Chapter
33Multiple Roles of Eicosanoids
in Blood Pressure Regulation*John Quilley and John C. McGiff***Key Findings**

- PGE₂ stimulates multiple receptor subtypes, including those of tubules that inhibit Na⁺ transport and those of the renal vasculature that elicit dilation and increase medullary blood flow. In concert, they contribute to the diuresis–natriuresis in response to elevation of renal perfusion pressure and/or expansion of extracellular fluid volume.
- TxA₂ receptor stimulation contributes to angiotensin-dependent hypertension. Increased TxA₂ production participates in the elevation of blood pressure in young spontaneously hypertensive rats.
- Among the many properties of 20-hydroxyeicosatetraenoic acid (20-HETE), vasoactivity and modulation of transport in key nephron segments underlie its essential role in the regulation of the renal circulation (autoregulation and tubuloglomerular feedback) and electrolyte excretion (cotransporter and Na⁺ pump inhibition), which impact directly on the regulation of blood pressure.
- The range and diversity of activity of 20-HETE also derive from cyclooxygenase-2–dependent transformation of 20-HETE in the renal vasculature to prostaglandin analogues.
- Production of antipressor epoxyeicosatrienoic acids (EETs) in rats by the cytochrome P450-arachidonic acid epoxygenase isoform 2C23 is stimulated by activating adenosine A_{2A} receptors in response to salt loading; and inhibition of EET synthesis raises blood pressure in salt-loaded rats.
- 11,12-EET is the endogenous regulator of epithelial Na⁺ channel in cortical collecting ducts; deficiency in 11,12-EET is a probable cause of a monogenic form of hypertension.

PROSTANOIDS

Prostaglandins are generally considered to be antihypertensive, although there is little doubt that PGH₂/TxA₂ contribute to the elevation of blood pressure in some forms of hypertension. The antihypertensive effects are based on the actions of prostaglandins that brake the vascular and renal tubular responses to stimulation of vasopressor systems and amplify the vasodilator and natriuretic effects of stimulation of vasodepressor systems. Thus prostaglandins moderate the effects of the renin-angiotensin system (RAS),¹ the sympathetic nervous system,² and vasopressin,³ while enhancing the effects of the kallikrein-kinin system.⁴

Inhibition of cyclooxygenase (COX) increases vascular resistance and enhances vasoconstrictor responses to angiotensin II (Ang II) and other constrictor hormones.¹ Identification of the inducible form of COX, COX-2, and the development of specific inhibitors of each isoform and COX-1 and COX-2 knockout mice has enabled investigators to distinguish the functional consequences produced by inhibiting either the inducible COX-2 or the constitutive COX-1. COX-2 activates the RAS by initiating synthesis of PGI₂ (prostacyclin), the renin secretagogue. COX-2 in preglomerular microvessels (PGMVs) also has an important role in metabolizing and, thereby, moderating the pressor activity of 20-hydroxyeicosatetraenoic acid (20-HETE), the principal product of the cytochrome P450 (CYP) pathway of arachidonic acid (AA) metabolism (Figure 33–1).

DEFINING THE PHYSIOLOGIC ROLE OF PROSTAGLANDINS

Until recently, the definition of the role of prostaglandins in hypertension has defied rigorous analysis because of the lack of appropriate investigative tools. With the characterization of prostaglandin receptor subtypes and the development of receptor subtype knockout models and selective receptor agonists and antagonists, the role of individual prostaglandins in disease processes is becoming clearer. Conventionally, investigations relied on measurements of prostaglandins or metabolites in biological fluids as indices of renal or systemic production and on the effects of nonsteroidal anti-inflammatory drugs (NSAIDs) to inhibit synthesis. Both have severe limitations, the latter because both pro- and anti-hypertensive prostanoids will be affected, and the former because the sites of synthesis and action of prostaglandins may be limited to discrete cell types, thus limiting the value of measurements in biological fluids such as plasma and urine. Similar limitations are being re-experienced in investigations of the more recently discovered CYP-derived eicosanoids, epoxyeicosatrienoic acids (EETs), and HETEs, for which receptors have not been defined and where inhibitors of enzyme activity, epoxygenases, and ω/ω-1-hydroxylases may affect multiple isoforms and the formation of both pro- and anti-hypertensive products. This is apparent from the use of NSAIDs; depending on the form of hypertension and the predominance of pro- or anti-hypertensive prostanoids, NSAIDs may increase or decrease blood pressure.

As renin release is stimulated by PGI₂ and requires COX-2 expression, renin-dependent hypertension can be

Figure 33–1. Schematic showing transformation of the vasoconstrictor, 20-HETE, by COX-2 and PGE₂ isomerase to 20-OH PGE₂, which produces vasodilation. 20-HETE, 20-hydroxyeicosatetraenoic acid; AA, arachidonic acid; COX-2, cyclooxygenase-2; CYP, cytochrome P450. (Redrawn from McGiff JC, Quilley J. *Am J Physiol Regul Integr Comp Physiol* 1999;277:R607–23. Used with permission.)

reduced by either COX inhibition or blockade of the IP receptor.^{5,6} It is interesting to note that IP receptor deletion protects against renovascular hypertension by disengaging (uncoupling) RAS from the obligatory PGI₂ component that activates renin production/release.⁶ Thus in wild-type mice, clipping of the left renal artery resulted in elevation of blood pressure that was associated with increased renal renin mRNA and plasma renin activity (PRA). In mice lacking the IP receptor, the elevations of blood pressure, PRA and renin mRNA were greatly reduced. This supports the earlier finding of Wang et al.⁵ that inhibition of COX-2 lowered blood pressure in a model of renovascular hypertension, an effect associated with reduced renin. Presumably, the same mechanism accounted for the blood pressure lowering effect of aspirin in patients with renovascular hypertension.⁷ However, most evidence suggests that prostaglandins subserve protective roles to limit the increase in blood pressure and maintain organ perfusion in response to activation of vasopressor systems; under such conditions, NSAIDs can precipitate acute renal failure and produce malignant hypertension.⁸ Thus inhibition of prostaglandin synthesis may have no untoward effects under normal conditions but may have catastrophic effects in situations where prostaglandin synthesis is directed at maintenance of normal tissue function in the face of potentially detrimental stimuli. For example, in the anesthetized, surgically stressed dog, inhibition of prostaglandin synthesis resulted in a precipitous increase in renal vascular resistance (RVR) with elevation of blood pressure (Figure 33–2), whereas in resting animals, NSAIDs affected neither renal blood flow (RBF) nor blood pressure.⁹

The exhibition of fundamental properties of prostaglandins depends on the experimental conditions as seen in the effects of endogenous versus exogenous PGE₂ on pressor systems. In response to either Ang II or norepinephrine infused into the renal artery, activation of the antipressor PGE₂ was evident in its increased concentrations in venous effluents (Figure 33–3), coincident with reversal of the renal vasoconstrictor action of the pressor hormone. By way of contrast, infusion of PGE₂ into the renal artery of chronically instrumented dogs evoked elevation of blood pressure despite the accompanying diuresis.¹⁰ The pressor response most likely was produced by activation of either EP₁ or EP₃ receptors (or both) that can elicit renal vasoconstriction with an attendant increase in blood pressure via activation of the RAS.

PROSTAGLANDIN RECEPTORS

There are five major types of receptors—EP, IP, DP, FP, and TP—that correspond to the various ligands produced by COX isoforms, namely, PGE₂, PGI₂, PGD₂, PGF_{2α}, and PGH₂/TxA₂, respectively. The receptors are classical G protein–coupled receptors with seven transmembrane domains.¹¹ As FP and DP receptors are not involved to a major degree in cardiovascular control and hypertension, they will not be addressed. For a comprehensive review of prostaglandin receptors and the kidney, see Breyer and Breyer.¹²

EP receptors

There are four G-protein–coupled EP receptors. The vasodilator effects of PGE₂ are linked to activation of EP₂ and EP₄ receptors with increased cAMP. Activation of these receptors explains the acute hypotensive effect of PGE₂.¹³ In EP₂ knockout mice, the hypotensive effect of exogenous PGE₂ was lost and converted to a pressor response, which was attributed to unmasking of the vasoconstrictor effects of PGE₂ that resulted from activation of EP₁ and EP₃ receptor subtypes. Thus activation of either the EP₁ or EP₃ receptor was associated with an increase in intracellular calcium [Ca²⁺]_i and vasoconstriction; deletion of the EP₁ receptor subtype in mice produced hypotension. Deletion of EP₂ receptors in mice elevated blood pressure when the mice were exposed to a high salt diet,¹³ which indicates a role for this receptor subtype in the excretion of salt, although expression in the kidney is low under normal conditions.

The natriuretic and diuretic effects of PGE₂ have been attributed also to activation of EP₁ and EP₃ receptors, which are both expressed in the collecting duct while EP₃ is also abundant in the thick ascending limb (TAL). Stimulation of EP₁ receptors increases (Ca²⁺)_i and inhibits Na⁺ and water reabsorption in the collecting duct, whereas activation of EP₃ receptors inhibits cAMP formation and, thereby, may modulate the effect of vasopressin. Stimulation of the EP₃ receptor of parietal cells inhibits gastric acid secretion whereas the EP₄ receptor is involved in mucus secretion; these cytoprotective mechanisms can be negatively affected by NSAIDs, which may result in gastric ulceration.

IP receptors

Stimulation of IP receptors produces vasodilation, inhibition of platelet aggregation and vascular smooth muscle cell proliferation.¹⁴ These effects result from activation of adenylate cyclase; antagonism or deletion of this receptor would be predicted to have deleterious cardiovascular effects, which may only be exhibited in disease states. Thus in IP knockout mice, blood pressure was unaffected although hypertension in response to renal artery constriction was blunted consistent with the role of PGI₂ as a renin secretagogue.¹⁵ Of great concern was the observation that these same mice were more prone to thrombogenesis,⁶ a finding that anticipated the proposed mechanism evoked by the increased incidence of thrombotic events in patients treated with COX-2 inhibitors.¹⁶

Figure 33-2. Effects of indomethacin on renal vascular resistance and renal venous prostaglandin concentrations (E=PGE₂, F=PGF_{2α}) in conscious dogs and in those subjected to anesthesia and laparotomy. The vertical lines in the upper panel represent the standard error of the mean for the determination of vascular resistance. (Redrawn from Terragno NA, Terragno DA, McGiff JC. *Circ Res* 1977;40:590-5.)

TP receptors

These receptors can be activated by PGH₂ and TxA₂, as well as isoprostanes, all of which produce vasoconstriction.¹⁷ Activation of TP receptors by either PGH₂ or TxA₂ contributes to hypertension of pregnancy¹⁸ and to the elevation of blood pressure in some forms of experimental hypertension, particularly those that involve activation of the RAS. In the rat, coarctation of the aorta between the renal arteries resulted in hypertension that was associated with activation of the RAS for the first 2 to 3 weeks, during which time blockade of TP receptors lowered blood pressure.¹⁹ The suggestion that TxA₂ contributes to the increase in blood pressure in response to stimulation of the RAS was confirmed by showing that TxA₂ was required for the full expression of the hypertensive response to Ang II.²⁰ In rats treated with an angiotensin-converting enzyme inhibitor to eliminate endogenous Ang II, the elevation of blood pressure to an infusion of Ang II for 7 days was reduced in animals given a Tx synthase

inhibitor. Further confirmation came from TP receptor knockout mice in which the elevation of blood pressure in response to an infusion of Ang II was blunted.²¹ Similar findings were reported by Kawada et al.²² who concluded that TP receptor stimulation, via the AT1 receptor, mediated Ang II-induced increases in RVR, generation of reactive oxygen species and formation of pressor prostanoids (PGH₂/TxA₂). As COX-1 knockout mice also showed an attenuated pressor response to Ang II,²³ it seems likely that this COX isoform is responsible for the generation of PGH₂/TxA₂ in response to Ang II. In apparent conflict with the assigned role of COX-1 in the generation of pressor prostanoids, Wang et al.²⁴ provided evidence that in rabbits infused with Ang II, COX-2-derived PGH₂/TxA₂ mediated the enhanced constrictor effect of Ang II in microdissected afferent arterioles. However, species differences (rat vs. rabbit) and experimental conditions (isolated arterioles vs. whole animal) do not allow direct comparison of these studies. Nonetheless, under normal

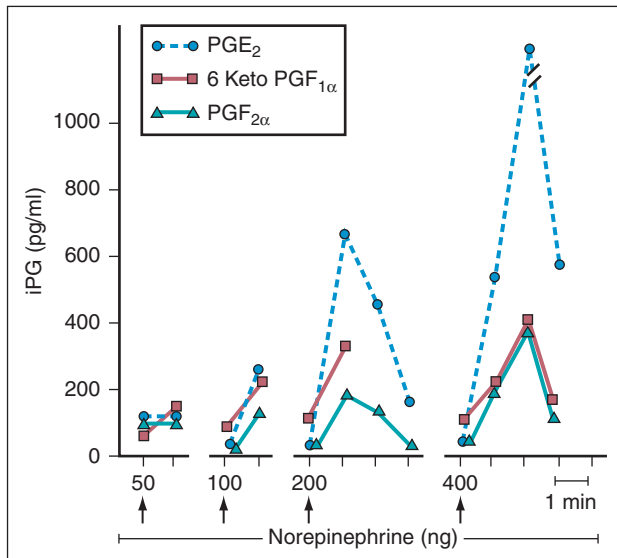

Figure 33-3. Line graphs showing norepinephrine-induced release of immunoreactive prostaglandins (iPG) from the rat isolated kidney. Norepinephrine, given by injection into renal artery at arrows, caused dose-related increases in perfusion pressure, from <10 mmHg to >100 mmHg (not shown). (Redrawn from Quilley J, McGiff JC. Eicosanoids. In: Swales ED, ed. *Textbook of Hypertension*. Oxford: Blackwell Scientific, 1994.)

conditions, TxA₂ does not contribute to the maintenance of blood pressure, as deletion of TP receptors in mice did not affect resting blood pressure but did increase the tendency for bleeding.²⁵

A role for PGH₂/TxA₂ in the development of hypertension in spontaneously hypertensive rats (SHR) was suggested based on increased release of TxA₂ from kidneys of the young SHR.²⁶ Additionally, in the 6-week-old SHR, TP receptor antagonism reduced RVR and increased glomerular filtration rate (GFR).²⁷ In the young SHR (6 weeks), Tx synthase inhibitors either delayed or prevented the development of hypertension.²⁸ An aortic vasoconstrictor factor of endothelial origin generated by COX that acts through the TP receptor has been described in the SHR; it is released by acetylcholine (Ach) after inhibition of nitric oxide synthase (NOS).²⁹ As Tx synthase is a hemoprotein like CYP enzymes, it is vulnerable to catabolism by the inducible heme oxygenase (HO-1), which inactivates enzymes having a heme moiety.³⁰ Thus Sessa et al.³¹ reported decreased Tx synthase activity in renal cortical microsomes from 7-week-old SHR treated with stannous chloride (SnCl₂) to induce HO-1 activity.

PREECLAMPSIA: RELATIVE DEFICIT OF PGI₂

An imbalance of anti- and pro-hypertensive prostanoids has been proposed to characterize toxemia of pregnancy; namely, a relative deficit in PGI₂ coupled with a relative excess of PGH₂/TxA₂.^{32,33} In normal pregnancy, blood pressure is not elevated despite increased cardiac output, salt and water retention, and activation of the RAS because increased activity of antipressor systems including

prostaglandins, represented by PGE₂ and PGI₂, counter the responses to vasopressor hormones.³⁴ Thus the attenuated vasoconstrictor responses to Ang II in pregnancy can be reversed by inhibition of prostaglandin synthesis.^{35,36}

Although TxA₂ is increased in pregnancy, the ratio of vasodilator to vasoconstrictor prostanoids remains higher in normal pregnancies than in those complicated by hypertension. A deficiency of PGI₂ precedes the elevation of blood pressure in pregnancy, and measurements of PGI₂ and TxA₂ metabolites may provide a useful index for women at risk of developing preeclampsia.³⁷ Under these conditions, low-dose aspirin improves the PGI₂/TxA₂ ratio and might be expected to counter the development of preeclampsia.^{38,39} Thus low-dose aspirin gradually and irreversibly inhibits COX-1 of platelets, which cannot generate new enzyme while sparing vascular PGI₂, as endothelial cells retain the capacity to generate new enzymes. Similarly, inhibitors of Tx synthase or TP receptors might prove useful for the prevention of preeclampsia.⁴⁰ However, the promise of these therapies has not been fully realized in a clinical setting; for example, Duley et al.,⁴¹ after examining results from 51 trials, concluded that low-dose aspirin produced small to moderate benefits in a small percentage of pregnant women considered to be at risk for preeclampsia.

It should be pointed out that other eicosanoids, namely EETs, have been implicated in cardiovascular regulation during pregnancy. Renal epoxygenase activity and expression of the major epoxygenase isoforms are increased during gestation in the rat.⁴² These findings are consistent with an earlier report of increased urinary excretion of the major metabolites of EETs, dihydroxyeicosatrienoic acids (DHTs) in pregnant women.⁴³ In the rat, inhibition of epoxygenase activity for 4 days in the last third of gestation (21 days) resulted in an increase in blood pressure, reminiscent of preeclampsia.⁴² Thus a relative deficit in EET formation may contribute to reduced intra-uterine blood flow and preeclampsia. However, in women with pregnancy-induced hypertension, the excretion of 11,12-DHT was further increased.⁴³ This finding may not translate into increased EETs acting to lower blood pressure as 11,12-DHT is inactive and a product of metabolism of 11,12-EET by soluble epoxide hydrolase (sEH). The question that remains is whether catabolism to DHTs occurs before EETs exert their vasoactivity.

CYCLOOXYGENASE-2 INHIBITORS: NEGATIVE CARDIOVASCULAR CONSEQUENCES?

Interestingly, studies with COX knockout mice indicate that COX-2-derived prostaglandins counter the pressor effect of Ang II.²³ The latter is increased in COX-2 knockout mice as well as by selective inhibition of COX-2. In contrast, COX-1-derived prostanoids contribute to the pressor effect as COX-1 deletion reduced the pressor response to Ang II. The COX-1-derived mediators of the response are most likely PGH₂/TxA₂, consistent with studies cited earlier that support a role for TP receptor activation by Ang II in renin-dependent hypertension.²³

Recently, there have been major concerns about the cardiovascular risks of long-term treatment with selective COX-2 inhibitors, which were developed with the view that these agents would be useful in the treatment of chronic inflammatory diseases without the adverse gastrointestinal effects¹⁶ associated with removal of cytoprotective COX-1–derived prostaglandins. Thus nonselective NSAIDs are potent anti-inflammatory agents that are associated with gastric ulceration. A seminal finding to this discussion is based on the report by Gimbrone et al.⁴⁴ that endothelial COX-2, induced by shear stress, is the primary source of vascular PGI₂. The second finding of great import to reviewing the potential toxicity of selective inhibition of COX-2 is the clinical report by McAdam et al.⁴⁵ who showed that inhibition of COX-2 greatly reduced the excretion of a major PGI₂ metabolite, 2,3-dinor 6-ketoPGF_{1 α} , which is considered to reflect systemic generation of PGI₂. Inhibition of vascular PGI₂ that acts as an endogenous antiplatelet agent provides an explanation for the five-fold increase in the risk of myocardial infarction in patients taking rofecoxib to selectively inhibit COX-2 versus those taking the nonselective NSAID, naproxen.⁴⁶ Vascular PGI₂ synthesis would be reduced by selective COX-2 inhibitors, whereas platelet TxA₂ synthesis of COX-1 origin would be spared, predisposing to thrombogenesis. This is in direct opposition to the beneficial effects of low-dose aspirin, which gradually and irreversibly inhibits COX-1 of platelets, which cannot generate new enzyme, while sparing vascular PGI₂.⁴⁷ Consequently, low-dose aspirin is antithrombotic and is recommended to prevent myocardial infarction.

Like NSAIDs, selective COX-2 inhibitors can aggravate existing hypertension or impair the action of antihypertensive agents in susceptible individuals.⁴⁸ There is a tendency for all NSAIDs to increase blood pressure (Figure 33–4), which reflects their effects on salt/water excretion (retention) and vascular reactivity (increased).⁴⁹ In healthy individuals, COX-2 inhibitors do not elevate blood pressure. In the presence of systemic circulatory disorders such as congestive heart failure, hepatorenal

syndrome, diabetes with nephropathy, and age-related declines in renal function, COX inhibitors will have adverse cardiovascular and renal effects with worsening of the underlying diseases. These include precipitating the onset of renal failure and compromising cardiac function. A recently recognized and potentially critical interaction involving inhibitors of COX relates to the disposition (metabolism) of the vasoconstrictor eicosanoid, 20-HETE, which is produced by and acts on PGMVs.⁵⁰ When the RAS is activated, 20-HETE is transformed by COX-2 and PGE₂ isomerase to 20-OH PGE₂, a dilator of renal resistance vessels.⁵¹ The failure of this conversion, particularly in the face of increased activity of the RAS, can have dire consequences for renal function that is fully analyzed in the next section.

ARACHIDONATE METABOLITES ARISING FROM CYTOCHROME P450

In the first study that linked CYP-AA metabolites to blood pressure regulation, Sacerdoti et al.⁵² demonstrated increased CYP-AA metabolism during the rapid phase of blood pressure elevation in the SHR. Between 5 and 20 weeks of age, systolic blood pressure of the SHR increased from 112 to 202 mmHg, the major increases occurring between 5 and 13 weeks, coincident with increased production of renal CYP-AA products which exceeded production by age-matched Wistar-Kyoto (WKY) rats (Figure 33–5). Once blood pressure levels were established in rats aged 13 weeks, total CYP-AA metabolism did not differ between SHR and WKY rats. However, as individual AA products were not measured and their sites of origin (nephron vs. renal vasculature) were not identified, aberrant CYP-AA metabolism by the adult SHR might have been overlooked. This distinction relative to individual eicosanoids and their sites of synthesis is critical to assigning decisive roles to single CYP-AA products in the pathogenesis of hypertension.⁵³ For example, deficient synthesis of 20-HETE by the TAL segment of the nephron has been proposed as the offending lesion responsible for blood pressure elevation

Figure 33–4. Mean arterial blood pressure in seven rabbits that received daily subcutaneous injections of indomethacin and in six that received only vehicle. (Redrawn from Colina-Chourio JA, McGiff JC, Nasjletti A. *Clin Sci* 1979;57:359–65.)

Figure 33–5. In response to SnCl₂ treatment beginning at 6 weeks, 4 days of age (at the arrow), BP showed a slow decline to normotensive levels by the 7th week coincident with a decline in CYP-dependent AA metabolism. In contrast, the BP and CYP-dependent AA metabolism in WKY rats were unaffected by SnCl₂ treatment. AA, arachidonic acid; BP, blood pressure; CYP, cytochrome P450; SHR, spontaneously hypertensive rats; WKY, Wistar-Kyoto rats.

in the salt-sensitive (SS) Dahl rat.⁵⁴ This singular finding would have escaped notice when using microsomal preparations derived from the renal cortex and medulla to assess aberrations in renal CYP-AA product synthesis.

The study by Sacerdoti et al.⁵² anticipated future directions in this area of research—it identified two principal CYP-AA products, 11,12-EET and 20-HETE, that figure prominently in ongoing studies (Figure 33–6). For example, increased production of 20-HETE, which raises the tone of the afferent arteriole of the SHR,⁵⁵ has been shown to contribute to the rightward shift in the pressure–natriuresis curve, the hallmark of hypertension.⁵⁶ This effect of 20-HETE can be countered by the vasodilator action of 11,12-EET and served as a centerpiece to future studies of vascular mechanisms involving CYP-derived AA products having opposing effects on vascular tone and reactivity. Autoregulation of RBF has been examined by Imig et al.⁵⁷ with respect to the 20-HETE versus EETs paradigm; they demonstrated that the dynamic interactions of an EET and 20-HETE determine the autoregulatory response of RBF to changes in perfusion pressure.⁵⁷ We are now able to define the separate and opposing contributions of vasoactive epoxides (11,12- and 5,6-EETs) and 20-HETE to vascular mechanisms operating at the level of the intact renal vasculature as well as at the level of critical renal vascular segments, PGMVs. We owe these capabilities to J.R. Falck,^{53,58} who has synthesized authentic standards of CYP-AA metabolites and selective inhibitors of each arm of CYP-dependent AA metabolism, the ω/ω -1-hydroxylases and epoxygenases. The critical role of 20-HETE in autoregulation of RBF was established by inhibiting ω -hydroxylases with either 17-ODYA or DDMS.^{57,59} In response to inhibition of ω -hydroxylases, increased renal perfusion pressure was not countered by

Figure 33–6. Arachidonic acid (AA) metabolism by cytochrome P-450-dependent monooxygenases to ω - and ω -1-hydroxyeicosatetraenoic acids (HETEs), epoxyeicosatrienoic acids (epoxides, EETs), and dihydroxyeicosatrienoic acids (diols, DHTs). 20-HETE and 5,6-EET can be converted by cyclooxygenase to analogues of prostaglandins. (Redrawn from McGiff JC, Quilley J. *Am J Physiol Regul Integr Comp Physiol* 1999;277:R607–23. Used with permission.)

increased RVR. Instead, a linear relationship obtained between RBF and perfusion pressure after inhibiting 20-HETE synthesis. In contrast, the autoregulatory response was exaggerated on eliminating the countering effect of 11,12-EET by inhibiting epoxygenases with MS PPOH.

Induction of heme oxygenase lowers blood pressure in spontaneously hypertensive rats

In the young (age 6–7 weeks) SHR, SnCl₂, an inducer of heme oxygenase-1 (HO-1), was used to deplete CYP enzymes and, thereby, reduce production of CYP-derived AA metabolites.⁶⁰ Induction of HO-1 depleted CYP enzymes, as HO-1 is the rate-controlling enzyme in heme catabolism that affects the availability of heme for hemoproteins such as CYP.⁶¹ Catabolizing the heme moiety (catalytic center) of CYP enzymes, in response to SnCl₂ induction of HO-1, produces biliverdin and its product, bilirubin, as well as ferrous iron and carbon monoxide (CO). Elevated blood pressure of the SHR returned to normal levels in response to SnCl₂, coincident with natriuresis indicating restoration of the normotensive pressure-natriuresis curve⁶⁰ (Figure 33–7). Increased renal levels of CYP-AA metabolites in the SHR were reduced by SnCl₂ to levels found in the WKY rats, coincident with reduction of blood pressure to normotensive values. SnCl₂ treatment affected neither blood pressure nor renal CYP-AA metabolite levels in normotensive WKY rats (age 6–7 weeks) (Figure 33–5).

A study of consequence to the proposed prohypertensive action of CYP-derived AA metabolites was designed to determine whether either age or duration of treatment was critical to normalizing blood pressure in the male SHR⁶² (Figure 33–8). The answer is “yes” on both counts. First, chronic treatment with SnCl₂, begun at age 5 weeks, prevented hypertension in the SHR. The age of initiation of SnCl₂ treatment is critical. In contrast to the 5-week-old SHR, blood pressure of the adult SHR (age 12–20 weeks) did not fall in response to SnCl₂. Second, suspension of SnCl₂ treatment at age 13 weeks in the SHR treated from 6 weeks of age did not result in the return of hypertension; that is, reduction of blood pressure was sustained through the duration of the study (ended at age 20 weeks). At the time of these studies, a selective inhibitor of ω-hydroxylase activity was not available for long-term use.

The products of heme catabolism can lower blood pressure. HO-1-derived vascular CO evoked by SnCl₂ treatment acts as an inhibitory modulator of the enhanced vascular reactivity produced by constrictors “via a mechanism that involves a TEA-sensitive K⁺ channel.”⁶³ Additionally, biliverdin as well as its product, bilirubin, are antioxidants, reducing oxidative injury to blood vessels, particularly the endothelium. These effects of the products of heme catabolism, which contribute to blood pressure reduction,⁶⁴ urge cautious interpretation when implicating diminished CYP-AA metabolite formation as the principal factor in the blood pressure-lowering response to induction of renal HO-1.

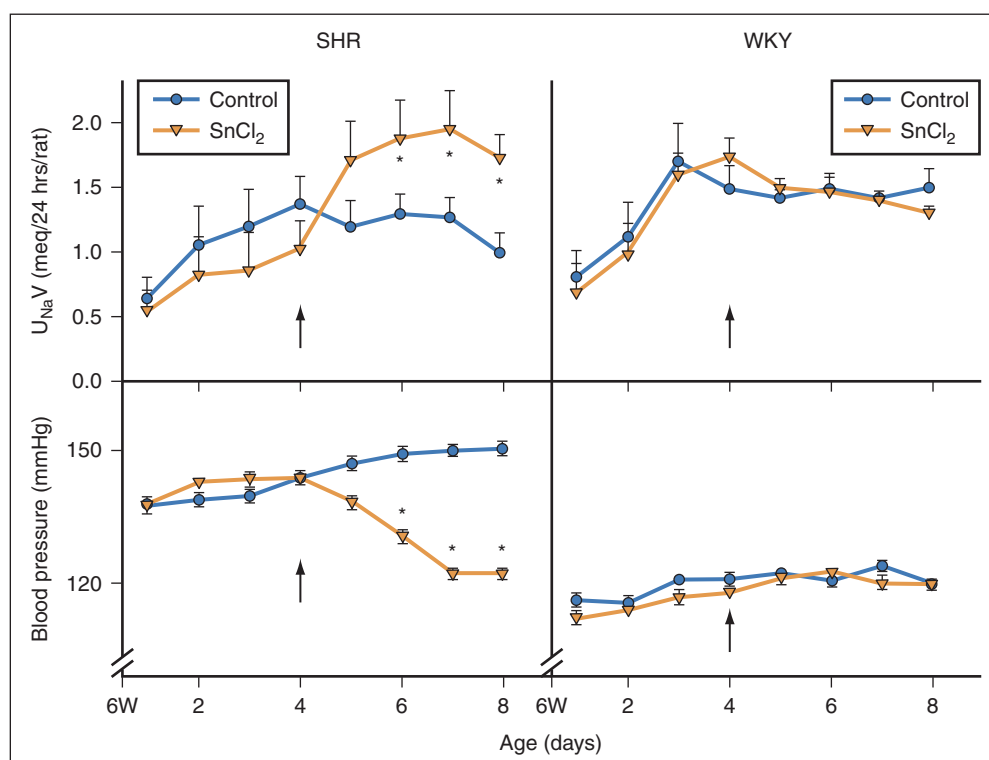

Figure 33–7. A decline in BP produced by SnCl₂ in the SHR (*left*) was associated with increased Na⁺ excretion. SnCl₂, given between the 6th and 7th weeks on a daily basis (*arrow*), was without effect on BP and Na⁺ excretion in WKY rats (*right*). **p*<0.05 compared to control. BP, blood pressure; SHR, spontaneously hypertensive rats; WKY, Wistar-Kyoto rats.

Figure 33-8. Line graph showing effect of chronic treatment of SHR with SnCl₂ (from age 5 to 20 weeks) on systolic BP (mean±SEM) compared with either untreated control SHR or SHR with SnCl₂ treatment suspended from age 13 to 20 weeks. Striped area represents the mean±1 SD of the systolic BP of control untreated and SnCl₂-treated WKY rats. BP, blood pressure; SD, standard deviation; SEM, standard error of the mean; SHR, spontaneously hypertensive rats; WKY, Wistar-Kyoto rats. Cytochrome P450-Arachidonic acid metabolites: Pressor versus antipressor effects

Notwithstanding these concerns regarding collateral effects produced by the induction of HO-1, the proposed important role of 20-HETE in the development of hypertension in the SHR is supported by recent studies.

20-Hydroxyecosatetraenoic Acid: Prohypertensive

1. Selective inhibition of ω -hydroxylase with 1-aminobenzotriazole lowered blood pressure in the young SHR.^{65,66}
2. Administration of CYP-4A antisense oligonucleotides to young SHRs decreased renal synthesis of 20-HETE accompanied by reduction of blood pressure.⁶⁷
3. Inhibition of NO synthesis produced 20-HETE-dependent hypertension in rats by eliminating the tonic inhibitory effect that NO exerts on ω -hydroxylase activity.⁶⁸ L-NAME, an inhibitor of NO formation, produced precipitous elevations of blood pressure, rapid declines in RBF and GFR, and brisk diuresis that could be reversed by inhibition of 20-HETE synthesis.

Epoxyecosatrienoic Acids: Antihypertensive

EETs participate in antipressor mechanisms counteracting vascular pressor mechanisms mediated by 20-HETE. EETs also inhibit Na⁺ reabsorption at several sites in the nephron.^{69,70}

1. Antagonism of the vasoconstrictor response to 20-HETE by EETs.⁵⁷
2. Modulation by 5,6-EET of renal vascular reactivity,⁷¹ and Na⁺ reabsorption produced by Ang II in the proximal tubules.⁷⁰

3. Inhibition by 5,6-EET of Na⁺ transport in the rabbit cortical collecting ducts (CCD) via prostaglandin stimulation.⁷² 11,12-EET is the endogenous inhibitor of the epithelial Na⁺ channel (ENaC) in the rat CCD.⁶⁹
4. 5,6- and 11,12-EETs are candidate endothelium-derived hyperpolarizing factors. They mediate NO and prostaglandin-independent vasodilator responses to Ach and bradykinin.^{73–75}
5. EETs prevent elevation of blood pressure in response to high salt intake,⁷⁶ which has been related to stimulation of the adenosine A_{2A} receptor (A_{2A}R) in PGMVs of the rat.⁷⁷
6. The antihypertensive potential of EETs is also displayed in the blood pressure lowering response to increasing tissue levels of EETs produced by inhibiting the principal enzyme, sEH, responsible for catabolism of EETs to DHTs.^{78,79}

The cumulative import of these studies on 20-HETE *vis-a-vis* EETs supports both a prohypertensive and antihypertensive role for CYP-AA products. Further, the studies on 20-HETE indicate participation in both pressor and antipressor mechanisms, whereas EETs are likely exclusively antipressors.

20-Hydroxyecosatetraenoic acid serves pressor and antipressor mechanisms

The assignment of a causative role to 20-HETE in the development of hypertension raises an apparent paradox, because both deficient⁵⁴ and excessive production of 20-HETE⁶⁰ by renal ω -hydroxylases have been linked to elevation of blood pressure. An attempt to explain these paradoxes requires some understanding of:

1. The diversity of ω -hydroxylase isoforms
2. Differences among ω -hydroxylases regarding localization in renal vasculature and nephron
3. Their individual regulation at the local and regional levels

There are four rat isoforms of ω - and ω -1-hydroxylases designated 4A1, 2, 3, and 4A8; these are distributed unevenly in the renal vasculature and nephron,^{80,81} and are differentially regulated by circulating and local factors. Peroxisome proliferator-activated receptor- α (PPAR α) has been assigned a pivotal role in the transcriptional regulation of CYP4A1 and 4A2/4A3 ω / ω -1-hydroxylase isoforms,⁸² whereas expression of the CYP4A8 and 4A2 isoforms are regulated by androgens via a circuitous pathway.^{83–85} The high sequence homology of CYP 4A2/4A3, 97% nucleotides and 96% amino acids,⁸⁶ makes differentiation of their individual effects and responses to regulators difficult to assess. This difficulty is indicated by 4A2/4A3 as opposed to these isoforms standing alone: 4A2 and 4A3. The CYP4A isoforms are variably affected by sex, age, hormones, and dietary influences.⁸⁷ The catalytic activities of the ω -hydroxylase isoforms vary by as much as 40-fold, with the 4A1 isoform having the highest catalytic efficiency.⁸⁸

Androgen-sensitive cytochrome P4A isoforms

Either androgen receptor blockade or early castration acts as a brake on the development of hypertension in the male SHR.⁸⁹ An androgen-sensitive CYP4A isoform that causes hypertension has been identified.⁸⁴ Increased activity of the rat CYP4A8 ω -hydroxylase has been linked to an androgen effect. This linkage is based on a study in the mouse. Deletion of the mouse CYP4A14 isoform, the homologue of rat CYP4A2/4A3 ω -hydroxylases, enhanced expression and activity of the mouse CYP4A12 ω -hydroxylase, the homologue of the rat CYP4A8 ω -hydroxylase, via an androgen-dependent effect that produced increased 20-HETE generation. The study in mice has uncovered a “hitherto unrecognized regulatory loop” involving deletion of CYP4A14, a fatty acid hydroxylase, which elevates androgen levels that act on the CYP4A12 ω -hydroxylase isoforms, resulting in increased 20-HETE synthesis. Thus disruption of the CYP4A14 gene produced mice with hypertension that is androgen sensitive, mediated by 20-HETE, prevented by castration, and restored by androgen replacement. In a companion study in rats, the connection between androgen stimulation of the CYP 4A8 isoform and production of hypertension was established.⁸⁵ Treatment of normotensive rats with 5 α -dihydro-testosterone produced hypertension, upregulation of the CYP4A8 gene and a four-fold increase in 20-HETE synthesis by renal microvessels.⁸⁵ Of note, AA epoxygenase activity was reduced “to a minimum.” These findings provide a conceptual basis for evaluating and understanding gender-specific differences in blood pressure.

The above findings prompted examination of the CYP4A human homologue (CYP4A11) of the androgen-sensitive 4a12 (–/–) ω -hydroxylase isoform as a potential genetic

determinant of hypertension in humans.⁹⁰ A functional variant of CYP4A11, which encodes a renal 20-HETE synthase, was identified that exhibited a thymidine-to-cytosine polymorphism at nucleotide 8590. This coding variant of the human CYP4A11 gene produced a CYP4A11 protein with diminished 20-HETE synthase activity that was more prevalent in hypertensive than normotensive white subjects. These findings suggest localization of the deficiency in 20-HETE production in these hypertensive subjects to one or more tubular segments because of the modulator action of 20-HETE on Na⁺ transport in key tubular segments and the pressor consequences of deletion of 20-HETE effects on tubular transport mechanisms. A comparable lesion, deficient 20-HETE synthesis in the TAL, has been described in the Dahl salt-sensitive hypertensive rat.⁵⁴

Either deficiency or excess of 20-hydroxyeicosatetraenoic acid produces hypertension

Either increased or decreased synthesis of 20-HETE can result in an identical abnormality⁷⁵—a rightward shift of the pressure-natriuresis curve that characterizes the hypertensive state.⁵⁶ Examples based on available evidence include increased 20-HETE synthesis in the SHR,^{60,65} and second, decreased 20-HETE synthesis in the Dahl SS hypertensive rat.⁵⁴ Each has been described to produce hypertension. How does either increased or decreased production of an individual eicosanoid eventuate in hypertension? The answer, based on our present and incomplete understanding of this field of research (which needs maturation) may lie in the renal site involved—vascular⁹¹ versus tubular⁹²—and in the complex biological profile of 20-HETE, that is, constriction of renal microvessels (pressor effect) versus inhibition of renal tubular NaCl reabsorption (antipressor effect). Further, 20-HETE can be transformed by a COX-2-dependent step in PGMVs to a vasodilator analogue of PGE₂ when the RAS is activated by low salt.⁵¹

In the SHR, increased synthesis of 20-HETE by PGMVs constricts renal microvessels, having the greatest impact on the afferent arteriole.⁵⁵ 20-HETE acts as a second messenger to Ang II and endothelin ET-1 in both the vasculature and nephron.⁵³ A current interpretation of the consequences of increasing the resistance of PGMVs, particularly those of the juxtamedullary zone, is to decrease medullary blood flow and medullary interstitial pressure,⁹³ which—based on the interplay of Starling forces—facilitates the movement of tubular fluid into the interstitium and the vascular compartment, producing increased salt and water reabsorption with expansion of extracellular fluid volume and elevation of blood pressure.⁵³

On the other hand, decreased production of 20-HETE by a critical tubular segment, the medullary TAL (mTAL), as proposed in the Dahl SS hypertensive rat,⁵⁴ will elevate blood pressure. Because 20-HETE reduces NaCl reabsorption in this segment by inhibiting the Na⁺-K⁺-2Cl[–] cotransporter⁹⁴ through its role as modulator, a deficiency of 20-HETE will promote Na⁺ reabsorption. In addition, decreased production of EETs by the Dahl SS rat will

reinforce the elevation of blood pressure produced by mTAL 20-HETE deficiency.⁷⁶

Epoxyeicosatrienoic acids–dependent renal vasodilatation: Activated by raising renal perfusion pressure

Additional evidence for an antihypertensive role for EETs has been uncovered in kidneys of normotensive rats: a dormant CYP-dependent vasodilator mechanism is activated by elevating perfusion pressure.⁹⁵ In addition, inhibition of prostaglandin synthesis eliminates a concurrent prostanoid vasoconstrictor response, allowing the epoxide-dependent vasodilator effect to be readily discerned.⁹⁶ When these conditions are met, AA dilates the renal vasculature. In their absence, AA constricts the renal vasculature on conversion to PGH₂ which activates the TP receptor. 5,6-EET is the putative EET mediator of the vasodilator effect of AA in the SHR,⁷¹ as 5,6-EET possesses a four-fold greater renal vasodilator potency than 11,12-EET in the SHR. Based on these findings, we tested the hypothesis that the dormant EET-dependent renal vasodilator mechanism is attenuated/suppressed in the SHR.⁹⁶ Unexpectedly, the renal vasodilator response to AA was potentiated in the SHR. Moreover, in Ang II–induced hypertension (10-day infusion), the vasodilator response to AA was abolished,⁹⁶ a finding in keeping with the downregulation of renal CYP 2C23 epoxygenase mRNA and enzyme levels in rats given Ang II and a high-salt diet for several weeks.⁹⁷

PREGLOMERULAR MICROCIRCULATION AND LIPID MEDIATORS

20-Hydroxyeicosatetraenoic acid: Basic mechanisms and activation by AT₂ receptors

The PGMVs—the arcuate and interlobular arteries and the afferent arterioles—occupy a key position in the regulation of the renal circulation.⁹⁸ Multiple signals feed into PGMVs from various sites including autonomic nerves, blood, renal tubules (macula densa) as well as those of autocrine and paracrine origin. These signals have the capacity to evoke lipid mediators, products of AA metabolism via COX, lipoxygenases (LOX), and CYP pathways. 20-HETE is an essential component of renal autoregulation⁵⁹ and tubuloglomerular feedback (TGF)⁹⁹ by virtue of its vasoconstrictor properties⁵³; namely, 20-HETE serves as the final effector that constricts PGMVs. Production of 20-HETE by ω -hydroxylase increases as renal arterial diameter decreases.¹⁰⁰ The vascular segments, PGMVs, that contribute to the greatest degree in regulating RVR and GFR, particularly the afferent arterioles, are heavily invested with 20-HETE synthetic ability.⁹³

20-HETE is released from PGMVs by Ang II via activation of AT₂ receptors⁹¹ (Figure 33–9), an unexpected conjunction as AT₁, not AT₂, receptor stimulation is usually associated with activation of pressor mechanisms. However, the rat renomedullary circulation has been reported to react oppositely to the renal cortical circulation in

Figure 33–9. Release of 20-HETE following 5-minute incubation with vasoactive hormones. Incubates were extracted, HETEs purified, derivatized, and quantitated using GC-MS (mean±standard error of measurement). Ang II, angiotensin II; BK, bradykinin; ET-1, endothelin; PE, phenylephrine. * $p < 0.05$. (Redrawn from Croft KD, McGiff JC, Sanchez-Mendoza A, Carroll MA. *Am J Physiol Renal Physiol* 2000;279:F544–51. Used with permission.)

response to stimulation of AT receptors¹⁰¹; namely, AT₁ receptor activation dilates medullary blood vessels which are antagonized by AT₂ receptor-mediated constriction. We interpret the AT₂ constrictor effect on medullary blood vessels to result from 20-HETE release from two possible sources that have been identified as synthesizing 20-HETE as a principal product: (1) the PGMVs of the juxtamedullary circulation,¹⁰² which should facilitate entry of 20-HETE into the postglomerular circulation and the long loops of the *vasa rectae*; and (2) proximal tubules¹⁰³ and/or mTAL tubules⁹⁴ with release of 20-HETE into the medullary interstitium.

