNT and the RENAAL studies.^{93,94} Both of these studies were designed to investigate the effects of ARBs on renal outcomes in patients with type 2 diabetes mellitus and overt nephropathy. In RENAAL, in addition to their standard antihypertensive therapy 1523 patients were randomized to receive losartan (50 to 100 mg/day) or placebo, and were followed up for a mean of 3.4 years. The IDNT study enrolled 1715 patients who were randomized to receive irbesartan 300 mg/day, amlodipine 10 mg/day, or placebo and followed for a mean 2.6 years. The primary outcome in both trials was a composite endpoint of a doubling of the baseline serum creatinine concentration, end-stage renal disease, or death. As shown in Table 81–6, risk of the primary endpoint was significantly reduced in both studies. A slowing of the rate of progression of nephropathy was reflected in a significant increase in the time to a doubling of the serum creatinine concentration, which is a measure that approximates a halving of the glomerular filtration rate. In the RENAAL study, losartan reduced the risk of end-stage renal disease by 28%. Patients treated with amlodipine in the IDNT trial had worse renal outcomes than those in the irbesartan group, although there was

RISK OF PRIMARY COMPOSITE AND COMPONENT ENDPOINTS IN THE REDUCTION OF ENDPOINTS IN NIDDM WITH THE ANGIOTENSIN II ANTAGONIST LOSARTAN (RENAAL) STUDY ⁹³ AND THE IRBESARTAN DIABETIC NEPHROPATHY TRIAL (IDNT) ⁹⁴

equal control of BP in the two groups. Corrections for any disparities in BP control between the treatment groups did not reverse the renoprotective effects afforded by the ARBs in either study.

Patients with normoalbuminuria

Diabetic nephropathy develops slowly, and the early pathologic changes of extracellular matrix accumulation in the glomeruli and interstitium are clinically silent. Thus, nephropathy has already started by the time microalbuminuria is detected. Studies such as IRMA 2 and IDNT strongly suggest that interfering with the RAS has renoprotective benefits. However, the patients in those studies already had clinically detectable diabetic nephropathy. Thus, the question remains as to the extent of the benefit that might be possible with earlier inhibition of the RAS (i.e., in diabetic patients without any overt clinical signs nephropathy).

The Bergamo Nephrologic Diabetes Complications (BENEDICT) study recruited patients with diabetes and hypertension who were normoalbuminuric. This study showed that ACE inhibition was able to reduce the development of microalbuminuria compared to the calcium channel blockade.⁹⁸ However, the possible benefits of ARBs in diabetic patients without overt nephropathy are not yet known. This question is now being addressed by the Randomized Olmesartan and Diabetes Microalbuminuria Prevention (ROADMAP) study. This primary prevention study has been designed to determine whether olmesartan can prevent or delay the development of microalbuminuria in patients with type 2 diabetes and normoalbuminuria who are at risk of developing nephropathy due to the presence of at least one cardiovascular risk factor. In addition to assessing olmesartan's effects on microalbuminuria, the design and size of the ROADMAP study are such that it should allow assessment of whether such early intervention will translate into protection from cardiovascular and renal events and mortality.⁹⁹ Such studies would help provide conclusive answers about whether BP reduction alone is responsible for renal protection or whether inhibiting the RAS is also required for these benefits.

Recommendations regarding use of ARBs in clinical practice

Evidence suggests that specific drug classes may have benefits that may extend their BP-lowering effects and that may be particularly beneficial for certain groups of patients.^{1,3} As mentioned previously, reducing the risk of cardiovascular disease should be the main aim of therapy (rather than simply reducing elevated BP). The choice of drugs for individual patients should be tailored to the patients' risk profile, including the presence or absence of target organ damage, clinical cardiovascular or renal disease, or diabetes.

Randomized clinical trials have demonstrated that ARBs have clinical benefits in a range of conditions that predispose patients to cardiovascular events, including left ventricular hypertrophy, isolated systolic hypertension, diabetes, micro- or macroalbuminuria, heart failure, and coronary artery disease.^{64,69,74,81,83,87,92,94,100} The results of

these trials are reflected in both U.S. and European hypertension management guidelines, which list heart failure with left ventricular systolic dysfunction, diabetes, and kidney disease as conditions in which there is compelling clinical evidence favoring the use of ARBs.^{1,3} A role for ARBs as alternatives to ACE inhibitors (especially in patients intolerant of ACE inhibitors, or as additions to ACE inhibitors in patients with heart failure) is recommended.^{1,3} Here, of course, it should be remembered that when used at a sufficiently high dose or with a more frequent dosing interval ARBs can produce the same degree of RAS inhibition as the addition of an ARB to an ACE inhibitor (without the side effects of ACE inhibitors). As well as supporting the use of ARBs as effective alternative or additional therapies to ACE inhibitors in patients with chronic heart failure, recent chronic heart failure guidelines state that use of ARBs should be considered in ACE inhibitor-intolerant patients with acute myocardial infarction complicated by heart failure and/or left ventricular systolic dysfunction.¹⁰¹

In terms of renoprotection, ARBs are suggested as a logical first choice for inclusion in the antihypertensive regimens of patients with diabetes mellitus and hypertension.^{1,3} Recent guidelines for the management of chronic kidney disease specifically recommend ARBs as preferred antihypertensive agents for patients with diabetic renal disease or nondiabetic renal disease with albuminuria.¹⁰²

The future for ARBs

In addition to hypertension, ARBs have been approved for use (or are either registered or in pre-registration stages) for several other indications, including congestive heart failure, post-myocardial infarction, and diabetic nephropathy. In addition, ongoing and planned trials are likely to extend the indications for which ARBs are approved even further. Pharmaceutical companies and research institutions now register the clinical studies with which they are involved, and this provides insights into possible directions for agents in clinical development.

Searching Internet sites that list these trials (such as <http://clinicaltrials.gov/> and <http://www.controlled-trials.com/>) reveals that a considerable number of studies involving ARB have been completed, are in progress, or are being prepared. The diabetes-sparing potential of ARBs is being investigated in trials such as the ongoing Nateglinide and Valsartan in Impaired Glucose Tolerance Outcomes Research (NAVIGATOR) trial.¹⁰³ The effects of ARBs in patients with atherosclerosis are uncertain, but studies such as the Effect of Valsartan on Endothelial Function, Oxidative Stress, Carotid Atherosclerosis, and Endothelial Progenitor Cells (EFFERVESCENT) trial and the Multi-centre Olmesartan Atherosclerosis Regression Evaluation (MORE) trial are likely to change this. If successful, such studies may further increase the number of indications for which ARBs are approved.

Many patients with hypertension will require at least 2 antihypertensive medications to achieve BP goals, and treatment guidelines suggest that one of these should be a thiazide diuretic.^{1,3} The antihypertensive efficacy of ARBs has been shown to be potentiated by the addition

of a thiazide diuretic,⁴⁰ and several ARBs are now available or being launched as fixed combination treatments with hydrochlorothiazide. Significant cardiovascular benefits have been reported with calcium channel blockers (CCBs),¹⁰⁴ and studies of treatments combining these with ARBs are also ongoing or planned.

Multifactorial interventions that combine agents that target different aspects of cardiovascular risk may provide a means for more effective reduction of cardiovascular risk.¹⁰⁵ Thus, agents such as statins may come to play an important role in reducing cardiovascular risk in patients with hypertension, and combinations of ARBs with statins is a logical development. The future is likely to see more developments involving rational combinations of different

drug classes for use in high-risk patients. Such combinations are likely to be based on long-term reduction of risk of cardiovascular and other diseases, such as diabetes and nephropathy. As such, it is apparent that ARBs are uniquely placed in terms of their known and potential efficacy and excellent tolerability profile and are likely to play an increasingly central role in the management of hypertension and cardiovascular risk.

ACKNOWLEDGMENTS

I would like to thank Phil Jones and Joanne Dalton of Adis Communications, who provided editorial support during the writing of this chapter.

Chapter
82Alpha Adrenoreceptor
Antagonists

Henry L. Elliott

Key Findings

- Selective alpha-1-adrenoreceptor antagonist drugs effectively block sympathetically mediated vasoconstrictor responses and thereby reduce peripheral vascular resistance (and blood pressure).
- There are no significant clinical contraindications to selective alpha-1-antagonist drugs. In fact, they have beneficial effects on glucose and lipid metabolism.
- Doxazosin is currently the preferred agent, particularly as an “add-on” treatment for all types of hypertension and as a combination partner with all classes of antihypertensive drug.
- Doxazosin (GITS formulation) has been shown to improve clinical outcomes when used in combination with other conventional antihypertensive drugs (see ASCOT results).

It is generally accepted that the sympathetic nervous system plays a role in the initiation and maintenance of the increased peripheral vascular resistance characteristic of established essential hypertension. Increases in arteriolar and venous tone, and hence blood pressure, are principally mediated by noradrenaline released from sympathetic nerve terminals and acting at alpha 1 adrenoreceptors located post-junctionally in the blood vessel wall (Figure 82-1).¹ Essential hypertension reflects, at least in part, an enhanced alpha adrenergic vasoconstrictor influence on blood pressure regulation.

As with most receptor systems, further research has identified several alpha adrenoreceptor subtypes. For example, the alpha-1b subtype is found in the urinary tract and is targeted in the treatment of benign prostatic hyperplasia (BPH). However, the classical post-junctional alpha-1 adrenoreceptor remains the primary target for blocking sympathetically mediated vasoconstrictor mechanisms and thereby promoting a reduction in blood pressure. Because an alpha-1 adrenoreceptor antagonist drug reduces vascular smooth muscle tone and peripheral vascular resistance without interfering with myocardial contractility, it appears to fulfill the fundamental requirements for an effective antihypertensive agent.

CLINICAL PHARMACOLOGY

Mechanism of action

The particular advantage of selective alpha-1 antagonists (alpha-1 blockers), compared to nonselective alpha antago-

nist agents, is that they do not interfere with local feedback control mechanisms involving prejunctional alpha adrenoreceptors within the neurovascular junction (Figure 82-1).² Thus, “spillover” of catecholamines into the systemic circulation (which occurs as a consequence of the blocked reuptake via pre-synaptic alpha-2 adrenoreceptors) is significantly reduced. Accordingly, the risk of cardiac stimulation and reflex cardioacceleration during chronic treatment is reduced. Of the selective alpha-1 blockers developed for the treatment of hypertension, the prototype drug prazosin has largely been superseded by longer-acting quinazoline derivatives, particularly doxazosin (see Box 82-1). Other agents with selective alpha-1 blocking activity, such as tamsulosin and alfuzosin and the unrelated agent indoramin, now have little or no place in the routine management of hypertension but are retained for the use in the management of BPH.

Figure 82-1. Depiction of the neuroeffector junction and the locations of pre- and post-junctional alpha adrenoreceptors.

Box 82-1**Drugs with Alpha-1 Adrenoreceptor Antagonist Activity**

Nonselective:

- Phenoxybenzamine
- Phentolamine

Selective:

- Quinazoline derivatives (prazosin, doxazosin, terazosin)
- Non-quinazolines: indoramin

Multiple actions:

- Carvedilol
- Labetalol

Nonselective alpha adrenoreceptor antagonists

Two nonselective agents—phentolamine (by parental administration) and the longer-acting agent phenoxybenzamine (by oral administration)—retain occasional clinical roles in specialist circumstances. These agents are used in the management of hypertension associated with the rare catecholamine-secreting tumor pheochromocytoma either as part of the perioperative management or as a constituent of the long-term antihypertensive drug treatment when surgical correction is not possible. These drugs may also have a role in the treatment of hypertensive crises associated with (for example) overdosage of sympathomimetic drugs, with autonomic dysreflexia, or as a consequence of the rebound hypertensive response that follows the abrupt withdrawal of centrally acting antihypertensive drugs such as clonidine.

Selective alpha-1 adrenoreceptor antagonists

Prazosin (the prototype quinazoline alpha-1 blocker) was a short-acting agent that required multiple daily dosing (unless administered as a modified release formulation), whereas the newer longer-acting quinazoline derivatives (including doxazosin and terazosin) have been licensed for once-daily administration for the treatment of hypertension (Box 82-1). There are basic similarities in the pharmacokinetics of the quinazoline derivatives, which have almost complete absorption from the gastrointestinal tract, bioavailability in the range of 40 to 70%, and hepatic metabolism as the principal route of elimination. Prazosin achieves its peak plasma concentrations within about 1 to 2 hours and has a relatively short half-life of about 4 to 6 hours. This translates to a short duration of action and the requirement for multiple daily dosing, unless used in a modified release formulation. In contrast, both terazosin and doxazosin are more gradually absorbed and do not achieve their peak plasma concentrations until 2 to 4 hours post-dose (with elimination half-lives in the range 8 to 16 hours). These characteristics lead to a more gradual onset

of action and a more sustained antihypertensive effect. For illustrative purposes, the clinical pharmacokinetic parameters of doxazosin and the prototype drug prazosin are compared in Table 82-1.

More recently, to further refine the pharmacokinetic characteristics and improve the therapeutic profile a once-daily GITS (Gastrointestinal Therapeutic System) formulation of doxazosin has been introduced.³ In practical terms, and for the routine management of hypertensive patients, doxazosin is now the most important quinazoline derivative and the most widely studied.

Specific pharmacokinetic studies with doxazosin

Pharmacokinetic studies have been undertaken in elderly patients, and although there were some age-related differences in the disposition characteristics neither the bioavailability nor clearance of doxazosin was significantly altered and the overall conclusion was that age was unlikely to influence the disposition of doxazosin to any clinically significant extent.⁴ In patients with varying degrees of renal impairment, there were no significant differences in half-life.⁵ There is no evidence that the pharmacokinetics of doxazosin are either time or dose dependent, and for dosages between 1 and 16 mg the steady-state pharmacokinetics show proportional increases in plasma concentration and in area under the concentration time curve (AUC).⁶

Pharmacokinetic/pharmacodynamic relationships

The relationship between the response to doxazosin and either drug dose or plasma drug concentration has been investigated in several studies. For example, in a clinical study of antihypertensive efficacy a linear relationship was identified with a progressive increase in effect with oral doses of 2, 4, and 8 mg.⁶ In a more detailed study, using integrated concentration-effect analysis (pharmacokinetic-pharmacodynamic modeling), linear relationships among dose, plasma drug concentration, and blood pressure response were identified in individual hypertensive subjects after single and multiple dosing.⁷ The consistency of the response to doxazosin has also been investigated in the same individual after oral and intravenous administration.⁸

COMPARISON OF THE CLINICAL PHARMACOKINETICS OF DOXAZOSIN AND PRAZOSIN

Parameters	Doxazosin	Prazosin
Bioavailability (%)	62-74	44-69
Volume of distribution (l/kg)	0.97-1.70	0.51-0.81
Clearance (ml/min/kg)	1-2	2-4
Elimination half-life (h):		
Single doses	9-16	2-4
Multiple doses	13-22	2-4

Table 82-1. Comparison of the Clinical Pharmacokinetics of Doxazosin and Prazosin

TOMHS: FINAL BP RESULTS, BP REDUCTIONS, CHANGE FROM BASELINE		
	Systolic	Diastolic
Chlorthalidone	14.6*	11.1* mmHg
Amlodipine	14.1*	12.2*
Acebutalol	13.9*	11.5*
Doxazosin	13.4*	11.2*
Enalapril	11.3	9.7
Placebo	8.6	8.6

Table 82–2. TOMHS: Final BP Results, BP Reductions, Change from Baseline

The results of these studies confirm the consistency and reproducibility of the concentration-effect relationship in individual hypertensive patients whereby an increase in dosage leads to an increase in blood pressure response. In addition, the relative magnitude of the chronic blood pressure response to doxazosin is well correlated with that of the acute response. The results of these studies also confirm that doxazosin, despite its close structural similarities to prazosin, is qualitatively different—with a gradual onset of action (even after intravenous administration) directly attributable to the parent drug and independent of an active metabolite.

CLINICAL INDICATIONS

Hypertension

Hypertension is the principal indication for treatment with a classical alpha-1 adrenoreceptor antagonist drug.

Antihypertensive efficacy

Early comparative clinical studies showed that the blood-pressure-lowering effects of various alpha-1 blockers were

similar and generally shown to be equivalent to alternative classes of antihypertensive drug. A useful illustrative example was the Treatment of Mild Hypertension Study (TOMHS). TOMHS was a randomized placebo-controlled parallel group study in 902 patients with mild (borderline) hypertension who were treated for 4 years with representative agents from the major antihypertensive drug classes (including the alpha blocker doxazosin) with the dosage constrained to 2 mg once daily.⁹ There were modest blood pressure reductions with all active treatments, and the principal blood pressure results are summarized in Table 82–2. Overall, the blood pressure reductions were similar with all active treatments in TOMHS and significantly greater than with placebo.

First-line treatment in essential hypertension (limited role)

There is little doubt that selective alpha blockers are clinically useful antihypertensive drugs. However, some recent doubts have been cast on the effectiveness of doxazosin as a first-line antihypertensive agent not only in terms of blood pressure reduction but in terms of risk reduction (particularly with respect to cardiac failure and stroke prevention). Thus, in the management of uncomplicated patients with essential hypertension alpha-1 adrenoreceptor antagonist drugs (including doxazosin) are no longer considered routine first-line agents. This is principally due to the general perception of a disappointing outcome result in ALLHAT (Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial).¹⁰

In ALLHAT, patients receiving doxazosin as their initial antihypertensive drug treatment were found to have poorer blood pressure control (by about 2 to 3 mmHg for systolic blood pressure; Figure 82–2) and higher incidences of heart failure and stroke relative to chlorthalidone-based treatment (Table 82–3). For this reason, doxazosin was prematurely withdrawn as a first-line treatment in ALLHAT. As a result, its role as a first-line option has been revised in most guidelines.

ALLHAT was the first prospective clinical outcome trial to incorporate and evaluate first-line treatment with an alpha-1 blocker (doxazosin), and the result is of major importance. It must be noted that there were no differences in the primary outcome measures of fatal CHD or nonfatal myocardial infarction. However, there were significant outcome differences because of higher rates for stroke and congestive heart failure and for angina and coronary revascularization procedures. Whether or not this is a simple and direct reflection of the small blood pressure difference in relatively high-risk patients remains unclear. The target blood pressure of less than 140/90 mmHg was achieved in 64% of the chlorthalidone group compared to 58% in the doxazosin group, and after 4 years of treatment the achieved blood pressures were respectively 135/76 and 137/76 mmHg.

Figure 82–2. Achieved blood pressure control in ALLHAT: chlorthalidone versus doxazosin.

ALLHAT OUTCOMES PER 100 PATIENTS PER 4 YEARS		
	Chlorthalidone (n=15,268)	Doxazosin (n=9067)
Primary endpoints:		
Nonfatal MI and fatal CHD	6.3	6.26 n.s
Secondary endpoints:		
Total mortality	9.08	9.62 n.s
CHD	11.97	13.06 ($p<0.05$)
STROKE	3.61	4.23 ($p<0.04$)
CVD (inc. CCF)	21.76	25.45 ($p<0.001$)

Table 82-3. ALLHAT Outcomes per 100 Patients per 4 Years

First-line treatment in special patient groups (examples)

Elderly hypertensive patients

The effectiveness of doxazosin in elderly patients, relative to young patients, has been reviewed in a survey involving 1486 patients of greater than 65 years of age.¹¹ In brief, the blood pressure reduction of 23/15 mmHg in those patients aged more than 65 years was directly comparable to the reduction of 21/14 mmHg in the younger group. Importantly, this study also provided substantial support for the good overall tolerability profile of doxazosin even though the elderly group reported more frequent episodes of dizziness (10.9 versus 5.1%). However, these authors concluded that this particular symptomatic complaint occurs more frequently in older patients in general and did not constitute a particular problem in relation to the doxazosin treatment.

Patients with hypertension and diabetes mellitus

The effectiveness of doxazosin has been compared with that of atenolol in a double-blind crossover comparative study involving 12 weeks of active treatment in hypertensive type I diabetic patients. Overall, there were modest reductions in blood pressure at 12/9 mmHg with doxazosin and 12/8 mmHg with atenolol.¹² However, only during the doxazosin phase was there any significant reduction in microalbuminuria. This potential benefit was not observed during the atenolol treatment phase. Several other clinical studies have confirmed the effectiveness of doxazosin in the management of hypertensive type II diabetic patients.

Patients with hypertension and renal disease

Alpha blockers are extensively metabolized, and there is no significant accumulation in patients with renal impairment. In addition, combination regimens are usually necessary in such patients and the alpha blockers can usefully be combined with all other types of agent.

Combination antihypertensive treatment (preferred/usual role)

Following the relative disappointment of ALLHAT, there has been a deliberate repositioning of doxazosin as a

combination partner. Thus, unless there is a very particular reason for initiating antihypertensive treatment with doxazosin (in a man with mild hypertension and BPH, for example) improvement in blood pressure control through the addition of doxazosin has become the preferred role. Because the majority of hypertensive patients require two or more drugs to reach target (<140/90 mmHg), it is important to establish that this is a safe and effective strategy. As emphasized in several recent national and international guidelines, intensive treatment to provide “tight” or optimal blood pressure control frequently requires combinations of antihypertensive drugs, particularly in high-risk patients. This combination role might be a particularly useful and important component of the regimens used in patients with renal impairment, for example, or with metabolic problems (particularly disorders of lipid and glucose metabolism) because other agents would be relatively contraindicated in such conditions. The antihypertensive efficacy of this combination approach to treatment has been confirmed both in specific small-scale studies and in major clinical outcome studies.

Specific combination treatment studies

Usefully additive antihypertensive activity has been observed when doxazosin has been combined with representatives from other major antihypertensive drug classes. For example, the effectiveness of amlodipine alone (10 mg daily), doxazosin alone (4 mg daily), and the combination of these two drugs was investigated in patients with moderate to severe hypertension.¹³ There were significant additive effects with the combination, particularly on standing blood pressure—whereby an additional reduction of 10/8 mmHg was achieved with the combination relative to amlodipine alone. There was no evidence of any significant reflex cardioacceleration or any increased likelihood of postural hypotension.

Also of interest was a small but well-designed study investigating the combination of enalapril and doxazosin in 9 hypertensive patients.¹⁴ Standing blood pressure was reduced by 12/8 mmHg by doxazosin alone (4 mg daily) and by 9/6 mmHg with enalapril alone (20 mg daily). However, the combination of doxazosin and enalapril, with dosages constrained to respectively 1 mg and 5 mg daily, was associated with a significantly greater reduction of 23/20 mmHg ($p<0.02$). Indeed, the effectiveness of this combination might be particularly useful in the management of the diabetic hypertensive not only by virtue of the antihypertensive efficacy but because of the combination of positive metabolic effects and the potential for nephroprotection. Thus, doxazosin now appears to be established as a combination partner for all antihypertensive drug treatments when blood pressure control requires improvement.

Combination studies with doxazosin in routine patient care

The usefulness and effectiveness of doxazosin as a general “add-on” therapy was specifically studied in a double-blind placebo-controlled study of 70 hypertensive patients who were inadequately controlled on existing treatment.¹⁵ Sitting and standing blood pressures were significantly reduced

by (on average) 12.4/4.9 and 10.5/3.8 mmHg, respectively. Fatigue was the only symptomatic adverse effect, which was reported significantly more often in the doxazosin group (24 versus 3%). There were small but significant reductions in LDL and total cholesterol during doxazosin treatment by approximately 4.8 and 9.1%, respectively (placebo adjusted).

The GATES (Doxazosin GITS As Combination Therapy in Hypertensive Patients: An Efficacy and Safety) study was designed to clarify the role of doxazosin (GITS) as an add-on treatment. This was a randomized prospective placebo-controlled study designed to assess the responses to the addition of doxazosin GITS in 167 patients not adequately controlled with either one or two conventional antihypertensive drugs.¹⁶ In brief, adding doxazosin GITS improved blood pressure control by an average of 9/8 mmHg such that 27% of previously uncontrolled patients achieved target. Because of adverse effects, there were some treatment withdrawals: 5 (5.6%) and 2 (2.3%) patients assigned doxazosin and placebo, respectively, were withdrawn because of perceived adverse drug reactions.

Doxazosin as a combination treatment in a clinical outcome trial (ASCOT)

The role of doxazosin GITS as an add-on treatment has been further assessed in ASCOT (Anglo-Scandinavian Cardiac Outcomes Trial).¹⁷ The principal result in ASCOT was that antihypertensive treatment based on the combination of amlodipine and perindopril was significantly more effective than the combination of atenolol with bendroflumethiazide.¹² The treatment algorithm (flow diagram) is shown in Figure 82–3, with doxazosin as a suitable combination treatment following initial treatment with either thiazide/ β -blocker or CCB/ACE inhibitor. The specific details of the impact of doxazosin are not yet published, but it is noted that 40% of the nondiabetic hypertensive patients and 68% of the diabetic patients in ASCOT had not achieved target blood pressure at the end of the trial despite an average of 2.2 antihypertensive drugs. In practice, therefore, there is a clear place for doxazosin as a “third” or “add-on” drug if blood pressure targets are to be achieved in 100% of patients.

Hypertension and related disorders

As with most antihypertensive drugs, claims have been made that alpha-1 antagonists possess nonhemodynamic pharmacologic properties that might lead to additional cardiovascular benefits. Beneficial metabolic effects on glucose and lipid metabolism have been most extensively studied as a specific additional property of alpha blockers. Although not considered an additional specific property of an alpha-1 blocker, regression of left ventricular (LV) hypertrophy is assessed for most types of antihypertensive drug because it is an important surrogate for improved cardiovascular outcomes in patients receiving antihypertensive drug treatment.

Metabolic effects

The small but potentially beneficial effects of alpha blockers on glucose and lipid metabolism have been consistently

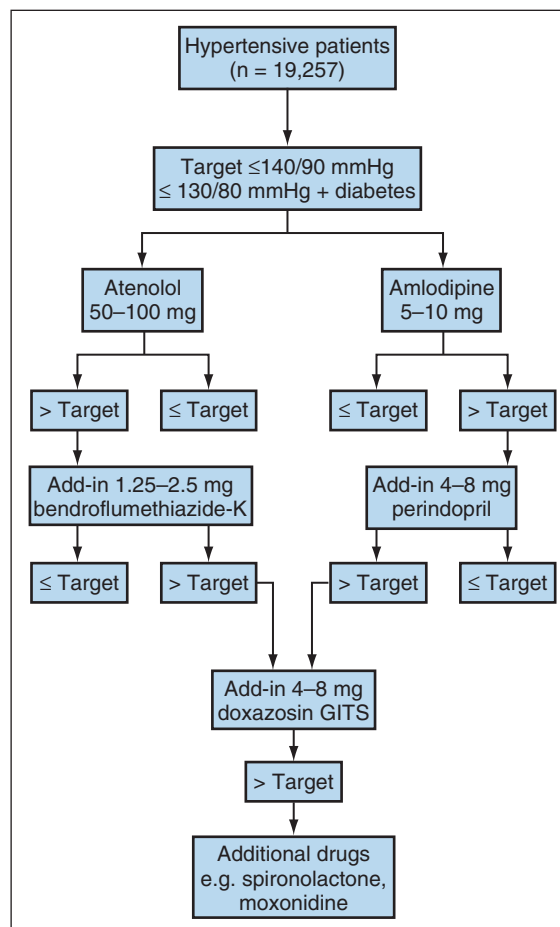

Figure 82–3. Treatment flow diagram in ASCOT.

identified. In fact, alpha-1 adrenoreceptor antagonist drugs are the only antihypertensive treatments consistently shown to have beneficial effects on plasma lipid profiles with modest reductions in total and LDL cholesterol and a small increase in HDL cholesterol. For example, in TOMHS doxazosin was associated with a significant increase in the total/HDL-cholesterol ratio by 2.6 compared to 1.2 with placebo ($p < 0.001$), and compared to 1 to 2 with acebutolol, 1.5 with amlodipine, and 1.4 with chlorthalidone ($p < 0.01$). This metabolic improvement is linked to the beneficial effect alpha blockers have on insulin responsiveness leading to increased peripheral glucose uptake. Thus, selective alpha blockers may be particularly well suited for the treatment of hypertensive patients with type II diabetes mellitus.^{18,19} Of particular additional interest, and linked to the beneficial effect on insulin responsiveness, was an observation that doxazosin treatment in patients with CHD resulted in significant dose-dependent increases in t-PA concentration leading to a net increase in fibrinolytic potential.²⁰

Regression of LV hypertrophy

Effective blood pressure reduction is the primary requirement for promoting the regression of LV hypertrophy, and whether or not different pharmacologic properties lead to a greater effectiveness remains to be clearly established in clinical studies. The results of a meta-analysis indicate that

treatment based on alpha blockers is correspondingly as effective as treatment based on most types of antihypertensive drug²¹ (Figure 82–4). This effect has also been demonstrated in a small study of 11 hypertensive patients over a 6-month treatment period.²² However, in this study not only was there a significant reduction in LV mass index—from 128.5 to 114 g/m² (a reduction of 12%)—but left ventricular systolic and diastolic function were also shown to be improved.

Genitourinary effects

Alpha blockers (particularly those with effects on the alpha-1b receptor subtype) are well recognized to have effects on the genitourinary system. Accordingly, alpha blockers are used for the relief of obstructive urinary symptoms in males with benign prostatic hyperplasia/ hypertrophy (BPH). Unfortunately, this predictable pharmacologic effect may occasionally lead to urinary incontinence in females.

There is evidence also that male sexual dysfunction occurs less frequently with alpha blockers than with other types of antihypertensive agent. This was seen in TOMHS, where erectile dysfunction was reported in only 3% of patients receiving doxazosin compared to 17% of patients receiving chlorthalidone. There is no evidence that this effect can be used therapeutically, although it may occasionally prove helpful to change to doxazosin treatment when a hypertensive male is having erectile problems during treatment with a thiazide diuretic.

Congestive cardiac failure

The role of selective alpha-1 antagonist drugs in the management of congestive cardiac failure was studied in the 1980s. The results were disappointing, and this indication is of historical interest only.

Figure 82–4. Regression of LV hypertrophy (meta-analysis). (Redrawn from Jennings GL, Wong J. Assessment of hypertensive organ damage. In: Hansson L, Birkenhager WH (eds.). *Handbook of Hypertension, Volume 18*. Amsterdam: Elsevier, 1997.)

COMPLICATIONS

Cardiovascular effects

Historically, the “first dose effect” with symptomatic orthostatic hypotension and possible syncope, accompanied by tachycardia and palpitations, is probably the most well-known adverse effect of alpha-blocking drugs. This well-recognized complication occurred upon treatment initiation but in general occurred only with short-acting and rapid-onset agents, particularly the prototype drug prazosin. In retrospect, these dramatic (and worrying) hypotensive reactions were attributable to the use of unnecessarily high starting doses—particularly in patients who were salt/volume depleted or receiving other antihypertensive treatment such as thiazide diuretics and beta blockers. The newer agents (including doxazosin), with a more gradual onset of effect and longer duration of action, administered in initially low dosages have minimized the risk of this dramatic early response. Unfortunately, although doxazosin continues to be associated to some extent with the “bad publicity” that surrounded prazosin it is of particular interest that the incidence of syncope with doxazosin in TOMHS was identical to that of the other drug groups⁹ (Table 82–4).

Adverse effects on other systems

With respect to tolerability, there were overall similarities between doxazosin and chlorthalidone in ALLHAT. For example, the most common reasons offered by the patients for discontinuing medication during the 4 years of trial were symptomatic adverse effects (20% in the chlorthalidone group and 19% in the doxazosin group); an unspecified refusal in 30 and 29%, respectively; and because of abnormal laboratory values in 5 and 1%, respectively.

As with most antihypertensive drugs, nonspecific upper-gastrointestinal symptoms with nausea and abdominal discomfort have been reported. Similarly, drowsiness, fatigue, confusion, and malaise have occasionally been reported. Because of their (unwarranted) reputation for causing profound postural falls in blood pressure there have been concerns that alpha blockers might impair cerebral perfusion, particularly in elderly hypertensives. This has not been confirmed in clinical studies.

TOMHS: SELECTED ADVERSE EFFECTS		
Drug	Reported (%)	Impotence (%)
Chlorthalidone	0	12
Acebutolol	1	8
Doxazosin	1	0
Enalapril	2	4
Amlodipine	1	3
Placebo	4	6

Table 82–4. TOMHS: Selected Adverse Effects

SUMMARY

Alpha-1-adrenoreceptor antagonist drugs have the immediate attraction that there are no patient co-morbidities that constitute absolute contraindications to their use. Thus, alpha blockers can safely and appropriately be administered to hypertensive patients with concomitant disease states such as diabetes mellitus or obstructive airway disease or renal impairment. However, it is difficult to ignore the disappointing results of ALLHAT, which have been taken to suggest that doxazosin and other alpha-1 blockers should no longer be considered routine first-line agents but alternative or additional agents.

Overall, the recent evidence favoring intensive blood pressure control has clearly identified the requirement for combination drug treatments if lower blood pressure targets are to be attained. The role of doxazosin GITS as an effective add-on treatment has been established in GATES, for example, and the predicted results of ASCOT suggest that this additive antihypertensive effect translates to outcome

benefits particularly in patients with high levels of absolute cardiovascular risk (for example, those with diabetes mellitus or with concomitant hypercholesterolemia). Because high-risk patients benefit most from intensive antihypertensive treatment, there are clear indications that a drug such as doxazosin (with its favorable metabolic profile) might be particularly useful as an add-on antihypertensive drug treatment. Overall, the tolerability profile of doxazosin has been shown to be similar (albeit not superior) to that of any of the competitor antihypertensive drug classes in TOMHS and ALLHAT (for example).

In summary, a selective alpha-1-adrenoreceptor antagonist drug (and particularly doxazosin) retains a useful and important role as a combination partner for all other types of antihypertensive drug. This role may be particularly important in patients at high cardiovascular risk because of hypertension that is proving difficult to control or because of concomitant metabolic problems such as obesity or type II diabetes mellitus.

Centrally Acting Agents

*Domenic A. Sica***Key Findings**

- Centrally acting agents stimulate α_2 -receptors and/or imadoline receptors on adrenergic neurons located within the rostral ventrolateral medulla, thereby reducing sympathetic outflow. Centrally acting agents also stimulate peripheral α_2 -receptors, which for the most part is of limited clinical significance.
- Central alpha-agonists have had a lengthy history of use—starting with α -methyldopa, which has seen its use decline because of annoying side effects.
- Patients requiring multi-drug therapy with otherwise resistant hypertension (such as diabetic and/or renal failure patients) are generally responsive to these drugs, as are patients with sympathetically driven forms of hypertension.
- Perioperative forms of hypertension respond well to clonidine. In addition, an anesthesia- and analgesia-sparing property of these drugs may offer a unique clinical benefit.
- Clonidine can be used adjunctively with other therapies in heart failure (HF), particularly when hypertension is present. Sustained-release moxonidine, however, is associated with early mortality and morbidity when used in the patient with HF.
- Escalating doses of drugs in this class often bring on salt and water retention, in which case a diuretic becomes useful adjunctive therapy.
- Drugs that reduce sympathetic neurotransmission have been some of the first compounds used in the treatment of hypertension. These agents are effective antihypertensives and establish a favorable hemodynamic profile in the course of reducing blood pressure (BP).
- The side-effect profile of compounds in this class is unpleasant and is a consideration that ultimately has some bearing on patient compliance.

INTRODUCTION

Although complex, and not understood in full detail, a relationship exists between the centrally modulated activated sympathetic nervous system (SNS) and hypertension. SNS activation is also an important element of HF pathophysiology and influences various developmental aspects of the metabolic syndrome. It has been estimated that from 15 to 30% of essential hypertension patients have a primary neurogenic stimulus as an etiology for their hypertension.¹

One aspect of the SNS contribution to hypertension that has proven bothersome is how best to experimentally establish an activity/effect relationship. The idea that plasma concentrations of catecholamines [particularly norepinephrine (NE)] faithfully reflect what transpires at nerve endings or within the central nervous system (CNS) is one that has died hard. In that regard, the measurement of circulated NE reflects a delicate balance between afferent signals and catecholamine release, metabolism, uptake, and sensitivity of the adrenergic receptors. Thus, many experiments attempting to establish the SNS contribution to various aspects of the hypertensive state were predestined to failure based on interpretive considerations relating to plasma NE concentrations.²

Nonetheless, vascular resistance is inversely related to the fourth power of vascular diameter, and the arteriolar sympathetic tone has a considerable influence on peripheral resistance. Sympathetic stimulation also has important effects related to stimulation of renal sodium reabsorption and renal release of renin. As a result of these multiple effects, sympathetic stimulation also has important effects on BP.

In more general terms, sympathetic activation (as reflected by an increase in both heart rate and/or plasma catecholamine levels) is regarded as a determinant of hypertension development and thus a target with some considerable potential for drug treatment. However, centrally acting antihypertensive agents still prove effective even in the absence of apparent signs of SNS activation.^{3,4} Of note, SNS activity need not be measurably abnormal but rather can perpetuate the hypertensive state if merely increased (albeit inappropriately so) relative to a patient's hemodynamic, volume, and neurohumoral circumstances. In addition, the SNS is adjoined to other regulatory pathways in a manner such that even a normal level of activity can unduly contribute to the prevailing BP. This is particularly the case when the interrelationship between the sympathetic and renin-angiotensin systems is considered.

MECHANISM OF ACTION**Molecular aspects of drug action and pharmacokinetics**

For effect, α -methyldopa (the first drug in this class) requires local conversion within the brain to an active metabolite (α -methylnorepinephrine). The antihypertensive action of α -methyldopa was originally believed to be via tissue

inhibition of dopa decarboxylase followed by a depletion of biogenic amines. However, this mechanism contributes minimally to its BP-lowering effect. Instead, α -methyl dopa lowers BP by conversion to α -methylnorepinephrine—an active metabolite that displaces NE from the α -adrenergic receptor (e.g., the concept of a false neurotransmitter; Figure 83-1).⁵

The other agents in this class do not require metabolic conversion and are functionally active as their respective intact molecules. For their main pharmacodynamic effect to occur, compounds in this drug class must cross the blood/brain barrier to gain access to their effect compartment within the CNS. As such, there is an implicit time lag between plasma concentrations and antihypertensive effect. The pharmacokinetics of the various centrally acting agents are similar, with a few noteworthy exceptions (Tables 83-1 and 83-2). The onset of action varies among the compounds in this class, with clonidine showing activity within 15 to 30 minutes of intake.

These compounds typically have a large volume of distribution, which in part relates to compartmentalization in the CNS. The systemic half-life for compounds in this class is not necessarily representative of their pharmacodynamic half-life. This finding relates to receptor affinity and depot effects in deep-tissue compartments. Finally, moxonidine and rilmenidine are extensively renally cleared and call for their being carefully dose adjusted in the patient with renal failure.^{6,7}

Pharmacodynamics

Centrally acting drugs stimulate central vasomotor adrenergic receptors (e.g., nucleus tractus solitarii), thereby

inhibiting central sympathetic outflow to the heart and peripheral vasculature. These compounds stimulate α_2 -receptors on adrenergic neurons found within the rostral ventrolateral medulla, a site that adjusts sympathetic outflow. Plasma catecholamine levels drop with centrally acting therapy, which may also relate to the stimulation of presynaptic α_2 -receptors in peripheral locations.

Clonidine stimulates both α_2 -receptors and imidazoline (I_1)-receptors as the basis for its peripheral sympathoinhibition. Guanfacine is considered a more selective α_2 -receptor agonist than clonidine (Table 83-3). Unlike clonidine, guanfacine does not inhibit dopamine turnover. More selective I_1 receptor agonists, such as moxonidine and rilmenidine, activate I_1 -receptors within the rostral ventrolateral medulla in the brain stem (with moxonidine having up to a 30-fold greater affinity for I_1 than α_2 receptors). In the course of I_1 receptor agonism, the firing rate of bulbospinal sympathoexcitatory neurons decreases, peripheral sympathoinhibition ensues, and BP is reduced. The antihypertensive activity of moxonidine and rilmenidine correlates most closely with its I_1 -receptor binding (Figure 83-2).⁸

The physiologic effects of withdrawal of SNS tone include parallel and balanced falls in peripheral vascular resistance and systolic/diastolic BP. The reduction in peripheral resistance seen persists during long-term treatment. Despite the vasodilator action of drugs in this class, reflex tachycardia does not develop—and heart rate may be somewhat reduced in the course of treatment. Cardiac output and renal blood flow typically remain unchanged with drugs in this class.⁹

Figure 83-1. Chemical structures of various centrally acting antihypertensive agents.

PHARMACOKINETICS OF CENTRALLY ACTING COMPOUNDS					
Drug	Absorption (%)	Tmax (hrs.)	Protein Binding (%)	Volume of Distribution (L/kg)	Half-life (hrs.)
α -methyldopa	25	2.0	< 15	0.6	1.7
Clonidine	75–100	1.5–2.0	20–40	2.0	6–15
Guanabenz	75	2–5	90	7.4–13.4	6–14
Guanfacine	> 90	1.5–4.0	70	6.3	17

RENAL AND PREGNANCY CONSIDERATIONS WITH CENTRALLY ACTING COMPOUNDS				
Drug	Renal Elimination ^a (%)	Dialyzability	Dose Adjustment in Renal Failure	FDA Pregnancy Category
α -methyldopa	70	Yes	Yes	C
Clonidine	58	Yes, but limited	No	C
Guanabenz	< 5	No	No	C ^b
Guanfacine	50	Limited	No	B ^c
Moxonidine ^d	50–75	Not known	Yes	Not classified
Rilmenidine ^d	52–93	Yes	Yes	Not classified

a. Elimination of the intact molecule.

b. FDA category C: Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.

c. FDA category B: Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).

d. Not available in the United States and thus the basis for no FDA pregnancy categorization.

Table 83–2. Renal and Pregnancy Considerations with Centrally Acting Compounds

CENTRAL NERVOUS SYSTEM RECEPTORS AS TARGETS OF CENTRALLY ACTING ANTIHYPERTENSIVES	
Compound	Receptor
α -methyldopa	α_2
Guanfacine	α_2
Guanabenz	α_2
Clonidine	α_2 and I ₁
Moxonidine	I ₁ > α_2
Rilmenidine	I ₁ > α_2

Table 83–3. Central Nervous System Receptors as Targets of Centrally Acting Antihypertensives

During exercise, these compounds reduce peripheral vascular resistance—suggesting that exercise-related changes in SNS activity are blocked. Centrally acting agents also reduce plasma renin activity (PRA), and with long-term treatment regress left ventricular hypertrophy.¹⁰ Agents in this class tend to produce dose-dependent salt-and-water retention, and as a result their effectiveness may diminish over time. This pseudotolerance to a BP-lowering effect can be undone with diuretic therapy.

INDICATIONS/CONTRAINDICATIONS AND OBJECTIVES OF THERAPY

Indications

The antihypertensive efficacy of both central α_2 -receptor and I₁-receptor agonists is well established, having been confirmed in large numbers of patients with essential hypertension. Clonidine, the standard in this class, has been shown in the Veterans Affairs Cooperative Study to be somewhat more effective in whites than in blacks (and is recognized as being more effective in older than in younger blacks).³ Centrally acting compounds compare favorably with other first-line antihypertensive drug classes—such as diuretics, beta blockers, angiotensin-converting enzyme (ACE) inhibitors, and calcium-channel blockers (CCBs)—in effectiveness. These compounds are also useful adjunctive therapies related to most other antihypertensive medication classes, particularly with vasodilators in that they can attenuate the pulse-rate change that occurs as these drugs reduce BP.

Centrally acting compounds are particularly useful for patients who have hypertension with associated anxiety, especially that marked by sympathetic overactivity. Drugs in this class are metabolically neutral and can be used safely in the diabetic patient. In addition, patients with

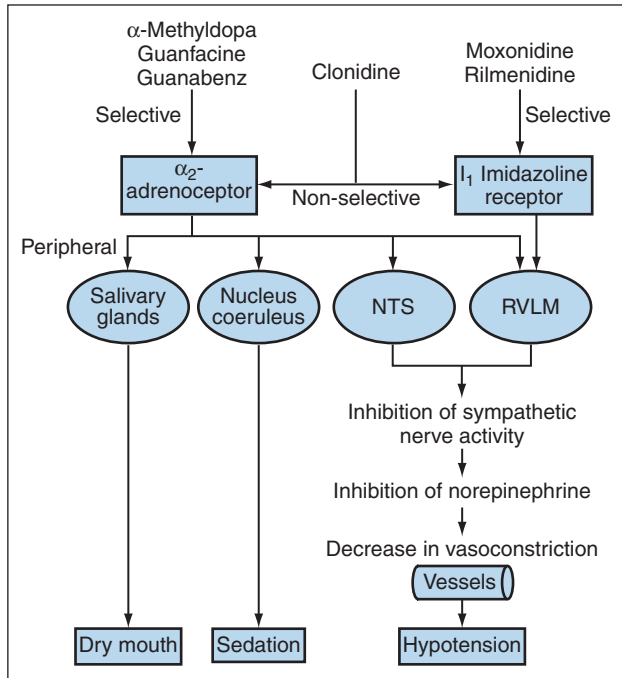

Figure 83–2. Mechanisms of action of various centrally acting antihypertensive agents. Dry mouth and sedation are side effects mediated by α_2 -receptor but not I_1 -receptor stimulation. (Adapted with permission from van Zwieten PA. The renaissance of centrally acting antihypertensive drugs. *J Hypertens* 1999;17:S15–21.)

chronic obstructive pulmonary disease safely tolerate these compounds. Clonidine is used in the perioperative setting in that it has the ability to control the sympathetically driven hypertension common to this setting and the ability to provide an anesthetic- and analgesic-sparing effect.¹¹

Drug differentiation and mode of delivery considerations

All five drugs that comprise the centrally acting medication class similarly reduce BP if comparable doses are being used (Box 83–1). α -Methyldopa and clonidine are the only two drugs in this class available for intravenous administration. Clonidine is the only compound in the class that is available in a transdermal delivery system.¹² Onset of action and effect half-life are two of the main features that separate compounds in this class. Clonidine seems to have the quickest onset of action and the shortest duration of effect. The half-life of drugs in this class is widely variable and poorly correlates with the duration of medication effect.^{6,7} As regards all compounds in this class, final dosing recommendations should be based on local prescribing information because there is a considerable geographic disparity in both usage and regulatory approval.

α -Methyldopa

From the early 1960s to the latter part of the 1970s, α -methyldopa was a popular drug for the treatment of hypertension. During that time it was found to be useful in all types and degrees of severity of hypertension.⁵ Methyldopa is available in an intravenous formulation as an ester of the parent drug and has been used for hyper-

tensive emergencies. Treatment of hypertensive urgencies and emergencies with intravenous α -methyldopa has been supplanted by more effective drugs. With time and the availability of newer better tolerated antihypertensive medications, oral α -methyldopa also began to fall out of favor—although it still retains a niche status in the treatment of pregnancy-induced hypertension.¹³ There is little evidence of adverse effects on fetal development with α -methyldopa. When used in doses ranging from 250 mg to 2.0 g per day it effectively reduces supine BP without causing orthostatic hypotension.

Clonidine

Oral clonidine has a rapid onset of action (30 to 60 minutes) and is of particular utility for managing hypertensive urgencies. However, it is relatively short acting and in managing hypertensive urgencies often requires frequent dosing.¹⁴ A transdermal patch delivery system for clonidine provides a constant amount of drug for seven days, but it takes one to two days to attain peak effect and this effect lingers from 8 to 24 hours after the patch is removed.¹⁵ Drug is best absorbed from the patch when it is placed on the chest or upper arm and not the lower torso.¹⁶ Transdermal clonidine is very useful in the management of the labile hypertensive patient who requires multiple medications, the hospitalized patient who cannot take medications by mouth, and the patient prone to early morning surges in BP. At equivalent doses, transdermal clonidine is more likely than oral clonidine to precipitate salt and water retention.¹²

Guanabenz

Guanabenz is mechanistically similar to clonidine but is somewhat longer acting. It is less likely to cause rebound hypertension (Figure 83–3), fluid retention, and orthostatic hypotension. Therapy should generally begin with 4 mg twice daily, with increments up to a total daily dose of as much as 64 mg. The most noteworthy metabolic action of guanabenz is a reduction in total cholesterol levels in the order of 10 to 20%. The presumed mechanism for this may be related to inhibition of hepatic cholesterol production and triglyceride synthesis, as well as stimulation of fatty acid oxidation.¹⁷

Guanfacine

Guanfacine differs from the other members of this class in that its prolonged (24 hours) duration of action typically allows it to be dosed once daily.¹⁸ Guanfacine appears to enter the brain more slowly and to maintain its antihypertensive effect longer than guanabenz. It is preferably dosed in the evening so that it can then blunt the early morning catecholamine surge. Evening dosing also allows any sedative effect to play out during sleep. As with other agents in this class, it works best when combined with a small dose of diuretic—which optimizes BP lowering. Guanfacine may be useful as an alternative to clonidine in patients developing intolerable sedation with the latter, and in patients recognized as being noncompliant with clonidine.¹⁹ Finally, guanfacine has orphan drug status for the fragile-X syndrome, which is the most common inherited cause of mental retardation.

Box 83–1**Dosing Considerations with Centrally Acting Agents****Available Compounds**

α -methyldopa, clonidine, guanfacine, guanabenz, moxonidine, rilmenidine

Dosing Considerations **α -Methyldopa**

Oral α -methyldopa is initially given two to three times daily in a dose of 250 mg. Individual maintenance doses are in the range of 0.5 to 2.0 g/day in two to three divided doses.

Clonidine

Oral clonidine is best given two to three times daily. Starting doses are in the order of 0.1 mg two to three times daily, with dose increase up to as high as 0.6 mg two to three times daily. A small dose of clonidine (0.1 to 0.2 mg twice daily) augments the BP-lowering effect of most other agents and can be reliably used as add-on therapy. Clonidine is a short-acting compound, and thus patients with excessive sympathetic activity can have a short-lived response to it. If being given together with a beta blocker, rebound hypertension is more common when it is abruptly stopped and beta-blocker therapy is continued. In certain countries, transdermal clonidine is available. The transdermal system dose range allows for release of 0.1 to 0.3 mg per 24 hours. There is a one- to two-day delay in the onset of action after initial patch application with transdermal clonidine, making it inappropriate for the management of hypertensive emergencies. Conversely, removal of the transdermal delivery system for clonidine does not immediately eliminate drug effect. Clonidine can also be used intravenously for perioperative hypertension, with a dose of 0.15 mg given two to four times daily. These side effects can also occur at lower doses.

Guanfacine

The initial response to guanfacine is delayed compared to clonidine, but its longer duration of action allows it to be effectively dosed in a range of 1 to 3 mg given once or twice daily in a split dose. Withdrawal phenomena are significantly less pronounced than observed with clonidine, which may relate to its longer duration of action. Adverse effects increase significantly with doses in excess of 1 mg/day.

Guanabenz

Guanabenz is given by mouth as the acetate, but doses are usually expressed in terms of the base. Guanabenz acetate 5 mg is equivalent to about 4 mg of guanabenz. In hypertension, the usual dose is 4 mg twice daily initially; the daily dose may be increased by amounts of 4 to 8 mg every 1 to 2 weeks according to response. Doses of up to 32 mg twice daily have been used.

Moxonidine

0.2 mg once daily. As needed, the dose can be slowly increased to 0.4 or a maximum of 0.6 mg. The dose must be reduced to 0.2 to 0.4 mg/day in patients with moderate renal failure (GFR of 30-60 mL/min) and the drug should not be used at GFR values less than 30 mL/min.

Rilmenidine

1 mg once daily, if necessary to be increased to 2 mg in one oral dose. At GFR values < 15 mL/min it should be given in a dose of 1 mg every other day.

Overdose

Large doses can paradoxically increase blood pressure particularly with clonidine.

Moxonidine

Moxonidine reduces BP as effectively as most first-line antihypertensives when used as monotherapy and is an effective adjunctive therapy in combination with other antihypertensive agents.⁶ Moxonidine does not reduce heart rate, as can occur with clonidine. The plasma half-life of moxonidine is only on the order of 2 to 3 hours. Thus, its much longer duration of action suggests CNS retention and tight binding to imidazoline I₁ receptors. Unlike other centrally acting agents, moxonidine undergoes extensive renal clearance and its dose has to be carefully adjusted according to the glomerular filtration rate (GFR).²⁰

The United Kingdom licensed prescribing information states that in patients with moderate renal impairment (GFR 30 to 60 mL/min) single doses of moxonidine should not exceed 200 μ g and the daily dose should not exceed 400 μ g. Moxonidine should not be given in severe impairment (GFR < 30 mL/min). In addition, moxonidine should

not be used in severe forms of HF and only with considerable caution in patients with moderate HF.²¹

Rilmenidine

Numerous studies have demonstrated that oral rilmenidine 1 to 2 milligrams (mg) daily, alone or in combination with other antihypertensives, is well tolerated and effective in the treatment of mild to moderate hypertension.⁷ An oral dosage of 1 mg daily appears to provide the optimum ratio of efficacy to tolerability (i.e., a lower incidence of adverse effects). Rilmenidine appears to enhance parasympathetic tone, which may account for the lack of effect on heart rate while producing a reduction in BP.²²

Uses independent of blood pressure

Centrally acting agents (in particular, clonidine) have a number of alternative uses beyond BP reduction. As such, they can be used to good effect in disease states other

Figure 83-3. Rebound hypertension following the discontinuation of clonidine.

than hypertension. For example, clonidine may be used to provide migraine prophylaxis, to alleviate post-traumatic stress syndrome, to suppress postmenopausal flushing, to minimize alcohol and opioid withdrawal symptoms, and to manage open-angle glaucoma.

Clonidine is also useful in various diarrheal states, including that which occasionally accompanies the short-gut syndrome.²³ Clonidine has also been used in the perioperative period both as an adjuvant to general and/or regional anesthesia; to improve analgesia after systemic, spinal, or peripheral opioids; and to control postoperative sympathetic responses.¹¹ Of note, clonidine sympatholytic activity primarily affects tonic activity and less so the reactivity of the SNS, which is a valuable pharmacologic feature in the perioperative setting.

The sympathoinhibition that occurs with clonidine can provide a diuretic-enhancing effect in cirrhotic patients with ascites and is viewed as a secondary approach to counteract the sympathetic hyperactivity, which distinguishes HF.²⁴ In this regard, modest doses of clonidine significantly attenuate cardiac and renal sympathetic tone in HF, which may conceivably counter the salt and water retention that marks this disease state.²⁵ Oral clonidine also appears to control ventricular rate in new-onset atrial fibrillation, with an efficacy comparable to that of standard agents.²⁶ Finally, clonidine can be used for the diagnosis of pheochromocytoma. When 0.1 mg of clonidine is administered hourly for three doses, plasma NE levels fall in patients with essential hypertension but remain elevated in patients with a pheochromocytoma.²⁷

Alternatives to therapy

If centrally acting agents are being used simply as add-on therapy in a multi-drug regimen, the issue of intolerance is resolved most simply by discontinuing the offending medication. In other instances (in which use of centrally acting agents are of a more crucial nature), drug classes such as beta blockers, combined alpha/beta blockers, and peripheral alpha blockers can be substituted. However, the occasional patient with a strong SNS component to their hypertension will develop paradoxical hypertension with beta-blocker therapy. Finally, in certain patients with a sympathetically driven form of hypertension behavioral modification strategies and/or anxiolytic therapy can be used. This approach can often keep the dose of a centrally acting agent in a tolerable range.

Cost effectiveness

Centrally acting agents can be quite cost-effective therapies in that these compounds are for the most part available generically. Thus, they minimally affect the incremental cost of hypertension management when multi-drug therapy is required to reach treatment goals. The considerably higher cost of transdermal clonidine has, however, proven a disincentive to its more widespread use despite its better tolerance.

COMPLICATIONS

Class side-effect considerations

As with any antihypertensive agent that inhibits SNS activity, most anticipated side effects (postural hypotension, weakness, sodium and water retention, gastrointestinal symptoms) may be related to the adrenergic action or to the resultant override of parasympathetic function, or to both. Somnolence and dry mouth (40%) are the most common adverse drug reactions and are the major reason central sympatholytics are discontinued.^{28,29} I₁-receptor stimulants appear to have a better tolerability profile, causing less dry mouth and drowsiness.^{6,7}

Other CNS depressants (such as sedative-hypnotics, benzodiazepines, antihistamines and/or ethanol) may add to the sedative effects within this drug class. The dry mouth with centrally acting agents relates to a α_2 -mediated drop-off in salivary flow rate and can be very annoying. If central-acting therapy is sufficiently long lived it can increase the likelihood of dental caries, periodontal disease, or oral candidiasis.³⁰

Class-member-specific side-effect considerations

Methyldopa

The intestinal absorption of α -methyldopa, and therefore its therapeutic effect, is reduced by simultaneously ingested iron. Additional side effects characteristic of α -methyldopa include somnolence and depressive reactions, which may relate to a change in brain biogenic amines.^{28,29} Hypersensitivity reactions, including hepatitis and Coombs-positive hemolytic anemia (due to the appearance of an antibody with specificity for red cell Rh determinants), have been

observed with α -methyldopa. This occurs in 10 to 20% of patients receiving at least 1 g of α -methyldopa daily over several months.³¹

In general, α -methyldopa can be continued in the presence of a positive direct Coombs test alone. However, if anemia occurs therapy should be withdrawn. A drug-induced hepatitis (with fever, eosinophilia, and increased transaminase values) can occur with α -methyldopa. This appears to be a self-limited process that remits with drug discontinuation. α -Methyldopa may also produce a flu-like syndrome marked by high fever (drug-induced fever). α -Methyldopa and its metabolic products can interfere with some assays for catecholamines and can interfere with other therapeutic agents, such as levodopa, bromocriptine, and monoamine oxidase inhibitors.

Clonidine

Clonidine can suppress sinus and atrioventricular nodal function, with the result sometimes being significant bradycardia. Patients with chronic kidney disease (CKD) and sinus node dysfunction are at risk of significant bradycardia with clonidine.³² In these patients, clonidine is best avoided. If clonidine is suddenly discontinued during treatment with high doses (usually > 1.0 mg, but sometimes lower doses), rebound hypertension may occur secondarily to an excessive sympathetic discharge.³³ Rebound hypertension may be more prominent if beta-blocker therapy is ongoing at the time of clonidine discontinuation. Such a rebound phenomenon has not been seen with moxonidine and rilmenidine.^{6,7}

Skin hypersensitivity to the transdermal clonidine occurs in 15 to 20% of patients. Skin reactions to transdermal clonidine can include subjective signs of pruritus and objective findings such as erythema, scaling, vesiculation, excoriation, and induration. Hyperpigmentation, depigmentation, and pseudolymphoma can also occur.¹² Allergic dermatitis occurs more commonly in whites than in blacks, and more commonly in women than in men.

Potential causes of the allergic contact dermatitis could be active drug, adhesive, diffusion membrane, solvent, or enhancer. Most studies have indicated that skin reactions are related to the active drug itself and not to other factors.¹² Clonidine overdose produces paradoxical hypertension when the depressor effects of central α_2 -adrenergic receptor stimulation are exceeded by the pressor effects of peripheral α_2 -adrenergic receptor stimulation, resulting in a predominantly vasoconstrictor response.³⁴

Guanfacine

Tricyclic antidepressants, such as imipramine and amitriptyline, reduce the antihypertensive action of guanfacine (and clonidine) in that they are antagonists of the same central α_2 -receptors these compounds target.³⁵

Guanabenz

The incidence of sedation in clinical trials is dose dependent and ranges from 20 to 50% with guanabenz. However, guanabenz-related sedation appears to diminish with time in patients receiving maintenance treatment. Guanabenz

has not been associated with weight gain and/or clinically apparent sodium retention.³⁶

Moxonidine/Rilmenidine

Monoamine oxidase inhibitors should not be given together with these compounds. Both compounds have fewer side effects than is the case with clonidine and α -methyldopa, owing to a lesser affinity for α_2 -receptors.^{6,7}

CONTRAINDICATIONS

Epidural clonidine hydrochloride is not recommended for obstetrical, postpartum, or perioperative pain management. The risk of hemodynamic instability, especially hypotension and bradycardia, from epidural clonidine hydrochloride may be unacceptable in these patients. All centrally acting agents are contraindicated in those with hypersensitivity to the compound. On a compound-specific basis, moxonidine is contraindicated in both advanced CKD and severe HF.⁶ Although not specifically contraindicated, clonidine should be used cautiously in patients with sinoatrial and/or atrioventricular disease—particularly if the patient is already bradycardic.³²

SIDE EFFECT MANAGEMENT

The side effects with centrally acting compounds can be most directly treated by discontinuing the compound to blame. However, there are sufficient patients for whom BP control is heavily dependent on therapy with centrally acting agents making medication discontinuation a less than desirable choice. In such cases, several therapy options exist. Medication can be split-dosed such that the same total daily dose is given but more frequently and at lower individual doses. This often lessens the sedating effect of these compounds, which is the most common reason for medication discontinuation and one that is drug concentration dependent.

In addition, nighttime dosing is an alternative—in which case the sedating effects of these medications can be exploited to facilitate sleeping. However, the decrease in salivary flow that accompanies these therapies (in particular, with clonidine) can be quite discomfiting and may promote caries development. If so, salivary substitutes can be considered. Another treatment option is to lower the total daily dose of a centrally acting agent and direct therapy to alternative drug classes that are less side-effect provoking. Within-class switches are sometimes of use. For example, a patient intolerant of either the sedating effects or the rebound hypertension with clonidine may be switched to a less sedating compound (such as guanfacine or even more so moxonidine or rilmenidine).³⁷ However, moxonidine and rilmenidine are not as widely available as guanfacine.

A final consideration is that a patient intolerant of oral clonidine can be converted to the transdermal form of clonidine, with which the side effects of sedation, fatigue, and/or dry mouth are considerably less. The transdermal delivery system can be particularly useful in reducing the risk of rebound hypertension.¹² Transdermal clonidine has

a not insignificant number of patients in whom it causes a skin rash.³⁸ Treatment with hydrocortisone cream or over-the-counter antacids (magnesium-aluminum hydroxide suspension) has been used in an attempt to ameliorate skin reactions. Hydrocortisone cream (0.5%), whether applied under or around the edges of the patch, has occasionally been effective in preventing (or lessening) the contact dermatitis. However, this has been poorly studied other than for the observation that pretreatment of the skin with hydrocortisone increases clonidine absorption and thereby plasma levels.³⁶

The variable response to hydrocortisone may reflect the relative weakness of this compound as a corticosteroid. Alternatively, an aerosolized spray of the more potent corticosteroid beclomethasone seems to favorably impact the skin sensitization seen with transdermal clonidine. The drying effect of the steroid spray does not affect the adhesion of the patch to the skin surface, which has been viewed as a drawback with hydrocortisone cream.^{39,40}

SUMMARY

Centrally acting antihypertensive compounds remain an important tool in the management of hypertension. There are significant numbers of patients whose hypertension is linked to the SNS in such a way that these drugs remain primary first-line therapies. However, centrally acting antihypertensive compounds are used most regularly in an adjunctive role for general control of hypertension irrespective of its origin.

The prototype compounds in this class (α -methyldopa and clonidine) are used less regularly because of a fairly onerous side-effect profile. However, there are several choices within the centrally acting antihypertensive medication class that increase the chances of finding a well-tolerated compound. Centrally acting antihypertensive compounds are fairly diversified in their actions and not only reduce BP but favorably influence a number of non-hypertensive conditions linked to sympathetic activity

Vasodilators

Gordon T. McInnes

Key Findings

- Vasodilators reduce blood pressure primarily by actions on vascular smooth muscle.
- Vasodilators can be classified as adrenergic inhibitors (ganglion-blocking drugs and post-ganglionic adrenergic inhibitors) and direct-acting vascular smooth muscle relaxants (hydralazine/endoralazine, minoxidil, diazoxide, sodium nitroprusside, and potassium channel agonists).
- Vasodilators are effective antihypertensive agents but are associated with severe side effects.
- Vasodilators now have a very restricted clinical role, mainly in hypertensive emergencies and in patients with severe hypertension refractory to other agents.

INTRODUCTION

Over the past three decades, antihypertensive drug therapy has made a tremendous impact on morbidity and mortality from cardiovascular disease. Because rigorous control of blood pressure is needed to maximally improve outcome and few patients achieve this with first-choice therapy, a wide selection of antihypertensive agents is desirable.

The lower blood pressure that occurs with most antihypertensive drugs is associated with decreased peripheral vascular resistance. In some cases, this effect is indirect as a result of actions upon neural or humoral control systems or through an autoregulatory response to lower blood pressure. Other drugs have direct actions upon vascular smooth muscle.

Among the most effective antihypertensive drugs are those that inhibit sympathetic activity. This may be achieved at practically any anatomic level of adrenergic function. The term *vasodilator* was originally reserved for direct-acting vascular smooth muscle relaxants. Individual vasodilators may act upon resistance vessels, large arteries, or venous capacitance vessels.

Differential actions at these sites play a major role in the hemodynamic profile of the drugs¹ (Table 84–1). A predominant action upon the resistance vessels causes an immediate fall in blood pressure, activation of baroreceptor reflexes, and increased cardiac output.² Orthostatic hypotension is not seen. By contrast, relaxation of the venous capacitance vessels causes a reduction of venous return to the heart and a fall in cardiac output associated with a fall in blood pressure.³ Cardiovascular baroreceptors are again activated.

Changes in the patterns of the large arterial waveform resulting from large arterial relaxation and dilatation of resistance vessels may have important consequences for the development of atheroma. These changes may not be reflected in blood pressure measured conventionally in the brachial artery.⁴ Therefore, it seems possible that different types of vasodilators may have differential consequences for cardiovascular morbidity, although there are no endpoint data to define a particularly favorable pattern.

There are other consequences of vasodilator therapy apart from activation of the sympathetic nervous system. Parasympathetic withdrawal contributes to the cardiac response.⁵ Renin and aldosterone levels are usually increased, partly as a result of increased sympathetic activity and partly as a result of decreased renal arterial perfusion pressure.⁶ Agents that have a predominant action upon resistance vessels produce edema by increased capillary hydrostatic pressure resulting in disturbance of the Starling equilibrium. This is not seen with venodilator drugs.

Every direct-acting smooth muscle vasodilator and most adrenergic inhibitors induce compensatory sodium and water retention and extracellular fluid volume expansion following reduction of arterial pressure.^{7,8} To maintain persistent and steady contraction of fluid volume, concomitant diuretic therapy is needed. A thiazide is generally the best choice for patients with relatively normal renal function because duration of action is greater than that of a loop diuretic. The diuretic enhances antihypertensive action by maintaining constriction of the extracellular and intracellular compartments.

ROLE OF VASODILATORS
IN HYPERTENSION

The heterogeneous action of vasodilators is reflected in the different indications for usage. Because of the availability of newer better-tolerated drugs, in most developed countries use is restricted to management of patients with severe hypertension not readily controlled with other agents, parenteral treatment of hypertensive emergencies, and control of hypertension in pregnancy.

Whereas use of vasodilators has decreased drastically in favor of newer agents with different mechanisms of action, these agents continue to be used widely around the world. This is undoubtedly related to the availability of generic formulations and lower cost.

CORRELATION OF RELATIVE ACTIVITY OF VASODILATOR DRUGS IN RESISTANCE AND CAPACITANCE VESSELS WITH CIRCULATORY EFFECTS			
	Arterioselective	Nonselective	Vesoselective
Cardiac output	↓↑	↑	↓ (upright)
Arterial pressure	↓	↓	↓ (greater upright)
Central venous pressure	No change	No change	↓
Pulmonary artery pressure	↑		↓

Table 84-1. Correlation of Relative Activity of Vasodilator Drugs in Resistance and Capacitance Vessels with Circulatory Effects

MECHANISM OF ACTION AND PHARMACOKINETICS

Adrenergic inhibitors

Central adrenergic efferent impulses pass through major cardiovascular centers in the hypothalamus, medulla, and other subcortical areas of the spinal cord to synapse with second neurons located in the sympathetic ganglia at the thoracolumbar level of the spinal column. These most distal neurons are stimulated at the ganglion level by the release of acetylcholine from the terminals of the central neurons, thereby propagating the peripheral outflow of adrenergic impulses. Neural impulses (passing distally via the adrenergic neurons) reach the heart or blood vessels, where norepinephrine is released from nerve terminals. Norepinephrine stimulates the effector organ (heart, venule, or arteriole) by attachment to specific binding sites, alpha- or beta-adrenergic receptors. Norepinephrine is metabolized within the nerve terminal by monoamine oxidase in the mitochondria.

Binding of norepinephrine at the effector receptor may result in several possible processes. Stimulation of the beta-adrenergic receptor will produce vasoconstriction of the arteriole and venule. Stimulation of the alpha-adrenergic receptor will promote peripheral vasodilatation and increase heart rate, myocardial contractility, and myocardial metabolism.

There are many loci at which antihypertensive agents may inhibit the adrenergic nerve stimulus, including efferent sensory pathways from the heart, vessels, and mechanoreceptors; centrally at the ganglion level; or at the nerve terminal. Certain antihypertensive agents may also inhibit norepinephrine biosynthesis or block its action at the adrenergic receptor.

Ganglion-blocking drugs

Ganglion blockers act by occupying receptor sites on the post-ganglionic axon to stabilize the membrane against acetylcholine stimulation. These drugs have no effect on pre-ganglionic acetylcholine release, cholinesterase activity, post-ganglionic neuronal catecholamine release, or vascular smooth muscle contractility.⁹

Adrenergic transmission to the heart and vessels is impaired, with the result that heart rate, myocardial contractility, and total peripheral resistance are reduced. The fall in arterial pressure and vascular resistance is not as great in

the supine as in the upright position because the adrenergic venomotor effect is enhanced by the gravitational effect of pooling blood when the patient is upright. Examples include hexamethonium, pentolinium, mecamlamine, pempidine, chlorisondamine, and trimetaphan. The only widely used agent in this class, trimetaphan, is excreted by glomerular filtration and active secretion (30% is unchanged in urine).

Post-ganglionic adrenergic inhibitors

When acetylcholine stimulates the post-ganglionic axon at the ganglionic levels, the impulse is propagated and cumulates in the release of norepinephrine at the nerve terminal with stimulation of adrenergic receptors in the vascular smooth muscle membrane. The impulse can be interrupted pharmacologically by a variety of mechanisms, including depletion of neurohumoral stores at the nerve terminal, prevention of norepinephrine uptake by the nerve terminal, inhibition of catecholamine biosynthesis, and therapeutic introduction of false neurotransmitters that block the adrenergic receptors on vascular smooth muscle.

Rawolfia alkaloids

Reserpine and more than 20 related compounds deplete the myocardium, blood vessels, adrenergic nerve terminals, adrenal medulla, and brain of catecholamines and serotonin.¹⁰ By depleting the nerve terminal of norepinephrine stores and inhibiting norepinephrine re-uptake, adrenergic transmission is altered so that vascular resistance falls. With prolonged treatment, the persistent arterial hypotension is associated with slight decreases in renal blood flow and glomerular filtration rate. This may be related to the reduction in cardiac output or a venodilator effect similar to that of ganglion-blocking drugs.¹⁰ Reserpine has oral bioavailability of 30%. Plasma half-life is prolonged (one to two weeks). Plasma protein binding is 96%.

Adrenergic neuron-blocking agents

These agents interfere with adrenergic neurotransmission at the post-ganglionic nerve terminals. Like reserpine there is depletion of catecholamine stores in nerve terminals, blood vessels, and the myocardium, but unlike reserpine there is little effect on catecholamine stores in the adrenal glands or brain.

After ingestion, there is a transient pressor phase associated with increased heart rate and cardiac output related

to catecholamine release. A prolonged period of cardiac, vascular, and nerve terminal catecholamine depletion follows, associated with progressive reduction in systemic arterial pressure (explained by reduction in vascular resistance). Hypotension is less marked in the supine posture or with agents that simultaneously contract or prevent reexpansion of plasma volume.^{7,8}

Guanethidine has oral absorption of 50 to 60% despite undergoing quite extensive pre-systemic metabolism (30 to 40%). Plasma half-life is two to eight days, and protein binding is less than 10%. Metabolism is in the liver. Bethanidine has complete oral absorption and undergoes no significant pre-systemic metabolism. Plasma half-life is 8 to 15 hours. Plasma protein binding is less than 10%. Bethanidine is excreted unchanged in the urine.

Debrisoquine has oral absorption of less than 85%. There is no pre-systemic metabolism and half-life is 10 to 26 hours. Protein binding is 25%. Metabolism is subject to genetic polymorphism via the P450 isoenzyme P450 II D1. Some 92% of Caucasians are extensive metabolizers, and 8% have poor metabolizer phenotypes. Plasma concentrations are several-fold higher in poor metabolizers. Bretylium was withdrawn as an antihypertensive agent because of incomplete and variable absorption after oral administration, rapid occurrence of tolerance, and a high rate of side effects. This drug is unsuitable for long-term use.

Monoamine oxidase inhibitors

Examples include pargyline, transcylopramine, phenylzine, and iproniazid. Pargyline was introduced primarily as an antihypertensive agent. Only a relatively few hypertensive individuals were studied and results were not striking.