Pressure natriuresis and 20-hydroxyeicosatetraenoic acid

A related issue regarding the central role of 20-HETE in regulating renal hemodynamic and excretory function is the contribution of 20-HETE to pressure natriuresis. Pressure natriuresis, that is, increased Na⁺ excretion in response to increased renal perfusion pressure, was identified by Guyton⁵⁶ as the central mechanism in the long-term regulation of extracellular fluid volume and blood pressure. Gross et al.¹⁰⁴ have demonstrated elevation of blood pressure with loss of pressure natriuresis in mice lacking the AT₂ receptor. This may be explained by the inability of PGMVs to generate 20-HETE consequent to deletion of AT₂ receptors,⁹¹ thereby eliminating the candidate lipid mediator of pressure natriuresis. Further, 20-HETE, on release from PGMVs into the blood entering the glomerulus, may be filtered to act on the luminal surfaces of proximal tubules and TAL, the nephron segments mainly responsible for pressure natriuresis. This assumes that 20-HETE is not protein-bound in the vascular compartment, which has been subject to debate. Additionally, 20-HETE entering the postglomerular circulation on release from PGMVs⁹¹ may act on the contraluminal surfaces of the nephron via diffusion into the interstitium.

20-HETE is also a principal product of AA metabolism in key tubular segments, the proximal tubules¹⁰³ and TAL,¹⁰⁵ at which sites locally generated 20-HETE can inhibit Na⁺ transport. Proximal tubular 20-HETE satisfies major criteria for mediating pressure natriuresis as it inhibits Na⁺-K⁺-ATPase (the Na⁺ pump) through activation of PKC¹⁰⁶ and produces internalization of the brush border Na⁺-H⁺ exchanger (NHE₃).¹⁰⁷ A hormone-inducible inhibitor of the Na⁺ pump was regarded as a feature of hypertension that accounts for the exaggerated natriuresis produced by volume expansion in clinical and experimental hypertension.¹⁰⁸

In view of the multiple sources and sites of action of 20-HETE in the kidney, the coordinated response of three critical components—PGMV, proximal tubules, and the TAL—each generating 20-HETE, can account for the cortical and juxtamedullary vascular and tubular components of pressure natriuresis. The renal medullary circulatory response to pressure natriuresis, increased medullary blood flow, also involves a prostaglandin-dependent mechanism.¹⁰⁹ Redistribution of RBF from the cortex to the medulla had been shown more than three decades ago to be effected by a PGE₂-dependent mechanism.^{110,111}

20-Hydroxyeicosatetraenoic acid disposition

Tissue levels and biological activity of 20-HETE are greatly affected by incorporation into tissue phospholipids,¹¹² and by metabolism via COX to prostaglandin analogues that possess different biological properties from those of untransformed 20-HETE.¹¹³ In addition, there are notable differences amongst species regarding disposition and metabolism of 20-HETE.⁵³ For example, in man, 20-HETE is excreted mainly as a glucuronide conjugate, there being negligible free urinary 20-HETE.^{114,115} The principal route of efflux of renal 20-HETE in the rat isolated kidney is via the renal vein with little appearing in the urine (McGiff, personal observation). However, deterioration of renal function may promote 20-HETE excretion.¹¹⁶ There is no universal agreement, however, on the paucity of urinary 20-HETE excretion in the rat, which probably reflects differences in the assay methods used to measure 20-HETE relative to their precision and sensitivity.

An eicosanoid conundrum: Excessive renal vascular 20-hydroxyeicosatetraenoic acid production without hypertension

The renal pathology in hepatic cirrhosis during the progression to hepatorenal syndrome is conspicuously innocuous, that is, “renal function progressively deteriorates without evidence of organic nephropathy.”¹¹⁷ Activation of the principal antidiuretic/antinatriuretic neurohumoral systems, the renin-angiotensin-adrenergic-aldosterone-ADH axis is a feature in patients with cirrhosis and ascites.¹¹⁸ In patients with cirrhosis, urinary excretion of 20-HETE was selectively increased when compared to 16-, 17-, and 18-HETEs. Urinary excretion of 20-HETE exceeded by several-fold excretion of TxA₂, the principal prostanoid product in cirrhosis.

Of the eicosanoids, only excretion of 20-HETE correlated ($p < 0.01$) with reductions in renal plasma flow in subjects with cirrhosis. These findings are compatible with assigning a significant role to 20-HETE in the progressive deterioration of renal function in patients with hepatic cirrhosis. However, they are in apparent conflict with those in experimental animals; namely, an established close relationship of 20-HETE production by PGMVs with the development of hypertension.⁵³ There are no easy answers to this conundrum. A selective stimulatory effect on a CYP4A isoform predominating in PGMVs such as 4A2, producing increased 20-HETE synthesis and restricted to renal microvessels, may explain the progressive renal functional abnormalities in hepatic cirrhosis. When inhibitors of ω -hydroxylase that pass Food and Drug Administration scrutiny for use in human studies become available, it will then be possible to test the following hypothesis: *Inhibition of renal ω -hydroxylase activity will reverse the renal hemodynamic abnormalities as well as the secondary salt and water retention that characterize hepatic cirrhosis with ascites.*

Angiotensin II interacts with products of all pathways of arachidonic acid metabolism

Arachidonate-derived products contribute to the regulation of tone and reactivity of the renal vasculature in general and PGMVs specifically,¹⁰² and through these vascular effects contribute to maintaining normal renal function. AA metabolites interact, most strikingly, with Ang II and ET-1, serving as modulators and mediators of the actions of the peptides.¹¹⁹ All species of eicosanoids, whether arising from COX, LOX, or CYP pathways, have been shown to interact with Ang II in the vasculature, acting either as second messengers (mediators) or modulators of the vascular effects of Ang II. Similar interactions involving Ang II and eicosanoids are evident in the nephron.¹²⁰ Species differences, as noted, in the renal circulatory responses to 20-HETE of the rat and rabbit can be striking.^{113,119} Also, within a regional vasculature, large arteries versus small arteries/arterioles show major differences in the distribution of peptide receptors as well as in the localization of oxygenases.^{53,121} Ang II-LOX product interactions have been demonstrated in responses of the vasculature of the intact kidney of the rat.¹²² However, in the rat renal preglomerular microcirculation, as noted, 20-HETE predominated in response to stimulation of AT₂ receptors by Ang II.⁹¹

On reexamining the most important renal microvessels, the afferent arterioles, the operation of a LOX product was also uncovered; 12(S)-HETE was shown to act as a second messenger, contributing to the constrictor response to Ang II.¹²³ Expression of 12-LOX may be set in motion by tissue injury.¹²⁴ Whether this also obtains for renal microvessels has yet to be established. Renal microvascular 12(S)-HETE synthesis in the rat was increased by Ang II as was [Ca²⁺]_i, the latter by four-fold. Blockade of L-type calcium channels abolished afferent arteriolar constrictor effects of Ang II. There is also definitive evidence noted above for recognizing the contribution of

20-HETE to the constrictor response of the afferent arteriole to Ang II.⁵⁵ How 20-HETE interacts, if it does, with 12-LOX or its product, 12-HETE, in the afferent arteriole is uncertain. A potential interaction described in platelets is based on 12-LOX metabolism of 20-HETE forming 12, 20-HETE,¹²⁵ a transformation that will most likely modify the vascular action of 20-HETE. Eicosanoid product formation in the vasculature differs substantially according to blood vessel size, the vascular bed under study and the presence of cardiovascular diseases. Species differences in eicosanoid synthesis are more likely to be quantitative rather than qualitative as observed in a classic study of nephron prostaglandin production by Bonvalet et al.¹²⁶ The rabbit nephron greatly exceeded that of the rat in prostaglandin production. However, the ratio of products formed was similar in both species: PGE₂ predominated; PGI₂ was much less than PGE₂ (1/20) and TxA₂ was vanishingly low when compared to PGE₂ synthesis (<1/100).

Cyclooxygenase-2 and transformation of 20-hydroxyeicosatetraenoic acid to 20-OH PGE₂

In the rabbit kidney, 20-HETE produces vasodilatation, an effect abolished by inhibition of COX which prevents conversion of 20-HETE to vasodilator prostaglandin analogues.¹¹³ The putative mediator of this renal vasodilator response to 20-HETE is its COX metabolite, 20-OH PGE₂, which unlike untransformed 20-HETE, dilates renal blood vessels⁵¹ (Figure 33–6).

Under conditions of low salt, mitigating factors can influence the outcome of the response of PGMVs to 20-HETE production via metabolism by COX-2 and membranaral PGE₂ isomerase which are coexpressed in response to low salt.¹²⁷ Regional variations in the regulation of COX-2 expression in the kidney have been linked to salt intake¹²⁸; low salt, as noted, induces COX-2 in the cortex, which impacts on control of the renal cortical circulation, whereas high salt activates COX-2 in the medulla, which is a key component via production of PGE₂ in salt and water excretory mechanisms. As Ang II releases 20-HETE in relative abundance from PGMV,⁹¹ and as renal cortical COX-2 is expressed in response to low salt,¹²⁸ a study was designed in an attempt to forge a link between 20-HETE and COX-2 in terms of possible modification of the vascular effects of increased 20-HETE production by PGMVs.¹²⁷ Microdissected arteries of 6- to 7-week-old rats were used because 20-HETE formation has been described to peak at this age.⁵² Interlobar arteries were separated from arcuate and interlobular arteries to discern segmental variations in production of CYP-derived AA metabolites. Because of the potential importance of COX-dependent transformation of 20-HETE,¹²⁹ vascular segmental changes in COX-1 and COX-2 expression were determined as well as those of ω/ω -1-hydroxylase CYP4A enzymes in interlobar arteries *vis-a-vis* arcuate and interlobular arteries. Low salt intake stimulated the RAS and activated renal cortical COX-2 expression. Low salt also increased 20-HETE production by PGMVs, a response greater in arcuate and interlobular than in interlobar

arteries¹²⁷ (Figure 33–10). However, inhibition of COX was required to demonstrate increased 20-HETE formation because of the avid metabolism of 20-HETE by COX-2.

The effects of low salt promoted conversion of 20-HETE via COX-2 to metabolites that have lost their ability to depress GFR.⁵¹ This COX-dependent mechanism presumably serves a defensive function as its inhibition by NSAIDs may contribute to the adverse effects of aspirin-like drugs—increased RVR and reduced GFR with Na⁺ retention—that result from the direct vasoconstrictor action of 20-HETE.⁹³ That is, during salt depletion as occasioned by diuretic therapy and when 20-HETE of renal vascular origin cannot be transformed to prostaglandin analogues because of concurrent treatment with a NSAID, the action of unconverted 20-HETE constricts PGMVs. In contrast, 20-HETE is converted by COX-2 and membranaral PGE₂ isomerase to 20-OH PGE₂ when NSAIDs are withheld (Figure 33–6). Metabolism of 20-HETE by COX-

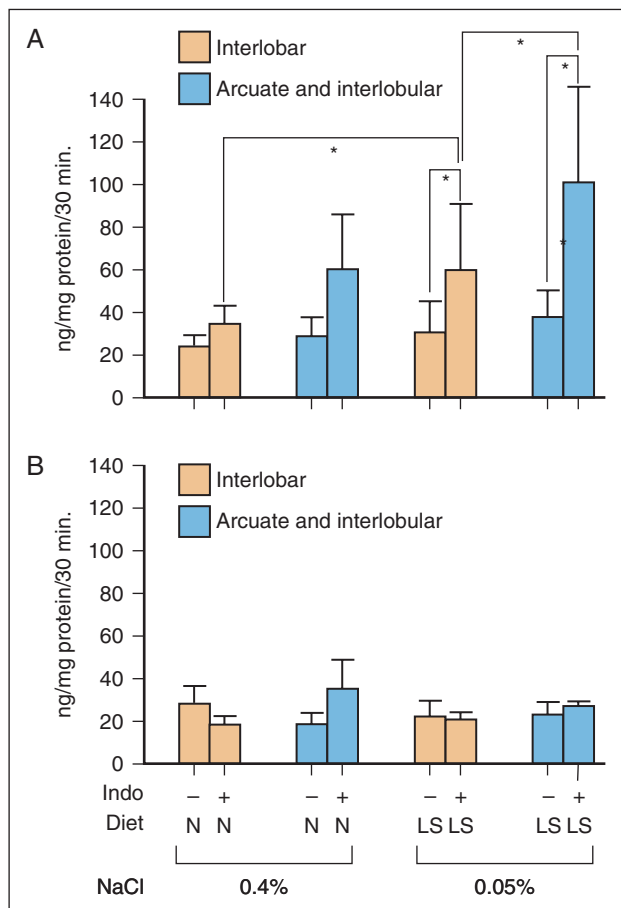

Figure 33–10. Release of 20-HETE (A) and epoxyeicosatrienoic acids (B) from arcuate and interlobular arteries and from interlobar arteries obtained from rats fed either a normal-salt (N) diet (0.4% NaCl, $n=8$) or low-salt (LS) diet (0.05% NaCl, $n=8$) for 10 days in the absence or presence of indomethacin (Indo, 10 μ m) (mean \pm standard error of measurement). Arteries were incubated with 1 mM NADPH and 7 μ M [¹⁴C] arachidonic acid for 30 minutes at 37°C. Samples were extracted and the supernates were separated by reverse-phase HPLC. * $p<0.05$. 2, we submit, represents an important regulatory mechanism in the PGMVs that governs tone and reactivity of these blood vessels and prevents precipitous falls in GFR in response to decreased salt intake.

Hydroxyeicosatetraenoic acid and salt-sensitive versus salt-resistant hypertensive humans

The principal tubular sites of 20-HETE production and activity, the proximal tubules and TAL, suggest a significant role for 20-HETE in the regulation of Na⁺ excretion in humans. In particular, this area of research raises questions regarding whether abnormalities in 20-HETE-dependent mechanisms are discernible in hypertensive subjects. Laffer et al.¹³⁰ have addressed the relationship of urinary 20-HETE excretion (μg/h) to excretion of Na⁺ (U_{Na}V in mmol/h) in human essential hypertension under conditions of salt loading. Two groups of hypertensive subjects could be identified—salt-sensitive and salt-resistant—that were differentiated according to their ability to activate renal 20-HETE production, as reflected in urinary excretion of 20-HETE, when challenged with salt loading.¹³⁰ In salt-resistant hypertensive subjects, the relationship between excretion of 20-HETE and Na⁺ in response to salt loading demonstrated a strong positive correlation. This relationship was absent in salt-sensitive hypertensive subjects. Instead, they demonstrated a relationship of Na⁺ excretion to both blood pressure and degree of obesity. A subsequent study based on the exploration of the negative correlation between obesity as reflected in body mass index (BMI) and urinary 20-HETE excretion, disclosed a negative correlation between circulating insulin and 20-HETE excretion in obese hypertensive subjects, that is, “the higher the levels of serum insulin, the lower the levels of urine 20-HETE.”¹³¹ This association is also supported from a study in rats with streptozocin-induced diabetes. Insulin inhibited the activity of CYP4A isoforms isolated from both liver and kidney.¹³²

PURINOCEPTORS

Recent studies have set the stage for viewing the preglomerular microcirculation, particularly the afferent arteriole, as sites in which 20-HETE and one or more EETs (likely 11,12-EET) act antagonistically in regulating arterial-arteriolar diameters in response to changes in renal perfusion pressure and salt intake.⁵⁷ These studies endorse an important concept; namely, that a counterpoised vascular mechanism in which products of CYP by each of its principal arms, epoxygenases and ω/ω-1-hydroxylases, operate in segments of the preglomerular vasculature. The resultant of the opposing effects of 20-HETE and 11,12-EET on tone and reactivity of PGMV, as noted, determines autoregulation of RBF. They are also involved in TGF⁹⁹ as their interactions determine the tone and reactivity of PGMV and, thereby, glomerular hemodynamics in response to the salt load presented to the macula densa. 20-HETE and 11,12-EET target the same effector mechanism, a K⁺ channel.¹³³ That is, the outcome of EET–20-HETE interactions in determining renal

vascular tone and reactivity is defined primarily by the resultant of their opposing effects on the open-state probability of the Ca²⁺-activated K⁺ channel of vascular smooth muscle.^{74,134}

The most recent additions to CYP-derived eicosanoid mechanisms operating in the PGMVs are the purinergic portals: ATP-activated P_{2X} receptors¹³⁵ and adenosine-activated A_{2A} receptors (A_{2A}R),⁵⁰ producing 20-HETE and 11,12-EET, respectively. Inscho et al.¹³⁶ have identified and characterized the operation of the ATP-P_{2X} receptor—ω-hydroxylase–20-HETE vasoconstrictor limb; subsequently, Cheng et al.⁵⁰ identified an A_{2A}R–epoxygenase–11,12-EET vasodilator limb. A critical coupling between A_{2A}R stimulation and CYP-related epoxygenase activity was uncovered; 11,12-EET is the likely candidate mediator of PGMV dilatation on adenosine activation of the A_{2A}R. Adenosine levels are increased by salt loading,^{77,137} as is the activity of renal epoxygenases that counteracts elevations in blood pressure produced by salt. Adenosine was identified as “the stimulus for increased renal epoxygenase activity in response to salt loading.”^{50,138} Blockade of the A_{2A}R prevented stimulation of EET synthesis elicited by adenosine in rats on a high-salt diet, an effect that greatly increased RVR.⁷⁷

TUBULAR TRANSPORT MECHANISMS: CYTOCHROME P450 PRODUCTS, TNF, AND CYCLOOXYGENASE-2

Medullary thick ascending limb

The TAL segment of the nephron occupies a pre-eminent position in the regulation of volume and composition of body fluids by virtue of its reabsorptive capacity, some 25% to 40% of filtered Na⁺, and establishing the medullary osmolar gradient that determines the ability to excrete a concentrated urine.¹³⁹ The prevailing oxygenase in the mTAL that metabolizes AA under basal conditions as defined by studies in rats and rabbits is the CYP pathway, the principal product being 20-HETE, with lesser amounts of 19-HETE and a third product, 20-COOH AA, that resembles 20-HETE in its ability to inhibit Na⁺-K⁺-ATPase.¹⁰⁵ 19-HETE was not examined in terms of its impact on transport function. However, 19-HETE has been shown to counteract the inhibitory action of 20-HETE on transport in proximal tubules,¹⁴⁰ and to attenuate the ability of 20-HETE to elevate tone and reactivity of renal arteries.¹⁴¹ As there has been no attempt thus far to assign a function to either 19-HETE or 20-COOH AA in the mTAL, experience dictates that future studies will require revising the paradigm at hand which is restricted to the effects of 20-HETE, namely (1) inhibition of the luminal cotransporter (Na⁺-K⁺-2Cl⁻)⁹⁴, and (2) reducing the open state probability of the ROMK channel¹⁴² (Figure 33–11), properties that summate to produce natriuresis and chloruresis. To date, the most compelling finding regarding blood pressure control that involved CYP-AA products in the mTAL, as noted, was deficient 20-HETE synthesis that produced hypertension in the Dahl SS rat by increasing the activity of the Na⁺-K⁺-2Cl⁻ cotransporter. When cor-

Figure 33–11. Modulation of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter and K^+ channel activity by 20-HETE in the TAL. Changes in either extracellular calcium or Ang II can stimulate release of AA via receptor-coupled G-protein activation of phospholipase (PL) A_2 . 20-HETE, 20-hydroxyeicosatetraenoic acid; AA, arachidonic acid; TAL, thick ascending limb. rected by stimulation of 20-HETE synthesis, blood pressure was lowered.⁵⁴

Furosemide also inhibits the TAL $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter, and has been shown to stimulate COX-2-dependent generation of PGE_2 .¹⁴³ The functional consequences of this interaction have been demonstrated by blunting of the natriuretic action of furosemide in response to COX-2 selective inhibitors.¹⁴⁴ Because the target of furosemide, the cotransporter, is also the site of action of 20-HETE, Laffer et al.¹³⁰ examined a possible relationship between the natriuretic response to furosemide and urinary 20-HETE excretion in hypertensive patients classified as either salt sensitive or salt resistant. The natriuretic action of furosemide was shown to be modulated by 20-HETE in hypertensive subjects according to their sensitivity to salt, being impaired only in salt-sensitive patients.

An antipressor mechanism served by TNF: Angiotensin II activates this pathway

The discovery of TNF production by TAL cells and defining its essential role in the expression of COX-2 in this nephron segment impacts on blood pressure regulation.¹⁴⁵ Expression of COX-2 occurred within 3 hours of exposure of mTAL tubules to Ang II, COX-2 replacing CYP as the principal oxygenase¹⁴⁶; production of TNF and PGE_2 were increased several-fold and ^{86}Rb uptake was inhibited significantly. TNF production was deemed essential to COX-2 expression in the mTAL because the inhibitory action of Ang II on ^{86}Rb uptake—which was COX dependent—was prevented by either TNF antisera or indomethacin.¹⁴⁶

Acting through its effect on expression of COX-2 and PGE_2 synthesis, TNF serves an antipressor mechanism. TNF mediates a profound and irreversible hypotension, referred to as circulatory shock, in Gram-negative sepsis.

Under more contained conditions, however, in sublethal doses TNF caused diuresis that was prevented by inhibition of COX.¹⁴⁷ In view of the hypotensive-natriuretic effects of administered TNF and the ability of Ang II to increase TNF production, Ferreri et al.,¹⁴⁸ in an *in vivo* study, examined whether endogenous TNF mediated an antipressor effect as a response to an Ang II infusion. In an Ang II-dependent model of hypertension (10-day infusion), TNF antisera administered on day 10 increased rat mean aortic pressure by more than 20 mmHg. TNF antisera did not elevate blood pressure in sham-operated normotensive rats. In Ang II-infused and in control normotensive rats, mTAL tubules were obtained on day 10; TNF and PGE_2 production were increased by three-fold and four-fold, respectively, in rats receiving Ang II as compared to tubules of normotensive control rats. These findings suggest that TNF operates in an antipressor mechanism that acts through expression of COX-2 with production of PGE_2 that moderates the elevation of blood pressure in response to Ang II. A similar mechanism evoked by Ang II was demonstrated in mice rendered hypertensive by infusion of Ang II.²³ Either administration of an inhibitor of COX-2, or gene knockout of COX-2, potentiated the pressor response to the peptide, an effect attributed to eliminating synthesis of one or more antipressor prostanoids. An alternative explanation is based on unmasking Ang II-induced 20-HETE production by giving a NSAID which prevents 20-HETE metabolism by COX-2 and allows the vasoconstrictor action of 20-HETE to be asserted.¹²⁷

Calcium receptor of thick ascending limb activates antipressor system

Increased Ca^{2+} intake can lower blood pressure by activating eicosanoid pathways similar to those recruited by Ang II.¹⁴⁶ In humans, raising serum ionized Ca^{2+} by 25% increases Na^+ excretion by 150%.¹⁴⁹ The antihypertensive mechanism evoked by increased extracellular ionized Ca^{2+} [$\text{Ca}^{2+}]_o$ was initiated by activation of a calcium-sensing receptor on the basolateral membrane of the mTAL¹⁵⁰ that, on long exposure (2–3 hours) like Ang II, induced via a TNF-dependent step, COX-2 expression, and PGE_2 synthesis (Figure 33–12). Stimulation of the calcium receptor (CaR) increased TNF synthesis by a mechanism that activated PKC with transcription of the TNF gene. Inhibition of PKC attenuated TNF production and prevented TNF activation of COX-2 expression in the mTAL. At this juncture, it is appropriate to review the temporal determinants of the pathways of arachidonate metabolism in the rat mTAL that regulate ion transport. Each pathway, CYP and COX, can be activated by either [$\text{Ca}^{2+}]_o$ or Ang II. The CYP pathway, which generates 20-HETE, represents a quick response (within 15 minutes), whereas the delayed response (2–3 hours), which requires expression of COX-2 and membranal PGE_2 isomerase, generates PGE_2 . The natriuretic-chloruretic effect of 20-HETE, the mediator of the quick response, is based on inhibition of the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter⁹⁴ and prevention of K^+ recycling¹⁵¹ (Figure 33–11). The signaling mechanism evoking the quick response requires the participa-

Figure 33–12. Effects of anti-TNF on Ca²⁺-mediated PGE₂ production. mTAL cells were pretreated for 15 minutes with a neutralizing concentration of anti-TNF antibody and then treated with 1.2 mM of CaCl₂ for 9 hours. Addition of purified IgG (isotype control) had no effect on PGE₂ production by cells incubated in the absence or presence of Ca²⁺. PGE₂ levels in supernatants were measured by ELISA. For each condition, an additional 0.42 mM of CaCl₂ were present in the media. **p*<0.05, *n*=3. (Redrawn from Wang D, Pedraza AL, Abdullah HI, et al. *Am J Physiol Renal Physiol* 2002;283:F963–70. Used with permission.)

tion of phospholipase A₂; blockade of phospholipase C was without effect.¹⁵² The delayed response evoked by either [Ca²⁺]_o or Ang II is based on the ability of PGE₂, the candidate mediator, to inhibit the Na⁺ pump¹⁵³ and the intermediate conductance K⁺ channel (ROMK).^{142,146} These findings disclose a mechanism that reduces blood pressure in response to increasing Ca²⁺ intake. The development of clinically acceptable calcimimetics might serve as an ancillary measure in the management of hypertension by evoking expression of COX-2 and production of PGE₂, resulting in inhibition of mTAL ion transport analogous to the effects of “loop diuretics.”

Proximal convoluted tubules: Interaction of 20-hydroxyeicosatetraenoic acid and endothelin-1

20-HETE serves as a second messenger for ET-1 in DOCA-salt hypertension.¹¹⁶ A study was designed to examine whether 20-HETE also serves as a second messenger for ET-1 in the nephron.¹⁵⁴ The impetus for this study was the unique renal functional effects of both ET-1 and 20-HETE¹⁵⁴; namely, diuresis despite renal vasoconstriction and depression of GFR, effects consonant with 20-HETE acting as a second messenger for the renal effects of ET-1.⁶⁸ Despite the negative effects of ET-1 on renal hemodynamics, release of CYP-AA metabolites by ET-1 increased Na⁺ excretion in the anesthetized rat.¹⁵⁴

The proximal tubules were selected to examine interactions of ET-1 and 20-HETE as this nephron segment is heavily invested with ω-hydroxylase forming 20-HETE as a principal eicosanoid.¹⁵⁵ ET-1 has also been shown to

inhibit proximal tubular ion transport.¹⁵⁶ Rat proximal tubular transport was examined in terms of 20-HETE acting as a mediator of the response to ET-1 by inhibiting ouabain-sensitive ⁸⁶Rb uptake.^{103,156} Dibromo-dodecaenoic acid (DBDD), a specific inhibitor of ω-hydroxylase, abolished the inhibitory effect of ET-1 on ⁸⁶Rb uptake as did BMS 182874, an ETA-selective receptor antagonist. These findings support the proposed role of 20-HETE acting as a second messenger, mediating the effects of ET-1 on Na⁺ transport in rat proximal tubules as has also been shown for the mitogenic response and renal injury produced by ET-1 in DOCA-salt hypertensive rats.¹¹⁶

Cortical collecting duct

EETs are involved in modulating Na⁺ transport in the cortical collecting duct (CCD), a site responding to aldosterone-regulated Na⁺ reabsorption.⁶⁹ The target of both aldosterone and AA is the ENaC on the luminal surface of the principal cells of the CCD.¹⁵⁷ ENaC is the principal pathway for Na⁺ reabsorption in the CCD. Wei et al.⁶⁹ identified 11,12-EET as the mediator of the AA-induced inhibition of ENaC activity in the rat CCD. This conclusion was abundantly supported by abolishing the response to AA by inhibiting epoxygenases and then demonstrating inhibition of ENaC activity by 11,12-EET despite the presence of the epoxygenase inhibitor. The 11,12-EET action on ENaC was unique, as other EETs, including 5,6-EET, were without effect. Further, 11,12-EET was shown to be synthesized by CCDs based on GC-MS criteria. Confocal imaging identified the 2C23 epoxygenase isoform in CCD cells, the epoxygenase isoform responsible for the bulk of EET production in the rat and normalization of blood pressure when the animal is challenged with a salt load.⁷⁶ The contribution of ENaC to regulation of blood pressure has been stated emphatically by Lifton et al.¹⁵⁸: “ENaC activity is absolutely required for normal salt homeostasis.”

Sakairi et al.⁷² demonstrated that 5,6-EET inhibits the Na⁺/H⁺ exchanger in the rabbit by increasing cytosolic Ca²⁺ concentration [Ca²⁺]_i, associated with stimulation of prostaglandin synthesis in the CCD. The effect of 5,6-EET on Na⁺ movement, as measured by electrogenic Na⁺ reabsorption in the rabbit CCD, was blocked by inhibition of COX activity. The action of 5,6-EET was stereoselective and evoked by either luminal or basolateral application of 5,6-EET; the other EETs affected neither [Ca²⁺]_i nor Na⁺ transport. This study confirms the earlier study of Jacobson et al.¹⁵⁹ that identified 5,6-EET as an inhibitor of net Na⁺ absorption by the rabbit CCD. Net potassium secretion was simultaneously reduced by 50%. Whether 5,6-EET serves as an endogenous mediator of Na⁺ transport in the CCDs cannot be answered by these studies as the focus was on the response of Na⁺ transport to exogenous 5,6-EET.

SUMMARY

The eicosanoids in their multiple forms act as mediators and modulators of blood pressure and can be involved in all phases of human hypertension, both primary and

secondary forms, as well as their counterparts in experimental models of hypertension. 20-HETE is the dominant renal eicosanoid, overshadowing PGE₂. There are many opportunities for interactions of these pathways, particularly in renal arterioles and small arteries, as exemplified in the ready metabolism of 20-HETE by COX into products that are both pro- (20-OH PGH₂, 20-OH TxA₂) and anti-pressor (20-OH PGE₂, 20-OH PGI₂). A persuasive rationale exists for nominating the prostaglandin endoperoxide analogue of 20-HETE, 20-OH PGH₂, as the mediator of TGF.

In each of the two major pathways of AA metabolism, prostaglandins and CYP-AA metabolites, having opposing actions, affect circulatory responses and tubular function: PGE₂ and PGI₂ versus TxA₂ and PGH₂, 20-HETE versus 11,12-EETs, and 20-HETE versus 19-HETE. The linkage of specific prostaglandin synthases to COX isoforms determine: (1) vasodilator-diuretic responses on COX-2 activation via linkage to PGI₂ and PGE₂ synthases; and (2) pressor responses on activation of COX-1 via TxA₂ and PGH₂ synthesis. Examples follow: autoregulation of RBF represents the result of the interactions of 20-HETE-mediated

vasoconstriction and 11,12-mediated vasodilatation; proximal tubular transport of Na⁺ is inhibited by 20-HETE, the action of which is opposed by 19-HETE.

Eicosanoid research is in the logarithmic phase of its development, offering boundless opportunities to scientists in biomedical fields. The main objective has been summarized by Christiane Nüsslein-Volhard: "The most important thing is not any one particular piece but finding enough pieces and enough connections between them to recognize the whole picture."¹⁶⁰ We are still some distance from this objective.

Role of Sex Steroids in Hypertension

Jane F. Reckelhoff, Licy L. Yanes, Radu Iliescu, Lourdes A. Fortepiani, and Julio C. Sartori-Valinotti

Key Findings

- Following menopause, blood pressure increases in women to levels even higher than in men.
- The roles that sex steroids play in mediating or protecting against cardiovascular disease (CVD) and hypertension are controversial. Men are at greater risk for cardiovascular and renal disease than are age-matched, premenopausal women.
- Animal studies have strongly implicated androgens as being mediators of CVD and hypertension, but human epidemiologic studies have shown that with chronic disease, including hypertension, serum testosterone levels are actually reduced. Whether androgens contribute to hypertension is not clear.
- Since premenopausal women are typically protected from CVD and hypertension compared to men, estradiol has been hypothesized to be protective against hypertension. However, the negative findings of recent studies on hormone replacement therapy in postmenopausal women have shaken our previous ideas.

SEX STEROIDS AND BLOOD PRESSURE IN HUMANS

Men are generally at greater risk for cardiovascular disease (CVD) and renal disease than are age-matched, premenopausal women. Studies using ambulatory blood pressure monitoring have demonstrated that blood pressure is higher in men than in women at similar ages.¹⁻⁵ For example, Wiinber et al.⁶ studied 352 normotensive (for age) Danish men and women, aged 20 to 79 years, and found that blood pressure increased with aging in both groups, but that men had higher 24-hour blood pressure, by approximately 6 to 10 mmHg, than did women, until the age of 70 to 79 years when blood pressure was similar for men and women.⁶ Khoury et al.⁷ performed ambulatory blood pressure monitoring on 131 men and women, aged 50 to 60 years, and found that men had higher blood pressure than did women.⁷ Findings were similar in a meta-analysis study performed by Staessen et al. In addition, NHANES III, the Third National Health and Nutrition Examination Survey, showed that in general, men had higher blood pressure than women through middle age.⁹ Furthermore, the incidence of uncontrolled hypertension is also greater in men than women.

Following menopause, however, blood pressure increases in women as well. The data from NHANES III confirmed

that by 60 to 69 years of age, Hispanic women and non-Hispanic black women developed higher blood pressure than men of similar ethnic background.⁹ The mechanisms responsible for the hypertension in these populations are complicated by comorbid conditions of obesity and type II diabetes, which can also lead to increases in blood pressure. In the non-Hispanic white population, in which the incidence of obesity and type II diabetes with aging were not as high, blood pressure also increased after the average age of menopause (51.4 years). Thus by 60 to 69 years of age, non-Hispanic white women had similar prevalence of hypertension as men, and by 70 to 79 years of age, this population of women had higher prevalence than did men.

SEX STEROIDS AND BLOOD PRESSURE IN ANIMALS

Gender-associated differences in blood pressure observed in humans have also been documented in various animal models. In hypertensive rat models, many investigators have found that males have higher blood pressure than do females. For example, male spontaneously hypertensive rats (SHR) have higher blood pressure than do females of similar ages.¹⁰ Similar gender differences in development of hypertension are also found in Dahl salt-sensitive rats,¹¹ deoxycorticosterone (DOC)-salt hypertensive rats,¹² and the New Zealand genetically hypertensive rat.¹³ Therefore, as found in humans and hypertensive rat models, males have higher blood pressure than age-matched females.

Whether there are sex differences in blood pressure in normotensive rats, as found in humans, is not clear. Calhoun and Oparil¹⁴ reported that 24-hour blood pressure measured at 12 weeks of age in male Wistar-Kyoto rats (WKY) was lower than in female WKY by approximately 9 mmHg (males, 96±3 mmHg; females, 105±1 mmHg).¹⁴ However, by 14 weeks of age there was no difference in blood pressure over 24 hours between the genders (males, 101±3 mmHg; females, 106±1 mmHg). In any case, the issue could be resolved if blood pressure were measured over a prolonged period of time (months) by telemetry.

BIOCHEMISTRY

Synthesis of sex steroids

Sex steroids are produced mainly by the gonads, although the synthesizing machinery is present in other tissues. The

enzymes involved in sex steroid synthesis are members of the cytochrome P450 (CYP) system. As shown in Figure 34–1, the rate-limiting step in sex steroid synthesis is the conversion of cholesterol to pregnenolone by the side-chain cleavage enzyme. Cholesterol is made available either from low-density lipoproteins in the extracellular fluid or from acetyl co-enzyme A in the cells. Pregnenolone is converted to progesterone or to dihydroepiandrosterone (DHEA) by 17α -hydroxylase (also known as $17,20$ -desmolase). DHEA can be converted to either androstenedione by 3β -hydroxysteroid dehydrogenase or to androstenediol by 17β -hydroxysteroid dehydrogenase. Androstenedione and androstenediol can be converted to testosterone by 17β - or 3β -hydroxysteroid dehydrogenase, respectively. Testosterone is then converted either to dihydrotestosterone by 5α -reductase or to estradiol by CYP 19-aromatase.

Sex steroid receptors

The two estrogen receptors, $ER\alpha$ and $ER\beta$, and the androgen receptor are typical nuclear receptors (reviewed in Black and Paschal¹⁵ and Barkhem et al.¹⁶). Both estrogen and androgen receptors are present on many cell types in various tissues, including tissues involved in the cardiovascular system such as the vasculature, the heart, and the kidney.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Evidence that sex steroids impact blood pressure: Role of androgens

Although the mechanisms responsible for the sex differences in blood pressure control are not clear, there is significant evidence that androgens, such as testosterone, play an important role in gender-associated differences in blood pressure regulation (Box 34–1). For example, studies using ambulatory blood pressure–monitoring techniques in children have shown that with increasing age, blood pressure increases in both boys and girls. However, after the onset of puberty, boys have higher blood pressure than do age-matched girls.^{17,18} At ages 13 to 15 years, systolic blood pressure was approximately 4 mmHg higher in boys than girls and at ages 16 to 18 years, boys had higher systolic blood pressures than girls by 10 to 14 mmHg. The blood

pressure in postpubescent boys also does not dip as low at night as in girls. A reduction in nocturnal dipping is recognized as a hallmark of early dysfunction in blood pressure regulation. These data clearly show that with adolescence and puberty when androgen levels are increasing, blood pressure is higher in boys than girls. Increased androgens in adults are also associated with increased blood pressure. For example, women with polycystic ovary syndrome or adrenal virilizing tumors, which are characterized by elevated testosterone levels, experience hypertension.^{19,20} Anabolic androgenic steroid use also leads to frank hypertension in borderline hypertensive men.

Another line of evidence that testosterone may impact blood pressure is found in rat studies. Castration at a young age (3 to 5 weeks) attenuates the development of hypertension in male SHR, Dahl salt-sensitive male rats, and male rats subjected to the two-kidney, one-clip (Goldblatt) maneuver or in male rats subjected to reduced renal mass.²¹ Chronic blockade of the androgen receptor with the antagonist flutamide attenuates blood pressure in male SHR to the level found in females. Furthermore, testosterone and dihydrotestosterone are capable of increasing blood pressure in normotensive rats.^{23,24}

Evidence that sex steroids impact blood pressure: Role of estrogens

Since male humans and rats have higher blood pressures than do females of both species, it is possible that female hormones may play a role in protecting females from developing higher blood pressures (Box 34–2). In women menopause is characterized by increases in blood pressure as determined by the NHANES III study and others.⁹ Interestingly, blood pressure does not increase during the transitional phase from perimenopause to menopause,²⁵ but rather the increase in blood pressure following menopause takes an average of 5 to 20 years to develop, suggesting that lack of female hormones may not be the only contributing factor to elevated blood pressure. However, salt sensitivity of blood pressure has been shown to increase in women with age,²⁶ suggesting a role for the loss of estrogens in promoting salt-sensitive hypertension.

Animal studies suggest that estrogens may protect against hypertension. For example, Hinojosa-Laborde et al.^{11,27} have reported using telemetry that ovariectomy results in

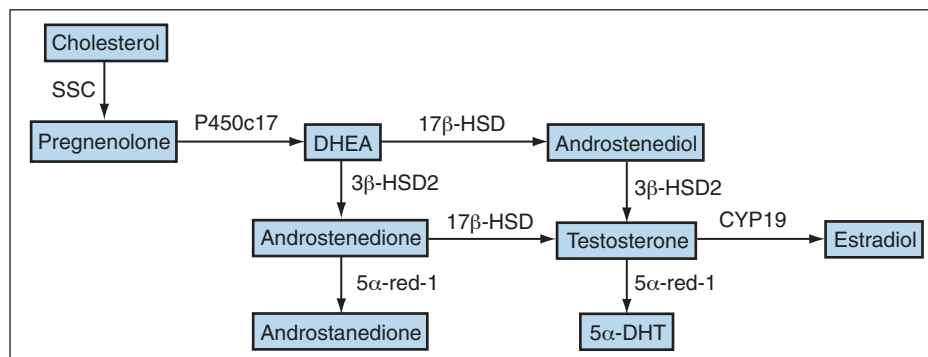

Figure 34–1. Synthesis of sex steroids. CYP19, aromatase; red, reductase; HSD, hydroxysteroid dehydrogenase; P450c17, 17α -hydroxylase; SSC, side chain cleavage enzyme.

Box 34-1**Mechanisms by Which Androgens Could Increase Blood Pressure**

- Increase sodium and water reabsorption
- Activate the renin-angiotensin system
- Stimulate endothelin synthesis
- Stimulate oxidative stress

Box 34-2**Mechanisms by Which Estrogens Could Protect Against Hypertension**

- Attenuate activation of renin-angiotensin system, reduce expression of AT1 receptors and converting enzyme, upregulate AT2 receptors
- Inhibit endothelin synthesis
- Act as an antioxidant; inhibit NADPH oxidase synthase, leading to reductions in oxidative stress

increased blood pressure in female Dahl salt sensitive rats whether on high- or low-salt diets. Ovariectomy of DOC-salt hypertensive rats also results in higher blood pressure than in intact females treated with DOC and salt.¹²

Abnormal pressure–natriuresis in hypertension: Impact of sex steroids

Substantial evidence supports the theory that some form of renal dysfunction plays a role in the development and maintenance of hypertension.²⁸ Many studies have demonstrated that “hypertension follows the kidney.” For example, Curtis et al.²⁹ reported that blood pressure returns to normal in hypertensive patients who receive kidneys from normotensive donors. Animal studies have also confirmed that transplantation of the kidney from a hypertensive rat into a normotensive animal results in hypertension.³⁰ Similar results have been obtained in renal transplantation studies between Dahl salt-sensitive and salt-resistant rats. A common defect that has been characterized in several forms of hypertension is a shift in the pressure–natriuresis relationship. The pressure–natriuresis relationship refers to the fact that increased arterial pressure elicits a marked increase in sodium excretion by the kidney. According to the renal body fluid feedback concept,²⁸ a long-term increase in arterial pressure or hypertension occurs as a result of reduction in renal excretory function or a rightward shift in the pressure–natriuresis relationship.

Studies in animals have suggested that sex steroids can affect the pressure–natriuresis relationship. For example, the pressure–natriuresis relationship is blunted in male SHR compared to females.¹⁰ Castration of the male SHR

restored the pressure–natriuresis relationship, whereas ovariectomy of female SHR had no effect. Testosterone treatment of ovariectomized female SHR resulted in an increase in blood pressure and a concomitant blunting of the pressure–natriuresis relationship. The androgen receptor is located predominantly in proximal tubule segments of the nephron, and treatment of normotensive rats with dihydrotestosterone increases blood pressure and proximal tubular sodium reabsorption.²⁴ These data provide initial support for the notion that androgens may have a direct effect on sodium reabsorption in the proximal nephron. Estrogen receptors have also been found in the kidney. Although no studies have been done to determine the biological significance of estrogen receptors in the tubular handling of sodium, it is tempting to speculate that perhaps estrogens may inhibit sodium reabsorption, either directly or via their effect on AT1 receptor expression.

When the kidney from male SHR was transplanted into females, there was not a significant rise in blood pressure, and female SHR with male kidneys had similar blood pressure as female SHR with female kidneys.³⁰ However, when the kidney from female SHR was transplanted into male SHR, blood pressure was not attenuated compared to blood pressure in a male SHR with male kidneys. These data indicate that the 25 to 30 mmHg higher blood pressure in the male SHR compared to the females is due to an extra-renal factor in the male that further increases blood pressure perhaps due to a reduction in pressure–natriuresis. Thus androgens may be this factor.

Mechanisms by which sex steroids could modulate blood pressure: Effect on renin-angiotensin system

The key system for controlling blood pressure and body fluid volume (i.e., pressure–natriuresis) is the renin-angiotensin system (RAS).³¹ Angiotensin II (Ang II) increases proximal sodium reabsorption by the kidney by stimulating epithelial transport. In the event of abnormal Ang II levels for the level of volume in the body, the blood pressure will increase with abnormal sodium and water reabsorption leading to blunting of the pressure–natriuresis relationship. Similarly, if total body fluid volume levels are “perceived” incorrectly and thus Ang II levels do not respond appropriately, increases in blood pressure will also occur.

Sex steroids modulate components of the RAS that may play a role in the control of blood pressure. James et al.³² measured plasma renin activity (PRA) in men and women over a 9-year period and documented that in this normotensive population, PRA was 27% higher in men than women regardless of age and ethnic heritage. Kaplan et al.³³ reported similar findings. Postmenopausal women also have higher PRA than premenopausal women do.

Estrogens have been shown to downregulate components of the RAS that could impact blood pressure. Ovariectomy of rats increases and estradiol repletion decreases the expression of AT1 receptors in vasculature and kidneys.^{34,35} In addition, estradiol reduces the expression and activity of angiotensin I converting enzyme (ACE).^{36,37} The reductions in both AT1 receptors and ACE should protect against

activation of the RAS. However, estradiol also causes release of angiotensinogen substrate from the liver,³⁸ and this could offset any potential protective effect if renin enzyme is not working at Vmax, and thus renin activity is increased by increased angiotensinogen substrate leading to increased angiotensin II. However, if renin levels are lower in females than males as indicated by higher PRA in men than women, and since renin is the rate limiting step for Ang II production, females may be expected to have lower circulating and intrarenal Ang II production.

There is evidence that estradiol also affects AT2 receptors in the kidney. Silva-Antonioli et al.³⁹ reported that female SHR exhibited higher expression of AT2 receptors in the kidney than male SHR. There was no sex difference in expression of AT2 receptors in mesenteric arteries, however. Therefore, since AT2 receptors are thought to be linked to nitric oxide synthase, it is possible that estrogens could modulate blood pressure via AT2 receptor-mediated increases in nitric oxide production.

Animal studies have also supported a role for androgens in modulating components of the RAS. Male SHR have higher PRA than do females, testosterone treatment of ovariectomized female rats causes increases in PRA, and PRA decreases with castration in male rats.²¹ Furthermore, there is a linear correlation between the level of serum testosterone and PRA in Sprague Dawley rats treated chronically (2 weeks) with increasing doses of testosterone. Data from two groups have independently shown in SHR and normotensive WKY rats that castration decreases and chronic testosterone treatment increases renal angiotensinogen mRNA.^{40,41} Chronically increased renal angiotensinogen could increase renal tissue Ang II if renin enzyme is not working at Vmax, which has been reported in both humans and rats.⁴² In support of this hypothesis, studies in mice have demonstrated that an increase in angiotensinogen gene copy numbers cause increases in blood pressure.⁴³

The effect of androgens on expression of AT1 and AT2 receptors has not been studied as well as estrogens. However, Silva-Antonioli et al.³⁹ reported that male SHR had higher levels of AT1 receptors in aorta, mesenterics, and kidney vasculature, whereas AT2 receptor expression was lower in males than females. These data support the concept that androgens may stimulate expression of the vasoconstrictor AT1 receptors and downregulate the expression of the vasodilator AT2 receptors in the kidney.

The RAS has been shown to play an important role in mediating the sex difference in blood pressure in SHR. Chronic blockade with the Ang II-converting enzyme inhibitor enalapril resulted in normalized blood pressure regardless of gender.²³ In male SHR and ovariectomized female SHR treated with testosterone, in which blood pressure was elevated by 30 mmHg, blood pressure decreased by 65% with enalapril, whereas in female, castrated male, and untreated ovariectomized female SHR, blood pressure decreased by only 40%. These data suggest that the RAS plays an important role in mediating hypertension in SHR independent of the sex of the animal, but more importantly that the androgen-promoted exacerbation of the blood pressure in male and testosterone-treated ovariectomized female SHR is also mediated by the RAS.

Another component of the RAS is aldosterone, which is stimulated by Ang II and responsible for increasing sodium reabsorption in the distal nephron. Whether androgens can impact aldosterone synthesis is not clear. There are higher aldosterone levels in men than in women,⁴⁴ with a positive correlation between aldosterone levels, dehydroepiandrosterone sulfate (a metabolite of testosterone), and blood pressure in a population of hypertensive men.⁴⁵ However, testosterone replacement in castrated male rats decreased corticotropin-stimulated aldosterone release.⁴⁶ Whether sex steroids are capable of modulating synthesis of mineralocorticoid receptors is also not clear and will require further study.

Mechanisms by which sex steroids could modulate blood pressure: Effect on endothelin

Endothelin is another vasoconstrictor that has been shown to be affected by sex steroids. For example, in male-to-female transsexuals, estradiol therapy caused a significant reduction in serum endothelin.⁴⁷ In premenopausal women, a differential ratio of ET_A to ET_B receptors has also been found, favoring a vasodilator effect of endothelin via ET_B receptors.⁴⁸ In recent animal studies, estradiol or its metabolites have been shown to inhibit endothelin synthesis in endothelial cells,⁴⁹ and improve endothelial dysfunction in ovariectomized female SHR⁵⁰ and DOCA-salt hypertensive rats.⁵¹ We found that postmenopausal SHR exhibit increased endothelin levels, and decreased ET_A and ET_B receptor mRNA in kidney cortex compared with young females.⁵² Therefore, estrogens should be cardiovascular protective due to their positive effect on endothelin inhibition.

In contrast, androgens have been shown to cause an increase in endothelin in humans. Female-to-male transsexuals receiving large doses of testosterone have elevated levels of serum endothelin compared to untreated females.⁴⁷ Whether androgens affect expression of endothelin receptors is not clear. In any case, androgens could cause increases in blood pressure and endothelial dysfunction leading to CVD by increasing vasoconstrictors.

Mechanisms by which sex steroids could modulate blood pressure: Role in oxidative stress

Sex steroids have been shown to have an effect on oxidative stress either directly or indirectly. Estradiol is a mild antioxidant and protects against oxidative stress,⁵³ which is thought to be a causative factor in endothelial dysfunction associated with hypertension.⁵⁴ Lacy et al.⁵⁵ reported that women with essential hypertension had lower levels of plasma hydrogen peroxide than did men. Premenopausal women have also been shown to have lower levels of oxidative stress, as measured by F₂-isoprostanes, than do men⁵⁶ or postmenopausal women,⁵⁷ which suggests a role for estrogens in the lower levels of oxidative stress. In animal studies, Strehlow et al.⁵⁸ found that 17 β -estradiol not only reduced Ang II-induced oxidative stress but increased expression of some of the isoforms of superoxide dismutase, an important antioxidant enzyme.

These data were also confirmed by Gragasin et al.⁵⁹ in cultured endothelial cells in which estradiol treatment reduced Ang II–mediated expression of NADPH oxidase and peroxynitrite production. The effect of estrogen was independent of the estrogen receptor, however.

There is also evidence that androgens may directly stimulate oxidative stress. Oxidative stress produced by renal intramedullary inhibition of superoxide dismutase has been shown to cause an increase in blood pressure in normotensive rats.⁶⁰ Our preliminary data suggest that treatment of mesangial cells from SHR with dihydrotestosterone at physiological doses increases oxidative stress and upregulates expression of p47^{phox}, a subunit of NADPH oxidase. P47^{phox} expression is also attenuated in SHR subjected to castration, and NADPH oxidase activity and superoxide production are higher in intact males than castrated males. Furthermore, apocynin, the inhibitor of NADPH oxidase, reduces blood pressure in male SHR, but has no effect on castrated males (Iliescu and Reckelhoff, unpublished observations).

It is also possible that sex steroids could affect oxidative stress indirectly via the RAS. Both supraphysiologic and physiologic doses of Ang II can cause oxidative stress. For example, Rajagopalan et al.⁶¹ found that pharmacologic doses of Ang II (0.7 mg/kg/d s.c. by minipump) increased blood pressure and superoxide levels in aortic segments of rats, while infusion of norepinephrine, which resulted in a similar increase in blood pressure as Ang II, had no effect on superoxide levels. In addition, these investigators found that increased superoxide levels could be normalized with losartan, the Ang II receptor antagonist, or with liposomes containing superoxide dismutase.⁶¹ In further experiments, Ang II increased superoxide production via increased NAD(P)H oxidase activity.⁶²

While supraphysiologic doses of Ang II can stimulate oxidative stress, chronic infusion of subpressor doses (i.e., doses that do not elicit an immediate blood pressure response) of Ang II (10 ng/kg/min) for 14 days into normotensive rats that were given enalapril to block endogenous Ang II formation, also result in the slow-onset development of hypertension and an increase in plasma F₂-isoprostanes, an indicator of oxidative stress.⁶³ It is possible that androgens could stimulate and estrogens could inhibit oxidative stress indirectly by their effect on the RAS.

Sex steroids could also affect oxidative stress indirectly by their effects on endothelin. Endothelin has been shown to cause oxidative stress by upregulating the subunits of NAD(P)H oxidase.⁶⁴ In addition, oxidative stress has been shown to upregulate endothelin.^{65,66} This would set up a vicious cycle. Therefore, since estrogens have been shown to downregulate endothelin, they should protect against oxidative stress in this way. In contrast, androgens should promote oxidative stress via its effects to upregulate endothelin as described above.

Another effect of androgens is to upregulate thromboxane receptors.⁶⁷ Thromboxane receptor number has been shown to increase with testosterone treatment in aortic vascular smooth muscle cells.⁶⁷ One of the consequences of oxidative stress is the nonenzymatic synthesis of vasoconstrictor F₂-isoprostanes whose activity is mediated

via thromboxane receptors. F₂-isoprostanes in turn potentiate the vasoconstrictor effects of Ang II and stimulate endothelin production to increase blood pressure even further. Thus androgens could increase the number of thromboxane receptors by which the F₂-isoprostanes cause vasoconstriction. It is doubtful that thromboxanes themselves play any role in mediating higher blood pressure in male SHR, since we have found that male SHR excrete less thromboxane B₂, the stable metabolite of thromboxane A₂, than do females; blockade of the thromboxane receptors, but not thromboxane synthase, reduces blood pressure in male SHR but not in females.⁶⁸ Therefore, it is possible that the ligand for the thromboxane receptor in male SHR is F₂-isoprostanes, which in turn would amplify the vasoconstrictor effects of Ang II and modulate endothelin synthesis to cause hypertension.

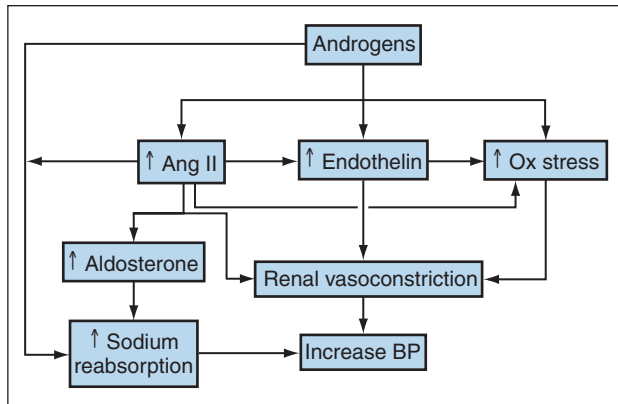

PERSPECTIVES

While there is significant evidence that sex steroids can modulate blood pressure, the mechanisms by which this occurs are not clear. Several clinical trials have shown that certain antihypertensive drugs have better efficacy in men than women and vice versa. For example, angiotensin-converting enzyme inhibitors have been shown to be more effective in men than women,⁶⁹ whereas, angiotensin receptor antagonists were more effective in women than men in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial.⁷⁰ Therefore, future clinical trials need to be powered to address sex differences in the responses to antihypertensive drugs in order to determine the most effective treatment for men and women.

Most clinical trials have not shown an antihypertensive effect of antioxidants, and this fact calls into question the role of oxidative stress in mediating hypertension in humans. However, as we have shown previously in hypertensive animals, males and females exhibit different depressor responses to antioxidants and clinical trials, to our knowledge, have not addressed different regimens of antioxidants depending on the sex of the participants. Therefore, future clinical trials will be necessary to determine what antioxidants are beneficial in reducing blood pressure in men compared to women and vice versa.

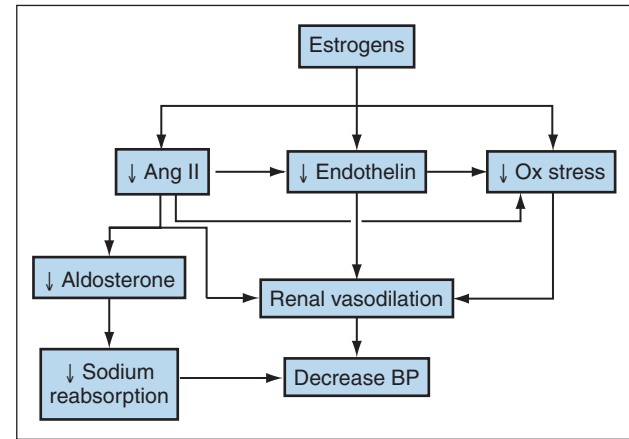

SUMMARY

This review has critically examined large numbers of fragmentary observations so as to create a coherent set of hypotheses (albeit complicated) by which the sex differences in blood pressure control could be explained. The hypotheses described in Figure 34–2 A represent the possible mechanisms by which androgens, mediated via Ang II, endothelin, and oxidative stress could mediate hypertension. As has been shown in animal studies, androgens could promote an increase in blood pressure in males by increasing renal angiotensinogen synthesis and thereby increasing intrarenal renin activity (and thus Ang II). Androgens may also affect the number and affinity of receptors for Ang II affecting sodium reabsorption and/or renal vasoconstriction. Ang II via AT1 receptors could directly cause renal vasoconstriction.

B

tion, and also stimulate proximal tubule sodium reabsorption and/or stimulate aldosterone-mediated distal tubule sodium reabsorption, blunt pressure–natriuresis, and increase blood pressure. Alternatively, Ang II could stimulate endothelin production and increase oxidative stress leading to renal vasoconstriction. Androgens may also directly stimulate sodium reabsorption, endothelin production, and/or oxidative stress. The combination of increased sodium reabsorption and renal vasoconstriction would lead to the increase in blood pressure.

As shown in Figure 34–2 B, in females, estrogens should inhibit renal Ang II production and AT1 receptor expression compared to males. The reduction in Ang II may decrease both endothelin synthesis and oxidative stress.

Alternatively, estrogens may directly inhibit endothelin synthesis and act as an antioxidant reducing oxidative stress. Another possibility is that estrogens may inhibit sodium reabsorption at the proximal tubule. The role that sex steroids play in control of blood pressure may potentially allow for sex-based treatment of hypertension and CVD in the future.

ACKNOWLEDGEMENT

The studies in this chapter were funded by National Institutes of Health (grants HL05197-11, HL69194, and HL66072).

Chapter
35Genetic Approaches
to Hypertension: Relevance
to Human Hypertension

Carlo Giansante and Nicola Fiotti

Key Findings

- Offspring of persons with hypertension have a 3.5-fold increased risk of having high blood pressure, and the risk is doubled when a sibling has hypertension.
- Hypertension is a multifactorial disease, in which a polygenic model interacts with the environment. A polygenic model is a model in which many small equal and additive loci would result in a Gaussian distribution for a phenotype.
- Mapping and candidate gene strategies do not show reproducible and consistent results in identifying the genes affecting hypertension.
- Several factors (such as polygenic inheritance, heterogeneity, epistasis, and developmental effects) hamper assessment of these genetic variants.

Clinicians have known intuitively for more than three decades that essential hypertension (EH) has a hereditary component. This intuitive knowledge was clinically demonstrated in the early 1990s. Ravogli et al., in a very small group of subjects (15 normotensive subjects whose parents were both hypertensive, 15 normotensive subjects with one hypertensive parent, and 15 normotensive subjects whose parents were not hypertensive), demonstrated that individuals whose parents were affected by hypertension had higher ambulatory blood pressure than those whose parents were not. The authors concluded that the higher blood pressure shown by individuals with a positive family history of parental hypertension reflected not a hyperreactivity to stress but rather an early permanent blood pressure elevation.¹

A stronger demonstration was offered by Dekkers et al.², who in a longitudinal study explored the influence of genetic susceptibility to EH in youth. This study recruited 745 subjects (mean age 12 years; range 4.9 to 23.9 years) and followed them for a 10-year period with annual blood pressure measurements. Family history of EH was defined as the occurrence of EH in one or both biological parents. The results showed that compared to subjects without a family history for EH those with a family history developed hypertension earlier, had higher systolic blood pressure (SBP) readings from childhood to adulthood, and had a greater increase in SBP when growing older. The effect of genetic susceptibility to EH was independent of sex and ethnicity, being the same for African American and

European American males and females. Such results, though convincing, suffer from both the rough definition of family history and the infeasibility of disaggregating family history from shared familial environments. The latter is one of the difficulties still encountered in assessing the genetic variations related to EH.

The identification of genes underlying Mendelian disorders has been enhanced significantly over the last decades by extraordinary achievements in gene mapping and the development of meticulous statistical methods. Such technological advances promoted several studies of EH, which is an important public health problem, with 25% of the adult population being affected in industrialized countries. Despite several years of meticulous and well-designed research, however, our knowledge about causes and mechanisms of EH is largely incomplete.

The aim of researching genetic variations related to hypertension goes beyond the better understanding of the pathophysiology of the disease. It involves several other relevant goals, such as the recognition of subjects at risk of developing EH before the onset of clinical symptoms, understanding the interaction between genes and environmental factors, and the customization of drug therapy according to the specific genotype so that administration of available drugs can be tailored to the individual.

From the very beginning, genetic epidemiologic studies clearly indicated that a plain Mendelian pattern of inheritance (in which a single gene mutation causes early onset of hypertension) occurs only in rare familial syndromes, whereas the vast majority of cases of EH are due to several genetic variants. The contributions of genetic variants to the overall blood pressure levels in general population is really small. For example, apparent mineralocorticoid excess (AME) (hypertension, polydipsia/polyuria, severe hypokalemia, and metabolic alkalosis)—a syndrome attributable to the mutation in the gene encoding 11 β -hydroxysteroid dehydrogenase type 2—has been diagnosed in only 40 patients worldwide in the past 20 years.³

The role of genes derives from the many and inter-related mechanisms accounting for the development of EH, such as salt sensitivity, fluid balance, impaired glucose tolerance, and obesity. If only a part of these mechanisms has a genetic regulation, a large number of genes (rather than a single gene) would be expected to explain the inheritability of this complex disease. In patients with hypertension, several patterns of genetic variations could then be found (compared to those without this condi-

tion)—making the interpretation of the results complex. Moreover, considering the interaction of many mechanisms it is also possible that the phenotypic effects of some genetic variations are concealed by some compensatory mechanisms.

With at least 30,000 genes in the human genome and the characterization of these genes in progress, the challenge is to break down the complexity of genetic disorders (e.g., diabetes, schizophrenia, and cancer), including hypertension.⁴ This chapter reviews present identified genetic variations that may contribute to the onset of EH, with particular attention on search strategies and likely future developments. A glossary of terms is given in Box 35–1.

Box 35–1

Glossary of Terms

- **Allele:** One of the variant forms of a gene at a particular locus (location) on a chromosome.
- **Candidate gene:** A gene, located in a chromosome region suspected of being involved in a disease, whose protein product suggests that it could be the disease gene in question.
- **Domain:** A specific region or amino acid sequence in a protein associated with a particular function or corresponding segment of DNA.
- **Gene:** The functional and physical unit of heredity passed from parent to offspring.
- **Genetic code (ATCG):** The instructions in a gene that tell the cell how to make a specific protein. A, T, G, and C are the “letters” of the DNA code. They stand for the chemicals adenine, thymine, guanine, and cytosine, respectively, which make up the nucleotide bases of DNA. Each gene’s code combines the four chemicals in various ways to spell out three-letter “words” that specify which amino acid is needed at every step in making a protein.
- **Haploid:** The number of chromosomes in a sperm or egg cell, half the diploid number.
- **Linkage:** The association of genes and/or markers that lie near each other on a chromosome. Linked genes and markers tend to be inherited together.
- **Locus:** The place on a chromosome where a specific gene is located; a type of address for the gene.
- **Mendelian inheritance:** Manner in which genes and traits are passed from parents to children.
- **Microsatellite:** Repetitive stretches of short sequences of DNA used as genetic markers to track inheritance in families.
- **Polymorphism:** A common variation in the sequence of DNA among individuals.
- **Promoter:** The part of a gene that contains the information to turn the gene on or off. The process of transcription is initiated at the promoter.
- **Substitution:** Replacement of one nucleotide in a DNA sequence by another nucleotide, or replacement of one amino acid in a protein by another amino acid.

GENETIC ANALYSIS OF BLOOD PRESSURE VARIABILITY: THE METHODS

Human DNA consists of a double string of three billion base pairs. They are organized in 23 pairs of chromosome within a 2- μ m nucleus. The compacted DNA is 50,000 times shorter than its extended length. In the extended form, human genomic DNA would be a little over 6 feet long. If it were a ladder with each rung one foot apart, it would be 568,000 miles long. To view this in perspective, the distance between the earth and the moon is about 240,000 miles and the circumference of the earth at the equator is 25,000 miles. Within these 6 billion nucleotides there are approximately 30,000 to 40,000 protein-coding genes. The gene coding regions in the human actually make up less than 5% of the 6 billion nucleotides. The function of the remaining 95% of the DNA is not clear.

Alterations of DNA provide an important way of ensuring survival of populations in the event of environmental changes. Availability of genes with alternative products (so-called thrifty genes) within a population has been a resource for the species because it allows a reduction in food availability to be overcome, facilitating survival during environmental changes. This could lend an evolutionary advantage over other species and may help to colonize new environments. It is well demonstrated that genetic material of all species changes spontaneously and this leaves some mutated versions of the genes in the population. The pressure of selection can then act, expanding alleles beneficial for evolution or disposing of those hindering it.

Mutations are important because they are the major source of the genetic variation that fuels evolutionary change. As it is, replication errors by the cells’ machinery tend to be fairly rare, occurring in only about 1 out of every 10^{-9} base-pair replications. From studies *in vivo* and other studies using human cells *in vitro*, the overall human mutation rate is estimated to be about 1×10^{-6} per gene per generation. This rate is similar to those measured in various prokaryotic and eukaryotic microorganisms. The estimated human mutation rate can be used to determine its impact on the likelihood of changes occurring in each generation. A rate of 1×10^{-6} mutations/gene $\times 3 \times 10^4$ genes/haploid genome equals 3×10^{-2} mutations per gamete (=3/100 or 1/33). $1/33 \times 2$ gametes per zygote implies a 6/100 chance that each zygote carries a new mutation somewhere in the genome. This seems like a very high number, but one needs to remember that most mutations are recessive and thus will not be expressed in the heterozygous condition.

Changes within the human genome occur mainly for missense/nonsense mutations, deletions, splicing, insertion/duplication, and less frequent mutations that will be established within the genome of a population provided they are not a limitation for the carrier. Their prevalence is recognized as a mutation when its allelic frequency is less than 1% and a polymorphism when its prevalence is higher. An estimation of genome variability can come from the number of single nucleotide changes within the

genome. In January of 2005, more than 5 million single-nucleotide polymorphisms (SNPs) have been submitted and validated at the Single Nucleotide Polymorphism NCBI database (http://www.ncbi.nlm.nih.gov/SNP/snp_summary.cgi). The data are constantly increasing. In 2001, the figure was about 2.1 million unique SNPs⁵ and the public SNP consortium identified 1.4 million.⁶ Marth et al.^{7,8} report false-positive rates of 10 to 15%, although false negatives are of greater concern.⁸ Fortunately, only a minor number of SNPs occur within genes and less than 1% in regulatory regions. In the human gene mutation database, 52,165 mutations within genes had been reported up to 2005. Identifying gene variants that contribute to hypertension may not only provide better understanding of the pathophysiology of the disease but elucidate the biochemical and pathophysiologic pathways that link various risk factors in hypertension.

Definition of the trait

Hypertension is defined as a clinical syndrome (a condition, not a pathologic identity) characterized by a stable increase of systolic and/or diastolic blood pressure above defined values. The blood pressure level used as a benchmark for a diagnosis of hypertension has changed in the last few years, making it somewhat awkward to analyze this trait as a discrete variable. Moreover, use of terms signifying different degrees of hypertension (borderline, mild, or severe) might further confuse the picture. The studies of genetic susceptibility to hypertension have to deal with an important issue, which is the precise definition of the condition.

During the 1960s, a heated debate between Sir George Pickering⁹ and Sir Robert Platt¹⁰ arose over the question of whether hypertension is a quantitative upper tail of a continuous distribution of blood pressure, and thus determined by a number of genes, or a qualitative trait due to an effect of a single major gene. At present, we can say that both Sir George and Sir Robert were right. Although several monogenic forms of hypertension have been clearly identified, EH is now understood as being a polygenic disease with complexities such as gene-gene and environment-gene interactions.

A careful definition of the condition sought is mandatory in avoiding contradictory and unsatisfactory results. The definition of hypertension established in May of 2005 by the American Society of Hypertension (<http://www.ash-us.org>) as a “progressive cardiovascular syndrome arising from complex and interrelated etiologies” is of little help in advancing comprehension, and from the research point of view confirms that genetic studies can be very complex and difficult. Lack of knowledge is reflected by a vague definition and the consequence is poor results. Two options in definition of the trait (qualitative and quantitative) are possible, but neither one perfectly reflects our definition of the condition as a pathophysiologic state—allowing us to recollect gene expression etiology and clinical conditions. Factors responsible for increased SBP might be different from those accounting for increased diastolic blood pressure. Even considering the mean blood pressure, other variables (e.g., heart

rate) should be taken into account—thus complicating the overall picture. In turn, all factors (vessel compliance, vascular tone, baroreceptor regulation, and so on) influencing each aspect of the trait (systolic or diastolic blood pressure) are subject to very strict regulation by environmental and genetic controls.

Even considering hypertension as a quantitative trait (i.e., high blood pressure), some problems could arise. In particular, analysis of genes involved in blood pressure regulation might encompass alleles involved in regulation within the physiologic range of pressure but not in extreme values.¹¹ Present data focus mainly on these definitions, although recently some other intermediate phenotypes (i.e., characteristics or features such as paradox hypertension, salt sensitivity, and postural changes) alleged to be more simply regulated have been published.

Investigative tools

Genetic epidemiology is a science born in the 1960s that encompasses classical epidemiology, statistics, and genetics. This science can answer several important questions about the genetic aspects of hypertension.

- Are there some genetic components influencing the presence of hypertension?
- What is the relative size of the genetic effect on hypertension, compared to nongenetically influenced effects (typically environmental)?
- What and where are the genetic components responsible?

Many studies have been published on these issues, each considering the effect of several biases and confounding factors (e.g., interaction of the phenotype with environment, genetic background, and other co-inheritable conditions such as type II diabetes and obesity). These variables require independent replication of the studies before a definite conclusion can be drawn. The types of studies used to answer to these three questions include genetic risk studies, segregation analysis, linkage studies, and association studies.

Genetic risk studies

These studies aim to assess the genetic components and distinguish between genetic and environmental factors. This task is particularly difficult to achieve for a condition such as hypertension, in which ethnic or genetic background could be linked to environmental factors. The typical approach is to study hypertension transmittance in families, siblings, or separately adopted twins.

Segregation analysis

After observing the risk of developing the condition due to genetic components, the next step is to assess its type (i.e., one gene with an important effect, few genes each with a moderate effect, many genes each with a small effect, or even a combination of these) and the transmission model of the genetic trait. For this step, multigenerational family trees are required to determine the type of inheritance. Segregation analysis is particularly useful when there are substantial numbers of affected subjects in each family.¹²

Linkage studies

These studies aim to detect where genetic components affecting hypertension are located within the human genome. This approach has been greatly helped by the recent completion of the map of human genome. The principle is the cosegregation of two genes/loci (one of which is the disease locus) with measurable genomic recombination between them. The method involves comparison of the genome of siblings and/or relatives. A statistical approach to the analysis of the linkage can consider some parameters (such as penetrance or disease allele frequency) of the inheritance, which is called parametric (and non-parametric when inheritance is not considered).

Association studies

Association studies analyze the allele associated with disease susceptibility, the principle being that the prevalence of a certain marker will be higher in affected compared to nonaffected individuals. Association studies may be family based (transmission/disequilibrium test, or TDT; also called transmission distortion test) or population based, such as the candidate gene approach. Alleles, haplotypes, or evolutionary-based haplotype groups may be used in association studies.

GENETIC RISK STUDIES

The relationship between genes and hypertension can be assessed in several ways. The first assessment is the degree of association in families and the eventual interferences played by the environment. These studies require nuclear families (index case and parents), affected relative pairs (siblings, cousins, any two members of the family), extended pedigrees, twins (monozygotic and dizygotic), and unrelated population samples. This type of approach is called familial aggregation (e.g., higher occurrence rates in siblings or offspring). Other traditional designs for distinguishing non-genetic shared family effects from genetic effects are the studies of twins.

Familial aggregation

Familial aggregation for a disease is measured by the relative recurrence risk (RRR) or familial risk ratio (FRR). These represent the probability that a particular type of relative (sibling, cousin, and so on) of an affected proband has a disease, divided by the prevalence of the disease in general population. These are quantities denoted by λ_R , where R denotes a relationship (S = siblings, O = offspring, DZ = dizygotic twin, and so on) and whose values are the risks of relatives of type R of affected individuals being themselves affected divided by the population prevalence.

In hypertension, RRR (i.e., λ_S) is ~ 3.5 (12), whereas λ_O is ~ 2 . λ in other relatives is strongly influenced by ethnic and environmental confounding, making its estimation less reliable. No clear evidence on sex chromosomes has been gathered so far, nor has any for half-siblings. Therefore, although there is evidence of familial aggregation in hypertension it is not sufficient to infer the importance of genetic susceptibility because environmental and cultural influences can also aggregate in families—leading to family

clustering and excess familial risk. A similar environment is a major confounding factor in familial aggregation.

Investigation into the environmental component of blood pressure regulation is far from over. Several factors hinder a precise estimate of family aggregation. They can be related to the timing of assessment or to strong interaction of blood pressure with the surrounding environment. Among the possible examples is the change in the rate of concordance and age of offspring. For DBP, an apparent reduction in heritability from 68 to 38% from young adulthood to middle age results from the increasing impact of individual environmental experience, with little or no influence from shared family environment.¹³ A strong interaction between blood pressure and environment, also within the same family, is the conclusion of two studies^{13,14} in which a significant correlation in blood pressure between spouses has been demonstrated even after standardization for important environmental variables such as education, socioeconomic status, smoking, exercise, age, and salt consumption.¹³ Fava et al.¹⁵ made the interesting and paradigmatic observation that although many intermediate phenotypes of hypertension could be inherited this is untrue for office measurements, the usual way of diagnosing hypertension.

Twin studies

The study of hypertension in two distinct individuals sharing the same genetic background is a valued opportunity to differentiate the effects of environment and genes. To estimate the genetic contribution to a trait, the comparison of monozygotic (MZ) pairs (who share all their genes) with dizygotic (DZ) twins (who share half their genes) has been traditionally used. The greater similarity of MZ twins compared to DZ twins is considered evidence of genetic factors. In theory, complete genetic determination of a disease would equate to MZ twins having 100% concordance and DZ twins having 50% concordance. The usual assumptions of a classic twin study are random mating, no interactions between genes and environment, and equivalent environments for MZ and DZ twins or the sharing to an equal extent of the environmental experiences of the two types of twins that are relevant for the development of the trait.

In studying a complex trait, phenotypic variance is divided into these components: inheritability, a component due to inherited genetic factors (A), a shared environmental component due to environmental factors common to both members of the pair of twins (C), and a nonshared environmental component due to environmental factors unique to each twin (E), being $1 = A^2 + C^2 + E^2$. All available data on these studies are subject to interethnic, age, and sex differences. A standard measure of similarity for a discrete variable used in twin studies is the concordance rate. This can be pairwise (Pr) or probandwise (Cc).¹⁶ The Pr concordance is a descriptive statistic and simply gives the proportion of affected pairs that are concordant for the disease. It is calculated as the proportion of twin pairs (with both twins affected) of all ascertained twin pairs with at least one affected: $Pr = C/(C+D)$, where C is the number of concordant pairs

and D is the number of discordant pairs. The probandwise (Cc) concordance is the proportion of affected individuals among the co-twins of previously ascertained index cases. It allows for double counting of doubly ascertained twin pairs and has the advantage of being interpretable as the recurrence risk in a co-twin of an affected individual. The following formula is used in estimation: $Cc = 2C/(2C+D)$. Concordance rate in hypertension depends on categorizing hypertension as a dichotomous variable. In this case, however, the pairwise concordance rate was .36 and .08 in MZ and DZ twins, respectively, and probandwise concordance could be estimated as .53 and .07, respectively, in a Norwegian twin cohort.¹⁷

Other factors must be considered in this assessment as expressions of the increasing environmental role in blood pressure regulation (e.g., age at separation as an expression of increased influence of nonshared environmental component). An intrauterine environmental component such as the circulatory system might represent a first step in this evaluation. Chorionicity (i.e., the sharing of some circulatory system during intrauterine life) does not seem to influence blood pressure regulation in adult twins,¹⁸ but in a Japanese twins cohort the intrapair concordance rate for blood pressure decreased from 0.78 (age of separation 26 and over) to 0.51 (age of separation 0 to 5) as the age of separation decreased.¹⁹ Therefore, a unique and precise estimate of the rate of concordance is impossible to obtain. In spite of this, some other interesting data can be obtained comparing the correlation of blood pressure. Solid evidence exists showing that concordance (correlation) of SBP in MZ twins is ~0.8, whereas in DZ twins it is ~0.46 (19;20) or 0.60 and ~0.30 according to different studies^{20–23} (Table 35–1).

One study in Caucasians has evaluated the effects of shared and nonshared environmental factors. Although the inheritability of hypertension in this study is about 50%, a larger proportion of nonshared environmental influences affect both systolic (.07 and .46 for shared and nonshared, respectively) and diastolic blood pressure (.08 and .41, respectively).²¹

Snieder et al. and others focused on inheritability of hypertension in African (AA) and European American (EA) twins. SBP levels were comparable in the two groups,

as was the estimated inheritability of about 57%. The environmental component accounted for the remaining 43%. Negligible differences could be detected after standardization for body mass index (BMI) and were equal in AAs and EAs. On the contrary, diastolic blood pressure was higher in AAs, compared to EAs with an increased estimated heritability: 0.58 in AAs and 0.45 in EAs.²²

Migration studies

Although migration studies can be of interest in many diseases, in hypertension they have been controversial because blood pressure as a physiologic variable might change even with migration within the same environment (thus inducing an overestimation of the environmental effect). Although this might argue against a genetic control (showing an increase in blood pressure with no changes in genome), it should instead be seen as a typical gene/ environment interaction that reflects poorly the mechanisms of blood pressure regulation. One study showed an increase in blood pressure for both men and women. The previously cited differences were only partially explained by age, BMI, heart rate, smoking, and alcohol use. This study demonstrates an important effect of migration on the rise in blood pressure with age and on the prevalence of hypertension but is not of much help in evaluation of environmentally induced changes in hypertension.²⁴

SEGREGATION ANALYSIS

After assessing and quantifying the genetic risk in hypertension (i.e., the role of genes in both blood pressure regulation and hypertension in families), the next step is to define its mode of inheritance. The previously cited RRRs within families may provide an estimation of the possible segregation modes, but only segregation analysis using maximum likelihood techniques are suitable in evaluating hypotheses representing different sources of genetic influence.

Segregation analysis aims to find a similar inheritance pattern among families by looking at multigenerational family data. Segregation analysis is suitable for revealing Mendelian inheritance patterns (autosomal or sex-linked and recessive or dominant), non-classical inheritance (mitochondrial diseases, genomic imprinting, parent of origin effect, genetic anticipation, and so on), or nonMendelian inheritance (no pattern). An important issue addressed by this analysis is about the number of genes affecting hypertension. Is it a single major gene (oligogene) or many genes of small effect (polygenes)? Further components of a genetic model (transmission probabilities, penetrance of each genotype, and allele frequencies in the population) might or might not be known. Accordingly, statistical methods can take into account or not (model free) frequencies and penetrance of disease. The methods usually look for segregation analysis in families, and large multigenerational families are of course more informative than small ones.

A potential pitfall is that segregation analysis is most useful in single-gene disorders due to a biallelic gene, but

CORRELATION COEFFICIENTS OF ARTERIAL OF BLOOD PRESSURE OF MONOZYGOTIC (MZ) AND DIZYGOTIC (DZ) TWINS

when multiple loci with multiple alleles are involved (as in most complex diseases) it becomes less powerful and the results have to be cautiously interpreted. Moreover, there is a risk in analyzing families for complex traits such as hypertension of putting together different families with different origins for their conditions and thus obtaining a confused picture of inheritance. Segregation analysis is a prerequisite for linkage analyses. Development of more powerful and complete statistical packages might help in understanding the inheritance of the trait.

The most complete and recent study on essential hypertension comes from Crockford et al.²⁵ After Pickering, they performed the analysis considering segregation analysis under the liability model of hypertensive status as a qualitative trait and compared this with results using systolic blood pressure as a quantitative trait. Both analyses, qualitative (hypertension) and quantitative (systolic and diastolic blood pressure), identified models with major genes and polygenic components to explain the family aggregation of SBP. Neither one of the methods (qualitative or quantitative) estimated precisely the parameters, but both identified the most complicated model evaluated as the most accurate. The conclusion is that the true model is considerably more complicated than those available for the analysis. The important finding is that segregation analysis of hypertension using relatively simple models is unlikely to provide accurate parameter estimates because of polygenic components.

Forms of hypertension with a very clear inheritance pattern further complicate the scenario. These are called Mendelian forms of hypertension due to the clear pattern and are briefly reported in material following. As mentioned previously, the Mendelian forms are very rare. There are six single-gene (or Mendelian) forms of hypertension: Liddle syndrome, apparent mineralocorticoid excess (AME), glucocorticoid-remediable aldosteronism (GRA), mineralocorticoid-receptor-activating mutation (MRAM), and familial hyperaldosteronism types I (FH-I) and II (FH-II). We briefly overview the principal characteristics of such disorders. A detailed description is provided in Chapter 36.

Liddle Syndrome

In 1963, Grant Liddle (a physician at Vanderbilt University) found a Tennessee family in which several of the members had extremely high blood pressure and laboratory signs of hypokalemia, increased K^+ excretion and Na^+ retention, and reduced plasma renin activity, angiotensin II, and aldosterone. It is an autosomal dominant disorder that does not show any positive response to spironolactone administration. To date, 10 mutations have been identified on the *SCNN1B* and *SCNN1G* genes.²⁶

Apparent mineralocorticoid excess

Patients affected by AME1, whose clinical features were previously cited, have a congenital deficiency of 11β -hydroxysteroid dehydrogenase type 2 that inactivates cortisol. Those affected by AME2 present a diminished function of the enzyme.

Mineralocorticoid-receptor-activating mutation

This disorder consists of a substitution, leucine for serine, at codon 810 (S810L). This substitution modifies the shape and specificity of the MR so that as opposed to normal subjects progesterone and spironolactone can activate the MR. The net result is the onset of early hypertension, particularly worse during pregnancy.²⁷

Glucocorticoid-remediable aldosteronism or familial hyperaldosteronism type I

GRA, also called familial hyperaldosteronism type I, is inherited as an autosomal dominant trait. The syndrome consists of an early onset of hypertension, low renin values, and hyperaldosteronism (which can be counterbalanced with glucocorticoids). The syndrome is caused by a chimeric gene deriving from a crossing-over between the promoter of the 11β -hydroxylase (*CYP11B1*) and the coding of aldosterone synthase activities (*CYP11B2*).²⁸

Pseudohypoaldosteronism type II or familial hyperaldosteronism type II (Gordon Syndrome)

Pseudohypoaldosteronism type II, also called Gordon syndrome,²⁹ is another rare Mendelian syndrome consisting of hypertension, hyperkalemia, hyperchloremia, and metabolic acidosis. It is counterbalanced with thiazide diuretics that inhibit the sodium chloride reabsorption in the kidney. The disorder is caused by mutations in two genes (*WNK1* and *WNK4*) that encode the protein kinases.³⁰

In conclusion, the genetic model best describing the transmission pattern of hypertension is called multifactorial (i.e., consisting of a polygenic model interacting with the environment). A polygenic model is a model in which many small equal and additive loci would result in Gaussian distribution for a phenotype whereas a few other loci might be responsible for rare forms of hypertension. This model applies to other complex diseases (such as diabetes, schizophrenia, or cancer) in which both multiple genes and environmental factors play a role in the development of the disease. Hypertension is presumed to result from additive effects of multiple genes with low penetrance and various, but generally weak, impact on phenotype. Individual mutations may not induce any particular phenotype but may produce a disease phenotype when they act in concert and in the presence of the necessary environmental conditions.

The last stage in genetic epidemiology of hypertension is the identification of the genes and of their variants modulating blood pressure and generating hypertension. No consensus has emerged about the best strategy for identifying complex disease genes.³¹ The issues relate to the total number of SNPs or genetic variations in the human genome and to the subset of SNPs on which to focus in disease association studies. The enormous bulk of studies aiming at identifying these genes can be broadly grouped into two types of studies. In the terminology of Peltonen and McKusick³² they can be defined as map based or sequence based.³³

These two definitions relate to different questions: the first asks where the genes are that are associated with the condition and the second asks which are the genes associated with the condition. The tool applied in the map-based strategy is the recombination fraction, whereas linkage disequilibrium (LD) forms the basis of sequence-based studies. However, the two approaches proceed from a similar assumption: the genetic marker studied is close to the actual disease gene and this will result in an allelic association at the family or population level. Another critical assumption of both strategies is that there is little allelic heterogeneity within loci.

Two approaches to the map-based strategy have evolved for traits showing Mendelian and non-Mendelian segregation patterns: (1) those that require prior specification of mode of inheritance for the trait under study (model-based/parametric methods) and (2) those that do not assume a specific trait inheritance (model-free/nonparametric methods). The latter are useful for initial exploratory analysis, and the former for more detailed multivariate geometric analysis.

MAP-BASED STRATEGY

During meiosis, genetic material undergoes recombination. Thus, adjacent loci or alleles within two homologous but separate chromosomes can be recombined and segregated into the same chromosome. If two adjacent markers are close, there will not be much recombination between them and they will cosegregate. Markers adjacent to a locus carrying the condition will segregate more often with the condition than those far apart. The recombination fraction (denoted as θ and measured in Morgans or, more commonly, in centiMorgans, cM) between the known genetic locus (marker, or Aa) and the unknown disease locus (gene, or Bb) lies at the heart of map-based analyses. The Morgan unit expresses a genetic distance based on recombination, not a physical distance, although it can be estimated that 1 cM corresponds to about 1 million bases. If the two loci are far apart or are in different chromosomes, segregation of one locus will be independent of the other (they are equally likely to cosegregate as not to). At $\theta = 1/2$ (0.50) four types of gametes (AB, ab, Ab, and aB) two recombinant and two nonrecombinant for a total of four from a pair of homologous chromosomes are equally likely to be produced.

This ($\theta = 1/2$) is the baseline value in linkage studies where the proportion of gametes the person transmits in which a recombination has occurred is 50% (and the other 50% has no recombinants). Fifty percent is the possibility of two loci in two different chromosomes to cosegregate into a gamete. Linked loci are transmitted to the same gamete more than 50% of the time ($0 = \theta < 1/2$), and the “parental-type” gametes are more frequent than the “recombinant-type” gametes. Model-based linkage analysis is based on a likelihood ratio, and the logarithm to base 10 of this likelihood ratio is called a Logarithm Of oDds (LOD) score. This is the logarithm of the ratio of a particular value of the recombination fraction versus free recombination (i.e., $\theta = 0.5$). Obviously,

numerous LOD scores can be obtained for a range of θ values. Whichever θ maximizes the LOD score, this is the evidence for linkage with the particular recombination frequency (θ) between the marker and the disease locus. LOD scores >1 are considered nominal evidence of linkage, LOD scores >2.2 as suggestive evidence, LOD scores >3.6 as genome-wide evidence, and LOD scores >5.4 as confirmed linkage. Linkage might lead to an association of a certain area with the condition, but this is usually intrafamilial. The association at the population level (linkage of genotype for a genetic marker to disease) might not be consistent.

The magnitude of linkage is affected by many factors, but if everything else is assumed to be equal the most important factor is the physical/genetic distance between the disease and marker alleles. The closer they are the lower the recombination frequency and the stronger the magnitude of linkage. This implies that close linkage between the marker and disease loci would result in longer periods of linkage disequilibrium within the population.

Within a model of multiple interacting loci, no single locus could account for more than a fivefold increase in the risk of first-degree relatives. Research strategies for detection of susceptibility genes in hypertension are important to be known, because some limitations might be important in understanding the disappointing results obtained thus far. Linkage studies aim to obtain a crude chromosomal location of the gene or genes associated with a phenotype of interest (e.g., a genetic disease or an important quantitative trait). Linkage is a phenomenon of cosegregating loci, not alleles, within families. Linkage studies are used for coarse mapping because they have a limited genetic resolution of about 1 cM. If two markers are close, there will not be much recombination between them and they will cosegregate. This results in a positive result in linkage analysis. This principle has been used in studies examining some areas of the genome, and in recent years (thanks to the completion of the human genome project and to technological advances) to the entire genome.