Veratrum alkaloids

These agents alter the responsiveness of vagal efferent nerve fibers in the coronary sinus, left ventricle, and carotid sinus so that any pressure will result in altered nerve traffic. The stimulus is interpreted in the medullary vasomotor center as reflecting a higher pressure than actually exists, as a result of an induced delay in the vagal repolarization process.

The altered input in the cerebral vasomotor centers results in a reflexive fall in blood pressure and heart rate. The latter response may be abolished by atropine. Because adrenergic function is not blocked but only reset at a different pressure level, the usual postural and adrenergic reflexive responses are not altered. The result is a significant fall in peripheral resistance with little change in cardiac output despite marked bradycardia. Cerebral and renal blood flow and glomerular filtration rate remain normal unless the hypotensive response is excessive.

Direct-acting vascular smooth muscle relaxants

Agents in this class act by decreasing arteriolar resistance. Mechanisms of action are variable, although the final common pathway is vascular smooth muscle relaxation (Figure 84-1).

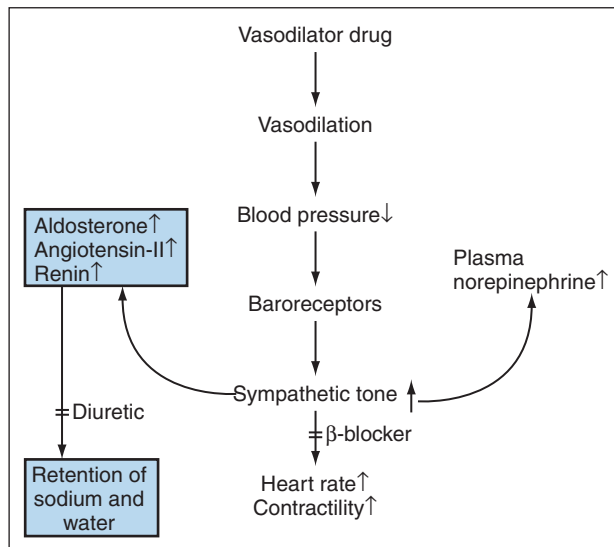

Figure 84-1. Reflex mechanisms triggered by vasodilation induced by vasodilator drugs.

Hydralazine

Hydralazine is a dilator of resistance vessels and has little action on venous beds.¹¹ After intravenous administration, hydralazine has slow onset of action of 15 to 20 minutes. Blood pressure fall is accompanied by baroreceptor-mediated sympathetic activation with tachycardia and sweating. After oral administration, onset of action is gradual and the duration of action is prolonged. The peak effect is seen 30 to 120 minutes after dosing. Higher doses do not increase the peak blood pressure reduction but prolong the duration of action.

The precise mode of action is unknown, but hydralazine causes activation of guanylate cyclase and accumulation of cyclic guanosine monophosphate (GMP).¹² By altering cellular calcium metabolism, hydralazine interferes with the movement of calcium that is responsible for initiating or maintaining the contractile state of vascular smooth muscle. Accumulation of cyclic GMP stimulates cyclic GMP-dependent protein kinase. This eventually leads to dephosphorylation of the light chain of myosin, which is thought to be involved in the contractile process in the phosphorylated form. Preferential dilation of arterioles (versus veins) minimizes postural hypotension, promotes increased cardiac output, and tends to lower diastolic more than systolic blood pressure. Blood flow increases in coronary, cerebral, and renal vascular beds.

In addition, a component of action is dependent on the presence of intact endothelium. Hydralazine may cause release of nitric oxide from the vascular endothelium. Hydralazine also stimulates the renin-angiotensin aldosterone (RAAS) system. This, together with a compensatory increase in heart rate and contractility, tends to counteract the antihypertensive effect.

Hydralazine is rapidly and completely (100%) absorbed from the gastrointestinal tract after oral administration.¹¹ The time to maximum serum concentration is one to two hours. Biotransformation commences in the gut wall and during first-pass through the liver (pre-systemic metabolism

of 65 to 90%).¹¹ The liver is the major site of metabolism of hydralazine. Of the administered dose, 80% is excreted in the urine almost entirely as metabolites. The major metabolic pathways are N-acetylation and hydroxylation, with subsequent glucuronidation. Plasma half-life is two to four hours.¹¹ Plasma protein binding is 87%.

The acetylation pathway is subject to genetic polymorphism. Elimination is more rapid in “fast acetylators” than in “slow acetylators.” “Slow acetylators” have almost twice the plasma concentration of “fast acetylators.” This leads to greater antihypertensive effect and greater risk of side effects in “slow acetylators.”

Endralazine

Endralazine is a vasodilator chemically similar to hydralazine. Acetylation is not a major route of metabolism and therefore response is not related to acetylator phenotype.¹³

Minoxidil

Treatment is associated with dilatation of resistance vessels.¹⁴ There is little or no action on the venous bed. Minoxidil acts by activation of adenosine triphosphate (ATP)-sensitive potassium channels in arterial smooth muscle.¹⁵ As a result, the smooth muscle membrane is hyperpolarized and calcium influx through voltage-gated calcium channels is inhibited. Cytosolic calcium concentration is reduced.

Oral absorption is 100%. Plasma half-life is 2.8 to 4.2 hours and plasma protein binding is negligible. Minoxidil is extensively metabolized in the liver. A sulphated metabolite is pharmacologically active and probably accounts for much of the activity of the parent drug.

Diazoxide

Diazoxide is a non-natriuretic thiazide congener that is an extremely potent vasodilator,¹⁶ acting on resistance vessels and without effect on the venous bed.¹⁷ The mode of action is opening of ATP-sensitive potassium channels in vascular smooth muscle cells.

Oral absorption is 85 to 95%. Plasma half-life is 28 hours. More than 90% of diazoxide is protein bound. Elimination is primarily by glomerular filtration. About 20% is metabolized in the liver to inactive metabolites.

Sodium nitroprusside

Sodium nitroprusside is administered as a slow intravenous infusion to produce rapidly reversible decrease in blood pressure.¹⁸ The mode of action is to increase GMP within vascular smooth muscle activating vasorelaxation. This effect is probably mediated by non-enzymatic degradation of nitric oxide. The result is activation of vascular smooth muscle soluble guanylate cyclase with generation of cyclic adenosine monophosphate (AMP).¹⁹

Sodium nitroprusside is mainly excreted through the kidney. Clearance is extremely rapid. Half-life for blood pressure lowering is 32 to 40 seconds. The antihypertensive effect is potentiated in renal failure, although because a dose-titration regimen is employed adjustment of dose is unnecessary. The drug is metabolized non-enzymatically to cyanide, which reacts with thiosulphates to form thiocyanate (which is also excreted through the kidney).²⁰ The

metabolic products of sodium nitroprusside are not active in the cardiovascular system.

Other potassium channel agonists

The recognition that minoxidil and diazoxide act through smooth muscle potassium channels increased interest in other agents with a similar mode of action and that may not give rise to the same serious side effects.^{15,21} Hyperpolarization of the vascular smooth muscle membrane inhibits the opening of voltage-operated calcium channels and increases excretion of calcium by sodium-calcium exchange, inhibiting intracellular calcium release and increasing uptake of norepinephrine by the extraneuronal catecholamine transporter. In addition, potassium channel activators cause vasodilatation of small and large arteries but have little effect on the venous circulation.

Pinacidil has high oral absorption. Its half-life is 1.6 to 2.9 hours. Plasma protein binding is 40%. Metabolism and elimination is by biotransformation in the liver via cytochrome P-450, followed by renal elimination. Nicorandil has a nitrate moiety incorporated in the molecule. This significantly modifies the pharmacologic vasodilator profile.²² Thus, nicorandil increases smooth muscle cyclic GMP.²³ Tachycardia is transient and cardiac output is not usually increased.

INDICATIONS/CONTRAINDICATIONS AND OBJECTIVES

Adrenergic inhibition Ganglion-blocking drugs

Because interference with transmission of the autonomic impulse at the ganglia level impairs adrenergic and parasympathetic impulse transmission, the clinical use of ganglion blockers is associated with severe side effects and unwanted parasympathetic inhibition. With the advent of newer agents, ganglion blockers have become mostly of academic interest.

The exception is trimetaphan, which is still useful as an antihypertensive agent. Trimetaphan is delivered by slow intravenous infusion.²⁴ The starting dose is 0.5 to 2 mg/min and the adequate dose is usually 0.5 to 6 mg/min. Reduction of arterial pressure is immediate. Marked interindividual variability necessitates direct arterial blood pressure monitoring. When the infusion is discontinued, return of arterial pressure to pre-infusion levels is prompt. Thus, when administered in severe hypertension long-acting antihypertensive therapy must be initiated before discontinuing the infusion.

Trimetaphan can be used in hypertension with dissecting aortic aneurysm where the drug reduces velocity of ventricular ejection and hence shearing force. In controlling hypertension in acute aortic dissection, during surgery, and in arteriography, trimetaphan may be more manageable than agents with more prolonged action. Under these circumstances, ganglion blockade will not be associated with the secondary reflexive stimulation of the heart that is found with other vasodilators.

There are several contraindications to trimetaphan, including atheromatous vascular disease because of reduced

blood supply, pyloric stenosis because of compromised gastric outflow via ganglionic blockade and in pregnancy because of the risk of paralytic or meconium ileus in the newborn. The duration of action of suxamethonium is prolonged by inhibition of pseudocholinesterase. The neuromuscular blocking action of trimetaphan enhances nondepolarizing muscle relaxants.

Rawlfia alkaloids

Reserpine and similar alkaloids are efficacious in reducing arterial pressure when used with a diuretic.^{25,26} Reserpine is generally added to the treatment regimen if response to a thiazide (or thiazide-like) diuretic is inadequate. Reserpine is also useful in treating hypertensive emergencies.²⁷ The maintenance dose of reserpine is up to 0.1 mg daily. Because reserpine has a long half-life, a loading dose is employed to obtain a reasonably rapid steady-state concentration.

Reserpine is contraindicated absolutely in depression and in those with a history of depression. The drug is also contraindicated in severe renal failure and is best avoided in peptic ulceration, ulcerative colitis, or asthma. Reserpine may cause complications in the neonate if used in pregnancy. These include nasal obstruction (anosmia), bradycardia, and hypothermia. Thus, reserpine is no longer a drug of choice in hypertensive emergencies in pregnancy. A reduced dose is recommended in the elderly.

Several drug interactions have been reported. There is enhanced peripheral vasodilatation and hypotension with alcohol. Enhanced falls in blood pressure are also seen with glyceryl trinitrate, L-dopa, fenfluramine, and phenothiazines. The pressor effects of phenylephrine and catecholamines are enhanced, whereas the effect of direct-acting amines (such as ephedrine) is diminished. There is excessive central nervous system excitation with monamine oxidase inhibitors. Reserpine lowers the convulsive threshold in epilepsy. The bradycardic effect of digoxin and the negative isotropic effects of antiarrhythmic agents, such as disopyramide and quinidine, are enhanced. There is increased myocardial depression with halothane and increased prolactin/breast enlargement with the oral contraceptive steroids.

Adrenergic neuron-blocking agents

Guanethidine

Because of prolonged action and because sympathetic inhibition is usually maximal at night, guanethidine needs to be administered only once daily. The starting dose of 10 mg is titrated to the required dose, which is usually 25 to 75 mg daily although up to 200 to 300 mg daily may be needed. Antihypertensive effect can be hastened by initiation with a loading dose.

Because fluid retention and expanded intravascular and extracellular fluid volumes are prominent, a diuretic is indicated, with the caveat that patients should be monitored carefully for hypokalemia and impaired renal excretory function. The phenomenon is due to fluid expansion because impairment of drug absorption over time seems unlikely. However, the common adverse effect of diarrhea may reduce absorption. Abrupt withdrawal is not associated with rebound hypertension because of the prolonged half-life. The mechanism of action leads to postural hypotension,

particularly after exercise or circumstances favoring vasodilatation (such as heat, alcohol, or pyrexia). This is a particular risk in the elderly and when a diuretic is added.

When urgent reduction of blood pressure is indicated, guanethidine can be given parenterally (intramuscular or intravenous). A slow intravenous infusion or intramuscular injection avoids the initial pressor response due to catecholamine release. The maximum effect after intramuscular use is seen in one to two hours. Guanethidine is safe in pregnancy. Loss of blood pressure control may be due to drug interactions. Uptake into adrenergic nerve endings is reduced by concomitant tricyclic antidepressant therapy.

Bethanidine

The initial dose of 5 to 10 mg three times daily is titrated as necessary to a maximum dose of 200 mg daily. Bethanidine was widely used as third drug in combination with a thiazide and a beta blocker. The drug accumulates in renal failure, whereby antihypertensive effects may be enhanced.

Debrisoquine

The dose range is 20 to 400 mg daily, administered by twice- or thrice-daily dosing regimens. Debrisoquine is used with a beta blocker and diuretic to avoid fluid retention. Poor metabolizers respond to 10 mg twice daily, which is therefore the usual starting dose unless the metabolic phenotype is known. The starting dose is 40 mg twice daily in extensive metabolizers.

Adrenergic neuron-blocking agents are contraindicated in pheochromocytoma. Withdrawal of neurally released norepinephrine induces extreme sensitivity to circulating catecholamines. These drugs may exaggerate hypertension consequent on sudden release of catecholamines from the tumor.

Monoamine oxidase inhibitors

Monoamine oxidase inhibitors may aggravate hypertension by inhibition of norepinephrine metabolism. Because monoamine oxidase is inhibited in the post-ganglionic nerve terminal, several weak pressor amines accumulate at this site. These substances are believed to act as false neurohumoral transmitters, tending to elevate blood pressure. Because of the potentially severe hypertensive crisis that may be associated with use, these drugs should be considered primarily of academic interest in the treatment of hypertension.

Veratrum alkaloids

Clinical use has been severely restricted by side effects.

Direct-acting smooth muscle relaxants

With the fall in total peripheral resistance and arterial pressure, reflex stimulation of the heart occurs so that tachycardia and palpitation results frequently unless the cardiac reflex responses are offset by an adrenergic inhibitor (usually a beta blocker). These agents should not be administered to hypertensive patients with heart failure, myocardial infarction, angina, or aortic dissection because the reflexive cardiac effects will aggravate the underlying cardiac condition.

Hydralazine

Hydralazine entered the therapeutic armamentarium shortly after the ganglionic-blocking agents and was one of the most effective drugs in the 1950s.²⁸ Usage declined rapidly in the 1960s but hydralazine returned to regular usage in stepped-care regimens of the late 1960s, in combination with a beta blocker and diuretic. Hydralazine has largely been replaced by other peripherally acting drugs and is now not widely used, although the drug remains effective and safe in specialist hands.

Hydralazine is usually administered three or four times daily, preferably starting with an individual dose of 12.5 to 25 mg. A lower dose (10 mg) may be used if there are side effects. The dose is then increased as necessary to a maximum of 200 to 300 mg daily. Slow acetylators show greater lowering of blood pressure.¹¹ The daily dose should not exceed 200 mg. High doses are more likely to be associated with development of anti-nuclear antibodies (ANA) and a lupus-like syndrome.¹¹ The acetylator phenotype can be determined readily by a simple urinary test of sulphonamide acetylation.²⁹ Periodic full blood count and ANA titers are recommended during chronic hydralazine therapy. Because hydralazine undergoes hepatic metabolism, dose adjustment is unnecessary in renal impairment.

Pretreatment with a beta blocker prevents sympathetic activation, reduces side effects, and potentiates the antihypertensive action.³⁰ Hydralazine is used with a beta blocker and diuretic to control moderate to severe hypertension. Where renal function is seriously impaired, a loop diuretic rather than a thiazide is needed to avoid edema. A multicenter trial³¹ evaluated hydralazine, labetalol, methyldopa, prazosin, and placebo for value as a third drug when added to ongoing beta-blocker and diuretic treatment. Overall, hydralazine was the most generally suitable third drug.

Much of the early information demonstrating that antihypertensive therapy can diminish morbidity and mortality involved hydralazine-treated patients.^{25,26,32,33} A combination of reserpine, hydrochlorothiazide, and hydralazine was used in the landmark Veterans Administration Cooperative Study Group Trials,²⁵ which demonstrated unequivocally the merits of antihypertensive therapy not only in severe but in moderate hypertension.

For urgent control of blood pressure, hydralazine can be given parenterally. Onset of action is in 15 minutes,² but the dose and frequency of administration required for blood pressure control are highly variable, the long duration of action makes dose titration difficult, and many patients do not respond adequately to any dose of hydralazine. Therefore, hydralazine is not an ideal drug for hypertensive emergencies. Sodium nitroprusside is more effective if continuous monitoring in an intensive therapy unit is available.

Although there have been no formal studies in pregnancy, and although the drug is teratogenic in some animals, hydralazine is widely used in pregnant women.³⁴ The main contraindication is coronary artery disease because increased cardiac output increases cardiac work and may provoke angina and myocardial ischemia or infarction. However, if hypertension is severe reduction in blood pressure and cardiac work will more than compensate. In

mitral valve disease, hydralazine may increase pulmonary artery pressure and induce congestive heart failure. Endralazine lowers blood pressure over 24 hours with once-daily dosing.³⁵

Minoxidil

Because of the severity of adverse effects, usage is limited to severe hypertension unresponsive to other treatments.³⁶ Minoxidil is usually administered twice daily with an initial dose of 2.5 to 5 mg. Once-daily dosing is sometimes employed. The maximum daily dose is usually 50 mg, although doses up to 100 mg have been used.

Pretreatment with a beta blocker limits sympathetic activation.³⁷ Sodium retention requires concomitant diuretic therapy in most. A loop diuretic is often necessary. Minoxidil is excreted into breast milk and therefore is best avoided in breast-feeding mothers. Safety in pregnancy has not been established.

Diazoxide

Oral diazoxide can be used in resistant hypertension as a twice-daily regimen, although the long half-life suggests that once-daily treatment may be sufficient. A graded sustained fall in blood pressure usually results. The initial dose is 50 to 100 mg twice daily, increasing as necessary to a total daily dose of 1 g.³⁸ The severity of side effects has rendered this usage largely obsolete.

Intravenous diazoxide is still occasionally used in the treatment of hypertensive emergencies. Diazoxide has been useful for the patient with hypertensive encephalopathy, and in those with severe, malignant, or accelerated hypertension (without heart failure) for whom rapid and immediate reduction in arterial pressure is mandatory. Blood pressure is lowered rapidly and consistently but rarely below normal. The first dose is usually effective and the action persists for several hours. The maximal daily dose is 150 mg. Higher doses previously used were associated with unacceptable hypotension and exacerbation of ischemic heart disease. For the same reason, rapid infusion is no longer recommended and the bolus should be administered over about 10 minutes.³⁹ Repeated doses can be administered every 5 to 15 minutes until target blood pressure is achieved. After each dose, the patient should remain recumbent and should be closely monitored for 30 minutes.

Diazoxide has been successful in severe hypertension in children. The usual effective dose is 5 mg/kg. Hypertensive crises induced by pheochromocytoma or due to monoamine oxidase inhibitor therapy should not be treated with diazoxide because blood pressure responds more specifically to alpha blockers. Safety in pregnancy has not been demonstrated conclusively.

Contraindications include subarachnoid hemorrhage, intracerebral hemorrhage, postoperative bleeding, functional hypoglycemia, and hypersensitivity to thiazides. In the case of dissection of aortic aneurysms, the increase in stroke volume and left ventricular ejection rate reflexively induced by diazoxide augment stresses in the aortic wall. The antidiuretic properties of diazoxide can lead to significant fluid retention which may precipitate congestive heart failure in patients with impaired cardiac reserve.

Sodium nitroprusside

Sodium nitroprusside is used for the short-term treatment of severely hypertensive patients at high risk, to normalize blood pressure before and during surgery for renal artery stenosis or pheochromocytoma, in hypotensive anesthesia, and in dissecting aortic aneurysm. Sodium nitroprusside is useful in hypertensive emergencies because of rapid onset of action, titratability, and rapid reversibility of excess blood pressure reduction.

The absence of tachycardia in most patients means that sodium nitroprusside is free of the cardiac symptoms produced by some other vasodilators. The drug is administered dissolved in 5% dextrose in water as an intravenous infusion using an infusion pump or drip regulator. The infusion should be protected from light using aluminum foil.

The drip rate is titrated against blood pressure. The average dose is 0.5 to 8.0 $\mu\text{g}/\text{kg}/\text{min}$. The rate should be increased slowly to prevent or reduce compensatory reactions (sharp rises in catecholamines and renin, tachycardia, and tachyphylaxis). The infusion should not be terminated abruptly to prevent excessive rebound in blood pressure. The starting dose is 0.3 to 1.0 $\mu\text{g}/\text{kg}/\text{min}$ and is increased gradually until the desired blood pressure reduction is achieved, preferably while monitoring intra-arterial blood pressure. To avoid excessive levels of cyanide and to lessen the possibility of precipitous blood pressure reduction, the maximum recommended dose is 8 $\mu\text{g}/\text{kg}/\text{min}$. If this is insufficient, another approach should be tried.

Prolonged infusions are undesirable because of the risk of thiocyanate intoxication, but if continuous therapy over several days is required acid/base balance should be assessed by measurement of plasma bicarbonate, lactate, and the lactate/pyruvate ratio. This is a more sensitive measure of intoxication than plasma concentration of thiocyanate or cyanide under these conditions because toxicity is associated with the development of acidosis.

Sodium nitroprusside is contraindicated in severe liver impairment, Leber's optic atrophy, and tobacco amblyopia. Precaution is needed in disturbed cerebral blood flow because of the risk of too rapid lowering of blood pressure. Caution is also required in hypothyroidism because thiocyanate inhibits iodine uptake and binding by the thyroid. Care should be taken in renal failure because excretion of thiocyanate is decreased.

Other potassium channel agonists

Pinacidil

Greatest experience in hypertension is with this agent.⁴⁰ Pinacidil is usually administered as a sustained-release preparation. In doses ranging from 12.5 to 37.5 mg twice daily, pinacidil has a useful blood-pressure-lowering action. Dose-dependent edema offsets the antihypertensive effect. This can be overcome by concomitant diuretic. Pinacidil is contraindicated in congestive heart failure and should be used with caution in coronary or cerebrovascular disease and tachyarrhythmias because of the tendency to tachycardia.

Because pinacidil undergoes hepatic metabolism, dose reduction is advised in severe hepatic dysfunction and in the elderly because renal clearance of the metabolite is reduced. Nevertheless, pinacidil has been used with success

in renal hypertension. Intravenous pinacidil can be used in emergencies. Because of tachycardia, pinacidil has no advantage over other drugs.

Nicarandil

Intravenous use produces a fall in blood pressure, but oral treatment (20 to 40 mg daily) in normotensive subjects during exercise produces little effect on blood pressure.

Chromakalim

This agent has been much less extensively investigated, but chromakalim lowers blood pressure in both hypertensive and normotensive subjects following oral doses of 0.75 to 1.5 mg.⁴¹

COMPLICATIONS

Major complications are listed in Tables 84–2 through 84–5.

Adrenergic inhibitors

Ganglion-blocking drugs

As a result of reduction in vasomotor tone, treated patients will pool blood in dependent capacitance vessels. This effect explains the phenomenon of orthostatic hypotension that can be associated with syncope.⁴² To enhance the antihypertensive effect in the supine posture, it is necessary to reduce intravascular (and extracellular) fluid volume and prevent the expansion of blood volume.^{7,8} Prolonged therapy with trimetaphan for 48 to 72 hours is associated with refractory responses (tachyphylaxis).⁴³

Reduction in cardiac output results in at least proportionate reduction of renal blood flow, sometimes associated with reduced creatinine clearance.⁴⁴ Because parasympathetic inhibition also results from ganglionic blockade, tonic activity leads to risk of paralytic ileus and acute urinary retention. Thus, abdominal pain with reduced bowel sounds, constipation, or reduced urinary output in a patient with aortic dissection may not reflect extension of the dissection into the mesenteric or renal arteries but instead may be a side effect of treatment. Other adverse drug reactions with trimetaphan include asthma attacks because of histamine release. Large doses may provoke muscle relaxation leading to cardiac arrest.

Rawlfia alkaloids

Parasympathetic activity remains unopposed, explaining many common side effects (including bradycardia, prolonged atrioventricular conduction, increased gastric acid excretion with possible secondary peptic ulceration, and frequency of bowel movements). These adverse effects may be counteracted by parasympathetic inhibitors.

Although arterial dilatation with increased blood flow has been considered greatest in the skin, other vascular beds are also involved. The frequent complaint of nasal mucosal congestion and suffiness is ameliorated by nasally administered vasoconstrictors.⁴⁵ However, prolonged use may result in chemical rhinitis.

As a result of depletion of brain catecholamines and serotonin, there may be behavioral alterations and subtle

ADVERSE REACTIONS DUE TO ADRENERGIC INHIBITORS: GANGLION BLOCKERS AND RAWOLFIA ALKALOIDS		
Drug	Common Side Effects	Other Side Effects

or overt depression (sometimes leading to suicide).⁴⁶ Less severe central complications include drowsiness and nightmares. Parkinsonism, dyskinesia, and dystonia can result from dopamine depletion in the basal ganglia. Congestive heart failure may be precipitated or worsened.

Adrenergic neuron-blocking drugs

Because of coincidental inhibition of venous tone,⁴⁵ venous return to the heart is reduced by peripheral pooling of blood in dependent areas of the body with upright posture. As a result, orthostatic hypertension is prominent.⁴⁷

Associated with the resulting fall in cardiac output, there is a proportionate reduction in organ blood flow. Severe hypotension may aggravate angina and lead to myocardial infarction, cerebrovascular insufficiency with syncope, or even stroke. The renal and splanchnic territories may receive a smaller proportion of total cardiac output, but glomerular filtration rate and renal function appear to return to normal with time.⁴⁸ With reducing skeletal muscle blood flow and adrenergic innervation of skeletal muscle, weakness may result. This can be exacerbated by diuretic treatment.⁴⁹ Muscle weakness may be aggravated still further during and immediately after exercise.⁵⁰

ADVERSE REACTIONS DUE TO DIRECT-ACTING VASCULAR SMOOTH MUSCLE RELAXANTS: HYDRALAZINE AND MINOXIDIL		
Drugs	Common Side Effects	Other Side Effects
Hydralazine	<ul style="list-style-type: none"> ■ Headache ■ Nasal stuffiness ■ Tachycardia ■ Palpitation ■ Flushing ■ Sweating ■ Peripheral neuropathy ■ Lupus reaction 	<ul style="list-style-type: none"> ■ Fluid retention, edema ■ Drug fever ■ Skin eruptions ■ Blood dyscrasias ■ Purpura

Other potassium channel agonists	<ul style="list-style-type: none"> ■ Headache ■ Dizziness ■ Palpitation ■ Tachycardia ■ Edema 	<ul style="list-style-type: none"> ■ Hypertrichosis ■ Nausea dyspepsia ■ Rashes ■ Increased ANA titers

Table 84-5. Adverse Reactions Due to Direct-acting Vascular Smooth Muscle Relaxants: Diazoxide, Sodium Nitroprusside, and Other Potassium Channel Agonists

Some side effects (orthostatic hypotension, excessive hypotension, bradycardia, increased gastric excretion) result from unopposed parasympathetic activity and impaired adrenergic function. Similarly, diarrhea, retrograde ejaculation, and fluid retention may be explained by reduced adrenergic transmission. Many of these side effects may be counteracted by reduction in dosage or the addition of a parasympatholytic agent or diuretic.

Because these agents act by entering the nerve terminal, any agent that prevents this will block the action. This is

the means by which tricyclic antidepressants act,⁵¹ and therefore these classes of drugs should not be prescribed concomitantly. Drugs that reduce efferent sympathetic output enhance postural hypotension and bradycardia. Examples include alpha blockers, beta blockers, and ganglion blockers. Cardiac glycosides may also enhance bradycardia.

Monoamine oxidase inhibitors

The major side effects are centrally mediated mental and emotional reactions, including euphoria, insomnia, and

acute psychosis. More important is the severe hypertensive crisis following the ingestion of foods containing tyramine, such as aged cheeses, beer, sherry, Chianti, and herring.⁵²

Veratrium alkaloids

Because of the narrow therapeutic index, the effective control of arterial pressure is not infrequently associated with side effects.

Direct-acting vascular smooth muscle relaxants

Side effects common to these agents include headache and nasal stuffiness attributable to local vasodilatation, fluid retention, and edema. The latter effects can result in pseudotolerance.

Hydralazine

Peripheral neuropathy is dose dependent and is rare at doses up to 200 mg daily.⁵³ This complication is more common in slow acetylators. Neuropathy is first manifest by paraesthesia, numbness, and tingling of the extremities. Pyridoxine deficiency is the likely cause and correction can be achieved by administration of pyridoxine.¹¹

The lupus reaction gives rise to malaise, myalgia, and arthralgia/arthritis, and is associated with raised ANA titers.⁵⁴ Raised titers are often encountered in asymptomatic patients and are not a contraindication to continuation, although the lupus syndrome is. Hydralazine does not worsen idiopathic systemic lupus erythematosus.

There may be more severe signs of systemic illness such as weight loss, splenomegaly, and effusion in serous cavities. Rashes may also occur. If not diagnosed promptly, the degree of temporary disability may be severe. Renal and cerebral involvement is rare. The hydralazine lupus reaction usually occurs after six months of therapy at doses over 400 mg daily and is almost always seen in slow acetylators. Patients with HLA DR4 phenotype are particularly susceptible.⁵⁵ The syndrome resolves when the drug is withdrawn, although months or years may be required for complete clearing.¹¹ After withdrawal of hydralazine, positive tests for ANA may persist for years.

Although the lupus reaction is reduced substantially at daily doses of 200 mg or less, there is still a significant incidence. In one study,⁵⁶ the incidence was 6.7% over three years. No cases were seen at 50 mg daily, 5.4% with 100 mg daily, and 10.4% with 200 mg daily. The incidence was higher in women (11.6%) than in men (2.8%). In women taking 200 mg daily, the three-year incidence was 19.4%. Thus, the true incidence of lupus syndrome is unacceptably high.

Decrease in white cell count is more common in blacks. Mild gastrointestinal side effects sometimes occur but present no clinical problems at conventional doses. Endralazine is not associated with the lupus syndrome.

Minoxidil

Increase in cardiac work may account for electrocardiograph (ECG) changes, which are often observed during the first few days of therapy. ECG changes include ST depres-

sion and T-wave inversion⁵⁷ but are not associated with cardiac enzyme elevation. However, reflex tachycardia may provoke angina in those with ischemic heart disease. Pulmonary edema may be the consequence of increased cardiac output.

An uncommon cardiac adverse event is pericardial effusion, which is rarely associated with tamponade.⁵⁸ Deaths have been reported. Dependent edema and ascites are extremely common.

A very common side effect of minoxidil is hirsutism, which is particularly bothersome in women. Hypertrichosis mainly affects the forehead and face and is most apparent in dark-haired individuals. There is no pharmacologic treatment for excess hair growth, and the only remedy is removal of hair or discontinuation of the drug. After discontinuation, hair growth reverses in a few months.

Diazoxide

Diazoxide shares the adverse effects of minoxidil. In addition, diazoxide causes impairment of glucose tolerance in the majority of patients. Hyperglycemia is due to inhibition of insulin secretion. The effect is probably mediated by action upon pancreatic islet cell potassium channels and can be reversed by sulphonylurea drugs.³⁸ Diabetic ketoacidosis and hyperosmolar non-ketonic coma are infrequent but can develop very rapidly. Conventional therapy with insulin and restoration of fluid and electrolyte balance is usually effective.

Increased hepatic enzymes, uremia, reduced creatinine clearance, reversible nephrotic syndrome, decreased urine output, hematuria, and albuminuria occur very occasionally. Thrombocytopenia with or without purpura may require discontinuation. Drug interactions include bleeding with anticoagulants and hypotension with beta blockers. Diuretics potentiate hyperuricemia by inhibition of tubular secretion of uric acid.

Sodium nitroprusside

Retrosternal discomfort, palpitation, dizziness, and abdominal discomfort can occur if blood pressure reduction is too rapid. Cyanide intoxication is rare unless the recommended dose is exceeded. Metabolic acidosis may be followed by hypoxia and tetanic spasms.

Other potassium channel agonists

When used as monotherapy, side effects of pinacidil are dose related. ECG T-wave changes have been reported in the initial phase of treatment.⁴⁰ Hypertrichosis is seen occasionally.⁵⁹

SUMMARY

Vasodilators are highly effective antihypertensive agents that dominated the management of hypertension in the 1950s and 1960s. However, treatment with these agents is associated with an unacceptable level of adverse reactions. With the advent of newer and better-tolerated antihypertensive agents, their use has declined dramatically. Many vasodilators can now be considered only of historical interest.

In developed countries, vasodilators have a limited clinical role. Some direct-acting vascular smooth muscle relaxants continue to have utility in the management of hypertensive emergencies (notably sodium nitroprusside) and in severe hypertension refractory to other antihypertensive agents (notably minoxidil). In developing countries, however (where the cost of newer agents may be prohibitive),

vasodilators continue to be prescribed more widely. The safe and effective long-term use of these drugs requires careful attention to adverse reactions with concomitant administration of beta blockers and diuretics to avoid the consequences of reflex cardiac stimulation and salt and water retention.

Chapter
85Novel Drug Treatments
for Hypertension*Henry Krum and Jennifer Martin***Key Findings**

- The treatment of hypertension is becoming more difficult because of the lower blood pressure (BP) targets set by evidence-based guideline recommendations.
- The renin-angiotensin-aldosterone system remains one of the key targets for therapeutic intervention in the treatment of systemic hypertension.
- Renin as an early and rate-limiting step in renin-angiotensin system activity is a particularly attractive therapeutic target.
- Newer renin inhibitors have been developed that overcome many of the limitations of older agents, particularly bioavailability.
- Aldosterone is an important independent hormone involved in the progression of a number of major cardiovascular disease states, including systemic hypertension.
- Selective aldosterone blockers (e.g., eplerenone) have been developed that do not possess the antiandrogenic and progestational adverse effects of earlier agents such as spironolactone.
- Aldosterone synthase inhibitors represent an alternative approach to blockade of the adverse actions of aldosterone on the cardiovascular system.
- Endothelin is another more recently described hormonal system that may be involved in the pathogenesis of essential hypertension.
- Endothelin receptor antagonists lower BP but will undoubtedly be reserved as third- or fourth-line agents for refractory disease because of side effects and teratogenicity.
- Rho-kinase is a recently described cell-signaling pathway that may be of relevance in the progression of hypertension.
- Blockade of the rho-kinase system should produce effects on BP complementary to blockade of other systems such as the renin-angiotensin-aldosterone pathway. Rho-kinase inhibitors have been developed and have been shown to exert vasodilator effects in hypertensive patients.

Treatment of essential hypertension has advanced considerably in the past few decades. We now have agents that are highly effective at lowering BP, are associated with minimal side effects, and are able to be given on a once-daily basis to aid adherence to therapy. The question therefore arises as to why we need new treatments in the management of this condition. There are several reasons for this. One of the

most important is that target BP goals continually move lower, based on epidemiologic and intervention study data. This is particularly true of hypertension associated with co-morbid conditions such as diabetes mellitus. For this reason, monotherapy alone is usually not able to lower BP to these target levels in many patients. The use of multiple classes of agents within the individual patient has therefore become the norm. However, certain agents cannot be used together with (and/or interfere with) the BP-lowering efficacy of other agents. Therefore, the clinical need for new therapies as add-on treatments for refractory hypertension and to attack new targets still remains highly relevant. This chapter assesses the development of new therapies directed at new targets and new approaches to old targets in the management of essential hypertension.

RENIN INHIBITORS

Blockade of the renin-angiotensin-aldosterone system (RAAS) is an important therapeutic strategy not only for the treatment of hypertension but for the clinical benefits it provides beyond BP reduction, such as in the management of heart failure and progressive kidney disease. To date, interruption of this system has been effected at multiple steps that include enzyme inhibition (angiotensin-converting enzyme and renin) in addition to receptor blockade (angiotensin II type 1 receptor and aldosterone) (Figure 85–1).

Angiotensin II, a major effector molecule of this system, is produced via a two-step process in which angiotensinogen (synthesised primarily in the liver) is cleaved by the aspartic peptidase renin (produced in the juxtaglomerular cells of the kidney) to give rise to angiotensin I. This biologically inactive decapeptide is then converted to the active octapeptide angiotensin II by the di-peptidyl carboxypeptidase angiotensin-converting enzyme (ACE) or by a range of other proteases that include chymase.

Although highly effective, the therapeutic response achieved with both ACE inhibitors and angiotensin receptor blockers (ARBs) is limited by the reactive rise in renin (and thus angiotensin peptides) that occurs with both drug classes. Renin is not only the rate-limiting step in angiotensin II formation but shows remarkable substrate specificity for angiotensinogen, making it an attractive target for therapeutic inhibition. Furthermore, the recent identification of a renin receptor in the glomerular mesangium and in arterial subendothelium suggests the possibility of additional advantages of renin inhibition beyond those of ACE inhibitors

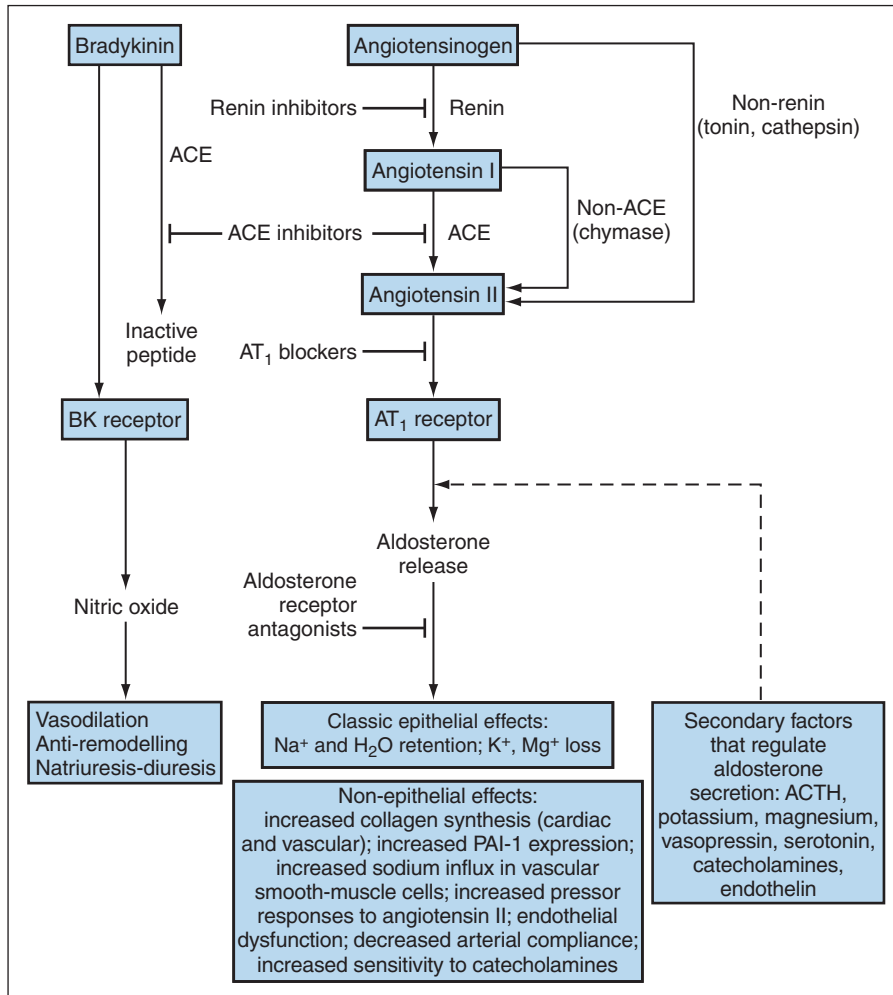

Figure 85–1. The renin-angiotensin-aldosterone system: a key regulator of blood pressure. Renin (a protease secreted into the circulation in response to various physiological stimuli) cleaves the protein angiotensinogen to produce the inactive decapeptide angiotensin I. Cleavage of angiotensin I by angiotensin-converting enzyme (ACE) produces the active octapeptide angiotensin II (as shown, ACE also inactivates bradykinin, and there are alternative routes for the generation of angiotensin II). Angiotensin II activates the angiotensin II type 1 (AT₁) receptor, a member of the G-protein-coupled receptor superfamily. Many of these effects, such as vasoconstriction and stimulation of aldosterone synthesis and release (which leads to sodium retention), tend to elevate blood pressure. Angiotensin II also activates the AT₂ receptor, the effects of which (Box 85–1) are less well understood but which could antagonize many of the effects of activation of the AT₁ receptor. Various points shown in the renin-angiotensin-aldosterone cascade have been the targets for pharmacologic intervention, and inhibitors of ACE, angiotensin-receptor blockers, and aldosterone-receptor antagonists are in clinical use at present. ACTH, adrenocorticotropic hormone; BK receptor, bradykinin receptor. (From Zaman MA, Oparil S, Calhoun DA. Drugs targeting the renin-angiotensin-aldosterone system. *Nature Rev Drug Discovery* 2002;Vol 1 No. 8:1:621–36.)

and ARBs.¹ For instance, binding of renin to this receptor not only increases its catalytic efficiency in angiotensin I formation but converts the otherwise inert pro-renin into an active moiety. Moreover, the interaction between either renin or pro-renin with its receptor leads to activation of the potentially pathogenetic mitogen-activated protein kinase (MAPK) pathway in the absence of angiotensin peptide formation.¹

Despite the attractiveness of renin inhibition and the success of early compounds in validating it as therapeutic target, further drug development had been marred by issues

of potency, bioavailability, duration of action, and costs of synthesis.² For instance, although potent, renin inhibitors such as remikiren and enalkiren showed poor oral bioavailability. Although this was improved somewhat with agents such as zankiren and telakiren,³ further development of renin inhibitors was halted in the mid 1990s—apparently for commercial reasons in the setting of angiotensin receptor blockers.⁴

More recently, programs to develop renin inhibitors have been reactivated. However, drug design for these new programs has been based on X-ray crystallography of renin's

active site with computational modeling rather than on the structure of angiotensinogen—leading to the synthesis of a series of novel renin inhibitors with the hope of overcoming previous problems.⁵ Of these, aliskiren (2(S),4(S),5(S),7(S)-N-(2-carbamoyl-2-methylpropyl)-5-amino-4-hydroxy-2,7-diisopropyl-8-[4-methoxy-3-(3-methoxypropoxy)phenyl]-octanamid hemifumarate, SPP100, Speedel/Novartis) is the most advanced of the new class of orally active, nonpeptide, low-molecular-weight renin inhibitors. It has several favorable attributes in its profile, including being highly potent (IC_{50} 0.6 nM) and specific for human renin with a plasma $T_{1/2}$ of approximately 24 hours.⁵ In healthy volunteers, aliskiren (40 to 640 mg/day) orally was well tolerated, inducing a dose-dependent decrease in plasma renin activity and in angiotensin I and II concentrations.⁶ In 226 patients with mild to moderate essential hypertension, aliskiren (37.5 to 300 mg/day) led to a dose-dependent reduction in ambulatory BP.⁷ More recently, in a larger trial 652 hypertensive subjects were randomized to receive either the ARB irbesartan or aliskiren 150, 300, or 600 mg.⁸ Over an 8-week study period, aliskiren 150 mg/day was as effective as irbesartan 150 mg/day in lowering BP (with similar safety and tolerability).

Based on these studies, it seems likely that renin inhibitors will provide improvements in cardiovascular and renal morbidity. Whether these agents are similar, inferior, or superior to ACE inhibitors and ARBs is at present unclear. Similarly, extensive clinical evaluation with hard endpoints will be required to ascertain whether the combination of renin inhibition with ACE inhibitors and/or ARBs in providing more complete blockade of the RAS also leads to further improvements in morbidity and mortality.

NOVEL ALDOSTERONE BLOCKERS

The hormone aldosterone has been a well-known target for therapeutic intervention for many decades. Aldosterone, as a hormone, was first described in 1954 when its steroid structure was discovered.⁹ It was known to have potent actions on sodium retention and potassium excretion at the renal distal convoluted tubule, and to a lesser extent at other epithelial sites such as salivary glands and the gastrointestinal tract. These so-called epithelial effects are mediated via the binding of aldosterone to the mineralocorticoid (type I glucocorticoid receptor), interaction of the ligand-receptor complex with DNA, and eventual modulation of gene expression.¹⁰

Recent evidence suggests that aldosterone also exerts a variety of nonepithelial effects based on the discovery of mineralocorticoid receptors in multiple nonepithelial sites.¹¹ In contrast to interactions with nuclear receptors, nonepithelial effects of aldosterone appear to be mediated via a second messenger system that involves the activation of a sodium hydrogen anti-porter.¹⁰ These nonepithelial receptors have been found to be present in heart¹² and vascular tissue,¹³ the stimulation of which causes pathologic fibrosis and remodeling. There are also recently discovered nonepithelial actions of aldosterone on kidneys, including direct induction of glomerulosclerosis and proteinuria (which may occur independently of effects on BP).

As would be predicted by its sites of action, stimulation of mineralocorticoid receptors contributes not only directly to hypertension but to its complications. These include left ventricular hypertrophy and concomitant heart failure (via inhibition of necrosis), pathologic fibrosis, increased catecholamine release, and stimulation of cardiac arrhythmias.

Selective aldosterone receptor blockers

Spirolactone has been approved for many decades in the treatment of mineralocorticoid hypertension, ascites associated with portal hypertension and chronic heart failure. It has been widely used for the treatment of undifferentiated (essential) hypertension. However, this agent has been limited by its nonspecificity for mineralocorticoid receptors, including antiandrogenic and pro-estrogenic actions. For example, in the RALES trial 10% of male patients noted gynecomastia.¹⁴

On this basis, a more highly selective agent for the mineralocorticoid receptor was developed by replacing the 17-alpha-thoacetyl group with a carbomethoxy group.¹⁵ This new agent (eplerenone) has been studied in a large program exploring the potential benefits of this agent as monotherapy and add-on therapy in patients with essential hypertension, both undifferentiated and in those with low-renin/high-aldosterone plasma levels.

To date, a number of double-blind randomized clinical trials have contributed to the database for the efficacy and safety of eplerenone in systemic hypertension. Key study program results are summarized below. An 8-week study randomized 417 patients with mild to moderate hypertension to eplerenone in different doses, spironolactone, or placebo.¹⁶ The mean changes in systolic blood pressure (SBP) and diastolic blood pressure (DBP), both from baseline to final visit and based on 24-hour ambulatory BP monitoring, were significantly greater for all eplerenone groups than the placebo group. Furthermore, the anti-hypertensive effect of eplerenone increased in a dose-response fashion. Eplerenone (100 mg) reduced BP by 75% compared to spironolactone (100 mg) and displayed an adverse event profile similar to placebo. In particular, no antiandrogenic or progestational side effects were observed.

The effects of eplerenone on left ventricular hypertrophy and renal function associated with mild to moderate hypertension were assessed in a 9-month study of patients who received one of eplerenone (n=50), enalapril (n=54), or the combination (n=49).¹⁷ Whereas BP effects were similar, mean reductions in left ventricular mass were 7.6%, 10.5%, and 14.1% in the three groups, respectively ($p=0.007$ eplerenone versus combination, $p=0.107$ enalapril versus combination). The equivalent figures for reductions in urinary albumin to creatinine ratio (UACR) were, respectively, 24.9%, 37.4%, and 52.6% ($p=0.001$ eplerenone versus combination, $p=0.038$ enalapril versus combination). More cough was experienced by patients assigned to the enalapril group than the eplerenone group (14.1% versus 3.1%, $p=0.033$).

To assess the renal effects of eplerenone, 257 hypertensive patients with type 2 diabetes mellitus and microalbuminuria were prescribed eplerenone (n=89), enalapril (n=83), or the combination (n=85) for 24 weeks.¹⁸ Reductions in

UACR were 62%, 45%, and 74% for the three groups, respectively ($p=0.015$ eplerenone versus enalapril, $p=0.018$ combination versus eplerenone and $p<0.001$ combination versus enalapril) despite similar reductions in BP. Both drugs were well tolerated (with no reports of gynecostasia), but hyperkalemia occurred in 8, 2, and 8 subjects of the eplerenone, enalapril, and combination groups, respectively.

To examine if low-renin essential hypertension was more responsive to aldosterone receptor antagonism than antagonism of angiotensin II (due to greater salt sensitivity), a sample of patients with this condition received either eplerenone ($n=86$) or losartan ($n=82$) for 8 weeks, after which hydrochlorothiazide could have been added if necessary for another 8 weeks.¹⁹ At week 8, mean change in SBP/DBP was significantly greater in the eplerenone group ($-15.8/-9.3$ mmHg versus $-10.1/-6.7$ mmHg, $p=0.017/0.050$). At week 16, mean change in SBP/DBP had evened out ($-18.3/-10.8$ mmHg versus $-15.0/-9.8$ mmHg), but fewer patients in the eplerenone group required dual therapy (32.5 versus 55.6%). Increases in renin activity were similar, but the increase in aldosterone levels was greater for the eplerenone group (week 8: +74.7% versus -18.7%, $p<0.001$; week 16: +89.8% versus -5.5%, $p<0.001$). The adverse effect profiles were similar.

An 8-week study assessed the coadministration of eplerenone with one of the following ACE inhibitors or ARBs among patients with mild to moderate hypertension: ACE inhibitor plus eplerenone ($n=87$), ACE inhibitor plus placebo ($n=90$), ARB plus eplerenone ($n=83$), or ARB plus placebo ($n=81$).²⁰ ARB plus eplerenone was significantly more effective than ARB alone in reducing BP (SBP/DBP: $-16.0/-12.7$ mmHg versus $-9.2/-9.3$ mmHg; $p=0.001/p=0.004$), whereas ACE inhibitor plus eplerenone seemed to be more effective than an ACE inhibitor alone in reducing SBP only (SBP/DBP: $-13.4/-9.9$ mmHg versus $-7.5/-8.0$ mmHg, $p=0.002/p=0.134$). Adverse events did not differ significantly across the treatment groups and were generally not severe.

These observations were further analyzed as group data, combining the ACE inhibitor and ARB groups.²¹ Compared to placebo, SBP/DBP was reduced by 5.9/2.4 mmHg more in the eplerenone group ($p<0.001$ and $p=0.006$, respectively) additional to ACE inhibitor or ARB. In an ad hoc analysis, neither baseline values of plasma renin activity serum aldosterone (or the ratio) predicted BP response to treatment.²¹

In summary, the effect of eplerenone on BP and left ventricular mass appears similar to that of ACE inhibitors, but eplerenone may confer greater reno-protection and be associated with fewer adverse events. It also appears superior to ARBs for the treatment of patients with low-renin hypertension. If BP is uncontrolled by ACE inhibitor or ARB alone, the addition of eplerenone can be safely considered, and need not be dictated by plasma renin activity nor aldosterone levels. Among patients with diabetes mellitus, eplerenone combined with ACE inhibitor appears to more efficacious than either agent alone in regressing left ventricular mass and renal impairment, and these effects may occur independently of BP reduction.

The caveat is that the long-term efficacy and safety profile of eplerenone remains uncertain. With regard to safety, there is no data at present to suggest that eplerenone is less likely to cause clinically significant hyperkalemia than spironolactone. Nevertheless, these data suggest considerable promise for eplerenone in the management of systemic hypertension. Other than hypertension, eplerenone has been found to be a potential new treatment for chronic heart failure post-myocardial infarction in a major multinational randomized clinical trial, EPHEBUS.²²

Aldosterone synthase inhibitors

Another approach to blocking the effects of mineralocorticoid receptor activation is to inhibit the production of the endogenous ligand aldosterone. This can be achieved via several approaches to interference with the pathway of aldosterone synthesis. The last step in this pathway is conversion to mature aldosterone by the enzyme aldosterone synthase.

Interestingly, transgenic overexpression of aldosterone synthase results primarily in marked coronary endothelium-dependent dilatation.²³ Selective aldosterone synthase inhibitors have been developed and are currently undergoing pre-clinical evaluation. One advantage may be the absence of reflex activation of the renin-angiotensin system as occurs with specific aldosterone receptor blockers where there is upstream activation of renin and angiotensin II to overcome the blockade. On the other hand, there are often multiple pathways of generation of mature peptides and blocking aldosterone synthase may not result in complete blockade of synthesis of mature aldosterone. This is analogous to similar observations with ACE inhibitors where other enzymes such as chymase may be operative in the conversion of angiotensin-I to angiotensin-II. Further study is required to determine the extent of the BP-lowering efficacy and safety of this approach to blocking aldosterone.

BLOCKADE OF THE ENDOTHELIN SYSTEM

Background

The endothelin family comprises three 21-amino-acid peptides (ET-1, ET-2, ET-3) with autocrine and paracrine actions.²⁴ Of these isoforms, ET-1 is by far the most vasoactive, mediating intense vasoconstriction upon exogenous infusion.

The 21-amino-acid endothelins are formed within endothelial (and other) cells from conversion of larger precursor peptides. Pre-pro endothelin (212 amino acids) is converted via specific endopeptidases to a 39-amino-acid peptide, pro- or “big” endothelin.²⁵ Big endothelin is in turn cleaved to the 21-amino-acid peptide via an endothelin-converting enzyme (ECE). ECE is a membrane-bound zinc-containing metalloprotease. A series of ECE isoforms has been described, with ECE-1 thought the major iso-enzyme involved in conversion of big-ET to ET-1 in the peripheral vasculature. Furthermore, other proteases (e.g., neutral endopeptidase) are also capable of this conversion.

Preformed 21-amino-acid endothelin is released in response to known endogenous stimuli such as low shear

stress, thrombin, transforming growth factor- β , tumor necrosis factor- α , angiotensin II, and vasopressin,²⁶ Endothelin produced by vascular endothelial cells is released predominantly in an abluminal direction [i.e., away from the lumen of the peripheral blood vessel toward the vascular smooth muscle cell (VSMC)], upon which it mediates net vasoconstriction.

Endothelin mediates vasoconstriction via ET_A and ET_B receptors located on VSMCs. The ET_A receptor has greater affinity for ET-1 than other endothelin isoforms, whereas the ET_B receptor has similar affinity for all endothelin isoforms. Following binding of ET-1 to specific endothelin receptors, G-protein-dependent activation of phospholipase C occurs, leading to the formation of inositol triphosphate and a rapid increase of intracellular calcium (mediating contraction).²⁷

In addition to VSMC endothelin receptors, ET_B receptors are located on endothelial cells and mediate vasodilation upon agonist activation. These vasodilator responses largely occur due to activation of nitric oxide and to a lesser extent vasodilator prostaglandins (e.g., prostacyclin) located within the endothelial cell.²⁸

ET-1 binds to these cell surface receptors, which are then internalized. The peptide is then degraded by various proteases, including neutral endopeptidase. There are some data to support the view that the ET_B receptor plays the key role in the removal of ET-1 from the circulation.²⁹

The contribution of endothelin to increased vascular tone in patients with essential hypertension is somewhat controversial. In some studies, there was an enhanced vasodilator response to the administration of the ET_A receptor antagonist BQ-123 in hypertensive patients compared to normal subjects. Furthermore, blockade of ET_B receptor by BQ-788 resulted in a decrease in blood flow in normal subjects but an increase in hypertensive patients, suggesting that an impairment of ET_B-receptor-mediated vasodilation is consistent with endothelial dysfunction in these patients. However, other studies have shown no difference in vasodilator responsiveness between normal and hypertensive subjects to ET receptor blockade.

Therapeutic blockade of the endothelin system in hypertension

There have been two major approaches to blockade of this system: (1) endothelin receptor antagonists that block (1) ET_A or both ET_A and ET_B receptor subtypes and (2) inhibition of the endothelin-converting enzyme, particularly the ECE₁ isoform.

Endothelin receptor blocking agents

There have been two major studies in human essential hypertension of endothelin receptor blockade. The study by Krum et al.³⁰ was a 4-week examination of endothelin blockade in patients with mild essential hypertension (n=293) conducted with bosentan (dual ET receptor blocker) at 4 doses: 100 mg once daily, 500 mg once daily, 1000 mg once daily, and 1000 mg twice daily. These doses were compared to placebo and enalapril 20 mg once daily as active comparator.

At doses of 500 mg/day or higher, bosentan lowered trough BP by up to 5.7 mmHg, significantly greater than placebo and similar to the BP-lowering effects of enalapril (5.8 mmHg). On 24-hour BP monitoring, mean daytime BP levels were significantly reduced by bosentan at all doses. The BP-lowering effect of bosentan was diminished at 24 hours in all but the twice-daily dose regimen.

Pharmacologic blockade of the endothelin receptor was confirmed by increased levels of the agonist to the receptor, endothelin-1. The BP-lowering activity of bosentan was not associated with evidence of reflex activation of neurohormonal systems. Specifically, there was no activation of the renin-angiotensin system (as measured by plasma levels of renin and angiotensin II) or the sympathetic nervous system (as measured by plasma levels of noradrenaline). This latter observation provided neurochemical support for the observed lack of reflex increase in heart rate in response to endothelin blockade and supported endothelin being a facilitator of both renin-angiotensin and sympathetic nervous system activity.

The second study is the HEAT study of the ETA selective receptor antagonist darusentan in a similar essential hypertension population³¹ (n=392). There were significant reductions in BP at all dose levels compared to placebo with the active treatment, without a reflex increase in heart rate.

Endothelin-converting enzyme inhibitors

Pharmacologic inhibition of the endothelin-converting enzyme has been able to be achieved for some years. The metalloprotease inhibitor phosphoramidon inhibits ECE. However, this agent also inhibits cleavage of other metalloproteases and as such is unsuitable for mechanistic studies requiring selective blockade of the ECE enzyme. Other agents have been developed that nonselectively block ECE as well as other metalloproteases such as angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP). These NEP/ACE/ACE inhibitors (e.g., CGS 26303) may be of therapeutic potential in their own right. However, they do not permit assessment of the contribution of ECE to various diseases. More recently, highly selective ECE inhibitors have been developed and studied *in vitro* and in various animal models.³²

SLV-306 has been developed as an NEP/ECE inhibitor and has been found to produce significant reductions in BP in undifferentiated essential hypertension patients.³³ This approach may offer advantages over NEP/ACE inhibition, which has been plagued by the side effect of excess angioneurotic edema. It is currently in late phase II trials for both hypertension and the indication of chronic heart failure.

Adverse effect profile of endothelin blockade in human hypertension

In the 4-week study of bosentan in hypertension³⁰ there was a small but dose-related increase in vasodilator-type side effects such as headache, flushing and leg edema. Similar vasodilator-type symptoms were observed with darusentan. Although these events were minor and not debilitating, they have to be viewed in the context of the asymptomatic nature of the disease and modern anti-

Conclusions

There is now considerable evidence that endothelin plays a role in the pathogenesis and progression of essential hypertension, other forms of systemic hypertension, and many hypertension-related disorders. This conclusion is based on several observations in animals and man comprising measurement of plasma levels, expression of gene and peptide in arteries, and vascular responsiveness to endothelin blockade. Furthermore, endothelin appears to have a role in cardiovascular disease beyond merely being a vasoconstrictor peptide but also having additional effects as a mitogen and growth promoter.

The limited clinical studies of endothelin blockade in hypertension conducted thus far demonstrate the potential for these agents to lower BP without reflex activation of other neurohormonal systems. There may be particular advantages in targeting populations particularly where endothelin has been more directly pathogenically implicated (such as black hypertension and cyclosporine-induced hypertension). Furthermore, endothelin blockade may be a preferred agent in hypertensive patients with concomitant diseases where the peptide has been pathogenically implicated (and the antagonist therapy approved for treatment)—such as pulmonary arterial hypertension. However, widespread acceptance of endothelin receptor antagonists for the treatment of hypertension (even as ancillary agents) will not occur until drugs are developed without significant side effects at the doses used to achieve beneficial BP-lowering effects.

VASOPEPTIDASE INHIBITION

The humoral control of the cardiovascular system involves both vasoconstrictive and vasodilatory peptides, with the natriuretic peptides (ANP, BNP, CNP) providing endoge-

Table 85–1. Natriuretic Peptides Have Contrasting Biological Effects to Ang II

nous antagonism to angiotensin II (Figure 85–2, Table 85–1). The natriuretic peptides are removed from the circulation primarily as a result of enzymatic degradation by neutral endopeptidase (NEP) and to a lesser extent through clearance by the natriuretic clearance receptor.³⁹ Moreover, in addition to the natriuretic peptides, NEP also catalyzes the degradation of the vasodilatory kinins and adrenomedullin. Thus, in theory inhibition of the renin-angiotensin-aldosterone system combined with potentiation of the natriuretic peptide/kinin should lead to improved cardiovascular hemodynamics and sodium/ water balance. Moreover, the structural similarities in the active sites of both NEP and ACE had made the simultaneous inhibition of these two enzymes an attractive target for drug development (Figure 85–3). Indeed, a number of such dual vaso-

nous antagonism to angiotensin II (Figure 85–2, Table 85–1). The natriuretic peptides are removed from the circulation primarily as a result of enzymatic degradation by neutral endopeptidase (NEP) and to a lesser extent through clearance by the natriuretic clearance receptor.³⁹ Moreover, in addition to the natriuretic peptides, NEP also catalyzes the degradation of the vasodilatory kinins and adrenomedullin. Thus, in theory inhibition of the renin-angiotensin-aldosterone system combined with potentiation of the natriuretic peptide/kinin should lead to improved cardiovascular hemodynamics and sodium/ water balance. Moreover, the structural similarities in the active sites of both NEP and ACE had made the simultaneous inhibition of these two enzymes an attractive target for drug development (Figure 85–3). Indeed, a number of such dual vaso-

peptidase inhibitors (VPIs) entered pre-clinical and clinical development in the 1990s. These agents (which vary in their inhibitory activity for ACE and NEP) include omapatrilat, SA 7060, MDL 100240, MDL 10017, fasidotril, sampatrilat, alatriopril, CGS 30440, and S 21402.⁴⁰ Of the dual vaso-

peptidase inhibitors, omapatrilat has been the most extensively studied in clinical trials. Initial studies with this compound showed it to be superior to ACE inhibitors as an anti-hypertensive agent⁴¹ and in the treatment of heart failure.⁴² Although the benefits beyond ACE inhibition were initially attributed to it, omapatrilat was shown to be a weak diuretic (with thiazides diuretic providing additional BP reduction).⁴³ These findings led to the conclusion that the efficacy of omapatrilat in hypertension and heart failure may be attributable to the potentiation of kinins. Despite the immense enthusiasm generated by initial studies, the larger definitive studies were not greeted with such enthusiasm.

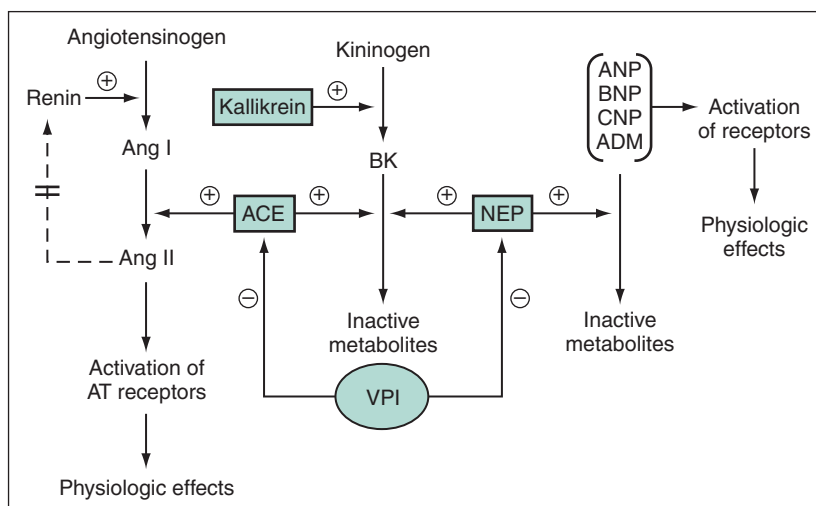

Figure 85–3. Major components of the renin-angiotensin, natriuretic peptide, and kinin-kallikrein systems. VPIs reduce the formation of angiotensin II (Ang II) and increase levels of natriuretic peptides by decreasing their degradation. These effects of VPIs are mediated by inhibiting ACE and NEP. ADM, adrenomedullin; ANP, atrial natriuretic peptide; BNP, brain natriuretic peptide; CNP, C-type natriuretic peptide. (From Gilbert RE, Kelly DJ, Atkins RC. Novel approaches to the treatment of progressive renal disease. *Curr Opin Pharmacol* 2001;1:183–89. With permission from Elsevier.)

For instance, in the omapatrilat cardiovascular treatment versus enalapril (OCTAVE) trial 25,302 hypertensive subjects were randomized to receive either omapatrilat 80 mg or enalapril 40 mg once daily. Omapatrilat reduced SBP 3.6 mmHg more than enalapril at week 8, with less use of adjunctive antihypertensive therapy needed to reach BP target. However, angioedema was much more frequent with omapatrilat than enalapril (2.17 versus 0.68%)—with two omapatrilat-treated subjects experiencing airway compromise.⁴⁴ Although the mechanisms underlying the development of angioedema with omapatrilat are incompletely understood, this adverse effect is viewed as pharmacodynamic rather than idiosyncratic (with rapid increases in bradykinin being contributory).⁴⁵

In the Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events (OVERTURE) study, 5770 patients with New York Heart Association class II to IV heart failure were randomized to treatment with either enalapril 10 mg twice daily or omapatrilat 40 mg once daily for a mean of 15 months.⁴⁶ Although omapatrilat reduced the risk of death and hospitalization, it was not more effective than ACE inhibition alone in reducing the risk of a primary clinical event. Again, a trend to an increased likelihood of angioedema was noted (omapatrilat 0.8% and enalapril 0.5%).

Thus, despite the immense theoretical appeal of blocking both ACE and NEP the limited incremental benefit of this drug class along with the greater possibility of angioedema limit its potential utility. However, the fact that newer VPIs such as M100240 (Sanofi Aventis) are entering early-phase human trials⁴⁷ suggests that this class of drug may still have a future in the clinic.

V RHO-KINASE INHIBITORS

The pathophysiology of hypertension involves several processes, including abnormally increased activation of myosin-II-regulated calcium signaling, impaired nitric oxide production, and pathologic remodeling of the vascular wall. Rho-kinase, a serine-threonine kinase, is an important mediator of these pathways. Increased activity of the Rho-kinase-mediated pathway in vascular smooth muscle has been demonstrated to have a central role in the genesis of enhanced vasoconstriction in animal models of hypertension,^{48,49} as well as in similar conditions with abnormal tonic smooth muscle contraction such as erectile dysfunction, vasospastic angina, pulmonary hypertension, and bronchodilation. Thus, inhibition of this pathway is theoretically appealing.

Rho-kinase pathway

An appreciation of the therapeutic potential of rho-kinase inhibitors is aided by an understanding of the mechanism of smooth muscle cell tone. Myosin II is the major molecular protein in smooth muscle cells, and its effects are controlled by electromechanical coupling (regulated by changes in cytoplasmic calcium contractility) and by phosphorylation/dephosphorylation of the myosin regulatory light chain (MLC). In fact, phosphorylation of MLC is one of the most important steps for vascular smooth muscle contraction and was traditionally believed to have been regulated by a

simple Ca-calmodulin-dependent activation of myosin light chain kinase (MLCK) and myosin phosphatase (MLCP). Evidence for the involvement of the small GTPase RhoA in calcium sensitivity in smooth muscle has now been demonstrated.⁵⁰

The exchange of GDP for GTP on RhoA and translocation of RhoA from the cytosol to the membrane are markers of RhoA activation. Activated RhoA binds to the rho-binding domain of rho-kinase, activating it. Rho-kinase is an important regulator of MLCP. When activated, it phosphorylates MLC via the myosin-binding subunit (MBS) of MLCP. Phosphorylation of MLC causes actin/myosin cross-bridge formation and muscle contraction. Relaxation is mediated by the dephosphorylation of MLC (Figure 85–4).

The endothelium has important roles to play in hypertension, one of the most important being the production of nitric oxide (NO). NO is an important mediator of smooth muscle function through its ability to induce vasodilation and to inhibit vasoconstriction.

RhoA has recently been found to have an important role in endothelial function. Interestingly, the role of RhoA in the endothelium arose from studies using HMG-CoA reductase inhibitors, which in addition to lowering LDL cholesterol decrease post-translational acylation of RhoA GTPase, increasing endothelial nitric oxide synthase (eNOS) expression and enhancing endothelial function. Thus, the importance of the RhoA/Rho-kinase pathway (by suppressing eNOS in endothelial cells and thus decreasing the synthesis of NO) in understanding endothelial dysfunction is now being recognized.

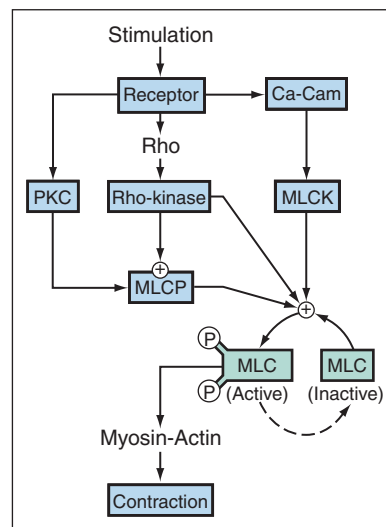

Figure 85–4. Effect of rho-kinase, PKC, and MLCK and MLCP in arterial smooth muscle. PKC, protein kinase C; MLC, myosin light chain; MLCK, myosin light chain kinase; MLCP, myosin light chain phosphatase. (From Kandabashi T, Shimokawa H, Miyata K, et al. Inhibition of myosin phosphatase by upregulated rho-kinase plays a key role for coronary artery spasm in a porcine model with interleukin-1b. *Circulation* 2000;101:1319–23.)

As well as its role in the regulation of actin-myosin contractility, rho-kinase plays an important role in the remodeling of the actin cytoskeleton via its role in adhesion, migration, proliferation, and cytokinesis of vascular smooth muscle cells. Rho-kinase is upregulated in a mouse model of myocardial infarction (MI)⁵¹ and is known to be involved in the *in vivo* pathogenesis of vascular remodeling⁵² and in cardiac hypertrophy.⁵³

Mechanism of action of rho-kinase inhibitors

The rho-kinase pathway can be inhibited at several stages: at the receptor by antagonists to the activating agonist (such as antagonists to arachadonic acid or PKC); by hydrolysis of bound GTP to GDP (preventing activation of RhoA); by complexing of free RhoA, preventing activation of rho-kinase and inhibition of MLCP; and by direct inhibition of rho-kinase (Figure 85–5).

The three most specific inhibitors of rho-kinase to date are hydroxyfasudil, fasudil, and Y-27632. Hydroxy-fasudil is 1-(5-isoquinolinesulfonyl)-homopiperazine (HA-1077), fasudil is (S)-(+)-2-methyl-1-[(4-methyl-5-isoquinoline)sulfonyl]-homopiperazine (H-1152P), and Y-27632 (Welfide Corporation, Osaka, Japan) is a (+)-(R)-trans-4-(1-aminoethyl)-N-(4-pyridyl) cyclohexanecarboxamide dihydrochloride monohydrate.

The compounds differ in their ability to inhibit rho-kinase. In particular, H-1152P (fasudil) has a greater affinity for rho-kinase, as compared to HA-1077 (hydroxy-fasudil) and Y-27632 (Table 85–2). These rho-kinase inhibitors also

have varying degrees of affinity for other serine-threonine kinases.