GENOME-WIDE SCAN

The genome-wide scan is best defined as a search for quantitative trait loci across the entire genome. The quantitative trait locus (QTL) is a chromosomal region containing a gene or genes that influence a trait of interest such as hypertension. This search is best performed comparing genomes of siblings or otherwise related subjects discordant for the trait or the disease. However, other study designs such as nuclear families, large pedigrees, and studies of normotensive sibling pairs have also been performed.³⁴ Genome-wide screens analyze hundreds of polymorphic markers, usually microsatellites, in a selected sample of individuals with or without a qualitative or quantitative trait. In contrast to candidate gene studies (see material following), a genome scan is designed primarily to detect genes not previously implicated in pathologic or physiologic regulation of blood pressure. The entire genome is

THE RESULTS OF GENOME-WIDE SCAN STUDIES						
Chrom.	Number of Loci	Lod Range Hypertens	Number of Loci	Lod Range Diastolic	Number of Loci	Lod Range Systolic
1	4	1,2–1,78	–	–	1	2,2

Y	–	–	–	–	–	–

Chrom. = chromosomes, number of loci = number of loci linked to the condition in the different studies, and lod range = range of lod scores measured within the chromosome and associated with hypertension and with diastolic and systolic blood pressure.

Table 35–2. The Results of Genome-Wide Scan Studies

screened with densely distributed microsatellite markers in order to detect linkage of groups of markers with the trait of interest. The density of markers and the throughput of marker genotyping have increased over the years, and the cost of marker genotyping has decreased, further facilitating QTL mapping by marker locus approach. Thus, availability of dense markers, high-throughput genotyping, and cost are no longer limiting factors for performing genome-wide scans for positional mapping of QTLs. The major problems at this time seem to be the difficulty of gathering high-quality phenotype data in a sample of adequate size using an appropriate study design and the analysis of these data using a method with high statistical power.

The locus approach, or whole-genome screening, due to availability of polymorphic markers and refinements of statistical methods is becoming very popular and several GWS have been published in the recent years (several reviews have focused on them).^{35–37} Each genome scan published differs in the number of subjects studied, ethnicity, family types, design, and the phenotypic strategy, some considering hypertension as a discrete trait and some considering blood pressure as a continuous variable.

Out of 23 chromosomes, at least 21 have some identified loci in linkage with hypertension, and some have been found in more than one study. Of course, involvement of a chromosome is quite far from identification of a gene. Even if some of the loci are going to survive grid tightening and metanalysis,³⁵ inconsistency of the findings and lack of comparability with other strategies represent a poor result for such effort.

The main results are reported in Table 35–2. No agreement on the loci involved has been reached considering all studies performed thus far, but a separate metanalysis for Caucasians seems to identify certain QTL in chromosomes 2 and 3 as linked to hypertension.³⁵ The major effort for the future will be to try matching the loci identified with map-based strategies with those identified with candidate gene strategy.

ASSOCIATION STUDIES

Linkage analysis is not useful for finding so-called susceptibility loci (i.e., loci that are neither necessary nor sufficient for disease expression). Association studies evaluate and compare allelic genetic frequencies as well as haplo-

type in affected and nonaffected subjects. Association studies have some practical advantages over linkage studies. Knowledge about the mode of inheritance of the disease is not required and this type of study has the necessary statistical power in order to detect genes of weak effect. Reliability of the results of an association study are linked, independently, to the good number of patients studied, to the ethnic homogeneity of the population studied, to large data sets, to small P values, and (most important) to independent replication of results.

Association studies allow a fine mapping and identification of the genes. Association may be detected as direct involvement of the gene or as in linkage disequilibrium (LD) with the gene at the population level. The classical association study is the case control study or candidate gene approach. In the candidate gene approach (or association studies) genes coding for proteins that are physiologically or biochemically relevant to the trait (defined candidate genes) are screened and the effects of variant alleles on the QT are investigated.

CANDIDATE GENE APPROACH

At present, association studies are the only means of confirming a functional role for a candidate gene in human populations. Even then, a confirmed association does not necessarily imply proof of cause. At best, it suggests a cause. This general limitation should be borne in mind among those who seek to unfold the pathophysiologic basis of hypertension in humans through genetic studies. The main concerns with this approach are as follows.

- The approach requires a good knowledge of the trait and of the related biochemical or physiological pathways, which rarely exists.
- The approach cannot lead to the detection of new QTLs.
- In theory, all genes could be analyzed. Further, every SNP or polymorphism should be analyzed, increasing enormously the risk of type I statistical error.
- Although this approach seems attractive, there is not yet sufficient evidence to support its general utility, at least not in human hypertension.

In spite of these limitations, this type of approach is the most used in the genetic assessment of hypertension. A bibliographical search offers more than 2,000 studies (discounting reviews; a listing can be found on the Web at <http://www.ncbi.nlm.nih.gov/entrez/dispmim.cgi?id=145500>) (see Box 35–2).

Even if a generalization cannot be discerned, given the different role of each protein it must be recognized that discordant results are often published, and the more the research goes on with genetic polymorphisms the more the enthusiasm topples. A paradigmatic example is the angiotensinogen polymorphisms. The angiotensinogen gene (AGT) is a thrifty gene, which increases the risk for common disease with growth of civilization via sodium and body fluid retention. Four different polymorphisms [A(-20)C, G(-6)A, T174M, and M235T] have been described in this gene, and their effect on blood pressure is contradictory: a double heterozygosity for Thr235 and

- Beta2-adrenergic receptor

Thr 174 increases by 10% the angiotensinogen plasma levels^{38,39} and is a risk factor for hypertension, but only in males. Presence of the -6A allele or the AGT 235T allele was associated with the most pronounced SBP response to atenolol treatment (P = .001 when -6 AA+AG was compared with GG and P = .008 for presence of the 235T variant compared with 235 MM).⁴⁰ Moreover, M235T is in linkage disequilibrium with allelic variants of AGT such as A-6G and A-20C, which account for different expression of the protein.^{41–44} In spite of all of this early evidence, two meta-analyses^{38,45} showed that allele 235T does increase the risk of hypertension, but only in Caucasians. The authors, however, raise much concern on publication bias and confounding, inviting a very cautious interpretation of the results. This skepticism has been confirmed in a recent large study (10,000 individuals), which did not reach any evidence of a role of these PM in blood pressure regulation, or incidence of vascular events.⁴⁶ For some

authors, this was the final word on the angiotensinogen polymorphisms.⁴⁷

Similarly, deletion insertion of 287 bp in intron 16 (D/I polymorphism) in ACE (on chromosome 17q23) showed some interesting data, but these results were not confirmed by other studies. A deletion seems associated to genetic risk for vascular disease but not for hypertension. Differences among subjects are ethnically related. Several studies have resequenced the gene and have shown more single-nucleotide polymorphisms in codifying and non-codifying regions;⁴⁸ but the conclusion should be that the D/I polymorphism has been demonstrated to affect plasma activity of ACE but not blood pressure or risk of vascular events.⁴⁹ Similarly, ACE I/D polymorphism is not a useful marker for predicting antihypertensive treatment response.⁵⁰

The general picture obtained is frustrating: limited evidence of genetic variants that determine hypertension have so far been found from both genome-wide scan and from association studies. Moreover, genomic studies did not reach a consensus on the likely location of blood pressure genes. Many reasons have been put forward to explain these results. Causative genes are numerous, have small clinical impact, and are unevenly distributed among populations. However, the fact that in other diseases or conditions many polymorphisms in many diseases cannot be confirmed after the first publication⁵¹ should induce researchers to revise the methodology applied thus far.

SUMMARY

Hypertension genetics still has many unexplored aspects, and many questions require further research. Genetic modeling of hypertension is enormously complex. Nevertheless, there is little doubt that hypertension is a multifactorial disease involving the interaction of the environment with several independent genetic variants. In rethinking approaches to genetics of hypertension it is helpful to consider that understanding the genetic aspects of multifactorial diseases has been a major challenge in other complex diseases—such as asthma, complex autoimmune diseases, cancer, and atherosclerosis, all of which have shared the same disappointing results. The lack of consistency between map- and sequence-based strategies might be due to inadequate statistical approaches or phenotypic characterization, but it is likely that more generalized problems vex the identification of genes

underlying complex traits.^{52,53} The most relevant of these are as follows.

- A number of genotypes or mutations/polymorphisms at different loci (which likely impact different physiological systems) must be transmitted to an individual before his/her system is sufficiently challenged to result in disease. Thus, despite the arbitrary nature with which blood pressure criteria are used to diagnose hypertension it may be necessary to have a number of genes before blood pressure will surpass these arbitrary thresholds. It may also be the case that number of genes must be had before additional pathologies associated with coronary heart disease (e.g., vascular damage) appear. This is called classical polygenic (or threshold) inheritance.
- Locus heterogeneity, in which defects in any of a number of genes or loci can confer disease susceptibility independently of each other. Thus, under heterogeneity individuals with similar phenotypic features or disease states may possess different genetic variants that lead to the disease.
- Gene interaction, in which the possession of a certain mutation or genotype will confer susceptibility to a degree dictated by the presence of other mutations or genotypes. This phenomenon (called epistasis) reflects basic interactive effects of mutations, genotypes, and/or their biological products.
- Gene/environment interactions occur when an allele or more alleles (haplotypes) have their deleterious effects only when the carrier is exposed to particular environmental stimuli.
- Time-regulated gene expression. A gene, whether in mutant/polymorphic form or not, has its most pronounced and deleterious effect at a certain developmental stage (e.g., puberty).

The possibility of having to deal with polygenic inheritance, heterogeneity, epistasis, and developmental effects in gene mapping and characterization studies is a major point for genetic epidemiologists and researchers. Traditionally, modeling and research have mainly focused on the testing of individual genes or genomic regions. Only recently have multiple genes or environmental factors been considered to influence particular traits. Available statistical models and methods are still not suitable for including so many variables and will probably need to accommodate an even wider array of complexities in the future in order to be realistic and useful.

Monogenic Forms of Human Hypertension

Beverley Burke, Johannie Gungadoo, Ana Carolina B. Marçano, Stephen J. Newhouse, Julian Shiel, Mark J. Caulfield, and Patricia B. Munroe

Definition

Monogenic forms of hypertension are rare inherited conditions with high blood pressure as part of the phenotype.

Key Findings

- The mutated gene product usually leads to incorrect electrolyte handling in the kidney.
- The phenotype of each condition can be variable.
- Key features of each include abnormal potassium levels (high or low), suppression of plasma renin, metabolic alkalosis or acidosis, abnormal aldosterone levels, and sodium retention.
- The ongoing elucidation of monogenic forms of hypertension is providing knowledge about new mechanisms of blood pressure control.

A monogenic disease can be defined as an inherited condition caused by a modification in a single gene. There are over 10,000 monogenic diseases that have been described, and although many are extremely rare they affect millions of people worldwide.¹ In the field of hypertension, there are 10 monogenic diseases that have high blood pressure as part of the phenotype. All diseases have now been defined at the molecular genetic level (Table 36–1). They include glucocorticoid remediable aldosteronism (GRA),² Liddle’s syndrome,³ pseudohypoaldosteronism type II (Gordon’s syndrome),⁴ congenital adrenal hyperplasia (CAH)-11 β hydroxylase deficiency⁵ and -17 α hydroxylase deficiency, apparent mineralocorticoid excess,⁷ the mineralocorticoid receptor in hypertension exacerbated in pregnancy,⁸ hypertension with brachydactyly,⁹ hypertension associated with peroxisome proliferator-activated receptor gamma mutations¹⁰ and more recently hypertension, hypercholesterolemia, and

MONOGENIC FORMS OF HYPERTENSION

Condition	Mode of Inheritance	Location	Gene and Reference
Glucocorticoid remediable aldosteronism	Autosomal dominant	8q24.3	11 β -hydroxylase/ aldosterone synthase (CYP11B1/CYP11B2) chimera ²
Congenital adrenal hyperplasia with 11 β -hydroxylase deficiency	Autosomal recessive	8q24.3	11 β -hydroxylase (CYP11B1) ⁵
Congenital adrenal hyperplasia with 17 α -hydroxylase deficiency	Autosomal recessive	10q24.32	17 α -hydroxylase (CYP17A1) ⁵
Apparent mineralocorticoid excess	Autosomal recessive	16q22.1	11 β -hydroxysteroid dehydrogenase (HSD11B2) ⁷
Gordon’s syndrome	Autosomal dominant	12p, 17q, 1q	Protein kinase, lysine deficient 1 and 4 (WNK 1, WNK 4) ⁴
Liddle’s syndrome	Autosomal dominant	16q	Sodium channel nonvoltage-gated 1, β and γ subunits (SCNN1B, SCNN1G) ³
Hypertension exacerbated by pregnancy	Autosomal dominant	4q31.23	Mineralocorticoid receptor (NR3C2) ⁸
Hypertension associated with PPAR γ mutations	Autosomal dominant	3p25	Peroxisome proliferator-activated receptor gamma (PPAR γ) ¹⁰
Hypertension and brachydactyly	Autosomal dominant	12p	Unknown ⁹
Hypertension associated with mitochondrial mutations		Mitochondrial genome	Mitochondrial tRNA isoleucine gene ¹¹

Table 36–1. Monogenic Forms of Hypertension

hypomagnesemia associated with mitochondrial gene mutations.¹¹ An interesting feature of most of these conditions is that the disease causing mutation directly affects salt/water homeostasis in the kidney.

Reabsorption of sodium and chloride from the bloodstream in the kidney is achieved through an integrated system of ion channels, exchangers, and transporters distributed throughout the length of the nephron (Figure 36–1).¹² The distal nephron consists of the distal convoluted tubule (DCT), the connecting tubule (CNT), and segments of the cortical collecting ducts (CCD). It is in the distal part of the nephron that the final adjustments to net renal sodium balance are achieved. In other words, the distal nephron is of critical importance in the maintenance of sodium homeostasis. The two main ion transport systems in this part of the nephron are the electroneutral apical thiazide-sensitive NaCl co-transporter (NCCT) and the renal

amiloride-sensitive epithelial sodium channel (ENaC).¹³ In the late distal tubule, NCCT and ENaC expression overlap. Fine control of sodium reabsorption is provided by modulating the activity of NCCT and ENaC via aldosterone and the mineralocorticoid receptor (MR). In turn, this is under the influence of the renin-angiotensin-aldosterone system.¹⁴ Sodium uptake in the distal tubule is closely linked to potassium and hydrogen ion secretion. Altered function in any of the ion transport proteins, or their regulators, participating in sodium reabsorption will affect blood pressure.

In this chapter we review the monogenic forms of hypertension caused by mutations in proteins now known to affect the regulation of salt/water homeostasis in the kidney: GRA, Liddle's syndrome, Gordon's syndrome, and two forms of CAH that have hypertension as part of the phenotype; namely, 11 β -hydroxylase deficiency

Figure 36–1. The major sites of sodium reabsorption in the mammalian kidney tubule. The distal nephron is of critical importance in the maintenance of sodium homeostasis. This diagram illustrates the structure of the nephron, indicating the location of the thick ascending limb of Henle (TAL), the distal convoluted tubule (DCT), and the cortical collecting duct (CCD). The key channels that regulate sodium homeostasis are the sodium chloride co-transporter (NCCT) and the epithelium sodium channel (ENaC). The renal outer medullary potassium channel (ROMK) is a key channel regulating potassium flux. The channels/hormones mutated in Gordon's syndrome, Liddle's syndrome, and GRA are indicated in italics. Also indicated is the renin-angiotensin system (RAS) because this is the major regulator of renal salt reabsorption. Other abbreviations: ACE (angiotensin-converting enzyme), MR (mineralocorticoid receptor), Na⁺ (sodium ion), Cl⁻ (chloride ion), and K⁺ (potassium ion). (Modified from Cope et al. WNK kinases and the control of blood pressure. *Pharmacology & Therapeutics* 2005;106:221–31.)

(11-OHD) and 17 α -hydroxylase deficiency (17-OHD). Genetic, pathophysiologic, and clinical aspects are discussed for each disorder. The remaining five monogenic forms of hypertension are briefly discussed in the summary.

GLUCOCORTICOID REMEDIABLE ALDOSTERONISM

Definition

Glucocorticoid remediable aldosteronism (GRA), also known as familial hyperaldosteronism type I (OMIM: 103900), was first described in 1966.¹⁵ It is an autosomal dominant condition characterized by elevated levels of circulating aldosterone (despite suppressed plasma renin levels), metabolic alkalosis, hypokalemia, hypertension, risk of stroke at a young age, and high levels of the adrenal steroids 18-hydroxycortisol and 18-oxycortisol. The symptoms of the disorder can be reversed by glucocorticoid (dexamethasone) administration.¹⁶

Genetics

Lifton and colleagues discovered the genetic mechanism causing GRA in 1992.^{2,17} Analysis of one large multi-generational pedigree with GRA revealed a novel fragment of the 11 β -hydroxylase gene, CYP11B1, to be present only in affected individuals. Linkage analysis using this fragment as a marker demonstrated complete linkage to GRA with a LOD score of 5.23. Subsequent investigations found this fragment to be part of a chimeric gene consisting of the 5' tissue-specific and regulatory sequences of 11 β hydroxylase (CYP11B1) and the coding sequence of aldosterone synthase (CYP11B2). The chimeric gene segregated with the disease phenotype and it was postulated that the gene product was the likely cause of GRA.¹⁸ Eleven additional GRA kindreds were subsequently tested for the chimeric gene in order to prove this was the disease causing mutation.¹⁷ Southern blot analysis revealed all affected individuals to have a chimeric gene. Sister and non-sister chromatid exchange was determined as the mechanism by which the chimeric gene was formed.¹⁷

The sequence 3' of exon 5 in CYP11B2 is crucial for the preservation of the CYP11B2 activity,¹⁹ and the sequence 5' of intron 2 of CYP11B1 is thought to be sufficient to ensure expression in *zona fasciculata* and responsiveness to ACTH. The crossover site of the chimera therefore ranges from intron 2 to intron 4 of CYP11B1 in GRA. Since the cause of GRA was originally described, there have been several other reports of pedigrees with the CYP11B1/CYP11B2 chimeric gene from different ethnic groups.^{20,21}

Physiology and pathophysiology

Aldosterone is a mineralocorticoid hormone expressed in the *zona glomerulosa* of the adrenal gland, and its production is regulated by angiotensin II and potassium. Its main function is to control salt/water homeostasis, blood pressure, and extracellular fluid potassium. Cortisol

is a glucocorticoid hormone, synthesized in the *zona fasciculata* of the adrenal gland. It is under the control of adrenocorticotrophic hormone (ACTH), and its function is to regulate the stress response, energy metabolism, and blood pressure control. The genes encoding CYP11B1 and CYP11B2, which are 95% identical, catalyze the final steps in the production of cortisol and aldosterone, respectively.²² Cortisol and aldosterone have similar affinities for binding to the mineralocorticoid receptor (MR), which is responsible for the fine control of renal salt reabsorption (see Chapter 23). Plasma concentrations of cortisol are normally/physiologically 100 to 1000 times higher than aldosterone. Thus, it is aldosterone that regulates the MR, and therefore the amount of salt retained by the body, under normal circumstances.²³

In GRA, the chimeric gene allows aldosterone to be ectopically expressed in the *zona fasciculata* while being regulated by ACTH. This increase in aldosterone production causes the MR to be hyperactivated, resulting in the retention of salt and water by the kidneys and therefore volume-expansion hypertension.¹⁷ However, it appears that high blood pressure in GRA is caused not just by excess aldosterone secretion. Two biochemically unique "hybrid steroids" may also be important.²⁴ 18-oxocortisol and 18-hydroxycortisol are created by the exposure of cortisol and corticosterone to aldosterone synthase activity in the *zona fasciculata*. These compounds are thought to have mineralocorticoid receptor activity, thereby contributing to the salt retention and subsequent high blood pressure.²⁵

Clinical implications and perspectives

The clinical phenotype of GRA is variable. Cerebrovascular complications (including hemorrhagic stroke) can occur at an early age, and the resultant ruptured intracranial aneurysms are significant events of mortality and morbidity.²⁶ The hypertension in GRA ranges from moderate to severe. However, it can be completely alleviated by suppressing steroid production in the inner cortical zones with a low-dose glucocorticoid such as dexamethasone. The administration of potassium-sparing drugs or mineralocorticoid receptor antagonists may be required instead of glucocorticoids to avoid disrupting growth in the young.²⁷

Diagnosis of GRA is now primarily by genetic analysis using a long template PCR method or Southern blotting.^{17,28} Previous diagnostic criteria (including measuring the urinary hybrid steroids 18-hydroxy/oxosteroids and the dexamethasone suppression test) have been shown to lack 100% specificity.^{16,29}

Although all anomalies of GRA can be remedied by glucocorticoid administration, the phenotypic consequence of harboring the chimeric gene is yet to be fully understood. Blood pressure variation has been described between GRA patients within the same family, and recently normotensive individuals carrying the chimeric gene have been identified.³⁰ These latest findings raise the question of additional undetermined genetic and/or environmental factors being involved in regulating blood pressure in such individuals.

LIDDLE'S SYNDROME

Definition

Liddle's syndrome (pseudohypoaldosteronism, OMIM: 177200) was first described in 1963 in a single kindred.³¹ It is an autosomal dominant disorder characterized by early onset hypertension, hypokalemic metabolic acidosis, and suppressed plasma renin and aldosterone levels.³² All affected individuals respond well to triamterene or amiloride, which are specific inhibitors of the epithelial sodium channel (ENaC), suggesting that defects in this channel or its regulators may cause the condition.³

Genetics

In 1994, Shimkets and colleagues found mutations in the β subunit of ENaC to cause Liddle's syndrome.³ Using Liddle's original kindred, complete genetic linkage was found with the gene encoding the β subunit of ENaC on chromosome 16, with a LOD score of 7.62. Mutation analysis revealed a novel variant to be present in affected individuals, but it was absent in the unaffected members of the family. Direct sequencing of this variant revealed a single base substitution, a C→T transition at the first nucleotide of codon Arg-564. This mutation was predicted to introduce a stop codon, causing 75 C-terminus amino acids to be deleted from the protein. Analysis of four further Liddle's kindreds found frameshift mutations or premature stop codons in the same region of this gene, confirming that mutations in the gene encoding the β subunit of ENaC caused Liddle's syndrome.³

Mutations were not found in the β subunit of ENaC in all families with Liddle's syndrome, suggesting the condition may be genetically heterogeneous. This was confirmed in 1995 when Hansson and colleagues discovered the β and γ subunits of ENaC to be closely linked on chromosome 16, and a nonsense mutation to be present in the γ subunit in affected members of a Liddle's kindred.³³ The single base substitution was at codon Trp-574, and this was predicted to lead to deletion of the last 76 amino acids of the protein. This mutation was in a location (i.e., the carboxy terminus of the protein) similar to those found in Liddle's patients with the β subunit mutations.

Thirteen mutations have now been reported in the gene encoding the β subunit (SCNN1B): missense, frameshift, and premature stop codons. Three mutations have been reported in the gene encoding the γ subunit (SCNN1G).^{34,35}

Physiology and pathophysiology

The amiloride-sensitive epithelial sodium channel (ENaC) plays a critical role in controlling salt/water homeostasis, extracellular volume, and blood pressure and is regulated by the hormones aldosterone and vasopressin in the distal nephron of the kidney.³⁶ ENaC is a heterotrimer composed of three subunits (α , β and γ) in a ratio of 2:1:1. The subunits share 32 to 37% amino acid identity. Each subunit consists of a short intracellular amino terminus, a short carboxy terminus, two transmembrane regions, and an extracellular loop.³⁷ Studies in *Xenopus laevis* oocytes have demonstrated that the α subunit alone has the ability

for sodium conductance, whereas the β and γ subunits augment the channels' activities.

Functional studies illustrating a potential mechanism by which mutations in the β and γ subunits of ENaC lead to Liddle's syndrome were published in 1995.^{33,38} A mutated β subunit was coexpressed in *Xenopus laevis* oocytes with rat wild-type α and γ subunits. Similarly, a mutated γ subunit was coexpressed with rat wild-type α and β subunits. Analysis revealed marked increases in amiloride-sensitive sodium current (five- to sixfold) and increased numbers of ENaC channels at the cell surface (two- to threefold) of both mutants compared to the wild type. Increased activity of ENaC is predicted to lead to increased sodium reabsorption and hypertension, the primary clinical features observed in Liddle's syndrome.

The *Xenopus laevis* oocyte studies demonstrated that mutant ENaC have increased activity and numbers at the cell surface compared to wild-type receptors. However, the reasons were not determined. Since then, there have been a few other studies focusing on delineating the precise mechanism. All mutations causing Liddle's syndrome affect a conserved proline-rich sequence PPPXY (PY motif) present on β and γ subunits. Proline-rich motifs such as those observed in ENaC subunits are thought to be involved in protein-protein interactions.

Nedd 4 is a widely expressed ubiquitin-like ligase. In 1996 it was shown that WW domains of Nedd4 directly interact with the PY motif of ENaC.³⁹ As mutations in Liddle's patients disrupt the PY domain, a mechanism proposed to explain the increased numbers of ENaC receptors at the cell surface and hence overactivity of the channel is that ENaC is not being effectively removed via the ubiquitination pathway from the cell surface.⁴⁰ More recently, a Nedd4-like protein has also been shown to directly interact via PY motifs in ENaC *in vitro*, suggesting that more than one pathway may be important for downregulation of ENaC.⁴¹ One mechanism proposed to explain increased amiloride-sensitive sodium current in Liddle's patients is that mutant ENaC are not totally inhibited by intracellular sodium ions compared to wild-type ENaC, which is known to be downregulated by intracellular sodium levels.⁴²

Clinical implications and perspectives

The clinical phenotype of Liddle's patients is variable and can also vary within families. However, the primary feature in most cases is hypertension. This is usually early-onset and severe, although there are also cases with mild hypertension.^{3,33,43} Hypokalemia is found in most cases, but it is not always present.^{43,44} Therefore, the diagnosis of Liddle's syndrome can be difficult, and it is best made by taking a full clinical history, checking for multiple family members with the condition, measurement of blood pressure and tests for hypokalemia, reduced plasma renin activity, and suppressed plasma aldosterone levels. Genetic screening is also useful because mutations causing Liddle's syndrome all cluster in the carboxy terminus of the protein, which enables easy screening by direct sequencing.

Administration of the ENaC antagonist amiloride or triamterene in combination with a low-salt diet corrects the abnormalities observed in Liddle's patients.⁴⁵ It has also

been shown that small doses of amiloride can control blood pressure effectively in the long term, can correct plasma potassium, and can increase plasma renin. However, plasma aldosterone levels remain low.⁴⁶

GORDON'S SYNDROME

Definition

Gordon's syndrome, also known as pseudohypoaldosteronism type II or PHA2 (OMIM: 145260), is an autosomal dominant disorder characterized by salt-dependent hypertension, hyperkalemia (despite normal glomerular filtration rate) due to impaired potassium excretion, and metabolic acidosis due to decreased urinary H⁺ excretion.⁴⁷ Suppressed plasma renin activity and hyperchloremia are variable associated findings.⁴⁸ The clinical features of PHA2 are chloride dependent and can be corrected with thiazide diuretics, which inhibit salt reabsorption in the distal nephron.^{49,50} The thiazide diuretics are specific inhibitors of NCCT activity, and patients with PHA2 are extremely sensitive to these drugs. This suggested that increased NCCT activity could be responsible for some of the associated PHA2 phenotypes.

Genetics

PHA2 loci have been mapped in different families to chromosomes 1q31 to 1q42 (referred to as PHA2A), 17p11 to 17q21 (PHA2B), and 12p13.3 (PHA2C).^{51,52} Not all PHA2 kindreds map to these regions, suggesting that at least one other (as yet unidentified) PHA2 locus may exist.⁵³ There are therefore at least four different genes that can cause PHA2. Wilson and colleagues discovered two PHA2 genes in 2001.⁴ In their study, mutations in two members of a novel family of serine/threonine kinases—WNK1 (OMIM 605232, encoded by *WNK1*) and WNK4 (OMIM 601844, encoded by *WNK4*)—were shown to cause PHA2C and PHA2B.

Wilson et al. studied a PHA2C kindred that included 10 living members with typical features of PHA2.⁴ Genome-wide linkage analysis in this pedigree revealed complete linkage of PHA2 to a locus at the telomeric segment of chromosome 12p, with a multipoint LOD score of 5.07. The affected family members had a deletion in the interval between markers D12S341 and D12S91. Closer examination of this region revealed affected family members having a 41-kb deletion within intron 1 of the newly discovered WNK1 gene.⁴ Another PHA2C kindred had a 21-kb deletion in the same gene. These deletions were not detected in any unaffected family members, and no WNK1 coding mutations were identified in any of the affected members.

Using bioinformatics tools, a WNK1 paralog was discovered and was identified as the *WNK4* gene.⁴ This gene mapped to chromosome 17q21, a region that had previously been linked to PHA2B. Examination of the *WNK4* gene in four PHA2B kindreds linked to chromosome 17q21 identified four missense mutations that cosegregated with the disease. All of the mutations result in a change of amino acid. Three of these mutations (Glu562Lys, Asp564Ala, and Gln565Glu) lie within exon 7 of the WNK4 gene—in a small

stretch of amino acids that is highly conserved among all members of the human WNK kinases, as well as their known orthologs in mouse and rat. The fourth mutation (Arg1185Cys) lies within exon 17 at a residue conserved between the WNK kinases in the second coiled-coil domain (see material following). None of these mutations was identified in any unaffected family members.⁴ Since the discovery of mutations in WNK1 and WNK4 causing Gordon's syndrome, only one novel mutation in WNK4 has been reported. Golbang and colleagues (2005) recently reported a missense mutation in exon 7 (Asp564His) in another affected kindred.⁵⁴

Physiology and pathophysiology *WNK kinases*

The recently discovered WNK kinases comprise a small group of unique protein serine/threonine kinases.^{55,56} Protein kinases are a superfamily of proteins that regulate the activity of other proteins by phosphorylating certain amino acid residues (serine, threonine, or tyrosine) in specific target proteins. Protein kinases play important roles in signal transduction pathways, activated in response to extracellular signals (e.g., cytokines and growth factors), to regulate almost every cellular function—including cell proliferation, apoptosis, metabolism, gene expression, cell-cell communication, and membrane transport.⁵⁷ Most serine/threonine kinases share a highly conserved catalytic domain of 250 to 300 amino acids subdivided into 12 domains, with several residues that are usually invariant.⁵⁸ One of these is a crucial lysine residue located in subdomain II that is involved in ATP binding and catalyzing phosphoryl transfer.⁵⁹ In the WNK kinases, this conserved lysine is replaced by a cysteine. Hence the acronym WNK, which stands for *With no K* (K = lysine). In WNK kinases, the catalytic lysine is found in subdomain I. Despite this novel substitution, the WNK kinases retain active kinase activity.⁵⁶

The WNKs are widely expressed in many tissues and cell lines. Interestingly, however, both WNK1 and WNK4 are predominantly expressed in the kidney and are exclusively found in the DCT and CCD—sites involved in net renal salt reabsorption as well as net potassium and hydrogen excretion⁴ (Figure 36–1). The identification of specific WNK1 and WNK4 mutations in patients with PHA2 proved these to be disease-causing genes. The mechanism by which they cause the phenotype of PHA2 has been shown to be via increased NCCT activity, due to either loss of normal inhibition or constitutive activation by mutant WNK1 or WNK4.^{60,61}

PHA2 phenotype of hypertension

WNK4 is an effective inhibitor of the NCCT and this is dependent on its kinase function.^{60–62} Mutant WNK4 proteins lacking kinase activity do not have this inhibitory effect. In addition, WNK4 proteins harboring the PHA2 missense mutations (Glu562Lys, Asp564Ala, or Gln565Glu) lose their ability to suppress NCCT activity. These observations demonstrate that WNK4 PHA2 mutations prevent inhibition of NCCT activity and imply that it is the unrestrained activity of this co-transporter that causes PHA2.

Yang et al. looked at the effects of WNK1 on NCCT activity.⁶¹ They found that unlike WNK4 WNK1 did not directly affect NCCT activity. The WNK1 protein, however, was capable of suppressing the inhibitory effect WNK4, suggesting that both kinases act in the same signaling pathway. The effect of WNK1 on WNK4 had the net result of increasing NCCT activity. These findings revealed a previously unrecognized interaction between the two WNK kinases. It is important to note that the inhibition of WNK4 by WNK1 requires the full-length kinase active isoform (L-WNK1). In PHA2, overexpression of L-WNK1 inhibits WNK4 activity, leading to increased NCCT activity and thus increased sodium reabsorption and hypertension.

There are two main WNK1 transcripts expressed in the kidney—the full-length “long” isoform (L-WNK1) and the more abundant “short” kidney-specific isoform (KS-WNK1)—and until recently little was known about the role of KS-WNK1 in the regulation of renal ion transport. Recent work by Naray-Fejes-Toth et al. has suggested that KS-WNK1 might be an important regulator of ENaC activity.⁶³ They expressed functional mineralocorticoid receptors in a kidney cell line and demonstrated rapidly induced expression of KS-WNK1 but not L-WNK1 in response to aldosterone at physiologic concentrations. This overexpression of KS-WNK1 resulted in increased transepithelial sodium transport via ENaC, suggesting that KS-WNK1 might be part of the mechanism by which aldosterone regulates sodium reabsorption in the CCD. These observations suggest that WNK1 might play an important role in aldosterone-induced sodium retention and the development of hypertension. Thus, in PHA2 patients high aldosterone levels as a result of hyperkalemia (potassium ions are a strong stimulator of aldosterone) could contribute to increased sodium reabsorption and therefore to hypertension via aldosterone-induced WNK1 expression.

PHA2 phenotype and hyperkalemia

One of the major features of PHA2 is hyperkalemia, suggesting that the WNKs could have a direct effect on ROMK1—the major K⁺ secretory channel in the distal nephron.⁶² Using *Xenopus laevis* oocytes in expression studies, Kahle et al. demonstrated that wild-type WNK4 is also a potent inhibitor of ROMK1 activity. In contrast to NCCT inhibition, inhibition of ROMK1 activity by WNK4 is not dependent on its kinase function. Instead, inhibition is mediated by clathrin-dependent endocytosis of ROMK1 from cell surface membranes, a mechanism distinct from WNK4 inhibition of NCCT. In addition, WNK4 constructs carrying the PHA2 mutations Q565E or E562K increased inhibition of potassium current and surface expression of ROMK1. Thus, PHA2 mutations that increase NCCT activity act to decrease ROMK1 activity. This would result in increased sodium chloride reabsorption by NCCT and contribute to elevated blood pressure and reduced potassium reabsorption—leading to hyperkalemia as a result of ROMK1 inhibition. This would explain most of the physiologic abnormalities seen in PHA2 patients.

PHA2 and hyperchloremia

WNK4 is expressed predominantly in the tight junctions of the DCT and CCD in the kidney, suggesting that WNK4 may also have a role in regulating paracellular chloride flux in the distal nephron. The chloride dependence of PHA2 further supports this notion. Two independent studies have now shown that wild-type WNK4 increases paracellular ion conductance secondary to a twofold increase in absolute paracellular permeability to chloride ions.^{64,65} This effect is kinase dependent, and is greatly enhanced by the WNK4 missense mutations that cause PHA2.^{65,66} In addition, WNK4 was shown to physically interact with and phosphorylate claudins 1 through 4.⁶⁵ These are major tight-junction membrane proteins known to be involved in the regulation of paracellular ion permeability.⁶⁷ In support of the “chloride-shunt” hypothesis proposed by Schambelan et al., PHA2-mutant WNK4 demonstrated increased association with and increased phosphorylation of these tight-junction proteins—providing a possible mechanism for increased paracellular permeability to chloride ions in PHA2 patients.⁵⁰ These findings suggest that WNK4 regulates paracellular Cl⁻ transport by phosphorylating claudins.

Clinical implications and perspectives

The clinical symptoms of PHA2 vary from family to family. However, all affected individuals have sodium-dependent hyperkalemia and hypertension.⁴⁷ Hyperkalemia is the feature always present and is used to distinguish it from other monogenic forms of hypertension. The severity and age of onset of hypertension varies.⁶⁸

After the discovery of mutations in WNK kinases causing Gordon's syndrome, genotype/phenotype comparisons were made. It has been observed that clinical symptoms differ between families with PHA2B or PHA2C. Patients with WNK1 mutations usually present with milder symptoms of the disease with a later age-of-onset of hypertension, normal calcium levels, and in some patients a milder degree of plasma renin suppression. In contrast, patients with WNK4 mutations develop hypertension at an earlier age, and have hypercalciuria and marked suppression of renin levels. Hyperkalemia is always present, but hypertension severity is variable even within families. This could be due to extrinsic factors such as low sodium intake.^{49,68,69}

Diagnosis of PHA2 is a combination of taking a clinical history, measuring blood pressure, and analysis of urine, plasma, and serum. The transtubular potassium gradient is used to detect low potassium concentrations in the urine from affected subjects. The presence of low plasma renin and high serum aldosterone concentrations are indicative of the condition. Genetic diagnosis is possible through mutation screening. However, this is not used routinely.

Thiazide diuretics are an effective treatment for PHA2. They act by inhibiting NCCT activity and therefore preventing excess sodium reabsorption in the distal nephron.⁷⁰ However, the long-term use of these drugs leads to side effects (especially on glucose metabolism), with subsequent development of type II diabetes.⁷⁰ The recent discovery of mutations in WNK kinases causing PHA2 places them as putative targets for new drugs for the condition.^{61,62,71} However, a more detailed understanding of WNK kinase functions and their

interactions in various tissues will be required before any attempts should be made for their use as therapeutic agents.

CONGENITAL ADRENAL HYPERPLASIA

Definition

Congenital adrenal hyperplasia (CAH) is a term used to define a group of autosomal recessive conditions in which affected individuals have abnormal steroid hormone production. Two forms of CAH exhibit hypertension: 11 β -hydroxylase deficiency (11OHD, OMIM: 202110) and 17 α -hydroxylase deficiency (17OHD, OMIM: 202110). 11OHD only accounts for 5 to 8% of all CAH cases worldwide, whereas to date only 150 validated cases of 17OHD exist.^{72,73}

Distinguishing clinical features of these two forms include cortisol deficiency, aldosterone suppression, high ACTH levels, adrenal cortex hyperplasia, hypokalemia, and hypertension. In 11OHD, the enzyme deficiency also results in androgen excess, whereas in contrast 17OHD patients suffer from signs of sex hormone deficiency.⁷⁴ The symptoms of CAH are treated with hormone replacement therapy and are aided by moderate dietary salt intake.

CAH due to 11OHD

Genetics

Mutations in the 11 β -hydroxylase gene CYP11B1 cause 11OHD.⁵ A single point mutation in exon 8 (G448A) was

found in 11 of 12 affected individuals from 6 Jewish families of Moroccan origin with 11OHD. The families were not related, but Moroccan Jews have a high prevalence of 11OHD and it is likely the mutations in this population result from a founder effect.⁵

Subsequent analysis of the CYP11B1 gene in other families with 11OHD has revealed mutations in all coding regions, but there is some clustering in exons 2, 6, 7, and 8.^{75,76} To date, there have been over 30 reported mutations in CYP11B1 causing 11OHD, and they include premature termination codons, missense mutations, frameshift mutations, splice site changes, insertions, and deletions.^{76–79} Most of the recorded mutations result in complete loss of enzymatic activity. However, partial impairment also occurs.^{75,80}

Physiology and pathophysiology

11 β -hydroxylase is a mitochondrial cytochrome P450 enzyme that catalyzes the last step of glucocorticoid biosynthesis to produce cortisol and corticosterone (Figure 36–2). In 11OHD individuals, a deficiency of 11 β -hydroxylase leads to reduced cortisol and corticosterone biosynthesis. The reduced levels of cortisol trigger the ACTH-dependent feedback mechanism, resulting in the overproduction of steroid precursors within the adrenal cortex. In the case of 11OHD, the steroid precursors 11-deoxycortisol (S) and 11-deoxycorticosterone (DOC) accumulate. The accumulation of unwanted metabolites results in two principal clinical effects: (1) inappropriate

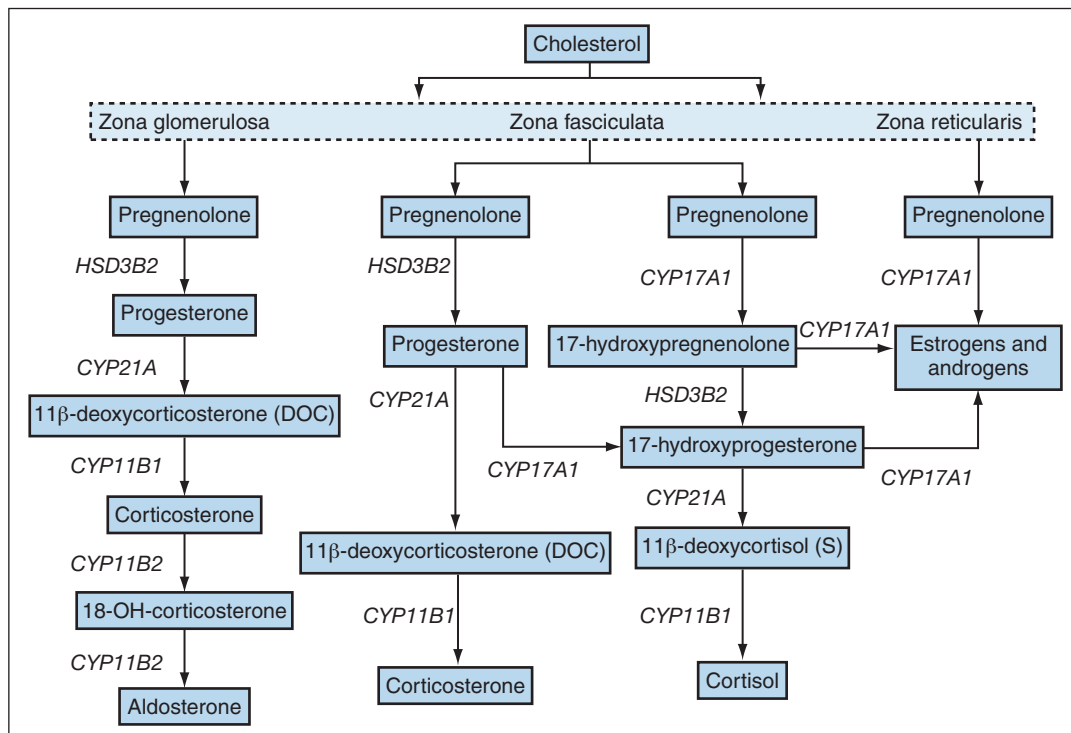

Figure 36–2. The biosynthetic pathway for steroids in the adrenal gland. The site of synthesis of each steroid and its precursor in the adrenal gland are shown in bold. The genes encoding enzymes in the pathway are indicated in italics. CYP11B1 encodes 11 β -hydroxylase, which converts DOC to corticosterone and S to cortisol. This gene is mutated in 11OHD. CYP17A1 encodes an enzyme with two functions: (1) 17 α hydroxylase activity (which catalyzes the initial step of cortisol synthesis) and (2) 17,20-desmolase activity, which is crucial for the production of sex hormones. This gene is mutated in 17OHD.

activation of the mineralocorticoid receptor, resulting in salt retention and hypertension, and (2) excessive production of androgens, resulting in the symptoms of androgenic excess.^{27,81}

DOC is a potent mineralocorticoid of relative unimportance in healthy individuals. However, in 11 OHD patients excessive levels of DOC and its metabolites cause mineralocorticoid receptor hyperactivation and thus hypertension develops despite reduced aldosterone levels.²⁷

The abnormalities in sex steroid synthesis arise as excess steroid precursors are shunted into the pathway of androgen biosynthesis. Thus, affected females present with masculinized external genitalia and males with hyperandrogenic symptoms such as acne, hyperpigmentation, and phallic enlargement.⁸²

Despite the functional characterization of several mutations, at present no clear correlations between genotype and severity of hypertension or the degree of virilization have been made.^{75,78} For reasons unknown, patients with identical CYP11B1 mutations demonstrate a range of different phenotypes.^{76,83}

Clinical implications and perspectives

The clinical and biochemical phenotype of 11OHD is variable. Hypertension has been reported in 66% of 11OHD cases and usually develops late in childhood or in early adolescence.⁷⁴ Premature closure of the epiphyses leads to short stature in adulthood, despite rapid somatic growth and bone age acceleration in childhood.²⁷ The cortisol deficiency in 11OHD patients can expose affected individuals to frequent minor illnesses because they lack the ability to mount a stress response.⁸⁰ Rarely reported clinical features include dilated cardiomyopathy⁸⁴ and the development of a retroperitoneal mass,⁸⁵ both of which are alleviated by hydrocortisone therapy.

Multisteroid analysis after an ACTH-stimulation test reveals abnormal circulating DOC and S levels in 11OHD patients.⁸⁶ Confirmation by molecular genetic analysis using mutation screening is available but is not routinely used.

Initial treatment depends on the severity of the phenotype and actual metabolite levels, but the attenuation of symptoms is usually achieved by the administration of glucocorticoids such as hydrocortisone or dexamethasone. In general, hydrocortisone is the drug of choice because it is short acting, can be given in pulses that mimic natural cortisol secretion, and has a lower potential for growth retardation in children.⁸⁰

Prenatal diagnosis, through the presence of elevated tetrahydro-S in the amniotic fluid or direct DNA sequence analysis from a chorionic villus sample, may be of significant use in populations with increased 11OHD prevalence, such as the Jewish families of North African origin.^{76,87,88} Immediate prenatal therapy to prevent genital masculinization has been successfully achieved with the administration of dexamethasone.⁸⁹ In this instance, it is the preferred treatment because compared with other glucocorticoids it crosses the placenta more efficiently, has a longer half-life, and shows minimal unwanted side effects to the developing fetus.^{90,91}

CAH due to 17OHD

Genetics

17OHD is an autosomal recessive disorder caused by mutations within the CYP17A1 gene. The CYP17A1 gene is located on chromosome 10q24.32 and encodes the 17 α -hydroxylase enzyme, which is expressed in adrenal gland and gonads.⁹²

The molecular basis of 17OHD was discovered in 1988 when affected individuals were found to harbor mutations within exons 1 and 8 of the CYP17A1 gene.^{6,93} Over 48 disease-causing mutations have since been described, including missense, nonsense, splice site, deletions, and insertions.^{94–101} Enzymatic function can be completely or partially abolished by these mutations.²⁷ Most of the mutations are random and spontaneous. However, clusters of patients with the same mutation have been described in Dutch and Brazilian populations, suggesting a founder effect.^{102,103}

Physiology and Pathophysiology

17 α -hydroxylase is also a member of the mitochondrial cytochrome P450 enzyme family. It has two distinct activities: 17 α -hydroxylation within the cortisol synthesis pathway and 17,20 desmolase activity within the sex steroid synthesis pathway (Figure 36–2). Thus, it is essential for the synthesis of cortisol and sex steroids.

Affected 17OHD individuals are unable to catalyze the 17 α -hydroxylation of pregnenolone or progesterone, and/or to carry out the 17,20 desmolase reaction of 17-hydroxypregnenolone, resulting in reduced secretion of cortisol and/or androgenic steroids, respectively. Hypertension occurs when the action of 17 α -hydroxylase is impaired. In this case, the excess pregnenolone is shunted down the corticosterone synthesis pathway, resulting in both corticosterone and DOC accumulation. Therefore, similar to 11OHD patients develop hypertension due to an excess of ligands for the MR.^{93,104}

When 17,20 desmolase activity is abolished, individuals fail to synthesize adrenal androgens or gonadal steroids—resulting in hypogonadism in females and pseudohermaphroditism in males. Individuals with isolated 17,20 desmolase deficiency have normal blood pressure levels.¹⁰⁵

Clinical implications and perspectives

17OHD was first reported in a patient with sexual infantilism and hypertension.¹⁰⁶ Previously thought to be extremely rare, the recent discovery of several novel CYP17A1 mutations suggests that the incidence rate of 17OHD is perhaps not as low as originally thought. In fact, 17OHD is relatively common in Dutch Mennonites¹⁰² and Brazilians of Spanish/Portuguese origin.¹⁰³

As with 11OHD, the phenotype of 17OHD varies considerably and depends on which of the enzyme's two activities is disrupted. Reasons for morbidity and mortality caused by 17 α hydroxylase disruption include the delayed recognition of hypertension resulting in strokes, myocardial infarction, and chronic renal failure. Deficiencies in sex steroid synthesis can cause sexual ambiguity, infertility, and malignant degeneration of gonads.^{73,107}

Similar to 11OHD, the ACTH stimulation test can be used to measure precursor/product ratios in 17OHD. In 17OHD, serum levels of DOC, corticosterone, 17-deoxysteroids, and progesterone rise to 5 to 10 times that of normal.⁷² The condition can be further characterized by the reduction of urinary 17-hydroxysteroid-derived compounds, and by elevated circulating levels of follicle stimulating hormone (FSH) and luteinizing hormone (LH). Molecular genetic diagnosis by direct sequencing is the most sensitive diagnostic tool but is presently only available in research laboratory settings.⁹⁶

Glucocorticoid replacement therapy is usually sufficient for normalizing the blood pressure of 17OHD individuals, but on occasion additional hypertensive drugs such as mineralocorticoid antagonist or calcium channel blocker may be required.⁷² Surgery, including reconstruction of ambiguous genitalia and removal of testicles, may be required in cases where sex steroid synthesis/17,20 desmolase activity is severely disrupted.

SUMMARY

In this chapter we have reviewed five monogenic forms of human hypertension: GRA, Liddle's syndrome, Gordon's syndrome, and two hypertensive forms of CAH (11 β -hydroxylase deficiency and 17 α -hydroxylase deficiency). All of these have been characterized at the functional level and in all cases hypertension is due to increased renal sodium and water retention.

There are at least five other monogenic forms of hypertension (Table 36–1), some of which still remain to be fully characterized at the genetic and physiological level. These include apparent mineralocorticoid excess (AME) caused by mutations in 11 β -hydroxysteroid dehydrogenase gene (11-HSD-2).¹⁰⁸ Mutations in 11-HSD-2 lead to cortisol binding to the mineralocorticoid receptor, and it is this inappropriate activation that disrupts renal electrolyte excretion and intravascular volume leading to hypertension.

Hypertension exacerbated by pregnancy is caused by mutations within the MR gene itself.⁸ The mutant receptor has altered ligand specificity, allowing it to be activated by progesterone and other mineralocorticoids, which normally

act as antagonists. Progesterone levels increase 100-fold in pregnancy, and therefore females with MR S810L mutation develop severe hypertension in pregnancy through MR hyperactivity.

Mutations within the peroxisome proliferator-activated receptor gamma (PPAR γ) gene have recently been attributed to a rare monogenic syndrome, which displays hypertension as part of the phenotype (the underlying cause of which is currently not yet understood).¹⁰ Further implications that PPAR γ has an important role in blood pressure regulation come from the successful use of PPAR γ agonists in the attenuation of hypertension.¹⁰⁹

Recently, a mutation in the mitochondrial genome has been found to cause hypomagnesemia, hypertension, and hypercholesterolemia.¹¹ The results from this paper suggest there may be links between the age-related loss of mitochondrial function and increases in both high blood pressure and cholesterol as people get older.

Finally, hypertension and brachydactyly type E, a condition which was first described in 1970s. The gene has yet to be found, and therefore the pathogenesis is not yet fully understood.^{9,110} A recent description of neurovascular anomalies associated with the condition may prove significant in understanding its mechanism of hypertension.¹¹¹

Since the discovery of the first gene causing a monogenic form of hypertension there has been a lot of excitement over the possibility that more subtle genetic variants in these genes may contribute to essential hypertension in the general population.³ In support of this hypothesis, associations have now been reported between WNK1,¹¹² WNK4,^{113,114} the β subunit of ENaC,¹¹⁵ and CYP11B2¹¹⁶ and essential hypertension in various populations. The discovery of novel mutations within these genes and their functional characterization may reveal some of the mechanisms leading to essential hypertension.

In summary, research into the causes of monogenic forms of hypertension has proved extremely successful, and we believe further studies in this area are likely to lead to the development of preclinical diagnostic tests and new therapeutic targets. These efforts might also shed light on the mechanisms causing essential hypertension.

Therapeutic Potential of Systemic Gene Transfer Strategy for Hypertension and Cardiovascular Disease

Shant Der Sarkissian and Mohan K. Raizada

Definition

- Gene therapy is a strategy in which a vector is used to deliver beneficial genes, thereby changing the expression levels of that gene to correct the altered expression in the pathological state.

Key Findings

- The principal benefits of gene therapy over the use of traditional pharmacotherapy are as follows.
- Minimal side effects due to the specificity of gene therapy's mode of action
- Elimination of patient noncompliance problems
- May prove useful in the cure of certain diseases (e.g., hypertension) whose symptoms are only treatable with current pharmacotherapy

Clinical Implications

Cardiovascular gene therapy in humans is at an investigational phase. However, with the impressive results of preliminary studies and with the improvement of the tools and the knowledge in gene manipulation gene therapy may eventually become part of routine care for patients.

EPIDEMIOLOGY OF HYPERTENSION AND CARDIOVASCULAR DISEASE

Cardiovascular (CV) disease extends across all population segments and represents the leading cause of morbidity and mortality in industrialized nations.^{1,2} A major risk factor for CV disease is arterial hypertension, which significantly increases the risk for peripheral artery disease, stroke, coronary artery disease, cardiomyopathies, and cardiac and renal failure.¹⁻⁵ Hypertension often goes undetected, and in those diagnosed with the disease only half receive adequate treatment and 70% of these patients do not fully comply with their treatment.⁶ Thus, only about 10% of all hypertensives nationwide are adequately managed.

This escalation of the prevalence of CV disease and hypertension, even with the multitude of modern-day pharmaceuticals available for treatment, has led many to conclude that traditional pharmacotherapy has reached an intellectual plateau and that novel approaches for the treatment and control of CV disease and hypertension

must be explored. As a result, our efforts have been diverted to explore the use of gene transfer approaches for the long-term control of these diseases, and the experimental successes of our peers and of our group suggest that gene modification can work in preventing and reversing hypertension and CV diseases.

GENE THERAPY AS AN ALTERNATIVE APPROACH FOR THE TREATMENT OF HYPERTENSION AND CARDIOVASCULAR DISEASE

A recent report from the American Heart Association indicates that the incidence of hypertension has risen 30% in the last decade in spite of the availability of effective drug therapies. This increase has several causes. First, all of these drugs have short half-lives and repeat administration is necessary for the success of the treatments because the disease is generally reexpressed once therapy is discontinued. Second, the question of patient noncompliance is a critical issue because some patients have difficulty abiding by the daily requirement of the treatment, particularly in view of the fact that some of these drugs have intolerable side effects.^{7,8} Third, because mild to moderate hypertension is usually asymptomatic patients often view pharmacotherapy as unnecessary and inconvenient. However, end-organ damage (a hallmark of the hypertensive state) may have already occurred once hypertension is diagnosed and unaware patients further precipitate the situation by not complying with their treatment regimen. Further drug development may yield more selective inhibitors with fewer side effects, but it seems unlikely that a cure for hypertension will come from pharmacologic intervention.

Gene therapy offers the possibility of producing long-term therapeutic effects with specificity tailored to a patient's own genetic profile. The benefits of this method over the use of traditional pharmacologic therapies are as follows.

- Compliance problems can be reduced or even eliminated because with GT a single injection can be effective for months, years, or even for the remainder of a patient's life.
- Side effects can be minimized because GT is very specific in its mode of action and specifically inhibits or enhances the expression of a particular gene.

- GT has the potential to maintain an optimally high and localized concentration of therapeutic genes over time, which may also reduce side effects.

The historic sequencing of the human genome, the advances in the understanding of CV biology and pathophysiology at the molecular level, and the improvements in gene targeting technologies and in tools for *in vivo* genetic manipulation and delivery have inspired active investigation into genetic treatments for hypertension and CV diseases. GT is an emerging field that offers targeted and time-controlled parameters especially relevant to CV diseases ranging from hypertension to ischemia to restenosis. Modification of gene expression offers a means to prevent, arrest, or reverse these pathophysiologic states. Moreover, the notion of treating localized disease with targeted therapy has emerged as one of the great promises of GT.⁹

The etiology of hypertension is poorly understood, with only a small percentage of sufferers demonstrating isolated genetic abnormalities. In the majority of cases, the cause of hypertension is unknown and falls into the category of primary hypertension. This has led many investigators to hypothesize that expression of the hypertensive phenotype is multigenetic and multifactorial,^{10,11} and therefore not considered appropriate for GT because GT has tended to be limited to diseases resulting from single gene mutations or to life-threatening diseases for which few alternatives are available. Nevertheless, drug companies have for years made advances in the control of hypertension with single pharmaceutical targets. The most successful drugs developed to reduce hypertension have been designed to inhibit β - or α -adrenergic receptors, calcium channels, angiotensin-converting enzyme (ACE), and angiotensin-II AT₁ receptors (AT₁R). Based on this, GT for hypertension is feasible and for its success it is only necessary to analyze and target only those genes that have already been targeted by successful pharmacotherapy. Thus, it would be imperative to first provide proof of concept for GT with the use of these genes.

There are two critical issues that determine the success of GT: (1) selection of the targeted gene (one could target pressor genes to inhibit their expression, whereas genes relevant to vasodilation could be overexpressed) and (2) mode of gene transfer (i.e., selection of nonviral or viral vectors). Each of these issues must be considered based on the type of CV pathophysiologies to be targeted.

GENE DELIVERY VEHICLES

GT is a strategy in which a vector is used to deliver beneficial genes either systemically or directly into the tissue, thereby changing the expression levels of that gene to correct the altered expression in the pathologic state. The simplest way to deliver exogenous genes is by directly injecting naked plasmid DNA. This method can be used for localized delivery into a particular tissue. Naked DNA delivery has little or no toxic or adverse side effects.¹² Disadvantages of this technique include inefficient delivery, limited time for transgene expression, high levels of vector breakdown in circulation, and lack of chromosomal inte-

gration.¹³ In fact, if naked plasmid DNA is in contact with cell membranes only a small amount will pass into the cell—leading to low gene transfer. Therefore, a carrier molecule or a viral vector is generally used to increase gene transfer efficiency. Each of these vehicles possesses its special characteristics, as well as advantages and disadvantages, which determine its use for a particular subset of CV diseases. For example, in hypertension research (where reversal and prevention is critical) long-term gene regulation is necessary, whereas in disorders such as ischemia or restenosis short-term gene control would prove more adequate. Currently, several methods are in use to facilitate the entry of nucleic acids into cells, and these can be divided into nonviral and viral vector-mediated systems. Table 37–1 summarizes the major pros and cons of different viral and nonviral gene delivery methods.

Nonviral mediated gene delivery

A wide variety of nonviral vector systems—such as synthetic cationic polymer carriers, liposomes, and hemagglutinating virus of Japan (HVJ-liposomes)—have been used to deliver genes *in vivo*.^{14,15} Liposomes are the most often used method for the delivery of genes by nonviral means because they are nonpathogenic and easily produced and do not have a size constraint.¹⁶ Liposomes increase infection efficiency over naked DNA delivery, minimize immunogenicity, and prevent DNA degradation in circulation. However, the inability of liposomal-delivered DNA to integrate into the recipient cell genome makes them less suitable in situations where long-term transgene expression is required (such as for the control of hypertension).^{17,18} Consequently, liposomes remain an ideal choice for short-term transgene expression and have been used to deliver transgenes relevant in the inhibition of cell proliferation during restenosis.¹⁹

Viral-mediated gene delivery

Viral-mediated gene delivery is emerging as the preferred choice of gene delivery vehicles. For some viruses, integration into the host genome is required for transgene expression. Replacing genes required for viral replication with an expression cassette containing the therapeutic genes transforms the viruses into safe vectors. An ideal replication-deficient recombinant virus is able to efficiently infect quiescent cells, integrate into the host genome, mediate long-term and stable expression, and remain controllable with minimal nonspecific effects.

Several types of viral-mediated gene delivery systems exist, each having its own unique qualities. The major classes of viral vectors include the adenovirus, the adeno-associated virus, and the retrovirus (including the lentiviral vector).^{20–22}

Adenovirus

Adenoviruses are large, linear double-stranded DNA viruses. Vectors derived from the human adenovirus serotypes 5 and 2 are commonly used for gene transfer, as these can be generated at high titers and express transgenes in both dividing and quiescent cells.²³ Other advantages of this vector include ease of manipulation, large insert capacity,

MAJOR ADVANTAGES AND DISADVANTAGES OF NONVIRAL VERSUS VIRAL GENE DELIVERY METHODS		
Vehicle	Pros	Cons
Nonviral		
Oligonucleotide	Easy to produce; safe to handle	Lack of target specificity; transient expression pattern
Liposome	Easy to produce; safe to handle	Lack of target specificity; transient expression pattern
Viral		
Adenovirus	Infects dividing and nondividing cells; high titers	Immunogenic; transient expression; lack of integration
AAV	Nonpathogenic; specific integration site (wild-type); infects nondividing cells	Very small payload
Retrovirus	Stable long-term expression; large payload; relatively nonimmunogenic	Random integration; only infects dividing cells
Lentivirus	Stable long-term expression; large payload; infects dividing and nondividing cells; low immunogenicity	Random integration; safety concerns; low titers

Adapted from Katovich MJ et al., *Current and Future Novel Targets of Gene Therapy for Hypertension*.¹⁷³

Table 37–1. Major Advantages and Disadvantages of Nonviral Versus Viral Gene Delivery Methods

and its extensive characterization.²⁴ Although adenoviral vectors have been readily used for studying various CV diseases, this vector has some drawbacks that may prevent its future use. First, most adenoviral vectors in their current form are episomal (i.e., they do not integrate into the host DNA and therefore only cause a transient transgene expression). Second, because most individuals have been exposed to natural adenovirus infections, immunologic responses may hamper gene transfer efficacy. In addition, because the adenoviral genes express hundreds of proteins adenoviruses stimulate the immune system and inflammatory responses. Newer second- and third-generation adenoviral vectors with many of the viral genes deleted have demonstrated significant improvements in terms of inflammation and immune response.²⁵ However, repeated gene transfer with this vector coupled with prior infection may still result in inflammatory responses with consequent tissue damage.²⁶ These limitations make current recombinant adenoviral vectors less than ideal for long-term GT in humans. Thus, the adenoviral vector remains a useful tool for gene transfer for experimental studies in animal models because it is easy to produce on a large scale.

Adeno-associated virus

The adeno-associated virus (AAV) has established its position as one of the most popular gene delivery systems. AAV has gained attention because of its safety, lack of immunogenic viral proteins, and efficient transgene expression in a very broad host range.²⁷ AAV infects all mammalian tissues tested,²⁸ and its ability to infect a large number of both dividing and nondividing cells makes it an appropriate vector for GT in adult tissues. However, the rate of transduction of nondividing cells remains much lower than for dividing cells.²⁹ AAV is not pathogenic and is not associated with disease, even though it has a broad

range of infectivity. Upon infection, the AAV remains intact for long periods of time.

Upon infection of a human cell, the wild-type AAV integrates preferentially into chromosome 19,²⁴ although a low integration frequency in the region of active genes and frequent chromosomal deletions have been demonstrated in animal studies.³⁰ Although there are eight serotypes, most AAV vectors have been derived from AAV-2. AAV-2 is a small single-stranded DNA virus that can only package limited amounts of DNA (i.e., up to 4.4 kb of insert). Although this carrying capacity may limit the AAV to delivering large genes, it is amply suited to deliver small genes and particularly antisense cDNA. Another limitation of AAV is its production. Although it can be purified and concentrated, it has to be rendered free of adenovirus and this makes production more complicated than for other vectors. Therefore, many drawbacks must be overcome before this vector system can be an ideal vector for GT.

Retrovirus

The pioneering work on gene delivery *in vivo* was performed with retrovirus vectors, typically the Moloney murine leukemia virus (MLV). Retroviruses enter mammalian cells through specific surface receptors, which can limit their range of infectivity. Once inside cells, the RNA genome of the retrovirus is reverse transcribed by reverse transcriptase into a double-stranded DNA provirus that is incorporated into a pre-integration nucleoprotein complex (PIC). The PIC typically does not pass through intact nuclear membranes and therefore integration of the provirus requires breakdown of the nuclear envelope via mitosis.³¹ Therefore, retroviruses are highly efficient in infecting dividing cells but have limited efficacy in nondividing cells. This raises the question of the suitability of

retroviruses for the GT treatment of certain diseases such as adult hypertension, although retroviruses may be useful for other pathologies such as restenosis (where cells are actively dividing).

The retroviral DNA is integrated into the host genome, leading to gene expression for extended time periods. However, the integration is random, which raises concerns about safety. Another major limitation of the retrovirus is its low titers during production.³²⁻³⁴ To overcome the cell-type range and titer limitations, retroviral vectors have been pseudotyped with envelope proteins from other viruses such as the G glycoprotein from vesicular stomatitis virus (VSV).³⁵ Vector development has been intense for retroviruses. New generations of the vector are less immunogenic, self-activating and inactivating vectors have been engineered,³⁶ and these newer vectors can integrate into specific locations in the host genome and have the improved ability to infect nondividing cells (which makes them ideal for hypertension therapy).³⁷

Lentivirus

Although lentiviruses belong to the general category of retroviruses, their special features have made it appropriate to describe them separately. Many of the lentiviral vectors used in GT have been developed from primate lentiviruses, and most notably based on the human immunodeficiency virus type 1 (HIV-1).³⁸ In contrast to conventional retrovirus particles, lentiviral vectors form PICs that can pass through the pores of intact nuclear membranes and therefore can also infect nondividing cells.³⁹ HIV vectors can accommodate fairly large gene inserts and can provide long-term expression through chromosomal integration. Lenti-vectors have a capacity of ~10 kb for genetic material and sufficient amounts of high-concentration vector (10E8 to 10E9 infection units/mL) can easily be produced.

Despite these advantages, the limitations of using lentiviral vectors in clinical trials have been primarily related to the vector's HIV origin. However, over the years many modifications have been made to reduce the risk associated with the use of this gene delivery system. The necessary components for the production of the recombinant virus are segregated on three different plasmid constructs. Homologous sequences between these constructs have been reduced to the bare minimum to prevent recombination.^{40,41} The transducing plasmid contains a functional cassette and viral long-terminal repeats (LTRs) containing self-inactivating (SIN) mutations that decrease the risk of replication-competent virus generation. As a result of these modifications, the lentivirus has become a safe, efficient, and well-characterized vector system that combines the advantages of retroviral and adenoviral vectors.

Although HIV based vectors have been extensively characterized, vectors based on nonprimate lentiviruses may be equally potent and more readily accepted by clinicians and patients. It is important to emphasize, however, that no data presently exist regarding the relative safety of primate versus nonprimate lentiviral vectors. Feline immunodeficiency virus (FIV) is one particularly

appealing nonprimate lentiviral vector. Phylogenetic analysis suggests that FIV is only distantly related to the primate lentiviruses,^{42,43} and epidemiologic evidence indicates that there has been no occurrence of seroconversion in human populations.⁴⁴⁻⁴⁶ FIV's low capacity for human cell infection is attributed to its envelope and low transcriptional activity in human cells.⁴⁷⁻⁵¹ Therefore, new generations of FIV have been developed⁵² with modifications in order to overcome the low infection and transcriptional activity in human cells. Lentiviruses (including FIV) are among the most promising vehicles for gene transfer to the brain.^{53,54} A recent series of studies involving FIV has targeted genes to sites and networks relevant to the brain renin-angiotensin system.⁵⁵

An ideal vector

Major strides have been made in the last several years to develop both nonviral and viral vectors for GT. The choice of a gene delivery method is dependent on the needs of a given pathophysiologic condition. For example, an ideal vector for the control of hypertension would be one that could transduce nondividing and dividing cells with equally high efficiency, have a long-term transgene expression, and have a high capacity to introduce regulatory elements. At this time, the retrovirus family (particularly the lentiviruses) seems to fit these criteria (Figure 37-1). However, the adenoviral vector or HVJ-based naked DNA delivery may serve a prominent role in which transient expression of a given transgene is needed. In either case, for a GT vector to succeed it must have the following common characteristics: (1) the vector should not cause disease or elicit an immune or inflammatory response, (2) the vector should integrate into the genome in a desired site with no risk of disrupting other genes and cause mutations, (3) the virus needs to be replication deficient to prevent the spread to other tissues, and (4) the vector should be easy to produce on a large scale in a pure form and in high titer.

GENE THERAPY FOR CARDIOVASCULAR DISEASES

The increased understanding of CV biology and molecular pathophysiology has enabled the design and evaluation of gene-based therapies (for a variety of CV conditions) currently being successfully applied in both animal experiments and in human trials. In the following section, we summarize GT approaches in the treatment of a number of CV diseases.

Restenosis and bypass graft failure

Interventions such as balloon angioplasty and bypass grafts are highly effective for the treatment of stenosis and ischemic disease. However, in 20% of patients restenosis post-angioplasty leads to the obstruction of arteries within 6 months of the procedure.^{56,57} Likewise, neointimal hyperplasia results in the re-occlusion of ~20% of peripheral arterial bypass grafts after the first year and of ~50% of coronary artery bypass grafts after 10 years. As a result, innovative gene transfer methods are being tried to inhibit restenosis post-angioplasty and in bypass grafts.

Figure 37-1. Lentiviral vector-mediated high-efficiency gene transfers in the myocardium. Lentiviral vector containing human placental alkaline phosphatase (PLAP) as a reporter gene was injected into the left ventricular cavity of the heart. Ten days following gene transfer, hearts were stained for PLAP. The control heart showed no staining (global view, panel A, and ventricular cross section, panel B). The lentivirus was able to efficiently transduce the entire heart (ventricles and atria, panel C, and magnified ventricular cross section, panel D). Histological sections of the ventricular wall reveals PLAP marker transduced with the lenti vector (panels E and F). Whole mount pictures were taken using a dissecting microscope and thin section pictures were taken at 10X objective magnification. (Reproduced by permission from [202].)

Intimal hyperplasia, which leads to vascular occlusion, develops in large part as a result of vascular smooth muscle cell (VSMC) proliferation and migration induced by a complex interaction of multiple growth factors (GFs) that are activated by injury. However, rapid regeneration of endothelial cells without replication of VSMC has also been hypothesized to modulate vascular growth. The process of VSMC proliferation is dependent on the coordinated activation of a series of cell cycle regulatory genes that result in mitosis. Therefore, GT strategies for restenosis have been largely directed toward the inhibition of VSMC migration and proliferation by targeting those specific genes.

The transition of G1 to S is a very important therapeutic target, and this checkpoint is regulated by the E2F family of transcription factors. The E2F transcription factor transactivates a variety of genes involved in cell cycle regulation. A synthetic DNA decoy has been used to sequester E2F and prevent gene transactivation, thereby arresting cells at the G1 checkpoint.⁵⁸ A proof-of-concept study, the Project in Ex-Vivo Vein Graft Engineering Via Transfection (PREVENT I), was the first study using genetic engineering techniques to inhibit cell cycle activation in vein grafts to treat peripheral arterial disease.⁵⁹ This study was followed with PREVENT II, the first randomized controlled trial of genetic suppression via transcription factor inhibition, which investigated the safety and feasibility of

E2F decoy oligodeoxynucleotides (ODNs) in preventing autologous vein graft failure after coronary artery bypass surgery. This trial demonstrated that E2F decoy was associated with a decreased vascular wall volume/index and a reduction of vein graft failure. Such strategy for the treatment of vascular occlusive disease has gained favor with several groups employing direct transduction of the vessel wall with genes designed to modulate cell cycle progression. Briefly, antisense or decoy ODN constructs against c-myc,⁶⁰ cdc-2,⁶¹ cdk-2,⁶² ras,⁶³ bcl-x,⁶⁴ and NFκB⁶⁵ have been tried. Expression of p21,⁶⁶ p27 and p16,⁶⁷ gax,⁶⁸ p53,⁶⁹ thymidine kinase,⁷⁰ cytosine deaminase,⁷¹ fas ligand,⁷² and retinoblastoma gene⁷³ have also been successfully investigated and have shown a decrease in the extent of intimal thickening in injury-mediated vascular proliferative disorders.

Other approaches limiting VSMC hyperplasia have involved the increase in local levels of nitric-oxide (NO). NO causes vasodilation, prevents cellular proliferation and clotting, acts as a scavenger of oxygen free radicals, and mitigates neointima formation. Finally, the *in vivo* transfer of plasmid DNA coding for endothelial NO synthase (eNOS: NO generating enzyme) in the rat carotid artery has improved vasomotor reactivity and has produced a 70% inhibition of neointima formation post angioplasty.⁷⁴ NOS transfection was also shown to produce a significant reduction in in-stent restenosis in pigs.⁷⁵

Therapeutic angiogenesis

Substantial research has focused on the administration of angiogenic GFs to promote the development of supplemental collateral blood vessels that constitute bypass conduits around occluded arteries. This strategy is termed therapeutic angiogenesis, and is most used in patients suffering from critical limb ischemia (CLI) or chronic myocardial ischemia (MI) who are not good candidates for surgical revascularization.

GT might be the best way to produce therapeutic angiogenesis, in that sustained but transient expression of GFs is required for the formation of new blood vessels. In fact, GT has provided promising new approaches for the treatment of ischemia and for the protection of vessels and myocardium after injury.⁷⁶ Early phase 1 trials using many different angiogenic GFs to stimulate neovascularization have disclosed potentially favorable results in limb salvage in patients recommended for lower extremity amputation^{77,78} and in reduced failure of lower extremity bypass grafts.⁵⁹ In addition, reduced angina, improved exercise tolerance, and improved myocardial perfusion have been reported in patients with coronary heart disease.⁷⁹⁻⁸²

Although many cytokines have angiogenic activity, vascular endothelial growth factor (VEGF) has been the best studied and the most widely used agent for therapeutic angiogenesis both in animal experiments and in clinical trials. The families of fibroblast growth factor (FGF)⁸³⁻⁸⁵ and of hepatocyte growth factor (HGF)⁸⁶ have also been identified as factors that can induce angiogenesis *in vivo*. Other cytokines and GF, such as monocyte chemoattractant protein-1⁸⁷ and platelet-derived growth factor (PDGF), may also indirectly increase angiogenesis by stimulating VEGF production.^{88,89}

Critical limb ischemia

Critical limb ischemia (CLI) is estimated to develop in 500 to 1000 individuals per million per year and is considered as one of the most suitable diseases for GT. In a large proportion of these patients, the extent of the occlusive disease makes the patients unsuitable for surgical revascularization and amputation is often chosen. Therefore, the need for alternative treatment strategies in patients with CLI is compelling.

Initial preclinical studies established that the angiogenic activity of a single intra-arterial bolus injection of VEGF is sufficiently potent to achieve increase of collateral vessels and capillaries in rabbits with severe unilateral hindlimb ischemia.⁹⁰ Subsequently, other studies established meaningful biological outcomes following direct injection of naked plasmid VEGF DNA into skeletal muscle of ischemic rabbit hindlimbs⁹¹ and AAV-mediated VEGF delivery into ischemic hindlimbs in diabetic mice.⁹² Based on the successes of these and other preclinical studies demonstrating the efficacy of VEGF-induced angiogenesis in models of peripheral ischemia,⁹³ randomized trials have begun to evaluate the therapeutic potential of VEGF GT in patients with CLI.^{77,78} These studies have shown that site-specific VEGF GT can achieve physiologically meaningful therapeutic angiogenesis in patients. Moreover, the safety and therapeutic efficacy of intramuscular

naked plasmid DNA encoding for FGF administered to patients with peripheral arterial disease has been reported,⁹⁴ and preclinical studies using HGF to stimulate angiogenesis in this disease model have also been undertaken.⁹⁵

Myocardial ischemia

Health care projections suggest that by 2020 ischemic heart disease will be the most prevalent global cause of death and disability.^{96,97} Recent advances in the understanding of the pathophysiology of ischemic heart disease coupled to improvements in GT offer the opportunity for the design of gene-based therapies for both the protection and rescue of the myocardium. GT strategies for ischemic heart disease have targeted angiogenesis and cytoprotection, as well as several different areas of cell function, including cell cycle progression and cell viability.

A human GT trial to treat coronary artery disease using the VEGF gene was initiated by late professor J. M. Isner.⁸¹ His group performed injections of naked plasmid encoding VEGF gene into ischemic myocardium, and (similar to human trials in peripheral arterial disease) transfection of VEGF resulted in a marked increase in blood flow and improved clinical symptoms without apparent toxicity.⁷⁹ Moreover, in a phase I coronary artery disease study direct myocardial gene transfer of naked DNA-encoding VEGF reduced angina and sublingual nitroglycerin consumption in patients even at 1-year follow-up.^{98,99} Several studies have also documented improved myocardial perfusion and functional recovery following GT for treatment of the ischemic myocardium using angiogenic GF other than VEGF such as FGF.^{84,100,101} It is now established that the deleterious processes initiated by coronary ischemic events may be exacerbated by reperfusion, a phenomenon referred to as ischemia/reperfusion (I/R) injury, which is clinically manifested in patients suffering from acute coronary syndromes.¹⁰²⁻¹⁰⁴

Reoxygenation of the ischemic myocardium results in the formation of reactive oxygen species, leading to activation of the inflammatory cascade, myocyte injury, and endothelial dysfunction.^{105,106} In time, repeated I/R injury leads to progressive impairment of contractile function and hemodynamic failure.¹⁰⁷ Therefore, a therapeutic approach aimed at potentiating endogenous antioxidant reserves could be used as a preventive measure against I/R-induced oxidative myocardial damage. A proof-of-concept study using an I/R model has been undertaken using direct injection of recombinant AAV for the delivery of human heme oxygenase (HO-1) gene into the rat myocardium.¹⁰⁸ The HO-1 gene conferred cytoprotective, anti-inflammatory, vasodilatory, and antioxidant properties. Moreover, the HO-1 gene transfer resulted in a significant reduction of the infarct size in treated animals as compared with untreated animals at 8 weeks post-GT.¹⁰⁸ Comparable findings were observed with extracellular superoxide dismutase (ecSOD),^{109,110} an enzyme that converts superoxide anions to hydrogen peroxide, which breaks down into water and oxygen. Other groups have also demonstrated the feasibility of cardioprotective GT using alternative targets such as using decoy ODNs

against NF κ B, a pro-inflammatory transcription factor activated by oxidative stress,¹¹¹ or the overexpression of stress-induced heat shock proteins such as HSP-70,¹¹² survival genes such as Bcl-2,¹¹³ and protein kinase B,¹¹⁴ as well as immunosuppressive cytokines.^{115,116}

GT is usually considered an acute intervention at the time of ischemia and/or reperfusion. However, problems lie in the delay in introducing the gene and the time for it to be transcribed and translated. Long-term use of GT ahead of the event is, however, a feasible option for myocardial protection because experimental and clinical findings suggest that novel preemptive gene transfer techniques may be beneficial for patients with (or who are at risk of developing) coronary ischemic events.

Heart failure

Rescue of contractile function in the failing myocardium is another major goal of myocardial GT. GT for heart failure (HF) is a promising alternative therapy because the targeted demographic of HF focuses on the elderly, who are generally not ideal candidates for heart transplant due to the increased surgical risk or to the limited availability of donor organs. The failing myocardium is characterized by alterations in calcium handling, decreased myofilament sensitivity, and adrenergic receptor downregulation and desensitization.¹¹⁷ The sarcoplasmic reticulum calcium ATPase (SERCA2a) is an important protein involved in HF because a defect in SERCA2a results in contractile dysfunction leading to HF. The adenovirus-mediated GT of SERCA2a has been shown to improve contractility in aortic-banded rats.¹¹⁸ In addition, the β 2-adrenergic receptor has been used as a target for GT in HF. Activation of this receptor controls catecholamine response through cAMP regulation, and a decrease in β 2-adrenergic receptors causes a decrease in cardiac responses to catecholamines and leads to HF. Similarly, adenovirus-mediated intracoronary delivery of the β 2-adrenergic receptor gene leads to improved contractility and hemodynamic function in an animal model.¹¹⁹

GENE THERAPY FOR HYPERTENSION

GT provides a powerful tool to influence the expression of a specific gene to compensate for the hypo- or hyperactivity of a defective gene. This can be achieved by overexpression of a normal gene or by suppression of a defective gene.

The preclinical GT studies for hypertension have adopted two approaches that represent the two sides to transferring DNA into cells. One is the sense approach (the normal DNA sequence direction), which consists of inserting extra copies of genes associated with ameliorating effects such as vasodilation and reduction of hypertrophy and proliferation. The other approach is the antisense approach (the opposite DNA sequence direction), which consists of silencing genes associated with exacerbating effects such as transmission of vasoconstrictor responses and growth promotion. Each of these approaches has advantages and disadvantages. As our knowledge of gene products involved in controlling the CV system expands,

GT for CV diseases (and hypertension in particular) presents several alternative choices of candidate genes to be targeted, which in return dictate the gene transfer approach to use in order to either increase or decrease the expression of the selected gene. Tables 37–2 and 37–3 summarize some of these studies.

Sense approach

Chao and associates have led the way in using the sense approach by overexpressing vasodilators such as kallikrein (kinin generating enzyme),^{120,121} adrenomedullin (ADM),¹²² atrial natriuretic peptide (ANP),¹²³ and eNOS¹²⁴ in several different experimental models of hypertension with measurable success at reducing high BP. Their studies have demonstrated that delivery of each gene, either by naked DNA or by using viral delivery, results in an impressive lowering of BP. This decrease in BP is accompanied by an attenuation of pathophysiology observed in major target organs of hypertension. For example, a single injection of plasmid containing human tissue kallikrein gene in adult or newborn spontaneously hypertensive rats (SHRs) effectively reduced BP for up to 10 weeks.¹²⁵ In salt-sensitive hypertensive rats, intravenous injection of adenovirus vector with kallikrein produced a transient reduction in BP and morphologic improvements in kidney and cardiac pathophysiology.^{120,126} In addition, this group established that a single intramuscular injection of the same virus leads to a continuous supply of BP reducing kallikrein in the circulation.¹²⁷ Similarly, human eNOS gene reduced BP for 2 to 12 weeks in the SHR,¹²⁴ and overexpression of ADM using the adenoviral vector provided protection against hypertension, cardiac hypertrophy, and renal damage in both salt-sensitive and volume-dependent hypertension.^{122,128} Even though the effects were not always very prolonged, reduction in end-organ damage was observed with these therapies.

Our group has used the sense approach to determine whether overexpression of the AT₂ receptor (AT₂R) reduces cardiac hypertrophy and cardiac fibrosis in two rat models of hypertension. In the first study, the AT₂R was overexpressed in 5-day-old SHR using a lentiviral vector. At 21 weeks following gene transfer, the lenti-AT₂R-treated SHR exhibited decreased left ventricular wall thickness and reduced heart/body weight ratio compared to normal animals. These beneficial outcomes were observed despite the elevated BP in these animals.¹²⁹ In another study, the AngII infusion rat model of hypertension was used to evaluate the role of AT₂R overexpression. Lenti-AT₂R overexpression resulted in the attenuation of left ventricular wall thickness, heart/body weight ratio, and decrease in myocardial fibrosis independently of high BP.¹³⁰ Together, both of these studies concluded that the AT₂R overexpression provides a cardioprotective effect against cardiac remodeling in both a genetic and non-genetic model of hypertension.

Recently, our group has begun using angiotensin-converting enzyme 2 (ACE2) as a potential target for GT. ACE2 is a newly discovered member of the renin-angiotensin system (RAS), which possesses 42% sequence homology with ACE^{122,131,132} and is a central regulator of

INCREASED GENE EXPRESSION (SENSE APPROACH) FOR THE TREATMENT OF HYPERTENSION AND CARDIOVASCULAR DISEASES						
Transgene	Model	Vehicle	Delivery	Effect on BP	Comments	Ref.
Kallikrein	SHR	Adenovirus	IM	No effect	Increased capillary density in ischemic muscle	174
	SHR	Adenovirus	IM	Decreased		127
	Dahl-SS	Adenovirus	IV	Decreased	Reversed cardiac hypertrophy; fibrosis and renal damage	175
	Goldblatt-2K1C	Adenovirus	IV	Delay of onset	Reduced left ventricular mass; protection from renal dysfunction	176
	SHR	Adenovirus	IV	Decreased		177
	SHR	ODN	IV	Decreased	Decreased BP in adult but not in young SHR	178
ADM	SHR	Plasmid DNA	IV	Decreased	Hypotensive effect reversed by kallikrein inhibitor	179
	Goldblatt-2K1C	Adenovirus	IV	Delay of onset	Reduced left ventricular mass; decreased myocyte diameter; decreased myocardial fibrosis	180
ANP	SHR	Plasmid DNA	IV	Decreased	Second injection further reduced BP	181
	Dahl-SS	Adenovirus	IV	Decreased	Decrease in cerebral infarction; reduced thickness of arterial wall	182
	Dahl-SS	Adenovirus	IV	Decreased	Reduction in cardiac myocyte size; attenuation of glomerular sclerotic lesions	183
NO	SHR	Plasmid DNA	IV	Decreased	No effect on 12 week old SHR	123
	SHR	Adenovirus	ICV	Decreased	Depressor response in WKY but greater in SHR	184
	SHR-SP	Adenovirus	IV	No effect	Improved endothelial function	185
	SHR	Adenovirus	ICV	Decreased	Decrease in HR and BP reversed by microinjection of soluble guanylate cyclase inhibitor	186
SOD	SHR	Adenovirus	IV	Decreased	Effect greater in anesthetized compared with awake rats; improved endothelial function	187
	SHR-SP	Adenovirus	IV	No effect	Improved endothelial function	188

Table 37–2. Increased Gene Expression (Sense Approach) for the Treatment of Hypertension and Cardiovascular Diseases

angiotensin peptides. Most importantly, ACE2 shifts the balance in the formation of the vasoconstrictor and proliferative AngII toward the vasodilatory and anti-proliferative angiotensin 1-7 [(Ang (1-7)] fragment. Therefore, ACE2 is hypothesized to have beneficial effects in hypertension and CV diseases. Our group seized the opportunity to evaluate whether overexpression of ACE2 would protect the heart from hypertension-induced cardiac remodeling in an AngII-infused rat model. Lentiviral vector containing ACE2 sense sequence was injected in 5-day-old Sprague-Dawley (SD) rats in a single intracardiac injection, which resulted in a long-term expression of the ACE2 transgene. Infusion of AngII for 4 weeks in untreated SD resulted in an increase in BP, left ventricular wall thickness, heart/body weight ratio, and myocardial fibrosis. Cardiac transduction of ACE2 resulted in a profound attenuation in cardiac remodeling, and significant improvement in hypertrophy. However,

this was associated with only a little decrease in high BP.¹³³ Thus, our observations demonstrate that ACE2 overexpression holds great potential for GT against cardiac remodeling in hypertension. We are now evaluating the role of ACE2 overexpression in the prevention of cardiac remodeling post-MI. These consistent and impressive results provide conceptual support for the usefulness of the sense approach for the control of cardiac remodeling.

Antisense approach

The principle behind this approach for hypertension therapy is that antisense (AS) sequences target adverse genes and decrease their expression by blocking the formation of the targeted protein at the transcriptional and translational level. Many research groups, including our own, have been highly successful in using this AS approach to target members of the RAS. Our research group has selected the RAS as a target for AS therapy to

DECREASED GENE EXPRESSION (ANTISENSE APPROACH) FOR THE TREATMENT OF HYPERTENSION AND CARDIOVASCULAR DISEASES							
Transgene	Model	Vehicle	Delivery	Effect on BP	Comments	Ref.	
AGT	SHR	ODN	IV	Decrease	Plasma AGT and AngII levels reduced	141	
	SHR	ODN	IV	Decrease	AGT and AngII levels reduced	142

Table 37-3. Decreased Gene Expression (Antisense Approach) for the Treatment of Hypertension and Cardiovascular Diseases

provide proof-of-concept for hypertension GT for the following reasons: (1) the role of the RAS in hypertension is well established, (2) the RAS provides an ideal target for gene delivery because it is widely distributed, and (3)

traditional pharmacologic agents that target the RAS are proven antihypertensive medications. For example, studies have shown that normotensive SD rats injected with AT₁ receptor (AT₁R)-AS virus are resistant to

hypertension induced by chronic AngII infusion.¹³⁴ In addition, delivery of ACE-AS¹³⁵ or AT₁R-AS^{136–138} prevents the development of both high BP and CV pathophysiology in the SHR. This observation was later extended to other genetic^{136–138} and nongenetic models of hypertension.¹³⁹ These findings are the first of their kind and support the idea that genetic targeting of the RAS is conceptually sound and technically feasible in the prevention of hypertension.

Experiments with nonviral delivery methods

The first conceptual support that AS targeting of the RAS could be effective in the treatment of hypertension was derived from the experiments with the use of AS ODNs. Oligomers are designed to hybridize to the mRNA, and this complex prevents protein translation because it is unable to read through the ribosome. Effective AS ODN have been targeted to the mRNA from renin, AGT, ACE, and AT₁R and tested in three different models of hypertension—including the genetic model (SHR),^{140–143} a surgical model [2-kidney, 1 clip hypertension (2K1C)],¹⁴⁴ and an environmental stress model (cold induced hypertension).¹⁴⁵ In each case, the BP-lowering effect was reproducible and persisted for days. Although these results are impressive, the antihypertensive effects seem to be of little improvement over traditional therapy. In contrast to vector delivery, ODNs can be used and understood as pharmaceutical agents because they act within a few hours, can be measured systemically, and have a dose-response relationship. However, long-term therapeutic potential of ODNs do not measure up to the vector delivery method.