Pharmacodynamics of rho-kinase inhibitors

Activated rho-kinase phosphorylates the catalytic site of myosin light-chain phosphatase, causing smooth muscle contraction. In addition to inhibition of both *in vivo* and *in vitro* rho-kinase, the three currently available rho-kinase inhibitors inactivate the myosin-binding subunit of myosin light-chain phosphatase—preventing phosphorylation of MLC by rho-kinase in vascular smooth muscle cells.^{54,55}

HA-1077, originally developed as an isoquinoline derivative of *N*-(2-guanidinoethyl)-5-isoquinolinesulfonamide (a calcium channel antagonist), is a vasodilator of the cerebral and coronary vasculature that inhibits the vascular contraction induced by agonists such as norepinephrine, histamine, angiotensin II, and endothelin. Continuous infusion of HA-1077 results in a dose-dependent decrease in peripheral vascular resistance and increased cardiac output, without a significant change in the right atrial pressure. Although its initial effects were thought to be due to calcium channel inhibition, HA-1077 displays vasodilatation even when these channels are antagonized. HA-1077, like the other rho-kinase inhibitors, inhibits other protein kinases (such as protein kinase C) but has a lower Ki for rho-kinase. For example, the inhibitory effect of fasudil on rho-kinase is >100 times more potent than on protein kinase C and myosin light-chain kinase. The IC₅₀ value of fasudil has been established as 1.9 mol/L when tested *in vitro*⁵⁶ and a comparable dose of intra-coronary fasudil (100 μg/kg) suppressed

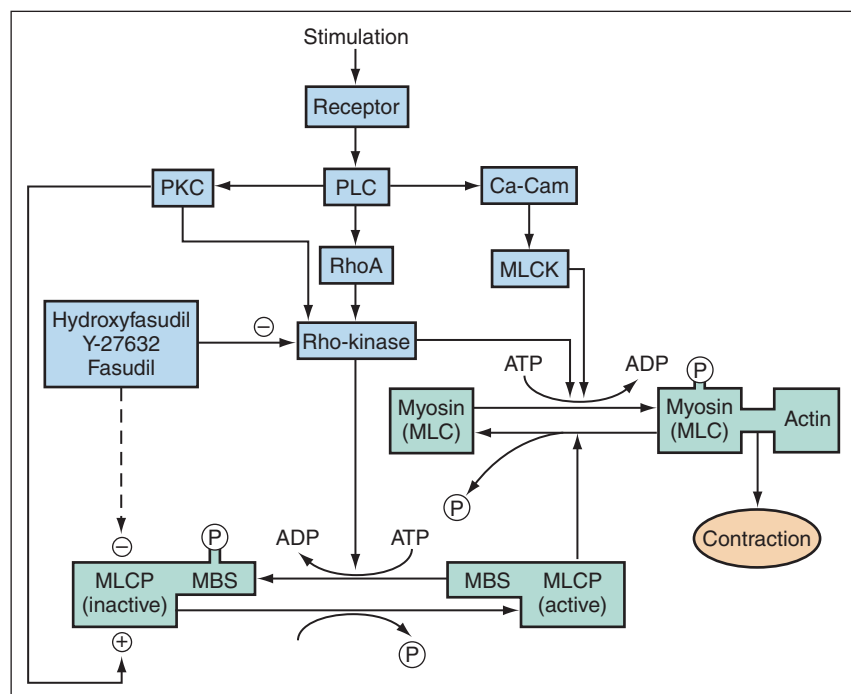

Figure 85–5. Inhibition of rho-kinase prevents phosphorylation of MLC-inhibiting contraction. (From Kandabashi T, Shimokawa H, Miyata K, et al. Inhibition of myosin phosphatase by upregulated rho-kinase plays a key role for coronary artery spasm in a porcine model with interleukin-1b. *Circulation* 2000;101:1319–23.)

coronary artery spasm in an *in vivo* porcine model⁵⁷ (300 µg/min for 15 minutes suppressed coronary artery spasm in humans).⁴⁹

The effects of Y-27632 have similarly been assessed using a number of cardiovascular models. In the halothane anesthetized canine model,⁵⁸ an intravenous dose of 0.01 mg/kg of Y-27632 significantly decreased the total peripheral vascular resistance and increased the cardiac output. Moreover, a 10 times higher dose of Y-27632 (0.1 mg/kg) exerted positive inotropic, chronotropic, and dromotropic effects together with hypotension and reduced left ventricular end-diastolic pressure. An intravenous dose of 0.01 to 5 mg/kg results in a range of concentrations that are known to significantly inhibit rho-kinase (0.1 to 10 µM).⁵⁶

Interestingly, these inhibitors appear to reduce BP more in diseased arteries rather than those with normal pressure. This may be because rho-kinase is upregulated in hypertension in spastic parts of endothelium such as occurs in vasospastic angina and during conditions of adverse cardiovascular remodeling such as post-myocardial infarction (MI).⁵⁶ In addition, growth factors such as transforming growth factor-β and macrophage inhibitory factor are upregulated post-MI and downregulated with a rho-kinase inhibitor.

Both fasudil and Y27632 impair thrombin-induced downregulation of eNOS expression^{59,60}. However, in contrast to Y27632, fasudil increases basal eNOS expression without affecting basal rho-kinase activity, thus suggesting that fasudil has additional rho-kinase-independent effects on eNOS expression.

Pharmacokinetics of rho-kinase inhibitors

Y-27632 has successfully been given via inhalation (1 mM, 2 min), orally (humans and in drinking water for rats), intracavernosally, and intravenously. However, pharmacokinetics measures have not commonly been reported. However, peak plasma concentrations of Y-27632 of 10 to 20 ng/mL (0.03 to 0.06 µM) and 100 to 200 ng/mL (0.3 to 0.6 µM) have been reported in animal models after the intravenous administration of 0.01 and 0.1 mg/kg of Y-27632, respectively. There has been a noticeably greater reduction in BP with intravenous as compared to oral and inhalational therapy, suggesting that the hydrophilicity of Y27632 results in low oral availability.^{56,61}

INDICATIONS

Hypertension

As rho-kinase is upregulated in hypertensive subjects but not in control normotensive subjects, rho-kinase inhibitors have predictably had more of a vasodilatory effect in hypertensive subjects.⁶² These drugs are known to have a dose-dependent vasodilatory effect, but with their effects on vascular remodeling they also play a role in the pathogenesis of increased systemic vascular resistance long term.

In addition, fasudil increases upregulation of NO synthase and endothelial NO synthase-derived NO (which reduces the pathologic LV remodeling after MI in mice⁶³ and ameliorates endothelial dysfunction). Y27632 and hydroxyfasudil additionally upregulate NO synthetase, suggesting that it is a class effect.

Ventricular remodeling

Rho-kinase activation is involved in the pathogenesis of LV remodeling. Thus, rho-kinase inhibition would be expected to have a favorable effect on remodeling. In fact, after MI in an animal model of myocardial infarction fasudil suppressed the increases in LV end-diastolic pressure, the ratio of RV weight to body weight, and the ratio of lung weight to body weight. Fasudil is known to suppress the increased expression of several profibrotic cytokines (such as macrophage inhibitory factor, TGF-beta, IFN-gamma, monocyte chemoattractant protein-1, and angiotensin II) that occurs post-MI, reducing pathologic cardiac remodeling.⁶⁴

Adverse effects

Potentially, rho-kinase inhibitors could cause symptomatic hypotension, especially if given intravenously. Phase I and II studies using both oral and intravenous doses with measurements of effect (as well as basic pharmacokinetic parameters such as plasma concentration, time to steady state, and area under the curve) will be required in order to decrease the likelihood of this problem. In fact, HA-1077 at a suprathreshold dose has caused systemic hypotension in dehydrated animals (although no serious adverse side effects were reported).

In addition, it is known that protein kinases play a crucial role in the transduction of signals in cellular systems. Thus, although it is known that rho-kinase inhibitors do have some effect on other protein kinases (albeit with higher dissociation constants and lower potency) whether these effects translates into beneficial or detrimental effects on cell growth and proliferation long term is as yet unknown.

SUMMARY

Preclinical and early clinical studies of the rho-kinase inhibitors have shown that these agents have beneficial vasodilator and vascular remodeling effects in hypertension, coronary artery spasm, angina, hypercholesterolemia, and other noncardiovascular conditions such as erectile dysfunction, pulmonary hypertension, cerebral vasospasm, arteriosclerosis, bronchial asthma, glaucoma, and cancer. Further work is necessary regarding elucidation of the relationship between dose and effect and dose and plasma concentrations, as well as surveillance of long-term effects of these agents—especially with respect to their effects on growth and downstream markers of activation of other protein kinases.

Chapter
86Fixed Low-Dose
Antihypertensive Therapy

Ryan M. Woodham and Suzanne Oparil

Key Findings

- Prevalence of hypertension in the U.S. population is increasing.
- Monotherapy is inadequate in ≈70% of patients.
- Fixed low-dose combination therapy (defined as a combination in a single tablet of low doses of antihypertensive agents whose mechanisms of action are complementary) is an effective, safe, and cost-effective method of decreasing blood pressure (BP) in most patients with essential hypertension.
- Many neurohormonal and cellular mechanisms cause hypertension, making defining a specific etiology and creating a cause-specific treatment plan difficult.
- Many antihypertensives work by affecting fluid and sodium balance, blocking the renin-angiotensin-aldosterone system or sympathetic nervous system, and decreasing systemic vascular resistance by blocking L-type calcium channels.
- Combinations of angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARB) diuretics, and calcium channel blockers (CCB) have additive effects in controlling BP and minimizing adverse effects of individual components.
- The “polypill” concept promises to increase compliance, decrease multiple CV risk factors, and decrease morbidity and mortality with cardiac disease.

Hypertension is a major clinical problem, with an increasing prevalence.¹ Increased BP is an important modifiable risk factor for cardiovascular disease (CVD), the most common cause for death and disability in developed and developing countries. Its control significantly reduces these risks.²

Observational studies have shown that mortality and morbidity from ischemic heart disease and stroke in persons 40 to 89 years of age increases in log linear fashion with increases in both SBP and DBP.³ For each increase in SBP of 20 mmHg or in DBP of 10 mmHg over the entire range from 115/75 mmHg to 185/115 mmHg, there is a twofold increase in mortality related to coronary disease and stroke. SBP and, accordingly, the prevalence of hypertension increase with age throughout life, whereas DBP decreases after age 60.^{4,5}

A cohort study using data collected from the Framingham Heart Study from 1990 to 1999 revealed that the rate of BP control, defined as a SBP <140 mmHg and a DBP <90 mmHg, was only 32.4% of the cohort as a whole.⁴ Control rates decreased with age and were lowest (23%)

in women >80 years of age. Poor BP control in the elderly is a particularly serious problem because hypertension is most prevalent in this age group. In the Framingham cohort, 74% of those >80 years old were hypertensive, compared to 63% of those aged 60 to 79 years and 27% of those <60 years old. Importantly, only 38% of patients in the oldest age group were receiving more than one antihypertensive medication. Previous studies (Figure 86–1) have demonstrated that between 2 to 4 agents on average are required to meet the current JNC 7 goal of SBP <140 mmHg and/or DBP <90 mmHg.

Clinical trial data indicate that lowering BP with antihypertensive drugs effectively reduces risk of a variety of CVD outcomes, including cardiovascular death and total mortality^{2,6–10} (Figure 86–2). Meta-analyses of data from randomized controlled trials have not shown significant differences in total major CVD outcomes between regimens based on ACE inhibitors, CCBs, or diuretics or BBs, although there were some differences in cause-specific outcomes.^{2,9,10} For outcomes other than heart failure, differences in achieved SBP lowering were related to the extent of risk reduction.² Thus, for the universe of hypertensive patients BP reduction appears to be more important than choice of antihypertensive drug(s) for reducing CVD risk.

For persons with BP >20/10 mmHg above goal (stage 2 hypertension), initial treatment with 2 drugs, usually including a thiazide-type diuretic, is recommended by the seventh report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC 7) because of the high risk of this patient group (Figure 86–3).^{11,12} Randomized controlled trials have shown that single drug treatment usually is not adequate to achieve goal BPs in most hypertensive patients, particularly those with systolic hypertension (Figure 86–1). For example, in the very large Anti-hypertensive and Lipid Lowering Treatment to Prevent Heart Attack (ALLHAT) trial (n=42,418) less than 30% of participants achieved goal BP (<140/90 mmHg) on monotherapy.¹³

Fixed-dose combination drugs have been available for the treatment of hypertension for over 40 years. Agents marketed in the 1960s included reserpine/dihydralazine/hydrochlorothiazide (Unipres) and methyldopa/hydrochlorothiazide (Aldoril).¹⁴ Importantly, the very earliest outcome trial of antihypertensive therapy in the United States, the Veteran’s Administration Cooperative Study on Antihypertensive Agents, demonstrated dramatic reduc-

Figure 86–1. Average number of antihypertensive agents needed to achieve the current JNC 7 BP goals. MAP, mean arterial pressure. (Data from Bakris GL, Williams M, Dworkin L, et al. Success and predictors of blood pressure control in diverse North American settings: The Antihypertensive and Lipid-Lowering treatment to prevent Heart Attack Trial (ALLHAT). *J Clin Hypertens* 2002;4:393–404.)

tions in CVD outcomes with a combination of hydrochlorothiazide, reserpine, and hydralazine compared to placebo.¹⁵ Fixed-dose combination antihypertensive drugs later fell out of fashion because of a perception of increased toxicity compared to monotherapy. However, a large variety of fixed-dose combination agents have been developed in recent years, in part in response to the realization that older higher-risk hypertensive patients require multiple antihypertensive agents for BP control. A list of currently available fixed low-dose combination therapies can be found in Table 86–1.

FIXED LOW-DOSE COMBINATION THERAPY: ADVANTAGES AND DISADVANTAGES

Advantages

Fixed low-dose combination therapy (defined as a combination in a single tablet of low doses of antihypertensive agents whose mechanisms of action are complementary) is an efficacious, safe, and cost-effective method of decreasing BP in most patients with essential hypertension.¹⁴ Initiating therapy with more than one agent offers the potential advantages of achieving BP control more rapidly and avoiding dose-related adverse effects of individual drugs by producing greater BP reductions at lower doses of the component agents. Fixed-dose combinations have several advantages that do not currently reside in any single molecule (Box 86–1). Fixed low-dose combination therapies enjoy these desirable characteristics, in part because combining agents with different

Box 86–1

Advantages of Fixed-dose Combination Therapy

- Increased compliance, simplified titration, and convenience of use
- Potentiation of antihypertensive effects of a single compound
- Additive or synergistic effect
- Enhancing effect in specific populations
- Diuretic with an ACE inhibitor, ARB, or beta blocker
- Attenuation in adverse events
- Decrease in diuretic-induced metabolic changes with ACE inhibitors or ARBs
- Decrease in calcium channel antagonist-related peripheral edema with ACE inhibitors
- Improved overall results, greater BP response, and lower cost when co-payments and pharmacy filling fees are considered

but additive mechanisms of action helps to maximize antihypertensive potency while minimizing dose-related adverse effects.

The greater efficacy of combination agents with different (and complementary) mechanisms of action relates to their ability to antagonize more than one of the many mechanisms of the pathogenesis of hypertension, as well as the ability of one component to block counterregulatory responses to the other. For example, diuretics activate the renin-angiotensin-aldosterone system (RAAS), reduce volume, and make BP more angiotensin dependent. Concomitant administration of an ACE inhibitor or an ARB blocks angiotensin II generation or action, minimizing the compensatory pressor effect of diuretic-induced RAAS activation and producing an additive BP-lowering effect.

Fixed-dose combinations offer convenience for the patient because they can usually be administered once daily. It has been shown that multiple daily doses of medications are associated with decreased adherence.¹⁶ Further, elderly patients usually suffer from a variety of medical conditions for which they require multiple medicines. In particular, elderly hypertensive patients frequently have target organ damage/concomitant CVD conditions that require treatment. Fixed-dose combination antihypertensive drugs are often useful in treating more than one such condition (e.g., ACE-inhibitor/diuretic or ARB/diuretic combinations for both heart failure and hypertension, and ACE-inhibitor/CCB combinations for both angina and hypertension). Thus, fixed-dose combinations can enhance patient adherence by simplifying medical regimens. An additional aid to medication adherence for most patients is low cost. Fixed-dose combinations have cost benefits that relate to the requirement for only a single co-payment and dispensing fee, as well as more competitive pricing in comparison to the individual components when purchased separately on most insurance plans.¹⁷

Figure 86–2. Associations of BP differences between groups with risks of major vascular outcomes and death. The circles are plotted at the point estimate of effect for the relative risk for every event type and the mean follow-up BP in the first listed group compared to the second listed group. Vertical lines are 95% CIs. CHD, coronary heart disease. CVD, cardiovascular disease. (Redrawn from Turnbull F, Neal B, Algert C, et al. Effects of different blood-pressure-lowering regimens on major cardiovascular events: Results of prospectively-designed overviews of randomized trials. Blood Pressure Lowering Treatment Trialists Collaboration. *Lancet* 2003;362:1527–35 with permission from Elsevier.)

Studies comparing low-dose combination therapy to monotherapy generally show a decreased incidence of dose-related adverse events with combination therapy.¹⁴ This is due in part to packaging of the components in doses lower than are usually seen in monotherapy. In addition, in many of the combinations one agent compensates for the adverse effects caused by the another (e.g., ACE inhibitors decrease the incidence of peripheral edema associated with dihydropyridine CCBs and the hypokalemia associated with diuretics).

Disadvantages

Fixed-dose combinations may not be well tolerated in patients at risk for orthostatic hypotension. Some older persons, diabetic patients, and persons with autonomic dysfunction may experience profound hypotension (particularly orthostatic hypotension) when therapy is initiated

with more than one agent.^{6,12,13} On the other hand, some fixed-dose combinations do not contain sufficient doses of the constituent drugs to provide BP control or to manage illnesses that commonly coexist with hypertension.¹⁴ For instance, the doses of BBs found in combination antihypertensive therapy may not be large enough to treat concomitant angina and coronary artery disease adequately. Similarly, the doses of ACE inhibitors and ARBs in combination therapy may be too low to manage heart failure effectively.

Fixed-dose combination therapy has been faulted for a lack of flexibility in titrating doses of individual components. This problem may be more theoretical than real, however, in that it is uncommon for physicians to use the full dose range of individual antihypertensive drugs.¹⁴ Most commonly, physicians begin treatment with the usual starting dose of an antihypertensive drug and rarely up-titrate.

Figure 86-4. Hypertension is caused by a number of different mechanisms. Renal mechanisms are likely the primary cause of hypertension, but other mechanisms likely moderate this response.

CURRENTLY AVAILABLE COMBINATION ANTIHYPERTENSIVES			
Class	Combination	Trade Name	Approval Date
ACE inhibitors and diuretics	Benazepril 5-20 mg/HCTZ 6.25-25 mg	Lotensin HCT	Feb-92
	Captopril 25-50 mg/HCTZ 15-25 mg	Capozide	Oct-84
	Enalapril 5-10 mg/HCTZ 12.5-25 mg	Vaseretic	Oct-86
	Lisinopril 10-20 mg/HCTZ 12.5-25 mg	Zestoretic; Prinzide	Jul-1989; Feb-1989
	Fosinopril 10-20 mg/HCTZ 12.5 mg	Monopril HCT	Nov-04
	Quinapril 10-20 mg/HCTZ 12.5-25 mg	Accuretic	Dec-1999
	Moexipril 7.5-15 mg/HCTZ 12.5 mg-25 mg	Uniretic	Jun-97
ARBs and diuretics	Losartan 50 mg/HCTZ 12.5-25 mg	Hyzaar	Apr-95
	Valsartan 80-160 mg/HCTZ 12.5-25 mg	Diovan HCT	Mar-98
	Irbesartan 150-300 mg/HCTZ 12.5 mg	Avalide HCT	Sep-97
	Telmisartan 40-80 mg/HCTZ 12.5-25 mg	Micardis HCT	Nov-00
	Olmesartan 20-40 mg/HCTZ 12.5-25 mg	Benicar HCT	Jun-03
	Candesartan 16-32 mg/HCTZ 12.5 mg	Atacand HCT	Sep-00
	Eprosartan 600 mg/HCTZ 12.5-25 mg	Teveten HCT	Nov-01
Potassium sparing diuretics and HCTZ	Amiloride 5 mg/HCTZ 50 mg	Moduretic 5-50	Oct-81
	Spironolactone 25-50 mg/HCTZ 25-50 mg	Aldactazide	Jan-78
	Triamterene 37.5-75 mg/HCTZ 25-50 mg	Dyazide; Maxzide	Dec-1965; Oct-1984
Calcium channel blockers and ACE inhibitors	Amlodipine 2.5-10 mg/Benazepril 10-20 mg	Lotrel	Mar-95
	Felodipine 2.5-5 mg/Enalapril 5 mg	Lexxel	Dec-96
	Verapamil 180-240 mg/Trandolapril 1-4 mg	Tarka	Oct-96
Beta blockers and diuretics	Atenolol 50-100 mg/Chlorthalidone 25 mg	Tenoretic	Jun-84
	Bisoprolol 2.5-10 mg/HCTZ 6.25 mg	Ziac	Mar-93
	Nadolol 40-80 mg/Bendroflumethiazide 5 mg	Corzide	May-83
	Propranolol 40-80 mg/HCTZ 25 mg	Inderide	Oct-86

Table 86-1. Currently Available Combination Antihypertensives

MECHANISMS OF ACTION AND THE RELATIONSHIPS TO COMBINATION ANTIHYPERTENSIVE THERAPY

Antihypertensive drugs work by antagonizing neurohormonal and cellular mechanisms that promote BP elevation.¹⁸ The complex pathophysiology of hypertension makes it difficult to define a specific etiology, and therefore to construct a cause-specific treatment plan in any individual patient. The use of combination therapies allows modulation of different pathways involved in the pathogenesis of hypertension and its complications.

There are multiple mechanisms of BP elevation that are interrelated. These include a genetic predisposition, increased renal sodium (Na⁺) retention, sympathetic nervous system (SNS) activation, endothelial dysfunction, and activation of the RAAS (Figure 86-4).¹⁹⁻²¹ It is also likely that abnormal renal sodium handling plays a primary role in hypertension, whereas other mechanisms (e.g., SNS activation, vascular remodeling, and endothelial dysfunction) may amplify or sustain the renal pressor effect.¹⁹⁻²¹

The RAAS is the best studied mechanism of BP and volume regulation, and development of pharmacologic antagonists to its various components has proved useful in the treatment of hypertension and related target organ damage (Figure 86-5).²¹ Importantly, the primary mechanism by which the RAAS contributes to acute changes in BP and volume homeostasis is by regulating renin release into the circulation.²² Circulating renin levels, as indexed by plasma renin activity (PRA), have been found to be an independent risk factor for myocardial infarction in hypertensive patients.^{23,24}

As renal mechanisms play a primary role in the pathogenesis of hypertension,¹⁹ and because of their extensive track record in preventing CVD outcomes in randomized controlled trials of antihypertensive treatment, thiazide diuretics are often recommended as first-line therapy for essential hypertension.^{11,12} Thiazide diuretics work by inhibiting NaCl reabsorption by the Na/Cl transporter in the distal convoluted tubule and thus block 5 to 7% of the reabsorption of the glomerular filtrate.²⁵ This leads to a reduction in water and salt reabsorption and there-

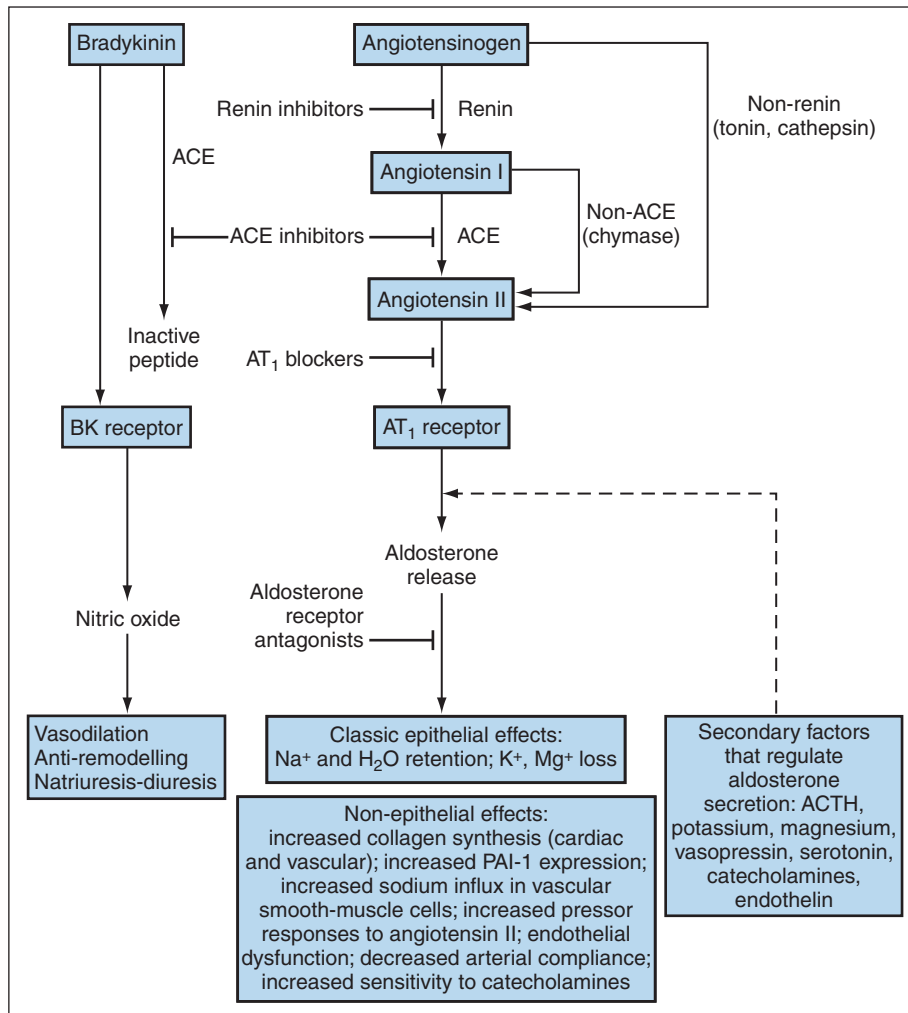

Fig. 86-5. The renin-angiotensin-aldosterone system. Multiple steps in the RAAS have been targeted to lower BP effectively. (Redrawn from Zaman MA, Oparil S, Calhoun DA. Drugs targeting the renin-angiotensin-aldosterone system. *Nat Rev Drug Discov* 2002; 1:621–36.)

fore a decrease in plasma and extracellular volume (Figure 86-6). Thiazide diuretics have flat dose-response curves, and exceeding the maximum dose recommended for any given agent increases adverse effects with little further reduction in BP.¹⁴ It is likely that the impaired glucose tolerance seen with the thiazides is in part related to the reduction in serum potassium levels caused by this drug class and may be prevented or reversed by better potassium management.^{26,27} Hypokalemia can be prevented by either supplementing potassium or combining thiazide diuretics with potassium-sparing agents.

The RAAS is an important mediator of hypertension and related target organ damage. This important physiologic/pathophysiologic cascade can be inhibited pharmacologically at 5 distinct steps in the pathway: renin release, renin-angiotensinogen interaction, ACE action, the AT₁ receptor, and the aldosterone (mineralocorticoid) receptor (Figure 86-5). As will be discussed later, BBs lower BP (at least in part) by inhibiting renin release from the juxtaglomerular apparatus.²⁸ Direct renin inhibitors, currently under development for clinical use, compete with angio-

teninogen for the catalytic site of the renin molecule and thereby inhibit generation of Ang I.²⁹ ACE inhibitors inhibit the conversion of Ang I to Ang II and decrease the degradation of bradykinin, resulting in increased levels of bradykinin that in turn lead to NO and prostacyclin release.³⁰ Decreased Ang II production reduces stimulation of the AT₁ receptor, resulting in arterial and venodilation and lowered systemic vascular resistance.

Blocking the RAAS may also prevent endothelial dysfunction and atherosclerosis by increasing levels of NO—a potent vasodilator, inhibitor of platelet aggregation, and suppressor of vascular smooth muscle cell migration^{18,31} In hypertensive patients, NO production and/or action may be diminished. In this situation, blocking Ang II generation halts activation of NAD(P)H oxidase, causing a decrease in superoxide anion generation and leading to increased NO bioavailability and thus improvement in endothelial function.³² The Study to Evaluate Carotid Ultrasound Changes in Patients Treated with Ramipril and Vitamin E (SECURE), a pilot study for the Heart Outcomes Prevention Evaluation (HOPE) trial, measured

Figure 86–6. Thiazide diuretics work by blocking the Na/Cl transporter and decreasing Na ion transport in the distal convoluted tubule. This in turn leads to decreased water absorption. Note: Bolded ions refer to higher concentrations.

the effectiveness of ramipril compared to a placebo in reducing the mean maximum intimal-medial thickness of the study patients' carotid arteries over a 5-year period.³³ SECURE demonstrated a statistically significant 37% reduction in progression of atherosclerosis with high-dose ramipril treatment compared to placebo. The mechanism responsible may be related to Ang II inhibition and increased bradykinin stimulation with concomitant NO release. Most importantly, the HOPE trial showed that the ramipril regimen reduced CVD outcomes, including myocardial infarction, stroke, heart failure, and cardiovascular death—confirming the clinical significance of ACE-inhibitor-induced vasoprotection.³⁴

As discussed previously, ACE inhibitors have fairly flat dose-response curves, and administration of higher-than-recommended doses does not result in improved BP control. However, because the duration of ACE inhibition with a given ACE inhibitor is dose dependent over a wide dose range, higher doses can prolong the duration of the BP response and thus offer clinically meaningful advantages.³⁵ The most common adverse effect of ACE inhibitors is cough, which is thought to be secondary to inhibition of bradykinin degradation.³⁰ ACE-inhibitor-induced cough is characteristically dry and nonproductive, but may be disturbing to the patient and usually requires discontinuation of the drug. It is not dose related and can occur in up to 35% of patients.³⁶ Angioedema is a less frequent but more serious and even deadly adverse effect particularly common in blacks.^{30,37,38} Acute renal failure secondary to decreased glomerular filtration rate can also occur with ACE inhibitors, particularly in the patient who is overdiuresed or has renal artery stenosis or decompensated heart failure.^{39–41} Hyperkalemia is a common dose-dependent adverse effect of ACE inhibitors, particularly when administered to patients with diabetes and/or chronic kidney disease.

ARBs lower BP by blocking the action of Ang II at the AT1 receptor. The effects of ARBs on the circulation appear to be similar to those of the ACE inhibitors. However, some evidence has suggested that ARBs may be less effective in reversing endothelial dysfunction and in preventing coronary events.⁴² These issues are currently being debated, and definitive evidence supporting an advantage for either drug class is lacking.⁴³ The Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ON TARGET) will provide the first head-to-head comparison of ACE inhibitor versus ACE-inhibitor/ARB combination treatment in high-risk patients with underlying CVD.⁴⁴ Pending the results of ON TARGET, compelling indications for the use of ACE inhibitors or ARBs in hypertensive patients are largely overlapping.^{11,12} The major advantage of the ARB class is that its side effect profile resembles that of placebo. Acute renal failure, hyperkalemia, and angioedema are rare with the ARBs.^{45,46}

Aldosterone is a product of the RAAS that increases BP mainly by causing renal sodium retention and stimulating sympathetic outflow from the central nervous system.⁴⁷ It also has pro-inflammatory and pro-fibrotic effects on the heart and vasculature that cause adverse structural remodeling, in part independently of BP. The mineralocorticoid receptor antagonists spironolactone and eplerenone lower BP and reverse the previously cited structural changes. Despite pharmacologic blockade of ACE and the AT1 receptor, levels of aldosterone will return to pretreatment levels over time—a phenomenon known as aldosterone rebound.⁴⁸ When upstream components of the RAAS are blocked, other mechanisms (such as elevated potassium levels and increased sympathetic nervous system activity) stimulate aldosterone secretion. The major dose-dependent adverse effect of mineralocorticoid receptor antagonists, particularly when combined with ACE inhibitors or ARBs, is hyperkalemia. The side effects of spironolactone (a nonselective mineralocorticoid receptor antagonist)—including decreased libido, impotence, and gynecomastia—are secondary to blockade of androgen receptors. Eplerenone is more selective for mineralocorticoid receptors and lacks these adverse effects.

CCBs block the voltage-dependent L-type calcium channel and thus block the influx of calcium into cardiac myocytes and smooth muscle cells, preventing actin-myosin interactions and leading to vasodilation and negative inotropic effects.⁴⁹ The CCBs are divided into two major classes: the dihydropyridines (which have mainly vascular effects) and the nondihydropyridines (which have mainly myocardial effects). Nondihydropyridines can further be subdivided into phenylalkylamine (verapamil)-like and benzothiazepine (diltiazem)-like drugs. The major dose-dependent adverse effect of the dihydropyridines is peripheral edema related to the mismatch between arteriolar and venular dilation, leading to fluid extravasation into tissues of the lower extremity. Other common adverse events include gingival hyperplasia and headache. Adverse events of nondihydropyridines (including bradycardia, A-V conduction abnormalities, constipation, and lethargy) are all dose related.

BBs lower BP by complex mechanisms that are not fully understood. In part, these relate to blockade of the sympathetic nervous system contribution to hypertension.⁵⁰ BBs reduce cardiac output and plasma volume, inhibit the RAAS and norepinephrine release, reset baroreceptor levels, and attenuate the pressor response of catecholamines to exercise and stress. Various BBs differ in their pharmacokinetics as well as their selectivity for beta receptor subtypes. Common adverse events noted with this class include bronchospasm, increased insulin resistance, bradycardia, and decreases in HDL cholesterol. A growing body of evidence has shown that BB monotherapy lacks efficacy in both reducing BP and preventing hypertension-related target organ damage and CVD morbidity and mortality.^{51,52} Thus, BBs should no longer be considered first-line therapies for most hypertensive patients but may still be used in fixed-dose combinations with diuretics (as indicated in material following).

CURRENTLY AVAILABLE FIXED-DOSE ANTIHYPERTENSIVE COMBINATIONS

ACE inhibitor- or ARB-diuretic combinations

ACE inhibitor- or ARB-diuretic combinations are the most commonly used fixed-dose combination antihypertensive agents because of an additive effect on BP reduction related to complementary mechanisms of action of the components and the favorable metabolic/cardio-, vaso-, and renoprotective effects of the ACE inhibitors and ARBs.^{11,12,53,54} The nuretic/diuretic action of the thiazides reduces extracellular fluid volume, cardiac output, and BP—activating the RAAS and enhancing the Ang II dependence of BP, thus potentiating the antihypertensive efficacy of the ACE inhibitors or ARBs.^{55,56} Importantly, combination with a thiazide greatly enhances the antihypertensive efficacy of ACE inhibitors and ARBs in patient groups weakly responsive to ACE/ARB monotherapy (e.g., African Americans and the elderly, particularly elderly women^{11,12,57}). The proven benefits of RAAS blockers in patients with concomitant CVD [including heart failure, post myocardial infarction, established atherosclerotic vascular disease (including stroke), diabetes, and renal disease] are so great that first-line use of these agents is recommended by JNC 7 for hypertensive patients with these “compelling conditions” (Figure 86–3).^{11,12} The increasing prevalence of these concomitant conditions and the emergence of treatment-resistant hypertension in the aging population, with its multiple medication requirements, have played a major role in increasing the use of ACE inhibitor- and ARB-diuretic combinations in clinical practice.

Randomized controlled clinical trials that compared the combination versus monotherapy with either ACE inhibitor or HCTZ have generally demonstrated greater BP-lowering efficacy with low-dose combinations over higher-dose monotherapy with either single agent.⁵⁸ In a representative trial, following a 4-week placebo washout period patients were randomized to 8 weeks of placebo,

lisinopril 10 mg, HCTZ 12.5 mg, HCTZ 25 mg, or combination therapy with lisinopril 10 mg and either HCTZ 12.5 mg or 25 mg.⁵⁹ Monotherapy with either agent lowered DBP by 6 to 8 mmHg over placebo, and combination therapy produced a further 6- to 7-mmHg reduction in DBP. BP control, defined as a decrease in DBP of >10 mmHg or achieving a goal of <90 mmHg, was highest with combination therapy: 70 to 80% compared to 40 to 50% with lisinopril or HCTZ monotherapy. Most similarly designed studies showed similar effects of combination versus monotherapy on BP reduction and control rates.⁵⁸

Similarly, studies of ARB-diuretic combinations have demonstrated significantly greater reductions in SBP and DBP with combination compared to monotherapy with either individual agent.⁵⁸ A representative factorial study evaluated the efficacy of regimens that included either olmesartan 10 to 40 mg a day, HCTZ 12.5 or 25 mg a day, placebo, or the combinations of olmesartan and HCTZ.⁶⁰ At the end of this 8-week trial the greatest effect on BP was noted in the arm receiving 40 mg of olmesartan and 25 mg of HCTZ, in which SBP decreased by 10.8 mmHg and DBP by 7.3 mmHg more than with olmesartan 40 mg monotherapy (Figure 86–7). Control (SBP <140 mmHg and DBP <90 mmHg) rates were greater in patients taking the highest dose of the combined agents than in those taking the highest doses of monotherapies.

Use of ACE inhibitor- or ARB-diuretic combinations decreases the incidence of metabolic side effects of the individual components.⁵⁸ Thiazides waste potassium, whereas ACE inhibitors and ARBs tend to conserve potassium and thus may cause hyperkalemia. By combining these agents, the incidence of both hyper- and hypokalemia can be decreased. This concept was well demonstrated in a study that used a factorial design to evaluate the effects of various doses of quinapril and HCTZ on serum potassium levels.⁶¹ In this study, patients were randomized to HCTZ 6.25 to 25 mg or quinapril 2.5 to 40 mg as either monotherapy or combination therapy. Serum potassium was measured at baseline and at the final visit, with a significant change in serum potassium defined as a decrease of ≥ 0.5 mmol/L. Thirty percent of patients receiving 25 mg HCTZ developed a significant fall in potassium, whereas combining 10 mg of quinapril with 25 mg HCTZ reduced this figure to 15%.

Thiazides dose dependently increase serum glucose, insulin resistance, and new-onset diabetes.²⁶ Although this problem is not as great as in earlier years (when thiazides were administered in doses higher than are commonly used today), it remains an important issue for clinicians. Reports differ as to whether diuretic-induced impaired glucose tolerance/diabetes has the same adverse effect on CVD outcomes as naturally occurring disorders of glucose metabolism.^{27,62,63} Randomized controlled trials such as ALLHAT have failed to demonstrate an increase in CVD events with diuretic treatment within the trial period despite substantial increases in new-onset diabetes.⁶⁴ This suggests that the importance of better BP control may outweigh the added risk that would be expected to accompany the adverse metabolic effects of these agents, at least over a relatively brief 5-year follow-up period.

Figure 86-7. Reduction (model fitted) in seated systolic blood pressure (seSBP) (Top) and seated diastolic blood pressure (seDBP) for 12 groups in the factorial design by olmesartan medoximil and hydrochlorothiazide (HCTZ) dosage. (Redrawn from Chrysant SG, Weber MA, Wang AC, Hinman DJ. Evaluation of antihypertensive therapy with combination of olmesartan medoximil and hydrochlorothiazide. *Am J Hypertens* 2004;17:252-9 with permission from *The American Journal of Hypertension Ltd.*)

In contrast to the adverse metabolic effects of diuretics, agents that antagonize the RAAS (such as ACE inhibitors and ARBs) have been shown in randomized controlled trials to uniformly increase insulin sensitivity and prevent new-onset diabetes.^{65,66} Reductions of 20 to 30% in new-onset diabetes have been reported with ACE inhibitor or ARB-based therapy compared to placebo or therapy based on diuretics, BBs, or CCBs (Figure 86-8). This difference is preserved even when a diuretic is added to an ACE inhibitor or ARB to facilitate BP control. These findings provide a strong conceptual basis for use of fixed-dose

ACE inhibitor- or ARB-diuretic combinations in antihypertensive treatment.

Potassium-sparing diuretic-thiazide combinations

Fixed-dose combination products containing a moderately high dose of a thiazide (e.g., 25 or 50 mg of HCTZ) and a potassium-sparing agent have been available since the 1980s.¹⁴ The advantage of these is the ability to deliver a major BP-lowering dose of thiazide without the penalty of potassium and magnesium loss. Hypokalemia or hypomagnesemia induced by a diuretic may increase the frequency of cardiac arrhythmias and resultant mortality in patients with CVD.⁶⁷⁻⁶⁹ This point was demonstrated by a controlled study in which lethal consequences (primary cardiac arrest) of antihypertensive treatment were seen with unopposed moderate- to high-dose thiazide diuretic use but not with combinations that included a potassium-sparing diuretic.⁶⁷

ACE inhibitor- or ARB-CCB combinations

ACE inhibitor- or ARB-CCB combinations have additive antihypertensive effects and in some cases offer the added advantage of minimizing adverse effects of individual components (e.g., edema with dihydropyridine CCBs).¹⁴ When used as monotherapy, CCBs lower BP and thus activate the RAAS—making BP more dependent on Ang II. Adding an ACE inhibitor or ARB blocks this compensatory mechanism, leading to improved BP reductions. Many CCBs that are used in combined preparations have more favorable pharmacokinetic/pharmacodynamic profiles than their RAAS blocking partners, extending the duration of antihypertensive action of the combinations.

The Anglo-Scandinavian Cardiac Outcomes Trial-Blood Pressure Lowering Arm (ASCOT-BPLA) presented evidence that a CCB-ACE inhibitor combination is more effective in lowering BP and reducing risk of mortality and major CVD events than traditional therapy with a BB-thiazide diuretic combination.^{70,71} This large trial involved 19,257 patients randomly assigned to either amlodipine-based treatment (with the option of adding perindopril, followed by agents from other drug classes as needed for BP control) or to atenolol-based treatment (with the option of adding bendroflumethiazide and then agents from other classes if the BP was not controlled). Control was defined as BP <140/90 mmHg in patients without diabetes and BP <130/80 mmHg in diabetics. The CCB-ACE inhibitor combination lowered BP by an average of 2.7/1.9 mmHg more than the BB-diuretic combination throughout the 5.5-year median follow-up period. The trial was stopped early because of excess mortality and morbidity in the atenolol-based arm. Significant reductions in a number of outcomes (including all-cause mortality, fatal and nonfatal stroke, CVD mortality, nonfatal myocardial infarction, and new-onset diabetes) were noted with CCB +/- ACE inhibitor compared to BB +/- diuretic treatment. Overall, throughout the trial 50% of participants were taking amlodipine plus perindopril and 55% were taking atenolol plus bendroflumethiazide as assigned. Importantly, by the end of the trial only 15 and 9% of participants

Figure 86–8. Studies evaluating new onset of type II diabetes mellitus. Absolute risk reduction = 1.7 (5% CI 1.3 to 2.1). (Redrawn from Gillespie EL, White CM, Kardas M, et al. The impact of ACE inhibitors or angiotensin II type 1 receptor blockers on development of new-onset type 2 diabetes. Copyright 2005 American Diabetes Association. From *Diabetes Care*:28:2261–66. Reprinted with permission from The American Diabetes Association.)

were taking amlodipine or atenolol monotherapy, respectively—providing additional evidence for the inadequacy of monotherapy for BP control in older higher-risk hypertensive patients.

The most bothersome adverse effect of dihydropyridine CCBs and the most common reason for discontinuation of therapy is peripheral edema.⁷² This dose-related adverse effect is due to arteriolar dilation without complementary venodilation. The incidence of peripheral edema is decreased by 50 to 90%, depending on the study and the definition of edema, when ACE inhibitors/ARBs are combined with dihydropyridine CCBs.^{73–75} The mechanism of this protective effect is thought to be complementary venodilation due to inhibition of the RAAS. A study of 1500 patients in a community practice setting who had peripheral edema while taking dihydropyridine CCB monotherapy demonstrated improvement of edema in 85% of subjects and complete resolution in 42% when placed on combination therapy that included an ACE inhibitor.⁷³ The particular drug combination tested in this study, amlodipine plus benazepril, has become the most commonly used CCB-ACE inhibitor combination in clinical practice because of its proven efficacy and tolerability.

BETA-BLOCKER/DIURETIC COMBINATIONS

BBs can be combined with diuretics to produce an additive effect on BP.^{14,76} For example, the 12-week VA Cooperative Study demonstrated decreases in SBP of 10.5 mmHg with nadolol monotherapy, 17.4 mmHg with bendroflumethiazide monotherapy, and 25.3 mmHg with the combination—supporting the concept that the BB-diuretic combination has additive effects on BP reduction.⁷⁶ BBs in this combination blunt the activation of the RAAS and sympathetic nervous system that is seen with

unopposed diuretic treatment, whereas diuretics attenuate BB-induced sodium retention.⁵⁸ Studies have demonstrated a 50% reduction in plasma renin activity during BB monotherapy, and it is likely that this mechanism accounts for a substantial proportion of the antihypertensive effects of the BB class.²⁸

Although combining low doses of BBs and diuretics may reduce some of the dose-related adverse effects of the monotherapies, the long-term usefulness of this combination is limited by adverse metabolic effects (hyperglycemia, insulin resistance, dyslipidemia, hyperuricemia) and sexual dysfunction.⁵⁸ For example, combining BB and thiazide treatment in the VA Cooperative Trial was associated with greater increases in serum glucose than either monotherapy.⁷⁶ Similarly, the ALLHAT study (which used the BB atenolol as a second-step antihypertensive agent) showed an increase in new-onset diabetes mellitus of 11.6% in the group randomized to a thiazide-like diuretic compared to 9.8% in the amlodipine arm and 8.1% in the lisinopril arm.⁶⁴ Further, ASCOT showed a 30% increase in new-onset diabetes in the BB/thiazide arm compared to the CCB/ACE inhibitor arm.⁷⁰ Major outcome trials have shown that BB-diuretic combinations are less effective than a variety of comparators (ARB-diuretic, ACE inhibitor-CCB) in preventing fatal and nonfatal CVD events.^{70,77} This, in addition to their unfavorable adverse effect profile, has dampened enthusiasm for use of BB-diuretic combination in antihypertensive therapy.

“POLYPILL”

Control of multiple risk factors, including elevated BP and elevated LDL cholesterol, significantly decreases global CVD risk.⁷⁸ A review of published randomized controlled trials demonstrates that by treating hypertension, decreas-

EFFECTS OF THE "POLYPILL" ON THE RISK FOR CHD AND STROKE AFTER 2 YEARS OF TREATMENT IN PATIENTS AGES 55 TO 64					
Risk Factors	Agent	Reduction in Risk Factor	% Reduction in Risk (95% CI)		
			CHD Event	Stroke	Source
LDL cholesterol	Statin	70 mg/dL	61 (51–71)	17 (9–25)	Law et al. ⁷⁹
Blood pressure	Three antihypertensive agents	11 mmHg diastolic BP	46 (39–53)	63 (55–70)	Law et al. ⁷⁹
Serum homocysteine	Folic acid (0.8 mg/day)	3 μmol/L	16 (11–20)	24 (15–33)	Wald et al. ⁷⁸
Platelet function	Aspirin (75 mg/day)	Not quantified	32 (23–40)	16 (7–25)	
Combined effect	All		88 (84–91)	80 (71–87)	

Table 86–2. Effects of the "Polypill" on the Risk for CHD and Stroke After 2 Years of Treatment in Patients Ages 55 to 64

ing LDL cholesterol, decreasing homocysteine, and inhibiting platelet dysfunction with aspirin it is possible to reduce CVD risk by 80% (Table 86–2). The "polypill" concept involves combining low doses of compounds that treat these risk factors in a single pill that can be taken by everyone at increased risk for CVD or stroke. In theory, this method could potentially decrease ischemic heart disease (IHD) by 88% and stroke by 80% and increase life span by approximately 12 years (with few adverse effects).⁷⁸ This strategy could be employed in large numbers of persons at risk for CVD, possibly even all persons >55 years of age.

The estimates of benefit of polypill therapy for hypertension on global CVD risk are based on a meta-analysis of 354 trials designed to determine the average reduction in BP, prevalence of adverse effects, and reduction in risk of stroke and CVD events produced by the five main categories of BP-lowering agents (CCBs, BBs, ACE inhibitors, ARBs, and diuretics) according to dose—singly and in combination.⁷⁹ It was shown that all five categories of antihypertensive agents produced similar reductions in BP. None of the studies used more than 2 drugs in combination, but the authors of the meta-analysis assumed that combining 3 agents would have an additive effect. They calculated that reducing SBP by 20 mmHg and DBP by 11 mmHg would result in a 46% reduction in CVD risk and a 63% reduction in risk of stroke. The proposed "polypill" includes a combination of 3 BP medications from the five major categories of antihypertensive agents at half standard dose to achieve better BP control without increasing dose-related adverse effects.

The Amlodipine/Atorvastatin Gemini study tested the efficacy of single-pill therapy with this CCB-statin combination in the treatment of concomitant hypertension and dyslipidemia in a total of 1220 patients with uncontrolled hypertension at baseline.⁸⁰ After 14 weeks of treatment, both BP and LDL cholesterol goals were achieved in almost 58% of participants. Only 5% discontinued therapy due to adverse events. The Gemini study is the first large-scale trial to examine the clinical-practice utility of single-pill therapy for the simultaneous treatment of more than one CVD risk factor. Its favorable outcome enhances the probability that this approach will be taken with additional drug combinations in the near future.

CONCLUSIONS

Fixed-dose combination antihypertensive drugs have been available for over 40 years but for a time lost favor due to the perception that they resulted in increased toxicity. More recently, it has become apparent that few hypertensive patients (particularly those who are older and at high cardiovascular risk) can be controlled with monotherapy. Therefore, combination therapy has been recommended by treatment guidelines and has become widely accepted by health care providers as either initial or maintenance therapy of hypertension. Low-dose fixed-dose combination agents, because of convenience and favorable side effect profiles, have become widely used in recent years. Most of the newer combination agents include ACE inhibitors, ARBs, or BBs in combination with diuretics. Less commonly, ACE inhibitors or ARBs are combined with CCBs.

To be approved for clinical use, a combination agent must be shown to have a greater antihypertensive effect than either of its components. This is accomplished by combining agents with complementary mechanisms of action. Further, in many cases the effects of one of the components may attenuate the adverse effects of the other (e.g., ACE inhibitors and ARBs tend to prevent hypokalemia and new-onset diabetes induced by diuretics). Fixed low-dose combination antihypertensives may also be more cost effective because they require only one co-pay and the component agents are usually marketed at a lower price when combined in a single pill. Combination medications are easier to take than monotherapies, as they can be taken as a single tablet once a day (thus increasing compliance).

The polypill concept embraces administration of multiple medications in a single pill to treat multiple CV risk factors. The first available agent (Caduet) has shown promise in reducing CV risk by producing significant improvements in both BP and LDL cholesterol levels. It has been suggested that a pill containing low doses of a statin, aspirin, folic acid, and multiple antihypertensive agents with complementary mechanisms of action could be used safely, effectively, and at relatively low cost to reduce CVD risk in entire at-risk populations (e.g., all persons over age 55 years and those with established CVD). Use of the polypill would exploit all of the advan-

tages of low-dose fixed-dose combination therapy discussed in this chapter and would obviate the need for

complicated dosing regimens and for multiple costly pharmaceutical agents prescribed individually.

Chapter
87Interactions Between
Antihypertensive Drugs
and Other Medications*Nigel J. Langford and Anthony Cox***Key Findings**

- Drug interactions are a significant cause of morbidity and mortality.
- Polypharmacy, common in hypertensive treatment and in an aging population, increases the potential for drug interactions.
- Many drug interactions, including those leading to adverse events, are avoidable.
- Interactions between hypertension agents and other drugs can be pharmacokinetic or pharmacodynamic in nature.
- As herbal treatments and health foods become increasingly popular, the clinician should be aware of the potential for significant interactions with prescribed drugs.
- Non-cardiac drugs such as NSAIDs, including those bought over the counter, should also be considered a source of potential interactions.
- Although antihypertensive agents are often prescribed in combination, there exists the potential for deleterious drug interactions—in particular from arrhythmias and electrolyte disorders.
- Although electronic decision support tools can create awareness of potential drug interactions, they can make it difficult to differentiate between clinically significant and non-significant interactions.

An interaction is said to occur when effects of one drug are changed by the presence of another substance.¹ The outcome may be harmful, beneficial, or insignificant. In those patients receiving treatment for hypertension, it is estimated that only 50% of patients will achieve target blood pressures on monotherapy.² Consequently, in the management of hypertension we commonly use a combination of drugs to obtain a target blood pressure. With the increasing prevalence of hypertension associated with increasing age, there is an increase in co-morbidities. Consequently, the practice of prescribing multiple medications for all these individual problems is common. Such a practice is referred to as “polypharmacy.”

Polypharmacy may be deleterious not only because of the increased potential for side effects and drug interactions but because taking unnecessary or borderline therapies reduces patient compliance and concordance with

effective drugs. There is also an increased risk of drug interactions. The number of potential interactions occurring can be calculated as the binomial coefficient of the number of drugs prescribed. For example, with a patient taking six drugs there are $5 + 4 + 3 + 2 + 1 = 15$ possible combinations of individual drugs that have to be examined for drug interactions.³ Such interactions may be further complicated by regional, ethnic, and pharmacogenetic differences in response to antihypertensive agents.

Such concerns are not just theoretical. In one English study it was estimated that 15 to 19% of hospital admissions owing to adverse events were secondary to interacting drugs,⁴ whereas other studies estimated the rate to be between 20 and 25% of adverse drug reactions.⁵

Harmful interactions are obviously to be avoided. Prescribers need a holistic approach to the prescribing of medication, taking account of co-morbidities, previously and currently prescribed medications, and the patient's lifestyle (including potential illicit agents). This chapter looks at harmful interactions that may result when using medications and antihypertensive therapy. Those combinations of antihypertensive agents used synergistically to achieve a beneficial effect are considered elsewhere.

DRUG INTERACTIONS

Conventionally, drug interactions may be split between pharmacokinetic interactions and pharmacodynamic interactions. Those interactions that affect the processes of absorption, distribution, metabolism, and excretion are known as pharmacokinetic interactions. Those interactions where the effect of one drug is changed by the presence of another drug at its site of action are known as pharmacodynamic. In addition, there are pharmaceutical interactions that require consideration.

Pharmaceutical considerations

Within most developed countries drug regulatory authorities and manufacturers have strict quality control checks in place to ensure purity and consistency of product. In less well developed countries such checks may be less vigorous. Alternatively, when these checkpoints fail there can be discrepancies between alleged product and actual product, leading to problems of overdose or to problems of underdosing and treatment failure.

Inappropriate storage of product prior to dispensing or administration can lead to degradation of product. This can result in reduction of the actual active ingredient or of the compounds' excipients, leading to failure of drug release or absorption.

Pharmacokinetic interactions

These interactions can occur at any time during the passage of the drug through the body, starting with ingestion and absorption. Some drugs mimic naturally occurring dietary agents and are actively absorbed into the body. Others rely on passive absorption across the mucosal membrane, mainly in the jejunum and ileum. Lipid-soluble drugs are more readily absorbed. Those drugs that ionize are less well absorbed. Drug interactions can interfere significantly with drug absorption. Examples include alterations in gastric pH, affecting release of sustained release preparations; the formation of chelates, the proposed mechanism of interaction between ferrous compounds and methyldopa; and alterations in gastric motility. Slowing gastric motility (although potentially increasing the amount of a drug absorbed) may increase the amount of drug that can be broken down in the stomach or metabolized by the intestinal wall, as with levodopa.

The presence of food in the gastrointestinal tract may unpredictably alter absorption. With some drugs, the presence of food may enhance absorption (as with hydrochlorothiazide). Food can also reduce the amount of first-pass metabolism, increasing the bioavailability of drugs such as propranolol and metoprolol. Consequently, it is not always easy to predict the result of such an interaction.

Once absorbed through the intestinal wall, the drug enters the portal circulation and is transported via the liver to the systemic circulation. The drug may be subject to metabolism anywhere along this route. The initial metabolism, also known as phase I reactions, refers to a set of reactions that result in relatively small chemical changes that make compounds more hydrophilic. The principal reactions are hydrolysis, hydroxylation, oxidation, dealkylation, or deamination—leading to the formation of more polar compounds. Following phase I metabolism, phase II modification may occur as a large polar group is added to the compound by transferase enzymes. In most cases, phase II metabolism follows phase I metabolism because the functional group generated in phase I is needed for attachment of the polar group. However, in some cases in which the parent drug has an appropriate site phase II metabolism can occur first.

Most important phase I reactions are catalyzed by the cytochrome P450 microsomal enzymes, a set of hem-containing proteins localized primarily in the hepatocytes and intestine. There are six main groups of isoenzymes important in drug metabolism. These groups are CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. Individuals have different amounts of these isoenzymes. Therefore, an interaction that occurs in one individual may vary significantly from another depending on the relative proportions of the enzyme available. Any agents that interfere with the CYP450 system have the potential to alter drug metabolism and hence drug action.⁶ Drug action is

altered via enzyme inhibition (reducing the rate of drug metabolism and increasing the amount of the parent drug in circulation) or via enzyme induction. Enzyme induction usually accelerates rates of metabolism, thereby reducing the amounts of parent compound in circulation. The chemical components are then distributed throughout the body before being excreted. The degree and extent this occurs depends on regional blood flow and the ability of the drug, or its metabolites, to diffuse across the cell membrane. The changes in regional blood flow are highly variable, depending on disease state as well as age and other drugs administered. Renal failure can lead to prolonged duration of action of certain agents, requiring dose alteration.

Within the circulation, many drugs bind loosely with plasma proteins. However, for a chemical agent to exert a pharmacologic effect it must be in its free form to either cross a membrane or bind with its receptor. The extent to which a drug is protein bound varies, depending on circumstances. In hypoalbuminemic states, acidic drugs are less well bound. Alternatively, basic drugs undergo increased binding with increased inflammatory responses. Often the changes in available drug are transient. However, if highly protein-bound drugs are given in reduced albumin states the effects the drug exerts can be significantly more pronounced.

Compounds may be passively or actively removed from the plasma by the kidney as they are excreted in the urine or in the bile. Interference of normal excretory pathways by drugs in the renal tubule can cause alterations in rates of drug excretion.

Pharmacodynamic interactions

Pharmacodynamic interactions are where the actions of one drug are changed in the presence of another. There are four main groups of pharmacodynamic interactions, all of which are important with antihypertensive medications.¹ The variability of such interactions may be further complicated owing to significant genetic differences between individuals. The first main group of pharmacodynamic interactions is of *synergistic interactions*. The action of an index drug is enhanced by another, such as the hypotensive action of one antihypertensive agent being enhanced when a second antihypertensive agent is given concurrently. The second group of interactions are labeled *antagonistic*, when the main action of an index drug is opposed by another, such as between beta-adrenoreceptor antagonists and beta agonists. The third group of pharmacodynamic interactions are *interactions secondary to changes in drug transport mechanisms*, such as occur at adrenergic nerve terminals when the actions of adrenergic neurone-blocking drugs such as guanethidine may be blocked by phenothiazine-type drugs or other indirectly acting sympathomimetic amines and tricyclic antidepressants (thereby negating their antihypertensive actions). The final group of pharmacodynamic interactions are *interactions due to disturbances in fluid and electrolyte balance*. Significant interactions with antihypertensive agents involve the thiazide diuretics and lithium. Thiazide diuretics block the secretion and excretion of lithium into the renal tubules, leading to increased lithium concentrations and subsequent toxicity.

Incidence of interactions

Adverse drug interactions occur commonly. Pirmohamed and colleagues found in their study of Liverpool hospitals that adverse drug-related events accounted for 6.5% of admissions. Drug interactions accounted for 16.6% of these admissions and were responsible for 50% of deaths recorded.⁴ An American study looking at hypertensive patients and their medication estimated that between 23 and 48% of their patients had a potential drug interaction of a high significance.⁷ However, it is estimated that between 50 and 84% of adverse drug events are avoidable.

Interacting agents

Food products

Food intake can have a significant impact in hypertensive patients, altering the efficacy of their prescribed anti-hypertensive medication. Dietary foods can have pharmacokinetic and pharmacodynamic interactions. Grapefruit juice, and to a lesser extent Seville orange juice, may interact significantly with certain calcium channel antagonists such as felodipine and nifedipine (as well as with other medications metabolized via the CYP3A4 pathway and P-glycoprotein pathway).⁸ Orange juice has also been linked to reduction in the bioavailability of celiprolol.⁹ Reduction in alcohol consumption can be beneficial in hypertensive patients. More recently, with concerns over salt consumption and links with hypertension alternative salt substitution preparations have become available—often containing significant concentrations of potassium chloride. Ray et al. advise close questioning of patients with unexplained hyperkalemia to avoid the inappropriate cessation of treatments such as ACE inhibitors due to patients taking potassium containing salt substitutes.¹⁰

Herbal and nonprescription products

Nonprescription products are commonly used in patients with cardiovascular problems. The most commonly used groups of agents are vitamins and mineral supplements, analgesics, and herbal remedies.¹¹ Commonly interacting herbal remedies include Saint-John's-wort and ephedrine containing compounds such as Ma Huang. Saint-John's-wort is well known to affect CYP3A4 and to interfere with the P-glycoprotein pathway. Consequently, the impact on other drugs is often difficult to predict (in particular because the impact of the Saint-John's-wort shows significant intra- and interindividual variability). It should also be noted that considerable variation occurs between differing manufacturers of herbal preparations, as well as variation due to the parts of the plant used and the weather conditions during the growing season.

The use of licorice has been linked to hypokalemia. The major component of licorice, glycyrrhizin, induces the retention of sodium and water, increases potassium excretion, and increases blood pressure. Doses of licorice between 150 and 250 mg daily for several weeks are enough to cause hypokalemia, even if ingested in the form of sweets.¹² Overconsumption should be avoided in those taking potassium-depleting diuretics.

Beta-adrenoreceptor antagonists

Epinephrine and norepinephrine are endogenous catecholamines involved in the regulation of virtually every organ system. They act via adrenergic receptors and can have a profound influence on morbidity and mortality. More specifically, the pharmacodynamic effects of beta-adrenoreceptor antagonists can be attributed to the high affinity for the beta-adrenoceptors in various organs—where a receptor-antagonist complex is formed that fails to activate the receptor. All beta-adrenoreceptor antagonists in present use are competitive antagonists.

Pharmacokinetic interactions involving beta-adrenoreceptor antagonists vary according to physicochemical properties. For example, lipid-soluble beta-adrenoreceptor antagonists such as metoprolol, bisoprolol, and carvedilol commonly involve the CYP2D6 enzyme in their metabolism. Those individuals who have reduced concentration of this enzyme are at increased risk of both adverse reactions and drug interactions. However, these individuals will be unaffected if prescribed water-soluble beta-adrenoceptor antagonists such as atenolol, nadolol, or sotalol because these drugs undergo less or no metabolism within the liver and are excreted primarily by the kidney. The liver can also give rise to further interactions via alterations in hepatic blood flow. Beta-adrenoceptor antagonists commonly reduce hepatic blood flow. This may lead to a decline in the rates of metabolism and clearance of other hepatically metabolized drugs, increasing their potential toxicity. Metoprolol and propranolol have been found to reduce lidocaine clearance by such a mechanism.³

In the Vaughan-Williams classification of antiarrhythmic agents, beta-adrenoceptor antagonists are class II agents. However, their actions also impinge on classes I and III. This gives a potential for interactions with antiarrhythmic agents from these classes leading to arrhythmias. Despite these theoretical concerns, the number of case reports involving beta-adrenoreceptor antagonists and other class I antiarrhythmic agents are surprisingly few. The reactions are usually pharmacokinetic in nature. For example, both concurrent propafenone and quinidine administration with a beta-adrenoceptor antagonist result in an increase in the beta-adrenoceptor concentration. A far more sinister interaction may occur between beta-adrenoceptor antagonists (such as sotalol) and concurrent drugs that cause lengthening of the QTc interval. Despite this, beta-adrenoceptor antagonists can be used beneficially with some class III agents such as amiodarone. Patients should be warned of the potential for hypotension, bradycardia, ventricular fibrillation, and asystole.

Macrolides, particularly erythromycin and clarithromycin (and the newer fluoroquinolones—moxifloxacin, sparflaxacin and grepafloxacin), potentially prolong the QTc interval. Concurrent administration of beta-adrenoceptor antagonists with similar properties has the potential to cause torsade de pointes. Although the risk is low,¹³ the two groups of drugs should be rarely prescribed and only if there is no feasible alternative.¹⁴ QTc prolongation is also seen with antimalarial therapy. Halofantrine, quinine, and quinidine all have the ability to prolong QTc intervals at therapeutic doses.¹⁵ Mefloquine and artemether are less

likely to alter ventricular repolarization, although a single case report exists of an interaction between propranolol and mefloquine resulting in cardiac arrest (the causality remains unproven).

Newer non-sedating antihistamines such as terfenadine and mizolastine also have the potential to prolong the QTc interval. Consequently, concurrent use with beta-adrenoceptor antagonists with similar properties can lead to significant arrhythmias.¹⁶

Beta-adrenoceptor antagonists and antipsychotic or antidepressant medication have the potential to interact. For example, propranolol and chlorpromazine can both cause hypotension. This effect appears to be potentiated with concurrent administration. The probable mechanism of action appears to be mutual inhibition of metabolism of each other, thereby increasing each other's plasma concentration. A similar interaction may occur between propranolol and thioridazine, with resultant hypotension. Other lipid-soluble beta-adrenoceptor antagonists may be affected.

Amisulpride, the phenothiazine group of drugs, pimozide, sertindole, and the tricyclic antidepressants all have the potential to prolong the QTc interval. Consequently, concurrent administration with beta-adrenoceptor antagonists with similar properties may predispose to torsade. These combinations should be avoided unless no alternative agents are available.

Concurrent use of beta-receptor antagonists and calcium-channel-blocking agents are common. Beta-adrenoceptor antagonists interact significantly with all groups of calcium-channel-blocking agents. They are used synergistically with group II calcium-channel-blocking agents the dihydropyridines. With class I antagonists, such as verapamil, they can induce heart block. Although studies have shown that diltiazem can be used safely with beta-adrenoceptor antagonists, case reports of life-threatening bradycardia have been published.¹⁷ The mechanism of action varies between beta-adrenoceptor antagonists. For example, with metoprolol the proposed pharmacokinetic mechanism of action is that metoprolol reduces the systemic clearance of verapamil (whereas verapamil increases metoprolol bioavailability, necessitating a lower dose of metoprolol).¹⁸

A single case report exists of a renal transplant patient stabilized on atenolol and ciclosporin, whose beta-adrenoceptor antagonist was changed to carvedilol. After 3 months of treatment, his ciclosporin dose was reduced by 20%.¹⁹ Other beta-adrenoceptor antagonists have not been recorded to produce such an effect. However, the observation that ciclosporin has the potential to worsen hypertensive disease is not uncommon. The exact mode of action is uncertain.

The combination of beta-adrenoceptor antagonists and clonidine has been used therapeutically to treat hypertension. Sudden withdrawal of clonidine can lead to severe rebound hypertension and hypertensive crisis. The mechanism of action is believed to be secondary to unopposed alpha-adrenoceptor activity. Consequently, it is recommended that beta-adrenoceptor antagonist withdrawal should occur slowly prior to clonidine withdrawal.

When used with beta-adrenoceptor antagonists, diuretics often produce an enhanced hypotensive effect. A potential concern with their use is hypokalemia. Arrhythmias are more likely to result if used concurrently with beta-adrenoceptor agents with class III activity.

Moxisylyte is an alpha-1 and alpha-2 antagonist used in the treatment of erectile dysfunction. Although administered via an intra-cavernosal route it can produce systemic effects, resulting in significant orthostatic hypotension.

Non-steroidal anti-inflammatory drugs are well known to exacerbate hypertensive disease. However, some agents interact specifically with beta-adrenoceptor antagonists. Indometacin has been shown to interact with propranolol, oxprenolol, atenolol, and labetalol—causing an increase in mean blood pressure. The effect may be even more marked in the treatment of pre-eclampsia. The exact mechanism by which this increase in blood pressure occurs is uncertain, although it has been postulated that it occurs via prostaglandin (PGA and PGE) inhibition. Piroxicam also appears to increase blood pressure, albeit to a lesser extent. The other NSAID agents (such as diclofenac, ibuprofen, sulindac, and tenoxicam) do not interact significantly.

Predictably, beta-adrenoceptor antagonists will have a pharmacodynamic interaction with beta-adrenoceptor agonists. Patients taking nonselective beta-adrenoceptor antagonists have experienced severe hypertension following administration of epinephrine, norepinephrine, or phenylephrine. These results have not been seen consistently and appear to occur most commonly in those patients taking nonselective beta-adrenoceptor antagonists compared with cardioselective agents.²⁰⁻²² It is proposed that this occurs via unopposed alpha activity that leads to vasoconstriction and hypertension (which may be followed by a marked bradycardia). Interaction between beta-2 agonists and beta-adrenoceptor antagonists is well documented. Severe adverse effects may result, and deaths have occurred following the concurrent administration of propranolol and salbutamol. Similarly, topical nonselective beta-adrenoceptor antagonists can also have severe adverse effects in asthmatics by blocking the normal action of beta-2 agonists. Uses of cardioselective beta-adrenoceptor antagonists are less likely to have such severe adverse effects, but even these agents have the potential to cause such effects because their beta-blockade is less selective at high doses.

Vasodilators

Vasodilators are potent antihypertensive agents that can cause a significant reduction in blood pressure in their own right. Specific drug interactions are limited. However, caution is advised with concurrent use of other agents that lower systemic blood pressure. They are often used in combination with beta-adrenoceptor antagonists and a thiazide diuretic.

Diazoxide and hydralazine, both vasodilator agents, interact significantly—resulting in severe hypotension. In a number of cases this has led to fatalities despite the use of pressor agents.

A single report exists of hydralazine interacting with apamiprol in a 60-year-old woman following urography,

causing a cutaneous vasculitis. The mechanism of such an interaction is postulated to occur owing to hydralazine's ability to induce LE-like syndromes.²³ Certain studies have indicated that the normal antihypertensive action of hydralazine may be opposed with concurrent use of either indometacin or diclofenac.

Hydralazine appears to increase the bioavailability of those beta-adrenoreceptor antagonists that undergo extensive first-pass metabolism.²⁴ The water-soluble beta-adrenoreceptor antagonists appear to be largely unaffected. Despite significant increases in bioavailability, the clinical effects appear to be largely unchanged.

Minoxidil has been used in the treatment of hypertension in patients who have received organ transplantation and are concurrently receiving ciclosporin. Using this combination of drugs in certain patients has resulted in hypertrichosis, which has resolved following minoxidil withdrawal. The mechanism of action is unknown.

Centrally acting antihypertensive drugs

In common with all antihypertensive agents, these drugs may be antagonized or potentiated by drugs that affect blood pressure. The mechanisms of those reported with clonidine and methyldopa follow no pattern. Methyldopa acts centrally, probably via a number of different mechanisms, to reduce blood pressure.

Early reports suggested that the combination of haloperidol and methyldopa could result in dementia. Such reports were reinforced, in that symptoms resolved following haloperidol withdrawal. However, the combination has since been used without problems.

The antihypertensive effects of methyldopa may be significantly decreased following coadministration of iron-containing compounds.^{25,26} The amount absorbed is significantly reduced, probably owing to the formation of iron-methyldopa chelates.²⁶ However, with other elements (such as lithium) the reverse can occur. Raised lithium concentrations leading to intoxication have been reported to occur with concurrent administration.^{27,28} The exact mechanism of action is uncertain.

Methyldopa is widely used in the treatment of hypertension in pregnancy. Salbutamol is occasionally used as a tocolytic. Case reports have suggested that concurrent use can cause severe adverse events, possibly as a result of increased fluid retention.²⁹

Clonidine acts primarily as a presynaptic CNS alpha-2 agonist, stimulating receptors in the nucleus *tractus solitarii* of the *medulla oblongata*. This inhibits sympathetic outflow, which results primarily in a reduction of sympathetically mediated vasoconstriction, cardiac inotropy, and chronotropy. It also has peripheral alpha1-agonist activity.

A significant fall in blood pressure was recorded in a patient receiving clonidine who also received intramuscular haloperidol. However, other reports of patients receiving clonidine and antipsychotic medication have failed to detect such effects. Consequently, caution is recommended in this group of patients. The normal antihypertensive action of clonidine may also be reduced, or completely abolished, following concomitant use with the tricyclic antidepressants.³⁰

Indeed, in some reports the blood pressure actually increased. Control of blood pressure with clonidine may be unaffected by the tetracyclic antidepressants such as mianserin.

Clonidine and beta-adrenoreceptor antagonists have been previously discussed. However, in addition there are reports of paradoxical increases in blood pressure in patients receiving combinations of clonidine and sotalol, and clonidine and propranolol.³¹ Exactly why such a reaction should occur is uncertain. Few interactions occur with calcium-channel-blocking agents, but care should be taken with verapamil in light of two isolated case reports of complete heart block.

Mirtazapine is a newer tetracyclic antidepressant whose action occurs secondarily to stimulation of the noradrenergic system through antagonism at central alpha-2-inhibitory receptors. Concomitant use of mirtazapine and clonidine in a patient resulted in a significant alteration of blood pressure control. The reaction is postulated to occur following central alpha-adrenoreceptor competition between the two agents.³²

Like other centrally active antihypertensive medications, moxonidine and beta-adrenoreceptor antagonist combination may lead to rebound hypertension upon drug withdrawal. Therefore, manufacturers advise that patients taking the combination should withdraw the beta-adrenoreceptor antagonist first to try to limit rebound hypertension. Owing to its centrally acting mode of action, moxonidine has the potential to interact with other sedatives and hypnotics and potentiate their actions. Such effects can be seen with the benzodiazepine group of drugs that lead to mild cognitive impairment and sedation. In addition, with benzodiazepines the hypotensive effects of moxonidine may be enhanced.

Adrenergic neurone-blocking drugs

Guanethidine and the related drugs debrisoquine and betanidine act by preventing the release of noradrenaline from post-ganglionic adrenergic neurones. Although not widely used in the United Kingdom, interactions³³ causing enhanced drops in blood pressure have been recorded with ethanol, general anesthetics, benzodiazepines, other muscle relaxants (such as baclofen and tizanidine), and other centrally acting and vasodilating antihypertensive agents. Its antihypertensive effects may also be antagonized by antipsychotic agents such as haloperidol and chlorpromazine, as well as by other directly and indirectly acting sympathomimetic agents such as norepinephrine, phenylephrine, oxymetazoline, phenylpropranoline, pseudoephedrine, and xylometazoline.

Alpha-adrenoreceptor antagonists

Alpha-adrenoreceptor antagonists with selectivity for the post-synaptic alpha-1 adrenoreceptor are a group of antihypertensive agents having high specificity in blocking sympathetic impulses to resistance and capacitance vessels. They cause lowering of blood pressure by reducing tone in arteriolar resistance vessels and by dilating venous capacitance vessels. Consequently, they have the potential to interact with other vasodilating agents such as ethanol

potentiating their antihypertensive effects. Indeed, with most other groups of antihypertensive agents there may be an increased incidence of first-dose hypotension. This effect may be less with doxazosin and tamsulosin.

Phosphodiesterase type-5 inhibitors have a relaxing effect on vascular smooth muscle. These agents have been shown to cause an overall reduction in both systolic and diastolic blood pressure. Consequently, when these drugs are used concurrently hypotension may result. Presently, the manufacturers of sildenafil recommend caution with concurrent administration of alpha-adrenoreceptor antagonists. Tadalafil is contraindicated with alpha-adrenoreceptor antagonists except for 0.4 mg tamsulosin, and vardenafil is contraindicated with all alpha-adrenoreceptor antagonists.

Diuretics

Diuretics (in particular, thiazides) are widely used in hypertension, and as such their potential for drug interactions with other medications is of particular importance (especially given the likelihood of other cardiac co-morbidities, and associated treatments, in the hypertensive population). The majority of significant interactions associated with diuretic use are related to their effects on plasma electrolytes. Interference with potassium, sodium, and calcium concentrations can lead to adverse effects, but the most troublesome effects are related to changes in potassium concentrations.

The risk of diuretic-induced hypokalemia can be worsened by the prescribing of other drugs associated with potassium loss, leading to the deleterious effects of hypokalemia (such as muscle weakness and cardiac arrhythmias). Drugs that can decrease potassium levels include acetazolamide, amphotericin, beta-2 agonists, corticosteroids, itraconazole, and theophylline.

Alternatively, the arrhythmogenic potential of other drugs (cardiac and non-cardiac) can be aggravated by the presence of diuretic-induced hypokalemia. Cardiac drugs whose arrhythmogenicity can be increased by diuretics include the antiarrhythmics quinidine, sotalol, and flecainide.

Diuretic-induced potassium loss, exacerbating potassium loss from myocardial cells, increases the sensitivity of the myocardium to digoxin. Although there has been debate about the importance of this interaction, it is currently believed that the use of furosemide and bumetanide in combination should be carefully monitored. However, non-cardiac drugs with arrhythmogenic potential (such as tricyclic antidepressants, erythromycin, and terfenadine) are also potentially dangerous in the presence of diuretic-induced hypokalemia.

Hyperkalemia

Potassium-sparing diuretics such as spironolactone, amiloride, and triamterene all have the potential to cause hyperkalemia. This risk is increased when used in association with potassium supplements and salt substitutes, as previously noted. The risk of hyperkalemia with spironolactone increases threefold if used with potassium supplements. The use of concurrent loop diuretics does not guarantee that hyperkalemia will not occur. Potassium supplements should be avoided, except under very close supervision, in those taking

potassium-sparing diuretics. The use of the immunosuppressants ciclosporin and tacrolimus with potassium-sparing diuretics or aldosterone antagonists also increases the risk of hyperkalemia.

Pharmacokinetic absorption

Furosemide's absorption can be markedly reduced by the coadministration of the anionic exchange resins colestyramine and colestipol. This can have a significant effect on the diuretic effect of furosemide, and it is advised that doses should be given 2 to 3 hours before using these agents. Similar effects are seen when combining thiazides with exchange resins, and it is recommended that doses be separated by 4 hours (although this is not likely to prevent the effect completely).

Furosemide's diuretic effect can be reduced by as much as 50% if phenytoin is used concurrently. This is demonstrated regardless of the route of administration (both intravenous and oral doses of furosemide are affected). Increased doses of furosemide may be required.

NSAIDs versus diuretics

The concurrent use of NSAIDs with loop diuretics can lead to a reduction in the hypertensive and diuretic effects of the loop diuretic. Although evidence for some NSAIDs is stronger (indometacin, diclofenac, piroxicam, and naproxen), all NSAIDs carry some risk. It is thought that NSAIDs interfere with the production of renal prostaglandins, leading to reduced renal blood flow and sodium and water retention. The combination does not necessarily need to be avoided, but should be monitored. Those at greatest risk include the elderly and those with renal problems, cardiac failure, or renal insufficiency. Although most evidence is with furosemide, similar problems can present with bumetanide. High-dose aspirin has been shown to have some effect on bumetanide,³⁴ but low-dose aspirin is unlikely to have a significant clinical effect.

A well-established interaction exists between thiazides and indometacin or naproxen. Ibuprofen may also interact similarly, but evidence for other NSAIDs is limited. Again, interference with renal prostaglandins is the proposed mechanism.

Glycosides and diuretics

Both loop diuretics and aminoglycosides exhibit ototoxicity at high doses. The British National Formulary advises that an increased risk of ototoxicity can occur with the coadministration of loop diuretics and aminoglycosides (such as gentamicin, kanamycin, and tobramycin). Concerns also exist that such combinations may lead to nephrotoxicity. Nonetheless, three randomized controlled trials have failed to find an increased risk of ototoxicity.³⁵ In addition, furosemide has the potential to increase aminoglycoside concentrations by inhibiting renal excretion. Aminoglycosides are thought to increase the permeability of cell membranes in the inner ear, which may allow loop diuretics to obtain access at lower doses. Several case reports have been reported, one of which involved the use of once-daily gentamicin with a single dose of furosemide

20 mg IV after the second day's dose.³⁶ This led to profound bilateral hearing loss.

Toxicity is more common in those with severely reduced renal function who receive high doses of loop diuretics at rates faster than 4 mg per minute. By monitoring aminoglycoside levels and renal function, and by being alert for symptoms of ototoxicity, normal use should not pose a great risk.

Spironolactone can significantly impair digoxin clearance,³⁷ although the extent of this interaction is variable. However, coupled with the interference of spironolactone with digoxin assays³⁸ monitoring of combined use is prudent to avoid digoxin intoxication.

Other interactions with diuretics

Both loop diuretics and thiazides can cause a compensatory increase in proximal tubular reabsorption, leading to an increase in serum lithium concentrations. Toxic lithium concentrations may occur within 3 to 5 days following commencement of a diuretic. Some advocate a 25- to 50% reduction in the lithium dose if diuretics are started in a patient stabilized on lithium.³⁹

A population-based study has shown that those who take lithium and are commenced on loop diuretics are six times more likely to be hospitalized with lithium toxicity. Although the study did not show that thiazides increased risk independently, care should be taken.⁴⁰ The reduced urinary excretion of calcium caused by thiazide diuretics can cause hypercalcemia and metabolic alkalosis when given in combination with high doses of vitamin D. This interaction is important both in those using vitamin D for osteoporosis and those being treated for hypothyroidism. The ingestion of high doses of calcium carbonate alone, present in some over-the-counter remedies for indigestion, in the presence of thiazides may also precipitate significant changes in serum calcium. Although this is not an absolute contraindication, calcium levels should be monitored to avoid excessive calcium levels.

ACE inhibitors

Commonly prescribed, ACE inhibitors have a number of interactions with other drugs, many of which are related to their effects on electrolytes or their effect on the renal system. NSAIDs, including aspirin, have been reported to attenuate the hypotensive action of ACE inhibitors due to their sodium- and water-retaining properties. At high doses, aspirin has been shown to reduce the blood-pressure-lowering effects of ACE inhibitors. At lower doses (75 mg) evidence is less clear, but there have been suggestions that outcome was poorer in post-infarction patients who received aspirin combined with ACE inhibition. Although studies have given conflicting information about the significance of this interaction, the well-established benefits of both ACE inhibitors and aspirin (particularly in patients with heart failure associated with ischemic heart disease) has led to recommendations that combined treatment not be withheld.⁴¹ A systematic review gave a similar conclusion.⁴²

More recently, an epidemiologic study in 24,012 patients showed that aspirin was associated in a reduction in risk of death, regardless of the co-prescription of ACE inhibitors.⁴³

NSAIDs and ACE inhibitors can interact variably within the kidney. Patients with underperfused kidneys may see further deterioration. Other patients with adequately perfused kidneys may benefit from combining an NSAID with an ACE inhibitor. Rarely, NSAIDs and ACE inhibitors may cause hyperkalemia when used in combination.

Concern has been raised about hypotension caused by the use of anesthetic agents in patients taking ACE inhibitors. Although care should be taken, there is debate about whether ACE inhibitors should be discontinued prior to surgery. Some evidence suggests that these risks are outweighed by the problems of controlling postoperative hypertension—at least following a coronary artery bypass graft.⁴⁴

ACE and lithium toxicity

Lithium toxicity has been reported in a number of patients co-prescribed ACE inhibitors. Lithium concentrations can be raised by 35% and clearance of lithium reduced by 26%. One in five patients can develop signs and symptoms suggestive of lithium toxicity. Case reports have included captopril, enalapril, and lisinopril, but it is likely to be a class effect. The mechanism is suspected to be related to fluid depletion and ACE inhibition of the constriction of efferent renal arterioles. This prevents a compensatory increase in the glomerular filtration rate and hence reduced lithium concentrations. Although not of clinical importance in all individuals, at-risk groups such as the elderly and those with heart failure, renal problems, or volume depletion should generally avoid this combination. A population study of 10,615 elderly patients in Canada, of whom 413 were hospitalized with lithium toxicity, found that the use of ACE inhibitors in the month prior to hospitalization was associated with a significantly increased risk of hospitalization with lithium toxicity.⁴⁵

ACE inhibitors and blood dyscrasias

The use of ACE inhibitors and azathioprine has been associated with blood dyscrasias. Anemia has been reported in kidney transplant patients taking enalapril or captopril when switched from ciclosporin to azathioprine. The interaction is not pharmacokinetic in nature. The anemia appears to be due to the erythropoietin-lowering effect of ACE inhibitors, which increases the risk of anemia.⁴⁶

A small number of case reports of leukopenia associated with the combination of captopril and azathioprine has been reported. Despite this limited evidence, manufacturers of captopril suggest that concomitant administration of ACE inhibitors with immunosuppressants may lead to an increased risk for leukopenia—particularly with higher doses.

Captopril has also been reported to increase the risk of neutropenia when used in combination with procainamide, with reported cases of neutropenia and serious infection. There is no evidence of a pharmacokinetic interaction. It is recommended that this combination be used with caution—especially in those with impaired renal function. Again, the manufacturers of other ACE inhibitors warn of the possible risk. Serious infections and neutropenia have also been reported using captopril with allopurinol.

Captopril has been associated with neutropenia in association with allopurinol. Although rare, it would seem that patients should be carefully monitored for signs of neutropenia on this combination. A number of manufacturers of other ACE inhibitors also warn of an increased risk of leukopenia when ACE inhibitors and allopurinol are used in combination.

ACE inhibitors and hypersensitivity

Hypersensitivity reactions to combined therapy with allopurinol and ACE inhibitors have also been reported. This has ranged from fatal Stevens-Johnson syndrome to fever, myalgia, and renal failure. No pharmacokinetic reaction has been shown in healthy volunteer studies. There has been one case of myocardial infarction related to severe coronary spasm induced by acute anaphylaxis with combined use of enalapril and allopurinol. Symptoms started within 20 minutes of allopurinol being given.⁴⁷ It should be noted that both drugs are able to cause hypersensitivity reactions alone, and in the case of allopurinol impaired renal function is an important risk factor. Although the validity of these reactions is unclear, vigilance of hypersensitivity reactions is advisable.

ACE inhibitors and clozapine

The atypical antipsychotic clozapine has been reported to interact with ACE inhibitors. Cases of syncope have been reported, with symptoms being seen within 5 hours of taking a dose. A patient on clozapine started on lisinopril had marked increases in clozapine levels. Behavioral changes were exhibited, including increasing disorganization, angry outbursts, and irritability. Sleep disturbances (frequent waking and nightmares) occurred, and the patient developed sialorrhea. Raised levels of the metabolite of clozapine (norclozapine) indicate possible impairment of renal excretion. After switching from lisinopril to diltiazem, clozapine concentrations decreased, as did sleep disturbances and irritability.⁴⁸

ACE inhibitors and antacids

Antacids are suggested to reduce the absorption of ACE inhibitors, and captopril, enalapril, and fosinopril are named in the British National Formulary. Although pharmacokinetic studies do show reduced bioavailability of both captopril and fosinopril in the presence of aluminium- and magnesium-based antacids, there is no evidence that the blood pressure effect of these agents was impaired, and it seems likely that any interaction is clinically unimportant.

ACE inhibitors and loop diuretics

The administration of an ACE inhibitor to patients prescribed loop diuretics is widely known to increase the risk of profound hypotension after the first dose. This effect is exacerbated by patient factors such as heart failure, renovascular hypertension, dialysis, and diarrhea and vomiting. Doses of 80 mg of furosemide (or higher) are a particular risk. Temporary withdrawal or reduction in the dose of diuretic will also reduce the potential for this interaction. If this regimen is not possible, doses of ACE should be given under close supervision. The hypotension is thought to occur

because of diuretic-induced hypovolemia, exaggerating the hypotensive effect of the ACE inhibitor.

ACE inhibitor renal impairment can be potentiated by loop diuretics,⁴⁹ and in 10 cases of renal deterioration linked to enalapril use 9 were linked to concurrent loop- or thiazides- use.⁵⁰ This underlines the importance of monitoring renal function in patients taking these drugs together.

ACE inhibitors and potassium-sparing diuretics

Due to the potassium-sparing nature of ACE inhibitors, clinicians have generally avoided prescribing these agents with potassium-sparing agents. Serious hyperkalemia is common, particularly in older people. Patients can exhibit severe symptoms of hyperkalemia, including heart block and ventricular fibrillation (and deaths have been reported). Cases have been reported with both spironolactone and other potassium-sparing drugs, such as amiloride. The increasing use of the aldosterone antagonist spironolactone in heart failure means that this combination is increasingly prevalent. Although the low-dose (25 mg) spironolactone prescribed in heart failure did not show significant increases in the incidence of hyperkalemia in the initial clinical trial,⁵¹ evidence has been accumulating that the real-world use of low-dose spironolactone carries a significant risk of hyperkalemia.^{52,53} The risk of hyperkalemia is also seen with eplerenone, which had a statistically significant increase in cases of hyperkalemia compared to placebo when used in heart failure,⁵⁴ and which has been advocated for use in low-renin hypertension.⁵⁵ Doses of spironolactone used to treat Conn's syndrome (between 100 and 400 mg) should not be used with ACE inhibitors.

Another area of controversy is whether ACE inhibitors can interfere with hypoglycemic agents such as the sulfonylureas and insulin. The evidence consists of varied case reports of hypoglycemia, some of which are significant. However, an interaction is not firmly established. Given the potential benefits of ACE inhibition, withholding ACE inhibitors is not necessary. Patients should be warned that such interactions are rare but should be watched for. Patients affected may be managed by reducing the dose of the hypoglycemic agents.

Angiotensin II receptor antagonists

Angiotensin II receptor antagonists share some common attributes with ACE inhibitors. Although their adverse effects are considered negligible by some commentators, they do share the potential for some similar interactions seen with ACE inhibitors. As would be expected, enhanced hypotensive effects will be seen when these are used in combination with other antihypertensive agents.

There have been case reports of lithium intoxication occurring in patients following the addition of candesartan,⁵⁶ losartan,⁵⁷ or valsartan⁵⁸ to their therapy. The mechanism may be similar to that for ACE inhibitors.

The potassium-retaining properties of angiotensin II receptor antagonists also mean that there is a potential for hyperkalemia with other potassium-retaining drugs. As with ACE inhibitors, concomitant ciclosporin use may increase

the risk of hyperkalemia. Care should also be taken when ciclosporin is used with diuretics to avoid hypotensive episodes.

An area of concern has been over the use of angiotensin II receptor antagonists with beta-adrenoreceptor antagonists and ACE inhibition. In the ValHeFT study, valsartan was added to standard therapy and reduced the combined endpoint of death or hospitalization for heart failure.⁵⁹ Patients taking valsartan with both an ACE inhibitor and a beta-adrenoreceptor antagonist appeared to have a reduced survival, although some caution is advocated with such subgroup analyses. The CHARM-Added trial used candesartan with ACE inhibition and showed a reduction in cardiovascular events⁶⁰ even in those taking beta adrenoreceptor antagonists.

Losartan may interact with ritonavir and nelfinavir, which may inhibit CYP2C9 metabolism and lead to increased plasma concentrations of losartan. Rifampicin's induction of the P450 isoenzymes CYP2C9 and CYP 3A4 is thought to be behind reduced losartan concentrations and an attenuation of the antihypertensive effect of losartan.

Indometacin use has been shown to attenuate the antihypertensive effect of losartan, candesartan, and valsartan. However, no evidence exists that aspirin has this effect. As with ACE inhibitors, an increased risk of renal effects is possible when angiotensin II receptor antagonists are given with NSAIDs and aspirin in doses above 300 mg.

Calcium-channel-blocking agents

This structurally varied group of drugs primarily acts on L-type Ca^{2+} channels in the tissues. Although the calcium-channel-blocking agents have common effects, they bind to distinct yet allosterically interacting receptors in the L-type Ca^{2+} channel—leading to differences in pharmacologic activity. This variation in activity is due to differences in specific tissues' reliance on exogenous Ca^{2+} , varied affinities of L-type Ca^{2+} channels to particular calcium-channel-blocking agents, and the varied distribution of those channels in body tissues. This is of importance when considering possible interactions.

The calcium-channel-blocking agents significantly vary in their cardio-depressant effects. The phenylalkylamine verapamil, and the benzothiazepine diltiazem to a lesser extent, have significant cardio-depressant effects—making them more likely to be involved in pharmacodynamic interactions with other hypertensive agents. This effect is largely absent in the dihydropyridine calcium antagonists such as nifedipine, which have no significant effects on the atrio-ventricular node.

The dangers of combining beta-adrenergic receptor agents and calcium-channel-blocking agents have been covered already in this chapter, but interactions can occur with other cardiovascular agents. The combination of verapamil or diltiazem with amiodarone is advised against on a theoretical basis because of the additive effects of the drugs on myocardial contractibility and on the atrioventricular node, although one case of sinus arrest and hypotension with combined amiodarone and diltiazem has been reported.⁶¹ Dihydropyridine calcium channel antagonists such as nifedipine and amlodipine should pose little risk.

A combined effect of digoxin and calcium-channel-blocking agents on the atrio-ventricular node is possible, although usually concern is focused on the effect of calcium-channel-blocking agents on digoxin serum levels. Verapamil is a particular concern and has been the cause of a number of deaths. The addition of verapamil to a patient previously stable on digoxin can cause severe (40 to 80% depending on the dose of verapamil) increases in serum digoxin concentrations over short periods (within 2 to 7 days), with patients exhibiting marked digoxin toxicity. Pre-emptive digoxin dose reduction by up to 50% is advocated by some. The proposed mechanism is reduced renal and biliary clearance of digoxin. Diltiazem can cause similar rises, although changes are more inconsistent. Care should be taken in patients with pre-existing renal conditions or serum digoxin concentrations at the higher end. Felodipine, nisoldipine, lacidipine, and nicardipine may produce clinically unimportant increases. Amlodipine and nimodipine do not interact.

As well as interactions involving the cardio-depressant activity of calcium-channel-blocking agents, interactions can also occur because calcium-channel-blocking agents are hepatically metabolized by the P450 cytochrome isoenzyme system. Their clinical effect can be reduced or increased by inhibitors and inducers, depending on the interacting drug present.

Ankle swelling is a well-known adverse effect of the dihydropyridine calcium channel blockers and may be aggravated by azole antifungals such as fluconazole and itraconazole. Case reports have been seen with felodipine, nifedipine, and isradipine. The mechanism is thought to be inhibition of the P450 CYP3A isoenzymes in the gut wall, which are involved in the metabolism of calcium-channel-blocking agents. Dosage reductions may be necessary.

P450 CYP3A isoenzymes are also thought to be involved in an interaction between felodipine and erythromycin. A treatment dose of erythromycin given to healthy volunteers taking felodipine showed significantly increased concentrations of felodipine. There is no evidence of a similar reaction with other calcium-channel-blocking agents.

Verapamil, diltiazem, and most dihydropyridine-type calcium-channel-blocking agents are CYP3A4 substrates that can lead to reductions in plasma concentrations of calcium-channel-blocking agents or an increase in plasma concentration of competing substrate. Amlodipine may be an exception, with no clinical relevant interactions related to CYP3A4.

Grapefruit juice is a CYP3A4 inhibitor that can have major effects on the bioavailabilities of felodipine, nicardipine, nifedipine, nimodipine, nisoldipine, nitrendipine, and also amlodipine to a lesser extent. There is no evidence that diltiazem is affected. Management can involve either a down-titration of the dose of the calcium antagonist or the cessation of grapefruit juice drinking. Patients who complain of adverse drug reactions linked to raised doses of calcium channel blockers should be asked questions about their diet. Felodipine may interact,⁶² but amlodipine appears to have no significant reaction.⁶³

Diltiazem and nifedipine serum concentrations are increased when given with cimetidine. Recommended

dosage reductions are 30 to 35% with diltiazem and 40% with nifedipine. The mechanism is inhibition of oxidative metabolism in the liver. Although other calcium channel blockers may interact, the interaction is thought to be clinically insignificant.

Calcium channel blockers have been reported to interact with statins. Both diltiazem and verapamil have been implicated as increasing the risk of muscle breakdown with both atorvastatin and simvastatin.⁶⁴ There is also an increased risk of myopathy with simvastatin if given with verapamil. Diltiazem, isradipine, and verapamil inhibit cytochrome P450 isoenzyme CYP 3A4, which is involved in the metabolism of atorvastatin, simvastatin, and lovastatin. Fluvastatin and pravastatin are not significantly metabolized by this isoenzyme.

The calcium-channel-blocking agents have significant interactions with ciclosporin. Verapamil, diltiazem, and nifedipine all increase ciclosporin concentrations. At the same time, they are thought to have a renoprotective effect and contribute to immunosuppression. Dose reductions of between 30 and 60% may be required with diltiazem, and both verapamil and nifedipine have both doubled or tripled serum ciclosporin concentrations in transplant patients. Although careful monitoring should be undertaken, this interaction has also been exploited in order to reduce the costs of ciclosporin therapy.⁶⁵

Nifedipine, amlodipine, and felodipine are less likely to interact. Isradipine, lacidipine, and nitrendipine appear not to.

The plasma concentration of tacrolimus is possibly increased by felodipine, and is increased by diltiazem and nifedipine. The mechanism is thought to be inhibition of P450 isoenzyme CYP3A4 and glycoprotein. Knowledge about other calcium channel blockers is limited, but tacrolimus levels should be monitored closely and dosages adjusted if necessary.

Anticonvulsants are a particular problem with calcium-channel-blocking agents, which can undermine epilepsy treatment and in turn have their own effects attenuated by anticonvulsants. Carbamazepine concentrations can be significantly increased, causing toxicity (by diltiazem use)—although nifedipine and amlodipine appear to be

safe alternatives. Alternatively, the dose of carbamazepine may be halved. Verapamil has a similar effect on carbamazepine. Elevated phenytoin levels have been reported with diltiazem, and in one case with nifedipine. Retrospective studies appear to suggest that nifedipine's interaction with phenytoin may be rare.

The anticonvulsants carbamazepine, phenobarbital, and phenytoin can all reduce felodipine and nimodipine levels. Phenobarbital and phenytoin can also reduce verapamil levels. Increased doses of calcium-channel-blocking agents may be required in epileptic patients.

Rifampicin increases the metabolism of some calcium-channel-blocking agents in the gut wall. These agents can become therapeutically ineffective unless dosages are increased. The main drugs of concern are nifedipine, verapamil, and to a lesser extent diltiazem. Evidence for other calcium-channel-blocking agents is more limited.

Coadministration of ritonavir and indinavir with either amlodipine or diltiazem can cause sharp increases in the plasma concentrations of the calcium-channel-blocking agents. If co-prescribed, lower initiation doses should be used.

SUMMARY

As prescribing increasingly becomes electronic, so decision support networks alert the prescriber to the possibility of an interaction occurring. All too often interactions are noted that have no practical significance.⁶⁷

Drug interactions are common. Although the easiest way to avoid such interactions would be use of monotherapy, as target blood pressures continue to drop so the need for multiple antihypertensive agents is increased. Unfortunately, with an aging population there is also an increased risk of co-morbidities also requiring treatment. As more medications become available and more conditions are deemed preventable or treatable, so the patient's prescription list continues to lengthen. Drug interactions are of increasing importance, and their adverse effects are a significant cause for hospitalization. Increasing awareness of drug interactions will obviously help to prevent such problems.

Lipid-Lowering Therapy

Ian S. Young and Brona V. Loughrey

Key Findings

- Hyperlipidemia is a key risk factor for atherosclerosis, and elevated lipids should be treated in all patients at high risk of cardiovascular disease.
- The primary target in lipid management is low-density lipoprotein (LDL) cholesterol. Important secondary targets include high-density lipoprotein (HDL) cholesterol, non-HDL cholesterol, and triglycerides.
- A statin is the first-choice lipid-lowering agent for the overwhelming majority of patients.
- Combinations of lipid-lowering drugs may be required to achieve lipid targets in high-risk patients.

INTRODUCTION

The key pathophysiologic features of atherosclerosis are lipid deposition and inflammation within the arterial wall.¹ The majority of important cardiovascular risk factors operate by increasing one or both of these processes. Oxidation of lipids deposited within the arterial intima represents an important inflammatory stimulus, and thus prevention of lipid deposition provides a mechanism of inhibiting both of these pathways. Arterial wall lipids mainly derive from lipid circulating in serum, and it is not surprising that there is overwhelming evidence that serum lipids are strong independent risk factors for the development of cardiovascular disease.

LIPIDS AND VASCULAR RISK

An enormous body of clinical and experimental research unequivocally identifies elevated plasma cholesterol as a causative factor in the progression of atherosclerosis.² Many prospective epidemiologic studies have identified a strong correlation between total cholesterol and increased incidence of cardiovascular disease (CVD). In general, the greater the level of total cholesterol the greater the risk of CVD, with no clear lower limit for cholesterol below which CVD risk no longer falls. The risk of CVD begins to increase more steeply above a total cholesterol level of approximately 5.0 mmol/L (200 mg/dL).

Some epidemiologic studies have suggested that very low levels of cholesterol may be associated with an increase in total mortality, attributable to a greater risk of death from cancer and other noncardiovascular causes. However, it is now generally felt that low cholesterol is a

consequence of the biochemical acute phase response present in any severely ill patient rather than a cause of increased risk. Since about 80% of total cholesterol in serum is contained in the LDL fraction, it is not surprising that LDL cholesterol has a similar relationship with CVD risk as total cholesterol. In the case of LDL cholesterol, risk increases more steeply above a level of approximately 3.0 mmol/L (120 mg/dL), but again there is no clear lower limit for LDL cholesterol below which risk no longer decreases.

In contrast to total cholesterol, LDL cholesterol, and triglycerides, HDL cholesterol concentration has an inverse association with CVD. The anti-atherogenic properties of HDL have been accounted for by the involvement of HDL in reverse cholesterol transport. However, HDL has numerous functions independent from lipid metabolism, which are protective against atherogenesis (including anti-inflammatory properties and an ability to protect LDL against oxidation³).

Serum triglycerides have a much weaker relationship with CVD risk than total or LDL cholesterol. Indeed, epidemiologic studies have often failed to identify an association between elevated total plasma triglyceride concentrations with greater cardiovascular risk. In part, the difficulties encountered identifying a strong correlation between triglycerides and CVD are due to the wide fluctuations in triglyceride concentrations throughout the day, the heterogeneity of triglyceride-rich lipoproteins, and the inseparable correlations between triglycerides and other CVD risk factors. However, meta-analyses of population-based prospective studies carried out by Austin et al.⁴ conclusively identified raised triglyceride concentrations as a strong independent risk factor for CVD, estimating that raised triglyceride levels were associated with a 13% increase in CVD risk in men and a 37% increase in women following adjustment for confounding factors.

Triglycerides were found to have a strong inverse correlation with HDL-C, although the association between triglycerides and CVD was independent of this relationship. A more sophisticated approach to examining the physiologic impact of triglycerides is to analyze the individual triglyceride-rich lipoproteins (TRLs), which include a heterogeneous population of particles with wide-ranging atherogenic potential. Accumulating evidence suggests that elevated plasma triglycerides, in the form of TRL, are independent cardiovascular risk factors (with an atherogenic potential comparable to raised LDL⁵). TRL is a broad term encompassing chylomicrons, very low-density

lipoproteins (VLDL), and their partially metabolized remnant lipoproteins. In view of the strong relationships between lipids and cardiovascular risk outlined previously, it is not surprising that abnormal lipids are a major cause of vascular disease (with, for instance, more than 30% of myocardial infarctions in hypertensive patients being explained by total cholesterol above 200 mg/dL).

CAUSES OF DYSLIPIDEMIA

Elevated lipid levels are mainly due to a combination of lifestyle and genetic factors. More than 50% of adults in most Western societies have a total cholesterol level above 200 mg/dL, reflecting a lifetime of a relatively high-fat diet along with a high prevalence of overweight and obesity and too little exercise. The genetic contribution to dyslipidemia most commonly takes a polygenic form, but there are several well-defined dyslipidemic conditions with a much stronger genetic contribution. The most important of these is familial hypercholesterolemia, a condition with an autosomal dominant pattern of inheritance due to a defect in the LDL receptor or apoB genes.

Familial hypercholesterolemia affects approximately one in five hundred individuals in most Western countries and if untreated is associated with a high incidence of premature cardiovascular disease. It should be suspected in families with a strong history of coronary heart disease affecting individuals aged less than 60 years.⁶ Testing is most easily done by measuring total and LDL cholesterol in family members, but increasingly genetic testing is also available. Type III hyperlipidemia should be suspected in individuals with markedly elevated cholesterol and triglycerides. It is associated with the apoE phenotype E2/2. Other inherited diseases of lipid metabolism are less common.

Dyslipidemia is also a secondary feature of other medical conditions and it is important to consider testing for these in hyperlipidemic individuals. Undiagnosed hypothyroidism is a particular pitfall, and is associated

with increased total cholesterol. Any decision about treating the cholesterol level should be deferred until normal thyroid function is restored. Fasting glucose should always be measured in individuals with high triglycerides, as the incidence of undiagnosed diabetes in this population is relatively high. Other conditions that may be associated with dyslipidemia include obesity, alcohol abuse, renal disease (particularly nephrotic syndrome), liver disease (especially cholestatic liver disease), and the use of certain drugs.

MECHANISMS OF ACTION

To understand the mechanisms of action by which pharmacologic agents reduce cholesterol it is first necessary to understand the main pathways of lipid metabolism.⁷ The main lipids present in serum are cholesterol and triglycerides, with smaller amounts of phospholipids and free fatty acids. Cholesterol is in the form of free cholesterol or cholesterol esterified to fatty acids. The vast majority of serum lipids are present in particles known as lipoproteins, which also include proteins known as apolipoproteins. The arrangement of lipids in lipoproteins follows a common pattern, with particles containing more hydrophobic lipids such as triglycerides and cholesterol esters in their core, with more hydrophilic lipids (free cholesterol and phospholipids) on the outside.

The amount of lipid differs significantly between different particles, with the largest particles (chylomicrons) containing most lipid and the smallest particles (high-density lipoproteins) containing the least (Table 88–1). In contrast, apolipoproteins differ between lipoprotein classes and determine the metabolic fate of lipoprotein particles by acting as receptor ligands or by activating or inhibiting enzymes involved in lipid metabolism. The key properties and features of different lipoproteins are summarized in Table 88–2. Lipid metabolism can be considered according to three main mechanisms:⁷ the exogenous pathway, the endogenous pathway, and reverse cholesterol transport.

CLASSIFICATION OF LIPOPROTEINS ^a			
Lipoprotein	Density (g/mL)	Mean Particle Diameter (nm)	Electrophoretic Mobility
Chylomicrons	<0.95	500	Origin
Very-low-density lipoproteins (VLDLs)	0.95–1.006	43	Pre-beta
Intermediate-density lipoproteins (IDLs)	1.006–1.019	27	Beta-1
Low-density lipoproteins (LDLs)	1.019–1.063	22	Beta
High-density lipoproteins (HDLs)	1.063–1.21	8	Alpha

a. Particle density increases and particle size decreases from chylomicrons to HDL. Agarose electrophoresis separates lipoproteins according to their characteristic electrophoretic mobility and is determined by particle charge and size.

Table 88–1. Classification of Lipoproteins^a

APOLIPOPROTEIN FUNCTIONS AND ASSOCIATED LIPOPROTEINS ^a		
Apolipoprotein	Main Functions	Associated Lipoprotein
Apo AI	Ligand for HDL, cofactor for lecithin cholesterol acyl transferase	Chylomicrons, HDL
Apo AII	Ligand for HDL, cofactor for lecithin:cholesterol acyltransferase	Chylomicrons, HDL
Apo AIV	Ligand for HDL, activates lecithin cholesterol acyl transferase	Chylomicrons, HDL
Apo (a)	Provides structural integrity for Lp(a)	Lp(a)
Apo B ₄₈	Provides structural integrity for chylomicrons	Chylomicrons
Apo B ₁₀₀	Provides structural integrity for VLDL, IDL, and LDL; ligand for LDL receptor	VLDL, IDL, LDL
Apo CI	Activates lecithin cholesterol acyl transferase, activates lipoprotein lipase	Chylomicrons, VLDL, IDL, HDL
Apo CII	Activates lecithin cholesterol acyl transferase, activates lipoprotein lipase, inhibits lipoprotein lipase	Chylomicrons, VLDL, IDL, HDL
Apo CIII	Inhibits hepatic lipase, modulates uptake by lipoprotein related receptor (via binding to proteoglycans)	Chylomicrons, VLDL, IDL, HDL
Apo D	Unknown	HDL
Apo E	Ligand for Apo B/E receptor, Apo E2 receptor, and lipoprotein-related receptor	Chylomicrons, VLDL, IDL, LDL
Apo J	Implicated in cell membrane protection	HDL

a. Apolipoprotein composition is important for the characterization of plasma lipoproteins. In addition to providing structural integrity, these apolipoproteins are implicated in lipoprotein transport and enzyme activity.

Table 88-2. Apolipoprotein Functions and Associated Lipoproteins^a

Exogenous lipid metabolism

Dietary lipids are absorbed by the mucosal cells of the intestine, which re-esterify cholesterol and free fatty acids to produce triglycerides and cholesterol esters. These lipids, along with phospholipids and unesterified cholesterol, are packaged together with apo B₄₈ to form the largest triglyceride-rich lipoproteins (nascent chylomicrons). Chylomicrons are characterized by the presence of apo B₄₈, which is a low-molecular-weight form of apo B₁₀₀. This apoprotein is specifically produced by the intestine⁸ and only contains residues 1 through 2152 (48%) of apo B₁₀₀, thus preventing chylomicrons from interacting with the LDL receptor.

Nascent chylomicrons are rapidly metabolized following their secretion into the general circulation. An exchange of apoproteins occurs between chylomicrons and HDL, and the chylomicrons acquire apo C and E apoproteins in exchange for apo A proteins. Chylomicron remnants become relatively deplete in triglycerides due to the hydrolysis of the particles' triglyceride core by lipoprotein lipase, an enzyme anchored to the endothelium. In addition, cholesterol ester is transferred from mature HDL to the chylomicrons in exchange for triglyceride by cholesteryl ester transfer protein (CETP)⁹.

Chylomicron remnants are rapidly cleared from the circulation by hepatic receptors specific for apo E. The exogenous pathway efficiently delivers triglyceride to skeletal muscle and adipose tissue and deposits chole-

sterol for processing in the liver. Chylomicrons are normally undetectable following a 12-hour fast.¹⁰

Endogenous lipid metabolism

Fatty acids surplus to oxidative requirements are utilized by the liver for the synthesis of triglyceride and phospholipid. Cholesterol can also be produced endogenously by a pathway that includes the rate-limiting enzyme β -hydroxy- β -methylglutaryl-coenzyme. A reductase (HMG CoA reductase), subject to positive inhibition by the end product (cholesterol). Although the liver has the capacity to synthesize cholesterol and triglyceride, it is more efficient to utilize preformed lipids derived from the diet or excess stores in adipose tissue.

In the fasting (postabsorptive) state, VLDL replaces chylomicrons as the most abundant triglyceride-rich lipoprotein and the metabolism of VLDL is similar to that of chylomicrons. The liver packages triglyceride, cholesterol, cholesterol ester, and phospholipid together with C apoproteins, apo B₁₀₀, and apo E to form nascent VLDL (which is secreted into the bloodstream). Similarly to chylomicrons, nascent VLDL becomes relatively deplete in triglycerides following its interaction with lipoprotein lipase and cholesterol ester transfer protein. The particle also sheds apo C and E proteins to produce a "VLDL remnant" known as intermediate-density lipoprotein (IDL). Unlike chylomicron remnants, IDL can be taken up by the liver or may undergo further delipidation and loss of apoproteins to yield LDL.

The VLDL class encompasses an extremely heterogeneous population of lipoprotein particles that differ in size (80 to 1200 nm), composition, and metabolic fate. Large buoyant VLDL tends to be metabolized to IDL, which is subsequently cleared via apo B/E receptor-mediated uptake in the liver.¹¹ Conversely, smaller VLDL particles complete the metabolic cascade by producing IDL which ultimately yields LDL. LDL is removed by apo B₁₀₀ receptor-mediated uptake in the liver, although LDL can also be utilized by extrahepatic tissue to provide cholesterol for normal cellular functions.

Reverse cholesterol transport

Reverse cholesterol transport incorporates HDL metabolism and involves the movement of cholesterol from extrahepatic tissue, including the vessel wall, to the liver for excretion.¹² The HDL lipoproteins are the smallest and most dense lipid particles. This heterogeneous population can be divided into two subclasses by ultracentrifugation: HDL₂ (1.063 to 1.125 g/mL) and HDL₃ (1.125 to 1.21 g/mL). Plasma concentrations of the HDL₃ subclass are more abundant than HDL₂ (3:1). The major apoprotein constituents of HDL are the A apoproteins (AI, AII, AIV), which are responsible for modulating HDL metabolism. The A apoproteins function as acceptors of cellular cholesterol (LCAT), serve as cofactors for lecithin cholesterol acyl transferase, and act as ligands for HDL receptors.

The liver and intestine synthesize and secrete nascent discoid HDL, which consists mainly of apo E, apo Cs,

phospholipids, and free cholesterol. The particle acquires apo A proteins, which provides the lipoprotein with the capacity to utilize LCAT and adenosine triphosphate-binding cassette protein A1 (ABCA-1). This transporter protein regulates the concentration of plasma HDL and the levels of intracellular cholesterol. The ABCA-1 transporter protein facilitates the efflux of intracellular cholesterol through an interaction with apo AI on lipid-deplete HDL. Following this, LCAT catalyzes the esterification of HDL cholesterol (and the hydrophobicity of the sterol-ester results in its relocation from the surface of the lipoprotein to the hydrophobic core of the particle). The surface of HDL is available to accept more free cholesterol, forming mature spherical HDL particles.

In addition, HDL functions as a chaperone for the transfer of cholesterol ester to the liver. The scavenger receptor class B1 (SR-B1) modulates the selective uptake of HDL cholesterol ester by hepatocytes. HDL complexes with SR-B1 and is endocytosed. Cholesterol ester is hydrolyzed by cholesterol ester esterase and secreted as biliary cholesterol or utilized to produce steroid hormones. The SR-B1 receptor is distributed predominately on hepatocytes, but SR-B1 is also expressed on macrophages (where it may influence cholesterol efflux). Alternatively, CETP promotes the transfer of cholesterol ester from HDL to the apo-B-containing lipoproteins in exchange for triglyceride, yielding a small and more dense HDL particle.

MECHANISMS OF ACTION AND PHARMACOKINETICS OF INDIVIDUAL DRUG CLASSES

Statins

The first drug of this class, lovastatin, went on the United States market in 1987 and since then statins have come to dominate the field of lipid-lowering therapy. Statins are competitive inhibitors of the enzyme hydroxymethylglutaryl coenzyme A (HMG CoA) reductase, which catalyzes the formation of mevalonate from HMG CoA¹³ (Figure 88-1). This is the rate-limiting step on the biosynthetic pathway of cholesterol in the liver. The affinity of statins for this enzyme is several thousand times that of its physiologic substrate, although this inhibition is partly offset by increased expression of HMG CoA reductase. Reduction of endogenous cholesterol synthesis leads to upregulation of the LDL receptor. Consequently, there is increased hepatic uptake of apoB-containing lipoproteins (especially LDL) and a reduction in the corresponding circulating cholesterol fractions. Triglycerides are reduced to a lesser extent. There is also a modest increase in HDL by a mechanism that is not well understood at present.

There are now several of this class of drug available, all given by mouth once daily (although the recommended dosages vary;¹⁴ Table 88-3). Cholesterol-lowering potency has increased as newer agents have been developed. Lovastatin and simvastatin are pro-drugs, whereas pravastatin, fluvastatin, atorvastatin, and rosuvastatin are active in themselves. All undergo hepatic first-pass metabolism, as is appropriate for drugs whose main

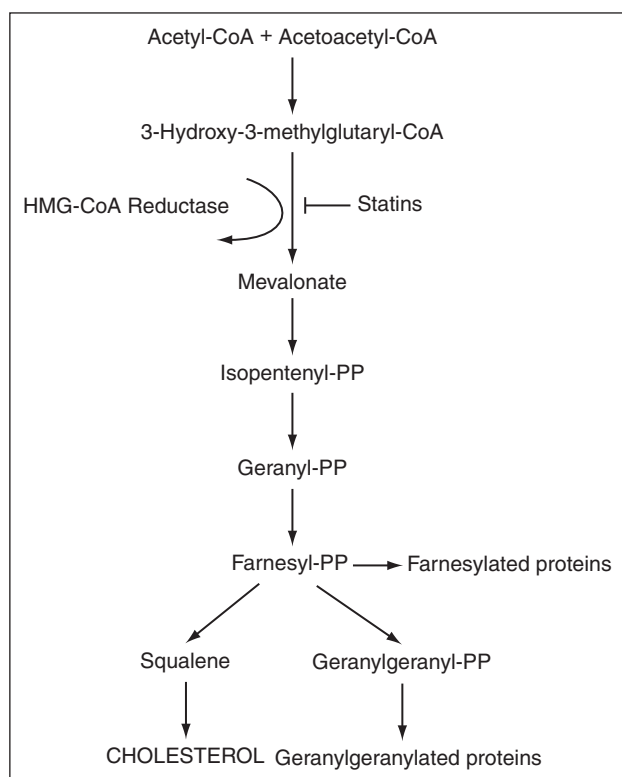

Figure 88-1. Cholesterol synthesis pathway showing point of action of statins. The synthesis of all intermediates distal to this point in the pathway is reduced.

TABLE 88-3

Drug	Reduction in TC (%)	Reduction in LDL-C (%)	Increase in HDL-C (%)	Reduction in TG (%)	Dosage Form Tablets (mg)	Metabolism	Protein Binding, (%)	T 1/2, h	Hydrophilic
Atonvastatin	25-45	26-60	5-13	17-53	10, 20, 40, 80	CYP3A4	98	13-30	No
Fluvastatin	16-27	22-36	3-11	12-25	20, 40, 80	CYP2C9	98	0.5-3.0	No

Rosuvastatin	33-46	45-63	8-14	10-35	5, 10, 20, 40	CYP2C9	88	19	Yes
Simvastatin	19-36	26-47	8-16	12-34	5, 10, 20, 40, 80	CYP3A4	95-98	1-3	No

Abbreviations: TC (total cholesterol), TG (triglycerides), and T1/2 (half-life).

Table 88-3.

site of action is the liver in order to limit systemic side effects. Simvastatin and atorvastatin are substrates of the cytochrome P450 isoenzyme CYP3A4, which gives rise to the possibility of interaction with other drugs metabolized by this pathway (such as cyclosporin and macrolide antibiotics). The newest agent, rosuvastatin, is partly metabolized by CYP2C9 (and there are reports that it can increase the anticoagulant activity of warfarin).

Fibrates

The fibrates have been in use as lipid-lowering agents for many years. Whereas the main target of statins is LDL, fibrates have more broadly beneficial effects on triglycerides and HDLc as well as modest LDLc-lowering effects. Clofibrate was the original member of this class, which now includes ciprofibrate, bezafibrate, fenofibrate, and gemfibrozil¹⁵ (Table 88–4).

Administration of fibrates results in a decrease in circulating VLDL and LDL and an increase in HDL. The exact mechanisms underlying these effects are complex and still not well understood. What is known is that the fibrates are ligands for the peroxisomal-proliferator-activated receptor α (PPAR α).¹⁶ This is one of a family of nuclear thyroid or steroid hormone receptors that when activated act as transcription factors by binding to response elements on certain target genes. The many proteins whose expression is altered by PPAR α agonists include apolipoproteins, lipoprotein lipase, and other enzymes involved in fatty acid uptake and metabolism.

In general, the fibrates are well absorbed orally and may be given once daily or in divided doses. Some modified-release formulations are available. They are extensively protein bound in plasma and undergo metabolism by the cytochrome P450 system before being excreted by the kidneys. There are a number of significant interactions. They enhance the effects of anticoagulants and hypoglycemic drugs, and fenofibrate should not be given along with cyclosporin because of the risk of renal impairment.

Nicotinic acid (niacin)

As with the fibrates, the vitamin nicotinic acid has been available for many years. However, there is renewed interest in it recently with the increasing recognition of the importance of HDL in cardiovascular risk. It is currently the single best available agent for raising HDL, and it has

beneficial effects on LDL and triglycerides.¹⁷ These do not become apparent until a dose at least 50 times the recommended daily intake of the vitamin is given. It undergoes extensive first-pass metabolism, but this is saturable such that there is greater systemic bioavailability with higher doses. There is now a modified-release preparation available to avoid the previous need for divided doses. Again, the mechanisms of action are not straightforward, but at least two are known: inhibition of lipolysis in adipose tissue and reduction of hepatic uptake of HDL.

Ezetimibe

Ezetimibe, given in a dose of 10 mg once daily, selectively inhibits intestinal cholesterol absorption. The main effect is a fall in circulating LDL, although there is also a small reduction in triglyceride levels. The exact mechanism of action is as yet unknown, although it appears that ezetimibe acts via the Niemann-Pick C1-Like 1 (NPC1L1) protein.¹⁸ It has few side effects or contraindications, and has no known significant interactions, although at present coadministration with fibrates is not recommended due to a theoretical increased risk of hepatobiliary disease.¹⁹ It is best used as an adjunct to statin therapy if targets are not achieved with monotherapy. A combined preparation of ezetimibe and simvastatin is now available.

Omega-3 fatty acids

A diet rich in oily fish is associated with a low incidence of cardiovascular disease even though the fat content is relatively high. Fish oil contains high levels of ω -3 fatty acids such as docosahexaenoic acid (DHA) and eicosapentaenoic acid (EHA), which when administered to humans lead to reduction in circulating triglycerides.²⁰ The exact mechanism behind this is not yet known, but it may be that they inhibit esterification and incorporation into VLDL of other fatty acids. They also appear to exert an antiarrhythmic effect on the myocardium. The maximal effect of fish oil is at a dose far beyond that which can be incorporated into even the most health-conscious Western diet, and there are supplements now available by prescription. The biggest problem with prescribing these is patient compliance, as the capsules are large and need to be taken several times daily for the treatment of hypertriglyceridemia.

PHARMACOKINETIC PROPERTIES OF FIBRATES					
Drug	Bezafibrate	Ciprofibrate	Clofibrate	Fenofibrate	Gemfibrozil
Oral bioavailability (%)	100	75	100	60	100

Route of elimination	Renal (unchanged)	Renal	Renal (metabolites)	Renal (glucuronide)	Renal (glucuronide)
Abbreviation: t _{1/2} = half-life.					

Table 88–4. Pharmacokinetic Properties of Fibrates

Plant stanols and sterol esters

Stanols are hydrogenated derivatives of plant sterols, which are components of plant cell membranes. These resemble cholesterol in structure and competitively inhibit intestinal absorption of cholesterol.²¹ Margarines and other preparations containing plant stanols are available in supermarkets as an aid to cholesterol reduction.

Resins

Colestyramine and colestipol were among the first available lipid-lowering agents. These are orally active anion-exchange resins that bind and prevent the reabsorption of bile salts in the gut.²² This impairs fat absorption and leads to increased uptake of circulating cholesterol by the liver for the synthesis of more bile acids. There is also, however, a compensatory increase in endogenous cholesterol synthesis by the liver such that the net fall in serum cholesterol is not as great as with other hypolipidemic drugs. Some patients also show increased hepatic triglyceride output. Poor palatability, frequent gastrointestinal side effects, and limited efficacy mean that the resins are no longer widely used.

INDICATIONS/CONTRAINDICATIONS AND OBJECTIVES

The main indication for the use of lipid-lowering therapy is to reduce risk of cardiovascular disease. Therapy is therefore indicated for any individual at significant risk of cardiovascular disease whose serum lipids are above target levels. The primary targets for lipid-lowering therapy are total and LDL cholesterol, but treatment goals for HDL cholesterol, triglycerides, and non-HDL cholesterol may also be considered. In practice, CVD prevention should focus on people with any form of established atherosclerotic CVD, people with diabetes mellitus, or people without established CVD but who have a combination of risk factors that puts them at high total risk of developing CVD for the first time.

In addition, certain individuals with particularly elevated single risk factors also require CVD prevention. This is likely to include individuals with elevated blood pressure >160 mmHg systolic or >100 mmHg diastolic, or lesser degrees of blood pressure elevation with target organ damage. Individuals with an elevated total: HDL cholesterol ratio of >6.0 or with an inherited dyslipidaemia will also generally require lipid-lowering treatment.²³ Individuals at high risk of CVD require a multifactorial approach to risk factor management, of which treatment for serum lipids will constitute only one part. Risk factor management will include both lifestyle change and pharmacologic management.

ESTIMATION OF TOTAL CARDIOVASCULAR RISK

The concept of using total cardiovascular risk to determine the need for lipid-lowering therapy in the asymptomatic population is widely accepted in Europe, the United States, and internationally. A variety of risk

prediction engines are used, most frequently based on the Framingham study. The level of total CVD risk at which lipid-lowering treatment is considered justified varies from country to country. The main risk factors taken into account include age, sex, smoking status, total to HDL cholesterol ratio, and blood pressure.

The advantages of this approach are that the total effect of risk factors acting on an individual can be taken into account when making treatment decisions, and that unnecessary treatment of single risk factors in individuals at overall low risk can be avoided. In the UK, risk tables are used, which are color coded to represent total CVD risk as low, medium, or high. In the United States, a scoring system based on the Framingham offspring study is used in conjunction with the National Cholesterol Education Program (NCEP) ATP III recommendations.²⁴

This predicts only risk of fatal and nonfatal myocardial infarction, the rationale being that this is closer to the endpoint used in the majority of large statin trials. The Joint European Societies' guidelines on CVD prevention use the Heartscore system, which has the advantage of being based on European prospective epidemiologic data.²⁵ Heartscore predicts fatal CVD risk rather than total CVD risk, and the risk threshold for treatment is therefore defined as >5% 10-year risk, rather than the 20% 10-year risk threshold used in the UK guidelines that employ total CVD risk.

TARGETS FOR TREATMENT

The primary targets for lipid-lowering therapy are total and LDL cholesterol. Relevant targets are defined in appropriate national and international guidelines, and are derived from intervention trials that have been predominantly carried out using statins. Older studies (4S,²⁶ WOSCOPS,²⁷ CARE²⁸) clearly demonstrated the value of reducing total and LDL cholesterol with statins. More recent studies have tended to focus on reducing total and LDL cholesterol to progressively lower levels. For instance, in the lipid-lowering arm of the ASCOT study (in which 10,305 subjects participated) a decrease in LDL cholesterol from 130 to 90 mg/dL reduced the primary endpoint of nonfatal myocardial infarction and fatal CHD by 36%.²⁹ In the CARDS trial, performed in subjects with diabetes and no previous history of cardiovascular disease, reduction in LDL cholesterol from 116 to 81 mg/dL produced a 37% reduction in major cardiovascular events.³⁰

Recent studies (including PROVE-IT³¹, IDEAL,³² and TNT³³) have also focused on comparing different statin regimes. For instance, in the PROVE-IT study pravastatin 40 mg per day was compared to atorvastatin 80 mg per day. Pravastatin 40 mg resulted in an LDL cholesterol level of 97 mg/dL compared with an LDL cholesterol level of 62 mg/dL in the atorvastatin 80-mg group. Reduction in LDL cholesterol to the lower level was associated with an additional 16% reduction in major CVD events.

Meta-analysis of the major statin trials demonstrates an essentially linear relationship between the degree of total or LDL cholesterol reduction and reduction in CVD events.³⁴ The reduction in CVD events is largely inde-

pendent of the starting cholesterol level, so that a reduction in LDL cholesterol of 40 mg/dL produces a reduction in CVD events of approximately 23%. Furthermore, there is no clear evidence for a lower level of total or LDL cholesterol below which CVD risk does not fall.

The selection of appropriate targets for total and LDL cholesterol therefore depends on a synthesis of the available evidence. Current European guidelines recommend a target of less than 174 mg/dL (4.5 mmol/L) for total cholesterol and less than 97 mg/dL for LDL cholesterol.²⁵ UK guidelines recommend that total cholesterol should be reduced to less than 155 mg/dL or by 25% (whichever is greater) and that LDL cholesterol should be reduced to less than 78 mg/dL or by 30%, whichever is greater.²³ The NCEP ATP III guideline (revised in 2004) recommends that LDL cholesterol should be less than 70 mg/dL in high-risk individuals.²⁴

Although the main target for lipid-lowering treatment should clearly be total and LDL cholesterol, it is also worth considering other lipid targets. These include targets for HDL cholesterol, triglycerides, and non-HDL cholesterol. Measures to achieve such targets should be taken once targets for total and LDL cholesterol have been achieved. As discussed previously, epidemiologic evidence suggests that CVD risk is particularly elevated in men with HDL cholesterol less than 40 mg/dL and women with HDL cholesterol less than 50 mg/dL. In addition, triglycerides above 65 mg/dL appear to be associated with increased CVD risk. Elevated triglycerides and low HDL cholesterol tend to go together, and are particularly common in patients with the metabolic syndrome or type 2 diabetes. Such individuals also have a preponderance of small dense LDL particles of increased atherogenicity.³⁵

In general, most guidelines do not recommend specific targets for HDL cholesterol or triglycerides. This is because there is a lack of studies with clinical endpoints that have specifically altered HDL cholesterol or triglycerides independently of other lipids. Fibrates and nicotinic acid are the drugs most commonly used to lower triglycerides and increase HDL cholesterol. Studies using fibrates (e.g., VA-HIT,³⁶ FIELD³⁷) and nicotinic acid (e.g., Coronary Drug Project³⁸) have demonstrated a reduction in coronary heart disease events. However, LDL and total cholesterol were also lowered in these trials and it is difficult to attribute the reduction in events unequivocally to changes in particular lipids.

On balance, it seems reasonable to consider measures to increase HDL cholesterol or reduced triglycerides in individuals in whom levels remain undesirable after total and LDL cholesterol targets are achieved. This may be particularly appropriate in younger individuals at very high risk. It is likely that future trials will attempt to specifically address the value of raising HDL cholesterol using new pharmacologic agents.

Non-HDL cholesterol (total cholesterol minus HDL cholesterol) includes all cholesterol contained in apolipoprotein particles (LDL particles and triglyceride-rich lipoproteins). Non-HDL cholesterol therefore contains all of the pro-atherogenic lipoproteins and has the advantage that it can be measured in nonfasting samples. An

appropriate target for non-HDL cholesterol is less than 130 mg/dL.

LIPID-LOWERING INTERVENTIONS

Lifestyle and diet

Having identified individuals at high CVD risk using appropriate national or international guidelines, initial lifestyle interventions to improve the CVD risk profile are recommended. These should include interventions to promote smoking cessation, optimal control of hypertension, and treatment of diabetes. Such advice should be given to all individuals at high CVD risk. This will include measures to promote weight loss where appropriate. In reference to dyslipidemia, specific advice should also be given to reduce total dietary fat to less than 30% of energy intake and to reduce the dietary cholesterol intake to less than 300 mg per day.²⁴

In addition, saturated fats should account for less than 10% of energy intake, and in order to achieve this saturated fats should be replaced by monounsaturated fats in the diet. At least five portions per day of fruit and vegetables should be recommended, along with regular intake of oily fish and other sources of omega-3 fatty acids (equivalent to at least two portions of oily fish per week).³⁹ Dietary advice should be accompanied by advice to carry out 30 minutes of aerobic exercise on most days of the week.

Lifestyle intervention of this type has the potential to reduce total and LDL cholesterol by approximately 10%, and to produce moderate increases in HDL cholesterol. There is significant variation in individual response to dietary intervention, and occasional individuals will achieve significantly greater cholesterol reduction. However, overall response to dietary intervention in terms of cholesterol reduction is usually insufficient to achieve targets and most individuals are likely to require pharmacologic treatment in addition to lifestyle intervention.

Incorporation into the diet of specific foodstuffs with lipid-lowering properties can produce greater effects. These include plant stanol and sterol esters, soluble fiber, and soy protein. A portfolio diet including a mixture of such active ingredients can produce an LDL cholesterol reduction of approximately 30%, equivalent to the starting dose of most statins.⁴⁰ However, long-term compliance with a diet of this type is likely to be acceptable to only a small minority of individuals.

Specific lipid-lowering agents

Statins

A statin is the first-choice lipid-lowering agent in the overwhelming majority of patients. As discussed previously, statins have consistently demonstrated across a wide variety of placebo-controlled clinical trials their ability to reduce total and LDL cholesterol and to prevent total and fatal cardiovascular disease events. Specifically, pravastatin, lovastatin, simvastatin, and atorvastatin have been used in clinical endpoint trials. Fluvastatin and rosuvastatin also reduce total and LDL cholesterol, and it is likely

that the reduction in LDL cholesterol is predictive of their clinical efficacy. Among other differences, the available statins differ in how effectively they reduce total and LDL cholesterol.

In practice, the choice of statin in individual patients is unlikely to matter significantly so long as appropriate reductions in total and LDL cholesterol are achieved. Any of the available statins will achieve a total and LDL cholesterol reduction of approximately 25%. In individuals in whom a larger reduction in total or LDL cholesterol is required to achieve target, one of the more effective statins (atorvastatin or rosuvastatin) is likely to be required. In any case, it is important to use an adequate dose of the chosen statin. If necessary, a low dose can be initiated and titrated up to achieve appropriate total and LDL cholesterol values. Using the highest doses of atorvastatin (80 mg) or rosuvastatin (40 mg), reductions in total and LDL cholesterol of more than 50% can be achieved.

In general, statins produce a similar degree of reduction in non-HDL cholesterol as in total and LDL cholesterol. Moderate reductions in triglycerides are also produced (10 to 30%), along with minimal increases in HDL cholesterol (0 to 10%). In patients who are unable to tolerate a statin as a result of side effects (see material following), it is usually necessary to use a combination of other lipid-lowering drugs. This would often include ezetimibe along with a fibrate or nicotinic acid in the first instance.

Fibrates

Fibrates may be used to lower triglycerides and to increase HDL cholesterol. They can also be used in combination with statins or other agents to provide additional reduction in LDL cholesterol. In most individuals with fasting triglycerides greater than 450 mg/dL, elevated total cholesterol is mainly due to cholesterol in the VLDL fraction. A fibrate is a suitable first-line lipid-lowering agent in this setting, and will typically achieve a triglyceride reduction of 30 to 50%. This will be associated with a decrease in total cholesterol (20 to 40%) and an increase in HDL cholesterol (5 to 15%). There is also likely to be a modest decrease in LDL cholesterol.

In patients who have already been treated with a statin, addition of a fibrate will further lower triglycerides and increase HDL cholesterol, and will provide a small additional decrease in LDL cholesterol. Fenofibrate has less potential than other fibrates to interact with statins, and is therefore the best fibrate to use in statin-fibrate combination therapy.

Nicotinic acid

In the pre-statin era, nicotinic acid was used as a total and LDL cholesterol-reducing agent. However, it is also the most effective drug currently available for increasing HDL cholesterol, and in addition lowers triglycerides significantly. Prolonged release forms of nicotinic acid are associated with reduced side effects (see material following), and are therefore preferred. Typical reductions in total cholesterol range from 5 to 15%, and LDL cholesterol from 5 to 20%.

Triglycerides are reduced from 10 to 40%, and HDL cholesterol increased from 15 to 30% (see Table 88-3). It is important to titrate the dose of prolonged-release nicotinic acid slowly upward in order to minimize the side effects, and a typical maintenance dose is 1000 to 2000 mg per day. Nicotinic acid is predominantly used in combination with a statin to provide additional LDL cholesterol reduction or to increase HDL cholesterol and reduced triglycerides once total and LDL cholesterol targets have been achieved.

Ezetimibe

Ezetimibe has become the lipid-lowering drug of choice to use in combination with a statin in patients who do not achieve total and LDL cholesterol targets on the maximum tolerated dose of the most effective statin. When added to a statin, ezetimibe produces an additional 15 to 25% reduction in total cholesterol and a 20 to 25% reduction in LDL cholesterol. There is a modest decrease in triglyceride of the order of 10%, and little change in HDL cholesterol. A single tablet combination of ezetimibe and simvastatin is available.

Omega-3 fatty acids

Omega-3 fatty acids are used predominantly to lower triglycerides in patients with severe hypertriglyceridemia. A dose of 2 g twice per day is normally required to produce significant triglyceride reduction. This is often used in addition to a statin fibrate combination in patients with severe hypertriglyceridemia. Triglyceride reductions of 10 to 20% usually result, and this may be associated with a small increase in LDL cholesterol.

Resins

Resins are most often used in patients unable to tolerate other lipid-lowering drugs. They provide effective reduction of total and LDL cholesterol, but their use may be associated with a small increase in triglycerides. Up to six sachets per day of cholestyramine or colestid are required for maximal effect.

Plant stanol and sterol esters

Stanol and sterol esters from plant sources can be incorporated into spreads or other food sources, and if 2 to 3 g per day are ingested a reduction in total and LDL cholesterol of about 10% can be achieved. This effect seems to be additional to the effect of most other lipid-lowering drugs, with the exception of ezetimibe.

COMPLICATIONS

In general, lipid-lowering treatment is safe and well tolerated. Some early studies suggested that very low levels of cholesterol were associated with an increased risk of cancer or death from accident/suicide as a result of altered neurologic function. However, subsequent large studies have not supported these suggestions.⁴¹ Epidemiologic studies consistently show that very low levels of cholesterol are associated with increased mortality from a variety of causes, but because cholesterol is a negative

acute phase reactant this is likely to be a consequence of underlying illness rather than implying any causative role for low cholesterol.

Statins

Overall, statins are safe and well-tolerated drugs. In placebo-controlled trials, withdrawal rates due to adverse events are typically between 2 and 5%. The most important statin-related side effects are disturbances of liver function tests and effects on skeletal muscle.⁴² Skeletal-muscle-related side effects of statins can be divided into two groups: myalgia (muscle aches or weakness without creatine kinase (CK) elevation) and myositis (muscle aches or weakness with a CK elevation).

Various lines of evidence confirm that the incidence of such side effects is very low. For instance, in the Heart Protection Study CK concentrations rose to between 4 and 10 times the upper limit of normal in 0.2% of the simvastatin 40-mg group compared with 0.13% of the placebo group. CK concentrations greater than 10 times the upper limit of normal occurred in 0.11% of simvastatin recipients versus 0.06% of placebo recipients.⁴³ Similar findings have been reported for most other statins. The most common statin-related muscular side effect is myalgia. Pooled data from 44 clinical trials in patients treated with various doses of atorvastatin reported an incidence of treatment-associated myalgia of 1.9% compared with 0.8% with placebo.⁴⁴ Again, similar figures have been reported for other statins.

The most serious presentation of statin-related myopathy is rhabdomyolysis, which involves severe skeletal muscle injury and cell death and is associated with dramatic elevations of CK, myoglobinuria, and renal insufficiency. The incidence of statin-associated rhabdomyolysis is probably about 1 per 100,000 prescriptions for all statins, with cases of fatal rhabdomyolysis having an incidence of less than one death per million prescriptions.

Myositis and rhabdomyolysis occur most frequently at higher statin doses for all statins. Other factors associated with an increased risk of statin-associated myopathy include age greater than 70, female sex, low body mass, multisystem disease (e.g., chronic renal insufficiency, heart failure), the perioperative period, and interactions with specific concomitant medications. The most important of these are listed in Box 88–1. In general, therefore, factors associated with increased circulating statin concentrations lead to an increased risk of muscle-related side effects. The risk of these can be minimized by using lower statin doses in these settings.

Opinion is divided as to whether it is advisable to monitor CK concentrations routinely in patients receiving statin treatment. There is not a good evidence base to guide this. Many clinicians will choose to measure CK at baseline before commencing treatment, and only to measure CK subsequently if the patient complains of relevant symptoms.

Adverse statin effects on the liver predominately relate to the elevation of aspartate transaminase (AST) and alanine transaminase (ALT). There are isolated case reports of acute liver failure associated with statin treatment, but

Box 88–1

Important Statin Interactions

- Fibrates (especially gemfibrozil)
- Nicotinic acid
- Warfarin
- Ciclosporin
- Tacrolimus
- Protease inhibitors
- Grapefruit juice

the major statin trials have not reported any cases of cholestasis or severe hepatitis, suggesting that these must be extremely rare. Clinically significant elevations of AST or ALT (greater than three times the upper limit of the reference range) have typically been reported in about 1% or less of patients receiving statin treatment. The incidence is likely to be somewhat greater (up to 3%) in patients on high doses of the most effective statins. Minor elevations of transaminases are very common in the general population, most often due to nonalcoholic fatty liver disease, but there is no evidence that patients with minor disturbances of transaminases are any more likely to develop significant liver dysfunction after starting on statin treatment.

It is generally recommended that AST and ALT should be measured at baseline before starting statin treatment, and subsequently at about six weeks to three months after commencing treatment or after dose titration. Provided AST and ALT remain less than three times above the upper limit of the reference interval, treatment can be continued. However, statin treatment should be stopped if the transaminases exceed these limits.

Fibrates

Like statins, fibrates are generally well tolerated, with few significant side effects. The most common reasons for discontinuation of treatment are minor gastrointestinal side effects. Occasionally, muscle-related side effects or abnormal liver function tests are observed, but these are less common than with statins. Fibrates increase biliary cholesterol concentrations, and are contraindicated in patients with gallstones.

Fibrates increase serum creatinine concentrations by 10 to 15%. This is not associated with any decline in renal function and the change is reversible when the fibrate is discontinued. The likely mechanism is an effect on renal tubular creatinine transport.⁴⁵ Fibrate treatment also produces a significant increase in plasma homocysteine concentration. It is currently unclear whether this has any clinical significance.

Statin fibrate combination therapy is widely used in specialist lipid clinics. It has been suggested that such treatment may be associated with an increased risk of muscle-related side effects.⁴⁶ This is likely to be less of a

problem when fenofibrate is used. It seems reasonable to warn any patient on combination statin/fibrate treatment that they should discontinue the treatment if they experience unusual muscular aches and pains or weakness.

Nicotinic acid

The most common significant side effect of nicotinic acid is flushing. This occurs in approximately 75% of patients, even with prolonged-release forms of nicotinic acid. Mainly as a result of flushing, tolerability of nicotinic acid is relatively poor compared with other lipid-lowering agents. If patients can be encouraged to persist with nicotinic acid, flushing will decrease with time. To minimize the risk of significant flushing, prolonged-release forms of nicotinic acid should be used. Intact tablets can be taken before bedtime with a light snack. Excessive consumption of alcohol or spicy foods should be avoided, and aspirin taken shortly before the nicotinic acid tablet is also helpful.

Use of nicotinic acid is associated with minor deterioration of metabolic control in diabetes. This is generally not sufficiently severe to be a clinical problem,⁴⁷ but may be more marked in occasional patients. Higher doses of nicotinic acid can be associated with the development of hyperuricemia and gout. Minor gastrointestinal side effects are also relatively common.

Ezetimibe

Ezetimibe is generally well tolerated and is associated with few side effects. Minor gastrointestinal side effects occur rarely, and there have been occasional reports of disturbed liver function tests (predominately a cholestatic pattern) and muscle-related side effects.

Omega-3 fatty acids

Omega-3 fatty acids are generally well tolerated, apart from minor gastrointestinal side effects such as nausea and dyspepsia.

Resins

The most common side effects associated with resins are related to the gastrointestinal system, and constipation in particular may occur. Because resins may interfere with the absorption of fat-soluble vitamins, the diet may require supplementation with vitamins A, D, and K during high-dose treatment. Hyperchloremic acidosis has been reported very rarely after prolonged use of resins.⁴⁸

SUMMARY

Hyperlipidemia is an important risk factor for atherosclerotic cardiovascular disease, and it is important that

serum lipids should be treated in high-risk patients. This includes patients with established cardiovascular disease or with diabetes mellitus or healthy patients at high risk of cardiovascular disease as a result of risk factors. The primary target for treatment is total and LDL cholesterol. Secondary targets include non-HDL cholesterol, HDL cholesterol, and triglycerides. The main aim of treating hyperlipidemia is reduction of cardiovascular risk. Treatment of hyperlipidemia should therefore occur in the context of addressing all cardiovascular risk factors.

Lifestyle and dietary advice should be given to all patients for whom reduction of serum lipids is considered necessary. However, this will rarely be sufficient to achieve lipid target levels. A statin is the first-line drug of choice to reduce total and LDL cholesterol in the vast majority of patients for whom lipid-lowering therapy is considered necessary. Other lipid-lowering drugs can be used in combination with a statin or alone to achieve targets if necessary (Box 88–2). In general, lipid-lowering treatment is well tolerated and is associated with few side effects. Future developments are likely to focus on the development of new agents with greater potential to increase HDL cholesterol, such as cholesterol ester transfer protein inhibitors,⁴⁹ and studies assessing the value of therapies to increase HDL cholesterol may lead to the establishment of firm HDL cholesterol targets in addition to current LDL cholesterol targets.

Box 88–2

Use of Pharmaceutical Agents to Manage Dyslipidemia

Primary Target

- LDL cholesterol
 - Statin
 - Ezetimibe
 - Nicotinic acid/fibrate/resin

Secondary Targets

- HDL cholesterol
 - Nicotinic acid/fibrate
- Triglycerides
 - Fibrate
 - Statin
 - Nicotinic acid/omega-3 fatty acids

Chapter
89Antithrombotic Therapy
in Hypertension

Gregory Y. H. Lip

Key Findings

- Current guidelines suggest that antiplatelet therapy (in particular, low-dose aspirin) is recommended for secondary prevention in patients with previous cardiovascular events to reduce the risk of stroke and myocardial infarction, provided the patients are not at excessive risk of bleeding.
- In hypertensive patients, low-dose aspirin is beneficial as primary prevention in patients older than 50 years of age with moderate increase in serum creatinine or a 10-year total cardiovascular risk of greater than 20%.
- In all hypertensives, low-dose aspirin should be preceded by well-controlled blood pressure.

Hypertension is clearly associated with increased risk for stroke. In the Framingham study, the presence of hypertension as a risk factor increased the risk of stroke 3.4-fold. In comparison, the presence of atrial fibrillation (AF) increased the risk of stroke 4.8-fold.¹

Although systemic (arterial) hypertension results in high intravascular pressure, the main complications of hypertension [coronary heart disease (CHD), ischemic strokes, and peripheral vascular disease (PVD)] are related to thrombosis rather than to hemorrhage. The association between hypertension and risk for stroke and CHD almost appears to have a dose-response relationship, with increasing risk for higher blood pressures.²⁻⁴ In middle and old age, there is a direct relationship between blood pressure and the risk of cardiovascular death without any evidence of a threshold down to a blood pressure of at least 115/75 mmHg.⁵ Correspondingly, blood pressure reduction trials have shown a reduction in CHD by 16% and stroke by 38%. It should not be forgotten that hypertension is a risk factor for both hemorrhagic and ischemic strokes.

Some of the complications related to hypertension, such as heart failure and AF, are themselves associated with stroke and thromboembolism.⁶ Increasing evidence also points toward a prothrombotic or hypercoagulable state conferred by the presence of hypertension, as evidenced by abnormalities of coagulation, platelets, and endothelial function in such patients.⁷ There is also the recognition that hypertension is associated with abnormalities of inflammation, which can “drive” the prothrombotic state and contribute to endothelial abnormalities in this condition.⁸⁻⁹

It therefore seems plausible that use of antithrombotic therapy may help to prevent thrombosis-related complications of hypertension.⁶ The antiplatelet agent aspirin has been recommended but frequently underutilized in the treatment and secondary prevention of many of the complications of hypertension.¹⁰ Until recently, limited information has been available on its role in the management of the asymptomatic hypertensive individual. Warfarin has also been found to be useful as thromboprophylaxis in hypertensive patients with AF.¹¹ However, if blood pressures remain uncontrolled such therapy carries significant risks, especially from intracranial hemorrhage.¹¹

WHAT DO THE GUIDELINES TELL US?