Experiments with viral vectors

Our research group and that of Dr. Phillips' independently have built on these observations to establish experimental protocols for the systemic delivery of AS using viral vector gene delivery systems. The retroviral vector turned out to be an ideal vehicle for providing conceptual evidence for the AS GT based on the fact that one could produce large quantities of this vector with high titers and that the retroviral transgene has the ability to integrate into the genome for sustained antihypertensive effects.¹⁴⁶ We used a retroviral vector gene delivery system to produce lifelong transduction of the AT₁R-AS, resulting in permanent control of high BP and of both vascular and cardiac pathophysiology associated with hypertension.^{7,136–138} The rationales for choosing the AT₁R as a target were several: (1) AT₁R antagonism is a proven traditional pharmacologic strategy for the control of hypertension, (2) a polymorphic substitution of adenine with cytosine in the AT₁R gene has been associated with severe hypertension,¹⁴⁷ and (3) interactions between ACE and AT₁R activity have been associated with the hypertensive state.¹⁴⁸

In our experiments, a single intracardiac injection of a retroviral vector containing AT₁R-AS cDNA in 5-day-old SHR produced lifelong antihypertensive effects without any visible side effects. High BP was prevented from developing throughout life and was comparable with daily

administration of losartan.¹⁴⁹ In addition, no BP-lowering effect was observed in the normotensive rat,^{8,146} and this is consistent with pharmacotherapy in which both AT₁R antagonists and ACE inhibitors have little effect on normotensive individuals.¹⁵⁰ This leads us to propose that the expression of AT₁R-AS in the normal rat would only come into play when the RAS is challenged. In fact, our observations support this hypothesis in that AT₁R-AS expressing normotensive rats when challenged with chronic low-dose AngII are completely protected from developing hypertension.¹³⁴ In contrast to traditional AT₁R antagonist therapy, AT₁R-AS treatment does not increase plasma AngII levels,¹⁴⁹ and this may be an additional factor for the reduced side-effect profile of AT₁R-AS GT.

It is relevant to point out that the expression of the AT₁R-AS gene is associated with a 20- to 40% decrease in the numbers of AT₁R in tissues¹⁴⁵ and that this modest decrease is sufficient to provide comparable beneficial outcomes as those seen with traditional pharmacologic therapies. The lowered plasma AngII levels with GT as compared with traditional drugs may provide some explanation for this observation. Increased sensitivity to vasoconstrictors such as KCl, phenylephrine, and AngII (a hallmark of the SHR vasculature) was prevented by the AT₁R-AS, while correcting endothelial dysfunction. The delivery of the AT₁R-AS gene was also associated with the attenuation of cardiac pathophysiology, which includes the prevention of cardiac hypertrophy, perivascular and myocardial fibrosis, and inhibition of neointima formation in the coronary artery of SHR.^{8,134,136,146,149}

These observations provide first proof-of-principle that AS GT may be feasible for hypertension. Further proof-of-concept was provided with the use of the AT₂R-AS. We argued that if the AT₂R is CV protective then its inhibition would increase BP in normotensive rats. A retroviral vector containing full-length AT₂R-AS cDNA was injected in 5-day-old normotensive SD rats to provide evidence for this hypothesis. Systolic BP in AT₂R-AS expressing normotensive rats was significantly increased compared to control rats. In addition, acute administration of AngII resulted in a significantly higher response in AT₂R-AS animals compared to controls.¹⁵¹

It is evident from the previous discussion that both sense and antisense strategies are technically sound and exciting approaches that offer innovative means for the long-term control of hypertension. Both approaches have their unique advantages and disadvantages. For example:

- The efficacy and efficiency of the AS strategy can be easily compared with the traditional pharmacologic approach. Such a comparison is difficult for the sense-based strategy because of the lack of an equivalent pharmacologic parallel.
- Introduction of a full-length gene in the sense approach that would result in a physiologically functional compensation would require a higher degree of transduction *in vivo*.
- Unlike with the AS approach, which can only attenuate gene expression in a cell that expresses it, the sense approach allows the transduction of genes in cells or tissues that do not normally express the therapeutic gene.

In the final analysis, we believe that the key to the success of GT with either of these strategies will be dependent on the availability of delivery vehicles that would be able to (1) transduce organs with high efficiency and specificity, (2) maintain long-term expression of a desired transgene, and (3) be regulated on demand. Development of such an ideal vector would be an important next step. Finally, for the sense and the antisense approach the outline of the GT development strategy used by our group remains the same as illustrated in Figure 37–2.

REGULATION OF GENE THERAPY

For GT to gain widespread consideration as a treatment alternative to pharmacotherapy a regulated system that exhibits cellular and tissue selectivity must first be developed. An ideal promoter driving the expression of a desired transgene that remains active for prolonged periods, that is switched on or off at will, and that is specific for a given tissue cell type such as cardiomyocytes or VSMC must be developed. This is crucial not only to

control the degree of transgene expression (and thus the therapeutic response in the targeted cells) but to turn off expression if any unforeseen side effects occur. Temporal and quantitative control of transgene expression, which can minimize nonspecific or toxic effects, can be accomplished *in vitro* and *in vivo* using a regulatable “gene switch.” A number of regulated gene expression systems that use exogenous ligands to control transgene expression have been developed in recent years. Among the different systems, the tetracycline-based activating (“tet-on”) or repressible (“tet-off”) systems—in which the delivery of the inducer drug (i.e., doxycycline) regulates gene expression—have been best characterized.^{152,153} In addition, recent advances in the field have demonstrated the possibility of highly efficient transfections of tet-regulated genes using lentiviruses.¹⁵⁴

Another emerging concept in GT for the regulation of gene expression is the use of physiologic signals to switch on therapeutic genes in chronic or life-threatening diseases. In this approach, a systemically injected “vigilant” (or conditional) vector awaits such signals as hypoxia to switch

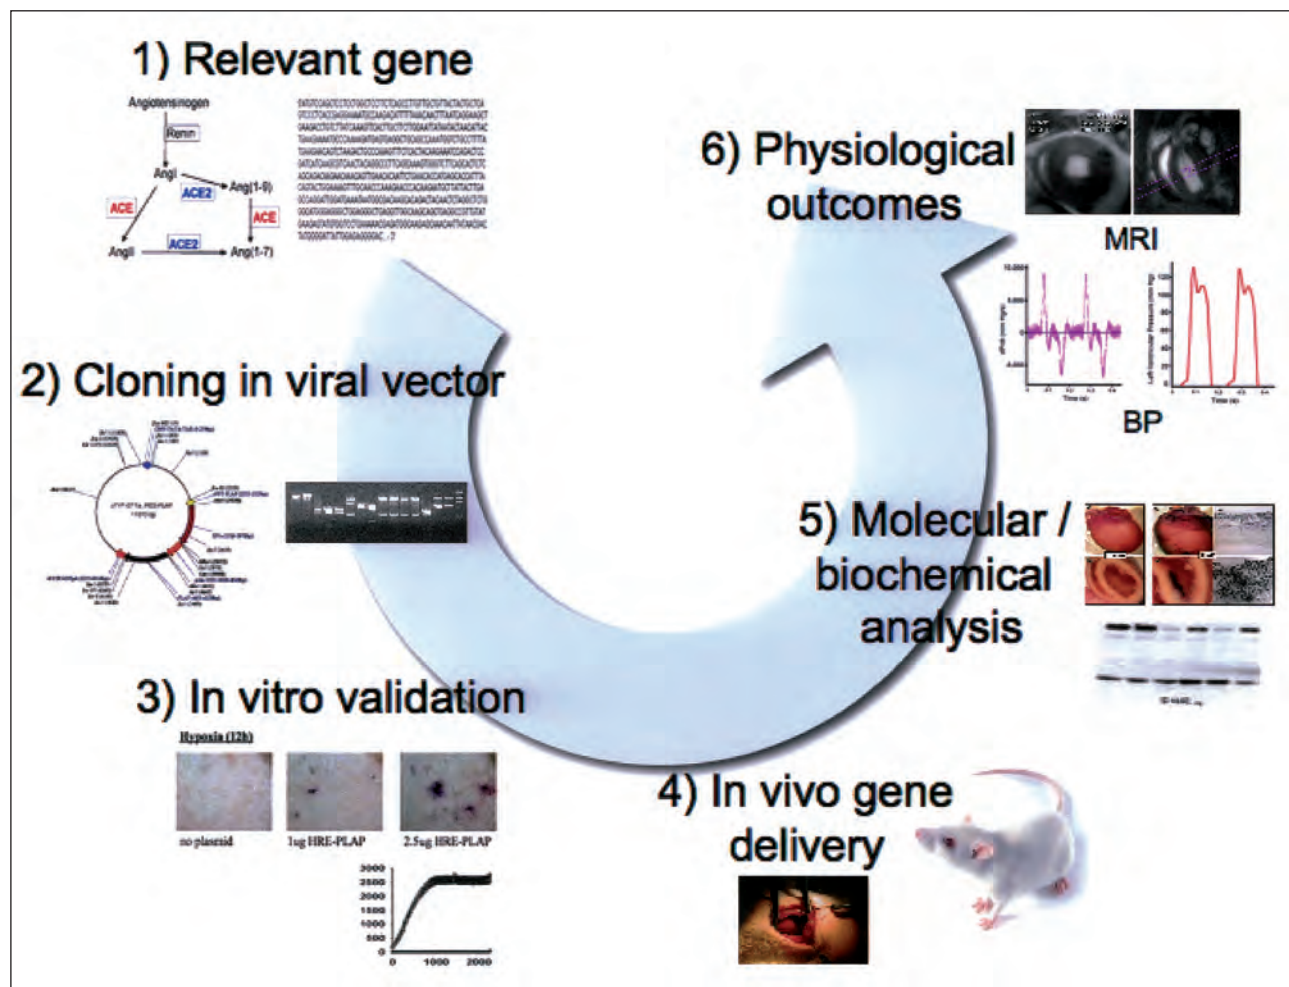

Figure 37–2. Outline of the gene therapy development strategy for cardiovascular diseases employed by Raizada et al. (1) Strategic identification of a relevant gene for investigation, (2) cloning of the gene in a viral vector of choice, (3) *in vitro* validation of the clone construct (immunohistochemistry, activity assay), (4) *in vitro* gene delivery (intracardiac injection in pups, direct tissue injection in adults), (5) molecular/biochemical analysis (immunohistochemistry, blots, and so on), and (6) measure of physiological outcomes (blood pressure, magnetic resonance imaging, and so on).

on genes that protect target tissues (such as the heart during MI) via high amplification of a protective gene.^{155–157} Conditional promoters require several key components. The first is a safe and stable vector that can be administered by systemic injection and that expresses transgenes in both dividing and nondividing adult cells in a particular organ or tissue. The second component is a “gene switch” (biosensor) that can detect the specific physiologic signal (e.g., hypoxia response element, HRE, which can detect a decrease in O₂ levels in MI). The third is a tissue-specific promoter that restricts transgene expression to the tissue or organ of interest (e.g., MLC2 ν myocyte promoter¹⁵⁶ or Tie2 endothelial promoter^{158,159}).

SAFETY ISSUES WITH GENE THERAPY

Safety of GT is of immense importance and has been a major concern. The first human trial in CV disease was started in 1994 to treat PAD using VEGF. Since then, many angiogenic GFs have been tested in clinical trials for different diseases, and the results seem to have exceeded expectations. These trials have shown that vascular gene transfer is safe and well tolerated, and whether using viral or nonviral vectors CV GT clinical trials have disclosed no evidence indicative of inflammatory or other complications, including death directly attributable to the vector used. However, a few incidents that have occurred during clinical trials have attracted renewed concerns about GT safety. For example, GT attempts to induce angiogenesis have raised appropriate concerns regarding the possibility of inducing pathological vessel growth. In fact, therapeutic angiogenesis has potential risks such as the production of nonfunctional vessels, stimulation of angiogenesis in tumors,¹⁶⁰ and hemorrhage or plaque rupture in atherosclerotic lesions.¹⁶¹ It is important to mention that so far there have been no clinical reports of such complications, but ongoing surveillance will continue to inform us regarding their potential.

Safety of viral vectors should also be of great concern if it is to be a therapeutic method of choice. Traditional GT involves the delivery of transgenes by viral vectors and integration into the host genome for long-term expression.¹⁶² However, insertion of foreign DNA can induce epigenetic changes¹⁶³ that may have implications in gene silencing or even tumor development. Therefore, it is imperative that the site of integration of the viral vector in the host genome and its influence on neighboring genes be established. Control of transgene expression also needs to be established with the use of vectors containing promoters that can be regulated. In addition, the vector must be free of immune and other adverse side effects. Deletion of unnecessary viral genes from vector constructs has significantly reduced cytotoxicity and immunogenicity and has prevented the generation of replication-competent particles and the spread of viral infections. Physiologic, pathophysiologic, and ethical aspects related to germ line transmission of the vector must also be evaluated by weighing the potential risks and benefits incurred by the treatment. This is particularly true with the improved transduction efficiency of newer viral vectors.

PERSPECTIVES

Nonviral delivery systems can be less immunogenic, easier to manufacture, and less costly. However, a major barrier has been the lack of genomic integration of the transgenes, which precludes long-term expression. The development of a nonviral transposon system (“Sleeping Beauty”) has provided a significant advance in overcoming this barrier. The system uses a reconstructed transposase capable of excising a transgene from within the transposon and inserting it into the host genome without insertional mutagenesis.¹⁶⁴

Another interesting approach that could lead to major advancement in GT has been the development of RNA interference (RNAi) technology, which was recently demonstrated to also induce stable gene silencing in mammalian cells.¹⁶⁵ Our research group has recently developed small interfering RNAs selectively silencing the AT_{1a}R as a first step toward this objective.¹⁶⁶

Yet another alternative to traditional GT is gene repair, where nucleic acids have been designed to correct site-specific genomic mutations.¹⁶⁷ An advantage of this *in situ* repair method is that it allows the targeted gene to remain under the control of its endogenous regulatory elements.

The transfer of the AS or sense genes to somatic cells is achieved by an *in vivo* approach. It would be possible to use an *ex vivo* approach in which target cells are harvested and transduced, and then reimplanted as genetically modified autologous cells. This method has no clear applicability to hypertension, although it may offer an opportunity to treat many other disorders. In addition, the plasticity of stem cells to transdifferentiate into many different cell types, coupled with the possibility of gene correction, offers an immense opportunity to treat many diseases without the need to harvest cells for *ex vivo* repair. Stem cell therapy is likely to play a major role in treating disorders such as ischemic cardiac disease, cardiomyopathies, peripheral arterial disease, as well as the aging heart.^{168,169} In fact, the possibility of correcting genetic defects in stem cells and then invoking their transdifferentiation into cardiac tissue may soon be possible. Finally, there are many diseases in which considerable damage occurs *in utero*, and the advent of *in utero* GT may offer substantial opportunities for prevention of damage and long-term cure of some of these disorders.¹⁷⁰

CONCLUSIONS

At present, demonstration of the clinical utility of CV GT in humans is at an investigational phase. However, GT for CV disease now appears to be not far from reality. The improvement of vector design, the ability to link specific genes to disease, the technological advances in microarrays and proteomics, and the harnessing of the power of stem cells will undoubtedly advance the role of GT in CV disease. As the tools for *in vivo* genetic manipulation and delivery continue to improve it is possible that GT might eventually become a part of routine care for patients with established CV disease, especially those in whom conventional treatments have been exhausted.

As for the treatment of hypertension, although many excellent pharmacological agents are commercially available the incidence of this disease is on the rise and will continue to affect millions of people throughout the world if new approaches are not clinically investigated and implemented. Therefore, we need to develop ways that would improve high BP control by providing longer-lasting effects with a single therapeutic dose and by reducing side effects that lead to poor compliance. GT for hypertension is one such alternative that would give the patient continuous biological control over high BP with minimal or no side effects. Although a great deal more work in basic science needs to be done before GT for hypertension can be applied to humans, so far the results are encouraging. AAV and lentivirus-based vectors have shown great promise in preliminary experiments.¹⁴⁶ However, new viral vectors or variations of these that have higher transduction efficiency should be tried. Better routes of delivery of viral vectors also need to be established.

Safety is also a key issue and it is imperative that the genomic site of integration of the viral vector be well

known and its influence on the neighboring genes established. Germ line transmission of transgenes by the vector must be determined, and tissue-specific targeting and the improvement of regulatable promoters must be continued. In addition, it would be interesting that other hypertension-related genes be targeted by GT; for example, Ca²⁺ channels, signaling-molecule-related genes, or genes relevant to matrix proteins. Finally, because prevention strategies for hypertension hold little promise for the treatment of humans due to lack of reliable genetic markers for early detection of the disease we must therefore determine whether the reversal strategy for established hypertension is a feasible option.

Our studies have established that genetic targeting of the RAS prevents hypertension for life in the SHR. These studies are consistent with data from other groups,^{171,172} and it appears that the strategy could constitute the basis for further developments. Taken together, the GT strategy is an exciting therapeutic approach that holds great potential for permanent control of hypertension.

Chapter
38

Pathophysiology of Obesity-Induced Hypertension and Target Organ Damage

John E. Hall, Alexandre A. da Silva, Elizabeth Brandon, David E. Stec, Zhekang Ying, and Daniel W. Jones

Key Findings

- Excess weight gain, especially when associated with increased visceral adiposity, is a major cause of human primary (essential) hypertension, accounting for 65 to 75% of the risk for hypertension.
- Increased renal tubular sodium reabsorption and impaired pressure natriuresis play a major role in initiating obesity hypertension.
- Abnormal kidney function and hypertension in obesity are mediated by increased sympathetic nervous system (SNS) activity, activation of the renin-angiotensin-aldosterone system (RAAS), and physical compression of the kidneys by extrarenal fat and by increased intrarenal extracellular matrix.
- Obesity is a major risk factor for vascular, cardiac, and renal disease through diabetes and hypertension and perhaps other mechanisms such as “lipotoxicity” (ectopic lipid accumulation within organs).
- With prolonged obesity and development of target organ injury (especially renal injury), obesity-associated hypertension becomes more difficult to control, often requiring multiple antihypertensive drugs as well as pharmacological therapy of other risk factors, including dyslipidemia, insulin resistance and diabetes, inflammation, and hypercoagulation.
- Until effective anti-obesity drugs are developed, the impact of obesity on hypertension and related cardiovascular, renal, and metabolic disorders is likely to become even more important in the future as the prevalence of obesity continues to increase.
- More emphasis should be placed on prevention of obesity and on lifestyle modifications that help patients maintain a healthier weight.

Obesity is rapidly becoming the most important public health problem in industrialized countries. Surveys throughout the world have revealed dramatic increases in the prevalence of obesity in adults and children in many countries, and current estimates indicate that over 1 billion people in the world are overweight or obese.^{1,2} In China alone, over 200 million people are overweight, and more than 20% of children in major Chinese cities are either clinically overweight or obese, compared to only a 1 to 2% prevalence in 1985.³

In the United States, over 64% of adults are overweight with a body mass index (BMI, kg weight/m² height) greater than 25 and almost one-third of the adult population is obese, with a BMI greater than 30.⁴ The same trends toward increasing obesity have been reported in other industrialized countries and there appears to be no abatement of this worldwide “pandemic.” Moreover, the rapid increase in obesity prevalence in young people, affecting at least 10% of children worldwide,⁵ suggests that obesity-associated medical problems are likely to worsen in the future unless these trends can be attenuated or reversed.^{6,7}

The global emergence of obesity has become a major economic challenge as well as the number one public health problem in many countries.² Excess weight gain is an important risk factor for many medical disorders, including osteoarthritis, sleep apnea, nonalcoholic fatty liver disease, gall bladder disease, diabetes, cerebrovascular disease, coronary heart disease, kidney disease, and several types of cancer (e.g., breast, colon, kidney, prostate). Table 38–1 shows the classification of overweight and obesity and the increasing risk for disease and premature mortality associated with increasing BMI.

The emerging epidemic of diabetes mellitus appears to be due largely to the increasing prevalence of overweight and obesity, with at least 60% of all cases of diabetes being directly attributable to excess weight gain.⁸ According to the International Diabetes Federation, diabetes alone accounts for 5 to 10% of the total health care budget in many countries. The American Diabetes Association has estimated that the total cost of diabetes in the United States for 2002 was \$132 billion, including direct and indirect costs. Total costs are predicted to rise even further, reaching \$156 billion in 2010 and \$192 billion in 2020.

Cardiovascular disease, occurring through multiple mechanisms (including hypertension, diabetes, dyslipidemia, and atherosclerosis) is another major consequence of excess weight gain (Figure 38–1). Many risk factors for cardiovascular disease are interdependent and are often grouped as the “metabolic syndrome.”^{9–11} However, excess weight gain (especially when associated with increased visceral adiposity) is the primary cause of each of these disorders in most patients.

Although obesity has not been widely recognized as an independent risk factor for renal disease, there is little doubt that excess weight gain is a major cause of the two main drivers of kidney disease: hypertension and type 2

CLASSIFICATION OF OVERWEIGHT AND OBESITY BY BMI, WAIST CIRCUMFERENCE, AND ASSOCIATED DISEASE RISK ^a				
Category	Class	BMI	Disease Risk ^b Men <40 in., Women <35 in.	Men >40 in., Women >35 in.
Underweight		<18.5	—	—
Normal		18.5-24.9	—	—
Overweight		25.0-29.9	Increased	High
Obesity	I	30.0-34.9	High	Very high
	II	35.0-39.9	Very high	Very high
Extreme obesity	III	>40	Extremely high	Extremely high

Table 38–1. Classification of Overweight and Obesity by BMI, Waist Circumference, and Associated Disease Risk^a

diabetes. Together, these two disorders account for approximately 70% of end-stage renal disease (ESRD). Accumulating evidence suggests, however, that obesity independently increases risk for kidney disease through mechanisms that are still somewhat obscure.¹² In this chapter we focus mainly on the pathophysiology of obesity-associated hypertension and target organ injury, recognizing that the metabolic, renal, and cardiovascular effects of obesity are closely intertwined.

Overweight and obesity as important causes of primary hypertension

Obesity is often considered a special form of hypertension rather than as a major cause of primary (essential) hypertension *per se*. Yet, excessive weight gain is the most common cause of human primary hypertension. Popu-

lation studies, for example, have shown that excess weight gain (as estimated by BMI, waist-to-hip ratio, abdominal diameter, and other indices of adiposity) is one of the best predictors for development of hypertension.^{13–15}

The relationships between BMI and systolic and diastolic blood pressure appear to be nearly linear (Figure 38–2) in diverse populations throughout the world.^{13–16} Moreover, the association between BMI and blood pressure occurs in non-obese normotensive subjects, as well as in hypertensive patients.^{13,14} Thus, the relationship between BMI and blood pressure appears to be continuous, extending from the range of very lean to very obese.¹⁴ The strength of the association between BMI and blood pressure, however, varies in different ethnic groups for reasons that are still poorly understood but may be related to differences in body fat distribution or other factors (genetic and environmental) that influence the susceptibility of blood pressure to increased adiposity.

The full impact of obesity on hypertension is difficult to assess with cross-sectional studies because the effects of excess weight gain on blood pressure are likely to worsen as obesity is sustained for many years and development of diabetes and target organ injury occurs. The time-dependent effects of obesity on diabetes have been clearly demonstrated (Figure 38–3). When obesity persists for more than five years, the adjusted relative risk for developing diabetes is 8.7 compared to 4.9 if a person has been obese for less than five years.¹⁷ Thus, the health consequences of obesity (including hypertension) are likely to worsen the longer a person is obese, although this is often not considered in cross-sectional studies.

The presence of nonlinear synergistic relationships among the multiple effects of obesity (including hyperlipidemia, glucose intolerance, hypertension and renal injury) may also lead to underestimation of the importance of obesity in causing cardiovascular disease. These *interdependent* effects of obesity are difficult to assess in population studies that seek to establish “independent” risk factors. Yet, even with these caveats risk estimates from the Framingham Heart Study suggest that approximately 78% of primary hypertension in men and 65% in women can be ascribed to obesity.¹⁵

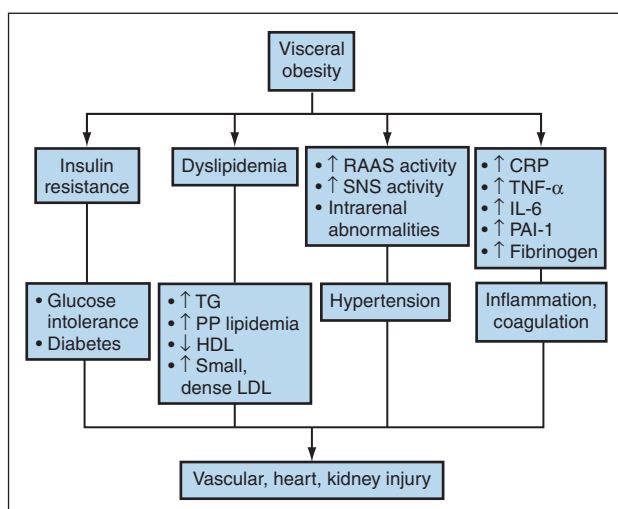

Figure 38–1. Cardiovascular, metabolic, and renal disease associated with visceral obesity. (Abbreviations: TG, triglycerides; PP, postprandial; HDL, high-density lipoprotein; LDL, low-density lipoprotein; RAAS, renin-angiotensin-aldosterone system; SNS, sympathetic nervous system; CRP, C-reactive protein; PAI, platelet activator inhibitor; TNF- α , tumor necrosis factor- α ; and IL-6, interleukin-6.)

Figure 38–2. Relationship between body-mass index and systolic and diastolic blood pressures in 22,354 Korean subjects. (Redrawn from data in reference 14.)

Clinical studies also suggest that obesity is an important cause of increased blood pressure in most patients with primary hypertension, and the therapeutic value of weight loss in lowering blood pressure has been demonstrated in normotensive and hypertensive obese subjects.^{13,18–20} Even modest weight loss of 5 to 10% often decreases blood pressure and may even reduce the need for antihypertensive medication.¹⁹ Clinical trials have also demonstrated the effectiveness of weight loss in primary prevention of hypertension.²⁰

Figure 38–3. Time-dependent effect of obesity to increase risk of type 2 diabetes. (Redrawn from data in reference 17.)

Although weight loss does not always completely normalize blood pressure in obese hypertensive patients, this is perhaps not surprising in view of the many pathologic changes that occur when excess adiposity is maintained for long periods of time. For example, prolonged obesity may lead to glomerular injury, loss of functional nephrons, and resetting of renal-pressure natriuresis to higher blood pressures.^{11,12} Some of these changes may not be easily reversible even with marked weight loss, and may make hypertension more difficult to control with antihypertensive medications.

Why are some obese persons not hypertensive?

One question that often crops up is why some overweight or obese persons are not hypertensive by the usual standards (i.e., blood pressure >140/90) if obesity is a major cause of hypertension? There are several potential explanations. First, it appears that blood pressure in “normotensive” obese people is higher than it would be at a lower body weight because weight loss often reduces their blood pressure. Excess weight gain shifts the frequency distribution of blood pressure toward higher levels, increasing the probability of a person’s blood pressure registering in the hypertensive range (Figure 38–4).

Second, as discussed previously the length of time a person is obese likely has an impact on the blood pressure. Many obese persons who are not yet considered hypertensive may be “pre-hypertensive,” a term recently introduced by the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7).²¹ It is increasingly recognized that reducing blood pressure in pre-hypertensive subjects may provide protection against future development of cardiovascular disease, especially when additional risk factors are present, as is the case for most obese subjects.

Third, the location of excess fat has a major impact on the blood pressure, with increased visceral adiposity carrying a much greater risk for hypertension and metabolic disorders compared to lower body or subcutaneous obesity.

Figure 38–4. Effect of weight gain to shift the frequency distribution of blood pressure to higher levels. Not all obese subjects have blood pressures in the hypertensive range (>140/90 mmHg), but excess weight gain raises blood pressure above the baseline level for an individual.

In fact, there are many individuals (especially older sedentary people) who may have a normal BMI but are “metabolically obese” (with increased visceral adiposity and reduced muscle mass). Conversely, there are significant numbers of individuals (especially women) who have increased BMI and increased lower body (subcutaneous adiposity) but do not have substantial visceral obesity.

For reasons that are still unclear, increased amounts of subcutaneous adipose tissue do not appear to increase blood pressure or metabolic risk. For instance, removal of large amounts of subcutaneous fat by liposuction (an average of over 9 kg, or over 20 lb) did not significantly improve insulin sensitivity, did not reduce plasma levels of inflammatory cytokines, and did not reduce blood pressure.²² These observations suggest that excess subcutaneous fat is not a major cause of insulin resistance, inflammation, or hypertension and reinforces the concept that the location of fat (i.e., visceral fat) is important in determining the blood pressure effects of increased adiposity.

HEMODYNAMIC AND HEART RATE CHANGES IN OBESITY HYPERTENSION

Studies in experimental animals have provided mechanistic insights into the cardiovascular and renal changes associated with excess weight gain. A highly reproducible rise in blood pressure is observed with weight gain induced by a high-fat diet in dogs and rabbits.^{23–25} Moreover, the metabolic, endocrine, cardiovascular, and renal changes caused by dietary-induced obesity in experimental animals closely mimic the changes observed in obese humans^{10,26} (Table 38–2).

Some of these changes occur rapidly after weight gain and later become obscured by pathologic changes. For example, glomerular hyperfiltration (characteristic of the early phases of obesity) subsides and may be replaced by a gradual decrease in glomerular filtration rate (GFR) as renal injury and nephron loss occur in association with prolonged obesity-induced hypertension and diabetes.

Obesity, blood flow, and cardiac output

Obesity is associated with expansion of extracellular fluid volume and blood volume and increased total tissue blood flow, thereby increasing venous return and cardiac output.^{10–12,26,27} Part of the rise in cardiac output is due to increased blood flow in the extra adipose tissue, and in most studies cardiac output increases in direct proportion to increases in body weight.^{23,24,26} However, much of the extra weight in obese persons is adipose tissue, and blood flow in adipose tissue is considerably lower than in many other tissues. Therefore, the rise in cardiac output in obesity is usually much greater than can be attributed to increased blood flow needed for the additional adipose tissue.

Studies in experimental animals and humans indicate that blood flow is increased in many tissues, including the heart, kidneys, gastrointestinal tract, and skeletal muscles.^{23,24,27} Some of the increased blood flow is due to growth of tissues and organs in response to increased

workload and metabolic demands associated with obesity. However, prior to the onset of vascular disease blood flows in tissues such as the kidneys, skeletal muscle, and heart are increased in obese subjects even when flow is expressed per gram tissue weight.^{23,24,27} Thus, it appears that obesity is associated with a functional vasodilation. The mechanisms responsible for obesity-induced vasodilation have not been fully elucidated but are probably due in part to increased metabolic rate, higher oxygen consumption, and accumulation of local vasodilator metabolites.

Despite higher resting blood flows in many tissues, there is reduced blood flow reserve during exercise or reactive hyperemia that occurs after briefly stopping tissue blood flow. This decreased blood flow reserve appears to be due in part to endothelial dysfunction, as discussed later in the chapter.

Obesity and heart rate

The elevated heart rate often found in obesity is mainly due to withdrawal of parasympathetic tone rather than increased sympathetic activity or increased intrinsic heart rate.^{28,29} Increases in body weight are associated with decreases in parasympathetic tone, increases in average heart rate, and decreases in heart rate variability. Conversely, weight reduction increases parasympathetic tone and heart rate variability while decreasing the mean heart rate.³⁰ Although obesity increases sympathetic activity in many tissues (including the kidneys and skeletal muscles), cardiac sympathetic activity (as assessed by measurements of norepinephrine spillover) is usually normal or may even be reduced because of baroreflex inhibition of cardiac SNS activity.³¹

IMPAIRED RENAL-PRESSURE NATRIURESIS IN OBESITY-RELATED HYPERTENSION

Excess renal tubular sodium reabsorption appears to play a major role in initiating the rise in blood pressure associated with weight gain, and obese subjects require higher than normal arterial pressure to maintain sodium balance, indicating impaired renal-pressure natriuresis.^{10,32} In the early phases of obesity, blood pressure is usually not very salt sensitive, so that the hypertension is not greatly exacerbated by high salt intake. With chronic obesity, increases in arterial pressure, glomerular hyperfiltration, neurohumoral activation, and metabolic changes may cause renal injury, further impairment of pressure natriuresis, increased salt sensitivity, and greater increases in blood pressure (Figure 38–5).

Three mechanisms appear to be especially important in mediating increased sodium reabsorption, impaired renal-pressure natriuresis, and hypertension associated with weight gain (Figure 38–1): (1) increased sympathetic nervous system (SNS) activity, (2) activation of the renin-angiotensin-aldosterone system (RAAS), and (3) physical compression of the kidneys by fat accumulation within and around the kidneys, and by increased abdominal pressure.

HEMODYNAMIC, NEUROHUMORAL, AND RENAL CHANGES IN EXPERIMENTAL OBESITY CAUSED BY A HIGH-FAT DIET AND IN HUMAN OBESITY										
Model	Arterial Pressure	Heart Rate	Cardiac Output	Renal Sympathetic Activity	Plasma Renin Activity	Na ⁺ Balance	Renal Tubular Reabsorption	GFR ^a	Insulin Resistance	
Obese rabbits (high fat diet)	↑	↑	↑	↑	↑	↑	↑	↑	↑	
Obese dogs (high fat diet)	↑	↑	↑	↑	↑	↑	↑	↑	↑	
Obese humans	↑	↑	↑	↑	↑	↑	↑	↑	↑	

Abbreviation: GFR, glomerular filtration rate.
 a. The GFR changes refer to the early phases of obesity before major loss of nephron function has occurred.

Table 38-2. Hemodynamic, Neurohumoral, and Renal Changes in Experimental Obesity Caused by a High-fat Diet and in Human Obesity

Figure 38-5. Effect of obesity to shift renal-pressure natriuresis curve to higher arterial pressure. With chronic obesity lasting for many years there may be a gradual loss of nephron function, further impairment of pressure natriuresis, increasing salt sensitivity, and higher blood pressures.

ROLE OF SYMPATHETIC NERVOUS SYSTEM IN OBESITY-RELATED HYPERTENSION

Several observations suggest that increased SNS activity impairs renal-pressure natriuresis and contributes to obesity hypertension:^{10,11,32-34} (1) obese subjects have elevated SNS activity, especially in the kidneys and in skeletal muscle, as assessed by microneurography and tissue catecholamine spillover, (2) pharmacologic inhibition of adrenergic activity reduces blood pressure to a greater extent in obese than in lean subjects, and (3) renal denervation markedly attenuates renal sodium retention and the development of obesity hypertension associated with a high-fat diet in experimental animals.

SNS activation in obesity is differentially controlled in various tissues and depends on fat distribution

As discussed previously, cardiac sympathetic activity does not appear to be substantially elevated in most obese humans,^{35,36} and the high heart rate observed in obese subjects appears to be related mainly to decreased parasympathetic activity.^{28,29} In contrast, SNS activity is usually increased in skeletal muscle and kidneys of obese compared to lean subjects.^{35-37,38}

SNS responses to weight gain may also vary depending on ethnicity and on other factors such as fat distribution. In Pima Indians, who have a high prevalence of obesity but a relatively low prevalence of hypertension, muscle SNS activity is lower than in whites and does not track well with adiposity.³⁹ In black men, SNS activity is higher,

and hypertension is more prevalent than in white men despite comparable levels of obesity.⁴⁰ In young, overweight black women adiposity is associated with high SNS activity.⁴⁰

Although the mechanisms for ethnic differences in SNS responses to obesity are uncertain, differences in fat distribution may be important. For reasons that are still unclear, visceral obesity elicits greater SNS activation than lower body or subcutaneous obesity.^{38,41} Unfortunately, the mechanisms responsible for the link between visceral obesity and SNS activation have not been widely studied, and in most human studies muscle SNS activity has been measured rather than renal SNS activity (the primary pathway by which the SNS causes chronic hypertension).¹¹ Because there is considerable heterogeneity in the control of autonomic outflow to different organs, measurements of muscle SNS activity may not necessarily reflect renal SNS activity. Thus far, a comprehensive analysis of the multiple factors that influence the relationships among visceral obesity, SNS activity, and hypertension in diverse populations has not been conducted.

Adrenergic blockade or renal denervation attenuates obesity hypertension

In experimental animals fed a high-fat diet, combined α - and β -adrenergic blockade markedly attenuates the rise in blood pressure during the development of obesity.⁴² Clonidine, a drug that stimulates central α -2 receptors and reduces sympathetic activity, also prevents most of the rise in blood pressure in dogs fed a high-fat diet.⁴³ In obese hypertensive patients, combined α - and β -adrenergic blockade for one month reduced ambulatory blood pressure significantly more than in lean essential hypertensive patients.⁴⁴ These findings suggest that increased adrenergic activity contributes to the development and maintenance of obesity hypertension in experimental animals and in humans.

The renal sympathetic efferent nerves mediate most, if not all, of the chronic effects of SNS activation on blood pressure in obesity. In obese dogs fed a high-fat diet, bilateral renal denervation greatly attenuated sodium retention and hypertension.⁴⁵ Thus, obesity increases renal tubular sodium reabsorption, impairs pressure natriuresis, and causes hypertension—in large part by increasing renal SNS activity.

Mechanisms of SNS activation in obesity

Several potential mediators of SNS activation in obesity have been suggested, including (1) hyperinsulinemia, (2) increased levels of free fatty acids, (3) angiotensin II (Ang II), (4) impaired baroreceptor reflexes, (5) activation of chemoreceptor-mediated reflexes associated with sleep apnea, and (6) cytokines released from adipocytes (i.e., “adipokines”), such as leptin, tumor necrosis factor- α (TNF- α), and interleukin-6 (IL-6). Although these mechanisms have been reviewed previously,⁴⁶⁻⁴⁹ there is scant evidence supporting cause-and-effect relationships for most of these factors and obesity-induced SNS activation.

Hyperinsulinemia does not mediate obesity hypertension in humans

Obesity is usually associated with fasting hyperinsulinemia and an exaggerated insulin response to glucose loads. The increased plasma insulin concentration occurs as a compensation for impaired metabolic effects of insulin, a condition known as insulin resistance. Some tissues such as the kidneys and SNS, however, are believed to remain sensitive to insulin and hypertension has been hypothesized to be one of the consequences of hyperinsulinemia.

Acute studies suggest that insulin infusion may cause modest sodium retention and increased SNS activity, and these observations have often been extrapolated to infer that hyperinsulinemia may be an important cause of obesity hypertension.³⁴ However, chronic hyperinsulinemia caused by insulin infusion or insulinoma in dogs and humans is associated with reduced, rather than increased, blood pressure due to the peripheral vasodilator effects of insulin.⁴⁷ Hyperinsulinemia also does not enhance the blood pressure or renal effects of other pressor substances such as norepinephrine or Ang II.⁴⁷ Moreover, hyperinsulinemia did not increase arterial pressure even in obese dogs that were resistant to the metabolic and vasodilator effects of insulin.⁵⁰ Thus, multiple studies indicate that hyperinsulinemia cannot explain SNS activation, increased renal tubular sodium reabsorption, impaired pressure natriuresis, or hypertension associated with obesity.

Do elevated fatty acids increase SNS activity and blood pressure in obesity?

Obese hypertensive patients have high fasting plasma non-esterified fatty acid (NEFA) concentrations and raising NEFA acutely increases vascular reactivity to α -adrenergic agonists.⁵¹ High levels of NEFAs also enhance acute reflex vasoconstrictor responses in the peripheral circulation⁵¹ and have been suggested to activate the SNS indirectly through hepatic afferent pathways.⁵² However, chronic infusions of long-chain fatty acids for several days directly into the cerebral circulation⁵³, the portal vein (unpublished observations), or intravenously in dogs did not alter renal function or increase arterial pressure. Thus, the role of elevated fatty acids in linking obesity, SNS activation, and hypertension has not been clearly established.

Impaired baroreceptor reflexes in obesity

Studies in experimental animals and in humans suggest that obesity is associated with impaired ability of baroreceptor reflexes to suppress SNS activity during acute increases in blood pressure induced by pharmacologic agents.⁴⁶ Moreover, weight loss increases the sensitivity of the cardiovagal baroreflex in overweight and obese young and older men.⁵⁴ However, despite impaired baroreflexes in obesity there appears to be at least some sustained activation of the baroreflex that in turn acts as a compensatory response to attenuate (rather than stimulate) increases in SNS activity and hypertension.⁵⁵ Thus, it seems likely that the arterial baroreflexes act to buffer

(rather than mediate) increases in SNS activity in obesity hypertension.

Obstructive sleep apnea and SNS activation in obesity

Obesity, especially when associated with increased visceral adiposity, is an important risk factor for obstructive sleep apnea (OSA). Associations between OSA and hypertension have been found in clinical and population studies and may contribute to hypertension in some obese individuals.^{56,57} The factors linking OSA and hypertension are unclear but may include enhanced effects of obesity on SNS and RAAS activation.⁵⁸

Patients with OSA have greater peripheral chemoreflex responses to hypoxia, including not only increased ventilation responses but enhanced muscle SNS responses.⁵⁹ Thus, when obesity is associated with OSA activation of the SNS and hypertension are likely to be more severe than in patients without OSA, and in general the effects of obesity and sleep apnea on blood pressure appear to be approximately additive.⁵⁷

Leptin and hypothalamic melanocortins may contribute to obesity-induced SNS activation

Accumulating evidence suggests that leptin may be an important link between obesity and SNS activation⁶⁰ (Figure 38–6). Leptin is secreted by adipocytes in proportion to the degree of adiposity and crosses the blood/brain barrier via a saturable receptor-mediated transport system. Leptin binds to its receptors in various regions of the hypothalamus and activates signaling pathways in the hypothalamus and in the hindbrain (e.g., nucleus tractus solitarius) that regulate body weight by decreasing appetite and increasing energy expenditure.⁶¹

Evidence that leptin acts as a powerful controller of body weight comes from genetic studies of mice and humans that demonstrate that missense mutations of the leptin gene cause early onset of morbid obesity.⁶¹ However, mutations of the leptin gene are very rare in humans and the importance of abnormalities of leptin production or sensitivity of leptin receptors in contributing to obesity in the general population is still unclear.

There is, however, substantial evidence that high levels of leptin, comparable to those found in severe obesity, can activate SNS activity and increase arterial pressure.^{10,60,62,63} The rise in blood pressure with chronic hyperleptinemia is slow in onset and occurs over a period of several days despite decreased food intake, which would otherwise tend to lower blood pressure.⁶³ Moreover, the hypertensive effects of leptin are enhanced when nitric oxide synthesis is inhibited,⁶⁴ as often occurs in obese subjects with endothelial dysfunction. The chronic effects of leptin to raise arterial pressure are completely abolished by α - and β -adrenergic blockade, indicating that they are mediated by adrenergic activation.⁶⁵

Another observation that points toward leptin as a potential link between obesity and hypertension is the finding that rodents with leptin deficiency or mutations

Figure 38–6. Possible links among leptin and its effects on the hypothalamus, sympathetic activation, and hypertension. Within the hypothalamus one of the key pathways of leptin's action on appetite, SNS activity, and blood pressure is stimulation of the pro-opiomelanocortin (POMC) neurons in the arcuate nucleus. These neurons send projections to the paraventricular nucleus and lateral hypothalamus, releasing α -melanocyte-stimulating hormone (α -MSH), which then acts as an agonist for melanocortin 3/4-receptors (MC3/4-R). These neurons then send projections to the nucleus of the solitary tract to effect changes in appetite, SNS activity, and blood pressure. Leptin also suppresses the NPY/AGRP neurons, but their role in controlling SNS activity and blood pressure is still unclear.

of the leptin receptor usually have little or no increase in arterial pressure despite severe obesity, insulin resistance, and dyslipidemia compared to their lean controls.^{10,66}

Similar results have also been found in obese children with leptin gene mutations. For example, Ozata et al.⁶⁷ reported that four young patients with homozygous missense mutations of the leptin gene had early onset of morbid obesity but no indication of hypertension. Each of these children also had impaired SNS activity, postural hypotension, and attenuated RAAS responses to upright posture.⁶⁷ Moreover, the absence of hypertension occurred in spite of severe insulin resistance, hyperinsulinemia, and most other characteristics of the metabolic syndrome. These observations are consistent with those in leptin-deficient mice and suggest that the functional effects of leptin may be important in linking obesity with SNS activation and hypertension.