The 2003 joint European Society of Hypertension and European Society of Cardiology Guidelines¹² for the management of arterial hypertension recommended antiplatelet therapy (in particular, low-dose aspirin) for patients with previous cardiovascular events to reduce the risk of stroke and myocardial infarction, provided the patients are not at excessive risk of bleeding. In hypertensive patients, low-dose aspirin was particularly beneficial in patients older than 50 years of age with moderate increase in serum creatinine or a 10-year total cardiovascular risk of greater than 20%. In all hypertensive patients, low-dose aspirin should be preceded by good blood pressure control.

Broadly similar recommendations are provided by the North American JNC-7¹³ and the British Hypertension Society guidelines.¹⁴ The latter recommends that “unless contraindicated, low-dose aspirin (75 mg/day) is (used) for all people needing secondary prevention of ischaemic cardiovascular disease (CVD), and primary prevention in people with hypertension over the age of 50 years who have a 10-year CVD risk $\geq 20\%$ and in whom BP is controlled.”

WHAT DO THE TRIALS TELL US?

In terms of secondary prevention, the Antithrombotic Trialists' Collaboration clearly shows the efficacy of antiplatelet therapy and vascular events in various high-risk groups, reducing stroke and vascular events by 22%.¹⁵ In an earlier analysis from the Antiplatelet Trialists' Collaboration,¹⁶ data in relation to diastolic blood pressure were provided and suggested that in patients with diastolic blood pressure >90 -mmHg antiplatelet therapy reduced

events from 20.2 to 18.1%, translating to a benefit of 41 per 1000 patients (Table 89–1). However, the benefits of aspirin as a secondary prevention post myocardial infarction may only be most apparent in the first 35 days, as subsequent death rate ratios beyond day 35 showed no significant difference between aspirin and placebo use and the survival curves beyond day 35 were essentially parallel.¹⁷

In the Primary Prevention Project,¹⁸ open-label aspirin 100 mg a day was given to participants, 69% of whom were hypertensive. This trial showed a reduction of total cardiovascular events (relative risk 0.77), cardiovascular deaths (relative risk 0.56), myocardial infarction (relative risk 0.69), and stroke (relative risk 0.67).

The only randomized placebo-controlled trial designed to investigate the effects of antithrombotic therapy (aspirin) on cardiovascular events and hemorrhagic complication in treated hypertensive patients was the large Hypertension Optimal Treatment (HOT) study.¹⁹ This trial was a primary prevention trial in patients with elevated blood pressure (DBP between 100 and 115 mmHg). The aspirin component of this trial was a double-blind placebo controlled design, aspirin 75 mg, or identical placebo tablets once daily. Major cardiovascular events were defined as fatal and nonfatal myocardial infarction, fatal and nonfatal stroke, and other cardiovascular deaths. Silent myocardial infarction was defined as new Q or QS waves without clinical signs of myocardial infarction.

In the HOT study,¹⁹ aspirin 75 mg resulted in a 36% reduction in myocardial infarction ($p=0.02$), with 45 fewer myocardial infarction events in the aspirin group compared to placebo. Interestingly, there were no significant differences in stroke events, but as cerebral scans were not routinely reported the possibility remains that some strokes were hemorrhagic. In HOT, there were 52 more gastrointestinal bleeds in patients given aspirin ($n=107$) compared to placebo ($n=55$), with no significant difference between aspirin and placebo for major bleeds. In a subsequent analysis²⁰ of aspirin on major cardiovascular events, a favorable balance between benefit and harm of aspirin was found in patients with a higher global baseline

cardiovascular risk and baseline systolic blood pressure >180 mmHg or diastolic blood pressure >107 mmHg. Furthermore, patients with serum creatinine >1.3 mg/dL has significantly greater reduction in cardiovascular events and myocardial infarction.²⁰ Importantly, uncontrolled blood pressures did significantly increase the risk of bleeding. The “numbers needed to treat” (NNT) for cardiovascular events in the overall HOT study was 176, versus “numbers needed to harm” (NNH) for bleeding of 188, which are quite close to each other. In contrast, among “high-risk” patients the NNT was 86, compared to an NNH of 205.

The Thrombosis Prevention Trial^{21,22} was a primary prevention trial in patients with high risk of ischemic heart disease. Data for subgroup analysis of patients treated with antihypertensive medication at entry or during trial was reported in a subsequent publication. In this trial,²² the relative risk of major cardiovascular events (coronary heart disease and stroke) by systolic blood pressure analyzed according to treatment suggests that aspirin gives a relative risk of 0.59 with systolic blood pressures <130 mmHg, a relative risk of 0.68 for systolic blood pressures of 130 to 145 mmHg, and a relative risk of 1.08 in the strata of systolic blood pressure >145 mmHg. In this trial, 5 to 10 episodes of cerebral hemorrhage occurred in men with blood pressures >145 mmHg in the combined warfarin plus aspirin treatment group (reflecting in a relative risk of 1.74).

Stroke is a devastating manifestation of hypertensive target organ damage. In an analysis of acute stroke trials,²³ aspirin use in this setting can be detrimental because it results in a 22% increase in the risk of hemorrhagic transformation. However, aspirin reduced the risk of recurrent ischemic stroke by 23%. In the MATCH trial²⁴ of clopidogrel with or without aspirin in TIA or stroke survivors, the addition of clopidogrel to aspirin resulted in no significant effects on vascular events, heart attacks, or strokes—even among the hypertensive subgroup ($n=5945$), which showed no difference in vascular events. However, there was a substantial increase in bleeding events by the addition of clopidogrel to aspirin.

TABLE 89–1. ASPIRIN VERSUS CONTROL IN HYPERTENSION: SUBGROUP ANALYSIS IN ANTITHROMBOTIC TRIALISTS' COLLABORATION META-ANALYSIS 1994				
DBP (mmHg)	<90		90+	
	Aspirin	Control	Aspirin	Control
Vascular events	1168	1451	2700	1073
No. patients	8330	8421	21,136	5308
[%]	14.0	17.2	12.8	20.2
<i>p</i>	<0.0001		<0.0001	
DBP = diastolic blood pressure. (Adapted from Antithrombotic Trialists' Collaboration 1994.)				

Table 89–1. Aspirin Versus Control in Hypertension: Subgroup Analysis in Antithrombotic Trialists' Collaboration Meta-analysis 1994

WHAT DOES THE COCHRANE REVIEW TELL US?

A Cochrane systematic review on antithrombotic therapy use in hypertension²⁴ concluded that for primary prevention in patients with hypertension antiplatelet therapy with aspirin could not be recommended because the magnitude of benefit (a reduction in myocardial infarction) was negated by a harm of similar magnitude, with an increase in major hemorrhage. For secondary prevention in patient with hypertension, antiplatelet therapy was recommended because the magnitude of the benefit over risk was many times greater. The analysis from the Cochrane review²⁴ is summarized in the following section.

Aspirin versus placebo

All-cause mortality was reported in one trial (HOT¹⁹), where mortality was 3.0% in the aspirin-treated patients compared to 3.2% in the placebo control group and was not significantly different ($p=0.36$). The cardiovascular and non-cardiovascular mortality were also not significantly different.

Cardiovascular events were evaluated in two studies.^{19,22} In the HOT trial, aspirin reduced myocardial infarction (ARR = 0.5%, NNT = 200) and major cardiovascular events (ARR = 0.57%, NNT = 176) compared to placebo. However, when all cardiovascular events (including silent MI) were considered the reduction failed to reach statistical significance. In the Thrombosis Prevention Trial, no significant difference was observed in the cardiovascular events in the hypertensive subgroup between the aspirin (8.5%) and placebo (7.5%). When the results of both studies were pooled for all cardiovascular events, there was no significant difference with aspirin compared to placebo (OR 0.93; 95% CI: 0.82 to 1.06). In the pooled results of two trials (HOT, Thrombosis Prevention Trial), there was no significant difference between the aspirin and the control group for ischemic strokes (OR 0.94, 95% CI: 0.76 to 1.17).

Hemorrhage

The hemorrhagic effects of aspirin alone when compared to placebo were evaluated in the HOT study.¹⁹ There was a significant increase in major bleeds (ARI = 0.65%, NNH = 154) and minor bleeds (ARI = 0.73%, NNH = 137) with aspirin compared to placebo. The differences in these events were mainly gastrointestinal (72 versus 34 for major bleeds and 30 versus 18 for minor bleeds) and nasal bleeds (22 versus 12 for major bleeds and 66 versus 24 for minor bleeds) in the aspirin group. There were no significant differences in fatal hemorrhagic events (7 in aspirin group versus 8 in placebo group).

Aspirin versus clopidogrel

The composite endpoint of stroke, myocardial infarction or vascular death, has been evaluated in one study in hypertensive patients and was not different in patients taking aspirin, 12.1%, as compared to clopidogrel, 11.0% [26]. Data on all-cause mortality, cardiovascular mortality, all cardiovascular events, stroke, myocardial infarction, or haemorrhagic events were not reported.

IMPLICATIONS FOR ANTIHYPERTENSIVE DRUG TREATMENT

Antiplatelet therapy use may have implications for the drug management of hypertension. There has long been some concern that aspirin may reduce the efficacy of ACE inhibitors, especially in heart failure patients.²⁷ Aspirin also influenced the mortality benefits of ACE inhibitors in the SOLVD studies, as well as the effect of ramipril in cardiovascular risk prevention in the HOPE study.²⁸ For example, subjects who are not taking aspirin had a 40% reduction in endpoints in the HOPE study compared to a 15% reduction among aspirin users.²⁶

Although low-dose aspirin does not significantly interfere with the blood-pressure-lowering effects of antihypertensive therapy,²⁹ aspirin use did influence major cardiovascular event rates. Patients never treated with an ACE inhibitor had a 21% reduction in major cardiovascular events, whereas patients treated with an ACE inhibitor at least during some part of the follow-up had a 13% reduction in major cardiovascular events.

ASSOCIATED CONDITIONS

Hypertension is clearly associated with conditions that may merit anticoagulation therapy. For example, AF is the most common cardiac arrhythmia, and hypertension is the most important medical condition associated with AF.³⁰ Hypertension features in major risk stratification criteria for thromboprophylaxis in AF, and the presence of hypertension is accumulated to other risk factors such as congestive heart failure, diabetes, or previous stroke in AF.¹¹ Heart failure is another condition associated with hypertension that has an excess risk of thromboembolism.³¹ In the two studies,³² the use of aspirin resulted in more hospitalizations (27%) compared to warfarin-treated patients, which was not seen in patients taking clopidogrel.

CONCLUSIONS

Stroke and cardiovascular disease are often thrombosis-related complications closely related to hypertension. Antiplatelet therapy plays some role in treating hypertension, at least in some cases. In essential hypertension, antiplatelet therapy should only be used for primary prevention if the patients are at high risk and blood pressure control is excellent. Current guidelines also recommend antiplatelet therapy as secondary prevention against further vascular events. Limited data exists for warfarin as primary or secondary prevention in patients with essential hypertension, who are in sinus rhythm.²⁴

However, certain hypertensive patient subgroups merit greater consideration of antithrombotic therapy use. In AF, for example, antiplatelet therapy is useful in low-risk patients. However, warfarin is needed for high-risk subjects. In heart failure, aspirin may cause more hospitalizations due to an interaction with ACE inhibitors, but further data from other trials are required.

Chapter
90Control of Blood Glucose and
Insulin Resistance*Kathleen Wyne and George L. Bakris***Key Findings**

- People with diabetes have an increased risk of high blood pressure and cardiovascular disease.
- Insulin resistance and hyperglycemia independently contribute to the development of cardiovascular disease.
- Reducing insulin resistance reduces cardiovascular disease risk if the treatment is begun early enough in the disease process.
- Inhibition of the renin-angiotensin system improves glucose utilization and reduces insulin resistance.
- Aggressive identification of diabetes in people with hypertension is needed to decrease the morbidity and mortality seen in this population.

Hypertension is estimated to be present in at least 73% of the people in the United States who have diabetes, but less than 40% are at goal.¹ Many of these people are diagnosed with hypertension prior to having been diagnosed with diabetes. As noted in both the ADA and JNC 7 guidelines, one should screen for diabetes at the time of diagnosis of hypertension and repeat screening on an annual basis.

The rationale for aggressive diagnosis and treatment of diabetes in people with hypertension is that the combination is associated with an increased risk of cardiovascular events. In the first few years of the U.K. Prospective Diabetes Study Group (UKPDS), the morbidity and mortality was much higher in the 40% of the cohort who had been diagnosed with hypertension prior to the diagnosis of diabetes. This prompted the addition of the blood pressure control substudy, which showed that blood pressure control had a significant impact on decreasing both microvascular and macrovascular disease.²⁻⁴

Although blood pressure control is clearly important, it does not prevent all complications related to hyperglycemia. The long-term evaluation of the Diabetes Control and Complications Trial (DCCT) cohort has shown that intensive glucose control has delayed benefits in preventing macrovascular disease in patients with type 1 diabetes.⁵ Thus, treatment must address the underlying disease and prevent any elevation in glucose.

The studies designed to investigate prevention of the complications of diabetes have focused on studying people

who already have diabetes and then improving glucose control to prevent development of additional complications. These short-term studies have shown that improving hyperglycemia prevents microvascular events but not macrovascular events.^{6,7} One exception has been the overweight subgroup in the UKPDS study, in which treatment with metformin was associated with a statistically significant decrease in myocardial infarctions (the significance of which is unknown).⁸ In a recent clinical study, treatment of diabetes with agents that improve insulin resistance in patients with established diabetes and vascular disease did not result in a decrease of composite vascular endpoints, but did decrease some secondary macrovascular endpoints.⁹

Given the length of time required to see this benefit in people with type 1 diabetes, it is possible that the window of opportunity has already been lost when type 2 diabetes is diagnosed (as most of these people have had a prolonged period of hyperglycemia prior to their diagnosis). Studies are now ongoing to understand the disease process (i.e., the insulin resistance and the changes in the vasculature) to allow development of therapies that will be effective once the hyperglycemia is diagnosed. Simultaneously, strategies are being developed to diagnose type 2 diabetes earlier to prevent the morbidity and mortality associated with the disease.

The metabolic changes that are associated with insulin resistance, abnormal glucose regulation, and ultimately the hyperglycemia used to identify type 2 diabetes begin long before the sugar is elevated. This is likely why the studies designed to prevent the complications associated with diabetes have not been very successful. Animal studies have shown that there are abnormalities in fat metabolism that begin long before the sugar rises, which leads to an elevation of circulating free fatty acids (FFAs). These lead to the production of inflammatory cytokines.

These cytokines are initially involved in local changes in the vasculature in the adipose tissue that alter insulin and angiotensin II signaling. Over time, the excess FFAs are deposited (termed ectopic fat deposition) in nonadipose tissues, which leads to lipotoxicity.^{10,11} This ectopic fat deposition can lead to abnormal cell function and potentially to cell death, but can also result in further inappropriate production of inflammatory cytokines and thus exacerbate the miscommunication between the vasculature and the adipose tissue.

LIPOTOXICITY

The metabolic abnormalities that occur in the adipose tissue are a combination of environmental (i.e., excess delivery of nutrients for storage) and genetic factors (i.e., an inability to store or metabolize the excess of nutrients). Although healthy lifestyle is one proven method of preventing this process, people appear to have different levels of sensitivity for developing the early stages of lipotoxicity. As the adipocyte enlarges, while trying to store the excess nutrients it also tries to metabolize them to minimize the mechanical stress on the cell. These changes, in addition to the intracellular energy fluxes, disrupt cellular homeostasis and lead to intracellular stress responses. One of these has been termed the endoplasmic reticulum (ER) stress response, which occurs when the intracellular stress alters the homeostasis in the endoplasmic reticulum, leading to activation of a signal transduction system linking the ER lumen with the cytoplasm and nucleus.

Intracellular signaling pathways are then activated or deactivated to preserve the cell's basic metabolic functions. These pathways lead to alterations in the activity of enzymes such as AMP-kinase and the c-Jun N-terminal kinase (JNK), which then affects the phosphorylation status of the insulin receptor and IRS-1 and in turn facilitates insulin resistance in the cell.¹² Insulin is then not able to activate its receptor to prevent lipolysis, and the unregulated release of FFAs results in an alteration of the circulating levels of the adipose-derived cytokines (which are also called adipocytokines).

These include adiponectin, leptin, TNF- α , Interleukin-6 (IL-6), and resistin. The enlarged adipocytes then secrete less adiponectin and more leptin and TNF- α as a form of communication to the nonadipose tissues to stimulate fatty acid oxidation with a goal of depleting the whole-body load of fatty acids. Teleologically, this would appear to be an appropriate response. However, if the nonadipose tissues are not able to respond appropriately to these adipocytokines and store the fatty acids instead of metabolizing them insulin resistance may also develop in other tissues throughout the body.

These adipocytokines also have other functions involved in responding to inflammation to provide adequate nutrition in the presence of stress (i.e., viral or bacterial infection). For example, TNF- α also stimulates preadipocytes to produce monocyte chemoattractant protein-1 (MCP-1). The local endothelial cells respond by also secreting MCP-1. This is compounded by the fact that the increased secretion of leptin by the adipocytes stimulates transport of macrophages to adipose tissue. The decreased production of adiponectin by adipocytes may also contribute to adhesion of macrophages to the endothelial cells.

Once these cells are activated, they contribute to perpetuating a cycle of macrophage recruitment, production of inflammatory cytokines, and impairment of adipocyte function (which results in alterations in insulin action).^{13,14} Consequently, the altered pattern of adipocytokines

(which were probably originally generated as a protective mechanism to initiate an inflammatory process) impacts the endothelium throughout the body and the nonadipose tissues. The activation of the macrophages and endothelial cells is associated with an increase in production of ROS and oxidative stress, which then leads to the vascular abnormalities associated with cardiovascular disease. These are compounded by the direct toxicity of glucose in the form of the advanced glycation end products (AGEs).

GLUCOSE TOXICITY: AGES AND RAGE

In the presence of any amount of hyperglycemia, non-enzymatic glycoxidation of proteins and lipids leads to the formation of a series of products (AGEs). The AGEs are the result of a nonenzymatic reaction of reducing sugars with primary amino groups of proteins called the Maillard reaction. AGEs have been shown to act directly to induce protein cross links, which are protease resistant and cause irreversible damage to cells and tissues.

Through cell surface receptors, such as the receptors for AGEs (RAGE), AGEs also induce the release of cytokines that lead to activation of cells such as monocytes/macrophages, vascular smooth muscles cells, and endothelial cells (resulting in the production of reactive oxygen species, ROSs, which induce the oxidation of DNA and peroxidation of membrane lipids). Inhibition of RAGE is associated with an attenuation of diabetes associated atherosclerosis in animal models. An endogenous soluble truncated form of RAGE (esRAGE) has been found, which apparently functions to bind circulating AGEs and neutralize them.¹⁵

The inability of the body to clear the AGEs contributes to both the direct toxicity to the vessel wall and the indirect toxicity through their ability to increase inflammatory cytokines. The direct effect is one of pure mechanical dysfunction caused by AGE cross-bridges established between macromolecules. This prevents the structural proteins from moving properly during vascular contraction and dilation, thus transforming vessel walls into stiff inelastic tubes and disturbing basement membrane adhesion properties. This may result in high blood pressure, leaky vessels, and in the case of the heart stiffness in the form of diastolic dysfunction. AGE accumulation may also damage the blood vessels by trapping proteins (i.e., immunoglobulins and lipoproteins) and cells in the vessel wall, thus stimulating the immune and inflammatory response that has been described in atherosclerosis.¹⁶

The pathways that may be affected by the binding of the AGEs to the cell surface RAGEs include the generation of inflammatory cytokines and growth factors, leading to intimal proliferation and an overproduction of extracellular matrix (which may also contribute to the stiffness of the vessel). This process could possibly then be exacerbated by the events occurring in the adipose tissue, the presence of oxidized lipoproteins, and perhaps infectious events (either viral or bacterial). The constitutive presence of AGE receptors on resting T lympho-

cytes (CD4, CD8) has led to the hypothesis that their activation in the vessel wall may trigger a low-grade sustained inflammatory state that could be accelerated by any elevation in glucose. Studies are ongoing to develop therapeutic agents to neutralize the toxic effect of AGEs. At this time, the only available therapeutic strategy to prevent the glucose toxicity is to prevent any elevation in plasma glucose (thus minimizing the production of AGEs).

MANAGEMENT OF HYPERGLYCEMIA AND INSULIN RESISTANCE

The inflammatory state initiated by the hyperglycemia and the insulin resistance must be treated by addressing each component of the disease process. Treatment now involves the combined use of agents with complimentary pharmacologic mechanisms (Table 90–1). Some agents treat only one aspect, whereas others impact multiple components of the aforementioned processes. Thus, the combined use of agents that maximally decrease sugar, insulin resistance, and inflammation should theoretically have the lowest incidence of CV events. Although data from observational studies support this contention, ongoing trials will help to definitively determine whether this assertion is valid.

GLUCOSE LOWERING

Treatment of type 2 diabetes

The currently available classes of antidiabetic agents reduce plasma glucose levels by targeting four processes: (1) replacing the relative insufficiency of the pancreatic beta cells by either stimulating it to produce more insulin (sulfonylureas, non-sulfonylurea secretagogues, incretin mimetics) or replacing it with exogenous insulin and/or replacing amylin deficiency, (2) stimulation of glucose uptake by muscle and adipose tissues (thiazolidinediones), (3) reduction of glucose output by the liver (biguanides, thiazolidinediones), and (4) reduction of glucose absorption by the gut (alpha-glucosidase inhibitors). As seen in Figure 90–1, these agents target the various pathophysiologic mechanisms of type 2 diabetes.^{17,18}

It should be noted, however, that diet and exercise remain the cornerstone for management of type 2 diabetes. As was noted in the DPP study, weight loss related to exercise yielded a much lower incidence of new-onset diabetes than metformin. Thus, caloric restriction, weight loss, and exercise can enhance insulin sensitivity and glycemic control. Early in the course of type 2 diabetes, anything that can enhance insulin sensitivity will result in prolonged time for the need of exogenous insulin. This results from exercise-associated enhanced insulin sensitivity and more efficient insulin utilization by the body. In spite of these lifestyle measures, everyone at sometime in the course of their diabetes will need medication to control their glucose level. The following section provides a brief overview of the available classes of the glucose-lowering agents.

GLUCOSE-LOWERING AGENTS	
Class	Trade Name
Alpha-glucosidase inhibitors: acarbose and miglitol	Precose Ultraset
Biguanides: metformin Incretin mimetics	Glucophage, generic
Exenatide	Byetta
Insulin	Humulin, Novolin, Lantus Humalog, Novolog
Insulin secretagogues: sulfonylureas	Diabeta, Glucotrol, Amaryl, generic
glyburide, glipizide nonsulfonylurea repaglinide, nateglinide	Prandin, Starlix
Pramlintide	Symlin
Thiazolidinediones: rosiglitazone	Avandia
pioglitazone	Actos
Fixed-dose Combinations Metformin/Secretagogue glyburide/metformin	Glucovance, generic
glipizide/metformin	Metaglip
Metformin/Thiazolidinedione rosiglitazone/metformin	Avandamet
pioglitazone/metformin	ACTOplus met

Table 90–1. Glucose-lowering Agents

Secretagogues

Glucose lowering can be achieved by increasing insulin secretion using secretagogues or augmenting glucose-stimulated insulin secretion using incretin mimetics. The secretagogues can be separated into two groups: sulfonylureas and non-sulfonylurea secretagogues. A number of sulfonylureas are available, in that this is one of the oldest classes of antidiabetic agents.¹⁹ The two adverse events most commonly associated with sulfonylureas are hypoglycemia and weight gain. The newer (second-generation) sulfonylureas (i.e., glyburide, glipizide, glymepiride) are more effective and are associated with lower incidences of adverse events than the older agents.

The non-sulfonylurea secretagogues are a newer class and include two currently available products: nateglinide (a phenylalanine derivative) and repaglinide, a benzoic acid derivative. They have shorter half-lives than sulfonylureas and a reduced risk of hypoglycemia. Because of their brief half-lives, resulting in shorter duration action, the non-sulfonylurea secretagogues are administered at meals to improve postprandial glycemic control. The short half-life and short duration of action may be particularly useful in patients who do not eat three meals daily or eat at irregular times (including geriatric patients, those with renal disease, and high school or college students). Their function is to lower glucose but they do not impact insulin resistance or inflammation.

Figure 90–1. The pathophysiology of type 2 diabetes mellitus. (Adapted from DeFronzo R, Bonadonna R, Ferrannini E. Pathogenesis of NIDDM: A balanced overview. Copyright 1992 American Diabetes Association. From *Diabetes Care*:15(3):318–368. Reprinted with permission from The American Diabetes Association.

Incretin mimetics

The insulin secretory capacity of the pancreatic beta cell can also be augmented by the incretin mimetics. The enhanced insulin response to oral over intravenous glucose is known as the incretin effect. This physiologic observation led to the discovery of compounds now called incretins, such as glucagon-like peptide-1 (GLP-1), produced by the gastrointestinal (GI) tract in response to glucose. GLP-1 and other incretins enhance glucose-dependent insulin secretion and exhibit other antihyperglycemic actions following their release into the circulation from the gut.¹⁸ Synthetic compounds have been developed that have some of the activities of the naturally occurring incretins, and have been named incretin mimetics.

The prototype of this class is exenatide, which has been shown to bind and activate the human GLP-1 receptor *in vitro*. Exenatide mimics certain antihyperglycemic actions of GLP-1, including promoting insulin release from beta cells in the presence of elevated blood glucose concentrations.²⁰ Exenatide has been approved for use in combination with sulphonylureas and/or metformin. Use with other agents (including non-sulphonylurea secretagogues, thiazolidinediones, or insulin) will require studies to optimize such regimens.

Nausea is a common side effect (~30%) at initiation of exenatide. This is decreased by starting at a low dose and waiting at least a month before increasing the dose and resolves over time. However, one study of dialysis patients given a single low dose found that they did not tolerate the nausea, suggesting that exenatide will require extensive studies to determine how (if it all) it should be dosed

in such a population. Exenatide should not be used in stage 4 or 5 CKD, as the renal clearance is reduced at least tenfold at this stage and studies have not been done to determine dosing in this population.

Amylinomimetics

Another addition to the armamentarium of glucose management is the injectable agent pramlintide. Pramlintide is a synthetic analog of human amylin, a naturally occurring neuroendocrine hormone synthesized by pancreatic beta cells that contributes to glucose control during the postprandial period. Pramlintide complements the effects of insulin in postprandial glucose regulation by decreasing glucagon secretion. Pramlintide exhibits linear pharmacokinetics, and peak serum levels are reached within 30 minutes of administration. The drug is predominantly eliminated by the kidneys, with a mean elimination half-life of 30 to 50 minutes. Clinical trials have shown that pramlintide suppresses post-meal glucagon secretion, slows gastric emptying, reduces postprandial glucose levels, and improves glycemic control while managing weight loss.^{21,22}

Pramlintide is approved for mealtime dosing as an adjunct to insulin in patients with type 1 diabetes mellitus who have not achieved control and in patients with type 2 diabetes mellitus who use mealtime insulin, with or without concurrent sulphonylurea and/or metformin, who have not achieved desired control. In patients with diabetes mellitus who are using pramlintide in addition to their insulin, the dose does not need to be modified in stage 3 or 4 CKD but it is not recommended for use in stage 5 CKD and it has not yet been studied in dialysis

patients. Pramlintide has been associated with an increased risk of insulin-induced severe hypoglycemia. Other adverse events include nausea, anorexia, fatigue, and vomiting. Pramlintide is not a substitute for insulin and should only be used in combination with insulin.

Thiazolidinediones

Rosiglitazone and pioglitazone are the only two currently available thiazolidinediones in the United States. Therapeutic benefits of using thiazolidinediones early in the treatment of type 2 diabetes include the preservation of beta-cell function, augmentation of insulin sensitivity, and minimization of hypoglycemic adverse events.¹⁹ Studies suggest that the thiazolidinediones increase the responsiveness of beta cells by reducing external factors (i.e., glucose and free fatty acids) that impair insulin secretion. Studies have also shown that treatment with thiazolidinediones significantly reduces proinsulin-to-insulin levels, indicating improved beta-cell function.

Preservation of beta-cell function and improvement of insulin sensitivity are the major efficacy rationales for the use of thiazolidinediones as first-line therapy, especially because current evidence suggests that deterioration of beta-cell function and resistance to insulin begin long before the diagnosis of diabetes. These data suggest that because thiazolidinediones preserve beta-cell function and improve insulin sensitivity, their use from the time of diagnosis of diabetes (or even before diagnosis) may improve glycemic control and prevent diabetic complications.

Rosiglitazone and pioglitazone have been proven safe and effective for long-term therapy in a number of clinical trials. The thiazolidinediones are rarely associated with hypoglycemia, and severe hypoglycemia (as can occur with sulfonylureas or insulin) is no longer a barrier to achieving glycemic targets. Using an agent that would minimize the occurrence of this adverse event is a good way to ensure compliance from the initiation of therapy, particularly in patients who have experienced hypoglycemic events on other therapies. Thiazolidinediones may cause weight gain and edema when initiated at high doses.

The thiazolidinediones have been associated with fluid retention and dilutional anemia, which is due to an increase in plasma volume, and are not recommended for use in patients with New York Heart Association class 3 or 4 cardiac status. Combination use with insulin may increase the incidence of cardiac failure.²³ Troglitazone, an older thiazolidinedione, was removed from the market because of hepatotoxicity. Studies show that hepatic failure is not a class effect with these agents. Rosiglitazone and pioglitazone have a more favorable hepatic safety profile than troglitazone or placebo. Scheduled monitoring of liver function tests is no longer required by the United States Food and Drug Administration (FDA).

Biguanides

The primary action of biguanides is to reduce the production of glucose by the liver. Metformin is the only biguanide available in the United States. Because the mode of action does not increase pancreatic insulin

secretion, hypoglycemia is generally not associated with biguanides. However, lactic acidosis (a serious metabolic complication) has very rarely been reported with the use of metformin, particularly in individuals with renal dysfunction or advancing age. There may be some vitamin B12 and folate malabsorption with metformin use, and thus it may be prudent to measure a hemoglobin, hematocrit with red blood cell indices, and vitamin B12 and folate levels at initiation and at least annually.

Certain drugs such as cimetidine and ranitidine may increase metformin blood levels by competing for common renal tubular transport systems. Metformin is excreted unchanged in the urine (primarily through tubular secretion) and does not undergo hepatic metabolism. In patients with decreased renal function (i.e., <50 to 70 mL/min, based on measured creatinine clearance), the plasma and blood half-life of metformin is prolonged and the risk for lactic acidosis (which is fatal in 50% of cases) increases significantly. For this reason, the precautions recommended by the FDA should be carefully followed in all patients. Importantly, serum creatinine should be monitored routinely in all patients receiving a biguanide.

The FDA recommends that a creatinine clearance be measured prior to initiating therapy in patients 80 years of age or older.²⁴ A more conservative approach would be to measure the creatinine clearance in any patient who is 70 years of age or older at the time of initiating therapy. The most common adverse events include abdominal pain, nausea, and diarrhea, which can be minimized by dosing after meals and by initiating therapy at low doses and increasing slowly.

Alpha-glucosidase inhibitors

Acarbose and miglitol are alpha-glucosidase inhibitors that act by delaying carbohydrate absorption in the small intestine. These agents are taken by patients at the beginning of each main meal. The main advantage of the alpha-glucosidase inhibitors is that they are only minimally absorbed and are rarely associated with hypoglycemia and weight gain. However, they frequently cause loose stools and flatulence when used at the recommended doses (i.e., 100 mg acarbose three times daily). When used in low doses (i.e., 12.5 to 25 mg acarbose once or twice daily), the side effect of loose stools may be useful in a patient preoccupied with constipation.

Post hoc analysis of the STOP-NIDDM trial database suggests that treatment of patients who have IGT with acarbose is associated with a reduction in the risk of cardiovascular disease and hypertension.²⁵ These data will need to be confirmed in a prospective, randomized, controlled clinical trial. Because of their mechanism of action, these drugs are contraindicated in patients with diseases of the gastrointestinal tract (e.g., inflammatory bowel disease). These agents are poorly absorbed, with less than 2% of an oral dose recovered in the urine as active (i.e., parent compound and active metabolite) drug.

Pharmacokinetic studies showed that patients with renal impairment (creatinine clearance <25 mL/min/1.73m²) attained about 5 times higher peak plasma concentrations

of acarbose than volunteers with normal renal function. Consequently, alpha-glucosidase inhibitors are not recommended for use in patients with severe renal impairment (serum creatinine >2 mg/dL) because this population has not yet been studied. The concern is that the risk of drug accumulation in renal impairment through the increased plasma levels may have the potential for hepatotoxicity. However, when used in very low doses (i.e., 12.5 to 25 mg acarbose once or twice daily) it is possible this will be less of a risk but studies are needed in the population with stage 4 or 5 chronic kidney disease. These agents do lower glucose, but it is not yet clear whether they have any beneficial impact on the underlying disease process.

Fixed-dose combinations

Fixed-dose combination pills for the management of type 2 diabetes have recently been introduced in the United States. The advantages include better efficacy with lower doses of each component, improved compliance, increased adherence, fewer complications (i.e., less hypoglycemia) due to lower dosing, and the financial advantage of the tablets usually priced at the same cost as the more expensive component alone. The currently available combinations include metformin/glyburide, metformin/glipizide, metformin/rosiglitazone, and metformin/pioglitazone.

There is also a rosiglitazone/glymepiride combination pill undergoing regulatory evaluation by the FDA. One strategy for utilizing these fixed-dose combination pills is to combine the different combination pills such that the patient receives a low dose of a secretagogue, a low dose of a thiazolidinedione, and the highest tolerable dose of metformin. This can be done by giving one combination tablet in the morning and a different one at night.

Insulin use in type 2 diabetes

Optimizing or initiating insulin requires careful attention to detail by both the patient and the diabetes educator. Initiation of insulin can be done very slowly (i.e., insulin glargine 10 units at bedtime or premixed insulin, 70/30 or 75/25, 5 units twice daily before meals). The patient can then adjust the insulin regimen using a simple algorithm once or twice a week, as shown in Table 90–2. The typical insulin dose per day, in the absence of kidney disease, is 0.4 to 1.0 units/kg in type 1 diabetes and 1 to 2 units/kg in type 2 diabetes. For example, a 70-kg person with type 2 diabetes would typically require at least 70 to 140 units

insulin/day. Using patient-managed algorithms allows the patient to slowly increase the dose and to have control over their insulin.²⁶

Does insulin have any benefits beyond glucose lowering?

Although insulin has been assumed for many years to have a detrimental effect on the vasculature by virtue of its growth factor-like effect, recent data have shown that insulin exerts desirable actions on the vasculature. It does so primarily by amplifying endothelium-dependent vasodilation, increasing endothelial constitutive nitric oxide synthase (eNOS) gene expression and activity (and therefore NO bioavailability), which in turn exerts a wide array of antiatherogenic actions.¹⁴ Endothelial dysfunction is characterized by impaired endothelium-dependent vasodilation, which is caused by a reduction of the bioavailability of vasodilators (in particular, NO). The inappropriate elevation of plasma FFAs seen in insulin resistance is associated with a decrease in circulating levels of most amino acids, including L-arginine, which may reduce the substrate for NO formation.

Direct inhibition of NO synthesis by FFA has also been reported. The cellular changes that occur due to excess accumulation of FFAs are associated with overproduction of reactive oxygen species, resulting in increased oxidative stress. By reacting with NO, reactive oxygen species may reduce vascular NO bioavailability and promote cellular damage. Hence, increased oxidative stress is considered a major mechanism involved in the pathogenesis of endothelial dysfunction and may serve as a common pathogenic mechanism of the effect of risk factors on the endothelium.

Given the relationship between endothelial dysfunction and atherosclerosis, it is likely that the status of endothelial function may reflect the propensity of an individual to develop atherosclerotic disease. Consequently, the beneficial effect of insulin on decreasing endothelial activation (thereby improving endothelial dysfunction) raises the possibility that insulin therapy should be initiated much earlier in the disease process than it has been under traditional diabetes management.

Does treating the insulin resistance impact hypertension?

Studies of patients who are insulin resistant but do not have DM provide the opportunity to assess whether altering the dysregulation of FFA metabolism will impact individual CV risk factors such as hypertension. The thiazolidinediones have been shown to produce small but usually statistically significant reductions in blood pressure in diabetic patients and nondiabetic insulin-resistant.

One study has shown that treatment of insulin resistance in nondiabetic hypertensive patients was associated with restoration of the normal circadian pattern of blood pressure on continuous ambulatory blood pressure monitoring.²⁷ Although the mechanism of the reduction in blood pressure with improving insulin resistance is not known, it is likely related to improving the lipotoxicity in the kidney and improvements in endothelial function.

INSULIN TITRATION ALGORITHMS		
Fasting Glucose or Pre-dinner Glucose (mg/dL)	Pre-mix Insulin Dose Adjustment	Glargine Insulin Dose Adjustment
<80	–2 units	–2 units
80–100	No change	No change
101–140	+2 units	+2–4 units
141–180	+4 units	+4–6 units
>180	+6 units	+6–8 units

Table 90–2. Insulin Titration Algorithms

Does treating insulin resistance in people with hypertension prevent diabetes?

There are now a number of analyses from trials that utilized traditional therapies for lowering blood pressure or lipids, which found in post hoc analysis that active treatment with an angiotensin-converting enzyme (ACE) inhibitor, an angiotensin II receptor blocker (ARB), a peroxisome proliferator-activated receptor (PPAR) ligand, or some but not all statin agents was associated with a decreased likelihood of being diagnosed with diabetes while participating in the respective trial (Table 90–3).^{28–30}

The decrease in being diagnosed with diabetes in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) is likely due to the benefit from the ACE inhibitor therapy and is probably an underestimate, as some were offset by the increased likelihood of diabetes in the presence of thiazide therapy. The incidence of newly diagnosed diabetes was a pre-specified endpoint in the HPS and the VALUE trials. The effect of simvastatin on newly diagnosed DM was not statistically significant in the HPS, which is consistent with the lack of basic science data to support a mechanism for such an effect of the statins.

Treatment with valsartan was associated with a significant decrease in the likelihood of being diagnosed with diabetes, as compared to amlodipine therapy, in the VALUE trial. This finding is not unexpected due to the data showing that angiotensin II signaling can interfere with insulin receptor signaling in the endothelial cell. In addition, the ARB telmisartan has been shown to improve the profile of adipocytokines released from adipose tissue in rodents.³¹ Last, it should be noted that although blockers of the renin angiotensin system can clearly reduce the incidence of insulin resistance outcome

trials with thiazide diuretics extending over a duration of five years demonstrate a mortality benefit in spite of not reducing the incidence of new-onset diabetes. Thus, lowering blood pressure to targets (and other risk factors) still confers benefit.

Whether these observations are of clinical utility is now being tested in two large international trials: DREAM (Diabetes Reduction Assessment with Ramipril and Rosiglitazone Medication) and NAVIGATOR (Nateglinide and Valsartan in Impaired Glucose Tolerance Outcomes Research).^{32,33} These trials will test whether inhibition of the renin angiotensin system by either an ACE inhibitor (DREAM) or an ARB (NAVIGATOR) will impact the progression from IGT to type 2 diabetes. Their comparators treat either the insulin resistance or the beta-cell defect, respectively.

SUMMARY

The combination of hypertension and diabetes is associated with significant morbidity and mortality. Treatment of hypertension in people at risk for diabetes should include agents that modify the renin-angiotensin system, as this may help slow the progressive insulin resistance and loss of beta-cell function. Preventing hyperglycemia is also important to prevent the glucose toxicity to the vasculature. Treating insulin resistance directly can also decrease endothelial activation and attenuate ongoing inflammation. Insulin therapy directly improves endothelial function and should be considered in all people with diabetes whose HbA1c is not at guideline goal using oral agents. Aggressive combination therapy is now warranted in the person with hypertension and diabetes to prevent complications.

Chapter
91Target Blood Pressure in
Hypertension Treatment:
The J-shaped Curve Controversy*N. C. Shah and Chim C. Lang***Key Findings**

- The target blood pressure is obviously the one associated with the greatest impact on cardiovascular and renal morbidity and mortality.
- Whereas the goal of 140/90 mmHg seems appropriate for relatively low-risk hypertensive patients, more intensive therapy to reach a goal below 130/80 mmHg is indicated for those with high-risk hypertension (including those with diabetes or renal insufficiency).
- There is no definite evidence of an increase in risk of aggressive treatment (a J-curve) unless diastolic blood pressure is lowered to less than 65 mmHg in elderly patients with isolated systolic hypertension.

It is well established that controlling blood pressure (BP) through the use of antihypertensive drugs reduces morbidity and mortality. It has been further demonstrated that lowering systolic BP (SBP) as well as diastolic BP (DBP) confers benefit. Recent evidence has emphasized the importance of optimal BP control, particularly in patients with high cardiovascular (CV) risk, such as those with diabetes mellitus and renal disease.¹⁻³ In patients with diabetes mellitus, the available data suggest that a BP below 130/85 mmHg reduces the incidence of CV events. In patients with slowly progressive chronic renal failure excreting more than 1 to 2 g of protein per day, reducing the BP to 130/80 or even to 125/75 mmHg might slow the rate of loss of renal function.¹⁻³

Epidemiologic studies have shown that after adjustment for other risk factors, treated hypertensive patients with “normal” BP are still at higher risk for CVD than normotensive persons.⁴ Moreover, in clinical trials the observed risk reduction for coronary events has been smaller than would be expected from the log-linear relationship between BP and risk according to epidemiologic data.⁵ Clinical trials have reported a 5- to 6-mmHg difference between DBP of treatment and control groups. The risk reduction of 14% for coronary events contrasts with the 20 to 25% reduction noted in epidemiologic reports. It has been argued that these discrepancies may be related to the existence of a J-shaped relationship between BP and risk in which treated patients with low BP are at increased risk for events. This chapter discusses the optimal target BP and reviews the controversy relating to the J-shaped relationship between BP and mortality in treating hypertensive patients.

THE OPTIMAL TARGET BP IN GUIDELINES

Elevations in SBP and DBP are established CVD determinants that have been designated major components of CVD risk estimation algorithms.⁶⁻⁸ These guidelines have noted the incomplete evidence on optimal targets for BP lowering, with better evidence for DBP targets than SBP targets—although for patients above the age of 50 years it is recognized that SBP is a more important prognostic determinant of adverse CVD outcome.⁹ The goal of 140/90 mmHg has been set for relatively low-risk hypertensive patients. More intensive therapy is aimed at reaching a goal below 130/80 mmHg for those with high-risk hypertension, including those with diabetes or renal insufficiency. Indeed, the British Hypertension Society guidelines state that “the overwhelming evidence for an optimal BP supports a ‘lower the better policy’ without any convincing evidence of a J-curve relationship.”⁷ Although these recommendations are accepted by many, there are some who may not agree because of disputed allegations suggesting that low DBP may be associated with an excess of cardiac events (i.e., the existence of a J- or U-curve relation between DBP and death).

THE J-SHAPED CURVE: DOES IT EXIST?

Whether such a J-curve exists has long been a debated topic. A plethora of reports has described the shape of the relationship between BP and risk, some concluding that there is a J-curve relation to one or another clinical outcome. Others have reported a linear relation. Population-based longitudinal studies of hypertension have usually shown a continuous and positive relationship between BP and mortality. In a recent meta-analysis by the Prospective Studies Collaboration¹⁰ involving more than 1 million individuals, it was reported that death from both ischemic heart disease and stroke increases progressively and linearly from BP levels as low as 115 mmHg systolic and 75 mmHg diastolic upward (Figure 91-1). Below these levels, there is little evidence of further benefit. It should be noted that the relation of BP to CVD and mortality is subject to considerable random fluctuation, especially in the “normotensive” BP range (where CVD incidence is low). Indeed, with correction for “regression dilution” the meta-analysis by the Prospective Studies Collaboration did reveal a statistically significant modest increase in CVD mortality for DBP <80 mmHg.

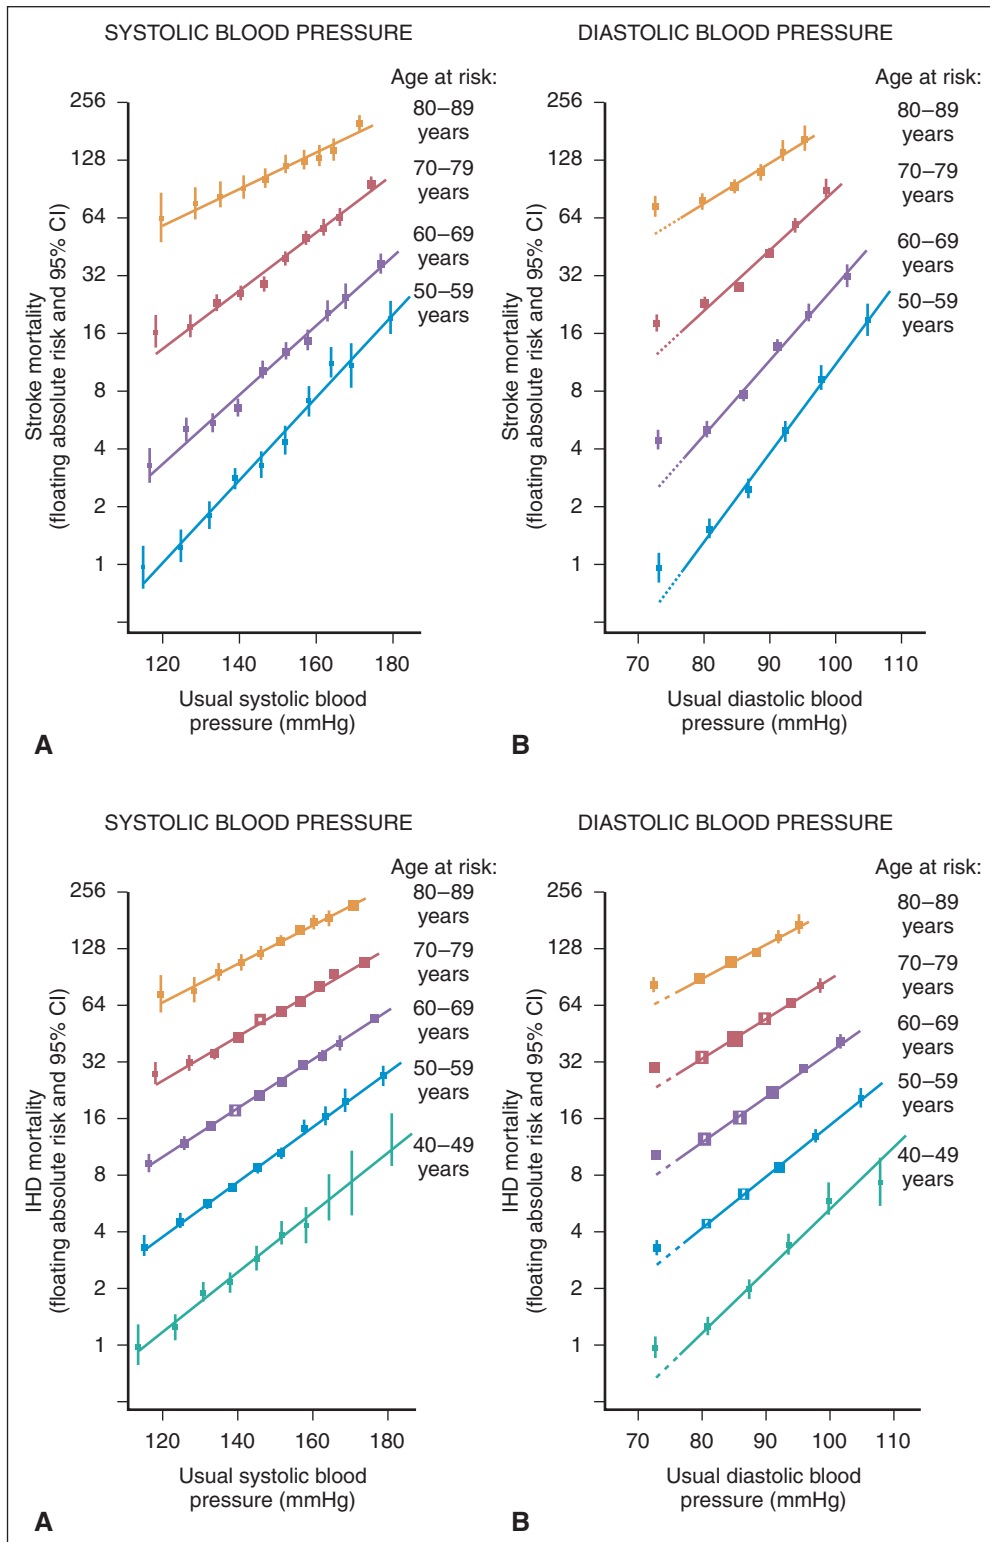

Figure 91-1. Upper panel: Stroke mortality rate in each decade of age versus usual BP at the start of that decade. Lower panel: Ischemic heart disease mortality rate in each decade of age versus usual BP at the start of that decade. (Reproduced from Lewington S, Clarke R, Qizilbash N, et al. Age-specific relevance of usual blood pressure to vascular mortality: A meta-analysis of individual data for one million adults in 61 prospective studies. *Lancet* 2002;360:1903-13, with permission from Elsevier.)

Early reports of the J-curve

It should be noted that reports of a J-shaped relationship had been reported previously. The reports of a J-shaped relationship have come from longitudinal cohort studies of treated patients.^{11–15} There is also evidence from clinical trial data on antihypertensive treatment groups, and in some trials from control groups.^{16–18}

Interpretation of the J-curve

Interpretation of these results has varied (Box 91–1). Several mechanisms have been suggested. It is possible that patients with occult coronary disease do worse at these lower BP levels because most coronary filling occurs during diastole. Similarly, underlying left ventricular hypertrophy can impair coronary reserve by diminishing the ability of the vessels to dilate as the coronary perfusion pressure is reduced.^{19,20} In one study,²⁰ for example, progressively lowering the systemic BP with nitroprusside led to decreased coronary flow in hypertensive patients with left ventricular hypertrophy but not in normotensive individuals or hypertensive patients without left ventricular hypertrophy. Observations from the Framingham Study²¹ are compatible with the potential importance of underlying coronary disease. A J-shaped curve for coronary deaths was noted for patients who experienced a myocardial infarction but not for those who had not. However, two additional findings are important. First, the increase in risk was noted only at relatively low DBPs (<75 mmHg). Second, the J-curve was independent of the use of antihypertensive drug therapy, suggesting that it was the combination of coronary disease and a low DBP that was important.

It should be emphasized that several authors have criticized the conclusions drawn from the results of the previously cited studies, arguing that the methods used were nonrandomized and the studies were uncontrolled, open, and retrospective.^{22,23} Arguments against a J-curve that have

been put forward include uncontrolled confounding factors related to poor health (such as heart failure and malignancy).^{24,25} With aging, atheromatous arteries are associated with a wide pulse pressure and low DBP. Thus, a low DBP is a reflection of, rather than a cause of, increased risk.²⁶ With respect to pulse pressure, Kannel et al.²⁷ recently examined this in an analysis of the combined original and offspring Framingham cohorts and found an increasing tendency for a J-curve relation of CVD incidence to DBP with successive increments in accompanying SBP. In both males and females, a statistically significant excess of CVD events was observed at a DBP <80 mmHg only when accompanied by an SBP >140 mmHg that persisted after adjustment for age and associated risk factors. Thus, it appears at least from this analysis that the excess CVD risk at low DBP is largely confined to patients who also have an elevated SBP, implying that it is elevated pulse pressure (or isolated systolic hypertension) that is responsible for the excess risk observed at low BP.

A similar relation of pulse pressure with primary outcome was recently reported in the INVEST trial, a 22,000-patient trial in which all patients had hypertension and CAD.²⁸ In INVEST, low DBP was distinctly associated with increased risk of MI but not stroke. It should also be noted that following the early reports of the J-curve several reports appeared indicating that hypertensive or normotensive patients who were elderly or who had CAD failed to demonstrate such a J-shaped curve with treatment even if diastolic pressure was <90 mmHg.^{29–31} Furthermore, there is little evidence from any of the previously mentioned studies suggesting a J-curve for the systolic BP. The risk of cardiovascular disease generally declines continuously at least to an SBP of 130 to 145 mmHg.¹² In a prospective evaluation³² of more than 6000 patients for 9 years, a J-curve appeared only in patients with mild to moderate hypertension whose DBP was lowered more than 25 mmHg from the baseline value. Optimal results were seen at an SBP below 134 mmHg in men and approximately 140 mmHg in women.

The benefit of lower BPs might also apply to patients who already have end-organ damage. One study monitored 5362 patients with a history of a myocardial infarction.³³ During the first 2 years of follow-up, there was no detectable association between SBP and the coronary mortality rate. During the ensuing 14 years, however, linear associations were noted between the risk of coronary death and both SBPs and DBPs. Patients with lower BPs were at lower risk. In addition, analysis of over 300,000 MRFIT screenees showed a continuous linear relationship between DBP and relative risk of CAD.³⁴ Thus, it appeared that the J-curve controversy had resolved at the end of the 1990s.

REAPPEARANCE OF THE J-CURVE

It should be noted that the J-curve reappeared in the late 1990s. Two studies suggested a J-curve for stroke when already low normal diastolic levels are inadvertently lowered further by antihypertensive drug therapy of isolated systolic hypertension. During average follow-up of 4.7 years of 2351 hypertensive patients older than 55 years (average

Box 91–1

Arguments for and Against the J-Shaped Relationship Between BP and Mortality in Hypertensive Patients

Arguments for (and proposed mechanisms):

- Diastolic hypotension reduces coronary filling pressure.
- Underlying left ventricular hypertrophy can impair coronary reserve as the coronary perfusion pressure is reduced in diastolic hypotension.

Arguments against:

- Studies reporting J-shaped curve were open, retrospective, and nonrandomized. Inadequate statistical methods with large losses to follow-up.
- Other analyses have not found a J-shaped relationship.
- Lower DBP attributed to uncontrolled confounding factors related to deteriorating health (heart failure or malignancy).
- The low DBP is a marker for widened pulse pressure.

age 71.5 years), those who received antihypertensive drug therapy experienced a progressive decrease in the incidence of stroke as their DBPs were lowered to between 65 and 74 mmHg but a significant increase in stroke when DBPs were lowered to less than 65 mmHg.³⁵ Reanalysis of the data from the Systolic Hypertension in the Elderly Program³⁶ involving 4736 patients with initial average BPs of 177/77 mmHg found a 14% increase in the risk of stroke in patients whose DBPs were inadvertently reduced by 5 mmHg with active drug therapy.

Patients being treated who did not have a cardiovascular event had an average DBP of 68 mmHg. Those who had an event had an average DBP of 65 mmHg. The risks were still less in patients whose DBPs were lowered than in those receiving placebo, whose systolic levels remained elevated. However, there are some concerns regarding both studies. In the study by Voko et al.,³⁵ we do not know

whether the low pressures were actually induced by antihypertensive treatment. The authors did not exclude the possibility of selection bias or low pressures resulting from interim occult cardiovascular damage, which could have predisposed those patients to stroke.

In a reanalysis of the SHEP trial,³⁶ the numbers of patients who achieved DBP <55 mmHg were small and a careful reading of this study suggests that levels of 45 mmHg were not deleterious. These phenomena were noted in the treatment arm but not in the placebo arm. It is not clear whether the increased event rate associated with low DBP in the treatment arm was a direct result of diastolic hypotension or the result of some subclinical disease that was unmasked by antihypertensive therapy. Importantly, the event rate in those patients in the active treatment arm with diastolic hypotension was still lower than the event rate of patients in the placebo arm. The authors had concluded that

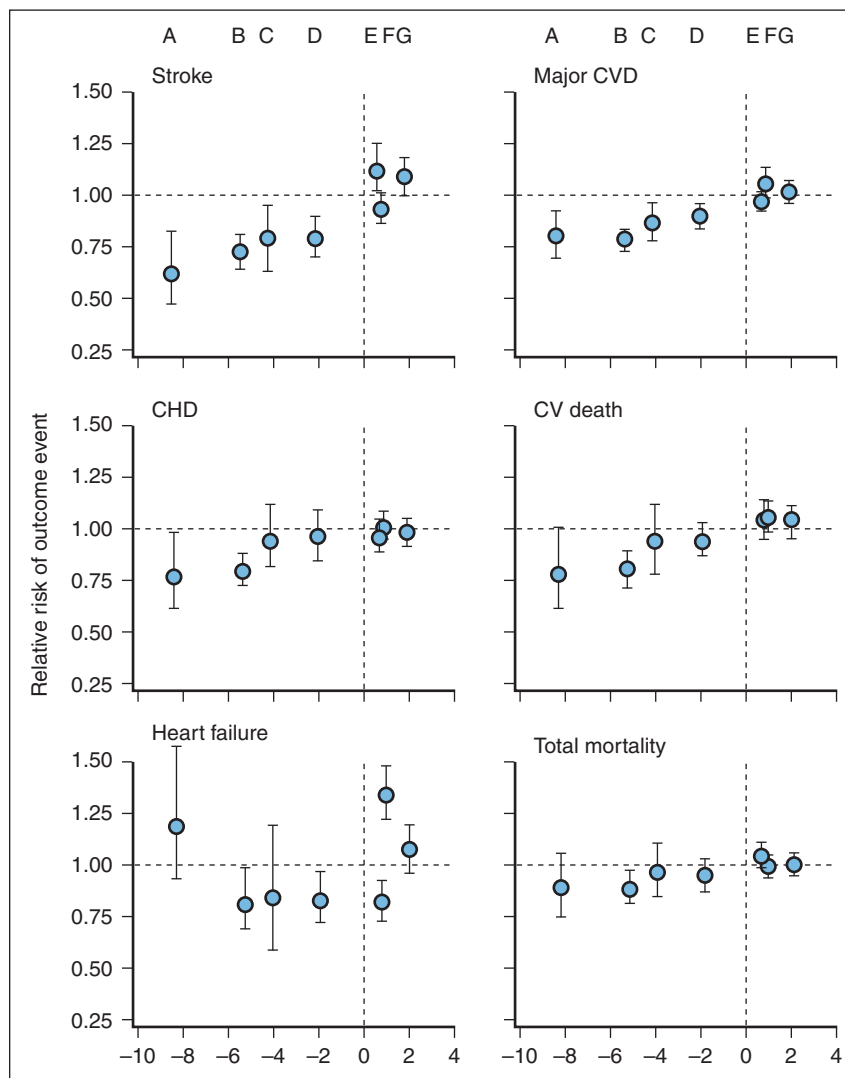

Figure 91–2. Associations of BP differences between groups with risks of major vascular outcomes and death. (Reproduced from the Blood Pressure Lowering Trialists' Collaboration. Effects of different blood-pressure lowering regimens on major cardiovascular events: Results of prospectively-designed overviews of randomised trials. *Lancet* 2003;362:1527–35, with permission from Elsevier.)

patients who achieve DBP levels of about 55 to 60 mmHg deserve more careful monitoring and more aggressive treatment of other CV risk factors.

TARGET BP AND J-CURVE: ANSWERS FROM PROSPECTIVE INTERVENTION TRIALS

It is clear that the only way to resolve the issue is to have specially designed prospective randomized studies of the potential benefits or drawbacks of intensive antihypertensive treatment that will help define the maximum benefit from antihypertensive therapy. There have been two studies of this nature. The BBB study³⁷ was conducted in hypertensive patients with no signs of IHD and showed no increase in cardiovascular events at DBP <80 mmHg. However, the power of the study was not sufficient to express a difference in the parameter.

The more important study was the Hypertension Optimal Treatment trial,³⁸ which was initially designed to settle the controversy over whether the J-curve exists in patients with combined systolic and diastolic hypertension by comparing outcomes in 19,000 patients (average pretreatment BP of 170/105 mmHg) randomized to three different DBP goal groups: less than or equal to 90, less than or equal to 85, or less than or equal to 80 mmHg. Treatment was begun with the long-acting dihydropyridine calcium channel blocker felodipine, 5 mg once a day. Either an angiotensin-converting enzyme inhibitor or a beta blocker was added if the target BP was not obtained with initial therapy. Further therapeutic options included increasing the doses of these agents or adding a diuretic.

After average follow-up of approximately 4 years, 78, 41, 28, and 22% of patients were taking felodipine, an angiotensin-converting enzyme inhibitor, a beta-blocker, and a diuretic, respectively. A significant problem emerged that reduced the power of this study: less separation in the DBP was achieved in the three target groups than had been planned. Mean DBPs attained for the less-than-or-equal-to 90, less-than-or-equal-to 85, and less-than-or-equal-to 80 mmHg groups were 85.2, 83.2, and 81.1 mmHg, respectively. This close degree of BP reduction in the three groups did not provide the power to detect any difference in protection with varying degrees of BP lowering. The data therefore did not disprove the existence of a J-curve. Analysis of the correlation between adverse cardiovascular events and

BPs achieved with antihypertensive drug therapy revealed that the fewest major events and the lowest cardiovascular mortality rate were noted at average BPs of 138/83 and 139/86 mmHg, respectively.

Interestingly, a recent subgroup analysis of the HOT study³⁹ suggests that a J-shaped curve may exist for current smokers only. Once smokers were excluded, the reduction of DBP to an average of 82 mmHg rather than 85 mmHg significantly reduced the major cardiovascular events not only in diabetics but in patients at high and very high risk, as well as in patients older than 65 years.

The last round of analyses by the Blood Pressure Lowering Treatment Trialists' Collaboration⁴⁰ had examined the effects of strategies targeting different BP goals (i.e., examining "more intensive versus less intensive regimens." It should be noted that the trials included in the analysis were the HOT study³⁸ (DBP≤80 versus ≤85 or ≤90 mmHg), AASK study⁴¹ (MAP≤92 versus 102 to 107 mmHg), ABCD (H)⁴² (DBP≤75 versus ≤90 mmHg), ABCD (N)⁴³ (DBP 10 below baseline versus 80 to 89 mmHg), and UKPDS-HDS¹ (DBP <85 versus <105 mmHg). The data showed that for every outcome other than heart failure larger reductions in BP produce larger reductions in risk (Figure 91–2). It was argued that the finding with heart failure may be due to the divergent effects of calcium-antagonist-based regimens on this outcome—an effect that seemed to be determined mainly by factors other than reduction in BP. The same observation was made with regard to doxazosin on the risk of heart failure in the ALLHAT study.⁴⁴ Nonetheless, it should also be noted that collected data on heart failure in clinical trials is problematic because of problems related to case definition and validity of diagnosis.⁴⁵

CONCLUSIONS

The optimal goal of antihypertensive drug therapy in most patients who are not at high risk with combined SBP and DBP is, as recommended by the guidelines,^{6–8} a BP of less than 140/90 mmHg. In elderly patients with isolated systolic hypertension, it is fair to say that caution is advised if DBPs inadvertently fall below 65 mmHg. Based on the available evidence, more aggressive therapy to attain a DBP of 80 mmHg or even lower might be desirable in some patients, notably (1) in patients with diabetes mellitus and (2) in patients with slowly progressive chronic renal failure excreting more than 1 to 2 g of protein per day.

Chapter
92Adherence, Quality of Life,
Cost Effectiveness, and the
Role of the Pharmacist

Barry L. Carter

Key Findings

- Hypertension control is poor in many populations due to physician inertia, inadequate systems of care, poor patient adherence, and other factors.
- Quality of life is generally better in patients with well-controlled blood pressure (BP) regardless of medication.
- In contrast to common beliefs, quality of life is frequently better with diuretics than with other agents or even placebo.
- Adherence to medications often requires multiple strategies. Pharmacists can assist physicians with monitoring for adverse reactions or poor adherence and recommend strategies to modify therapy to improve BP control.

Several chapters in this book and national organizations describe the problem of poor BP control in the United States.¹ Clinical trials, however, have shown that BP control rates of 70 to 80% can be achieved by forced medication titration and close monitoring.²⁻⁵ There are many reasons for poor BP control, but one common problem is clinical inertia or lack of aggressive treatment by physicians.⁶⁻⁸ One study found that “resistant hypertension” was due to poor patient adherence in 13% of cases and due to suboptimal treatment regimens in 61% of cases.⁹ However, adherence and quality of life can impact BP control. This chapter examines patient adherence, quality of life, and the cost of medications. Strategies for improving BP control, including the role of the pharmacist in assisting the physician, are also explored.

ADHERENCE

Various studies have found discrepancies regarding long-term persistence with antihypertensive medications, which may relate to the patient population being studied. Patients with long-established treated hypertension tend to have medication persistence rates as high as 97% and 82% after 1 and 4.5 years of observation, respectively.¹⁰ However, persistence may be as low as 45% for newly diagnosed patients.¹⁰⁻¹² It is clear, however, that some patients fail to adhere to lifestyle modifications, omit medication doses, forget to take medications, or discontinue therapy.

These behaviors contribute to poor BP control and may lead to increased complications, hospitalizations, and cost.¹³ Importantly, when patients adhere to lifestyle modifications they are much more likely to have an antihypertensive withdrawn.¹⁴

Evaluating medication adherence

The assessment of adherence by clinicians is frequently superficial and inadequate. Often, the patient is only asked: “What medications are you taking?,” “How are you taking your medications?” or “Are you taking your medications?” These questions do not adequately assess adherence.

There are strategies that can be used to improve the information, but no method of assessing adherence is ideal.¹⁵ Several adherence assessments used in research studies such as pharmacy databases are not practical for assessing an individual patient. All methods of assessing adherence can be time consuming or expensive.

A self-reported questionnaire has been validated in patients with hypertension, and the questions are shown in Box 92-1.¹⁶ This questionnaire had a strong predictive validity for BP control when evaluated in 290 patients. Although this questionnaire has been validated, these are all closed-ended questions. This author prefers to change the wording of the first question to an open-ended question such as “How many times in the last week have you missed {medication name}?” This question is then repeated for each medication and explored further when the patient admits to missing any doses.

Box 92-1**Self-reported Adherence Questionnaire**

1. Do you ever forget to take your medicine?
2. Are you careless at times about taking your medicine?
3. When you feel better do you sometimes stop taking your medicine?
4. Sometimes if you feel worse when you take the medicine do you stop taking it?

From Morisky DE, Green LW, Levine DM. Concurrent and predictive validity of a self-reported measure of medication adherence. *Med Care* 1986;24(1):67-74.

There are several other questionnaires that have been used to evaluate adherence or ability to take antihypertensive medications, including the Brief Medication Questionnaire,¹⁷ the Medication Adherence Self-Efficacy Scale,¹⁸ and the Hill-Bone Compliance to High Blood Pressure Therapy Scale.¹⁹ All of these tools have been good predictors of BP control. Self-report, however, tends to overestimate adherence. However, it is the most convenient approach for the clinical setting.^{15,20}

Once in awhile a patient will firmly and repeatedly deny that they miss doses but the clinician may be suspicious based on BP trends. In these cases, pharmacy refill records may be revealing and explain poor BP control.^{15,21,22} These refill records can usually be obtained by contacting the patient's pharmacist. As with all methods for assessing adherence, refill records have limitations. Refill records may overestimate adherence if patients fill their medications but do not take them (stockpiling). Alternatively, refill records may underestimate adherence if the physician tells the patient to lower a dose or cut pills in half or if the patient is given samples that are not documented in the medical record.

Other strategies used in clinical trials include performing pill counts or using automated devices with electronic caps.^{15,23,24} Pill counts are not practical in most clinical situations because they require a precise knowledge of fill dates, dosage, and directions that may not be consistent. Electronic caps are required for each bottle, and are generally too costly to use when treating patients. For most clinical trials, it is suggested that two methods be used to assess adherence, which will provide a better overall picture of adherence than using just one method.¹⁵

Barriers to adherence

Several barriers to good patient adherence have been identified and are outlined in Box 92-2.^{13,18,25-27} Most

Box 92-2

Patient Barriers to Adherence

- Insufficient knowledge
- Negative beliefs about hypertension or its treatment
- Poor self-efficacy or lack of control
- Younger age, male gender, minority race
- Cognitive impairment
- Active depression
- Alcohol or substance abuse
- Smokers
- Large-city dwellers
- Low socioeconomic status
- Lack of single medical provider
- Complicated or costly medication regimens
- Adverse drug reactions
- Rapid lowering of BP or excessive initial medication dose

studies have found that older individuals adhere better to medication regimens than younger patients, but these findings have not been consistent.^{10,12,21,28} There are also conflicting data about adherence in men and women, but most studies have found women tend to adhere better than men.^{10,13}

Some patients have negative beliefs about treating their hypertension, inaccurate perceptions about medications, or lack knowledge about the BP goal. Thus, their adherence is lower than other patients.^{18,27} Some patients have a vague but real fear that medications may cause adverse reactions in the future or that they should not take too much medication. These beliefs can interfere with adherence. Patients living in large urban centers, those with low socioeconomic status, or those with depression and substance abuse are much more likely to have poor medication adherence.^{28,29}

Patients who take complex medication regimens and multiple daily doses may have major barriers to adherence.^{18,26,27,30} Generally, complex regimens should be avoided. Although it may be counterintuitive, some studies have found that patients taking greater numbers of medications or those with multiple chronic conditions adhere better than patients with less complex conditions.^{10,21,31} This finding is likely explained by the Health Belief Model, which suggests that patients who believe they are sicker may tend to adhere better to their treatment.²¹

Strategies for facilitating adherence

One Cochrane review of the literature and an expert panel on compliance from the American Heart Association provided recommendations based on scientific evidence to support strategies to improve adherence.^{32,33} It is important to recognize that patient education alone is not sufficient to improve adherence. There are several facilitators to good patient adherence, some of which can be modified. Facilitators to adherence are displayed in Box 92-3.^{13,18,26,27}

Box 92-3

Adherence Facilitators

- Female gender
- Higher education and/or higher socioeconomic status
- Married
- Multiple chronic conditions, especially a prior cardiovascular event
- Higher levels of BP
- Strong patient-provider relationship
- Patients who are involved with their treatment decisions
- Patient knows BP goal
- Self-monitoring of BP
- Monotherapy or combination therapy
- Clinic and refill reminders, pill boxes, adherence aids

Some patients intentionally decide not to adhere to their medications based on the risks and benefits as they perceive them.³⁴ Additional education or adherence aids may not benefit these patients, and the clinician may have success by evaluating the patient's culture or health beliefs. It may be possible to improve adherence by including the patient in treatment decisions or in performing self-monitoring. Patients should be taught to accurately measure their BP and keep a log of BP values.

Patients who have stronger social and family support systems have better adherence. Behavioral strategies that empower patients to improve their ability to take medications (self-efficacy) and include family or other individuals (social support) may improve adherence.¹⁸

When designing an antihypertensive regimen, lower starting doses and slower dosage increases may cause fewer side effects and may improve adherence.^{1,35,36} However, it is important to achieve goal BP within the first 6 months of therapy and thus dosage should be titrated frequently.

Many patients can effectively adhere to twice-daily regimens, but once-daily therapy is generally preferred.^{5,37,38} Regimens that include three or four doses per day, including medications for other indications, should be avoided because most patients have great difficulty adhering to such a regimen. If regimens become too complex, it may be possible to switch some of the medications to combination pills.^{1,32} When patients have problems remembering to take their medications, pill boxes, unit-of-use packaging, administration routines (e.g., taking medication with breakfast or brushing teeth), and refill reminders are important strategies.^{18,32,39}

QUALITY OF LIFE IN HYPERTENSION

There has been a great deal of discussion about adverse reactions or quality of life when patients take various classes of antihypertensive medications. Quality of life is much more comprehensive than just adverse reactions, as discussed in the following sections.

Adverse effects with antihypertensives

It is frequently assumed that diuretics and beta blockers are poorly tolerated, whereas newer medications [such as angiotensin-converting enzyme inhibitors (ACEIs), calcium channel blockers (CCBs), or angiotensin receptor blockers (ARBs)] have far fewer side effects. Complicating these impressions is the commonly held belief that hypertension is asymptomatic. A further problem is that patients with hypertension have a higher prevalence of confounding conditions such as depression or impotence attributable to medications.^{29,40} Patients receiving treatment for hypertension have lower quality of life scores than non-hypertensive controls.⁴¹ Interestingly, quality of life scores were higher in hypertensive patients with controlled BP than in those with uncontrolled BP. Treated patients with a BP of >140/90 mmHg had more symptoms and lower quality of life than treated patients whose BP was controlled. This and other studies suggest that hypertension is not an asymptomatic condition and that quality of life

improves in large populations when BP is controlled.⁴²

Studies that examine persistence with antihypertensives by class of agent have had conflicting results, with some finding no difference in persistence and other studies suggesting that some drug classes are better tolerated.^{11,12,22,43,44} These studies usually suffer from potential selection bias. A meta-analysis of 190 studies and 28,922 patients found the highest rate of discontinuation due to adverse events occurred with CCBs (dihydropyridine 6.9% and non-dihydropyridine 5.7%) and alpha-adrenergic blockers (6.0%), ACEI (4.7%), beta blocker (4.5%), and placebo (4.3%).⁴⁵ The lowest rates of discontinuation for adverse events were seen with diuretics (3.1%) and angiotensin receptor blockers (3.1%). This study found that adverse reactions and adherence following treatment with beta blockers was similar to placebo, whereas these rates were better with diuretics and angiotensin receptor blockers. Only CCBs and alpha-adrenergic blockers were worse than placebo or the other drugs.