Leptin's stimulatory effect on SNS activity and blood pressure appear to be mediated mainly by activation of the hypothalamic pro-opiomelanocortin (POMC) pathway (Figure 38–6). Humans with POMC or melanocortin 4-receptor (MC4-R) mutations have early onset of morbid obesity and metabolic disorders similar to those observed in patients with leptin gene mutations. Chronic blockade

of the melanocortin 3/4 receptor (MC3/4-R) in rats also causes rapid weight gain, insulin resistance, and large increases in plasma leptin but no increase in arterial pressure and a decrease in heart rate.⁶⁹ As weight gain and hyperleptinemia usually raise blood pressure and heart rate, the possibility arises that a functional MC3/4-R is important in linking excess weight gain with increased SNS activity and hypertension. Moreover, antagonism of the MC3/4-R completely abolished leptin's acute effects on renal SNS activity⁶⁸ as well as the chronic hypertensive effects of leptin.⁷⁰

The effects of leptin-POMC neuronal activation appear to be mediated mainly by the MC4-R, rather than the MC3-R, in that the chronic hypertensive effects of leptin are completely abolished in MC4-R knockout mice.⁷¹ Although the importance of the POMC pathway and MC3/4-R in controlling appetite is well established their roles in regulating SNS activity and raising blood pressure in obese humans have to our knowledge not been investigated.

RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM ACTIVATION IN OBESITY

Obese subjects (especially those with visceral obesity) often have mild to moderate increases in plasma renin

activity (PRA), angiotensinogen, angiotensin-converting enzyme (ACE) activity, Ang II, and aldosterone levels.^{10,57,72} Activation of the RAAS in obese subjects occurs in spite of marked sodium retention, extracellular volume expansion, and hypertension—all of which would normally tend to suppress renin secretion, Ang II formation, and aldosterone secretion. Moreover, weight loss is usually associated with reductions in plasma renin activity and aldosterone.^{57,73}

Potential mechanisms for increased renin secretion and Ang II formation include (1) increased loop of Henle sodium chloride reabsorption and reduced sodium chloride delivery to the macula densa and (2) activation of the renal sympathetic nerves. Increased angiotensinogen formation by adipose tissue has also been suggested to contribute to elevated Ang II levels in obesity,⁷² although the importance of this pathway is still unclear. Regardless of the precise mechanisms involved, RAAS system activation appears to contribute to elevated blood pressure in obese subjects.

Role of Ang II in obesity hypertension

A significant role for Ang II in stimulating sodium reabsorption, impairing renal-pressure natriuresis, and mediating hypertension in obesity is supported by the finding that Ang II receptor blockade (ARB) or ACE inhibition blunts sodium retention, volume expansion, and increased arterial pressure in obese dogs.^{74,75} ARB also reduced blood pressure to a greater extent in obese-prone compared to obese-resistant rats fed a high-fat diet.⁷⁶ In obese Zucker rats, there is increased sensitivity to the blood pressure effects of Ang II because RAAS blockade lowers blood pressure to a greater extent than in lean rats despite comparable (or perhaps even lower) PRA.⁷⁷

Whether the effects of Ang II to raise blood pressure in obesity are due primarily to direct actions on the kidneys, to stimulation of aldosterone secretion, or to SNS activation is unclear. The direct renal sodium-retaining effects of Ang II are well known, as are the direct effects of Ang II to stimulate aldosterone secretion and to increase SNS activity in some conditions.⁷⁸

Unfortunately, there have been no large-scale clinical studies comparing the effectiveness of RAS blockers in obese and lean hypertensive patients although smaller clinical trials have shown that both ARBs and ACE inhibitors are effective in lowering blood pressure in obese hypertensive patients, as discussed later in the chapter. Retrospective analysis of the Antihypertensive Lipid Lowering Heart Attack Trial (ALLHAT) data should also provide some useful information because there were many overweight and obese subjects in this trial and an ACE inhibitor was compared to other types of antihypertensive therapy.⁷⁹

Activation of the RAAS may also contribute to the glomerular injury and nephron loss associated with obesity. By constricting efferent arterioles, increased Ang II formation exacerbates the rise in glomerular hydrostatic pressure caused by systemic arterial hypertension.⁷⁸ Studies in type 2 diabetic patients, who are usually over-

weight or obese, clearly indicate that ACE inhibitors or ARB slow the progression of renal disease.^{80–82} However, further studies are needed in nondiabetic obese subjects to determine the efficacy of RAAS blockers compared to other antihypertensive agents in treating hypertension and reducing the risk of renal injury.

Role of aldosterone and mineralocorticoid receptor activation in obesity hypertension

Studies in experimental animals and in humans have provided evidence that antagonism of mineralocorticoid receptors (MRs) may provide an important therapeutic tool not only for lowering blood pressure but for attenuating target organ injury in hypertension.^{83,84} Antagonism of MRs in obese dogs markedly attenuated sodium retention, hypertension, and glomerular hyperfiltration (Figure 38–7).⁸⁵ Moreover, this protection against sodium retention and hypertension occurred despite marked increases in PRA, suggesting that combined blockade of MR and Ang II might be especially effective in preventing obesity-induced sodium retention and hypertension. The observation that MR antagonism attenuated glomerular hyperfiltration may have important implications for renal protection in obesity, although there are to our knowledge no studies that have tested this directly in obese humans.

There are few clinical studies that have tested the role of MR activation in obesity hypertension. Administration of the MR antagonist spironolactone, however, appears to provide significant antihypertensive benefit in resistant obese patients.⁸⁶ The reductions in blood pressure during MR antagonist occurred despite concurrent therapy with an ACE inhibitor or ARB, calcium channel blocker, and thiazide diuretic.⁸⁶ The observation that MR blockade lowered blood pressure when added to ACE inhibitors or ARB suggests that activation of the MR in obesity can occur independently of Ang-II-mediated stimulation of aldosterone secretion.

One question that emerges from these studies is why MR blockade is so effective in lowering blood pressure and altering renal function in obesity hypertension despite only mild increases, or even slight decreases (e.g., after administration of ACE inhibitors or ARB), in plasma aldosterone. One possible explanation is that enhanced sensitivity to the effects of aldosterone-mediated MR activation increases renal sodium reabsorption. For example, obesity-induced increases in the abundance of epithelial sodium channels (ENaCs), which limit the rate of sodium transport across the apical membrane of aldosterone-sensitive renal tubule epithelial cells, would tend to amplify the effects of MR activation to increase renal sodium reabsorption and blood pressure. Although increased abundance of the β subunit of ENaC in the renal cortex of obese Zucker rats⁸⁷ has been reported, it is unclear whether there is concomitant increase in the expression of the other subunits necessary to form functional ENaCs or whether such an increase plays a significant role in obesity hypertension.

Figure 38-7. Changes (Δ) in mean arterial pressure (mmHg), cumulative sodium balance (mmol), and glomerular filtration rate (mL/min) in control, untreated dogs, and mineralocorticoid receptor antagonist (eplerenone) treated (10 mg/kg, twice daily) dogs fed a high-fat diet for five weeks to develop obesity. (Redrawn from data in reference 85.)

Do glucocorticoids activate the MR in obesity hypertension?

Another potential explanation for the marked effects of MR blockade to reduce blood pressure, despite normal or even reduced plasma aldosterone, is that the MR is activated by glucocorticoids in obesity hypertension. Normally, the renal tubular MR is “protected” from activation by glucocorticoids due to the action of 11 β -hydroxysteroid dehydrogenase 2 (11 β -HSD2), which converts active cortisol into inactive cortisone (see

Chapter 68). Deficient 11 β HSD2 in the renal tubules leads to excessive activation of the MR by cortisol, causing sodium retention, hypokalemia, and hypertension⁸⁸ as occurs in the monogenic form of hypertension “apparent mineralocorticoid excess.” Although some experimental models of hypertension (including the Dahl salt-sensitive rat) have reduced expression of 11 β -HSD2 in the kidney, there are, to our knowledge, no studies that have assessed this mechanism in human obesity hypertension.

Obesity may also increase tissue levels of active glucocorticoids. Visceral obesity may be associated with increased adipocyte expression of 11 β -HSD1, which converts inactive cortisone to active cortisol, and some investigators have suggested that central obesity may reflect “Cushing’s disease of the omentum.”⁸⁹ Support for the possibility that excess tissue 11 β -HSD1 promotes hypertension comes from studies in transgenic mice that produce large amounts of 11 β -HSD1 in adipocytes. When 11 β -HSD1 cDNA was linked to the adipocyte fatty-acid-binding protein promoter, a sevenfold amplification of 11 β -HSD1 occurred, leading to a phenotype of visceral obesity, insulin resistance, and hypertension.⁹⁰ However, the significance of these findings for understanding human obesity hypertension is unclear because other investigators have reported no change or even reduced adipose tissue 11 β -HSD1 in obese compared to lean subjects.⁸⁸ Thus, the mechanisms responsible for the potent effects of MR blockade to reduce blood pressure in obesity hypertension are still unclear and await further investigation.

RENAL COMPRESSION CAUSED BY VISCERAL OBESITY

Visceral obesity initiates several changes that may lead to compression of the kidneys, increased intrarenal pressures, impaired pressure natriuresis, and hypertension.^{10,11} For example, intra-abdominal pressure rises in proportion to sagittal abdominal diameter, reaching levels as high as 35 to 40 mmHg in some subjects.⁹¹ In addition, retroperitoneal adipose tissue often encapsulates the kidneys and penetrates the renal hilum into the renal medullary sinuses, causing additional compression and increased intrarenal pressures.^{10,11}

Obesity also causes increased formation of renal medullary extracellular matrix that could contribute to intrarenal compression and sodium retention.^{10,11} Total glycosaminoglycan content and tissue hyaluronan, a major component of the renal medullary extracellular matrix, are markedly elevated in the inner medullae of obese dogs and rabbits compared with their lean controls (but not in the outer medulla or the cortex).^{92,93} Although the cause of increased hyaluronan in the renal medulla is unknown, its accumulation is usually associated with increased interstitial fluid pressure, tissue edema, and inflammation.

Because the kidney is surrounded by a capsule with low compliance, increased extracellular matrix would raise interstitial fluid hydrostatic and solid tissue pressures and cause compression of the delicate loops of Henle and vasa recta. In support of this hypothesis, renal interstitial fluid

hydrostatic pressure was elevated to 19 mmHg in obese dogs compared to only 9 to 10 mmHg in lean dogs.⁹⁴ Although small increases in interstitial fluid pressure may inhibit renal sodium reabsorption, large increases of the magnitude found in obese dogs would tend to reduce renal medullary blood flow, slow the flow rate in the renal tubules, and raise fractional sodium reabsorption, especially in the loop of Henle.⁹⁴

Increased loop of Henle sodium chloride reabsorption caused by renal medullary compression could explain the renal vasodilation, glomerular hyperfiltration, and stimulation of renin secretion in obesity (Figure 38–8). Increased sodium chloride reabsorption in the loop of Henle would decrease sodium chloride delivery to the macula densa and cause (via tubuloglomerular feedback) reductions in afferent arteriolar resistance and increases in renal blood flow, GFR, and renin secretion.⁷⁸

The increased GFR and elevated blood pressure would tend to return distal sodium chloride delivery toward normal in the face of increased loop reabsorption, and therefore help to restore sodium balance. Although these physical changes in the kidneys cannot account for the initial increase in arterial pressure that occurs with rapid weight gain, they may help explain why abdominal obesity is much more closely associated with hypertension than with lower body obesity.

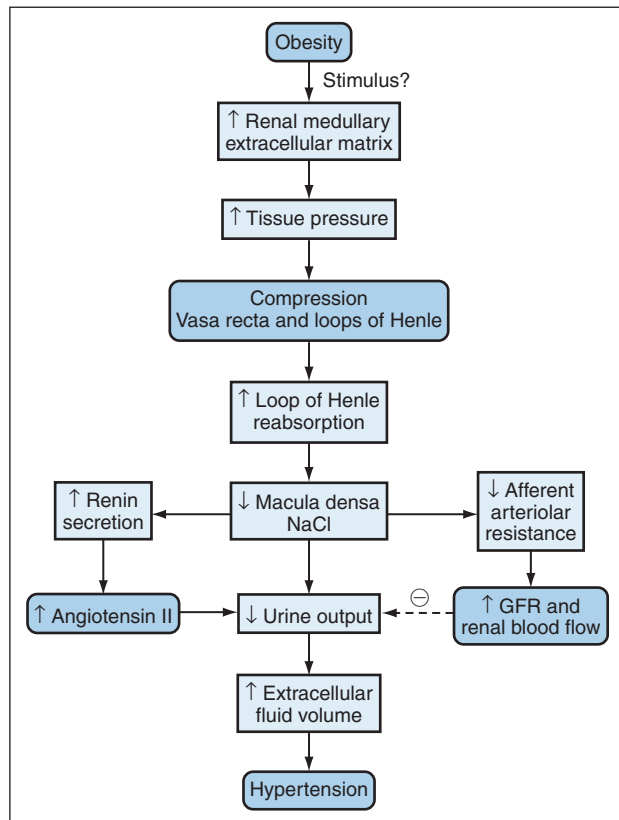

Figure 38–8. Possible mechanisms by which obesity-induced renal medullary compression may contribute to activation of the renin-angiotensin system, increased loop of Henle sodium reabsorption, volume expansion, and hypertension.

OBESEITY AND TARGET ORGAN INJURY

Adipose tissue as source of inflammatory cytokines and hormones

Adipose tissue is believed to be a source of inflammatory cytokines such as TNF- α , interleukin-6 (IL-6), and C-reactive protein (CRP), and obesity has been suggested to be a state of low-grade inflammation.^{95,96} Visceral fat is estimated to produce about three times more IL-6 than subcutaneous adipose tissue.⁹⁷ Although adipocytes themselves secrete IL-6, this accounts for only 10% of the total adipose tissue IL-6 production. Much of the IL-6 and TNF- α produced by adipose tissue appears to come from other cell types associated with adipocytes, including immune cells, monocytes, and fibroblasts.^{97,98}

Adipose tissue also secretes non-cytokine substances that may increase cardiovascular risk^{96,98} (Figure 38–9). For example, some studies suggest that adipose tissue hosts all of the components of the RAAS and secretes Ang II.⁹⁹ Adipose angiotensinogen mRNA expression may be higher in visceral than in subcutaneous adipose tissue, and weight loss reduces angiotensinogen in adipose tissue of obese humans.⁹⁹ However, the physiologic significance of the adipocyte RAAS and the mechanisms controlling its activity are still uncertain.

Although it is clear that adipocytes release many cytokines (“adipokines” or “adipocytokines”) and hormones that are potential mediators of inflammation, direct cause-and-effect relationships for hypertension or target organ injury have not been well established for most of these factors. It is not known, for example, whether chronic treatment with aspirin or other nonsteroidal anti-inflammatory drugs reduces the level of inflammatory cytokines and cardiovascular disease in obese patients.

The picture is further complicated by the observation that visceral fat (rather than subcutaneous fat) confers

Figure 38–9. Hormones and cytokines (“adipokines”) released from white adipose tissue. (Abbreviations: PG, prostaglandin; ASP, acylation-stimulating protein; IGF-1, insulin-like growth factor 1; apoE, apolipoprotein E; TGF- β , transforming growth factor- β ; adipoQ, adipocyte complement-related protein of 30 kDa, also called Acrp30; PAI-1, plasminogen activator inhibitor-1; TNF- α , tumor necrosis factor- α ; sR, soluble receptors; IL-6, interleukin-6; and MIF, macrophage migrating inhibitory factor.) (Redrawn from reference 98.)

most of the risk for cardiovascular and metabolic disorders associated with obesity even though subcutaneous fat also secretes many of the adipokines that have been hypothesized to cause inflammation, hypertension, and increased cardiovascular disease. Defining the importance of the many substances released by adipose tissue in cardiovascular regulation and in mediating target organ injury awaits further investigation.

Endothelial dysfunction, vascular stiffening, and injury of blood vessels

As discussed earlier in this chapter, obesity is associated with elevated resting blood flows in many tissues prior to the development of vascular damage. However, blood flow reserve during exercise or reactive hyperemia is reduced in obesity. For example, the reactive hyperemia and maximum blood flow observed after temporary occlusion of the brachial artery is reduced in obese compared to lean subjects.¹⁰⁰ This impaired flow reserve appears to be due in part to endothelial dysfunction. Obesity is associated with impaired endothelial-mediated vasodilation,¹⁰¹ and weight reduction improves flow-mediated vasodilation in obese individuals.¹⁰²

Accelerated arterial stiffening occurs in elderly, middle-aged, and even in young adults (20 to 40 years of age) who have excess adiposity as estimated by increased BMI, abdominal visceral fat, larger waist circumference, and increased waist/hip ratio.¹⁰³ Moreover, higher aortic pulse-wave velocity (a measure of aortic stiffness) strongly correlates with increases in BMI, waist circumference, and waist/hip ratio independent of systolic blood pressure, race, and sex.¹⁰³ Important effects of excess weight gain to impair vascular function may be apparent even in children.¹⁰⁴

The mechanisms responsible for the deleterious effects of obesity on the vasculature are still poorly understood but are likely due to interactions of multiple disorders, including increased blood pressure, inflammation, hyperglycemia, lipotoxicity caused by excessive non- β -oxidative metabolism of fatty acids, oxidative stress, and activation of multiple neurohumoral systems. As discussed previously, there is evidence that excess visceral adipose tissue itself is an important source of cytokines and other factors that create a vascular milieu of inflammation and oxidative stress and that contribute to endothelial dysfunction, vascular stiffening, and eventually atherosclerosis.¹⁰⁵

Even short-term increases in free fatty acid levels may impair endothelial-dependent vasodilation. For example, infusion of a mixture of several fatty acids for only two hours impaired the vasodilator response to methacholine chloride, an endothelial dependent vasodilator.¹⁰⁶ The mechanism for this effect is unclear, but may be related to a reduction in the cytosolic free coenzyme A (CoA) pool due to acylation of CoA by the increased free fatty acid.¹⁰⁶ Thus, infusion of carnitine (which plays a pivotal role in the metabolism of fatty acids by transporting activated acyl groups across membranes and buffering intracellular acyl-CoA pools) almost completely reversed the impairment of endothelial-dependent vasodilation caused by infusion of a mixture of fatty acids.¹⁰⁶

With chronic increases in tissue fatty acid levels, accumulation of fatty acid metabolites (including acyl-CoA and ceramide) may in the tissues have deleterious effects such as increased formation of reactive oxygen species, endothelial dysfunction, and cell death.¹⁰⁷ However, the precise cellular pathways by which tissue accumulation of fatty acids causes endothelial dysfunction and tissue injury are still unclear and represent an important area for future investigation.

When obesity is sustained over many years and is associated with hypertension, glucose intolerance, and dyslipidemia, the vascular dysfunction becomes progressively worse and eventually manifests as atherosclerosis and injury to various organs throughout the body including the heart, brain, and kidneys. It is important to remember that obesity, especially when associated with increased visceral adiposity, is the main cause of the entire cascade of events that often culminates in vascular disease and target organ injury.

These risk factors for vascular disease interact in a manner that is more than additive. In the Prospective Cardiovascular Munster (PROCAM) study, for example, the risk for myocardial infarction was increased about twofold by hypertension and twofold by diabetes. When hypertension and diabetes occurred together, the risk was increased more than eightfold (Figure 38–10).¹⁰⁸ When hypertension, diabetes, and hyperlipidemia were all present (as occurs in many obese patients), the risk for myocardial infarction was increased almost twentyfold.¹⁰⁸

Obesity is major risk factor for chronic renal disease

Obesity is not included as a cause of kidney failure in renal data registries, and has therefore not been widely recognized as a major risk factor for ESRD. However, the impact of obesity on renal disease is obvious considering

Figure 38–10. Interaction among cardiovascular risk factors in the Prospective Cardiovascular Munster (PROCAM) study. The incidence of myocardial infarction is shown in a group of 2,574 men with (1) no risk factors, (2) hypertension only, (3) diabetes only, (4) hypertension and diabetes, or (5) hypertension plus diabetes and hyperlipidemia. (Redrawn from data in reference 108.)

that diabetes and hypertension (both of which are closely associated with excess weight gain) account for more than 70% of ESRD. Moreover, the rapid rise in the prevalence of ESRD in the past two decades has paralleled increasing obesity and diabetes.¹⁰⁹ Most of the increasing prevalence of ESRD has been attributed to the increase in type 2 diabetes, although patients with type 2 diabetes are usually hypertensive and the increased blood pressure likely contributes to renal injury.

Population studies suggest that obesity is an important cause of renal disease even after adjustment for hypertension, diabetes, or preexisting renal disease.^{110,111} In the Framingham Offspring cohort,¹¹⁰ increased BMI was positively related to a low GFR in the fifth or lower percentile (≤ 59.25 mL/min per 1.73 m² in women, ≤ 64.25 mL/min per 1.73 m² in men) after long-term follow-up. In a retrospective analysis of 320,252 adults who were followed for 15 to 35 years, the rate of ESRD increased in a stepwise manner as BMI increased¹¹¹ (Figure 38–11). This relationship was not affected by blood pressure levels or diabetes, and the analysis was adjusted for age, sex, race, education level, smoking status, history of myocardial infarction, serum cholesterol level, proteinuria, hematuria, and serum creatinine level. Thus, observational studies suggest that obesity may be an important risk factor for renal disease through mechanisms other than hypertension and diabetes.

Obesity exacerbates development of nondiabetic renal diseases

Obesity also amplifies the effects of other primary renal insults, even those that are usually considered to be relatively benign, such as unilateral nephrectomy.¹¹² Retrospective analysis of patients who underwent unilateral nephrectomy (13.6 ± 8.6 years previously) revealed that

62% of those with a BMI >30 developed proteinuria or renal insufficiency, whereas only 12% with a BMI <30 developed these disorders¹¹² (Figure 38–12).

Patients with immunoglobulin A (IgA) nephropathy and who were overweight (BMI >25) at the time of renal biopsy had more severe renal lesions and increased proteinuria (as well as a much faster decline of renal function and progression to chronic renal failure) compared to patients with IgA nephropathy and a BMI <25 .¹¹³ Moreover, moderate weight loss in overweight patients with chronic nondiabetic proteinuric nephropathies markedly reduced proteinuria, whereas in overweight subjects who did not lose weight renal function worsened with time.¹¹⁴ These observations suggest that obesity greatly exacerbates the loss of renal function in patients with preexisting glomerulopathies, and that weight loss may lessen the impact of renal injury from other causes.

Early structural and functional renal changes in obese subjects

Even when there is no evidence of preexisting renal disease, excess weight gain causes early structural and functional changes in the kidneys that may eventually lead to more serious renal disorders. For example, structural changes in the kidneys were observed in dogs placed on a high-fat diet for only seven to nine weeks.¹¹⁵ These changes included enlargement of Bowman's space, increased glomerular cell proliferation, increased mesangial matrix, thicker basement membranes, and increased expression of glomerular-transforming growth factor β .¹¹⁵ Moreover, these early renal changes occurred with only modest hypertension, no evidence of diabetes, and only mild metabolic abnormalities.¹¹⁵

Obese humans often develop proteinuria, frequently in the nephrotic range, that may be followed by progressive loss of kidney function even in the absence of diabetes or severe hypertension.¹¹⁴ The most common types of renal lesions observed in renal biopsies of obese subjects are focal and segmental glomerulosclerosis and glomerulomegaly.¹¹⁶ A review of 6,818 biopsies indicated that the incidence of obesity-related glomerulopathy, defined as combined focal glomerulosclerosis and glomerulomegaly, rose tenfold from 1990 to 2000, coincident with the rapid increase in the prevalence of obesity during this period.¹¹⁶

The mechanisms of obesity-induced renal injury are not fully understood but likely involve a combination of hemodynamic and metabolic abnormalities. As discussed previously, obesity causes marked glomerular hyperfiltration and prerenal

Figure 38–11. Adjusted relative risk for ESRD by BMI. In this retrospective cohort study of 320,252 adults followed for 15 to 35 years, the rate of ESRD increased in a stepwise manner as BMI increased. This relationship was not affected by blood pressure levels or diabetes. The model was adjusted for age, sex, race, education level, smoking status, history of myocardial infarction, serum cholesterol level, proteinuria, hematuria, and serum creatinine level (Redrawn from data in reference 111).

Figure 38–12. Percentage of patients who did not develop renal insufficiency after unilateral nephrectomy and who were lean (BMI <25, solid line) or obese (BMI >30, dashed line) at the time of unilateral nephrectomy. (Redrawn from data in reference 112.)

vasodilation that permit greater transmission of the increased arterial pressure to the glomerular capillaries.¹¹⁷ These renal hemodynamic changes, along with metabolic abnormalities (such as hyperglycemia and hyperlipidemia) exacerbate the effects of increases in arterial pressure to cause renal injury. A synergistic relationship may exist between metabolic abnormalities and increased glomerular pressure in causing chronic renal vascular disease and nephron loss, similar to the synergistic effects of hypertension, diabetes, and dyslipidemia in increasing the risk for coronary artery disease and myocardial infarction.¹⁰⁸ However, there are no large-scale studies that have tested this idea.

Caloric restriction and weight loss may prevent or attenuate renal disease

There is compelling evidence in rodents that excess caloric intake causes progressive nephron loss and that caloric restriction protects against glomerular injury. Modest food restriction (8 to 18% below the usual *ad lib* amounts) in the obese Zucker rat, for instance, reduces renal injury and increases life span by approximately 30%.¹¹⁸ Similar beneficial effects of food restriction have been observed in other models of obese and nonobese rodents, indicating that food restriction can largely prevent chronic renal disease in rats.

Short-term weight loss also reduces proteinuria in non-diabetic obese humans, even in overweight subjects with nephropathies caused by factors other than obesity.¹¹⁴ The renal benefits of weight loss are evident regardless of whether they are induced by diet and exercise or by surgical methods (e.g., gastroplasty), although there have been no large studies directly comparing the effectiveness of different methods of weight loss on progression of renal dysfunction. Most of these studies have lasted only a few weeks or months.

Studies lasting for at least a year, however, have shown remarkable reductions in proteinuria (>80%) with a weight loss of about 12%.¹¹⁹ Although the long-term consequences of weight loss in protecting against renal disease have not been rigorously tested in humans, there is little doubt that weight loss reduces hypertension and prevents or reverses the development of type 2 diabetes, the two main risk factors for development of ESRD.

Obesity causes of cardiac hypertrophy/remodeling, impaired systolic and diastolic function, and increased risk for heart failure

Obesity is associated with eccentric and concentric cardiac hypertrophy.^{120,121} Moreover, cardiac hypertrophy is more severe in obese than in lean subjects with comparable hypertension.¹²² Because blood volume and venous return are increased, there is increased preload, cardiac dilation, and development of eccentric left ventricular hypertrophy in obese subjects. The rise in blood pressure also increases cardiac afterload, leading to increased left ventricular wall thickness. Thus, when obesity is combined with increased blood pressure cardiac workload is greatly amplified and marked left ventricular hypertrophy occurs. High sodium chloride intake often occurs concurrently with high caloric intake and exacerbates obesity-induced cardiac hypertrophy, even when the high-salt diet does not raise arterial pressure.¹²³

Functional changes in the heart occur rapidly after excess weight gain. For example, in rabbits fed a high-fat diet for 12 weeks cardiac filling pressures were increased and diastolic dysfunction (associated with decreased left ventricular compliance) was evident even at this early stage of obesity.¹²⁴ Although left ventricular filling pressure in obese subjects may be within the upper limits of normal at rest, it increases disproportionately with increased venous return during exercise (often exceeding 20 mmHg). With longer durations of obesity, greater impairment of left ventricular diastolic function occurs and left ventricular systolic dysfunction may develop.¹²⁵

The mechanisms responsible for cardiac diastolic and systolic dysfunction in obesity are not well understood but probably involve structural changes in the heart, such as increased TGF- β expression, fibrosis, and functional changes such as impaired β -adrenergic receptor signaling.^{126,127} There may also be increases in intramyocellular lipids that lead to increased formation of reactive oxygen species, myocardial cell dysfunction, and apoptosis, a phenomenon known as “lipotoxicity.”¹²⁸

Although extreme obesity is widely recognized as a risk factor for heart failure, there is also evidence that overweight and lesser degrees of obesity pose a risk. For example, data from the Framingham study indicate that in obese subjects (BMI >30) the risk of heart failure was double that of subjects with a normal body-mass index.¹²⁹ A graded increase in the risk of heart failure was observed across categories of body-mass index even after adjustment for other established risk factors caused by obesity, such as hypertension and diabetes. These observations suggest that although obesity often accompanies other

established heart failure risk factors (e.g., hypertension, left ventricular hypertrophy, and diabetes mellitus) there are other pathways by which excess adiposity may increase the risk of heart failure.

Established risk factors such as increased blood pressure, cardiac hypertrophy, and diabetes clearly play an important role in linking obesity to heart failure. Obesity markedly increases the workload on the heart, with attendant high cardiac output and high blood pressure, and could unmask latent ventricular dysfunction of other etiologies. The RAAS and SNS are activated in obesity, as discussed previously, and increased activity of these systems has been implicated in the pathophysiology of chronic heart failure.

As previously mentioned, lipid accumulation in and around myocytes may also contribute to cardiac cell death and eventually cardiomyopathy.¹³⁰ Although adipocytes have the capacity to store large amounts of excess free fatty acids in cytosolic lipid droplets, cells of non-adipose tissues such as the heart have a limited capacity for storage of lipids. When this capacity is exceeded, the excess lipid may lead to cell dysfunction or cell death. In addition, intramyocardial lipid accumulation can occur because of increased blood fatty acid levels and increased cellular uptake (as occurs in obesity) and/or because of mitochondrial dysfunction and decreased oxidation of fatty acids (as occurs in heart failure).

Heart failure patients with severe metabolic dysregulation have marked intramyocardial triglyceride accumulation,¹³¹ and the lipid-overloaded human heart has a transcriptional profile similar to that of animal models of lipotoxicity and contractile dysfunction, suggesting that impaired fatty acid metabolism or excess fatty acid uptake may contribute to cardiac dysfunction.¹³¹ In addition, chronic dependence on mitochondrial fatty acid oxidation for energy production (as occurs in the diabetic heart) may lead to cellular lipotoxicity, mitochondrial dysfunction, and cell death.

The gradual loss of cardiomyocytes may then impair cardiac function and increase the risk of heart failure. Although studies in obese rodents indicate that cardiac steatosis (lipid accumulation) can lead to lipotoxic cardiomyopathy,^{128,130} the importance of this mechanism in causing cardiac dysfunction and heart failure in obese humans, and the cellular mechanisms involved, await further investigation.

Hypercoagulation and increased risk for thrombosis in obesity

Increased risk for thrombosis may also contribute to a higher incidence of target organ injury in obesity. Obesity is associated with polycythemia, and there is epidemiologic evidence that hypercoagulation and impaired fibrinolysis activity are related to BMI or waist-to-hip ratio.^{132–134} For example, obese patients (especially those with increased visceral fat) have higher plasma concentrations of all pro-thrombotic factors (fibrinogen, vonWillebrand factor, and factor VII) compared to nonobese controls.

Plasma concentration of plasminogen activator inhibitor-1 (PAI-1) is also higher in obese patients compared to

nonobese controls and is directly correlated with visceral fat. The increased flux of free fatty acids in obesity may promote thrombosis by increasing protein C, PAI-1, and/or platelet aggregation. Adipose tissue production of leptin and other inflammatory mediators has also been suggested to be an important factor in causing increased thrombosis.¹³⁴

TREATMENT OF OBESITY HYPERTENSION

Weight loss and lifestyle modification

Although obesity is rapidly becoming the most important and most prevalent health care problem of the modern world, few effective treatments are available to prevent or treat obesity. For morbidly obese patients (BMI >40) or for patients with a BMI >35 and co-morbid conditions, various surgical procedures (especially gastric bypass surgery) are becoming increasingly popular and usually produce significant weight loss. However, the long-term consequences of these procedures in reversing cardiovascular and renal disease and on overall mortality are still uncertain.

Only two drugs—sibutramine (a sympathomimetic that induces satiety and increases thermogenesis) and orlistat (a gastrointestinal lipase inhibitor)—are currently approved by the Food and Drug Administration (FDA) to promote weight loss. Both of these drugs have significant side effects that limit their use in many patients, and their long-term effects on morbidity and mortality are unknown.

Recently, another anti-obesity drug (rimonabant) has been tested in several clinical trials. Rimonabant, a selective blocker of the cannabinoid receptor type 1 (CB1), has been shown in several large trials to cause significant weight loss and reduction in waist circumference over a one-year period of treatment compared to placebo.¹³⁵ Therapy with rimonabant is also associated with favorable changes in serum lipid levels and an improvement in glycemic control in prediabetes patients and in type 2 diabetic patients. However, the long-term (over a period of many years) benefits of rimonabant, as well as other anti-obesity drugs, in maintaining weight loss and in reducing blood pressure and cardiovascular disease are uncertain.

Until more effective and safer pharmacologic treatments are available, voluntary weight loss initiated by lifestyle modification (including increased physical activity) is still the best option for most overweight patients.¹³⁶ Several studies have shown that weight loss lowers blood pressures in normotensive or hypertensive obese subjects,^{137,138} and may prevent the development of hypertension in persons with “high normal” blood pressures.¹³⁷ Even modest (5 to 10%) weight reduction can improve control of blood pressure and reduce the amount of medication necessary to achieve goal blood pressures.^{19,139,140} Weight loss is also effective in reducing other risk factors (e.g., blood glucose and lipids) for cardiovascular and renal disease in most hypertensive patients.

Current guidelines for achieving weight loss usually recommend the development of an individualized plan

for lifestyle modification as a first step in reducing caloric intake and increase energy expenditure.¹³⁶ However, lifestyle modifications alone have not proved successful in producing significant long-term weight loss in most obese patients. One major challenge to successful prevention and treatment of obesity has been the lack of adequate involvement of health care professionals.

Less than half of obese adults report that their physicians advised them to lose weight.¹⁴¹ On the other hand, patients whose physicians advised them to lose weight were three times more likely to attempt to lose weight as those who received no such advice from their physicians.¹⁴² The successful management of obesity requires the same attention and planning for effective treatment as other important chronic medical conditions, such as hypertension.

Drug therapy of hypertension in obese patients

Until effective strategies for preventing and treating obesity are developed, the therapeutic strategy for managing most obese patients will continue to be aimed at treating the cardiovascular, metabolic, and renal consequences of obesity. Currently, there are no specific recommendations or treatment algorithms for obesity hypertension. Moreover, there are no specific treatment goals for obese hypertensive patients, although it has been suggested that goals for obesity hypertension should be similar to those recommended for other high-risk patients (e.g., diabetes, <130/80 mm Hg).¹⁴³ Other chapters in this book are devoted to drug therapy of hypertension and we will therefore provide only a brief summary of special considerations for the obese hypertensive patient.

Selection of specific drugs for antihypertensive therapy in obese subjects is often empiric or based on clinical experience and knowledge of the physiology of obesity hypertension.¹⁴⁴ The potential advantages and disadvan-

tages of different antihypertensive drugs in obese patients have been previously reviewed and some of these are outlined in Table 38–3.^{144,145} However, there have been no large clinical trials that have tested the effectiveness of different drugs in reducing blood pressure and in preventing cardiovascular and renal disease in obese compared with lean subjects.

The Antihypertensive Therapy and Lipid-Lowering Heart Attack Trial (ALLHAT), however, included many overweight subjects and provides useful information about the relative effectiveness of the four main classes of antihypertensive drugs tested: diuretics, β -adrenergic blockers, ACE inhibitors, and calcium antagonists.¹⁴⁶ In addition, some inferences may be drawn from randomized controlled clinical trials of drug therapy in essential hypertension patients because most of these trials have included many subjects who were overweight or obese.

Optimal blood pressure control

For many obese patients, the coexistence of additional risk factors such as hyperlipidemia, glucose intolerance or diabetes, and atherosclerosis strongly suggests that goal blood pressures should be lower than in lean hypertensive patients who do not have these risk factors. For patients with renal disease or diabetes, the blood pressure goal is <130/80 mmHg. Although overweight and obese individuals have increased risk for renal disease and diabetes, there have been no clinical trials assessing optimal blood pressure in obesity hypertension.

Recent recommendations stress that optimal blood pressure is <120/80 mmHg for all individuals, and this seems especially appropriate for obese hypertensive patients with multiple metabolic abnormalities. Because hypertension may be more difficult to control in obese subjects, combination drug therapy is often required to achieve goal blood pressures. As discussed previously,

ANTIHYPERTENSIVE THERAPY IN OBESITY HYPERTENSION: POTENTIAL BENEFITS AND ADVERSE EFFECTS		
Drug Class	Potential Benefits	Potential Adverse Effects
Diuretics	<ul style="list-style-type: none"> • Diuresis • Natriuresis 	<ul style="list-style-type: none"> • ↓ Insulin sensitivity • ↑ LDL, triglycerides

Table 38–3. Antihypertensive Therapy in Obesity Hypertension: Potential Benefits and Adverse Effects

weight loss substantially reduces the number of medications needed to control blood pressure.

Diuretics

Because of their ability to reduce renal sodium and water reabsorption and decrease extracellular fluid volume, diuretics are useful in lowering blood pressure in many obese hypertensive patients.¹⁴⁷ Some clinicians prefer diuretics in obese patients because of the strong evidence from randomized controlled clinical trials indicating that reducing blood pressure with diuretics lowers cardiovascular morbidity and mortality.²¹ However, because obese patients often have glucose intolerance and dyslipidemia some clinicians avoid diuretics, if possible, to prevent worsening these metabolic abnormalities.¹⁴⁸

Although studies using high doses of diuretics have demonstrated significant adverse metabolic effects (e.g., increases in insulin resistance and plasma lipids), low doses of diuretics are less frequently associated with these effects, and, when used in combination with other agents, can be very useful in treating obesity hypertension.²¹ However, because most clinical trials have been conducted over a relatively short period of time (five years or less) the overall impact of the potential adverse metabolic effects of diuretics in obese patients is still uncertain.

Beta-adrenergic blockers

In obese patients, β -blockers may be useful in counteracting some effects of obesity-induced sympathetic activation, such as stimulation of renin secretion. β -blockers are also especially beneficial in patients after myocardial infarction, and studies have demonstrated that these drugs decrease morbidity and mortality in diabetic patients (most of whom are overweight or obese).¹⁴⁹ However, β -blockers may make it more difficult for obese patients to lose weight. In addition, in some studies β -blockers are associated with worsening glucose control, higher lipid levels, and increased body weight.¹⁴⁴ Thus, although β -blockers may be indicated in obese hypertensive patients with ischemic heart disease and/or arrhythmias other drugs may be preferable for initial therapy in those who have no evidence of heart disease.

Angiotensin-converting enzyme (ACE) inhibitors

ACE inhibitors are useful in treating obesity hypertension. In a 12-week multicenter double-blind trial in which 77 obese patients were treated with lisinopril, 76 with hydrochlorothiazide (HCTZ), and 79 with placebo, findings suggested that ACE inhibition is effective in reducing blood pressure, particularly in young white patients, and may offer some advantages in patients with high risk of metabolic disorders.¹⁵⁰ The ability of ACE inhibitors to attenuate glomerular hyperfiltration and urinary protein excretion provides an advantage in managing blood pressure in obese patients prone to renal disease. Improved insulin sensitivity associated with ACE inhibitors is another advantage of these drugs.

One of the few randomized controlled trials in obese hypertensive patients included an ACE inhibitor. The Treatment of Obese Patients with Hypertension (TROPHY)

study compared the blood pressure responses to the ACE inhibitor lisinopril and to the diuretic HCTZ in obese hypertensives.¹⁵⁰ Both agents effectively lowered systolic and diastolic blood pressure after 12 weeks of therapy. African Americans and older participants were more likely to respond favorably to the diuretic, whereas Caucasian and younger participants were more likely to respond to the ACE inhibitor.¹⁵⁰

Studies in patients with hypertension and/or congestive heart failure have demonstrated that responses to ACE inhibitors depend on sodium intake and volume status. With high sodium intake, the effectiveness of ACE inhibitors is diminished. However, when these drugs are used in combination with diuretics they are effective even in patients who do not have elevated PRA.²¹

Angiotensin II receptor blockers (ARBs)

The effectiveness of ARBs has not been well characterized in obese hypertensive patients. In a study of 68 obese hypertensive patients treated with the ARB candesartan and 59 obese hypertensive patients treated with HCTZ, the ARB was found to have an antihypertensive effect similar to that of HCTZ.¹⁵¹ Unlike diuretic treatment, however, ARB improved insulin sensitivity and appeared to exert a sympathoinhibitory effect in obese hypertensive patients.

Some ARBs are partial agonists for peroxisome proliferator activator receptor-gamma (PPAR γ) and have been shown in rodents to reduce visceral fat accumulation and liver steatosis.¹⁵² However, metabolic improvements, including increased insulin sensitivity, reduction in adipocyte cell size, and a trend toward reduction in intramyocellular lipids have also been reported with ACE inhibition in rodent models,¹⁵³ making it unclear whether the beneficial metabolic effects of ARBs are due to PPAR γ activation or to Ang II blockade. Although these effects could be beneficial in obese patients, additional studies in obese hypertensive humans are needed.

Studies in patients with essential hypertension suggest that ARBs have blood-pressure-lowering effects very similar to those of ACE inhibitors.²¹ There are some differences between these two drug classes (e.g., the effect of ACE inhibitors to increase kinin levels) that may be responsible for subtle differences in the incidence of complications such as angioedema and cough. It is likely that obese patients would have similar blood pressure responses to ACE inhibitors and ARB, although this has not, to our knowledge, been tested in a major clinical trial.

Extensive trials have been completed in hypertensive patients, including those with diabetes, to examine the effects of ARBs on cardiovascular morbidity and mortality and on progression of renal disease. Two different ARBs were demonstrated to prevent or decrease proteinuria in hypertensive patients with type 2 diabetes mellitus.^{81,82,154} Thus, ARBs may be especially useful in obese patients with renal disease.

α 1-adrenergic blocking agents

Results of ALLHAT suggest that α -adrenergic blockers as monotherapy are not as effective as thiazide diuretics in

preventing heart failure and cardiovascular disease. Therefore, these drugs will likely be used less as monotherapy for patients with essential hypertension, including those who are obese. Because they lower plasma lipids, they may continue to play a role in combination therapy for managing obese hypertensive patients with dyslipidemia.¹⁵⁶ They may also be useful as part of a combination of medications in many patients with resistant hypertension, which is common in obese patients.^{57,144}

Calcium channel blockers

These drugs are frequently used to treat obese hypertensive patients. Their effectiveness does not seem to depend much on sodium intake, the RAAS, or SNS activity. Because calcium channel blockers are effective in a broad range of hypertensive patients, including obese subjects, they have been widely used.²¹ However, some studies suggest that calcium channel blockers are less effective in obese than in lean hypertensive patients.^{146,157} The dihydropyridine calcium antagonists also have the potential disadvantage of further increasing heart rate in obese patients. The non-dihydropyridine calcium antagonists, in contrast, lower heart rate.²¹

It is obvious that randomized controlled clinical trials measuring morbidity and mortality as well as the physiologic consequences of different treatments would be helpful in guiding drug selection for obese hypertensive patients. In the absence of such trials (which are unlikely to be conducted in the near future), clinicians will need to make decisions based on their understanding of the pathophysiology of obesity hypertension and the characteristics of the individual patient. The overall therapeutic goal is, of course, to reduce morbidity and mortality by selecting pharmacologic therapy appropriate to control blood pressure, attenuate the development of cardiovascular and renal disease, and effectively treat the metabolic disorders associated with obesity.