One well-controlled study found that a diuretic (1.1%), beta blocker (2.2%), or ACEI (4.8%) was associated with lower adverse reactions than placebo (6.5%), a CCB (6.5%), clonidine (10.1%), or prazosin (13.8%).⁴⁶ Hydrochlorothiazide treatment was associated with the lowest rate of adverse reactions and had the fewest rates of discontinuation due to adverse events, including fewer than those receiving placebo. This study demonstrates the importance of placebo-controlled trials when evaluating adverse reactions.

The Treatment of Mild Hypertension Study (TOMHS) treated patients with placebo ($n=234$), chlorthalidone ($n=136$), acebutolol ($n=132$), doxazosin ($n=134$), amlodipine ($n=131$), or enalapril ($n=135$).⁴² Patients whose BP was not controlled had another antihypertensive added (chlorthalidone; except in the chlorthalidone group, who received enalapril), and in fact 33% of those on placebo received chlorthalidone. Chlorthalidone and acebutolol both had significant improvements in quality of life scores compared to placebo. The other drug groups tended to have improvements over placebo that were not statistically significant. Again, this study demonstrates the importance of evaluating placebo-controlled trials when considering adverse reactions or quality of life changes over time.

Of course, patients and physicians frequently attribute symptoms to an antihypertensive drug. It often does not matter if this assessment is accurate because the patient may refuse to continue the medication either way. If the patient believes the medication is causing a side effect, the clinician will need to address the matter and this frequently requires changing doses or agents. Frequent follow-up is important, especially early in therapy or with patients newly diagnosed with hypertension because these patients are at high risk of discontinuing therapy or dropping out of the health care system. If patients are going to discontinue their medication, this is most likely to occur early in therapy.¹⁰

Quality of life assessments

The foregoing observations make an assumption that there is a relationship among adverse reactions, quality of

life, and medication adherence (which is not necessarily true). Validated quality of life instruments typically measure physical health, bodily pain, vitality, social functioning, role limitations, mental health, and general health. Thus, adverse reactions to medications do not necessarily correlate well with quality of life measures. What about the relationship between quality of life and adherence? Intuitively, one would assume there should be a relationship but the data are not compelling. One study evaluated this relationship in 100 patients with hypertension, 199 patients at high risk for medication problems, and 365 elderly patients.⁴⁷ They studied six different quality of life instruments. Correlations between quality of life and adherence were very weak, and the weakest correlations occurred in the patients with hypertension. Although very weak, there was a negative correlation between physical and mental domains on quality of life instruments and adherence to antihypertensive medications, which the authors speculated may be related to adverse drug reactions.

In summary, quality of life scores appear to improve when BP is controlled—suggesting that hypertension may not be asymptomatic after all. Quality of life does not correlate well with adverse reactions or adherence. This is likely due to the fact that quality of life questionnaires are much more comprehensive than simply measuring adverse reactions. Quality of life may not correlate well to adherence for several reasons. Research has demonstrated that patients who perceive themselves as very sick may adhere better to their therapy (Health Belief Model). In this case, their scores for perception of their health, role limitations, or bodily pain may be low. However, because of these symptoms they may adhere to their medications.

COST EFFECTIVENESS OF ANTIHYPERTENSIVE TREATMENT

Whenever possible, inexpensive regimens should be designed. This can be accomplished using evidence-based treatment strategies. The cost of medications, including co-payments, is a significant predictor of adherence.^{1,18,48,49} An interesting study evaluated nonadherence to medications as a function of drug affordability between 1997 and 2002.⁴⁸ The authors found that self-reported nonadherence to medications due to cost increased from 4.7% in 1997 to 5.9% in 2002. Blacks (8.4%) and Hispanics (6.7%) reported more nonadherence due to cost than did whites (5.5%) ($p < 0.001$). As expected, health insurance coverage was strongly associated with medication nonadherence due to cost. Those with private insurance reported much lower rates of nonadherence than those without insurance (3% versus 18%, $p < 0.001$). Interestingly, patients who were dually eligible for both Medicare and Medicaid were more likely to be nonadherent due to cost (11.4%) than overall Medicare beneficiaries (7.0%). These authors estimated that 16.6 million Americans were unable to purchase a prescribed medication in 2002. Obviously, cost-effective strategies should be employed to improve patient adherence and BP control.

In many areas of medicine there is often a trade-off between cost and efficacy. However, this is not true in hypertension—where the least costly medications (thiazide diuretics) are at least as effective in overall cardiovascular outcomes, and superior for select outcomes, when compared to more expensive medications.⁵⁰ An economic analysis found that 40% of 2.05 million prescriptions for antihypertensive drugs could have been for less costly agents based on scientific evidence.⁵⁰ Even when the potential need for laboratory monitoring was included in the analysis, these changes would have saved \$11.6 million (or about one-fourth of the overall costs). If Medicaid pricing were used, the savings could have been \$20.5 million. Replacing thiazides for CCBs resulted in the largest reduction in cost. The authors estimated that \$1.2 billion could be saved nationally if prescribing patterns followed national guidelines and scientific evidence.

Many patients require two or more medications to manage hypertension, and some require alternative agents to manage coexisting conditions. The most versatile and cost-effective regimen is a thiazide-like diuretic (hydrochlorothiazide or chlorthalidone) and a generic ACEI such as lisinopril.^{50,51} Many patients can have their BP and/or proteinuria effectively managed with this regimen, and as noted previously it is very well tolerated. For patients who require additional agents or who do not tolerate this regimen, there are many other options available that include low-cost medications. Any regimen that includes a CCB or angiotensin receptor blocker will be much more costly and should only be considered for specific indications in select patients.

ROLE OF THE PHARMACIST

Pharmacists in a wide variety of settings can be a valuable resource for physicians in assisting with patient management and improving BP control. Pharmacists have performed a wide variety of functions, including screening and referral, monitoring for adverse reactions and nonadherence, making recommendations to the physician for alterations in therapy, and disease-state management. Pharmacists can assist the physician with several items (listed in Box 92–3), including: (1) reinforcing the physician's BP goal with the patient, (2) teaching the patient to use BP monitoring devices sold in the pharmacy, (3) recommending regimen redesign to reduce complexity, adverse reactions, or cost, and (4) providing refill reminders, pill boxes, adherence aids, or other strategies for improving adherence.

In addition to community pharmacies, clinical pharmacists are frequently located in academic clinics, VA medical center clinics, and even private physician offices. In some of these settings, pharmacists assist physicians with managing hypertension or provide pharmacist-managed hypertension services.⁵² Approximately 40 states have enacted legislation or rules that allow physicians and pharmacists to establish collaborative relationships, and the pharmacist can manage certain chronic conditions via protocol.⁵³ Although most of these collaborations occur in structured settings such as academic clinics, some include

community pharmacies. The following sections discuss these areas as a function of the type of setting in which the pharmacist practices.

Community pharmacies

Although most community pharmacies continue to provide traditional services (medication dispensing and counseling), it is increasingly common to find pharmacies that provide more advanced services. Many patients visit their community pharmacy nearly once a month. If the physician and pharmacist have a good working relationship, the pharmacist can assist with screening and referral of patients with elevated BP, monitoring for adverse reactions and poor adherence, and making recommendations to the physician for overcoming these problems. The pharmacist can also assist the physician by providing patient education and counseling about the medications and strategies to improve BP control in an effort to reinforce the physician's treatment plan.

Several studies have been conducted in community pharmacies in which pharmacists measured BP and made recommendations to the physician to modify therapy.⁵⁴⁻⁵⁶ McKenney conducted an intervention in which the community pharmacist collaborated with two physicians in an urban health center.⁵⁶ The pharmacist met with the physicians in their office and reviewed study patients' medical records. The pharmacist assessed patients monthly and made recommendations to the physicians. The control group had a deterioration in physician-measured BP (163/93 to 166/101 mmHg), whereas the BP in the intervention group improved (157/99 to 146/90 mmHg) and the difference between groups was significant ($p < 0.001$). The intervention group, but not the control group, experienced significant improvements in medication adherence and knowledge of hypertension. One of the fascinating features of this study was that BP control and adherence deteriorated once the service was discontinued.

Carter performed an evaluation of a similar intervention except that the community pharmacy was a clinic pharmacy within the building of a private rural clinic.⁵⁴ Because of the close proximity of the pharmacists and physicians, the pharmacists reviewed medical records and made face-to-face recommendations to the physicians. Following monthly evaluations with the pharmacist, BP measured in the physician's office was significantly reduced at 6 months in the intervention group (146/83 versus 135/75 mmHg, $p < 0.001$) but not the control group (147/82 versus 142/82 mmHg). In this study, several measures of quality of life improved in the intervention group but not the control group. In addition, a blinded peer review panel evaluated the quality of prescribing. There was no change in the quality of prescribing in the control group but the appropriateness of the BP regimen ($p < 0.01$), potential benefit of the regimen ($p < 0.05$), and assessment of the patient for adverse reactions ($p < 0.001$) were all improved in the intervention group.

Even though the above were small studies, they all demonstrated improved BP control and medication adherence when community pharmacists provided these services. Although these collaborative programs are

uncommon in community pharmacies, they are increasing nationwide.

Primary care clinics

Most examples of advanced services provided by pharmacists are found in academic family medicine clinics, internal medicine clinics, or in Veterans Affairs medical centers.⁵² One study was conducted in a managed care setting and evaluated physician/pharmacist co-management of hypertension.⁵⁷ Patients were randomized to either usual care ($n=99$) or the co-managed group ($n=98$). BP was reduced more in the co-managed group than in the usual care group at 6, 9, and 12 months (22 versus 9, 25 versus 10, and 22 versus 11 mmHg, respectively; $p < 0.001$).

Several other studies have found similar results.⁵⁸⁻⁶⁴ In another study, a pharmacist worked with physicians in a medical residency training program.⁵⁸ The pharmacist role was to assist physicians with improving BP control. Patients ($n=95$) were randomized to a control or intervention group. Systolic BP declined 11 mmHg in the control group and 23 mmHg in the intervention group ($p < 0.001$). Physicians accepted 93% of the 162 recommendations made by the pharmacist. Medication charges *increased* by \$6.50 in the control group but *decreased* by \$6.80 in the intervention group.

One study in a VA found that not only was BP significantly reduced when management was assisted by a clinical pharmacist but BP control was sustained for 4 years following management by the pharmacist or a nurse.^{59,60} In larger group practices and academic centers, there are typically nurses or nurse practitioners and perhaps physician assistants in addition to clinical pharmacists. Each setting must determine how to efficiently utilize the practitioners in the office. In this case, clinical pharmacists would be best suited to assist with patients who have BP that has been difficult to control; who have complex regimens, adverse reactions, or problems with adherence; or who need assistance with reducing medication costs.

In many primary care settings that employ clinical pharmacists, the pharmacist assists with programs for designing cost-effective medication regimens. Some patients do require more expensive therapies, and these pharmacists (or in some cases pharmacy technicians) assist with indigent programs offered by the pharmaceutical industry. One study found significant improvements in disease outcome with such a program.⁶⁵

Kaiser Permanente of Colorado is one of the best-performing managed care organizations in the United States.⁶⁶ In this organization, hypertension management is an integrated program among physicians, nurse practitioners, clinical pharmacy specialists, and others. Although different clinics within the region have different structures, they all achieve high BP control rates. In one model, patients with regular hypertension visit a registered nurse, who sees the patient, gathers a history, and measures vital signs. When BP is above goal, the nurse consults with the clinical pharmacy specialist to determine if changes in medication therapy are needed. If so, the clinical pharmacy specialist develops a therapeutic plan based on national

guidelines. This interdisciplinary approach has resulted in innovative practice models that are likely the reason this Kaiser region has the highest BP control rates of any Kaiser region and most other managed care organizations. Figure 92–1 displays a potential model for interdisciplinary management of hypertension.

Pharmacist-managed hypertension clinics

Pharmacist-managed hypertension clinics are not common and have primarily been developed in VA medical centers. One survey found that one-third of hypertension clinics in VA medical centers were managed by pharmacists.⁶⁷ These clinics still have a physician medical director and policies and procedures to ensure a structured evidence-based approach to treatment. One study used blinded judges to evaluate the medication regimens and found that pharmacists scored better than physicians when selecting appropriate antihypertensive drugs ($p<0.01$); selecting the proper quantity, dose, and directions ($p<0.05$); and avoiding drug interactions ($p<0.05$).⁶² The studies by Monson and Bond, in which most of the management of hypertension was performed by clinical pharmacists, was conducted within renal or arthritis clinics in the Madison VA.^{59,60}

Finally, a study was conducted in San Antonio in a largely indigent Hispanic population.⁶³ BP control was similar in the pharmacist or physician-managed groups but BP was controlled in 97% in the pharmacist group compared to 78% in the physician group ($p<0.05$).

The previously cited studies strongly suggest that BP and medication regimens can be improved and adverse reactions avoided when pharmacists assist physicians with managing hypertension. Pharmacists in any setting can assist with developing cost-effective treatment strategies, track prescription refill history, educate patients on the use of pill boxes or other devices, and help the physician by reinforcing treatment goals.

SUMMARY

Hypertension control is poor in many populations due to physician inertia, inadequate systems of care, poor patient adherence, and other factors. There are many provider and organizational quality improvement strategies that should be used to improve BP control in individual patients and within a panel of patients in a clinic. Table 92–1 displays these strategies. Quality of life is generally better in patients with controlled BP regardless of medication. In contrast to common beliefs, quality of life is frequently better with diuretics than with other more expensive agents or even placebo. Adherence to medications is challenging for some patients, and multiple strategies need to be used to support patients in their effort to correctly take their medications. Pharmacists can assist physicians with monitoring for adverse reactions or poor adherence and recommend strategies to modify therapy to improve BP control. In some settings, pharmacists may collaborate with physicians and nurses to optimize BP control.

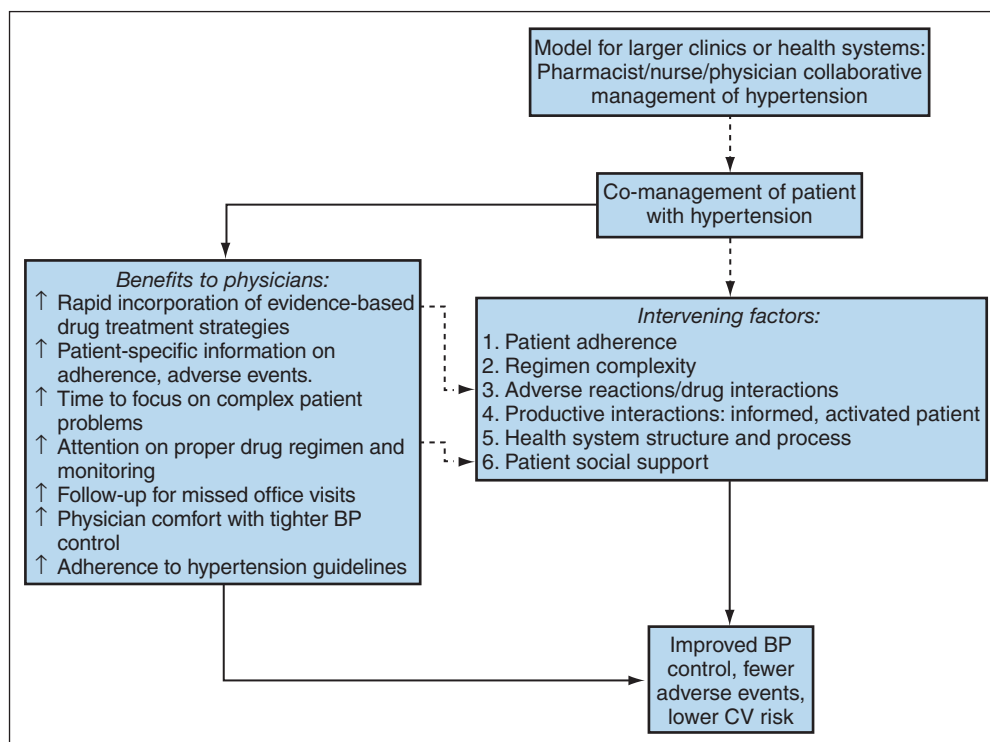

Figure 92–1. A potential model for interdisciplinary management of hypertension.

STRATEGIES FOR IMPROVING BP CONTROL	
Actions by Providers	Strategies
Foster effective communication with patients <ul style="list-style-type: none"> ■ Provide clear, direct messages about importance of lifestyle modification or therapy ■ Include patients in decisions about prevention and treatment goals for BP ■ Incorporate behavioral strategies into counseling 	<ul style="list-style-type: none"> ■ Provide verbal and written instruction and rationale for treatments ■ Develop counseling skills ■ Use contracting strategies ■ Establish BP goals and a plan ■ Anticipate barriers or occasional low adherence and discuss solutions
Document BP goals and respond to patient's progress toward goals <ul style="list-style-type: none"> ■ Create an evidence-based practice ■ Assess patient's adherence at each visit ■ Assess the patient's progress toward goal BP at each visit ■ Develop reminder systems to ensure identification and follow-up of patient status 	<ul style="list-style-type: none"> ■ Document the goal BP in the medical record ■ Determine methods of evaluating hypertension outcomes ■ Use self-report on adherence, pill counts, or electronic data ■ Contact pharmacist to obtain refill history ■ Use telephone follow-up
Actions by the Clinic or Office	Specific Strategies
Organization of the office or clinic must: <ul style="list-style-type: none"> ■ Develop an environment that supports hypertension prevention and treatment interventions ■ Ensure continuity with one provider ■ Provide tracking and reporting systems ■ Benchmark BP control rates by provider or by clinic ■ Provide education and training of providers ■ Provide adequate reimbursement for allocation of time for all health care professionals ■ Rapidly and efficiently incorporate innovations into medical practice 	<ul style="list-style-type: none"> ■ Develop training in behavioral science and office set-up for all personnel ■ Use pre-appointment and refill reminders ■ Use telephone follow-up ■ Schedule evening/weekend office hours ■ Provide group counseling for patients and families ■ Develop computer-based systems such as electronic medical records ■ Require continuing education courses in communication, behavioral counseling ■ Hire behavioral counselors to provide adherence counseling ■ Develop incentives tied to desired patient and provider outcomes ■ Incorporate nurse and/or pharmacist case management of hypertension ■ Effectively store and document BP data obtained from patient self-monitoring ■ Provide continuous quality improvement training

Chapter
93Nonpharmacologic
Management of Hypertension*Saverio Stranges and Francesco P. Cappuccio***Key Findings**

- Nonpharmacologic interventions represent an essential approach to the primary prevention of high blood pressure and an important component of the treatment of hypertension.
- Current lifestyle modifications that effectively lower blood pressure include weight reduction; reduction of dietary sodium intake; increased potassium intake; moderation of alcohol consumption; adoption of a diet rich in fruit, vegetables, and low-fat dairy products with a reduced content of saturated and total fat; and regular aerobic exercise.
- Obesity is an important determinant of cardiovascular disease, and the relationship between obesity and hypertension is well documented.
- Weight gain, even of a modest magnitude, is itself an important risk factor for the development of hypertension in adulthood. In contrast, average reductions of 4.4/3.6 mmHg for systolic and diastolic blood pressure, respectively, are reported for a 5-kg weight loss.
- The amount of dietary sodium is an important determinant of blood pressure levels and of hypertension risk both in individuals and populations, and conversely, the reduction of dietary sodium intake reduces blood pressure and helps control hypertension.
- Several antihypertensive drugs blocking the renin-angiotensin system (e.g., angiotensin-converting enzyme inhibitors, beta-blockers, and angiotensin II receptors antagonists) have an additive effect on blood pressure reduction in those patients already on a reduced salt diet.
- The risk of hypertension is 30-50% higher in individuals who are physically inactive, and aerobic exercise is associated with a significant reduction in systolic and diastolic blood pressure of 3.8/2.6 mmHg, respectively.

Cardiovascular diseases (CVDs) are the leading cause of mortality, morbidity, and disability worldwide.¹ Although CVDs are proportionally more relevant in developed countries, currently 70% of the total number of cardiovascular deaths occur in developing countries. In fact, in the past several decades, the process of changes in patterns of diseases and their interaction with the socio-economic transformation, known as “epidemiologic transition,”² has caused an increasing burden of CVD in many developing countries. Thus, preventing CVD represents a formidable public health challenge not only in developed but also in developing countries.

The strategy for the primary prevention of CVD resides in the detection and management of major risk factors. Seventy-five percent of the global burden of CVD results from smoking, high blood cholesterol, and high blood pressure or a combination of these factors. Globally, excess blood cholesterol causes more than 4 million premature deaths a year, tobacco causes almost 5 million, and high blood pressure causes 7 million.¹ In particular, hypertension affects approximately 1 billion individuals worldwide, thus representing the most common cardiovascular condition in both developed and developing countries as well as the number one attributable risk for death throughout the world.³ Indeed, according to a recent World Health Organization report, about 62% of cerebrovascular disease and 49% of ischemic heart disease are attributable to suboptimal blood pressure levels (systolic blood pressure >115 mmHg) with little variation by gender.¹

The burden of hypertension-related diseases is likely to increase as the population ages, as suggested by recent data from the Framingham Heart Study, whereby normotensive individuals at 55 years of age have a 90% lifetime risk to develop hypertension.⁴ Accordingly, prevention and treatment of hypertension are increasingly regarded as a public health priority in both developed and developing countries. In developed countries, because of the magnitude of the incidence of CVDs and the potential benefits of hypertension prevention; in developing countries, because of the rising magnitude of CVD incidence given the size of the populations, limited resources available, increase in hypertension prevalence, and marked trend to urbanization with the subsequent epidemiologic transition.⁵

Nonpharmacologic interventions, also termed “lifestyle modifications,” represent an essential approach to the primary prevention of high blood pressure and an important component of the treatment of hypertension. They represent as well cost-effective measures in the context of a multifaceted public health strategy to reducing blood pressure at a population level. The current lifestyle modifications that effectively lower blood pressure include weight reduction if overweight or obese; reduction of dietary sodium intake; increased potassium intake; moderation of alcohol consumption; adoption of a dietary plan based on the DASH (Dietary Approaches to Stop Hypertension) diet, that is, a diet rich in fruit, vegetables, and low-fat dairy products with a reduced content of saturated and total fat; and regular aerobic exercise.⁶ These lifestyle

modifications are effective in reducing blood pressure, increasing the efficacy of pharmacologic therapies, and reducing the global risk of CVD.

In this chapter, we will review the available literature and discuss the importance of these nonpharmacologic measures, for which the current evidence consistently demonstrates their efficacy in lowering blood pressure. In addition, we will evaluate the appropriateness of recommendations at a population level regarding some of these measures (i.e., reduction of dietary sodium intake) and the different approaches to intervention needed to implement a successful strategy to prevent hypertension in developing and developed countries.

WEIGHT REDUCTION

Obesity is a worldwide public health priority.⁷ In the United States, the prevalence of obesity, defined as body mass index (BMI) of 30 kg/m² or more, as well as of overweight (BMI ≥ 25 kg/m²) has steadily increased since the second half of the last century as the population has aged. Data from the U.S. National Health and Nutrition Examination Survey (NHANES), obtained in 2003–2004, indicate that 32.2% of American adults (20 years or older) are obese whereas only one-third (33.7%) are in the range of normal weight (BMI < 25 kg/m²).⁸ The obesity trends in the United Kingdom have been similar; recent prevalence data indicate that over half of women and about two-thirds of men are either overweight or obese.⁹ Obesity and overweight are becoming increasing public health issues in many developing regions as well (e.g., Latin America, Middle East) and represent major contributors to the global burden of disease.¹⁰

Obesity is an important determinant of CVD, and is strongly associated with several cardiovascular risk factors such as diabetes, high cholesterol, and high blood pressure. In fact, obesity is an independent risk factor for coronary heart disease, stroke, and total cardiovascular morbidity and mortality.¹¹

The relationship between obesity and hypertension is very well documented. Blood pressure is strongly correlated with BMI. In the INTERSALT study, the relationship between BMI and blood pressure was examined in over 10,000 men and women, from 20 to 59 years of age, sampled from 52 centers around the world.¹² BMI was linearly associated with systolic and diastolic blood pressure, independent of age, alcohol intake, smoking habits, and sodium and potassium excretion. The prevalence of obesity-related hypertension varies with age, ethnicity, and gender of the population studied.¹³ Approximately one-third of cases of hypertension are attributable to obesity, although in young adults (under 45 years of age) the figures may be substantially higher. For example, in the sample of young adults of the Framingham Offspring Study, 78% of cases of hypertension in men and 64% in women were attributable to obesity.¹⁴ Additionally, variations have been observed by ethnic group. For example, results from the Atherosclerosis Risk in Communities Study suggest the association to be stronger in whites than in African Americans.¹⁵

Not only is obesity associated with high blood pressure, but weight gain, even of a modest magnitude, is itself an important risk factor for the development of hypertension in adulthood. This effect seems to be independent of baseline BMI and baseline blood pressure, present in both genders, stronger in young adults, and weaker in people of black African ancestry; conversely, weight loss reduces the risk of hypertension.^{16–18}

While many of the earlier studies examined the association between obesity and blood pressure relying on BMI as an indicator of relative weight, more recent investigations have emphasized the importance of body fat distribution in this association. Specifically, abdominal adiposity has been reported as a stronger determinant of hypertension risk than relative weight.^{15,19–21} In epidemiologic studies, several anthropometric measures have been used as proxy measures for body fat distribution, such as waist-to-hip circumference ratio, waist circumference, and abdominal sagittal diameter. Current clinical guidelines propose waist circumference as a reference measure of central adiposity in adults because its measurement is the least affected by observer bias.²²

Given the overwhelming evidence on the relationship between body weight and blood pressure, weight reduction has been proposed as a measure to reduce blood pressure in both individual patients and the community at large. Over the past three decades, several randomized controlled clinical trials have reported on the beneficial effects of weight loss interventions on the prevention and treatment of hypertension. For example, the results of the multicenter randomized clinical Trials of Hypertension Prevention (TOHP), Phases I and II, indicate that both short- and long-term weight loss is successful in reducing blood pressure. In TOHP I, an 18-month intervention was significantly associated with 77% reduction in the incidence of hypertension after a 7-year follow-up.²³ Likewise, in TOHP II, a longer-term intervention of 36 months resulted in significant reductions in systolic and diastolic blood pressures and in a lower incidence of hypertension even in presence of modest weight loss.²⁴

In the latest published meta-analysis of 25 randomized controlled trials, which included only trials based on weight reduction through energy restriction, increased physical activity, or both, average reductions of 4.4/3.6 mmHg for systolic and diastolic blood pressure, respectively, were reported for a 5-kg weight loss²⁵ (Figure 93–1). A dose-response relationship was observed, that is, the greater the weight loss, the greater the blood pressure reduction. Furthermore, the lowering effect of weight reduction on blood pressure was independent of age, gender, and initial BMI, although the effect appeared greater in patients on antihypertensive medication. This meta-analysis also highlights the problem of lack of compliance during long-term interventions because the maximal effect was reached before the end of the trials. Additionally, the long-term effects of weight reduction on blood pressure are not fully understood; however, they seem to be in magnitude less than those reported in short-term trials. In fact, a recent systematic review, based on studies with follow-up of 2 or more years, demonstrated decreases of 6.0/4.6 mmHg

A

B

Figure 93–1. Short-term effect of weight reduction on systolic in untreated (A) and treated (B) individuals. (Data from Neter JE, Stam BE, Kok FJ, Grobbee DE, Geleijnse JM. *Hypertension* 2003;42:878–84.)

for systolic and diastolic and blood pressure, respectively, for 10-kg weight loss, about half of that predicted from the short-term trials.²⁶ Several factors such as initial blood pressure, length of follow-up, medication changes, and physiologic restrictions may contribute to this reduced effect in the long-term studies. Nevertheless, weight loss programs represent an essential component of a multi-

faceted nonpharmacologic intervention to manage hypertension; in addition, they are adjuvant measures to pharmacologic therapies, as they decrease the dosage of antihypertensive medication needed to reach blood pressure control.²⁷ Indeed, clinical trials have reported on the efficacy of combined lifestyle interventions including weight loss, hypo-caloric/low-salt diet, and regular exercise in reducing blood pressure levels to an extent comparable to that achieved with antihypertensive medication.^{28,29}

Several biological mechanisms may explain the link among obesity, weight change, and blood pressure. In particular, an overactivity of the renin-angiotensin-aldosterone system has been regarded as a possible key mechanism of the hypertensive response in obese individuals, whose circulating levels of renin activity and aldosterone are higher than in nonobese subjects. Recent data support this mechanism suggesting that the overactivity of this system in obese individuals can be lowered by a reduction in body weight.³⁰ Further mechanisms may reside in inhibition of the natriuretic peptides system, which is critical to prevent excess salt and water retention, promote vascular relaxation, and inhibit sympathetic outflow; increased activity of the sympathetic nervous system; reduced insulin sensitivity; and hyperinsulinemia.³¹

Overall, the current evidence from clinical trials and observational studies strongly supports the notion that

prevention of weight gain in normal-weight individuals and weight loss in overweight and obese individuals, in combination with other lifestyle modifications (e.g., hypocaloric diet, salt reduction, moderation in alcohol consumption and increased physical activity), are highly effective strategies for the prevention and management of hypertension both in individuals and population at large.⁶

DIETARY SODIUM REDUCTION

Epidemiologic evidence

Numerous animal studies, ecologic analyses, observational epidemiologic investigations, and clinical trials have supported a relationship between salt (sodium chloride) intake and blood pressure. The amount of dietary sodium is an important determinant of blood pressure levels and of hypertension risk both in individuals and populations. This relationship is direct and progressive without an apparent threshold. Thus, the reduction of dietary sodium intake is one of the most important and effective lifestyle modifications to reduce blood pressure and control hypertension.^{6,32}

That habitual sodium intake could be associated with blood pressure levels was suggested several millennia ago, in the history of human mankind, after the transition from food gathering to food producing with the addition of salt to preserve food and the consequent shift to a high-salt diet.³³ Above and beyond earlier anecdotal observations, the relationship between dietary sodium and blood pressure has become the focus of intensive scientific scrutiny over the past decades. One of the earlier epidemiologic studies to address this question was also the INTER-SALT study.³⁴ This study tested both the within- and cross-population association between 24-hour urinary sodium excretion, reflecting the amount of sodium intake, and blood pressure levels. The within-center results showed a significant, positive, independent and linear association between 24-hour urinary sodium excretion and blood pressure levels. Specifically, a 100-mmol per day higher sodium intake (about 2.3 g/day) would predict a 3- to 6-mmHg higher systolic and up to 3 mmHg higher diastolic blood pressure. Similar results were obtained in different subgroup analyses: men, women, young, elderly, and for participants without hypertension. In the cross-population analysis, significant, independent relations were found between 24-hour urinary sodium excretion and median systolic and diastolic blood pressure, prevalence rate of hypertension, and rise of systolic and diastolic blood pressure with age. These results were further supported by findings from the Multiple Risk Factor Intervention Trial. In this cohort of more than 11,000 participants followed up for 6 years, sodium intake, as assessed by questionnaire, was significantly, directly, and independently related to systolic and diastolic blood pressure in both individuals receiving and not receiving antihypertensive medication.³⁵

In addition to these observational investigations, over 50 randomized clinical trials have supported more persuasively a role of salt intake reduction in the prevention and management of high blood pressure. In the largest of

these trials, DASH, 412 participants were randomly allocated to two dietary regimens: one following a control diet, which was representative of the average diet in the United States; and one following the DASH diet, rich in fruit and vegetables, low-fat or fat-free dairy products, and reduced in saturated and total fat content. Inside each arm of the trial, participants were randomly assigned to three groups with increasing amounts of sodium intake. As estimated from 24-hour urinary collections, the three sodium levels (lower, intermediate, and higher) provided 65, 107, and 142 mmol per day, respectively, which correspond approximately to intakes of 1.5, 2.5, and 3.3 g of sodium per day, respectively.³⁶ In this trial, a sodium reduction alone from a high to a low level was associated with a blood pressure reduction of 8.3/4.4 mmHg among hypertensive individuals and 5.6/2.8 mmHg among normotensive individuals. Moreover, the combination of this amount of sodium reduction and the DASH diet further reduced blood pressure by 11.5/5.7 mmHg and 7.1/3.7 mmHg, respectively, among those with and without hypertension. In subgroup analyses, significant effects of sodium reductions on blood pressure levels were present in both genders, and all racial and age groups, although they were more marked among African Americans, women (for systolic blood pressure), and persons aged more than 45 years.³⁷

Pooled estimates from meta-analyses of clinical trials on the effects of salt reduction on blood pressure levels indicate a fall in systolic and diastolic blood pressure of 7.1/3.9 mmHg, respectively, in hypertensive individuals and 3.6/1.7 mmHg in normotensive individuals per 100 mmol reduction of 24-hour urinary sodium excretion (about 6 g salt/day). For example, He et al.³⁸ estimated blood pressure reductions of 5.0/2.7 mmHg in hypertensives and 2.0/1.0 in normotensives for a median reduction in urinary sodium of 78 mmol per day (Figure 93–2). In the latest published meta-analysis of 40 randomized trials, an average reduction in urinary sodium excretion of 77 mmol per day was associated with a reduction in blood pressure levels of 2.5/2.0 mmHg.³⁹ Blood pressure response was significantly larger in hypertensive than normotensive individuals (systolic: –5.2 vs. –1.3 mmHg; diastolic: –3.7 vs. –1.1 mmHg).

Accordingly, findings from randomized clinical trials have supported a role for reduction in dietary sodium in the primary prevention and management of hypertension. For example, in the Trials of Hypertension Prevention, phase II, a sodium reduction of 100 mmol per day, alone or combined with weight loss, prevented hypertension by 20% throughout 48 months of intervention in overweight adults.⁴⁰ Likewise, in the Trial of Nonpharmacologic Interventions in the Elderly (TONE), a sodium reduction of ~40 mmol per day was associated with a 30% decrease in the need for antihypertensive medication after 3 months of intervention in hypertensive individuals aged 60 to 80 years.²⁸

The response of blood pressure to dietary changes in sodium intake, as to other environmental stimuli, may vary among individuals. This phenomenon has been called “*salt sensitivity*,”⁴¹ and it is likely to be due to the

Figure 93–2. Effect of reduced sodium intake on systolic pressure in hypertensive and normotensive individuals. SE, standard error. (Reprinted by permission from Macmillan Publishers Ltd: He FJ, MacGregor GA. *J Hum Hypertens* 2002;16:761–70.)

degree of response of the renin-angiotensin system.^{42,43} The weaker the response of this system to a change in sodium intake, the larger the response of the blood pressure will be. This phenomenon explains why the blood pressure–lowering effect of sodium reduction is larger in hypertensive individuals, elderly, and “low-renin” black populations. These groups are all characterized by weaker responses of the renin-angiotensin system to changes in the amount of sodium ingested, showing a greater blood pressure fall as a result of a reduction of dietary sodium. Indeed, although a significant reduction of blood pressure induced by reduced sodium intake has been observed in children and adolescents as well,⁴⁴ this response increases with age and is largest in the elderly. For example, in a double-blind randomized trial, a modest reduction in sodium intake in people over age 60 induced a significant reduction in blood pressure without untoward effect, irrespective of the initial blood pressure.⁴⁵ Furthermore, the blood pressure fall observed in the elderly as a

result of a dietary sodium reduction may reduce the need for antihypertensive medication.³¹ These observations are relevant to the prevention of hypertension-related diseases in developed countries, where the majority of strokes occur in the elderly and individuals with blood pressure levels below the treatment threshold for hypertension.⁴⁶ Nevertheless, several antihypertensive drugs blocking the renin-angiotensin system (e.g., angiotensin-converting enzyme inhibitors, beta-blockers, and angiotensin II–receptor antagonists) have an additive effect on blood pressure reduction in those patients already on a reduced salt diet.⁴⁷

Furthermore, people of black African origin often show a greater blood pressure response when dietary salt is reduced.^{36,43,48} For example, the efficacy of a moderate reduction in salt intake has recently been tested in two short-term trials in both urban and rural areas of West Africa, namely Nigeria and Ghana, where the prevalence of hypertension is increasing.^{49,50} In both studies a

moderate reduction in salt intake was associated with a significant reduction in blood pressure comparable to that seen in white populations. In areas such as sub-Saharan Africa, the prevalence of hypertension is increasing and health care resources are scarce, and thus the identification of people with hypertension is still haphazard. The effectiveness of a reduction in salt intake at a population level might prove extremely important for policymakers.

Finally, there is growing evidence on the genetic determinants of blood pressure sensitivity to sodium as well as its ethnic variations. Recently, genes involved in the regulation of the renin-angiotensin system, in transmembrane ion exchange, and in the modulation of sympathetic activity have been the focus of intense research. For example, in a study on a large population sample of white middle-aged men, an association between the Gly40Ser mutation of the glucagon receptor gene and an increased sodium reabsorption at the proximal tubule was observed,⁵¹ which suggested a possible genetic contributor to the blood pressure sensitivity to salt. However, this genetic variant is almost absent in other ethnic groups, particularly in those of black African origin who are known to be most “salt sensitive.”⁵² Conversely, the C(-344)T polymorphic variant of the aldosterone synthase gene (CYP11B2) has been shown to modulate the relationship of blood pressure and plasma aldosterone levels with age.⁵³ Overall, the associations among functional mutations related to altered renal sodium handling and changes in sodium intake have not been clearly explained yet. A reasonable hypothesis seems to be that each functional mutation has an influence in the individual response of blood pressure to sodium intake.

Given the overwhelming evidence of the efficacy of dietary sodium reduction in the prevention and management of hypertension, the debate is currently based on issues regarding the long-term outcome benefits, and thereafter the appropriateness of a population-wide strategy to reduce dietary salt intake. The major benefit of sodium reduction is the lowering of blood pressure. It has been argued that the blood pressure reduction realistically achievable at a population level (i.e., 1 to 3 mmHg in systolic blood pressure) is small, not clinically significant, and with long-term benefits remaining unclear.⁵⁴ However, in a recent meta-analysis of 61 prospective studies, it has been estimated that even a reduction of 2 mmHg in systolic blood pressure would determine a 10% reduction in stroke mortality and a 7% reduction in mortality from coronary heart disease or other cardiovascular causes, meaning a large number of premature deaths and disabilities avoided.⁵⁵ Other results corroborate these estimates, and suggest that the benefits of such a small reduction in blood pressure, induced by salt reduction, in the population would be almost immediate.³⁸ Moreover, although the principal benefit of salt reduction is the blood pressure reduction, it is not the only one. There is a large body of evidence that supports other benefits: regression of left ventricular hypertrophy, reduction in proteinuria and glomerular hyperfiltration, reduction in bone mineral loss with age and osteoporosis, protection against stomach

cancer and stroke, and protection against asthma attacks and possibly against cataracts.⁵⁶ Conversely, some potentially harmful effects have been reported following severe short-term sodium reductions, such as increased levels of renin, aldosterone, catecholamines, serum cholesterol and triglycerides.⁵⁷ However, these effects are likely caused by an acute volume concentration and are not detected after a moderate long-term sodium reduction.

In light of the present evidence, reduction of dietary salt intake appears to be a plausible population-wide recommendation for the prevention and treatment of hypertension.^{6,32} A decrease of dietary sodium to no more than 100 mmol per day (2.3 g sodium or 5.8 g sodium chloride) represents a reasonable goal at a population level given the current dietary patterns of high levels of salt intake worldwide. However, this reduction will be only feasible in Western societies if efforts are made by the food industry, manufacturers, and restaurants to decrease the amount of salt added to processed food. In fact, in these societies, a large proportion of sodium intake (75% to 80%) comes from processed food and bread.⁵⁸ On the contrary, in developing countries where the prevalence of hypertension continues to increase, more traditional health promotion strategies would be applicable and nutritional education might have an important effect in these settings.^{46,50,59}

Public health strategies to reduce salt intake in developed countries

In developed countries, the estimated prevalence of hypertension is, on average, 28% in North America (Canada and United States) and 44% in Western Europe.⁶⁰ The elevated prevalence of hypertension is a major public health concern in these countries as it accounts for 72% of cerebrovascular diseases and more than 50% of coronary heart diseases.¹ Community-based intervention trials to reduce blood pressure by means of salt reduction are scanty. For example, a community-based intervention trial in Portugal over 2 years involved a whole town to receive a health education program to reduce salt intake while another town was not given any advice and used as a control.⁶¹ In the two towns, initial salt intake was high and 30% of persons were hypertensive. In the intervention community, a reduction of the population average blood pressure was achieved with a reduction in salt intake. Specifically, average blood pressure fell by 3.6/5.0 mmHg at 1 year and 5.0/5.1 mmHg at 2 years, due to a general distribution shift. By contrast, in the control community systolic/diastolic blood pressures either increased or remained stable, respectively. The difference in trends between the two communities was highly significant. However, in developed countries a sustained and long-term reduction in salt intake based on educational and behavioral interventions only is likely to be unsuccessful in reducing blood pressure at a population level, because the majority of an individual's salt intake is not added by the person but is already present in foods. Indeed, given that 75% to 80% of salt intake comes from salt added to bread and processed foods,⁵⁸ a population-wide strategy involving the food industry would be more effective in

the long term. The North Karelia Project is a meaningful example to support this concept. This program was launched in 1972 in Finland to prevent noncommunicable diseases and, primarily, to reduce mortality and morbidity from CVDs.⁶² The interventions implemented during this trial were extensive: collaborations with the community, the health services, and the food industry were added to a mass media campaign. The results have been outstanding. Over 25 years, the age-adjusted mortality rate from CVD among men aged 25 to 64 years fell by 73%.

These results clearly show that a comprehensive and collaborative program involving the food industry and health and community services is essential to successfully implement strategies of primary prevention of CVDs in developed countries. Moreover, the cost-effectiveness analysis of the North Karelia Hypertension Program, which was part of the overall project, showed that hypertension treatment represents a cost-effective treatment.⁶³ However, it would be even more cost-effective if hypertension could be treated as effectively without medications. This analysis showed that a comprehensive intervention is likely to improve the population's health and save money. The program included information campaigns, development of new industry food products with less salt, welfare losses from taxes/subsidies on food production with little salt, and, assuming a 2-mmHg reduction of systolic blood pressure, the cost of avoided treatment for myocardial infarction and stroke, cost of avoided antihypertensive treatment, hospital costs in additional life-years and productivity gains from reduced morbidity and mortality.

A recent global and regional analysis of population interventions including government cooperation with the food industry and change of legislation on salt content of processed food consistently showed cost-effectiveness in limiting CVDs.⁶⁴ This strategy has been adopted recently by the UK Department of Health, the Food Standard Agency, and the food industry showing a simple way of implementing a nonpharmacologic measure to limit the burden of CVDs in developed countries.

A complementary approach to lower salt intake, in developed countries, may reside in the use of salt substitutes. The American Heart Association recommends the use of non-chloride salts of sodium as they do not increase blood pressure.⁶⁵ This recommendation has been supported by results of clinical trials. For example, in a double-blind randomized placebo controlled trial including 100 men and women aged 55 to 75 years with untreated mild-to-moderate hypertension, a significant decrease in blood pressure of 7.6/3.3 mmHg was observed in individuals using a mineral salt substitute (sodium:potassium:magnesium, 8:6:1). The effect was sustained as long as the patients used the salt substitute.⁶⁶

In conclusion, in developed countries comprehensive population strategies to reduce average levels of salt intake are required. Indeed, the expected benefits of a modest reduction in blood pressure across the whole population would be significant, especially on stroke, coronary heart disease, and all other cardiovascular conditions for which high blood pressure is a causative risk factor. The benefits would be greater in the elderly,

because they have a much higher stroke incidence (greater absolute risk); additionally, in this age group, the majority of strokes occur at levels of blood pressure not always requiring drug therapy (more stroke events attributable to the effect of blood pressure).

Public health strategies to reduce salt intake in developing countries

In developing countries, noncommunicable diseases are increasingly becoming an important threat to the health of populations.¹ Worldwide, stroke is second only to ischemic heart disease as a cause of death, and most of these deaths occur in developing countries.¹⁰ For example, data from Tanzania suggest a high burden of stroke, comparable to that observed in developed countries.⁶⁷ Likewise, in areas like sub-Saharan Africa the prevalence of hypertension is elevated and comparable to figures from developed regions.^{3,59} Thus, preventing the impending epidemic of CVD in these countries is critical as they are facing a dramatic demographic change and already experiencing a “double” burden of disease, that is, communicable and noncommunicable. In fact, in the 30-year period from 2000 to 2030, the population of elderly persons is projected to double in many sub-Saharan African countries. The repercussion of these changes will be substantial on the prevalence of CVDs given that age is an independent predictor of cardiovascular mortality and morbidity. Moreover, the burden of diseases attributable to hypertension (e.g., stroke, heart and renal failure) is much greater in sub-Saharan Africa than in the Western societies since competing risk factors like tobacco smoking and high serum cholesterol are not highly prevalent yet.¹⁰ Likewise, many developing countries in Asia are facing the emergence of a CVD epidemic; the prevalence of hypertension varies among countries and between rural and urban settings from 5% to 35%.³ Furthermore, in other developing areas, like the former socialist countries of Eastern Europe, a CVD epidemic is already in place.

Salt consumption in developing countries is becoming more common as urbanization increases. However, interventions to reduce salt intake at a population level have not been extensively studied in these countries. The population approach to reduce salt consumption is particularly relevant in developing countries due to the cost-effectiveness of these measures.⁶⁸ Furthermore, in countries of sub-Saharan Africa where effective health-care provision for chronic diseases is haphazard, a population strategy to limit salt consumption might prove extremely effective. It can be predicted that the same reduction in salt intake obtained with a behavioral intervention will be more effective in black African-origin populations than in Caucasian populations due to the higher salt sensitivity of black African-origin populations and because most of the salt ingested is added to food by the consumer, whereas processed food is used relatively scarcely compared to developed countries.⁴⁶ Two short-term trials in sub-Saharan Africa have confirmed that simple, cost-effective, and culturally adapted behavioral and educational interventions to reduce blood pressure can be successfully implemented^{49,50} (Figure 93-3). Concerns

Figure 93–3. Trials on sodium reduction and systolic blood pressure in Africa. (Data from Adeyemo AA, Prewitt TE, Luke A, et al. *Ethn Dis* 2002;12:207–12; and Cappuccio FP, Kerry SM, Micah FB, Plange-Rhule J, Eastwood JB. *BMC Public Health* 2006;6:13.)

about population-wide strategies to limit salt consumption in developing countries pertain to the perceived risk of counteracting worldwide policies directed to the prevention of iodine-deficiency disorders through universal salt iodization. There is an urgent need to consider alternative vehicles for the deliveries of iodine to populations. In the meantime, an increase in the proportion of iodine fixed to salt could be considered.

The proportion of a disease that can be attributed to a specific risk factor in a population (i.e., population attributable risk) is a function of the incidence of the disease and the strength of the association between disease and a specific risk factor. Thus, when we consider the prevalence and relative risks of traditional risk factors for stroke such as modifiable risk factors (i.e., hypertension and smoking), atrial fibrillation, and other risk factors (i.e., diabetes, coronary heart disease or obesity) contributing to the overall incidence of stroke, the proportion of disease in populations that can be attributed to these risk factors varies from developed to developing regions.

To illustrate this concept we chose to compare aggregated data from developed countries and data available from sub-Saharan Africa.⁶⁹ A reduction in salt intake that prevented 10% of hypertension would have a greater impact in a sub-Saharan population than in a Western population. In fact, in sub-Saharan Africa 11 times more strokes are estimated to be prevented in people under age 65 when compared with developed countries. The benefit of a public health intervention aiming at reducing salt intake, thereby reducing the prevalence of hypertension, would be substantial in developing countries (almost a 20% reduction in the incidence of stroke in people under age 65). Given the size of the populations in sub-Saharan Africa, and considering that the incidence of stroke in people under 65 is estimated to be approximately seven times greater in this region compared with developed countries, one might expect the benefits of such an inter-

vention to be significantly greater in this region than in developed countries.

In conclusion, in developing countries, which are experiencing an increasing burden of CVD, multiple risk factor interventions and community-based programs of primary prevention should be encouraged. In particular, public health measures to promote dietary changes such a reduction in salt intake should be strongly recommended given that the prevalence of hypertension is likely to increase in these countries.

DIETARY POTASSIUM INCREASE

There is an established inverse association between dietary potassium intake and blood pressure levels. The evidence is supported by findings of animal studies, observational epidemiologic investigations, and clinical trials. In addition, meta-analyses of randomized controlled trials on the efficacy of potassium supplementation

(Table 93–1) in reducing blood pressure levels in both normotensive and hypertensive individuals consistently demonstrate this inverse relationship.

Specifically, in an early meta-analysis including 19 clinical trials with both normotensive and hypertensive individuals, an overall effect of potassium supplementation of -5.9 mmHg (95% confidence interval [CI], -6.6 to -5.2) and -3.4 mmHg (95% CI, -4.0 to -2.8) was reported for systolic and diastolic blood pressure, respectively. The magnitude of the blood-pressure lowering effect of potassium supplementation was greater in individuals with high blood pressure (-8.2 mmHg, 95% CI, -9.1 to -7.3 , for systolic, and -4.5 mmHg, 95% CI, -5.2 to -3.8 , for diastolic blood pressure) and appeared to be more pronounced the longer the duration of the supplementation.⁷⁰ Likewise, in a later meta-analysis including 33 randomized controlled trials, potassium supplementation was associated with a significant reduction in mean systolic and diastolic blood pressure of -3.1 mmHg (95% CI, -1.9 to -4.3) and -2.0 mmHg (95% CI, -0.5 to -3.4), respectively.⁷¹ The average effect size was larger in trials conducted in hypertensive individuals (-4.4 and -2.5 mmHg for systolic and diastolic blood pressure, respectively). Furthermore, in this meta-analysis, the blood pressure-lowering effect of potassium supplementation was greater in studies in which participants were simultaneously exposed to a high intake of sodium. Finally, a recent meta-analysis by Geleijnse et al.³⁹ including 27 potassium trials showed a significant, inverse association between increased potassium intake (median 44 mmol/24 h) and blood pressure levels, although the effect size reported was slightly smaller than that previously published, that is a decrease in systolic and diastolic blood pressure of -2.4 mmHg (95% CI, -1.1 to -3.7) and -1.6 mmHg (95% CI, -0.5 to -2.6), respectively. Consistent with the two previously published meta-analyses, blood pressure response was larger in hyper-

META-ANALYSES OF POTASSIUM SUPPLEMENTATION

tensive than normotensive individuals (systolic -3.5 vs. -1.0 mmHg, $p=0.089$; diastolic: -2.5 vs. -0.3 mmHg, $p=0.074$) (Table 93–1).

The hypothesis of an inverse association between dietary potassium intake and blood pressure levels originated from findings of population studies showing that the prevalence of hypertension may be low in populations consuming high potassium diets. The INTERSALT cooperative study was one of the earlier epidemiologic investigations to estimate the effect of potassium intake on blood pressure levels. This study tested both the within- and cross-population association between 24-hour urinary sodium, potassium, and sodium/potassium ratio, reflecting the amount of dietary intake of these micronutrients, and blood pressure levels. In these centers, a reduction in systolic and diastolic blood pressure of 3.4/1.9 mmHg was related to a higher potassium intake of 50 mmol per day. Furthermore, the sodium/potassium ratio was positively and significantly related to the blood pressure levels of individuals in both men and women. These relationships were more marked with increasing age.³⁴ Moreover, two large prospective studies on American cohorts of health professionals examined the association between dietary potassium intake and prevalence of hypertension. Specifically, Ascherio et al.⁷² analyzed a cohort of 30,681 U.S. male professionals, aged 40 to 75 years, without diagnosed hypertension for a follow-up period of 4 years. A significant, inverse association was found between potassium intake and risk of hypertension after adjustment for energy intake, age, relative weight, and alcohol consumption. When adjusted additionally for dietary fiber and magnesium intake, the association was no longer significant. The same result was observed before in a large cohort of women, the Nurses' Health Study cohort.⁷³ These results are not surprising given the high correlation between potassium and other micronutrients (e.g., calcium and magnesium), because they are present simultaneously in foods such as fruit, nuts, vegetables, cereals, and dairy products. Indeed, these results underscore the difficulty in differentiating the importance of the potassium effect when adjusted for other micronutrients in epidemiologic studies, and the need for randomized trials to determine whether there is a protective role of a specific dietary micronutrient in the regulation of blood pressure.⁷⁴

Numerous clinical trials have reported on the effect of potassium supplementation on blood pressure levels in both normotensive and hypertensive individuals. Although results have not been always consistent, pooled estimates from meta-analyses consistently support a significant inverse association between potassium intake and blood pressure levels^{39,70,71} in both normotensive and hypertensive individuals, as previously mentioned (Table 93–1). The lowering effect of potassium supplementation on blood pressure levels seems to be independent of the baseline potassium status, since it has been shown in individuals with low dietary potassium intake⁷⁵ and in individuals consuming normal/high potassium diets.⁷⁶ Moreover, this effect appears similar in women and men, whereas it is stronger among hypertensive individuals and individuals of black African origin, as also confirmed by pooled estimates of a published meta-analysis.⁷¹ For example, findings from two intervention trials in participants of black African origin show, on average, a larger reduction in blood pressure levels after potassium supplementations than that reported in other ethnic groups.^{75,77} Furthermore, the lowering effect of potassium supplementation on blood pressure is dependent on the concurrent intake of dietary sodium and vice versa. This means that the effect is larger in individuals on a high-sodium diet and smaller in individuals on a low-sodium diet; conversely, the lowering effect of a reduction in dietary sodium intake on blood pressure is larger in individuals on a low-potassium diet and smaller in individuals on a high-potassium diet.³² Accordingly, the ratio of urinary sodium–potassium excretion is more closely related to changes in blood pressure levels than either urinary sodium or potassium excretion individually.^{34,71} For example, in a study examining racial differences in the role of salt sensitivity in the development of high blood pressure, a high-potassium supplementation attenuated the rise in blood pressure levels following an increased dietary sodium intake in 24 normotensive black men and less markedly in 14 normotensive white men.⁷⁸ Moreover, in a 2×2 factorial trial examining the individual and simultaneous effects of reduced dietary sodium intake and increased potassium intake on blood pressure in 212 hypertensive individuals, the lowering effects on blood pressure levels were similar for either a reduced sodium intake or an increased potassium intake, individually.

However, when both interventions were implemented together, there was no further lowering effect on blood pressure levels.⁷⁹ Thus, these data suggest sub-additive effects of reduced salt intake and increased potassium intake on blood pressure.

Fruit, vegetables, and nuts are the main sources of dietary potassium in the form of inorganic or organic salts. These foods, especially fruit and vegetables, are rich in potassium as well as in other essential micronutrients; therefore, diet is a suitable strategy to increase the levels of potassium intake and prevents the need for supplements. Several randomized controlled trials have reported on the lowering effects on blood pressure of dietary interventions providing large intakes of potassium. For example, in the Dietary Approaches to Stop Hypertension (DASH) trial, the two groups that increased fruit and vegetable consumption, with larger amounts of potassium as a result, experienced significant reductions in blood pressure levels.³⁶ Likewise, in another trial examining the effects of fruit and vegetable consumption on plasma antioxidant concentrations and blood pressure, a significant reduction in blood pressure levels was detected.⁸⁰ Furthermore, the results of a recent randomized controlled trial conducted in 59 volunteers suggest that a substantial reduction in mean arterial blood pressure levels (i.e., 7.0 mmHg) may occur even at low-dose potassium supplementations (24 mmol of slow-release KCl per day) equivalent to the content of five portions of fresh fruit and vegetables per day.⁷⁶ Not only does the increase in dietary potassium help to reduce blood pressure, but it is a feasible and effective measure to reduce the need for antihypertensive medication. In 1991, Siani et al.⁸¹ found that after dietary advice, which specifically aimed at increasing potassium intake, the intervention group increased potassium intake compared to the control group. More importantly, as a result of the dietary intervention, blood pressure could be controlled using less than 50% of the initial pharmacologic therapy in 81% of the patients in the intervention group compared with 29% of the patients in the control group. Thus, an increase in potassium intake from natural dietary sources may be a feasible and effective measure to reduce antihypertensive medication.

The mechanisms responsible for the lowering effect of increased potassium intake on blood pressure are not fully understood. Several hypotheses have been put forward.⁸² High-potassium intake might exert a vascular protective effect and reduce the development of atherosclerosis. It may also reduce arteriolar thickening in the kidney. Moreover, potassium infusion increases acetylcholine-induced vasodilatation, and this effect is inhibited by the consequent infusion of the nitric oxide synthase inhibitor L-NMMA (L-nitromonomethylarginine). This suggests that potassium could lower blood pressure by a nitric oxide-dependent vasodilatation. Conversely, potassium depletion in humans is accompanied by sodium retention and calcium depletion, and also by an altered response to vasoactive hormones. These metabolic effects together with the direct vasoconstrictive effects of hypokalemia might be the cause of the

augmentation in blood pressure during a decrease of potassium intake.

Given the existing evidence, the adoption of a high-potassium diet is a reasonable, effective nonpharmacologic measure to improve blood pressure control in hypertensive individuals and to reduce the risk of hypertension in the general population. The level of intake that should be recommended is still a controversial issue depending on the levels of potassium status in a specific population, and the presence of conditions or drug therapies that can impair potassium excretion. However, a recent statement from the American Heart Association sets the recommended level of potassium intake, among healthy individuals, as 4.7 g/day (120 mmol/day).³² This level of intake has been based primarily on findings from clinical trials,⁷¹ and the potassium content of the DASH diet.³⁶ Indeed, in Western populations current levels of potassium intake are generally much lower than this recommended level. Moreover, in individuals affected by disease conditions impairing potassium excretion (e.g., diabetes, chronic renal insufficiency, end-stage renal disease, severe heart failure, and adrenal insufficiency) or on drug therapies that may interfere with potassium excretion (e.g., ACE inhibitors, angiotensin-receptor blockers, non-steroidal anti-inflammatory agents, and potassium-sparing diuretics), a lower level of intake (i.e., <4.7 g/day [120 mmol/d]) is recommended to prevent the risk of hyperkalemia.⁸³ In conclusion, an increase in potassium intake from natural dietary sources is a feasible and effective measure of preventing and treating hypertension.

MODERATION OF ALCOHOL CONSUMPTION

Extensive epidemiologic evidence suggests that heavy alcohol consumption is associated with elevated blood pressure and increased risk of hypertension, independent of age, gender, ethnic group, and other potential confounders.⁸⁴⁻⁸⁶ For example, findings from the multinational INTERSALT study showed that heavier drinkers of both sexes had higher mean systolic and diastolic blood pressures than nondrinkers.⁸⁵ The increased risk of hypertension occurs at levels of consumption above two drinks per day in men and above one drink per day in women and lighter-weight individuals.^{6,32} The observational data have been corroborated by findings of randomized controlled trials showing a blood pressure-raising effect of alcohol, which is reversible in both normotensive and hypertensive individuals.^{87,88} In a recent meta-analysis of 15 randomized controlled trials, the authors estimated a reduction in systolic and diastolic blood pressure of 3.3/2.0 mmHg, respectively, for a median 76% reduction in alcohol consumption from a baseline of three to six drinks per day⁸⁹ (Figure 93-4). Blood pressure reductions were similar in hypertensive and normotensive individuals. Importantly, the relationship between reduction in mean percentage of alcohol and decline in blood pressure was dose dependent. Findings from this meta-analysis also suggest that the reduction in blood pressure following a reduction in alcohol intake can be sustained

Figure 93-4. Effect of alcohol reduction on systolic and diastolic blood pressure. (Data from Xin X, He J, Frontini MG, Ogden LG, Motsamai OI, Whelton PK. *Hypertension* 2001;38:1112-17.)

over time. Therefore, altogether these results reinforce recommendations for moderation of alcohol consumption to prevent and treat hypertension.

There are still open questions, however, about this relationship. For example, it remains unclear whether, in the range of low-to-moderate alcohol consumption, the association is linear, or J-shaped, or whether there is a threshold effect. In the Kaiser-Permanente Study,⁸⁴ there was no difference in hypertension-related hospitalization between nondrinkers and light drinkers (i.e., less than two drinks per day), which suggests a threshold effect. Conversely, findings from the INTERSALT study suggest a continuous relationship between alcohol consumption and blood pressure in men and, if anything, a weaker relation at levels below 300 mL per week.⁸⁵ However, recent findings from the Nurses' Health Study II showed a J-shaped association between alcohol consumption and risk of developing hypertension, with light drinkers demonstrating a modest decrease in risk and more regular heavy drinkers demonstrating an increase in risk.⁸⁶ Other open questions concern the possible effect of different patterns of alcohol consumption on blood pressure elevation. Indeed, increasing, although not conclusive, evidence suggests that the association between alcohol consumption and blood pressure levels is a function not only of the average quantity consumed but also of the pattern in which alcohol is consumed. These patterns

include beverage preference, frequency and intensity of consumption, and drinking in relation to food consumption. For beverage preference, findings from observational studies are inconsistent^{86,90}; moreover, a recent randomized controlled trial did not detect a beverage-specific effect on the association between alcohol consumption and blood pressure.⁹¹ For frequency and intensity of consumption, some studies suggest that episodic heavy drinking may be associated with elevated blood pressure levels compared to regular drinking.^{85,92,93} For example, in a crossover study of hospitalized hypertensive patients, heavy alcohol intake (4 pints of beer per day) significantly raised blood pressure, whereas alcohol withdrawal was associated with a significant fall in blood pressure.⁹² More recently, findings from a study on the health consequences of binge drinking in 1154 men and women aged 18 to 54 years, showed that consumption of eight or more drinks on one occasion was associated with a significant increased risk of coronary heart disease and hypertension compared to a regular pattern of drinking.⁹³ However, no effect on the risk of other CVD was observed. Episodic drinking produces greater differences in blood pressure compared to regular drinking. This result is corroborated by the conclusions of the INTERSALT study.⁸⁵ Additionally, the effects on blood pressure of daily heavy drinking are more prominent than those of weekend heavy drinking.⁹⁴ However, other studies have reported

inconsistent findings.^{86,95} Furthermore, two population-based cross-sectional studies have examined the association between drinking pattern in relation to food consumption and hypertension risk.^{90,96} Trevisan et al.,⁹⁶ in a large sample of adult men and women from the Italian Nine Communities Study, found that drinkers of wine with and without meals experienced significantly higher systolic blood pressure levels and a higher prevalence of hypertension than wine drinkers mostly with food, even after adjustment for differences in volume of alcohol consumption among the various drinking pattern categories. This association was similar in the two sexes. These findings were recently replicated in an analysis of 2609 white male and female healthy individuals from the Western New York Health Study.⁹⁰ Specifically, individuals reporting drinking mostly without food exhibited a significantly higher risk of hypertension than those drinking mostly with food, after adjustment for several confounders including total volume of alcohol consumed in the past 30 days. More interestingly, in this study drinking without food was associated with a significantly 45% increased risk of hypertension even in individuals with light to moderate alcohol intake (i.e., less than 2 drinks per day). This finding suggests that drinking without food may counteract the benefits associated with moderate alcohol use on the cardiovascular system. However, longitudinal studies are needed to support these findings and clarify the role of drinking pattern in the relationship between alcohol consumption and blood pressure.

In conclusion, moderation of alcohol consumption is a well-documented and effective recommendation to lower blood pressure among habitual drinkers. Currently, the recommended threshold is two or fewer alcoholic drinks per day in men and one or less per day in women and lighter-weight persons (one unit is equivalent to half a pint of beer, one glass of wine, or one measure of spirits).^{6,32} Extended recommendations should pertain to the way in which alcohol is consumed among habitual drinkers. Specifically, a regular consumption versus a heavy episodic drinking pattern, preferably in relation to mealtimes, appears a reasonable, additional lifestyle behavior that should be adopted by habitual drinkers.

IMPORTANCE OF DIETARY PATTERNS

Diet plays a major role in the regulation of blood pressure and is one of the most important determinants of blood pressure levels in both individuals and populations. There are large variations in dietary patterns across populations that are likely to account for a considerable part of the observed differences in mean blood pressure levels, with populations consuming mostly plant-based diets having lower blood pressure than populations in industrialized countries. Additionally, even within industrialized countries, individuals consuming diets with increased intakes of fruit and vegetables and decreased intake of saturated fats tend to have, on average, lower blood pressure than individuals following more typical Western diets.⁹⁷ Differences from cross-cultural analyses have been corroborated by findings of numerous observational epidemiologic

investigations and randomized controlled trials, which have reported on the important role of dietary patterns in the development of hypertension. In this section, we will focus on two dietary patterns, for which the current evidence is consistent with regard to their efficacy in lowering blood pressure: the vegetarian diet and the DASH diet.

Vegetarian diet

Observational data clearly support the benefits on blood pressure levels derived from the adherence to a vegetarian dietary regimen with no or very small quantities animal-based products.⁹⁷ Many epidemiologic investigations have been conducted in selective population subgroups, in which a vegetarian diet is part of a multifaceted lifestyle including proscription of alcohol, tobacco use, and other “unhealthy” behaviors. The Seventh-Day Adventists represent one of the most studied population subgroups. Their members are expected, by religious belief, to abstain from alcohol and tobacco, and to follow a vegetarian diet supplemented with eggs and milk. Overall, they tend to have lower mortality from cancer, heart disease, and diabetes than non-Adventists living in the same communities. However, within this group, dietary patterns are not completely homogeneous and may resemble more typical Western habits. For example, in a cross-sectional analysis of a large cohort of 34,192 California Seventh-Day Adventists, the prevalence of hypertension was nearly double among Adventists who followed a diet similar to a typical American diet than in vegetarian Adventists.⁹⁸ These findings emphasize the independent role of dietary patterns in the risk of hypertension within this group of individuals characterized otherwise by common lifestyle behaviors. Furthermore, the age-dependent rise in blood pressure levels typically experienced by individuals living in industrialized countries, may be largely attenuated by long-term adherence to a vegetarian dietary regimen.⁹⁹ Overall, available data from observational studies indicate that vegetarians have lower systolic (3 to 14 mmHg) and diastolic (5 to 6 mmHg) blood pressure, and lower prevalence of hypertension than nonvegetarians (2% to 40% vs. 8% to 60%, respectively).⁹⁷

Additionally, randomized controlled trials have reported on the blood pressure–lowering effects of vegetarian diets in both normotensive and hypertensive individuals, independently of common nondietary and dietary determinants of blood pressure. Indeed, a recent meta-analysis of 24 randomized placebo-controlled trials to estimate the effect of fiber supplementation on blood pressure overall and in population subgroups showed a moderate but significant reduction in blood pressure levels.¹⁰⁰ Specifically, fiber supplementation (average dose, 11.5 g/day) changed systolic blood pressure by -1.1 mmHg (95% CI, -2.5 to 0.2) and diastolic blood pressure by -1.3 mmHg (95% CI, -2.0 to -0.5), with larger reductions in older individuals (>40 years) and in hypertensive subgroups. The main characteristics of a vegetarian diet include a higher intake of fiber, potassium, and polyunsaturated and monounsaturated fatty acids, and a lower intake of

alcohol, animal proteins, and saturated fats, which are all plausible contributors to the lower mean blood pressure levels in vegetarians, as compared to the general population. However, the lowering effects on blood pressure derived from a vegetarian diet are likely due as well to other nondietary factors (e.g., increased physical activity) that tend to cluster with dietary components as part of a comprehensive “vegetarian” lifestyle.

Dietary approaches to stop hypertension Diet

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure⁶ and a recent “scientific statement” from the American Heart Association³² emphasize the importance of adopting a dietary regimen resembling the so-called DASH diet as one major lifestyle modification to prevent and treat hypertension. The DASH dietary plan provides large intakes of fruit, vegetables, and low-fat dairy products; includes whole grains, poultry, fish, and nuts; and has limited amounts of red meat, sweets, and sugar-containing beverages. Thus, in comparison with habitual diets of Western societies, the DASH dietary pattern provides higher intakes in potassium, magnesium, calcium, fiber, and proteins, and lower intakes in total fat, saturated fat, and cholesterol.¹⁰¹

The blood pressure–lowering effect of this diet is the result of the combined effects of these nutrients when consumed together in food, rather than of the specific effect of a single nutrient. Indeed, the DASH trial was designed to test the effects on blood pressure of a change in dietary patterns, rather than the effects of a change in a single nutrient, as generally tested in previous trials.¹⁰² This trial was an 11-week feeding program including 459 adults with ($n=133$) and without hypertension ($n=326$). For 3 weeks, participants followed a control diet that was low in fruit, vegetable, and dairy products. The fat content was representative of average consumption in the United States. Then, for the next 8 weeks, participants were randomly allocated in three groups and each group was fed three different diets. One group was fed the same control diet; the second group a diet richer in fruit and vegetables but similar to the control diet for other nutrients; and the third group was fed the DASH diet, that is, a diet rich in fruit and vegetables, low-fat or fat-free dairy products and reduced saturated and total fat content (in other words, a diet high in potassium, magnesium, calcium, fiber, and protein). The sodium intake was held constant in the three groups. Alcohol intake and body weight did not change during the trial or among the groups. Overall, findings indicated a gradient in the reduction in blood pressure among the diets. The DASH diet significantly reduced systolic and diastolic blood pressure by 5.5/3.0 mmHg, respectively, compared to the control diet, whereas the “fruit and vegetables” diet significantly reduced systolic and diastolic blood pressure by 2.8/1.1 mmHg, respectively, compared to the control diet. Among subjects with hypertension, the blood pressure reductions in the DASH group were more marked, that is 11.4/5.5 mmHg for systolic and diastolic blood pressure,

respectively, compared to the control diet. Interestingly, the blood pressure–lowering effects of the DASH diet occurred within the first 2 weeks of the trial. Further subgroup analyses showed significant effects of the DASH diet in all major subgroups (e.g., gender, race, age, body mass index, etc.), although the effects were more marked among African Americans (6.9 and 3.7 mmHg) than in whites (3.3/2.4 mmHg).¹⁰³

In 2001, findings from a further trial on the same population testing the effects of the DASH trial in combination with a reduction in sodium intake were published.³⁶ A total of 412 participants were randomly allocated to two dietary regimens, one following a control diet representative of the average diet in the United States and one following the DASH diet. Within these two dietary regimens, participants were randomly assigned to three decreasing levels of salt consumption, defined as high (150 mmol/day, 3.5 g of sodium/day, reflecting typical consumption in the United States), intermediate (100 mmol/day, 2.3 g of sodium/day, reflecting the upper limit of the current recommendations), and low (50 mmol/day, 1.6 g of sodium/day). Each feeding period lasted 30 consecutive days.

Overall, findings indicate that (1) the DASH diet may lower blood pressure independent from the level of sodium intake, (2) the blood pressure–lowering effect of a reduction in sodium intake may occur by reducing the sodium intake even to levels below the currently recommended limit (i.e., 100 mmol/day); (3) the effects of sodium reductions are observed in all major subgroups; and (4) greater lowering effects on blood pressure may derive from the combination of the two interventions than from adopting either the DASH diet or low-sodium diet individually. In fact, the difference in systolic blood pressure between the DASH low-sodium group and the control high-sodium group was a substantial reduction of 7.1 mmHg in participants without hypertension and 11.5 mmHg in participants with hypertension. The last finding resembles the effect of a single-drug therapy in hypertensive individuals. Thus, the combination of the DASH diet and reduced sodium intake represents an alternative to drug therapy for individuals with mild hypertension and willing to comply with long-term dietary changes.

More recently, findings from the Optimal Macronutrient Intake Trial to Prevent Heart Disease (OmniHeart) have extended the observations derived from the DASH trials.¹⁰⁴ In fact, OmniHeart investigators examined the effects of three dietary patterns with documented lowering effects on blood pressure and serum lipids, among 164 adults with pre-hypertension or stage-1 hypertension. One diet, resembling the DASH diet, was rich in carbohydrates (58% of total calories); the other two dietary regimens partially replaced carbohydrates with either a higher content of proteins (about half from plant sources) or a higher content of unsaturated fats (predominantly monounsaturated fats). The feeding periods lasted 6 weeks and body weight was held constant. Systolic blood pressures were lowered in each of the three intervention groups compared with baselines. However, blood

pressures were further lowered in the two dietary regimens providing a partial substitution of carbohydrates (10% of total kilocalories) with either proteins or unsaturated fats (1.4 and 1.3 mmHg, respectively). Thus, these findings indicate that, along with known determinants of blood pressure (i.e., micronutrients [sodium and potassium], body weight, alcohol consumption, and the DASH diet), macronutrients and the qualitative composition of diet are also important factors to consider for the prevention and management of hypertension. Finally, the role of dietary macronutrients on blood pressure was investigated in the International Study on Macronutrients and Blood Pressure (INTERMAP) study. This was a large cross-sectional epidemiologic study of 4680 persons, aged 40 to 59 years, from four countries.^{105,106} The study found that vegetable protein intake was inversely related to blood pressure, consistent with recommendations that a diet high in vegetable products be part of a healthy lifestyle for prevention of high blood pressure and related diseases. The effect on blood pressure with a higher vegetable protein intake of 2.8% kilocalories was -2.14 mmHg systolic and -1.35 mmHg diastolic ($p < 0.001$ for both); after further adjustment for height and weight, these differences were -1.11 mmHg systolic ($p < 0.01$) and -0.71 mmHg diastolic ($p < 0.05$).

REGULAR AEROBIC EXERCISE

Engaging in regular aerobic exercise represents an essential component of lifestyle modification to reduce cardiovascular risk, and is an important part of current recommendations for the prevention and treatment of high blood pressure.⁶ It has been estimated that the risk of hypertension is 30% to 50% higher in individuals who are physically inactive.¹⁰⁷ At least 30 minutes per day of aerobic activity of moderate intensity (e.g., quick walking) on five or more occasions per week is the recommended level set by current guidelines for the prevention and management of high blood pressure.⁶ Aerobic exercise comprises activities like walking, running, cycling, or swimming. Although all forms of dynamic exercise seem to be effective in reducing blood pressure, adherence to the intervention program is crucial to be successful in achieving and maintaining the benefit. In a recent meta-analysis of 54 randomized controlled trials including 2419 participants, aerobic exercise was associated with a significant reduction in systolic and diastolic blood pressure of 3.8/2.6 mmHg, respectively¹⁰⁷ (Figure 93–5). Blood pressure reductions induced by aerobic exercise were observed in both normotensive and hypertensive individuals and in normal-weight and overweight subgroups. Although the blood pressure–lowering effect of aerobic exercise can be considered clinically moderate, it constitutes, however, a valuable public health strategy for the prevention and treatment of high blood pressure. In fact, a modest reduction in the population's blood pressure levels would translate into a significant decrease in the incidence of hypertension-related diseases.

Conversely, resistance training, also known as isometric or static exercise (e.g., weight training or body building),

is not included in current recommendations for the prevention and management of high blood pressure because of the lack of conclusive evidence on its effectiveness in lowering blood pressure and the potential for long-term hypertensive effects. However, two recent meta-analyses of randomized controlled trials indicate that resistance training is not associated with chronic elevations of blood pressure and, instead, may induce a moderate reduction of blood pressure levels in healthy adults, whereas its efficacy in lowering blood pressure in hypertensive individuals and the elderly is still a controversial issue.^{108,109} Currently, the evidence suggests that moderate-intensity resistance training could be performed in combination with aerobic exercise in the context of a comprehensive exercise program to prevent CVD in healthy adults.¹¹⁰

Furthermore, a few trials have examined the efficacy of the simultaneous implementation of current lifestyle recommendations, including regular exercise, to prevent and treat high blood pressure. For example, in the Diet, Exercise, and Weight Loss-Intervention Trial (DEW-IT), 44 hypertensive overweight adults on monotherapy for hypertension were randomly allocated to either a control group or comprehensive lifestyle intervention group.²⁹ The intervention comprised a low-sodium and hypocaloric version of the DASH diet, for 9 weeks, along with a supervised moderate-intensity exercise program three times per week. The control group received no intervention. At the end of the trial, in the intervention group the average total weight loss was 4.9 kg, and the differences in 24-hour ambulatory systolic and diastolic blood pressures were 9.5/5.3 mmHg, respectively, whereas the differences in daytime blood pressures were 12.1/6.6 mmHg, respectively. Thus, this trial clearly emphasized the efficacy of comprehensive lifestyle modifications as adjuvant therapy in hypertensive adults who are already on drug therapy; moreover, blood pressure reductions of the magnitude observed in this study resemble blood pressure reductions obtainable by means of pharmacologic therapy. These findings were extended by recent results of the PREMIER clinical trial, which examined the combined effects of the DASH diet with “established” recommendations, comprising weight loss, exercise, and restriction of sodium and alcohol.¹¹¹ Participants were 810 adults with above-optimal blood pressure, including stage-1 hypertension (120 to 159 mmHg systolic and 80 to 95 mmHg diastolic), and who were not on antihypertensive medications. They were randomly allocated to one of three intervention groups: (1) “established,” a behavioral intervention that implemented established recommendations; (2) “established plus DASH,” which also implemented the DASH diet; and (3) an “advice-only” control group. At the end of the trial (after 6 months) in the group assigned to lifestyle modification only, the mean net reduction in blood pressure was 3.7/1.7 mmHg, compared to the control group, whereas for the group that followed the established recommendations together with the DASH diet, the mean net reduction in blood pressure was 4.3/2.6 mmHg, compared to the control group. Thus, these findings indicate the feasibility of comprehensive lifestyle modifications

Figure 93–5. Effect of aerobic physical activity on systolic blood pressure. (Redrawn from Whelton SP, Chin A, Xin X, He J. Effect of aerobic exercise on blood pressure: a meta-analysis of randomized, controlled trials. *Ann Intern Med* 2002;136:493–503.)

and their beneficial effects on blood pressure for both nonhypertensive individuals with above-optimal blood pressure and hypertensive individuals who are not receiving medication therapy.

Several mechanisms are likely responsible for the blood pressure-lowering effects induced by regular exercise.¹¹² For example, a “hemodynamic” mechanism would involve the reduction of both resting cardiac output and peripheral

vascular resistance. Furthermore, a “humoral” mechanism would determine the reduction of the activity of the renin-angiotensin-aldosterone system and of the sympathetic nervous system activity and an increase in prostaglandins with vasodilator effect. Finally, recent findings suggest that an enhancement in insulin sensitivity may represent a further mechanism for the beneficial effects of physical activity on blood pressure and hypertension risk.¹¹³

CONCLUSIONS

Extensive and consistent evidence provides the scientific basis for clinical and public health strategies directed to long-term lifestyle modifications to prevent and reduce the burden of disease related to high blood pressure in both individuals and populations. The current lifestyle modifications that effectively lower blood pressure include weight reduction if overweight or obese, reduction of dietary sodium intake, increased potassium intake, moderation of alcohol consumption among regular drinkers, adoption of a dietary plan based on the DASH (Dietary Approaches to Stop Hypertension) diet, and regular aerobic exercise.

In the clinical setting, a comprehensive lifestyle intervention represents a cost-effective therapeutic option among nonhypertensive individuals with above-optimal blood pressure levels, as well as among hypertensive indi-

viduals who are not receiving medication therapy and are compliant with sustained lifestyle changes. In addition, comprehensive lifestyle modifications represent an essential adjuvant therapy in hypertensive individuals who are already on drug treatment.

In the public health arena, there is an urgent need to develop and implement population-wide strategies aimed at substantial “societal” changes to tackle the current epidemic of hypertension in both developed and developing countries. However, these changes will be realistic only if collaborative initiatives are implemented at multiple levels: governments, manufacturers, health-care providers, researchers, and the general public. In particular, the increasing burden of hypertension is a serious public health challenge in developing countries due to the lack of resources. Nevertheless, community-based strategies of health promotion (e.g., salt reduction) are warranted in these settings.

Multidisciplinary Management of Hypertension and the Role of the Nurse

Cheryl R. Dennison and Martha N. Hill

Description

- Multidisciplinary teams, including nurses, physicians, and other health care providers, achieve effective control of hypertension in many practice settings.

Key Features

- The skills and clinical judgment of multidisciplinary team members contribute to a more comprehensive approach with increased individualization of hypertension care.
- Improving the processes and outcomes of hypertension care requires that the multidisciplinary team demonstrate the following five core competencies: (1) patient-centered care, (2) partnering, (3) quality improvement, (4) information and communication technology, and (5) public health perspective.

Clinical Implications

- The benefits of multidisciplinary teams, including nurses who participate in or lead hypertension care, have been demonstrated in a wide variety of studies from uncontrolled community- and clinic-based surveys to randomized multisite clinical trials, and in developing as well as developed countries.
- The roles of the nurse and NP in multidisciplinary hypertension management involve all aspects of hypertension management, including detection, referral, and follow-up; medication management; patient education, counseling, and skill building; coordination of care; and managing the clinic or office.

The management of hypertension requires long-term, effective collaboration among health care professionals, patients, and communities. A multidisciplinary team approach has consistently produced effective control of hypertension in clinical trials and many practice settings.¹⁻⁶ Since the late 1960s, when the detection, evaluation, and treatment of hypertension became a public health mandate, nurses have contributed to improved care and outcomes for patients with hypertension. The benefits of nurses participating in or leading hypertension care has been demonstrated in a wide variety of studies from uncontrolled community- and clinic-based surveys to randomized multisite clinical trials, and in developing as well as developed countries.^{1,7-20} The proactive involvement of nurses, and other providers such as pharmacists, nutritionists, social workers, and community health

workers, allows flexibility in matching patient needs with the competencies of providers and staff members who have different yet complementary skills and interests.

Nurses are the largest health profession; they practice in all settings where patients are seen including specialty clinics, private practice offices, worksite settings, primary care clinics, hospitals, and community centers. Patients with hypertension are identified, evaluated, and treated in all of these settings as well as hypertension specialty clinics. As the health care environment is challenged across the world by increasing rates of chronic illness, aging populations, and concerns about escalating health care costs, awareness is increasing that a team approach to chronic illness, such as hypertension management, is needed. Physicians working in collaboration with other health care professionals and communities can help patients develop the knowledge and skills required to control their hypertension and to optimize their health. In this chapter, we describe the multidisciplinary team approach and the specific roles of the nurse and nurse practitioner in hypertension management in outpatient or ambulatory settings and provide examples of their effectiveness.

DESCRIPTION OF TECHNIQUE

Multidisciplinary team management of hypertension

Multidisciplinary team management of hypertension can be conceptualized in steps as delineated in Table 94-1. The first step involves screening for detection of hypertension and referral for hypertension management. Step 2 involves patient education, counseling, and skill building, as well as coordination of care across the care continuum. Step 3 involves diagnostic testing and medication management. Steps 2 and 3 are iterative and often are addressed concurrently. Various members of the multidisciplinary hypertension care team are best prepared, in terms of skills, education, and licensure, to implement each of the steps.

The number of patients with chronic conditions, such as hypertension, is rapidly increasing. To engage patients as active participants, rather than passive recipients, and to provide effective care, the hypertension management team must demonstrate the following five core competencies:

MULTIDISCIPLINARY TEAM MANAGEMENT OF HYPERTENSION	
Steps in Management of Hypertension	Multidisciplinary Team Interventionists
Step 1 Screening, detection, and referral	Nurse, community health worker, community resource (e.g., drug store BP check), other health care professionals
Step 2 Patient education, counseling, and skill building and coordination of care	Nurse/nurse practitioner, health educator, nutritionist, physician, pharmacist, social worker, community health worker, other health care professionals
Step 3 Diagnostics and medication management	Physician, nurse practitioner

Table 94-1. Multidisciplinary Team Management of Hypertension

(1) patient-centered care, (2) partnering, (3) quality improvement, (4) information and communication technology, and (5) public health perspective²¹ (Box 94-1). First, the multidisciplinary hypertension team needs to organize care around the patient or, in other words, adopt a patient-centered approach. This requires interviewing and communicating effectively, assisting changes in health-related behaviors, supporting patient self-management, and using a proactive approach. Second, providers need communication skills that enable them to collaborate with patients, work closely with other providers, and to join with communities to improve outcomes for patients with

hypertension. Third, they need skills to ensure that the safety and quality of patient care are continuously improved. Fourth, competencies in information and communication technology that can assist them in monitoring patients across time, and in using and sharing information, are needed. Finally, the team must adopt a public health perspective in their daily work, including a systems view across the continuum of care. Education and skill building within the team may be necessary.

To achieve effective management of hypertension, in addition to engaging the patient as an active partner in care, it is essential that all team members understand the value of their own contribution, and the roles and skills of other professionals, as well as the importance of multidisciplinary collaboration. When pharmacists, nutritionists, social workers, community health workers, and others join nurses and physicians, the expertise of each discipline supplements and complements that of the others. In addition, involving family, friends, community resources, and other health professionals can assist patients in modifying lifestyle behaviors and maintaining these changes over time.

Case conferences, chart review sessions, and journal clubs are effective strategies to assemble the hypertension management team and to improve the quality of hypertension care. Team case conferences are an ideal forum for discussion of guidelines and the extent to which they need to be modified, if at all, for implementation at the individual patient level. Selecting a case with particularly complex and challenging issues for the conference can be an effective method to gain input from the multidisciplinary team in revising the plan of care to assist the patient in achieving blood pressure control. Sample questions to guide a multidisciplinary hypertension management team case conference²² are provided in Box 94-2. Journal clubs can provide a forum to increase team awareness of new or revised treatment guidelines as well as newly published research findings that may lead to changes in practice patterns and improved patient outcomes.

Classic hypertension care and control clinical trials, such as HDFP,⁹ MRFIT,¹² SHEP,²³ and TOMHS,²⁴ demonstrated that extensive and continuous interventions provided by multidisciplinary teams improved adherence and outcomes. These and other studies of multidisciplinary

Box 94-1

Core Competencies of Multidisciplinary Hypertension Management Team

1. Patient-centered care
 - Interviewing and communicating effectively
 - Assisting changes in health-related behaviors
 - Supporting self-management
 - Using a proactive approach
2. Partnering
 - Partnering with patients
 - Partnering with other health care providers
 - Partnering with communities
3. Quality improvement
 - Measuring care delivery and outcomes
 - Learning and adapting to change
 - Translating evidence into practice
4. Information and communication technology
 - Designing and using patient registries
 - Using computer technologies
 - Communicating with partners
5. Public health perspective
 - Providing population-based care
 - Systems thinking
 - Working across the care continuum
 - Working in primary health care–led systems

From World Health Organization. *Preparing a Health Care Workforce for the 21st Century: The Challenge of Chronic Conditions*. Geneva: World Health Organization, 2005 (publication 11500621).

Box 94–2**Questions for Management Case Conference of Multidisciplinary Hypertension Team**

- Have blood pressure goals been set, clearly communicated to the patient and all members of the care team, and achieved?
- What type(s) of care does the patient require (e.g., aggressive titration of medications, behavior modification counseling)?
- What team members are skilled and licensed to provide the various elements of care?
- What team members provide the various elements of care in the most effective and efficient manner?
- Does this patient need to be referred to specialty medical care, social work, nutritionist, or others?
- What are the barriers to hypertension control? What is the plan for overcoming barriers to blood pressure control?
- Does the patient have family or others who offer social support and assist the patient with blood pressure control behaviors? How can this support be engaged?
- Does the patient have the resources to pay for the needed care, including prescription medications? If not, what is the plan to activate the necessary resources?

team interventions designed to meet patient, provider, and organizational needs, and minimize barriers to blood pressure control have been effective in a variety of clinical and community settings.^{1,5,6,19} In addition, the clinical effectiveness as well as cost effectiveness of a multidisciplinary team approach to care compared to physician care alone for chronic illness, including hypertension, have been demonstrated.⁵

One innovative program in which a nurse practitioner–led, multidisciplinary team addressed patient’s beliefs and concerns in a multifaceted manner, providing outreach, follow-up, feedback, and free medication, if needed, has been highly successful.¹ In this randomized clinical trial with 309 hypertensive urban black men aged 21 to 54 years, Hill and colleagues¹ evaluated the effectiveness of a more-intensive (MI) comprehensive educational-behavioral-pharmacologic intervention by a nurse practitioner-community health worker-physician (NP/CWH/MD) team and a less-intensive (LI) education and referral intervention in controlling blood pressure (BP) and minimizing progression of left ventricular hypertrophy (LVH) and renal insufficiency.¹ At 36 months, the mean systolic BP (SBP)/diastolic (DBP) change from baseline was $-7.5/-10.1$ mmHg for the MI group and $+3.4/-3.7$ mmHg for the LI group ($p=0.001$ and 0.005 for between-group differences in SBP and DBP, respectively). The proportion of men with controlled BP ($<140/90$ mmHg) was 44% in the MI group and 31% in the LI group ($p=0.045$). Left ventricular mass was significantly lower in the MI group than in the LI

group (274 g, MI; 311 g, LI; $p=0.004$). There was a trend towards slowing of the progression of renal insufficiency (incidence of 50% increase in serum creatinine) in the MI group compared to the LI group (5.2%, MI; 8.0%, LI; $p=0.08$).

The role of the nurse

Nurses have demonstrated the necessary critical clinical judgment to provide high-quality hypertension management. The roles of nurses include all aspects of hypertension management (Box 94–3), although the role of any individual nurse may vary by education, staffing needs of the practice site, and needs of the patients. For example, in a physician private practice office, the nurse’s involvement may be limited to measurement of vital signs before the patient is seen by the physician. Alternatively, in another setting the nurse may not only measure blood pressure when assessing vital signs, but also assess adherence with the prescribed treatment regimen and barriers to optimal adherence, provide counseling regarding risk factor modification, such as smoking cessation or dietary sodium reduction, and as the patient visit concludes, the nurse may assess the need for prescription renewals and finally reinforce the recommended treatment plan. Nurse involvement in hypertension management provides an ideal example of nurse specialty practice with a variety of potential roles.

In managing a cohort of patients in a hypertension clinic, the nurse may be responsible for taking a thorough medical history and for ordering appropriate diagnostic tests. This allows physicians to devote their efforts during a subsequent visit to performing the physical examination and formulating an appropriate treatment plan based on extensive information and diagnostic data provided by the nurse. In settings in which the nurses do not have advanced practice credentials, physicians are responsible for making the diagnosis of hypertension and for determining secondary causes, which may influence decisions about appropriate treatment. Physicians help to formulate a treatment plan and provide consultation to nurses in managing complex cases.

The role of the nurse practitioner/Advanced practice nurse

Nurse practitioners (NPs) are registered nurses who have acquired the expert knowledge base, complex decision-

Box 94–3**Roles of Nurses and Nurse Practitioners in Hypertension Management**

- Detection, referral, and follow-up
- Diagnostics and medication management
- Patient education, counseling, and skill building
- Coordination of care
- Management of clinic/office

making skills, and clinical competencies for expanded practice.²⁵ In addition to advanced education and clinical training, the role function that distinguishes an NP from other nurses is the legal authority to write prescriptions. The legal aspects of practice, including required continuing education, credentialing, and scope of practice, including prescribing medication, are regulated by government and depend on local custom and requirements.

With the increasing emphasis on health promotion and disease prevention, and recognition of the benefits of a multidisciplinary approach to care, NPs are part of the solution to care. It has been established in developed countries that 60% to 80% of primary and preventive services traditionally performed by physicians can be provided by nurses with similar or better clinical outcomes, high levels of patient and provider satisfaction, and at lower cost.^{26,27} This cost effectiveness is explained by a variety of factors relating to lower salary, cost of liability insurance, and cost of education of NPs compared to physicians.²⁶ Furthermore, in a randomized trial comparing physician primary care ($n=510$) to NP primary care ($n=806$), Mundinger and colleagues²⁸ found that at 6 months there were no differences in patients' health status, health care utilization, or satisfaction, and for patients with hypertension, diastolic blood pressure was significantly lower for NP patients (82 vs. 85 mmHg, $p=0.04$).

Depending on local practice regulations, NPs caring for patients with hypertension can practice independently, using protocols developed jointly with the collaborating physician. NPs follow the same hypertension treatment guidelines as do physicians. The effective implementation of guidelines requires not only dissemination and awareness but a commitment by all providers and staff to set expectations for the new standards, encourage implementation, create and explain incentives for adoption, build skills, and provide resources (i.e., tools). Nurses and NPs play an important role in enforcing the use of hypertension treatment guidelines.

INDICATIONS/CONTRAINDICATIONS AND OBJECTIVES

Specific roles

The roles of the nurse and NP in hypertension management involve all aspects of hypertension management,²⁹⁻³¹ including detection, referral, and follow-up; diagnostics and medication management; patient education, counseling, and skill building; coordination of care; and managing the clinic or office.

Detection, referral, and follow-up

Nurses routinely measure blood pressure in most health care settings as part of initial and ongoing assessments of each patient. In addition, nurses lead blood pressure screening and verification initiatives in community, work-site, church, school, and other settings. Once blood pressure is measured and recorded, the nurse analyzes the data to determine if the readings are in the normal, prehyper-

tensive, or hypertensive range per site protocol. A system to flag charts can help ensure that uncontrolled hypertension is recognized and treated. In addition, the nurse assesses the patient's level of cardiovascular risk. There are a number of tools, such as the interactive tool found on the National Heart, Lung, and Blood Institute website, that are helpful in guiding healthcare providers as they assess cardiovascular risk; these tools also can be used in patient education efforts.³² It may be necessary to refer the patient for specialist evaluation for persistent uncontrolled blood pressure despite intervention or for abnormal renal or vascular findings. The nurse plays an important role in implementing referrals and educating patients regarding the purpose and importance of referral.

Follow-up between visits via telephone and/or mail can be effective to reinforce goals and enhance provider-patient relationship. Moreover, it is essential to follow up on missed appointments to maintain contact with the patient and to reinforce the importance of achieving blood pressure goals. Nurses often are the first health professionals to detect hypertension, and therefore have a key role in communicating with patients and other health professionals to enforce treatment guidelines through development and appropriate revision of the patient's treatment plan.

Diagnostics and medication management

Nurses or NPs may also be responsible for the diagnostic and pharmacologic aspects of hypertension management. Using well-defined protocols based on national treatment guidelines such as the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII), NPs can prescribe and titrate medications to achieve blood pressure control.³³ Nurse management of antihypertensive medication has been demonstrated to result in greater rates of blood pressure control than those achieved with standard care.^{1,2,8,28,34} These improved outcomes have resulted from nurses placing a greater number of patients on medications, altering drug regimens more frequently in response to inadequate blood pressure control, and placing a higher proportion of patients on multiple drug regimens in order to achieve greater control.^{1,2,8,28,34} Greater use of antihypertensive medications may produce higher costs initially, as noted in a study conducted by Logan and colleagues.³⁵ However, if the goals of a clinic are to keep patients in treatment and achieve greater adherence and blood pressure control rates, then prescribing the most effective regimen is paramount.³⁶ In addition to management of hypertension, nurses have been shown to effectively manage other cardiovascular risk factors, such as diabetes¹⁸⁻²⁰ and dyslipidemia.³⁷

Patient education, counseling, and skill building

In the majority of hypertension clinics as well as in other settings, nurses provide the education, counseling, and skill building necessary to ensure that patients are undertaking lifestyle changes that may favorably influence blood pressure. A combination of strategies is required to maximize long-term adherence and blood pressure

control by actively engaging patients in care and preventing, recognizing, and responding to adherence problems. Effective, evidence-based strategies to promote blood pressure control are identified in Box 94–4, and are clustered under the following general approaches: (1) identify knowledge, attitudes, beliefs, and experiences, (2) educate about conditions and treatment, (3) individualize the regimen, (4) provide reinforcement, (5) promote social support, and (6) collaborate with other professionals.^{22,34,38} It is important to consider that patient education is a means to an end. That is, knowledge is necessary but insufficient to bring about desired behaviors without development of skills and multiple other reinforcing factors. The ultimate goal is for the patient to have the necessary skills and resources, including knowledge,

Box 94–4

Strategies to Promote Blood Pressure Control

Identify Knowledge, Attitudes, Beliefs, and Experience

- Assess patient’s understanding and acceptance of the diagnosis and expectations of being in care.
- Discuss patient’s concerns and clarify misunderstandings.

Educate about Conditions and Treatment

- Inform patient of blood pressure level.
- Agree with patients on a goal blood pressure.
- Inform patient about recommended treatment, providing specific oral and written information.
- Elicit concerns and questions and provide opportunities for patient to state specific behaviors to carry out treatment recommendations.
- Emphasize need to continue treatment, that patient cannot tell if blood pressure is elevated, and that control does not mean cure.
- Teach self-monitoring skills.

Individualize the Regimen

- Include patient in decision making.
- Simplify the regimen.
- Incorporate treatment into patient’s daily lifestyle.
- Set, with the patient, realistic short-term objectives for specific components of the treatment plan.
- Encourage discussion of side effects and concerns.
- Encourage self-monitoring of blood pressure.
- Prioritize critical aspects of the regimen.
- Implement treatment plan in steps.
- Modify dosages or change medications to reduce side effects.
- Minimize cost of therapy.
- Indicate that you will ask about adherence at next visit.
- When weight loss is established as a treatment goal, discourage quick weight-loss regimens, fasting, or unscientific methods, since these are associated with weight cycling that may increase cardiovascular morbidity and mortality.

Box 94–4—cont’d

Provide Reinforcement

- Provide feedback regarding blood pressure level.
- Ask about behaviors to achieve blood pressure control.
- Give positive feedback for behavioral and blood pressure improvement.
- Hold exit interviews to clarify regimen.
- Make appointment for next visit before patient leaves the office.
- Use appointment reminders and contact patients to confirm appointments.
- Schedule more frequent visits to counsel nonadherent patients.
- Contact and follow-up patients who missed appointments.
- Consider clinician–patient contracts.
- Consider home visits.

Promote Social Support

- Educate family members to be part of the blood pressure control process and provide daily reinforcement.
- Suggest small-group activities to enhance mutual support and motivation.

Collaborate with Other Professionals

- Draw on complementary skills and knowledge of nurses, pharmacists, dietitians, optometrists, dentists, and physician assistants.
- Recognize shared practice goals.
- Refer patients for more intensive counseling.

to follow treatment recommendations and achieve and sustain blood pressure control.

Identify knowledge, attitudes, beliefs, and experience

A classic framework is useful in guiding nurses and other professionals to provide patient education, counseling, and skill building, and to facilitate patients’ attainment of the following four critical behaviors that are necessary to achieve and sustain long-term blood pressure control: (1) make the decision to control blood pressure, (2) take medication as prescribed, (3) monitor progress toward the goal, and (4) resolve barriers that prevent reaching the goal.³⁹ The premise of this evidence-based framework is that the patient is an active participant, decision maker, and problem solver, with the nurse or other health professional functioning as advisor and guide favors successful management of hypertension. The patient’s understanding and acceptance of the diagnosis and expectations of being in care are assessed, patient concerns addressed, and misunderstandings clarified.

Educate about conditions and treatment

Adequate knowledge of hypertension, consequences of uncontrolled hypertension, and treatment regimen is essential to achieve blood pressure control. It has been shown that patients who receive education and counseling on hypertension management exhibit increased adherence.⁴⁰ The nurse practices patient-centered care, engaging the patient in shared decision making and establishing mutually agreed upon blood pressure goals. The patient must always be informed of blood pressure and related diagnostic testing values. This provides an ideal opportunity to assess patient knowledge, educate, establish clear goals, and discuss progress toward goals with the patient. The nurse emphasizes the need to continue treatment even when blood pressure control has been achieved, that is, control does not mean cure. The nurse also plays a key role in educating patients regarding the necessary self-monitoring skills (e.g., home blood pressure monitoring). Patient knowledge is necessary but insufficient if appropriate action does not follow. In addition to patient education and skill building, effective communication, and a trustful relationship between the patient and nurse are of paramount importance to achieve sustained blood pressure control.

Individualize the regimen

Successful education and counseling to promote adherence to treatment regimen and blood pressure control require that nurses and other health professionals individualize care to maximize the patient's motivation to control their hypertension by remaining in care, maintaining a healthy lifestyle, taking prescribed medication, and monitoring progress toward goals. Nurse efforts to individualize the regimen should focus on patient response to the treatment regimen as well as self-care behaviors and skills necessary to hypertension control. The nurse can assist the patient to incorporate the treatment regimen into the patient's daily lifestyle that is required for long-term sustainability. The nurse works with the patient to mutually develop realistic outcomes-oriented goals and strategies for attaining the goals. Equally important, the nurse follows up with the patient frequently to assess progress toward goals and if necessary to revise strategies for attaining goals.

Nurses are trained to provide counseling regarding lifestyle modification, which is recommended for all hypertensive patients with lifestyle risk factors, such as obesity, excessive alcohol consumption, and high-sodium diet.³³ Weight loss, which may be the most successful nonpharmacologic technique for lowering blood pressure, requires behavior change in both diet and physical activity patterns.³³ Such nonpharmacologic approaches include helping patients to initiate or maintain an aerobic exercise program and to limit sodium intake and alcohol consumption to one to two drinks per day.³³ In addition, many hypertensive patients present with multiple risk factors for cardiovascular disease. The nurse also can provide education and counseling for smoking cessation and lipid reduction to help patients further lower their risk of cardiovascular disease. Modifying lifestyle behaviors requires many clinical interventions: assessment of an

individual's baseline behaviors, education about how to make the appropriate changes, counseling to develop strategies such as setting short-term goals and self-monitoring that will ensure the achievement and maintenance of the changes, constant follow-up with the patient to determine whether adherence is a problem, working with patients to identify and resolve barriers to blood pressure control, and reinforcement of progress toward the goal of change in behavior.⁴¹

The extent to which patients are able to adhere to treatment recommendations is a major issue in blood pressure control and depends on many factors. Review of adherence in randomized controlled trials on cardiovascular disease prevention strategies identified the following successful approaches: signed agreements, behavioral skill training, self-monitoring, telephone/mail contact, spouse support, self-efficacy enhancement, contingency contracting, exercise prescriptions, external cognitive aids, persuasive communication, nurse-managed clinics, and work- or school-based programs.⁴² Improving adherence to evidence-based guidelines is a multilevel challenge, and multiple strategies are required beginning with patient education, counseling, and skill building.⁴

Another important aspect of individualizing the regimen to promote blood pressure control involves assessing potential barriers to blood pressure control. Nurses are motivated and trained to assess common barriers to blood pressure control. Barriers may include: knowledge deficits, lack of health care or pharmacy insurance, inadequate communication with clinicians, cost of medication, complexity of the regimen, adverse effects of medication, transportation to and from the visit, work schedule, inconvenient clinic/office location or difficulty scheduling appointments, child or elder care, or other competing life demands.^{43,44} Following identification of barriers, the nurse works with the patient and collaborating health professionals to minimize or eliminate the barriers, thereby promoting blood pressure control.

Provide reinforcement

It is important to work with individual patients to ensure that they understand what is necessary to achieve treatment goals and that they participate in treatment decisions. Nurse responsiveness to patient concerns with joint problem solving to prevent or minimize barriers to care and treatment as well as reinforcement and support are crucial. Provision of reminders, outreach, and follow-up services are beneficial. Follow-up between visits via telephone and/or mail can be an effective method to reinforce goals and enhance the provider-patient relationship. It is essential to follow up on all missed appointments to maintain contact with the patient and to reinforce the importance of achieving blood pressure goals. Success in implementing the treatment regimen to achieve blood pressure control requires frequent monitoring of blood pressure, modification of the treatment regimen, and interaction with the patient. These roles require training and dedicated time to provide the education and counseling necessary to build skills for and reinforce successful behavior change.

Promote social support

Nurses can also be effective in educating family members and/or friends to participate in the blood pressure control process. Family members can play a fundamental role by providing daily reinforcement of the patient's efforts to achieve blood pressure control. If the patient desires greater family participation, the nurse should encourage the patient to invite family members to attend and participate in clinic visits. In addition, some patients may benefit from small group activities, such as clinic support groups or group visits, to enhance social support and motivation.

Collaborate with other professionals

In planning care, the nurse works in conjunction with the patient, physician, and other members of the multidisciplinary hypertension management team. Nurse-supervised community health workers, nurse case managers, and nurse practitioners, in collaboration with physicians and other health professionals, in a variety of settings have effectively improved the outcomes of patients with hypertension.^{1-6,19} Involving family, friends, community resources, and other health professionals can help patients to achieve and sustain blood pressure control.

Achieving and sustaining goal blood pressure levels over time requires continuous educational and behavioral strategies, an individualized regimen, and reinforcement so that patients have the knowledge, skills, motivation and resources to carry out treatment recommendations. Successful blood pressure control requires that patients know what steps to take and develop skills in problem identification and problem solving to address barriers. Strategies to help patients develop these skills need to be adapted so that they are culturally salient and feasible for staff to implement.

Coordination of care

Long-term maintenance of hypertension control requires regular monitoring of blood pressure, refilling of prescriptions, providing counseling and reinforcement of behavior change efforts, and titrating therapy as indicated. Each patient's management must be individualized with costs minimized. Patients often see different providers at several settings for various health problems, fill prescriptions in more than one pharmacy, receive inconsistent messages, and experience interruption of therapy and inadequate communication among providers. Nurses are skilled at building and maintaining both informal and formal collaborative linkages among providers, resources, and services within and external to their practice setting. Nurses can assist patients in understanding complex treatment regimen and navigating through the complex, challenging, and commonly confusing health care structure.⁴⁵

Manage the clinic/office

A nurse may be in the position of managing or planning for the initiation of a hypertension clinic. Nurses frequently direct and/or coordinate the efforts of other team members who are working within the clinic or providing direct consultation. To enhance consistency and

quality of care and to facilitate adherence to treatment guidelines, decision support systems (electronic and paper), such as flow sheets and feedback reminders, may be developed. In addition, it may be the responsibility of the nurse to hire, supervise, and train the community health workers, to deliver appropriate intervention strategies, and other staff, such as office assistants and receptionists, to take blood pressures, schedule appointments, make reminder telephone calls, obtain laboratory results, and enter data to support evaluation of clinical outcomes.³⁶ Nurses influence utilization of resources including appropriate length of visit and caseload size as well as optimizing reimbursement for services in the hypertension clinic setting.

It is imperative that all health professionals who measure blood pressure use correct measurement technique.^{46,47} In addition to ensuring proper blood pressure measurement technique among staff, nurses often are responsible for ensuring that blood pressure measurement equipment is properly calibrated and functioning.⁴⁶

Documentation of clinical outcomes is becoming increasingly important and necessary. Often it is the nurse in the hypertension care setting who has responsibility for tracking process and outcome measures for quality improvement efforts. Integrated systems with continuous quality improvement approaches enhance provider's delivery of care and patient outcomes. Tracking blood pressure, frequency of visits, medications, patient adherence, hospitalizations, and emergency room visits, using informatics technologies enables timely evaluation of clinical outcomes and the costs incurred in providing antihypertensive treatment.

COMPLICATIONS

The advantages of multidisciplinary management of hypertension, involving nurses, are numerous. Nurses provide effective hypertension care by adhering to treatment guidelines and protocols resulting in improved outcomes, including patient satisfaction and retention in care, and physician satisfaction.

The barriers to optimal implementation of multidisciplinary team management of hypertension include inadequate awareness of the role of nonphysician health care professionals in hypertension care, lack of time and resources, and lack of incentives and reimbursement. Inadequate financial reimbursement for patient education and counseling is a critical barrier that must be addressed at the policy level. In some settings, the barriers also include lack of practical implementation tools, such as decision support systems, and local social norms and ethics that preclude nurses from assuming greater responsibility for patient care and outcomes. A major barrier to nurse practitioners' practice in some provinces or states involves practice regulations or reimbursement plans.

SUMMARY

The prevalence and asymptomatic nature of hypertension and the need for lifelong treatment to prevent compli-

cations pose challenges that require professional expertise beyond that of physicians. Nurses and other health care professionals are critical to optimal hypertension management. A multidisciplinary team approach with collaborative partnerships, based on recognition of the roles of nurses and other health professionals and a supportive environment, are essential to successful multidisciplinary management of hypertension. Improving the processes and outcomes of hypertension care requires that the

multidisciplinary team demonstrate the following five core competencies: (1) patient-centered care, (2) partnering, (3) quality improvement, (4) information and communication technology, and (5) public health perspective. The meaningful implementation of multidisciplinary team management of hypertension involves bringing nurses, physicians, and other health professionals together to improve patient care, investing in team development, and influencing health policy.

Chapter
95World Health Organization/
International Society of
Hypertension (WHO/ISH):
Hypertension Guidelines and
Statements*Judith A. Whitworth*

Hypertension is a major contributor to global mortality and disease burden. The *World Health Report 2002: Reducing Risks, Promoting Healthy Life* quantified the disease burden consequent on elevated blood pressure at 4.5%.¹ To quote Derek Yach who was executive director, Noncommunicable Disease and Mental Health, World Health Organization [WHO], the 2002 report “focuses on cardiovascular and other risks to global health and quantifies the substantial public health gains for populations and individuals as a result of a reduction in cardiovascular and other health risks. The report also highlights the fact that a large segment of the world population is at high cardiovascular risk due to one or more cardiovascular risk factors, including hypertension. As such, and to improve the health outcomes of populations at risk in a cost-effective and equitable manner, countries should, in the future, implement population and individual-based strategies in a complementary manner. The corporate view of WHO is that there is a need to establish comprehensive guidelines for the management of cardiovascular risk which will inform policy-makers, public health experts and clinicians ... to bring about a much needed paradigm shift from treating cardiovascular risk factors in isolation to a more holistic multiple risk factor approach and also facilitate key policy decisions that are integral to implementation of population-based strategies for reduction of cardiovascular risk.”

The *World Health Report* showed that above a theoretical minimum of 115 mmHg, the association of systolic blood pressure with cerebrovascular disease (CVD), risk for stroke, ischemic heart disease, hypertensive disease, and other cardiac disease was continuous. Approximately 62% of CVD and 49% of ischemic heart disease globally was attributable to suboptimal blood pressure (systolic blood pressure >115 mmHg). Importantly, blood pressure ranks third as a risk for global burden of disease, after underweight and unsafe sex, and before tobacco, alcohol, unsafe water, cholesterol, and overweight. The report estimated that hypertension causes over 7 million premature deaths, 4.5% of the global disease burden, and 64 million disability-adjusted life years lost.¹

WHO and the International Society of Hypertension (ISH) have collaborated over decades to produce several guidelines and statements on management of hypertension. The WHO/ISH Guidelines on hypertension were published in 1983,^{2,3} 1986,^{4,5} 1989,⁶⁻⁸ 1993,⁹ and 1999.¹⁰⁻¹² The collaboration has also given rise to statements, most notably the 2003 Statement on hypertension,¹³ but also to statements on prevention of hypertension¹⁴ and on the risk profile of calcium antagonists.¹⁵

The WHO/ISH Guidelines are intended to have wide publication and distribution and are not subject to copyright. Accordingly, this chapter contains extensive quotes from the 1999 Guidelines. The 2003 Statement is appended in full (see Appendix).

1999 WHO/ISH GUIDELINES

The 1999 WHO/ISH Guidelines were extensive and comprehensive and written for specialists in clinical practice; a shorter version was also prepared for family practitioners.

The 1999 Guidelines were very close to the 1993 Guidelines in the key areas of goals of therapy and antihypertensive choice. These 1999 Guidelines were reinforced by subsequent meta-analyses indicating that blood pressure lowering (as opposed to specific drug class)¹⁶ is fundamental in reducing cardiovascular mortality and morbidity and a large body of evidence suggesting blood pressure goals should be modified downward.¹⁷⁻²²

Key points from 1999 WHO/ISH Guidelines

Key points from the 1999 guidelines are summarized in Boxes 95-1 through 95-12, and Table 95-1.

WHO/ISH Statement 2003

In 2000, WHO decided to formalize methodology for clinical management guidelines using standardized methods for grading evidence. In 2001, a working group was set up under the auspices of the WHO/ISH Guidelines and Liaison Committees to update the 1999 Guidelines in three areas:

1. The ascertainment of overall cardiovascular risk to establish both the thresholds for initiation of

Box 95-1**The 1999 WHO/ISH Guidelines**

- These Guidelines provide recommendations that are based on the collective expert interpretation by the WHO-ISH Guidelines Subcommittee of the available evidence from epidemiologic studies and clinical trials.
- The primary aim is to offer balanced information to guide clinicians, rather than rigid rules that would constrain their judgment about the management of individual patients, who will differ in their personal, medical, social, ethnic, and cultural characteristics.
- The WHO-ISH Guidelines are written for a global audience from communities that vary widely in the nature of their health system and availability of resources.
- It is hoped that national and regional experts will use them as a basis for drawing up recommendations that are specifically designed for management of patients in their own region.

Box 95-2**Hypertension versus Normotension
(WHO/ISH 1999)**

- Blood pressure levels are continuously related to the risks of cardiovascular disease and the definition of hypertension (or raised blood pressure) is, therefore, arbitrary.
- Much blood pressure-related disease occurs among individuals who would normally be considered normotensive.
- Most of the evidence about the benefits and risks of lowering blood pressure comes from studies in patients selected on the basis of high blood pressure.
- It is not clear whether estimates of treatment effect obtained from trials in hypertensives can be extrapolated to individuals with lower blood pressure levels.
- There is a strong rationale for expecting high-risk patients without hypertension to benefit from blood-pressure lowering and trials are required to investigate this possibility.

treatment and the goals for treatment of people with hypertension in general and for various subgroups

2. The appropriate treatment strategies for both nondrug and drug therapies
3. The cost effectiveness of drug treatment

In other areas the 1999 Guidelines would remain current. Subsequently the work done by the guidelines group was incorporated into a WHO/ISH statement.¹³ The 2003 statement superseded the 1999 Guidelines in the three

Box 95-3**Contribution of Blood Pressure and Other
Factors to Cardiovascular Disease Risk
(WHO/ISH 1999)**

- Among patients with mild hypertension, differences in the risks of cardiovascular disease are determined not only by the level of blood pressure, but also by the presence or levels of other risk factors.
- For example, a man aged 65 years with diabetes, a history of transient ischemic attacks, and a systolic/diastolic blood pressure of 145/90 mmHg will have an annual risk of a major cardiovascular event that is more than *20 times greater* than that in a man aged 40 years with the same blood pressure but without either diabetes or a history of cardiovascular disease.
- In contrast, a man aged 40 years with a systolic/diastolic blood pressure of 170/105 mmHg will have a risk of a major cardiovascular event that is about two or three times greater than that of a man of the same age with a systolic diastolic blood pressure of 145/90 mmHg and similar other risk factor levels.
- Thus differences in the absolute level of cardiovascular risk between patients with hypertension will often be determined to a greater extent by other risk factors than by the level of blood pressure.

Box 95-4**Underestimation of Effects of Blood
Pressure-Lowering Treatment in Randomized
Controlled Trials (WHO/ISH 1999)**

- Estimates of treatment effects in the trials of blood pressure lowering regimens generally provide conservative estimates of the full potential effects of treatment.
- In the trials, there was considerable crossover between treatment groups:
 - Proportion of patients assigned to active therapy groups stopped treatment
 - Proportion of those assigned to control groups began active treatment
- Such crossover is likely to have reduced the average difference in diastolic blood pressure between groups by 1 to 2 mmHg, in which case, the full relative effects of treatment on stroke and coronary heart disease would be somewhat greater than the effects observed.
- The average duration of treatment in the trials was only about 5 years, and it is possible that longer-term treatment over many years, as is usual for hypertensive patients, might have led to larger relative risk reductions.
- Low-risk patients were recruited to many trials, and the absolute effects of treatment among higher-risk patients seen in broader clinical practice are, therefore, likely to be greater than those typically observed (see Box 95-5).

Box 95–5**Relative and Absolute Effects of Treatment
(WHO/ISH 1999)**

- The relative effect of treatment reflects the proportional difference between treatment groups in the incidence of disease events:
In the Systolic Hypertension in the Elderly (SHEP) trial,²² the incidence of major coronary heart disease (CHD) events over 4.5 years in patients assigned active treatment was 4.4% while in those assigned the placebo it was 5.9%. This represents a relative risk of 0.73 or a relative risk reduction of 27%.
- The absolute effect of treatment is generally of greatest interest to doctors and patients:
In the SHEP trial, the absolute reduction in CHD risk over 4.5 years was 1.4%. This indicates that 14 events were prevented among every 1000 patients assigned active treatment, and that one major CHD event was avoided among every 71 patients assigned active treatment.
- Estimates of *relative* treatment effects from randomized trials provide a guide to the likely relative effects of treatment in other nonstudy patient populations. However, estimates of *absolute* treatment effects from trials of blood pressure lowering are of limited generalizability because of complex inclusion and exclusion criteria frequently resulted in the recruitment of patients at lower average risk than those seen in broader clinical practice.
- The best predictor of absolute treatment effects for any individual patient will be provided by application of the estimate of the relative risk reduction from trials to an estimate of the absolute disease risk for the individual in question.
- A simple table for estimating the absolute cardiovascular disease risk of individual hypertensive patients is provided for use with these guidelines.

Box 95–6**Situations in Which Ambulatory Blood Pressure Monitoring Should Be Considered
(WHO/ISH 1999)**

- Unusual variability of blood pressure over the same or different visits.
- Office hypertension in subjects with low cardiovascular risk.
- Symptoms suggesting hypotensive episodes.
- Hypertension resistant to drug treatment.

Box 95–7**Isolated Office (“White-Coat”) Hypertension (WHO-ISH 1999)**

- In some patients, office blood pressure is persistently elevated whereas daytime blood pressure outside the clinic environment is not.
- This condition is widely known as “white-coat” hypertension, although the term “isolated office” hypertension is preferable because the office-daytime blood pressure difference presumably depends on multiple factors, and does not correlate with the pressor response to blood pressure measurements by the doctor, the so-called “white-coat” effect.
- It is likely that only a small fraction of the hypertensive population exhibits isolated office hypertension, if the diagnosis is restricted to subjects whose ambulatory systolic/diastolic blood pressure measurements are truly normal (below 125/80 mmHg).
- Furthermore, there is continuing debate as to whether isolated office hypertension is an innocent phenomenon or whether it carries an increased burden of cardiovascular risk.
- Physicians should aim at its identification (by use of home or ambulatory blood pressure measurements) whenever clinical suspicion is raised.
- The decision to treat or not should be based on the overall risk profile and the presence or absence of target-organ damage. Close follow-up is essential for subjects with isolated office hypertension whom the physician chooses not to treat.

Box 95–8**Lifestyle and Blood Pressure
(WHO-ISH 1999)**

- It is important that lifestyle measures be instituted within the framework of a structured plan that includes the use of counseling and monitoring by appropriate health professionals such as nurses, dietitians, clinical psychologists, and other therapists, as well as the responsible physician.
- Recommendations should be tailored for each individual and greater use should be made of modern and well-validated counseling techniques.
- Lifestyle measures that are widely agreed to lower the blood pressure and that should be considered in all patients in whom they may apply are weight reduction, reduction of excessive alcohol consumption, reduction of high salt intake, and increase in physical activity.
- Particular emphasis should be placed on cessation of smoking and on healthy eating patterns that contribute to the treatment of associated risk factors and cardiovascular diseases.

Box 95–9**Benefits of Drug Treatment
(WHO-ISH 1999)**

- All classes of antihypertensive drugs have specific advantages and disadvantages for particular patient groups.
- There is as yet no evidence that the main benefits of treating hypertension are due to any particular drug property rather than to lowering of blood pressure *per se*.
- The randomized trials conducted to date have not provided any clear evidence of differential effects on outcome of different agents producing the same blood pressure reduction.
- However, most individual studies have been too small to detect plausibly modest differences in important outcomes such as stroke or myocardial infarction.

areas it considered. The full statement follows this chapter (see Appendix).

The WHO/ISH guidelines and statement differ from other major guidelines, particularly the European²³ and U.S. guidelines,²⁴ in their purpose and in their target audience. Global capacity to assess and manage hypertension is very different from that in Europe and the United States. A WHO global capacity assessment of 167 countries found that 61% had no national hypertension guidelines, 45% did not have health professionals appropriately trained to manage hypertension, in 25% antihypertensives were unaffordable, in 12% basic drugs were unavailable, and in 8% basic equipment for managing hypertension was unavailable.²⁵

The classification of hypertension used in all guidelines is arbitrary, and reflects a simplified dichotomous approach of normotension versus hypertension when the reality is that blood pressure–related risk is continuous. It is now recognized that CVD prevention should be comprehensive rather than focused on single risk factors, and that comprehensive risk management should focus on lowering blood pressure rather than the old notion of simply treating hypertension. Accordingly the WHO/ISH statement emphasizes risk stratification. It should be noted that, as emphasized in the European guidelines, risk in this context means *added* risk, that is, low risk means low added risk. There is general agreement in contemporary documents on thresholds for treatment and targets for blood pressure lowering. Thresholds given are 140/90 mmHg systolic in low- to medium-risk and less than 130/80 mmHg in high-risk patients.

All guidelines recommend lifestyle measures for prevention and management of hypertension. These include weight loss in the overweight, increased physical activity, moderation of alcohol intake, healthy diet (fruit, vegeta-

Box 95–10**Absolute Effects of Treatment on
Cardiovascular Risk (WHO-ISH 1999)**

- From the results of randomized controlled trials, it appears that each reduction of 10–14 mmHg in systolic blood pressure and 5–6 mmHg in diastolic blood pressure confers about two-fifths less stroke, one-sixth less coronary heart disease and, in Western populations, one-third less major cardiovascular events overall.
- In patients with grade 1 hypertension, monotherapy with most agents will produce reductions in systolic/diastolic blood pressure of about 10/5 mmHg. In patients with higher grades of hypertension, it is possible to achieve sustained blood pressure reductions of 20/10 mmHg or more, particularly if combination drug therapy is used.
- The estimated absolute effects of such blood pressure reductions on cardiovascular disease (CVD) risks (fatal plus nonfatal stroke or myocardial infarction) are as follows:

Patient group	Absolute risk (CVD) events over 10 years	Absolute treatment effects (CVD) events over 10 years prevented	
		10/5 mmHg	20/10 mmHg
Low-risk patients	<15%	<5	<9
Medium-risk patients	15–20%	5–7	8–11
High-risk patients	20–30%	7–10	11–17
Very-high-risk patients	>30%	>10	>17

- Between these strata, the estimated absolute treatment benefits will range from less than five events prevented per 1000 patient years of treatment (low risk) to more than 17 events prevented per 1000 patient years of treatment (very high risk).
- The absolute benefits for stroke and coronary heart disease will be augmented by smaller absolute benefits for congestive heart failure and renal disease.
- These estimates of benefit are based on relative risk reductions observed in trials of about 5 years' duration. Longer-term treatment over decades could produce larger risk reductions (see Box 95–4).

bles, and low saturated fat), reduction of dietary sodium, and increased dietary potassium intake.

There is a very large literature on choice of initial therapy in hypertension management. To a significant degree, however, this emphasis is outdated. An equally large body of data suggests most patients will not be controlled on monotherapy. The WHO/ISH statement emphasizes that

Box 95–11**Monotherapy versus Combination Therapy
(WHO-ISH 1999)****Drug Monotherapy**

When drugs from the main classes available are used as monotherapy at the recommended doses, they produce very similar blood pressure reductions. In general, the sizes of the blood pressure reductions increase with the initial level of blood pressure, but typically the placebo-adjusted reductions average about 4% to 8% for both systolic and diastolic blood pressure. Thus for patients with blood pressures of about 160/95 mmHg, the usual reduction produced by monotherapy would be about 7 to 13 mmHg systolic and 4 to 8 mmHg diastolic. Clearly, for many patients with hypertension, such reductions in blood pressure would not restore optimal or even nonhypertensive blood pressure levels.

Drug Combination Therapy

Combination therapy of several of the available drug classes has been shown to produce blood pressure reductions that are greater than those produced by any group of individual agents used alone. The Hypertension Optimal Treatment (HOT) study in which blood pressure was lowered to below 90 mmHg in over 90% of patients, demonstrated that combination therapy was necessary in 70% of participants. Combinations with fully additive hypotensive effects will deliver blood pressure reductions that are around twice as great as those obtained with a single drug, of the order of 8% to 15%, or 12 to 22 mmHg systolic and 7 to 14 mmHg diastolic for patients with blood pressure of 160/95 mmHg.

Effective Drug Combinations

Diuretic and β -blocker

Diuretic and angiotensin-converting enzyme (ACE) inhibitor (or angiotensin II antagonists)

Calcium antagonist (dihydropyridine) and β -blocker

Calcium antagonist and ACE inhibitor

α -blocker and β -blocker

Effective drug combinations use drugs from various classes in order to obtain the additive hypotensive effect that comes from combining drugs with different primary actions, while minimizing the compensations that limit the fall in blood pressure. Combinations of limited value generally result from combining drugs that work through similar mechanisms so that their hypotensive actions may be less than additive, or drugs that have similar side effects so that the risk of adverse effects is increased.

benefits of hypertension treatment largely derive from blood pressure reduction, but also recognizes the strong evidence that specific agents benefit patients with compelling indications. For patients without such compelling indications, on the basis of comparative trial data, availability, and cost, the WHO/ISH statement recommends that (low-dose) diuretics be considered for first-line therapy.

The WHO/ISH statement places significant emphasis on feasibility and cost effectiveness, which are of great impor-

Box 95–12**Causes of Refractory Hypertension
(WHO-ISH 1999)**

- Unsuspected secondary cause (e.g., renal and endocrine)
- Poor adherence to therapeutic plan
- Continued intake of drugs that raise blood pressure (e.g., nonsteroidal anti-inflammatory drugs)
- Failure to modify lifestyle including:
 - Weight gain
 - Heavy alcohol intake (e.g., binge drinking)
- Volume overload due to:
 - Inadequate diuretic therapy
 - Progressive renal insufficiency
 - High sodium intake

Causes of Spurious Refractory Hypertension

- Isolated office (white-coat) hypertension
- Failure to use large cuff on large arm

tance globally in the context of limited health budgets. Cost effectiveness encompasses benefits for expenditure and differs from affordability, which relates to prevalence and cost of treatment in a particular country setting. It follows that where resources are limited, cost-effective treatment may not be affordable, and priority for drug therapy should be given to those at higher risk. The Statement noted that in many (but not all) settings, thiazide diuretics are the cheapest available drugs and most cost effective. However, where compelling indications are present, drug classes providing additional benefits, even if more expensive, may be more cost effective. Where added risk is low, whether treatment is cost effective will depend on drug cost, but in high-risk patients with large benefits from treatment, more expensive drugs may be more cost effective.

The WHO/ISH 2003 Statement joins the 2002 *World Health Report* and the WHO/ISH 2000 Statement on prevention¹⁴ in stressing that population strategies to reduce blood pressure are very cost effective worldwide. The WHO/ISH statement indicates that both population-based and high-risk group strategies are needed for prevention of CVD, with comprehensive targeting of unhealthy lifestyle (diet, tobacco, inactivity), hypertension, glucose intolerance, hyperlipidemia; and CVD management.

Prevention and control of the global epidemic of cardiovascular disease requires a comprehensive program directed toward both populations and high-risk individuals, and focused on comprehensive risk factor reduction.

APPENDIX: 2003 WORLD HEALTH ORGANIZATION (WHO)/INTERNATIONAL SOCIETY OF HYPERTENSION (ISH) STATEMENT ON MANAGEMENT OF HYPERTENSION

World Health Organization/International Society of Hypertension Writing Group

ABSTRACT

Objective

Hypertension is estimated to cause 4.5% of current global disease burden and is as prevalent in many developing countries as in the developed world. Blood pressure–induced cardiovascular risk rises continuously across the whole blood pressure range. Countries vary widely in capacity for management of hypertension, but worldwide the majority of diagnosed hypertensives are inadequately controlled. This statement addresses the ascertainment of overall cardiovascular risk to establish thresholds for initiation and goals of treatment, appropriate treatment strategies for nondrug and drug therapies, and cost effectiveness of treatment.

Conclusions

Since publication of the WHO/ISH Guidelines for the Management of Hypertension in 1999, more evidence has become available to support a systolic blood pressure threshold of 140 mmHg for even “low-risk” patients. In high-risk patients there is evidence for lower thresholds. Lifestyle modification is recommended for all individuals. There is evidence that specific agents have benefits for patients with particular compelling indications, and that monotherapy is inadequate for the majority of patients. For patients without a compelling indication for a particular drug class, on the basis of comparative trial data, availability, and cost, a low dose of a diuretic should be considered for initiation of therapy. In most places, a thiazide diuretic is the least costly option and thus most cost effective, but for compelling indications where other classes provide additional benefits, even if more expensive, they may be more cost effective. In high-risk patients who attain large benefits from treatment, expensive drugs may be cost effective, but in low-risk patients treatment may not be cost effective unless the drugs are inexpensive.

INTRODUCTION

Cardiovascular disease (CVD) is responsible for one-third of global deaths and is a leading and increasing contributor to the global disease burden.¹ Importantly, CVD is eminently preventable. In order to achieve significant reductions in the avoidable CVD burden, a combination of population-based and high-risk strategies is necessary. These strategies should target lifestyle-related risk factors such as unhealthy diet, physical inactivity, and tobacco use, as well as the inter-

mediate manifestations of these lifestyles, including hypertension, glucose intolerance, and hyperlipidemia. In addition, strategies aimed at improving management of those already affected by CVD should be an integral component of a comprehensive approach for the prevention and control of CVD.

Hypertension is already a highly prevalent risk factor for CVD throughout the industrialized world. It is becoming an increasingly common health problem worldwide because of increasing longevity and prevalence of contributing factors such as obesity, physical inactivity, and an unhealthy diet.^{2,3} The current prevalence in many developing countries, particularly in urban societies, is already as high as those seen in developed countries.^{4,5} Worldwide hypertension is estimated to cause 7.1 million premature deaths and 4.5% of the disease burden (64 million disability-adjusted life years). The proportion of global disease burden attributable to hypertension is substantial¹ (Figure 95A–1).

Hypertension plays a major etiologic role in the development of cerebrovascular disease, ischemic heart disease, and cardiac and renal failure. Treating hypertension has been associated with about a 40% reduction in the risk of stroke and about a 15% reduction in the risk of myocardial infarction.⁶ Although the treatment of hypertension has been shown to prevent CVD and to extend and enhance life, hypertension remains inadequately managed everywhere.^{7–13} In addition, hypertension often coexists with other cardiovascular risk factors such as tobacco use, diabetes, hyperlipidemia, and obesity, which compound the cardiovascular risk attributable to hypertension. Worldwide, these coexistent risk factors are inadequately addressed in patients with hypertension resulting in high morbidity and mortality.^{7–9}

It has become increasingly evident that risks of stroke, ischemic heart disease, and renal failure are not confined to a subset of the population with particularly high levels of blood pressure but rather that risk occurs in a con-

Figure 95A–1. Global distribution of disease burden attributable to six major risk factors.

tinnium, affecting even those with below average levels of blood pressure.¹⁴ Globally, data indicate that about 62% of cerebrovascular disease and 49% of ischemic heart disease are attributable to suboptimal blood pressure (systolic blood pressure >115 mmHg).¹

A global capacity assessment survey conducted by WHO shows that there is wide variation in the capacity for management of hypertension in various countries.¹⁵ Of the 167 countries surveyed, national hypertension guidelines were not available in 61%, health professionals were not trained to manage hypertension in 45%, antihypertensives were not affordable in 25%, and basic equipment and drugs for the management of hypertension were not available in primary health care in 8% and 12% of countries, respectively.

This statement addresses the following issues: (1) the ascertainment of overall cardiovascular risk to establish both the thresholds for initiation of treatment and the goals of treatment for people with hypertension in general and for various subgroups, (2) the appropriate treatment strategies for both nondrug and drug therapies, and (3) the cost effectiveness of drug treatment.

ASSESSMENT OF RISK

Decisions about the management of hypertensive patients should not only take blood pressure levels into account, but also the presence of other cardiovascular risk factors, target-organ damage, and associated clinical conditions (Table 95A-1). The risk stratification table from the 1999 WHO/ISH *Guidelines*¹⁶ has been minimally amended to indicate three major risk categories with progressively increasing absolute likelihood of developing a major cardiovascular event (fatal and nonfatal stroke and myocardial infarction) within the next 10 years: (1) low risk—less than 15%, (2) medium risk—15% to 20%, and (3) high risk—greater than 20% (Table 95A-2). The simplicity of the

method enables a rapid preliminary assessment of cardiovascular risk and provides a flexible risk stratification system that can be customized to a range of practice settings with varying levels of resources. However, the categorical method used is less accurate than those using continuous variables, and this is a limitation of this risk stratification chart. Other techniques to assess individual patients' risk status have been published¹⁷⁻²¹ and may provide more accurate estimates. These risk charts use risk prediction equations derived from the Framingham heart study.¹⁹ It should be noted that while the Framingham equations provide an acceptable prediction of risk in northern European populations, their predictive validity in other ethnic groups is less clear.

The risk charts and tables differ in the age categories used, duration of risk assessment and risk factor profiles used. The current New Zealand and Joint British charts^{20,21} are similar in concept. While the former assess 5-year risk of all cardiovascular disease in eight discrete categories, the latter assess 10-year risk of coronary heart disease in three risk categories. Several recent studies have formally evaluated these charts for their comparative accuracy and patient preference.²²

Threshold for blood pressure lowering in hypertensive patients at low and medium risk

Before 1999 when the WHO/ISH *Guidelines on Management of Hypertension* were published,¹⁶ evidence of the benefits of initiating drug therapy to lower blood pressure at thresholds less than 160 mmHg systolic pressure was limited to observational data. While some evidence from early randomized controlled trials (RCTs) did support an intervention threshold of 90 mmHg diastolic blood pressure, almost all trials confirmed the benefits of treatment at levels of 160 mmHg systolic and 100 mmHg diastolic and above.^{6,23} Both new clinical trial evidence and obser-

FACTORS INFLUENCING PROGNOSIS		
Risk Factors for Cardiovascular Disease	Target-Organ Damage	Associated Clinical Conditions
Levels of systolic and diastolic blood pressure (grades 1-3)	Left ventricular hypertrophy (electrocardiogram or echocardiogram)	Diabetes
Males >55 years	Microalbuminuria (20-300 mg/day)	Cerebrovascular disease
Females >65 years	Radiologic or ultrasound evidence of extensive atherosclerotic plaque (aorta, carotid, coronary, iliac and femoral arteries)	Ischemic stroke
Smoking	Hypertensive retinopathy grade III or IV	Cerebral hemorrhage
Total cholesterol >6.1 mmol/L (240 mg/dL) or LDL cholesterol >4.0 mmol/L (160 mg/dL) ^a		Transient ischemic attack
HDL cholesterol M <1.0, F <1.2 mmol/L (<40, <45 mg/dL)		Heart disease
History of cardiovascular disease in first-degree relatives before age 50		Myocardial infarction
Obesity, physical inactivity		Angina
		Coronary revascularization
		Congestive heart failure
		Renal disease
		Plasma creatinine concentration: females >1.4, males >1.5 mg/dL (120, 133 μmol/L) Albuminuria >300 mg/day
		Peripheral vascular disease

^aLower levels of total and LDL cholesterol are known to delineate increased risk but they were not used in the stratification table.

Table 95-A1. Factors Influencing Prognosis

STRATIFICATION OF RISK TO QUANTIFY PROGNOSIS			
Other Risk Factors and Disease History	Blood Pressure (mmHg)		
	Grade 1 SBP 140–159 or DBP 90–99	Grade 2 SBP 160–179 or DBP 100–109	Grade 3 SBP ≥180 or DBP ≥110
I: No other risk factors	Low risk	Medium risk	High risk
II: 1–2 risk factors	Medium risk	Medium risk	High risk
III: 3 or more risk factors, or target-organ damage, or associated clinical conditions	High risk	High risk	High risk

DBP, diastolic blood pressure; SBP, systolic blood pressure.

Table 95–A2. Stratification of Risk to Quantify Prognosis

vational data published since 1999 support the lowering of the systolic blood pressure threshold.^{24–28} While there has been no new clinical trial evidence to support lowering thresholds to below 160 mmHg systolic and 90 mmHg diastolic in hypertensive patients at low risk, observational data published since 1999 do support the lowering of the systolic threshold.^{24,25} These observational data suggest that even low-risk patients with blood pressure ≤140 mmHg systolic and/or ≤90 mmHg diastolic are likely to benefit from lower pressures. Although women are at lower absolute risk of cardiovascular disease for a given level of blood pressure and RCT evidence includes a greater proportion of men than women, the treatment threshold should be the same in both men and women.

Absolute risk of cardiovascular disease for any given level of blood pressure rises with age, but only limited RCT evidence is currently available about the benefits of treating those aged over 80 years. For now, the treatment threshold should be unaffected by age at least up to 80 years. Thereafter, judgment should be made on an individual basis and therapy should not be withdrawn from patients over 80 years of age. This is suggested by a meta-analysis of data from patients above 80 years of age in which the group on antihypertensive treatment showed a significant reduction in stroke incidence compared to the control group.²⁹

Thresholds for blood pressure lowering in hypertensive patients at high risk

Since 1999, several new trials in high-risk patients^{26–28} have demonstrated morbidity and mortality benefits of lowering blood pressures from thresholds significantly below 160 mmHg systolic and/or 90 mmHg diastolic. These trials^{26–28} support the hypothesis that additional blood pressure lowering in high-risk complicated patients, irrespective of initial blood pressure results in a reduction in the number of cardiovascular events. Similarly, other smaller trials that evaluated the effect of angiotensin II receptor blockers (ARBs) on the progression of nephropathy also suggest that treatment for such patients should begin at lower thresholds.^{30–32} As with the uncomplicated patients, this seems likely to be the case for older or female hypertensive patients.

Targets for blood pressure lowering in hypertensives at low and medium risk

No new trial evidence about blood pressure targets in medium-risk hypertensive patients is available beyond that known in 1999 from the Hypertension Optimal Treatment (HOT) trial, which found optimal reduction of major cardiovascular events at about 139/83 mmHg.³³ However, HOT trial data suggested that most of the benefit was achieved by lowering the systolic blood pressure to about 150 mmHg and the diastolic blood pressure to about 90 mmHg in nondiabetic patients.

However, clinic- and population-based survey data continue to suggest that the lower the blood pressure levels achieved, the lower the cardiovascular event rate.^{34,35} In those over age 55, the systolic level assumes greater importance,³⁶ so the primary goal of therapy is to lower systolic blood pressure and the pragmatic target of below 140 mmHg is reaffirmed. This also has strategic value because aiming at below 140 mmHg as a systolic blood pressure target makes it more likely that more patients will reach values at or slightly above 140 mmHg. There is no apparent reason to modify this target for women or older patients with uncomplicated hypertension.

Targets for blood pressure lowering in hypertensive patients at high risk

Effective blood pressure control has considerable and immediate benefits in patients with established cardiovascular disease (CVD), diabetes, and renal insufficiency.^{36–28,30–32} While several new trials^{26–28} have shown clear cardiovascular benefits associated with lowering blood pressure significantly below 160/90 mmHg, none of these trials has attempted to identify the optimal blood pressure target for such patients. However, several trials have shown that in patients with diabetes reduction of diastolic blood pressure to about 80 mmHg and of systolic blood pressure to about 130 mmHg was accompanied by a further reduction in cardiovascular events or diabetes-related microvascular complications, as compared to patients with less stringent blood pressure control.^{37,38} Based on clinical trial evidence, and also on extrapolation from epidemiologic studies, a target of <130/<80 mmHg seems appropriate. There is no evidence of a need to

modify these target blood pressures for female or older patients with hypertension.

Feasibility and resource implications

The blood pressure thresholds for treatment discussed above will result in as many as 25% of all adults—and more than 50% of those over the age of 65—in some populations requiring antihypertensive therapy. Further, less than half of all hypertensive patients will attain the blood pressure targets recommended above with monotherapy.^{33,39,40} Most will need at least two antihypertensive drugs, and as many as 30% of patients will need three or more drugs in combination to attain target blood pressure levels. Even in healthcare systems with generous resources, control of blood pressure is often unsatisfactory. One-half of all patients may drop out of care entirely within 1 year of diagnosis.⁴⁰ Of those who continue under medical supervision, only about half tend to adhere to their prescribed medication⁴¹ and adherence is significantly influenced by drug choice, comorbidity, and health services' utilization.⁴¹

Further, numerous surveys have shown that about three-quarters of all patients with hypertension do not have optimal blood pressure control.^{10–12} The reasons for this are complex, but include failure to detect hypertension, failure of patients or doctors to initiate and/or continue with treatment, incomplete adherence to treatment by patients and to guidelines by doctors, and lack of adequate therapy to control blood pressure.^{10–12,40,41}

The high prevalence of hypertension and the difficulties in attaining and maintaining blood pressure targets outlined above pose particular problems for healthcare systems that have very limited resources. The cost of drug therapy can be kept low by using the least expensive drugs and generic formulations. Priority for drug therapy where resources are limited should be given to all hypertensive patients with high and then medium cardiovascular risk (Table 95A–2). In those with low cardiovascular risk (Table 95A–2), the decision to treat or monitor without treatment should be based on estimated cardiovascular risk and patients' choice. Although some patients in the blood pressure range of 140 to 159/90 to 99 mmHg have a 10-year cardiovascular risk higher than 20% (Table 95A–2), and should be treated, many patients are at low cardiovascular risk, albeit substantially higher

than those with optimal BP. Low-risk patients have a correspondingly lower chance of gaining benefits from treatment (Table 95A–3). These patients should be given lower priority for treatment when resources are limited.

Regarding blood pressure targets where resources are limited, it should be remembered that recommendations are not based on robust clinical trial data. Furthermore, although based on a *post-hoc* analysis, the data from the HOT trial³³ suggest little disadvantage associated with a systolic blood pressure target of less than 150 mmHg. This is therefore a reasonable “fallback” target when resources are limited or adequate treatment fails to attain target values. It is also important to remember that even partial control of blood pressure provides substantial protection against cardiovascular complications.

It must be noted that in all parts of the world, population strategies to reduce blood pressure are very cost effective.¹ Legislative action and voluntary agreements with industry to ensure reduction of salt in processed food can lead to substantial reductions in salt intake resulting in significant shift of population blood pressure levels to a more optimal distribution (Figure 95A–2). Therefore high-risk approaches to management of hypertension should always be complemented with population-wide approaches.

TREATMENT STRATEGIES

Value of lifestyle modifications

A variety of lifestyle modifications have been shown in clinical trials to lower BP⁴² and to reduce the incidence of hypertension.⁴³ These include weight loss in the overweight,⁴⁴ physical activity,⁴⁵ moderation of alcohol intake,⁴⁶ a diet with increased fresh fruit and vegetables and reduced saturated fat content,⁴⁷ reduction of dietary sodium intake,^{47–49} and increased dietary potassium intake.⁵⁰

Other lifestyle changes have not been found in multiple clinical trials to have a significant or lasting antihypertensive effect. These include calcium⁵¹ and magnesium supplements,⁵² reduction in caffeine intake,⁵³ and a variety of techniques designed to reduce stress.⁵⁴

The overall antihypertensive effect of effective lifestyle interventions varies with the patient's adherence to therapy.

CHANCE OF PREVENTING CARDIOVASCULAR EVENT DURING 5-YEAR ANTIHYPERTENSIVE TREATMENT	
10-Year Cardiovascular Risk (%)	5-Year Number Needed to Treat (Assuming BP Reduction of 10/5 mmHg and Relative Risk Reduction by Treatment of 25%)
30	27
20	40
15	53
10	80
5	160
2	400

Table 95–A3. Chance of Preventing Cardiovascular Event during 5-Year Antihypertensive Treatment

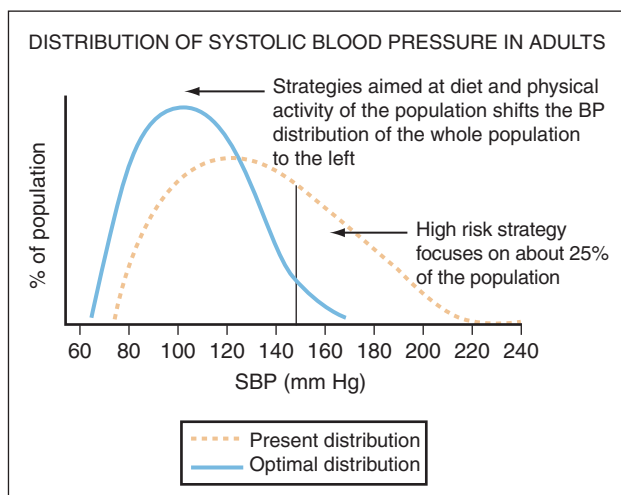

Figure 95A-2. Present and optimal systolic blood pressure distribution of the population. These smoothed curves portray the present distribution (interrupted lines) and the optimal distribution (continuous line) of systolic blood pressure in adults. A combination of population and high-risk strategies of blood pressure control is necessary to achieve the optimal blood pressure distribution.

When adherence is optimal, systolic blood pressure has been reduced by more than 10 mmHg,⁴⁷ but in less controlled clinical practice more modest effects have been seen.⁴² Trials to evaluate the effects of lifestyle interventions on levels of blood pressure have not been designed or powered to evaluate reductions in overall or cardiovascular mortality or morbidity. Nonetheless, these lifestyle modifications are recommended for all patients with hypertension since even small reductions in blood pressure are associated in long-term, large-scale population studies with a reduced risk of cardiovascular diseases.⁵⁵

In addition to their possible influence on blood pressure, observational studies have found that other lifestyle modifications, in particular cessation of smoking, have been found to reduce cardiovascular disease (CVD) mortality.⁵⁶ Moreover, weight reduction, dietary manipulation, and physical activity reduce the incidence of type 2 diabetes^{57,58} and a low saturated-fat diet improves dyslipidemia.⁵⁹

Therefore, regardless of the level of blood pressure, all individuals should adopt appropriate lifestyle modifications. The protective effects of modifying lifestyle include a reduction in the incidence of hypertension, diabetes, and dyslipidemia, a reduction in mortality by cessation of smoking, and a lowering of blood pressure that, in itself, is likely to reduce cardiovascular morbidity and mortality. Furthermore, unlike drug therapy, which may cause adverse effects and reduce the quality of life in some patients, nonpharmacologic therapy has no known harmful effects, improves the sense of well-being of the patient, and is often less expensive.

Choice of initial drug therapy

Data from more than 20 RCTs have been published since 1967 comparing diuretics, β -blockers, and calcium channel blockers (CCBs) against a placebo in hypertensive

patients.^{6,23,60} The data conclusively demonstrate reductions in both mortality and morbidity with these three drug classes. A meta-analysis of data from RCTs comparing two newer classes, that is, angiotensin-converting enzyme inhibitors (ACEIs) and CCBs, against older classes, that is, diuretics and β -blockers, in almost 75,000 hypertensive patients was published in 2000.²³ For the endpoints of total cardiovascular mortality, the meta-analysis shows no significant convincing differences between drug classes or between groups of old and new drugs. However, the available data do not exclude small to modest differences between different classes or drugs on specific fatal or nonfatal outcomes. For instance, in these comparative trials, ACEIs were associated with a lower incidence of coronary heart disease than CCBs, whereas CCBs were associated with a lower incidence of stroke than diuretic \pm β -blockers.²³

Two other large trials have been published since the meta-analysis in 2000, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)⁶¹ and the Second Australian National Blood Pressure Study (ANBP2).⁶² In ALLHAT, over 42,000 hypertensives with an initial mean blood pressure of 146/84 (90% already receiving antihypertensive therapy) were randomly assigned to a diuretic (chlorthalidone), an α -blocker (doxazosin), an ACEI (lisinopril), or a CCB (amlodipine). The α -blocker limb was prematurely stopped because of increased risk of the secondary endpoint of combined cardiovascular disease (CVD) (to which heart failure was a major contributor), although there was no difference in coronary events or mortality.⁶³

The effects of the other two choices in ALLHAT compared to diuretic on the primary endpoint of fatal and nonfatal coronary disease were identical. Some differences were seen in protection against various secondary endpoints, in particular a higher risk of stroke with the ACEI in the Afro-American enrollees and a higher risk of heart failure with both ACEI and CCB. The lesser protection with the ACEI may be attributed in large part to the 3-mmHg lesser fall in systolic blood pressure provided by that agent compared to diuretic.

In the ANBP2 trial,⁶² a diuretic was compared to an ACEI in 6083 patients who were generally older but with fewer cardiovascular risk factors than the ALLHAT participants. Those assigned to an ACEI had fewer cardiovascular events, particularly the men, and despite equal reductions of blood pressure, differences were of borderline statistical significance only when events subsequent to the first event were included.

In the LIFE trial,⁶⁴ among patients with ECG-determined left ventricular hypertrophy, therapy based on an angiotensin II receptor blocker (ARB) was more protective against a composite cardiovascular endpoint than therapy based on a β -blocker despite very similar blood pressure reductions. In fact the benefits were largely attributable to a protection against stroke and were particularly striking in the diabetic subgroup.⁶⁵

With the exception of ALLHAT, these trials typically included Caucasian patients in North America, Europe, and Australasia, and in recent trials most participants had

multiple cardiovascular risk factors. It is likely, however, that these relative risk reductions would apply to all patients with hypertension. In no trial were all enrollees maintained on the initial one drug to which they were assigned and in most trials the majority received two or more drugs to achieve the predetermined goal of therapy. Despite these potential limitations, the available data conclusively document the value of antihypertensive therapy and suggest that the benefits are largely derived from their reduction in blood pressure.

For the majority of patients without a compelling indication for another class of drug, a low dose of a diuretic should be considered as the first choice of therapy on the basis of comparative trial data, availability, and cost.

As previously noted, some patients need to have their blood pressure reduced to lower levels than previously recognized and will often require more than one drug.^{26,27,33,38,64} However, pending results of trials such as the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT),⁶⁶ there are no comparative RCT data on mortality or morbidity to guide selection of optimal combinations. In the absence of such data, and since a diuretic should enhance the efficacy of all classes, a diuretic most often will be a component of combination therapy. A diuretic is often available in single tablets combined with other classes of drugs. Where they are no more expensive, such combined formulations may be preferable, since they have advantages in terms of compliance and blood pressure-lowering efficacy. Other combinations of drugs with complementary actions may be appropriate for patients' needs.

Choice of drugs in different populations

Most drugs used to treat hypertension have also been evaluated for a number of specific indications. These include ACEIs, ARBs, β -blockers, CCBs, and diuretics in patients with concomitant diabetes, nephropathy, coronary and cerebrovascular disease, heart failure, and left ventricular hypertrophy. When studies have shown greater reduction in various fatal and nonfatal major-disease endpoints with one or another type of drug class, that class is considered to have a compelling indication for its use. Table 95A-4 indicates the clear and compelling indications for which certain drugs are preferred, based on greater reductions in either mortality or morbidity in large, long-term randomized trials.

In addition, comparisons have been made between the ability of different classes of drugs to regress left ventricular hypertrophy (LVH) and to slow the progression of nephropathies. For regression of LVH, CCBs, ACEIs, and ARBs have been found to be more effective than β -blockers and diuretics.^{64,67,68} In two comparative studies, a greater reduction in proteinuria has been found with initial therapy with ACEIs or ARBs than with other classes, in particular CCBs.^{31,69} Multiple placebo-controlled trials have shown significant reductions in proteinuria and a slowing of progression of renal damage in both nondiabetic and type 1 diabetic nephropathies with ACEIs⁷⁰ and in type 2 diabetic nephropathy with ARBs.³⁰⁻³² Whether ACE inhibitors and ARBs have similar benefits on the progression of renal damage as each other in type 1 and type 2 diabetic nephropathy remains untested, and whether they are superior to agents

COMPELLING INDICATIONS FOR SPECIFIC ANTIHYPERTENSIVE DRUGS			
Compelling Indications	Preferred Drug	Reference for Evidence	Primary Endpoint
Elderly with isolated systolic hypertension	Diuretic	71	Stroke
	DHPCCB	72	Stroke
Renal Disease			
Diabetic nephropathy (type 1)	ACEI	73	Progression of renal failure
Diabetic nephropathy (type 2)	ARB	30-32	Progression of renal failure
Nondiabetic	ACEI	70	Progression of renal failure
Cardiac Disease			
Post-myocardial infarction	ACEI	26,74	Mortality
Left ventricular dysfunction	β -blocker	75	Mortality
	ACEI	76	Heart failure
CHF (diuretics almost always included)	ACEI	76,77	Heart failure
	β -blocker	78	Mortality
Left ventricular hypertrophy	Spirinolactone	79	Mortality
	ARB	64,65	Mortality
Cerebrovascular Disease			
	ACEI + diuretic	27	Recurrent stroke
	Diuretic	28	Recurrent stroke

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CHF, congestive heart failure; DHPCCB, dihydropyridine calcium-channel blocker.

Table 95-A4. Compelling Indications for Specific Antihypertensive Drugs

CONTRAINDICATIONS AND CAUTIONS FOR SPECIFIC ANTIHYPERTENSIVE DRUGS			
Drug	Contraindications	Drug	Cautions
ACEIs, ARBs	Pregnancy	α -blockers	CHF
	Bilateral renal artery stenosis		
	Hyperkalemia		Clonidine
β -blockers	High degree of heart block	Methyldopa	Hepatotoxicity
	Severe bradycardia <50/min		
	Obstructive airways disease	Reserpine	Depression
Diuretics	Gout		Active peptic ulcer
		CCBs	CHF

Table 95–A5. Contraindications and Cautions for Specific Antihypertensive Drugs

other than β -blockers⁶⁴ in terms of preventing major cardiovascular events in this situation is not as yet clear.

In addition to these compelling indications, certain drugs may logically be chosen for other reasons. Thus, when used as monotherapy, a diuretic or CCB may lower blood pressure more in Afro-Americans and older patients than an ACEI or a β -blocker^{80,81} and an α -blocker will relieve symptoms of prostatism.⁸² Central α -agonists (e.g., clonidine), or peripheral adrenergic blockers (e.g., reserpine), may be used as inexpensive therapies in certain settings despite the absence of outcome data.

Specific drugs are either contraindicated or should be used with caution in certain conditions (Table 95A–5). A few of the contraindications such as use of ACEIs and ARBs in pregnancy are absolute, but most indicate that specific drugs could aggravate various conditions. The cautions indicate the greater propensity of certain drugs to induce side effects, but do not preclude their use if patients have strong indications for those drugs and if the patients are carefully monitored.

Cost effectiveness

Cost effectiveness is determined by the relationship between the benefits obtained for the expenditure. The prevalence of a condition and the total cost of treating it in a specific setting, on the other hand, determine affordability. Because of limited resources, cost-effective treatment may not be affordable. The two main determinants of cost effectiveness are the cost of drug therapy and the initial cardiovascular risk of the patient.

An overview of the totality of trial evidence suggests that the major classes of antihypertensive drugs are largely equivalent in efficacy and safety. In most places, a diuretic is the cheapest option and is, therefore, most cost effective. However, for certain compelling indications (Table 95A–4), other classes will provide additional benefits; even if they are more expensive, they may be more cost effective. For equivalent blood pressure lowering within each class, the least expensive is the most cost-effective drug.

It should be noted that in very high-risk patients who attain large benefits from treatment, treatment with multiple drugs, even those drugs that are expensive might be cost

effective. Conversely, the treatment of patients with low risk may not be cost effective unless the antihypertensive drugs used are inexpensive.⁸³

ACKNOWLEDGMENT

Contributors to this statement are listed below. Contributors were recommended by WHO and by the WHO/International Society of Hypertension Liaison Committee. The deliberations were chaired by S. Mendis and J.A. Whitworth who appointed two additional members, N.M. Kaplan and N. Poulter, to the writing committee. The Writing Group was comprised of Norman Kaplan, Shanthi Mendis, Neil Poulter, and Judith Whitworth.

Treatment Guidelines: The United States JNC7

Daniel W. Jones

The seventh report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure was published in 2003, first in an express version¹ and then in a comprehensive version.² The express version was published to facilitate application by busy clinicians. The comprehensive version was intended to provide more detail and careful documentation necessary for researchers and professionals focusing more deeply on hypertension. This 2003 report (JNC7) was a revision of the sixth report published in 1997 (JNC6).³

These reports have been prepared for more than three decades by the National Heart, Lung, and Blood Institute through the National High Blood Pressure Education Program, a coalition of 39 major professional, public, and voluntary organizations, and seven federal agencies. The work of the Joint National Committee was led by a 10-member executive committee appointed from the National High Blood Pressure Education Program Coordinating Committee membership. The report is an evidence-based report except where evidence does not exist to provide guidance. In those instances the report was consensus based.

CLASSIFICATION OF BLOOD PRESSURE

The JNC7 report departed from historical approaches and from other guidelines in its approach to classification of blood pressure. The classification added a new term, “prehypertension,” for those at risk for developing hypertension. Table 96–1 shows the classification of blood pressure for adults as detailed in the JNC7 report. There is also a departure from the JNC6 report in that the classification which is used to make decisions regarding initial drug therapy does not take into consideration other risk factors but only measured blood pressure as a determination for treatment decisions.

BLOOD PRESSURE CLASSIFICATION			
BP Classification	SBP (mmHg)		DBP (mmHg)
Normal	<120	and	<80
Prehypertension	120–139	or	80–89
Stage 1 hypertension	140–159	or	90–99
Stage 2 hypertension	≥160	or	≥100

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

Table 96–1. Blood Pressure Classification

BLOOD PRESSURE MEASUREMENT

The JNC7 and previous reports outlined the need for careful measurement of blood pressure. Recommendations for the use of a properly calibrated and validated instrument are noted. Recommendations from the most recent American Heart Association guidelines for the measurement of blood pressure again were used as the basis for recommendations.⁴

The JNC7 guidelines offered information on ambulatory blood pressure monitoring and self measurement of blood pressure as well. The report suggests that ambulatory blood pressure monitoring is warranted for evaluation of “white-coat” hypertension in the absence of target-organ injury; to assess patients with apparent drug-resistant hypotensive symptoms with antihypertensive medications; episodic hypertension; and autonomic dysfunction. The report notes that self-measurement of blood pressure might be beneficial in evaluating response to antihypertensive medication, improving patient adherence with therapy, and for evaluating possible “white-coat” hypertension.

PATIENT EVALUATION

Few changes were made in the recommendations for patient evaluation from previous reports. Routine laboratory and diagnostic tests recommended before initiating therapy in the report include an electrocardiogram, urinalysis, blood glucose, hematocrit, serum potassium, creatinine (or the corresponding estimated glomerular filtration rate), calcium, lipid profile after a 9- to 12-hour fast that includes a high-density lipoprotein cholesterol and low-density lipoprotein cholesterol and triglycerides. Optional tests for the clinician to consider include measurement of urinary albumin excretion for the albumin/creatinine ratio.

TREATMENT

The goal of therapy for most patients with hypertension is to reduce systolic blood pressure to below 140 mmHg and diastolic blood pressure to less than 90 mmHg. In patients with hypertension and diabetes or renal disease, the blood pressure goal is <130/80 mmHg.

Lifestyle therapy recommended in the report includes “weight reduction in those individuals who are overweight or obese, adoption to the Dietary Approaches to Stop Hypertension (DASH) eating plan, dietary sodium reduction, physical activity and moderation of alcohol consumption.” Table 96–2 shows the recommended lifestyle

LIFESTYLE MODIFICATIONS	
Modification	Approximate SBP Reduction (Range)
Weight reduction	5–10 mmHg/10 kg
Adopt DASH eating plan	8–14 mmHg
Dietary sodium reduction	2–8 mmHg
Physical activity	4–9 mmHg
Moderation of alcohol consumption	2–4 mmHg

DASH, Dietary Approaches to Stop Hypertension; SBP, systolic blood pressure.

Table 96–2. Lifestyle Modifications

modifications with expected reductions in systolic blood pressure.

Pharmacologic therapy is perhaps the most controversial part of the JNC7 report. There are some subtle differences here with other guidelines including the European guidelines.⁵ The JNC7 guidelines note that five classes of drugs have evidence of reducing complications of hypertension, including angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, beta blockers, calcium channel blockers, and thiazide diuretics. The report also suggests that “thiazide type diuretics should be used as initial therapy for most patients with hypertension either alone

or in combination with one of the other classes demonstrated to be beneficial in randomized controlled outcome trials.... If a drug is not tolerated or is contraindicated then one of the other classes proven to reduce cardiovascular event should be used instead.” An algorithm summarizing the recommendations is shown in Figure 96–1. Of note, the European guidelines do not give any priority to thiazide diuretics but simply recommend that clinicians choose among the five classes known to reduce mortality.⁵

Evidence supports “compelling indications” that require certain antihypertensive drug classes for high-risk conditions. Table 96–3 shows the classes recommended for several compelling indications.

COMPARISON OF JNC7 GUIDELINES TO EUROPEAN GUIDELINES

When the JNC reports were initially released, some of the differences vis-à-vis European guidelines generated considerable debate. In reality there are many more similarities than differences. In general, the U.S. and European guidelines are similar where the evidence is strong and different where the evidence is weaker. The guidelines certainly agree on lifestyle therapy for all and that lowering blood pressure to goal is the most important part of treatment. Both guidelines recommend selecting among classes with certain mortality benefit including thiazide diuretics, ACE inhibitors, angiotensin receptor blockers, beta blockers, and

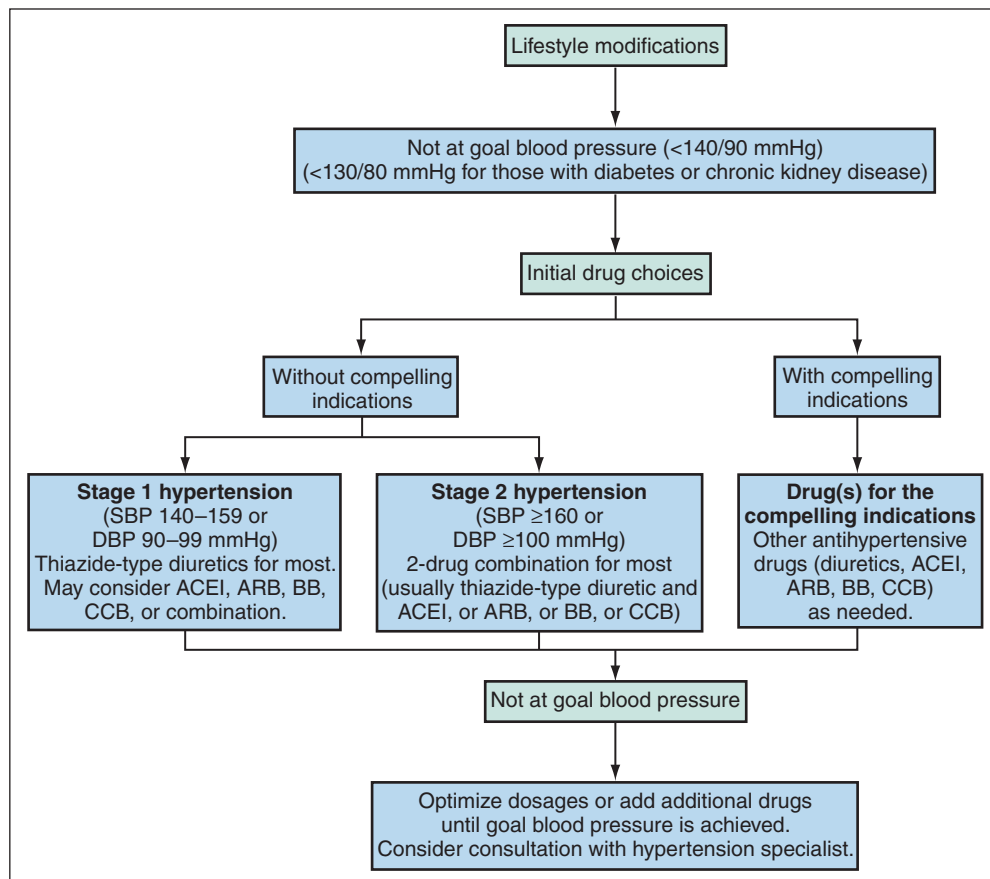

Figure 96–1. Algorithm for treatment of hypertension.

calcium channel blockers. Both guidelines suggest beginning with a combination in some patients, particularly those with higher levels of hypertension. Both guidelines call for specific classes in some circumstances, and both guidelines call for a goal blood pressure of 140/90 mmHg in most and 130/80 mmHg or lower in some patients.

There are differences in the guidelines in classification. The JNC7 guidelines use a new classification with a simplified approach to staging hypertension and the addition of “pre-hypertension.” The guidelines also include some subtle differences regarding blood pressure level at which to initiate lifestyle therapy. The JNC7 guidelines call for initiation of lifestyle therapy at a blood pressure of 120/80 mmHg and the European guideline at 130/80 mmHg. The JNC7 report calls for initiation of drug therapy based on the level of blood pressure alone and for all at 140/90 mmHg and above.

The European guidelines call for initiation of drug therapy based on total cardiovascular risk and level of blood pressure, and consider antihypertensive therapy optional for “low-risk” individuals at 140 to 159/90 to 99 mmHg. As noted earlier, the U.S. guidelines suggest “thiazide type diuretics for most.” The European guideline suggests that clinicians choose among the five classes of antihypertensive agents.

SUMMARY

The JNC7 guidelines are based on the best available evidence and provide guidance to clinicians for management of patients with hypertension. A stronger adherence to guidelines would lead to better treatment and control rates and lower cardiovascular disease rates in the future.

COMPELLING INDICATIONS FOR INDIVIDUAL DRUG CLASSES		
Compelling Indication	Initial Therapy Options	Clinical Trial Basis
Heart failure	THIAZ, BB, ACEI, ARB, ALDO ANT	ACC/AHA Heart Failure Guideline, MERIT-HF, COPERNICUS, CIBIS, SOLVD, AIRE, TRACE, ValHEFT, RALES
Post–myocardial infarction	BB, ACEI, ALDO ANT	ACC/AHA Post-MI Guideline, BHAT, SAVE, Capricorn, EPHEBUS
High CAD risk	THIAZ, BB, ACE, CCB	ALLHAT, HOPE, ANBP2, LIFE, CONVINCENCE
Diabetes	THIAZ, BB, ACE, ARB, CCB	NKF-ADA Guideline, UKPDS, ALLHAT
Chronic kidney disease	ACEI, ARB	NKF Guideline, Captopril Trial, RENAAL, IDNT, REIN, AASK
Recurrent stroke prevention	THIAZ, ACEI	PROGRESS
CAD, coronary artery disease.

The 2003 Guidelines for the Management of Hypertension of the European Society of Hypertension and European Society of Cardiology

Alberto Zanchetti

Key Findings

- The 2003 guidelines are the first specifically prepared in the area of hypertension management by European scientific organizations. They have an informative and educational purpose rather than a prescriptive one.
- Hypertension is defined in the context of a stratification of total cardiovascular risk that takes into account not only the levels of systolic and diastolic blood pressures, but also the presence or absence of other risk factors, target-organ damage, diabetes, and cardiovascular or renal disease.
- Because of the importance of subclinical damage in determining total cardiovascular risk, noninvasive procedures (such as ultrasound cardiac and vascular assessment, and search for microalbuminuria) are encouraged whenever these procedures may help in profiling the cardiovascular risk of the individual patient.
- Initiation of antihypertensive therapy is decided on the basis of total cardiovascular risk. Accordingly, grade 1 hypertension (systolic blood pressure [SBP] 140–159 or diastolic blood pressure [DBP] 90–99 mmHg) without any additional risk or disease may be managed by lifestyle changes only for several months before recurring to drug therapy, while high normal blood pressure (SBP 130–139 or DBP 85–89 mmHg) accompanying diabetes or clinical disease usually benefits from antihypertensive agents.
- The main benefits of antihypertensive therapy are due to lowering blood pressure *per se*. Therefore, all major classes of antihypertensive agents are considered suitable for initiation and maintenance of antihypertensive therapy. However, specific drug classes differ in some effect or in special groups of patients. Drugs also differ in terms of adverse disturbances, with important reflections on patients' compliance to treatment.
- To reach target blood pressure (at least below 140/90 mmHg in all hypertensive patients, and below 130/80 in diabetics and renal patients), a large proportion of subjects will require combination therapy with more than one agent. Combination therapy with two agents at low doses can also be used to initiate therapy in some patients.
- In patients at high risk, antihypertensive therapy may be beneficially associated with lipid lowering and antiplatelet therapies.

FIRST EUROPEAN GUIDELINES

The 2003 guidelines are the first ones prepared in the area of hypertension management by European scientific organizations.¹ Until that time, the European Society of Hypertension did not draw up specific guidelines on hypertension but chose to endorse guidelines previously prepared by the World Health Organization (WHO) and the International Society of Hypertension (ISH), and to incorporate them, with some adaptation, into joint recommendations of various European scientific societies for the prevention of coronary heart disease. However, in 2003 it was considered that the WHO/ISH guidelines are obviously written for a global audience from countries that vary widely in the extent of healthcare provision and the availability of resources. On the other hand, Europe was a much more homogeneous community, with populations with greater longevity but a higher incidence of chronic cardiovascular disease despite a high proportion of resources being devoted to disease prevention. The Councils of both the European Society of Hypertension and the European Society of Cardiology thought that preparation of European guidelines was a rational response to the suggestion of the WHO/ISH guidelines that national experts draw up recommendations specifically directed to patients in their own region. Giuseppe Mancia was asked to convene a representative group of European experts (28-member Guidelines Committee), and I chaired the Writing Committee consisting of R. Cifkova, R. Fagard, S. Kjeldsen, G. Mancia, N. Poulter, K.H. Rahn, J.L. Rodicio, L.M. Ruilope, J. Staessen, P. Van Zwieten, B. Waeber, and B. Williams.

PURPOSE OF GUIDELINES

The European guidelines are introduced by a statement that, in the Committee's opinion, guidelines should have an informative and educational purpose rather than a prescriptive one (Box 97–1). In the frame of this view, an extensive document with critical discussion of all relevant evidence available was first prepared,¹ which was later complemented by a brief set of practice recommenda-

Box 97-1**Purpose of European Guidelines**

- ESH and ESC feel that guidelines, to be effective, should have an educational purpose rather than a prescriptive one.
- Therefore, the two societies have first prepared a detailed document discussing all evidence available, and then have prepared succinct recommendations for the practicing physician.
- The ESH/ESC guidelines intend to leave a reasonable margin of choice to the individual doctor treating individual patients.

ESH, European Society of Hypertension; ESC, European Society of Cardiology.

tions² directed to those practitioners wishing to receive concise advice. This marks, perhaps, the most important difference from other guidelines, as the European document intends to provide information on all the complexities of hypertension management, and although providing some simple, but not oversimplified, paradigm of decision, leaves a reasonable margin of choice to the individual doctor treating individual patients. In accordance with this view, the European Guidelines Committee considered that, although large randomized controlled trials and meta-analyses provide the strongest evidence about several aspects of therapy, scientific evidence is drawn from many sources, and where necessary all sources of evidence and information were used, without rigid classification of recommendations according to strength of available evidence (Box 97-2).

DEFINITION AND CLASSIFICATION OF HYPERTENSION

The European guidelines consider that the continuous relationship between the level of blood pressure (both systolic and diastolic values) and cardiovascular morbidity and mortality makes any numerical definition and classification of hypertension arbitrary, and to quote a 30-year-old definition by Geoffrey Rose,³ "Hypertension should be defined in terms of a blood pressure level above which investigation and treatment do more good than harm," in order to indicate that any numerical definition must be a flexible one resulting from evidence of risk and availability of effective and well-tolerated drugs.

For practical reasons, however, a numerical classification is useful, and is indeed used by all available guidelines. The 2003 European guidelines have retained, with few modifications, the classification of the 1999 WHO/ISH guidelines. This classification is reproduced in Table 97-1. There are two differences between this classification and that provided by the Joint National Committee Report 7 (JNC 7) for the United States.⁴ A likely minor one concerns the subdivision of hypertension into three grades, whereas JNC 7 lumps grades 2 and 3 into a single

Box 97-2**Values and Limitations of Event-Based Randomized Trials****Values**

- Randomization is the safest procedure to avoid bias.
- Large number of patients guarantee power to detect differences in primary endpoints.
- Endpoints are well-defined events of clinical relevance.

Limitation

- Selection of patients (most often patients at elevated cardiovascular risk) makes extrapolation to patients at a different risk level doubtful.
- Most trials are not powered for secondary endpoints.
- Therapeutic programs in trials often diverge from those followed in clinical practice.
- Compliance of patients is much higher than in clinical practice.
- Controlled randomized trials last for 4 to 5 years, whereas life expectancy in middle-aged hypertensives is of 20 to 30 years.

group (stage 2), although it is felt that the division in three grades may be useful in order to better convey the concept of a continuous increase in risk with an increase in blood pressure. The other difference is more substantial: the European guidelines have not followed JNC 7 in classifying the very large number of subjects with blood pressures of 120 to 139/80 to 89 mmHg as prehypertensives, and have preferred to keep them split into two groups—normal blood pressure (120–129/80–84 mmHg) and high-normal blood pressure (130–139/85–89 mmHg). This avoids medicalization of millions of people, while preserving the concept that subjects with "high-normal

DEFINITIONS AND CLASSIFICATION OF BLOOD PRESSURE LEVELS (mmHG)

Category	Systolic	Diastolic
Optimal	<120	<80
Normal	120–129	80–84
High normal	130–139	85–89
Grade 1 hypertension (mild)	140–159	90–99
Grade 2 hypertension (moderate)	160–179	100–109
Grade 3 hypertension (severe)	≥180	≥110
Isolated systolic hypertension	≥140	<90

Notes: When a patient's systolic and diastolic blood pressures fall into different categories, the higher category should apply. Isolated systolic hypertension can also be graded (grades 1, 2, 3) according to systolic blood pressure values in the ranges indicated, provided that diastolic values are <90.

Table 97-1. Definitions and Classification of Blood Pressure Levels (mmHg)

blood pressure” have a greater likelihood to develop hypertension in the subsequent 10 years than those with “normal blood pressure,” as shown by the Framingham study.⁵

Apart from the merits of the different terms given to the numerical classification and subdivision of hypertension, an important feature of the European guidelines is that decisions about the management of patients with hypertension should rarely be made on blood pressure alone, but also on the presence or absence of other risk factors, target-organ damage, diabetes, and cardiovascular or renal disease, as well as on other aspects of the patient’s personal, medical, and social situation. An algorithm for stratification of total cardiovascular risk is illustrated in Table 97–2. The terms low, moderate, high, and very high added risk are calibrated to indicate an approximate absolute 10-year risk of cardiovascular disease of less than 15%, 15% to 20%, 20% to 30% and more than 30%, respectively, according to Framingham criteria,⁶ or an approximate absolute risk of fatal cardiovascular disease of less than 4%, 4% to 5%, 5% to 8%, and more than 8% according to the SCORE chart.⁷ These categories can also be used as indicators of relative risk, leaving the doctors free to use one or the other approach without the constraint of arbitrary absolute thresholds of risk that are more friendly to health providers than to patients. Indeed, the guidelines call attention to the danger that intervention thresholds based on rather short-term absolute risk may lead to concentrating most resources on the oldest subjects, easily classified at high absolute risk, while young subjects at high relative risk may remain untreated, even though their treatment may exert benefits through a much longer potential life span. Accordingly, European guidelines suggest basing decisions on relative risk for subjects younger than 60 and on absolute risk levels for older patients.

Finally, as seen in Table 97–2, European guidelines give particular importance to target-organ damage, diabetes mellitus, and associated clinical conditions (such as a previous myocardial infarction or stroke). Presence of these most often implies a high or very high added risk even in

Box 97–3

Methods for Blood Pressure Measurements

- Blood pressure values measured in the doctor’s office should commonly be used as references.
- Twenty-four-hour ambulatory blood pressure monitoring may be considered when:
 - Office blood pressure values are considerably variable. Blood pressure is high in the office in subjects at low total cardiovascular risk.
 - There is large discrepancy between office and home blood pressure.
 - Resistance to drug therapy is suspected.
- Self-measurement of blood pressure at home should be encouraged in order to:
 - Provide more information for the doctor’s decision.
 - Improve patient’s compliance.
- Normal values are different for office (<140/90 mmHg), 24-hour ambulatory (<125/80 mmHg) and home (<135/85 mmHg) blood pressure.

subjects with “normal” or “high-normal” blood pressure, thus substantiating the concept that the definition of hypertension (i.e., the blood pressure level deserving to be actively lowered) is a variable, flexible one, depending on the individual’s total cardiovascular risk.

DIAGNOSTIC EVALUATION

As in all guidelines, the European guidelines diagnostic procedures comprise repeated blood pressure measurement, medical history, physical examination, and laboratory and instrumental investigations. The value of various methodologies for measuring blood pressure is summarized in Box 97–3. As to laboratory and instrumental investigations, it is apparent from Box 97–4 that European guidelines have taken a rather liberal attitude in recommending, if expertise and resources are available (as

STRATIFICATION OF RISK TO QUANTIFY PROGNOSIS					
Other Risk Factors and Disease History	Blood Pressure (mmHg)				
	Normal SBP 120–129 or DBP 80–84	High Normal SBP 130–139 or DBP 85–89	Grade 1 SBP 140–159 or DBP 90–99	Grade 2 SBP 160–179 or DBP 100–109	Grade 3 SBP ≥ 180 or DBP ≥ 110
No other risk factors	Average risk	Average risk	Low added risk	Moderate added risk	High added risk
1–2 risk factors	Low added risk	Low added risk	Moderate added risk	Moderate added risk	Very high added risk
≥3 risk factors, target-organ damage, or diabetes	Moderate added risk	High added risk	High added risk	High added risk	Very high added risk
Associated clinical conditions	High added risk	Very high added risk	Very high added risk	Very high added risk	Very high added risk

DBP, diastolic blood pressure; SBP, systolic blood pressure.

Box 97-4**Diagnostic Evaluation: Laboratory Investigations****Routine Tests**

- Plasma glucose (preferably fasting)
- Serum total and HDL cholesterol; fasting serum triglycerides
- Serum creatinine
- Serum uric acid
- Serum potassium
- Hemoglobin and hematocrit
- Urinalysis (dipstick test and urinary sediment)
- Electrocardiogram

Recommended Tests

- Echocardiogram
- Carotid ultrasound
- Postprandial plasma glucose (when fasting value ≥ 6.1 mmol/L)
- Microalbuminuria
- Quantitative proteinuria (if dipstick test positive)
- Funduscopy (in severe hypertension)

they commonly are in Europe), a series of investigations in addition to the strictly necessary (or routine) ones. Echocardiography is recognized as much more sensitive than electrocardiography in diagnosing left ventricular

hypertrophy and predicting cardiovascular risk. The availability of echocardiography has increased in Europe, and when treatment decisions are uncertain, an echocardiographic examination may help in more precisely classifying the overall risk of the hypertensive patients and in directing therapy. The same is recognized to be the case for ultrasound examination of the carotid arteries with measurement of the intima-media thickness and detection of plaques, and for microalbuminuria (obligatory investigation in all diabetic patients, but also recommended in nondiabetic hypertensives).

THERAPEUTIC APPROACH**When to initiate antihypertensive treatment**

Decisions on initiation of antihypertensive treatment are based not only on the blood pressure values repeatedly measured on several occasions but on stratification of total cardiovascular risk. Accordingly, Table 97-3 has been drawn on the same pattern as Table 97-2. When blood pressure is in the normal or high-normal range and no other risk factor is present (average risk), no intervention is recommended, but if one or two additional risk factors are associated, lifestyle changes are recommended. In the presence of target organ damage, diabetes, or clinical conditions, antihypertensive drugs should be prescribed even when blood pressure is lower than 140/90 mmHg, particularly if it is in the high-normal range. This recommendation is based on evidence from the PROGRESS (Perindopril Protection Against Recurrent Stroke Study),⁸

INITIATION OF ANTIHYPERTENSIVE TREATMENT					
Other Risk Factors and Disease History	Normal SBP 120–129 or DBP 80–84	High Normal SBP 130–139 or DBP 85–89	Blood Pressure (mmHg) Grade 1 SBP 140–159 or DBP 90–99	Grade 2 SBP 160–179 or DBP 100–109	Grade 3 SBP ≥ 180 or DBP ≥ 110
No other risk factors	No intervention	No intervention	Lifestyle changes for several months, then drug treatment if preferred by the patient and resources available	Lifestyle changes for several months, then drug treatment	Immediate drug treatment and lifestyle changes
1–2 risk factors	Lifestyle changes	Lifestyle changes	Lifestyle changes for several months, then drug treatment	Lifestyle changes for several months, then drug treatment	Immediate drug treatment and lifestyle changes
≥ 3 risk factors, target-organ damage, or diabetes	Lifestyle changes	Drug treatment and lifestyle changes	Drug treatment and lifestyle changes	Drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes
Associated clinical conditions	Drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes	Immediate drug treatment and lifestyle changes

DBP, diastolic blood pressure; SBP, systolic blood pressure.

Table 97-3. Initiation of Antihypertensive Treatment

HOPE (Heart Outcomes Prevention Evaluation),⁹ and ABCD (Antihypertensive Therapy in Type 2 Diabetes: Implications of the Appropriate Blood Pressure Control in Diabetes) trials.^{10,11} Within the traditional hypertensive range, and particularly for patients with grade 1 hypertension, if the added total cardiovascular risk is low or moderate, treatment should be started with lifestyle changes and drugs added after several weeks or a few months if blood pressure does not reach the goal. When total risk is higher, drug treatment should be immediate but always accompanied by lifestyle recommendations. Lifestyle changes are an important component of antihypertensive treatment, but in many patients they are only effective when implemented with a structured behavioral program. Therefore, lifestyle changes cannot be considered as an easy and cheap approach to management of hypertension.¹²

Goal of treatment

According to the concept that what really matters is to achieve reduction in the total risk of cardiovascular morbidity and mortality, guidelines recommend treatment of all reversible risk factors and not only lowering of the raised blood pressure (Box 97–5). As to target blood pressure, it is recommended that both systolic and diastolic blood pressures be intensively lowered, at least below 140/90 mmHg and to lower values if tolerated, in all hypertensive patients, and below 130/80 mmHg in diabetics. However, guidelines acknowledge that these values may be difficult to achieve, particularly in the elderly, and that strong evidence in favor of reducing blood pressure below 140/90 is available only for diabetics and patients with a previous cardiovascular event, and that in diabetics only one study, ABCD-NT,¹¹ has shown significant benefit (stroke reduction) by achieving systolic blood pressures slightly below 130 mmHg.

Lifestyle measures

Lifestyle measures play an important role in the treatment of hypertension as well as in the correction of associated risk factors or disease; detailed recommendations

are given in the European guidelines, as summarized in Box 97–6. It is pointed out, however, that lifestyle measures have not yet been shown to prevent cardiovascular complications in hypertensive patients, and should never delay unnecessarily the initiation of drug treatment, especially in patients at higher levels of risk, nor should such measures detract from compliance with drug treatment.

Pharmacologic treatment

The European guidelines have chosen to have recommendations about pharmacological therapy preceded by analysis of the available evidence of the benefits obtained by antihypertensive therapy and of the comparative benefits obtained by the various classes of agents. It is obviously acknowledged that the strongest type of evidence is that provided by large randomized trials based on fatal and nonfatal events. It is, however, recognized that even event-based trials have some limitations (Box 97–2), and randomized studies using intermediate endpoints (i.e., subclinical organ damage changes) have also been evaluated. Admittedly, evidence that regression or retardation of subclinical organ damage is associated with reduction of cardiovascular events is indirect, but it is also known that at least some of these alterations have predictive value of subsequent fatal and nonfatal events. Treatment-induced alterations of metabolic parameters, or induction or worsening of the metabolic syndrome or diabetes have also been considered as they may have an impact during the course of the patient's life and are taken into account when assessing total cardiovascular risk.

Regarding the choice of antihypertensive drugs, the European guidelines conclude that a very large number of randomized trials, both those comparing active treatment with placebo (Figure 97–1) and those comparing active treatment regimens based on different compounds, clearly show that the main benefits of antihypertensive therapy are due to lowering of blood pressure *per se*. However, there is evidence, often from studies of intermediate outcomes, that specific drug classes may differ in some effect or in special groups of patients, and this may help determine the choice in particular situations. Drugs also differ in terms of adverse disturbances, particularly in individual patients, with important reflections on patients' compliance

Box 97–5

Goal of Treatment

- Treatment should be directed to all reversible risk factors identified, including smoking, dyslipidemia, or diabetes, and the appropriate management of associated clinical conditions, as well as treatment of the raised blood pressure.
- It can be recommended that systolic and diastolic blood pressure be intensively lowered, at least below 140/90 mmHg and to definitely lower values if tolerated in all hypertensive patients, and below 130/80 mmHg in diabetics and renal patients.
- However, systolic blood pressure below 140 mmHg may be difficult to achieve, particularly in the elderly.

Box 97–6

Lifestyle Changes

- Lifestyle measures should be instituted whenever appropriate in all patients, including subjects with high normal blood pressure and patients who require drug treatment.
- The lifestyle measures to be considered include:
 - Smoking cessation
 - Weight reduction
 - Reduction of excessive alcohol intake
 - Physical exercise
 - Reduction of salt intake

Figure 97-1. Risk reduction of fatal and combined fatal and nonfatal event in patients with active antihypertensive treatment versus placebo. CHD, coronary heart disease; CV, cardiovascular.

to treatment. In principle, all major classes of antihypertensive agents—diuretics, β -blockers, calcium antagonists, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor antagonists—are considered suitable for the initiation and maintenance of antihypertensive therapy. These conclusions are also illustrated in Box 97-7.

Table 97-4 summarizes indications and contraindications for the major classes of antihypertensive agents. Guidelines also recognize that, to reach target blood pressure, a large proportion of patients will require combination therapy with more than one agent. While the traditional approach to antihypertensive therapy has been that of starting with monotherapy and then resorting to combination therapy only when monotherapy fails, European guidelines suggest that when physicians think combination therapy is likely to become necessary (high initial blood pressure values, target-organ damage present), they can start therapy with a two-drug combination preferably at low doses (Figure 97-2). In general, antihypertensive therapy should be started gradually in most hyper-

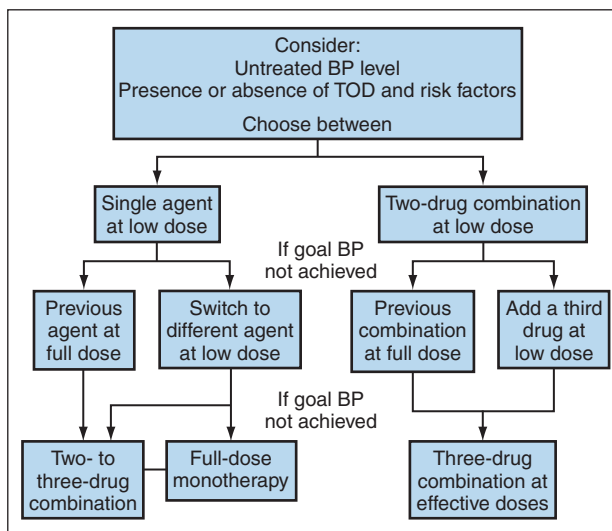

Figure 97-2. Choice between monotherapy and combination therapy. BP, blood pressure; TOD, target-organ damage.

tensive patients, especially in the elderly, but whenever important damage or clinical disease is present, treatment should be prompt and target pressure achieved in a few weeks, rather than months. The two-drug combinations found to be effective and well tolerated are indicated in Figure 97-3.

Therapeutic approaches in special conditions

European guidelines separately discuss therapeutic approaches in the elderly; diabetic patients; patients with renal disease, concomitant cerebrovascular or coronary disease or congestive heart failure; and pregnancy hypertension. For the elderly, it is pointed out that specific trials have clearly shown that reduced mortality and morbidity

Box 97-7

Choice of Antihypertensive Drugs

- The choice of drugs will be influenced by many factors including:
 - Previous experience of the patient
 - Cost of drugs (not to predominate over efficacy and tolerability)
 - Risk profile, organ damage, clinical cardiovascular or renal disease or diabetes
 - Renal disease or diabetes
 - Patient's preference
- The physician should tailor the choice of drugs to the individual patient, after taking all these factors, together with the patient's preference, into account.
- Particular attention should be given to adverse events, even to subjective disturbances, as these may be an important cause of noncompliance.
- Patients should always be asked about adverse events, and drugs or dose changed accordingly.

INDICATIONS AND CONTRAINDICATIONS FOR MAJOR CLASSES OF ANTIHYPERTENSIVE DRUGS			
Class	Conditions Favoring Use	Contraindications	
		Compelling	Possible
Diuretics (thiazides)	Congestive heart failure Elderly hypertensives Isolated systolic hypertension	Gout	Pregnancy
Diuretics (loop)	Renal insufficiency Congestive heart failure		
Diuretics (antialdosterone)	Congestive heart failure Postmyocardial infarction	Renal failure Hyperkalemia	
β -Blockers	Angina pectoris Postmyocardial infarction Congestive heart failure (up-titration) Pregnancy Tachyarrhythmias	Asthma Chronic obstructive pulmonary disease A-V block (grade 2 or 3)	Peripheral vascular disease Glucose intolerance Athletes and physically active patients
Calcium antagonists (dihydropyridines)	Elderly patients Isolated systolic hypertension Angina pectoris Peripheral vascular disease Carotid atherosclerosis Pregnancy		Tachyarrhythmias Congestive heart failure
Calcium antagonists (verapamil, diltiazem)	Angina pectoris Carotid atherosclerosis Supraventricular tachycardia	A-V block (grade 2 or 3) Congestive heart failure	
ACE inhibitors	Congestive heart failure Left ventricular dysfunction Postmyocardial infarction Nondiabetic nephropathy Type 1 diabetic nephropathy Proteinuria	Pregnancy Hyperkalemia Bilateral renal artery stenosis	
Angiotensin II-receptor antagonists (AT1-blockers)	Diabetic nephropathy Diabetic microalbuminuria Proteinuria Left ventricular hypertrophy ACE-inhibitor cough	Pregnancy Hyperkalemia Bilateral renal artery stenosis	
α -Blockers	Prostatic hyperplasia (BPH) Hyperlipidemia	Orthostatic hypotension	Congestive heart failure

ACE, angiotensin-converting enzyme.

Table 97-4. Indications and Contraindications for Major Classes of Antihypertensive Drugs

are achieved by blood-pressure lowering. For patients with diabetes or with nondiabetic renal disease, intensive lowering of blood pressure is necessary and this will require combination therapy, regularly including an agent blocking the renin-angiotensin system, especially when proteinuria is present. The finding of microalbuminuria in diabetics is an indication for antihypertensive therapy, irrespective of blood-pressure values. Previous cerebrovascular and coronary heart diseases also require intensive blood-pressure lowering.

In prevention of congestive heart failure, calcium antagonists appear to be less effective than thiazide diuretics and ACE inhibitors. In pregnancy, the goal of treating hypertension is to reduce maternal risk, but the agents selected must be safe for the fetus. Methyl dopa, labetalol, calcium antagonists, and β -blockers are the drugs of choice, although the β -blockers appear to be less effective than calcium antagonists. ACE inhibitors and

angiotensin-II antagonists should not be used in pregnancy, and diuretics are inappropriate in pre-eclampsia, which is generally associated with reduced plasma volume.

Treatment of associated risk factors or disease

The emphasis given in the European guidelines to assessment of total cardiovascular risk is paralleled by intervention recommendations. Box 97-5 indicates that the goal of treatment is to achieve reduction in total risk of cardiovascular morbidity and mortality. Therefore, guidelines recommend lipid-lowering (statins)¹³ and antiplatelet (low-dose aspirin)¹⁴ therapies in hypertensive patients, even in the absence of overt cardiovascular disease, if estimated 10-year cardiovascular risk is greater than 20% (high risk in the stratification algorithm of Table 97-2). However, low-dose aspirin administration should be preceded by good blood pressure control.¹⁴ In diabetic

patients, achieving satisfactory control of glycemia is also important: treatment goals are set to ≤ 6.0 mmol/L (110 mg/dL) for plasma preprandial glucose concentration and to less than 6.5% for HbA_{1c}.

IMPLEMENTATION OF GUIDELINES

Guidelines acknowledge that despite major efforts to diagnose and treat hypertension, this condition remains a leading cause of cardiovascular morbidity and mortality worldwide, and goal blood pressure levels are seldom achieved. This unsatisfactory delivery of care should be improved. The availability of guidelines should not only help clinicians to make decisions in everyday practice, but also make the health authorities in all countries aware of the critical points to consider in order to improve hypertension management. A powerful instrument for implementation is acceptance of guidelines by national hypertension societies and their dissemination in national languages. It is also acknowledged, however, that in order to be accepted by practicing physicians, guidelines should avoid being excessively prescriptive: European guidelines humbly recognize that guidelines provide information and advice concerning a disease or medical condition in general, whereas individual physicians are dealing with individual patients differing in their personal, medical, and cultural characteristics.

Chapter
98Treatment Guidelines:
The Developing World*Kolli Srinath Reddy, Nitish Naik, and Dorairaj Prabhakaran***Key Findings**

- Hypertension is one of the leading causes of death and disability both in the Third World and developed countries.
- The same protection is afforded from blood pressure control as in developed countries.
- There is a wide heterogeneity in the burden of hypertension in the Third World countries.
- While it would be difficult to make hypertension management guidelines for each country, it would be pragmatic to use an approach similar to the World Health Organization Risk Factor Surveillance (STEPS) surveillance program.
- The guiding principles that should be considered in developing guidelines for therapy should include (1) knowledge of available strategies for the prevention and management of hypertension, (2) capacity to detect and manage hypertension, (3) barriers to prevention and management of hypertension at an individual level, (4) best available evidence for the various drug classes, (5) optimal first line of therapy, and (6) ethnic variability in response to drugs.
- In many low-income countries, at their current level of health expenditure, risk assessment may need to be entirely clinical, based on patients' blood pressure level, age, gender, smoking status, body mass index, and previous history of cardiovascular illness.

Hypertension is one of the leading causes of death and disability both in the Third World and developed countries. It plays a major etiologic role in the occurrence of cerebrovascular diseases, coronary heart disease (CHD), and cardiac and renal failure.¹ Worldwide, hypertension contributes to 49% of the population attributable fraction of ischemic heart disease.² In a large majority of Third World countries, similar to developed countries, hypertension is emerging as a major contributor to mortality and morbidity. Further, the contribution of hypertension to CHD risk appears to be similar across all ethnicities.³ Given higher population growth in developing countries, it is expected that by 2020 these nations will account for 84% of the world's population. Therefore, not only is the burden of hypertension high among these nations, with increasing population, economic progress, and the epidemiologic transition underway, developing countries are likely to witness a manifold increase in the burden of hypertension by 2020.

Although this high burden is alarming, there are immense opportunities for prevention and appropriate management of hypertension. Several clinical trials involving drugs and lifestyle therapy have demonstrated the feasibility and success in the management of hypertension. Control of hypertension results in approximately 40% reduction in the risk of stroke and a smaller but meaningful (approximately 15%) reduction in CHD.⁴ However, most of these have been based on data gathered from developed countries. The same protection is likely, afforded from blood pressure control in developing countries, but resource constraints in Third World or developing countries merit consideration, especially when new, expensive drug classes are promoted.

Awareness and optimal management of hypertension are inadequate worldwide.⁵ Therefore, several attributes of hypertension should be considered while formulating guidelines. These include the burden of hypertension in a given country, its co-occurrence with other cardiovascular disease (CVD) risk factors such as diabetes and obesity, the available capacity to detect and manage hypertension, and the resource constraints of the country being studied. In this chapter we address these issues and discuss the need and basis for specific guidelines among developing countries.

DISEASE BURDEN

In 2000 there were approximately 972 million patients with hypertension worldwide⁶; 639 million of them resided in Third World countries. Modeled projections indicate an increase to 1.15 billion hypertensive patients by 2025 in Third World nations, which is an increase of 80% compared to 2000.⁶ In India, the absolute number of people with hypertension is expected to rise from the current estimated figure of approximately 118 million to over 200 million by 2025. Similar trends are expected in China.⁷

There is a great heterogeneity in the burden of hypertension in the Third World countries. Although systematic national data on prevalence are not available from most of the Third World, the highest prevalence rates of hypertension have been reported from the Latin American countries such as Mexico, Paraguay, and Venezuela, where prevalence rates vary from 32% to 36.9%.⁶ Lower rates of hypertension have been reported in some parts of sub-Saharan Africa with an estimated prevalence of 14%.⁶ Countries such as China and India have intermediate prevalence in urban areas (approximately 20% to 30%).⁶ Even within a given region, wide variations have been reported. Recent

studies in urban India report a prevalence of 30% to 40% in adults, while the prevalence of hypertension in rural regions is about 12% to 17%.⁸ Local practices have also been shown to influence the prevalence of hypertension. For example, in the predominantly rural setting of Assam, India, providing salt to tea garden workers has resulted in high rates of hypertension compared with other CVD risk factors.⁹

Time series trends also suggest a rising prevalence of hypertension. In China, the third national hypertension survey reported an increase in the overall prevalence of hypertension from 7.8% in 1979–1980 to 11.4% in 1991. The last survey in 2000–2001 (conducted by the International Collaborative Study of Cardiovascular Disease in ASIA [InterASIA]) reported a further increase to 27.2%.¹⁰ Similar trends in hypertension prevalence have been reported in India. Rising population-based, mean blood pressure parallels the increase in prevalence of hypertension. For example, the World Health Organization's *Atlas of Heart Disease and Stroke* profiled a sustained increase in the mean systolic blood pressure level in India, from a low of 120 mmHg in 1942 to 130 mmHg in 1997.¹¹ Compounding this high burden is lack of awareness and insufficient and ineffective treatment. In urban Chennai, in India, the prevalence of hypertension was 22.8% and 19.7% in men and women, respectively. However, only 37.3% of hypertensives were aware of their hypertension status, and only half of these were on any kind of drug therapy. Only 40% of those who were treated had adequate blood pressure control.¹² Even where educational levels are high, as in worksite settings, awareness and treatment status are sub-optimal. Prabhakaran et al.¹³ reported awareness of hypertension in only one-third of survey participants, and in this group blood pressure was adequately controlled in only 38%, although more than two-thirds (66.4%) of those surveyed had graduate (university or college) or higher level education. Similarly, in a large community survey in China, only 42.6% were aware of their hypertension, and 6.6% of hypertensives had adequate control of blood pressure.⁷ In this study, rates of awareness, treatment, and control were higher in women than in men, and higher in urban than in rural areas.

The awareness, treatment, and control status of hypertension in Africa is similarly unsatisfactory. Two recent surveys in Tanzania indicate that less than 20% of hypertensives were aware of their diagnosis, and approximately 10% of these reported receiving treatment and less than 1% were adequately controlled.¹⁴ In South Africa awareness among women was higher than among men (47% vs. 20%), and treatment and control status among women was marginally better. Thus, given the resource constraints of these countries it is important to identify high-risk populations for hypertension and to target treatment programs on these groups.

ETHNIC VARIATIONS

Although disease patterns in the developing world are likely to mirror and follow the same patterns seen in developed nations, variations in disease manifestation, severity, and

response to treatment are expected due to variations in both genetic and environmental influences.¹⁵

It has been demonstrated that the prevalence of hypertension is higher in African Americans as well as people of Afro-Caribbean descent than in white Americans.¹⁶ This condition also occurs at an earlier age, is more severe, and is more often associated with target organ damage than among white Americans. Similar variations have been described among ethnic minorities settled in developed nations.¹⁷ Variations in therapeutic response to antihypertensive drugs have also highlighted ethnic diversity. The response of African Americans to angiotensin receptor blockers (ARBs) has been suggested to be far less than that in whites; however, the differences are not as substantial upon accounting for sodium intake. Of note, the largest source of variation in blood pressure response, for example, to ACE inhibitors, is within racial/ethnic groups and not between them, as discussed in Chapter 57. Similarly, beta-blockers may be less effective in African Americans. Conversely, African Americans often respond better to diuretics than whites. These variations in therapeutic response have relevance when planning treatment guidelines as they affect patient safety, therapeutic response, and quality of life.

These racial/ethnic influences on blood pressure are established early on in life, with blood pressure following a higher and an earlier trajectory. In one such study conducted in California, a higher prevalence of blood pressure was noted in Asian girls, suggesting increased predisposition for earlier hypertension.¹⁸ Recent data from a national survey performed on 5641 children aged 5 to 14 years in Pakistan reported overall prevalence of high blood pressure at 12.2% (95% CI 11.3% to 13.1%).¹⁹ This is considerably higher than the 5% prevalence of hypertension reported in the U.S. Third National Health and Nutrition Examination Survey (NHANES III), conducted in 1988 to 1994. Results in the previous survey were even more significant upon consideration that the Pakistani children had significantly lower body mass index values than their Western counterparts.

Studies of ethnic minority children in the United Kingdom have also shown higher levels of blood pressure among children of South Asian descent compared to the white population. Indian, Pakistani, and Bangladeshi boys had higher systolic blood pressure than their white counterparts in the Health Survey for England 1999.²⁰ After controlling for age and height, Pakistani boys had a higher mean systolic blood pressure than a comparable general population. Indian, Pakistani, and Bangladeshi girls had higher diastolic pressure than girls in the general population. These results suggest the need for targeting children and teenagers to develop primordial prevention strategies in these populations.

NEED FOR TREATMENT GUIDELINES IN THE DEVELOPING WORLD

Guidelines are based on research evidence or consensus among experts, and are intended to help healthcare providers in choosing appropriate therapy and to create awareness among the general public for self-referral and screening. The need for guidelines in increasing awareness cannot be

overemphasized, considering the success of the U.S. National High Blood Pressure Education Program (NHBPEP), which has been in place for 34 years. The program has been one of the most successful endeavors in public health. It has significantly increased awareness in the general population as well as medical and paramedical professionals about the importance of documenting blood pressure and the need for appropriate therapy. According to the NHANES, 73% of U.S. adults were aware of hypertension in 1988–1991, compared to 53% in 1960–1962.²¹ In addition, better control of hypertension has been partly responsible for improved survival in the U.S. population, with reductions in age-related mortality for coronary artery disease and stroke. Hypertension prevalence also declined in the community due to adoption of healthier lifestyles. The success of this program spurred the development of public education programs for coronary artery disease, diabetes, and cholesterol, among others. Many nations have adopted similar programs to enhance physician and public awareness about the need to recognize and treat hypertension. Such programs need to be developed and integrated with other health programs in developing countries.

Therapy guidelines developed in the West are very strong on evidence but are not necessarily context-specific and resource sensitive. Detection, diagnosis, and evaluation guidelines are based on resource-intensive settings, some of which may not be relevant to developing country settings. Therefore, such guidelines are not widely used by physicians in developing countries. A global assessment survey conducted by the World Health Organization (WHO) shows that there is wide variation in the capacity for management of hypertension.²² Of the 167 countries surveyed, there were no national guidelines in 102 countries. Further, in 45% of the countries surveyed, health professionals were not adequately trained to manage hypertension, and antihypertensive drugs were not affordable in 25% of the countries. A consensus statement from the South Asian Association for Regional Cooperation suggests that patients are unlikely to comply with prescribed therapy if the cost of drugs is more than 5% of their disposable income.²³ Therefore, optimal implementation of therapy guidelines requires high resource sensitivity. While it would be difficult to make guidelines for each country, it would be pragmatic to use an approach similar to WHO's surveillance program.²⁴

The WHO STEP wise approach to Risk Factor Surveillance (STEPS) is a simple, standardized method for collecting, analyzing, and disseminating data for NCD risk factors in a strategic, coordinated, cost-effective, and sustainable manner.²⁴ STEPS is a sequential process, starting with data collection on key risk factors via questionnaires (Step 1), followed by measurement of simple physical measurements (Step 2) and collection of blood samples for biochemical assessment (Step 3). STEPS provide collection of standardized data and sufficient flexibility for use in various country situations and settings; thus, it provides opportunities for making inter-country comparisons.

Similar to the STEPs program, treatments and investigations identified as essential can be implemented at all levels. Those classified as expanded or ideal could be used in secondary or tertiary care settings where such resources

may be available. To identify therapies that could be added to the STEPS approach (core, expanded, and ideal therapies), we reviewed recommendations by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7), American College of Cardiology/American Heart Association, European Society of cardiology, and British Heart Foundation for management of hypertension. Using these recommendations as a framework and based on costing and feasibility of administration, we suggest a simple classification as illustrated in Table 98–1. Thus, for example, advice on reduced salt intake could be provided by a nonphysician health care provider, and the resource-intensive investigations and multiple drug therapies could be restricted to individuals with severe hypertension (e.g., >160/110 mmHg) and provided by physicians or cardiologists from secondary or tertiary care centers.

Principles in establishing guidelines for developing countries

Guiding principles in developing guidelines for therapy should include (1) available strategies for the prevention and management of hypertension, (2) capacity to detect and manage hypertension, (3) barriers to prevention and management of hypertension at an individual level, (4) best available evidence for the various drug classes, (5) the optimal first line of therapy, and (6) ethnic variability in response to drugs.

WHY TARGET HYPERTENSION?

As mentioned previously, high blood pressure is believed to contribute to nearly 2 million deaths annually in high-mortality developing countries. Worldwide, hypertension accounts for nearly 13% of all deaths. At least 21 million years of productive life will be jeopardized due to cardiovascular diseases in countries such as Brazil, China, India, Mexico, and South Africa. Despite these disturbing figures, noncommunicable diseases have not yet emerged as a disease priority for launching preventive public health programs in many developing countries. This is invariably the consequence of inadequate resources due to intensive budgeting of scarce fiscal resources for public health programs focused on communicable diseases. However, it must be realized that hypertension management represents the ideal “entry program” for cardiovascular disease control due to the following factors:

1. It is widely perceived by the general public as well as health care professionals as providing a recognized “clinical” demand, thereby eliciting stronger motivation.
2. Clinicians from a wide range of specialties (such as internists, cardiologists, nephrologists, endocrinologists, neurologists, obstetricians, ophthalmologists, etc.) deal with hypertension in their practice and can therefore recognize and address hypertension.
3. It is unlikely to face resistance from powerful lobbies as, for example, a tobacco control program would.
4. The program can serve as a platform for comprehensive cardiovascular disease reduction from which ancillary programs such as diabetes control, obesity control, and tobacco control, among others, can be initiated.

MANAGEMENT OF HYPERTENSION AND FEASIBILITY: VARIOUS MODALITIES AT DIFFERENT LEVELS OF CARE					
Drug/Investigations		Recommending Guidelines	Feasibility in Different Settings		
			Primary	Secondary	Tertiary

Table 98-1. Management of Hypertension and Feasibility: Various Modalities at Different Levels of Care

Potential strategies for intervention in developing countries

Hypertension control requires both a community-based approach as well as personal interventions to appropriately target hypertension. A community-based approach attempts to address hypertension through general measures by adopting healthy lifestyles such as restricting excessive salt consumption, preventing obesity, smoking cessation, increased physical activity, and so on. Even small reductions in blood pressure achieved through such interventions have large effects on hypertension-related morbidity and mortality. It has been projected that even a 5-mmHg reduction in systolic blood pressure in the community can reduce stroke mortality by 14%, mortality due to coronary artery disease by 9%, and all-cause mortality by 7%.²⁵

Evidence for community-based interventions

Community-based interventions do not attempt to treat hypertension in isolation; instead, they are packaged to affect all major conventional CHD risk factors including diabetes and lipid abnormalities. The effectiveness of community-based programs for cardiovascular disease prevention has largely been based on the experience of

the North Karelia Project in Finland,²⁶ the first public health cardiovascular disease prevention program. In the 1970s, the Finnish population ranked very high globally in rates of cardiovascular mortality. The program targeted blood pressure as well as other cardiovascular risk factors including smoking and elevated cholesterol. Outcomes included a 28% decrease in smoking in the intervention group along with a 3% decrease in blood cholesterol and blood pressure as compared to the control group. These changes in risk factors had a tremendous impact on cardiovascular events—there was a 22% reduction in age-adjusted cardiovascular disease-related mortality in the intervention group. In addition, coronary artery disease-related mortality rates across Finland fell by 11%. Although the results were encouraging, in view of the simultaneous decline in CHD mortality rates in other parts of Finland, the utility of community-based programs has been questioned. A pooled analysis by Ebrahim et al.²⁷ suggested that community-based programs have limited utility in reducing the CHD burden. However, it is likely that community-based programs may perform differently in developing countries due to the rapidly increasing burden of hypertension and other CHD risk factors and the low level of awareness of these risk factors.

Several community-based intervention programs have been attempted in developing nations to control risk factors. These have been modeled on similar programs in the developed world. The Tianjin Project in China, launched in 1984, was a major noncommunicable disease prevention project.²⁸ This intervention program focused on reducing salt intake, decreasing smoking, and controlling hypertension among nearly 9 million urban residents. This public health program resulted in significant reductions in salt intake with reductions in prevalence of hypertension and smoking. The Mirame Project in Chile was initiated in the metropolitan region of Chile when surveys demonstrated high-risk behavior in children, even among those in lower socioeconomic groups.²⁹ Prevalence of smoking was estimated to be 84%, 30% were physically inactive, 15% were obese, and 8% had elevated blood pressure. Three years of intervention significantly lowered risk factor prevalence in these school children and their families. In Mauritius, a switch in the use of cooking medium from palm oil to soybean oil resulted in dramatic reductions in serum cholesterol due to lowered intake of saturated fats.³⁰ This low-cost public health policy measure, introduced by government-initiated legislation, has had significant long-term effects on overall cardiovascular mortality and morbidity in Mauritius.

Thus, integrated community-based strategies that target lifestyle-related risk factors could be effective tools if strategies are meticulously planned and the target population appropriately defined. These require participation from international bodies such as the World Health Organization, national and local government bodies, health ministries, food and allied industries, nongovernmental organizations, and various other sectors, and may also need enabling legislation where appropriate. While some of these programs in their entirety can be initiated by at least the low middle-income developing countries, it may still be out of reach currently for low-income developing countries at their current level of health care infrastructure and organization. In the latter countries, along with policy level initiatives to promote healthy lifestyle (enhanced tobacco taxation, promotion of consumption of locally available fruits and vegetables by influencing marketing policies and managing potassium additives to salt) thoughtfully designed multiple risk-factor intervention programs that target specific populations such as employees at worksites and school children may be useful.

Issues in management of hypertension at individual level

Pharmacologic intervention to control hypertension requires awareness about the disease as well as the patient's motivation to continue therapy. Physicians are responsible for counseling patients about the need to adopt lifestyle measures, as well as tailoring therapy to individual patients' needs, achieving target goals, and stratify patients based on risk factor profile. As care of hypertension is delivered across a wide spectrum of medical specialties ranging from doctors armed with only bachelor degrees in medicine to specialists in medicine and cardiologists, treatment algorithms that are simple and offer rational choice of antihypertensive therapy are also key inputs for the success of

national programs in low-income developing countries. Even low-cost, off-patent antihypertensive drugs will be prohibitively expensive for some countries in this category even though in countries that have a well-organized pharmaceutical industry, such as India, the cost of antihypertensive drugs is a fraction of the cost in the West. Due to lower input costs, these countries are better positioned to afford a variety of drug classes. However, even in these countries, national programs will only be able to maintain the most basic drug formulary. Thus, physician education through national treatment guidelines will help curb indiscriminate drug prescription patterns. The feasibility of such a program in a low-resource setting has been demonstrated in Cuba where hypertension awareness and control improved significantly due to concerted efforts at the primary health care level.³¹

Cost effectiveness of treatment guidelines is also affected by two other important factors. While the Western world has lowered the threshold for drug and lifestyle intervention in hypertension, such an approach will not be cost effective for much of the developing world. While hypertension represents a continuum of risk with no absolute "normal" and "abnormal" levels, absolute risk of a cardiovascular event due to high blood pressure is governed by blood pressure level, as well as but also the presence or absence of other cardiovascular risk markers. Thus, while the JNC VII guidelines have adopted a strategy of a blood pressure cut-off to initiate therapy, the treatment guidelines advocated by New Zealand Heart Foundation and the British Hypertension Society place emphasis on assessing absolute CDV risk before initiating drug therapy. Based on this approach, it was estimated that blood pressure treatment should be restricted to those with absolute levels of 170/100 mmHg or higher, and those with blood pressure levels between 150/90 to 169/99 mmHg and a predicted 5-year CVD risk of 15%. Such an approach would be cost neutral, and could prevent up to one-third additional adverse events than the approach of treating all those with BP > 140/90 mms of mercury without accounting for other risk factors.³²

The cost effectiveness of guidelines aimed at evaluating absolute CVD was recently evaluated by Gaziano et al.³³ They assessed the cost effectiveness of current South African guidelines for hypertension in the setting of a developing country. The authors evaluated the cost of therapy and its effectiveness by using two levels of blood pressure (160/95 mmHg and 140/90 mmHg) and four levels of absolute CDV risk (>40%, 30%, 20%, and 15% 10-year probability) to initiate pharmacotherapy. Using this model, the incremental cost effectiveness of treating hypertension in those with a 10-year CVD risk of more than 40% was \$700 versus \$11,000 for those with an absolute risk of 15%. Thus, for national treatment guidelines to be more cost-effective in low-income developing countries, both absolute blood pressure level as well as absolute CVD risk should be determined. The recent revision of the South African guidelines according to a model based on absolute risk is a step in this direction. This form of risk assessment would help identify and treat high-risk individuals who would otherwise be inadequately treated and at the same time

prevent scarce funds being diverted for pharmacotherapy of patients at low risk, with little absolute benefit in terms of lower CVD events in the population. However, for such a strategy to be successful, low-cost algorithms that are resource sensitive and incorporate clinical data and relevant point-of-care investigations need to be developed and validated in these countries.

In many low-income countries, given the prevailing level of health expenditure, risk assessment may need to be entirely clinical, based on the patient's blood pressure level, age, gender, smoking status, body mass index, and previous history of CVD. Intervention may be initiated with aspirin, beta-blocker, diuretic, and a generic low-dose statin, even in a polypill form, to improve compliance. Legislators and government officials must be persuaded to increase public sector expenditure on noncommunicable diseases in these countries if the United Nations' millennium development goals are to be realized.

Issues in health care delivery

Stumbling blocks in hypertension control in developing nations are summarized in Box 98–1. These include the absence of nationwide programs and low levels of robust primary health care services, physician knowledge about the choices and goals of therapy, lack of continuing medical education programs, knowledge of risk stratification, motivation to impart patient education, and government participation in noncommunicable disease prevention, and absence of national programs. All these issues have to be addressed using novel and innovative approaches. For example, strategies such as using nonphysician health care providers in detecting hypertension, providing lifestyle advice, and follow-up of those on monotherapy, where adequate numbers of physicians are not available, is likely to be acceptable, especially in cases where physicians are reluctant to relocate to remote areas. Further development of simple training modules to target multiple risk factors and estimating the absolute risk for an individual patient would be very useful to physicians overloaded with clinical and administrative

care. A simple example is the development of risk assessment charts similar to the one created by the New Zealand Heart Foundation.³⁴ If sufficient data for development of such charts are not available, adopting an existing tool used in a country that is similar in demography or race/ethnicity.

DRUG CLASSES: EVIDENCE

Most national and international guidelines advocate thiazide diuretics as the first-line therapy in mild hypertension cases as stand-alone therapy or in combination with beta-blockers, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, or ARBs. These guidelines continue to be promoted despite concerns about the development of diabetes in patients on these classes of drugs (as in the ALLHAT study).³⁵ However, their extremely low cost compared to all other therapies, as well as efficacy, makes them attractive initial options for the Third World. Although beta-blockers have been first-line treatment for decades, the utility of these drugs has recently been questioned, especially after the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT).³⁶ In this trial, despite equivalent reductions in blood pressure, patients in the amlodipine-perindopril arm had a mortality advantage over the atenolol-thiazide arm, which led to premature termination of the trial. In a meta-analysis, Carlberg et al.³⁷ questioned the effectiveness of atenolol in reducing strokes, where it was shown to be only marginally superior to placebo. This and other concerns regarding the development of diabetes and adverse effects on libido and lipid profile challenge the long-accepted practice of prescribing beta-blockers as first-line therapy in hypertension. However, their cost advantage makes them a better choice than other classes of drugs for use as anti-hypertensive drugs in the developing world, especially in patients with overt CVD. The newer long-acting calcium channel blockers have rapidly gained favor for hypertension management. They are effective in blacks, elderly patients, and patients with isolated systolic hypertension, and are also marginally better than other drugs in preventing stroke. ACE inhibitors and ARBs have been shown to be effective in patients with hypertension and heart failure, prevent renal damage in patients with diabetes mellitus, and in prevention of stroke (ACE inhibitors with diuretics). In most low-income developing countries, their use will be restricted due to high cost.

First-line therapies in developing nations

Recent evidence suggests that beta-blockers are harmful as compared to ACE inhibitors and calcium channel blockers, and diuretics should not be the first-line therapy in individuals prone to diabetes. Since beta-blockers are cheap options in many developing countries, and should be considered if there are no contraindications and if other drugs are prohibitively expensive. Where generic versions of several classes of drugs are cheap and easily available, physicians could adhere to the most contemporary evidence-based recommendations. In people with high risk for diabetes and metabolic syndrome, such as South Asians, it would be prudent to avoid beta-blockers as the first-line therapy. Similarly, extrapolating from the evidence con-

Box 98–1

Stumbling Blocks for Hypertension Control in Developing Nations

- Lack of robust primary health care services
- Lack of physician knowledge about goals of therapy and choice of therapy
- Lack of motivation to impart patient education
- Aberrant physician practices resulting from influence of medical representatives
- Lack of knowledge of risk stratification
- Lack of continuing medical education programs
- Lack of government participation in non-communicable diseases
- Lack of national programs

cerning African Americans in the United States, black people living in sub-Saharan Africa and South Africa are less likely to benefit from beta-blocker or ACE inhibitor monotherapy, and diuretics and calcium channel blockers should be considered as first-line therapy. Where necessary, there should be no hesitation in using multiple drug therapies.

CONCLUSIONS

Hypertension is a major cardiovascular risk factor in both the developing and the developed world. Lack of adequate public and physician awareness of the significance of hypertension attest to the increasing relevance of formulating nation-wide programs for hypertension education and control in the developing world. National programs along

with clinical guidelines can provide a framework to prescribe, monitor, and implement necessary educational and clinical activities to promote control of hypertension, and this can favorably influence clinical practice and reduce costs of hypertension control. Emphasis should also be laid on promoting societal changes to reduce mean blood pressure at a population level. It has been estimated that a population-level reduction of blood pressure by 2% can reduce the incidence of stroke and ischemic heart disease by 10% in Asia alone.³⁸ A concerted effort by health care practitioners, professional organizations, education and vocational institutions, print and electronic media, nongovernmental organizations, and governments may be needed to increase awareness of lifestyle modifications in preventing hypertension.