Obstructive sleep apnea

Obstructive sleep apnea (OSA) is considered a cause of secondary hypertension but is usually associated closely with obesity.⁴⁹ Sleep apnea can exacerbate underlying disease or cause problems for those who are otherwise healthy. Although very common in obese subjects, this life-threatening disorder is often overlooked in the assessment and treatment of hypertensive patients. The association between sleep-disordered breathing and hypertension is seen in all gender, ethnic, and age groups.¹⁵⁸

In the Wisconsin Sleep Cohort study, an independent relationship between sleep-disordered breathing and incident hypertension was seen in a four-year follow-up.¹⁵⁹ Individuals with mild to moderate OSA had a 42% greater chance of having hypertension than did persons with normal sleep patterns. Those with more severe OSA were two to three times more likely to develop hypertension compared to those without evidence of OSA.¹⁶⁰ Thus, there is a clear association between the severity of OSA and hypertension. In addition to daytime hypertension, OSA causes nocturnal surges in blood pressure.^{49,159,161} OSA also causes pulmonary hypertension,

increased sympathetic activity, hypoxia, cardiac arrhythmias (e.g., atrial fibrillation), and sleep disturbance.¹⁶¹

Increased sympathetic activity may be a key factor in mediating increased arterial pressure in OSA.^{49,161} Impaired endothelial function and decreased release of nitric oxide may also play a role.¹⁶² An understanding of the physiologic changes in OSA that cause hypertension may provide an opportunity to develop noninvasive treatments that improve blood pressure control in obese patients.

All patients with obesity hypertension should be questioned about symptoms of their sleep disturbance, including snoring, choking or gasping during sleep, daytime somnolence, and morning headaches. Treatment of OSA with continuous positive airway pressure (CPAP) decreases daytime and nocturnal blood pressures.¹⁶³ Identification of OSA and effective treatment with weight loss, continuous positive airway pressure, or surgical intervention may be necessary to achieve adequate blood pressure control in some obese patients. A reduction in hypertension and cardiovascular events and improvements in quality of life may result from management of this frequently overlooked disorder.

SUMMARY AND PERSPECTIVES

There has been an alarming increase in the prevalence of overweight and obesity in most industrialized countries and even in underdeveloped countries, resulting in a worldwide rise in diabetes mellitus, hypertension, and renal disease. Excess weight gain is the key risk factor for increased blood pressure in most patients with essential hypertension, and also appears to be a major cause of chronic renal disease. Obesity initially raises blood pressure by increasing renal tubular reabsorption, impairing pressure natriuresis, and causing volume expansion. These changes are due to activation of the SNS and RAAS and to physical compression of the kidneys when visceral obesity is present (Figure 38–13).

Sympathetic activation in obesity may in part be mediated by increased levels of leptin, acting via complex

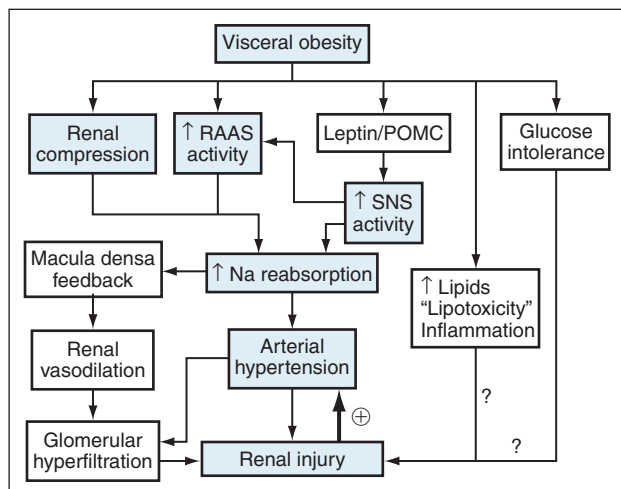

Figure 38–13. Summary of potential mechanisms by which obesity causes hypertension and renal injury.

hypothalamic pathways (especially stimulation of POMC neurons and subsequent activation of MC3/4R). Renal vasodilation, glomerular hyperfiltration, and increased blood pressure initially help to compensate for increased tubular reabsorption in obesity. However, the resultant increases in glomerular hydrostatic pressure and wall stress (along with activation of neurohumoral mechanisms, hyperlipidemia, and hyperglycemia) eventually cause glomerular injury and loss of nephron function. Blockade of the SNS and RAAS are therefore effective in reducing blood pressure in many obese patients. With prolonged obesity, there may be progressive renal dysfunction that worsens the hypertension. In some obese individuals, renal injury may progress to ESRD, especially if other preexisting glomerulopathies are present.

Weight reduction is an essential first step in the management of obesity-associated hypertension and renal disease. There are, however, few drugs available to produce signifi-

cant long-term weight loss and few guidelines for treating obesity-associated hypertension other than the recommendation of reducing weight. Special considerations for the obese patient, in addition to controlling blood pressure, include correcting the metabolic abnormalities and protecting the kidneys from further injury. More emphasis should be placed on lifestyle modifications that help patients maintain a healthier weight and prevent obesity, and consequently hypertension and associated cardiovascular and renal disease. Efforts to prevent the development of obesity are critically needed in populations throughout the world.

Exercise and Hypertension

Kevin P. Davy and Christopher L. Gentile

Key Findings

- Physical inactivity is a major risk factor for the development of hypertension.
- There is an inverse relation between the amount of physical activity and the level of arterial BP.
- Regular aerobic exercise training decreases systolic and diastolic BP in both normotensive and hypertensive individuals.
- The BP-lowering effect of regular aerobic exercise is independent of changes in total body adiposity. Whether reductions in abdominal visceral fat with exercise training contribute independently of total body adiposity is unclear.
- Consistent with public health recommendations, BP lowering can be achieved with as little as 30 minutes per day of moderate-intensity walking activity.

Physical inactivity is a major risk factor for cardiovascular diseases, including hypertension.¹ Regular physical activity has long been regarded as an effective means of reducing risk.² The results of numerous epidemiologic and experimental studies support the idea that physical activity plays an important role in the etiology, prevention, and treatment of hypertension. Thus, regular physical activity has been included in the broader recommendation of lifestyle modification to prevent and manage hypertension.³

ROLE OF PHYSICAL INACTIVITY IN THE ETIOLOGY OF HYPERTENSION

Physically inactive individuals demonstrate higher levels of blood pressure (BP) compared with their more active peers,⁴ and there is an inverse relation between the amount of physical activity performed and both the level of BP and incidence of hypertension.⁵ Furthermore, low levels of physical activity are associated with an increase in the incidence of hypertension.^{6–10} Taken together, these facts indicate that physical inactivity appears to play an important role in the development of hypertension.

An observation that may cause some to discount physical inactivity as an important cause of hypertension is the fact that not all sedentary individuals have hypertension by clinical standards (i.e., 140/90 mmHg). However, it is also a possibility that most individuals experience an increase in BP with physical inactivity, but the baseline BP is variable. A person with a low baseline BP may not attain hyper-

tensive levels of BP with physical inactivity, but BP is higher than observed in the physically active state. On a population basis, physical inactivity likely shifts the frequency distribution of BP, so that a much greater fraction of sedentary individuals would be hypertensive compared with active subjects. This would be consistent with observations that regular aerobic exercise reduces BP in normotensive and hypertensive subjects,^{11–13} as well as the observation that cessation of exercise training increases BP.¹⁴ Furthermore, it is important to emphasize that the association between BP and cardiovascular mortality is evident at BPs as low as 120/80 mmHg¹⁵ and perhaps lower. Thus, any elevation in BP above normal would be associated with an increased risk. In turn, any reduction in BP in individuals with elevated baseline levels should confer cardiovascular protection.

Obesity, particularly abdominal obesity, substantially increases the risk of developing hypertension.^{16,17} Physically inactive individuals have higher levels of total body and abdominal visceral fat compared with their active peers.^{4,18} Importantly, the scenario described previously does not preclude a role for other important factors such as obesity and weight gain in hypertension development.^{16,17} Rather, physical inactivity and obesity interact to further increase BP and its cardiovascular sequelae.^{9,19} Indeed, physical inactivity amplifies the risk of hypertension with weight gain,^{9,19} particularly in those with an excess accumulation of abdominal visceral fat.²⁰

ROLE OF PHYSICAL ACTIVITY IN THE TREATMENT OF HYPERTENSION

Regular physical activity is recommended for individuals with elevated BP.³ The results of several meta-analyses on the topic have concluded that regular aerobic exercise lowers resting systolic (~4 to 7 mmHg) and diastolic (~2 to 6 mmHg) BP in hypertensive individuals.^{12,13,21} The conclusion of more traditional literature reviews has been that regular aerobic exercise produces a much larger reduction in systolic (~11 mmHg) and diastolic (~8 mmHg) BP in hypertensives.¹¹ Importantly, the reduction in BP with exercise training is dependent on sustaining regular physical activity¹⁴ because detraining is associated with a return in BP to its initial level.

There is increasing evidence that ambulatory BP is a stronger predictor of adverse outcomes^{22–25} than resting BP. The results of randomized controlled studies suggest that regular aerobic exercise training reduces ambulatory BP,

but the effect is generally smaller than observed for resting BP.²⁶ In addition, regular physical activity appears to exert a larger influence on daytime compared to nighttime BP. The reduction in daytime BP may be due to both a reduction in BP at rest as well as during submaximal activities of daily living.

Characteristics of the stimulus

The intensity, frequency, duration, and mode of the exercise stimulus all may influence the magnitude of reduction in BP (Box 39–1). The general characteristics of the exercise stimulus in previous studies vary considerably and range from an intensity of ~40 to 80% of maximal oxygen consumption 2 to 6 times per week for a duration lasting from 4 weeks to 1.5 years. Many modes of exercise have been studied, including walking, jogging/running, cycling, and swimming.²⁶

The magnitude of BP lowering appears to be as great or greater with low- to moderate-intensity exercise (i.e., <70% of maximal aerobic capacity) compared with high intensity exercise (i.e., >70% maximal aerobic capacity).^{11,13,26} This would seem important from a public health perspective because low to moderate intensities are recommended by the Institute of Medicine,²⁷ the American College of Sports Medicine, and the Centers for Disease Control and Prevention²⁸ and may be preferred by most individuals engaging in regular physical activity for the purposes of improving health.²⁹

Neither the frequency nor duration of exercise training exerts any clear influence on the magnitude of BP lowering.^{11,13,21,26} Most of the BP lowering is observed in the first 2 to 3 weeks of initiating exercise training, with little or no further reductions observed with time.^{11,30}

Regular aerobic exercise involving walking, jogging/running, cycling, and swimming all appear to result in significant BP lowering.²⁶ Whether a particular mode has superior efficacy compared with other modes has not been directly tested.

The result of a recent meta-analysis suggests that strength training may lower systolic and diastolic BP by ~3 mmHg, although the efficacy of strength training for lowering BP in hypertensives remains unclear.²⁶ Strength training increases arterial stiffness in normotensive individuals.³¹ However, whether this also occurs in hypertensive individuals is not

known. Taken together, these observations question the utility of resistance exercise as a sole therapeutic strategy for lowering BP in hypertensive individuals.

The relative benefit of intermittent compared with continuous physical activity on BP lowering has received little attention to date. Preliminary evidence suggests that reductions in BP may be observed when exercise is performed for 10 minutes 3 times a day (5 days/week) at a low to moderate intensity.³² Whether this intermittent pattern of physical activity is more (or less) effective than continuous physical activity in sustaining the BP lowering is not at all clear.

Characteristics of the individual

There are numerous individual characteristics that have the potential to modify the magnitude of BP lowering with exercise training (Box 39–2). Of the characteristics studied, baseline BP appears to exert the most significant influence.^{11,13,21,26} Individuals with the highest baseline BP generally demonstrate the largest reduction in BP with regular aerobic exercise. Therefore, regular aerobic exercise appears to be most beneficial for those in most need of its BP-lowering potential.

The prevalence of hypertension is similar in men and women and increases with advancing age in both genders. In this respect, middle-age and older individuals experience somewhat larger and more consistent reductions in BP with exercise compared with young individuals.^{11,13,26} The effect of exercise on BP in children is less clear.³³ With regard to ethnicity, there are considerable differences in the prevalence of hypertension among ethnic groups. Despite these differences, exercise training appears to reduce BP in adult men and women of all ethnic groups studied to date,^{11,13,21,26} including African Americans, the group with the highest prevalence of hypertension.

Obesity increases the risk of hypertension^{16,34} and is considered by some to be a form of resistant hypertension.³⁵ However, the presence of obesity or the baseline level of total body adiposity (i.e., body mass index or body fat percentage) does not appear to predict the magnitude of BP lowering with exercise.^{11,13,26}

There is considerable variability in the BP lowering observed with exercise training, suggesting that genetic variation may play a role.^{11,26,36} Recent evidence suggests that hyper-

tensives with one or both ACE I alleles demonstrate larger reductions in systolic BP with exercise training compared with individuals homozygous for the ACE D allele.³⁷ It is important to emphasize that although not all hypertensives may demonstrate BP lowering with exercise nonetheless exercise training may provide numerous other benefits (see material following). Importantly, the risk of mortality is reduced in physically active hypertensives.³⁸

INFLUENCE OF REGULAR AEROBIC EXERCISE ON DISEASE RISK AND TARGET ORGAN DAMAGE IN HYPERTENSIVE INDIVIDUALS

Cardiovascular risk factors

Individuals with hypertension frequently exhibit a clustering of other cardiovascular and metabolic disease risk factors such as insulin resistance, glucose intolerance, dyslipidemia, impaired fibrinolysis, and low-grade inflammation.³⁹ In addition, hypertension and type 2 diabetes frequently coexist.⁴⁰ Regular exercise training is generally associated with increases in insulin sensitivity, glucose tolerance, and high-density lipoprotein cholesterol and with reductions in total cholesterol, low-density lipoprotein cholesterol, triglycerides, and markers of inflammation (e.g., c-reactive protein).⁴⁰ Thus, regular physical activity has the potential to markedly lower disease risk beyond BP lowering in hypertensive individuals.

Left ventricular mass and function

Left ventricular hypertrophy and ventricular dysfunction are associated with an increased risk of heart failure and are common consequences of hypertension. Thus, regression of left ventricular hypertrophy is an important goal of antihypertensive therapy and is frequently observed with BP lowering. Indeed, exercise training reduces left ventricular mass in hypertensive adults.^{41,42} The magnitude of reduction in left ventricular mass appears to be most closely related to the magnitude of reduction in systolic BP.⁴² The mechanism or mechanisms responsible for the reduction in left ventricular mass have not been determined. In contrast to that observed in normotensive older adults,^{43,44} neither systolic nor diastolic function appears to improve with exercise training in hypertensives.⁴²

Large artery stiffness

Large artery stiffening is independently associated with the development of hypertension.⁴⁵ In addition, arterial stiffness is an independent predictor of coronary events,⁴⁶ stroke,⁴⁷ and all-cause mortality⁴⁸ in individuals with hypertension. In contrast to observations in normotensive older adults,⁴⁹ the available evidence suggests that regular aerobic exercise is not effective in reducing large artery stiffness in adults with elevated BP.⁵⁰ However, the previous studies on this issue were relatively short in duration (i.e., 3 months), and the subjects did not experience weight loss. Whether longer-duration exercise training (with or without weight loss) is necessary to reduce large artery stiffness in this population is unknown.

Endothelial function

Endothelial dysfunction has been linked to several cardiovascular complications (e.g., arterial spasm, thrombosis, and myocardial infarction), which occur more frequently in hypertensive individuals.¹ Endothelial-dependent vasodilatation is impaired in hypertensive individuals, and the degree of impairment is influenced by the severity of hypertension^{51,52} and by the presence of obesity.⁵³ Furthermore, the ability of the endothelium to release t-PA is also impaired in hypertensives.⁵⁴ Regular aerobic exercise enhances endothelium-dependent vasodilatation in hypertensive individuals.⁵⁵ The improvement appears to be due, at least in part, to enhanced nitric oxide production because the effect of physical activity is abolished following intra-arterial infusion of the nitric oxide synthase inhibitor NG-monomethyl-L-arginine.⁵⁶ Whether other mechanisms, such as reduced endothelin-mediated vasoconstriction and/or oxidative stress, contribute has not been determined. Regular exercise training increases endothelial t-PA release in nonobese and obese middle-age and older adults with normal BP,⁵⁷ although there is unfortunately no evidence in hypertensive individuals.

Kidney function

Prolonged hypertension is associated with an increase in urinary protein excretion and gradual loss of nephron function that worsens with time and aggravates hypertension. In addition, kidney disease progresses much more rapidly in the presence of hyperglycemia and dyslipidemia.⁵⁸ Unfortunately, little is known regarding the influence of regular exercise training on kidney function in hypertensive individuals. In general, lowering of BP and improvement in glucose and lipid metabolism would be expected to reduce kidney damage in hypertensive individuals. Certainly, regular physical activity would be expected to reduce kidney damage when accompanied by significant weight loss.⁵⁹

MECHANISMS MEDIATING THE BP-LOWERING EFFECT OF ACUTE AND CHRONIC EXERCISE

In 1898, Hill⁶⁰ noted, perhaps for the first time on record, that "...after such exertion the pressure falls to normal far more rapidly than the pulse-frequency. The arterial pressure becomes depressed below the normal pressure after severe muscular work." Since that time, numerous studies have documented the phenomenon of postexercise hypotension.^{26,61}

In normotensive individuals, moderate-intensity physical activity lasting 30 to 60 minutes may lower BP immediately postexercise ~5 to 10 mmHg in the supine posture for up to ~2 to 3 hours.⁶¹ The postexercise hypotension (i.e., the reduction in BP after a single bout of exercise) may reach 16 to 20 mmHg in older hypertensive patients,⁶² and may remain lower up to ~24 hours after exercise.⁶³ These reductions in BP following a single bout of exercise compare favorably with the reductions observed following exercise training. However, the degree to which the phenomenon of postexercise hypotension contributes to the

lower BP observed following exercise training remains unclear.

It also is possible that the postexercise hypotension observed with acute exercise could be superimposed on the reduction in BP following exercise training. The duration of exercise necessary to elicit a significant postexercise hypotension is not known. If a significant postexercise hypotension were evident following, for example, 10 minutes of exercise a hypertensive patient might perform a vigorous 10-minute walk in the morning, afternoon, and evening.⁶⁴ As such, they might experience significant reduction in BP that would last every hour of the day. It is important to emphasize that the results of some previous studies suggest that the postexercise hypotension observed is sufficient in magnitude and duration to significantly lower the average 24-hour ambulatory BP level.²⁶

The mechanisms responsible for postexercise hypotension are not clear. In young normotensive individuals the reduction in BP appears to be due to a pronounced fall in systemic vascular resistance that is not completely offset by an increase in cardiac output.^{61,65,66} The significant vasodilatation does not appear limited to the previously active skeletal muscle but includes inactive regions as well.^{61,65,66}

The postexercise hypotension observed in hypertensive patients is associated with a decrease in cardiac output and no change in system vascular resistance.^{62,63} The factors contributing to the reduction in cardiac output may include a reduction in plasma volume, impaired diastolic filling, and/or reduced myocardial contractility. The reasons for the apparent difference in mechanisms contributing to postexercise hypotension in normotensive and hypertensive individuals remain unclear.

It is widely held that any long-term reductions in blood pressure, including those associated with exercise training, are due to alterations in kidney function. Although direct evidence for this notion is lacking, exercise training has

Figure 39-1. Improvement in renal excretory function following reductions in the activity of sympathetic nervous and renin-angiotensin systems.

been associated with reductions in muscle sympathetic nerve activity,⁶⁷ total and renal norepinephrine spillover,^{68,69} plasma norepinephrine concentration,^{26,70} and plasma renin activity.^{71,72} These reductions in the activity of sympathetic nervous and renin-angiotensin systems and/or other factors (e.g., amelioration of oxidative stress, endothelin-1, and so on) could translate into an improvement in renal excretory function such that lower levels of BP are required to maintain sodium and water homeostasis following exercise training (Figure 39-1). However, the BP-lowering effect of regular physical activity has been observed in patients without functioning kidneys (i.e., end-stage renal disease patients undergoing dialysis),^{73,74} suggesting that alterations in the kidney are not necessary for the BP-lowering effects of chronic physical activity. Alternatively, this observation may lend further merit to the notion that the BP-lowering effect of physical activity is not a chronic adaptation but is rather due primarily to the reduction in BP associated with the last bout of exercise (i.e., postexercise hypotension).

PHYSICAL ACTIVITY PER SE VERSUS WEIGHT LOSS?

Weight loss is generally associated with reductions in BP.^{16,75,76} Thus, it is possible that the reductions in BP observed with exercise training could be due at least in part to weight loss. However, most studies have concluded that the reduction in BP with exercise training is independent of changes in whole-body adiposity.^{11,13,26}

Regular aerobic exercise has been suggested to be an effective means of reducing abdominal visceral fat, and abdominal visceral fat has been more closely associated with BP and the presence of hypertension than measures of total adiposity.⁷⁷⁻⁸³ There are several proposed mechanisms by which abdominal visceral fat might contribute to hypertension, including compression of the kidney, sympathetic neural activation, ectopic fat deposition, and local production of renin-angiotensin system components.¹⁶ Whether the reductions in abdominal visceral fat with exercise training could be contributing to the observed reductions in BP through alterations in these or other factors is unclear (Figure 39-2).

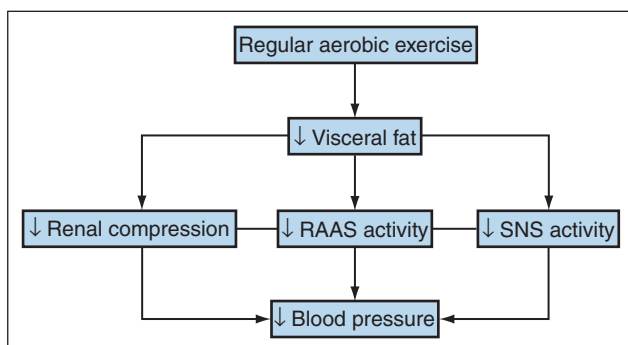

Figure 39-2. Mechanisms by which reduction in abdominal visceral fat might contribute to lower blood pressure.

REGULAR PHYSICAL ACTIVITY AND MULTIPLE LIFESTYLE INTERVENTIONS: ARE THE BP-LOWERING EFFECTS ADDITIVE?

The majority of studies suggest that regular aerobic exercise and weight loss produce similar or only slightly greater reductions in BP than either intervention alone.^{84,85} Furthermore, the results of studies that combine multiple lifestyle interventions suggest that the magnitude of BP reduction is in the range of that observed with any single intervention (i.e., weight loss, sodium restriction, or exercise).⁸⁶

Despite similar reductions in BP compared with a single intervention, there are benefits of combining therapies. For example, regular physical activity is one of the best predictors of weight maintenance.⁸⁷ Thus, improved weight maintenance and subsequent BP control may be one benefit of combining physical activity with weight loss. From a practical standpoint, some individuals may respond better to weight loss than regular physical activity (for example) and the benefits of these interventions extend beyond lowering BP. Although these issues require further study, they should be considered when implementing nonpharmacological interventions in hypertensive patients.

REGULAR AEROBIC AND MEDICATION REQUIREMENTS IN HYPERTENSION

Antihypertensive medications can be costly and are frequently associated with side effects in some individuals. As such, nonpharmacological therapy of hypertension should be effective in both lowering BP as well as in preventing or reducing the need for antihypertensive medication. In this regard, the antihypertensive effects of regular aerobic exercise can significantly reduce the amount of medication required to control BP.⁴¹

ROLE OF PHYSICAL ACTIVITY IN THE PREVENTION OF HYPERTENSION

There is no sign that the rising prevalence of obesity seen over the past two decades is dwindling,⁸⁸ and the prevalence of hypertension appears to be following closely behind.⁸⁹ The majority of the U.S. population is not engaged in adequate levels of physical activity to promote health⁹⁰ and is gaining weight at a rate of ~2 pounds per year.⁹¹ Physical inactivity and weight gain are almost invariably associated with elevated BP, perhaps in an additive or synergistic manner. In addition, regular physical activity reduces the risk of weight gain.⁸⁷ Thus, physical activity and prevention of weight gain should be complementary therapeutic targets for reducing the problem of hypertension. This is particularly important among those with elevated BP or prehypertension because the risk of developing hypertension in the future is significant for these individuals.⁹²

SUMMARY

Physical inactivity is a major risk factor for the development of cardiovascular diseases, including hypertension. There is extensive evidence supporting the favorable role of regular physical activity in the prevention and treatment of hypertension. The mechanisms responsible are unclear. Exercise training does appear to lower BP independently of changes in total body adiposity. However, it is not yet known whether reductions in abdominal visceral fat with exercise training contribute. In addition, BP can be lowered with a single bout of exercise. However, whether this phenomenon contributes to the BP lowering observed with exercise training is uncertain. Finally, the amount of physical activity necessary to lower BP may be as low as 30 minutes/day of continuous or intermittent low- to moderate-intensity exercise on most or all days of the week. The amount of physical activity necessary to prevent weight gain and hypertension may be greater.

Electrolyte Intake and Human Hypertension

Vamadevan S. Ajay, Dorairaj Prabhakaran, and Kolli Srinath Reddy

Key Findings

- Essential or primary hypertension is a sustained systolic blood pressure (BP) of greater than 140 mmHg or a diastolic BP of greater than 90 mmHg among adults of 18 years and above. Normal BP is systolic pressure of < 120 mmHg and a diastolic pressure of < 80 mmHg. Pre-hypertension is a systolic pressure of 130 to 139 mmHg or a diastolic pressure of 85 to 89 mmHg. Individuals with pre-hypertension (which is not a disease category) are at high risk for developing hypertension.
- Those in whom large changes in BP are caused by a severe abrupt change in salt intake or excretion are said to be sodium sensitive.
- Those in whom the least change in arterial pressure occurs after abrupt change in salt intake or excretion are said to be sodium resistant.
- BP may be affected by intake of electrolytes such as Na⁺ and K⁺, and possibly Ca²⁺ and Mg²⁺.
- Renal mechanisms (including nephron heterogeneity, non-modulation, and altered pressure natriuresis) are involved in electrolyte-intake-related hypertension.
- From epidemiology and intervention studies, Na⁺ or K⁺ intake has been shown to elevate or lower (respectively) BP.
- Interventional studies with Ca²⁺ and Mg²⁺ supplementation have inconsistent effects on BP.

INTRODUCTION

Dietary electrolytes have an established relationship with human BP. Considerable evidence suggests a positive association between dietary sodium chloride (common salt) intake and BP.¹ In addition, dietary patterns associated with low intakes of potassium, calcium, and possibly magnesium are associated with higher levels of BP.²

An understanding of the association of the dietary electrolytes and BP has important implications not only for the prevention and treatment of hypertension but for developing population-based strategies to decrease cardiovascular disease risk by shifting the overall BP distribution toward lower levels. In this chapter we review the relationship of electrolyte intake and human hypertension.

SODIUM AND ESSENTIAL HYPERTENSION

The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure defines *essential* or *primary hypertension* as a sustained systolic pressure of greater than 140 mmHg or a diastolic BP of greater than 90 mmHg among adults of 18 years and above.³ Normal BP is systolic pressure of < 120 mmHg and a diastolic pressure of < 80 mmHg. *Pre-hypertension* is a systolic pressure of 130 to 139 mmHg or a diastolic pressure of 85 to 89 mmHg. Individuals with pre-hypertension (which is not a disease category) are at high risk for developing hypertension.

Those individuals in whom a severe abrupt change in salt intake or excretion induces large changes in BP are referred to as salt sensitive, whereas those in whom these maneuvers cause the least change in arterial pressure are termed salt resistant.⁴ Weinberger defines salt sensitivity as a 10-mmHg or greater difference in mean BP between the level measured after 4 hours of infusion of 2 L normal saline compared to the level measured the morning after a day of a 10-mmol sodium diet, during which three oral doses of furosemide were given at 10 AM, 2 PM, and 6 PM.⁵

Changes in human dietary intake

Eaton and Konner have suggested that each species, including man, is genetically programmed to eat and metabolize specific foods (and that there is an optimum type and composition of food needed by them).⁶ Therefore, whereas a lion or tiger is programmed to eat animal food exclusively, the cow or the deer is programmed to eat plant foods only. The nutrients provided by such food habits of these animals are believed to provide optimum nutrition to them. In wild animals, the genetic programming does not include any processing of food in the form of removal of or enrichment with any nutrient components.

Humans have the capacity to consume and metabolize both plant and animal food.^{6,7} The human genetic program, which has remained essentially unchanged for the past 100,000 years, is most compatible with unprocessed mixed foods (that is, foods without removal of any nutrient components and without addition of any nutrients or other compounds). According to this theory, man-made changes in the composition of foods and diets would cause (or at least predispose man to) several pathological conditions (including elevated BP).^{6,7}

One of the major reasons for the increased burden of hypertension worldwide is alteration in dietary habits and the way foods are being processed. Thus, a shift from simple foods to highly processed complex food (the preservation of which requires salt) has led to changes in the electrolyte consumption pattern of several populations. In addition, a shift to processed food results in lower consumption of fruits and vegetables (which are rich in dietary potassium and other micronutrients).

Evidence for the role of excess sodium intake in hypertension

Animal models

Animal models provide strong evidence for the link between high sodium intake and elevated BP. Experiments in chimpanzees, which are phylogenetically close to the human, show that the addition of NaCl (5, 10, and then 15 g/d) to the chimpanzee's usual diet (a fruit-and-vegetable diet low in NaCl and high in potassium) over 20 months results in significant and progressive elevations of BP.⁸ After 84 weeks of added NaCl, the mean systolic and diastolic BPs increased by 33 mmHg and 10 mmHg (respectively) relative to both baseline values and a control group.

Within six months of cessation of the high-NaCl intake the elevated levels were completely reversed. In African green monkeys, a diet containing 6% salt for three months significantly increased the systolic and diastolic BP by 27 and 15 mmHg, respectively. Dahl salt-sensitive rats, a genetic animal model of hypertension, develop hypertension when they are fed a high-salt diet.⁹ Hypertensive rats are also susceptible to salt-induced hypertension, although they exhibit hypertension and end-organ damage without high salt treatment.¹⁰ Animal studies suggest that diets high in NaCl may also have deleterious cardiovascular consequences independent of BP (e.g., cerebral arterial disease and stroke, left ventricular hypertrophy, renal vascular disease, and glomerular injury).¹¹

Human studies

Observational studies

The International Study of Salt and Blood Pressure (INTERSALT) evaluated both within-population and a cross population hypotheses on the relationship between BP and sodium excretion in more than 10,000 adults (aged 20 to 59 years) at 52 centers around the world.¹ In this study, the 24-hour sodium excretion was significantly related to median systolic and diastolic BP, the upward slope of systolic and diastolic BP with age, and the prevalence of high BP.¹ The within-population analyses demonstrated that for individuals the relationship between sodium excretion and BP was similar for nonhypertensive and all participants, indicating that varying degrees of salt sensitivity of BP occur throughout the population.

This study concluded that for individuals a difference of 100 mEq (6 g salt) per day of sodium intake is associated with an average difference of 3 to 6 mmHg in systolic BP. For populations a 100-mEq/day lower sodium intake is associated with reduction in the rise of systolic BP by 10 mmHg in persons aged 25 to 55 years. Another study,

Cardiovascular Diseases and Alimentary Comparison (CARDIAC), carried out in at least 3,681 men and 3,653 women aged 50 to 54 years from 60 centers in 25 countries worldwide examined the relationship between 24-hour sodium excretion and BP.¹²

This study showed that systolic BP and diastolic BP were positively associated with 24-hour sodium excretion. The cross-center correlation analyses indicated positive correlations between urinary salt excretion and systolic or diastolic BP in both men and women, although the association was significant only in the men (0.98 and 0.68 mmHg per urinary salt excretion (g/day) for systolic and diastolic BP, respectively).

Another example is a community-based program on prevention of hypertension from North Karelia, Finland, initiated in 1972. In this study from 1972 to 1977, BP levels improved among patients and eventually started to stabilize during 1977 to 1982, although only 10% of the population aged 35 to 64 years was treated with anti-hypertensive medication.¹³ Upon exploring the factors contributing to the BP level, analyses confirmed that high sodium intake, high BMI, high fat intake, and alcohol drinking were significantly associated with BP both in the general population and in hypertensive persons. Furthermore, a high level of dietary sodium was also associated with unsatisfactory outcome of drug treatment among hypertensives. The North Karelia Salt Project also demonstrated that it is difficult to reduce salt intake at the community level during a short period and that a well-conceived program for a relatively long time period would be required to reduce the mean BP levels of the population.¹³

Intervention trials

The Dietary Approaches to Stop Hypertension (DASH) trial evaluated the effects on BP of three dietary patterns over eight weeks in 459 adults with high-normal BP or mild hypertension.¹⁴ The dietary interventions included (1) a control diet with potassium, calcium, and magnesium levels close to the 25th percentile of U.S. consumption, (2) a diet rich in fruits and vegetables, and (3) a "combination" diet rich in fruits, vegetables, and fat-free or low-fat dairy products. Compared with the control diet, the intervention diets had a relatively higher content of potassium, calcium, magnesium, fiber, protein, carotenoid, and folate (whereas total fat, saturated fat, and cholesterol levels were lower).

NaCl content was equivalent in all three diets (7.5 g/d). Systolic and diastolic BPs were significantly reduced by a greater extent with the combination diet (−5.5/−3.0 mmHg), followed by the diet enriched with fruits and vegetables (−2.8/−1.1 mmHg) among men and women and across all ethnic groups compared to the control diet group. BP reduction was more pronounced in hypertensive persons (−11.4/−5.5 mmHg), followed by normotensives (−3.5/−2.1 mmHg).

The DASH-II trial assigned individuals with BP ranging from 120/80 to 159/95 to a control diet or the DASH combination diet randomized to one of three dietary sodium levels [high (150 mmol/d), intermediate (100 mmol/d), or

low (50 mmol/d)] in a randomized crossover design.¹⁵ The corresponding urinary sodium excretion values were 143 mmol/d on the high-, 107 mmol/d on the intermediate, and 66 mmol/d on the low-sodium diets (respectively), indicating a quite good adherence to the goal sodium intake. There was a graded reduction in BP with each level of reduced salt intake on both the control and DASH combination diets.

The mean difference in BP between those on the highest and lowest levels of sodium intake receiving the DASH diet was 12 mmHg (equivalent to that of potent antihypertensive drugs), substantiating that the DASH diet had a greater effect in reducing BP on the two higher levels of salt intake in comparison to the control diet. Among subgroups, African Americans had the greatest decrease in BP with dietary salt reduction. As in the earlier DASH trial, no adverse effects of dietary salt reduction were observed.

Evidence from ecological studies

Migration studies provide substantial evidence for the relationship between salt intake and BP. They primarily demonstrate acculturation of individuals from low-salt-eating countries whose BP rise with changes in their lifestyles in the new environment, leading to increased consumption of salt. The seminal Kenyan Luo migration study carried out in a Kenyan agricultural community in which subsistence farmers traditionally ate a low-salt/high-potassium diet demonstrated the effect of migration on BP elegantly. Upon migration to an urban community their diet underwent marked changes.¹⁶ Specifically, there was a substantial increase in salt intake coupled with low potassium intake similar to the diet in westernized societies. BP in these migrants rose after a few months (+6.9/6.2 mmHg for systolic and diastolic), whereas it did not increase in a control group who did not migrate (suggesting that some of the changes in BP are associated with urbanization, resulting in changes in dietary electrolyte consumption patterns).

Similarly the Yi Migrant Study from China demonstrated that changes in lifestyle, including higher intake of dietary sodium, contribute to a rise in BP.¹⁷ The Yi people, an ethnic minority residing in a remote mountainous environment in southwestern China, consume a sodium-poor diet. Their BP rose very little with increasing age (0.13 and 0.23 mmHg/yr for systolic and diastolic, respectively). In contrast, Yi migrants who lived in urban areas who consumed a sodium-rich diet experienced a much greater increase in BP with progressive aging (0.33 and 0.33 mmHg/yr for systolic and diastolic, respectively).

Similar to Yi migrants, a significant positive relationship was found between sodium intake and BP among native (Han) men living in the urban areas. These findings support the role of environment in determining the dietary electrolytes intake and their impact on BP. Apart from these intra-country migrations, there are several examples of migration from one country to another leading to alterations in dietary practice with potential increases in sodium intake (resulting high BP in migrants compared to non-migrants).^{18,19}

POTASSIUM AND ESSENTIAL HYPERTENSION

Introduction

Potassium (K) intake has been hypothesized to play an important role in determining BP levels, cardiac output, and peripheral vascular resistance (indirectly contributing to the epidemic of hypertension). Potassium acts indirectly by reducing body sodium levels. The excretion of excess sodium is markedly improved by increased intakes of potassium, calcium, and magnesium.²⁰

Both in normal subjects and hypertensive subjects, BP is influenced by the dietary potassium intake.²¹ In normal humans, dietary potassium depletion raises BP, and this is associated with a blunted ability to handle acute sodium load and sodium retention. A low-potassium diet (16 mmol/day) for 10 days increases systolic and diastolic pressures by 7 and 6 mmHg, respectively, relative to 10 days on a high-potassium diet (96 mmol/day) among the borderline hypertensive patients.²² Dietary sodium excess increases urinary potassium excretion among normal human subjects. This is associated with a small fall in plasma potassium concentration. This effect can be attenuated by dietary potassium supplementation. This supplementation also attenuates the BP increase seen in diabetic children on a high-sodium diet.²²

The BP-lowering effect of potassium involves several mechanisms, such as increased natriuresis, reduced sympathetic nervous activity, and decreased pressor response to noradrenaline and angiotensin II. Among hypertensives, an increase in the level of potassium intake by approximately 1.8 to 1.9 g a day lowers the BP of hypertensive subjects so that the average fall in systolic BP is approximately 4 mmHg and that of diastolic pressure about 2.5 mmHg.²⁰

In addition, potassium may protect against stroke and other cardiovascular diseases by mechanisms unrelated to BP. Potassium is also linked to antiatherosclerotic properties and is claimed to improve glucose tolerance.²⁰

Thus, dietary supplementation of potassium can lower BP in normal and some hypertensive patients. Compared to NaCl restriction, the response to potassium supplementation is slow to appear, taking approximately four weeks. Dietary potassium supplementation also reduces the need for antihypertensive medication and may even reduce organ system complications (e.g., stroke). Salt-sensitive hypertension responds to an extent because supplementation with potassium increases the urinary excretion of sodium chloride.²²

Pathogenetic mechanisms

The antihypertensive effect of dietary potassium supplementation involves several mechanisms. It is hypothesized that dietary potassium stimulates Na⁺-K⁺-ATPase in vascular smooth muscle cells and adrenergic nerve terminals, resulting in vasodilatation.^{23,24} Further, dietary potassium supplementation also potentiates endothelium-dependent relaxation.²⁵ In later stages these changes may relate to more than a simple increase in turnover of Na⁺-K⁺-ATPase, resulting in a quasi-permanent increase

in the number of enzyme molecules (termed *potassium adaptation*).

High intake of potassium over a long term induces an increased capacity for potassium secretion in the colon, as well as in a segment of the collecting duct of the kidney.²⁶ Aldosterone has been cited as the stimulus for both of these effects. Thus, long-term potassium loading and chronic hyperaldosteronism induce similar changes in epithelia in the colon and kidney, capable of potassium secretion. Apart from increased potassium secretion, these changes encompass an increase in the number of Na⁺-K⁺-ATPase pump sites, resulting in attenuation of the vasoconstriction seen in various hypertensive states. Increased turnover of the pumps (acute administration of K⁺) or increased number of pumps (chronic administration of K⁺) or both results in increased pumping.²²

Potassium adaptation accounts for the stability of plasma potassium concentration in the face of altered potassium intake and for the delay in the antihypertensive response to dietary potassium supplementation in hypertensive subjects (the delay is more than four weeks versus one to two days in the case of sodium restriction). Hence, increased dietary potassium can lower BP in animals and humans, particularly if they have salt-sensitive hypertension (decreasing the need for antihypertensive medication).

Evidence for the role of potassium deficiency in hypertension

Animal models

There are several animal studies on the effect of potassium intake and changes in BP. Studies have documented reduction in BP in rats with reduced renal mass-saline hypertension after increased dietary potassium intake. Potassium intake significantly reduces arterial BP in the spontaneously hypertensive rat (SHR, a strain of rats generally used for studies in hypertension and cardiovascular research) through a phenomenon associated with a restoration of the endothelium-derived hyperpolarizing factor (EDHF)-mediated responses in the mesenteric vascular bed.^{22,27}

It has been reported that the Dahl salt-sensitive rat receiving a 1% sodium chloride diet has a minimum BP when eating 1.6% KCl and responds to a reduction in KCl intake with an increase in BP.^{22,28} Further, among rats a small increase in dietary potassium confers some protection against the effects of excess dietary sodium (attenuating the increase in pressure and increasing longevity, mainly by preventing strokes).²²

Human studies

Observational studies

The international cooperative INTERSALT study (which explored the relationships among population mean sodium, potassium intake, and BP) showed that BP tends to be inversely related to urinary potassium excretion and directly related to the ratio of urinary sodium excretion to potassium excretion.²¹ In this study, a significant positive association was found between 24-hour urinary sodium excretion and systolic BP as well as between the sodium/potassium ratio and systolic BP. It is reported that potas-

sium excretion of individuals was significantly and independently related inversely to their systolic BP.

Intervention trials

The DASH study demonstrated the role of dietary potassium in reducing BP. The DASH study has been discussed in detail in the section "Evidence for the Role of Sodium in Hypertension." Although the antihypertensive effect of DASH diet has been mainly attributed to a higher dietary potassium level (through consumption of fruits and vegetables), the contribution of potassium in the beneficial antihypertensive effect of the DASH diet is difficult to assess because multiple dietary changes occur at initiation of the diet.²²

Ethnic differences

Several studies have showed that African American subjects consumed less potassium than Caucasian subjects and that high BP in African American subjects is associated with low potassium intake. The increased prevalence of high BP in the African American subjects may not be related to greater dietary intake of sodium chloride, as the intake of sodium appears similar in African and Caucasian Americans and could be largely due to low-potassium diets.²²

A study on effects of race and dietary potassium has demonstrated that in most normotensive black men, but not white men, salt sensitivity occurs when dietary potassium is even marginally deficient but is dose-dependently suppressed when dietary potassium is increased within its normal range. It is believed that such suppression might prevent or delay the occurrence of hypertension, particularly in the many blacks in whom dietary potassium is deficient.²⁹

CALCIUM AND ESSENTIAL HYPERTENSION

Metabolic studies suggest that calcium may have a role in the regulation of BP. Elevated free calcium in the cytoplasm of smooth muscle cells of the vascular system creates an increased resistance in the small arterioles precipitating high BP. Several mechanisms have been invoked to explain the role of calcium in hypertension. Dietary components such as vitamin D and minerals (such as magnesium, sodium, potassium, and phosphorus) may modify calcium metabolism through alteration in the membrane pump, which controls the flow of calcium in and out of the cell. Vitamin D is essential for intestinal absorption of calcium and for the synthesis of calcium-binding protein, which serves as a carrier of calcium to the serosal side of the membrane (where calcium is actively transported out of the cell via the Na⁺/Ca²⁺ exchanger). Thus, vitamin D deficiency will result in elevated free calcium in smooth muscle cells.³⁰ Cellular calcium metabolism may be partly mediated by calcium-regulating hormones that tend to be elevated in essential hypertension such as PTH and calcitriol.³¹

Recent studies using Na⁺/Ca²⁺ exchange inhibitors and studies in mice demonstrate that salt-dependent hyper-

tension is triggered by Ca^{2+} entry through $\text{Na}^+/\text{Ca}^{2+}$ exchanger type 1 (NCX1) in arterial smooth muscle.³² Endogenous cardiac glycosides (such as ouabain, marinobufagenin, proscillaridin A, and bufalin), which contribute to salt-dependent hypertension, seem to be necessary for NCX1-mediated hypertension. When cardiac glycosides inhibit Na^+ , K^+ -ATPase in arterial smooth muscle cells, the elevation of local Na^+ on the submembrane area is believed to facilitate Ca^{2+} entry through NCX1 (resulting in vasoconstriction).

Few epidemiological studies reported that people with a higher intake of calcium tend to have lower BP. A Cochrane review combining 13 RCTs found that participants receiving calcium supplementation compared to control found a significant reduction in systolic BP (mean difference of -2.5 mmHg) but not diastolic BP (mean difference of -0.8 mmHg).³³ The review concluded that due to the poor quality of trials and due to their heterogeneity the evidence in favor of causal association between calcium supplementation and BP reduction is weak and is probably due to bias. The review suggested the need for larger, longer-duration, and better-quality double-blind placebo controlled trials in assessing the effects of calcium supplementation on BP and cardiovascular outcomes.

MAGNESIUM AND ESSENTIAL HYPERTENSION

Magnesium homeostasis has important bearing on other cations, such as calcium and potassium. In humans, optimal BP depends on a balance of both Na:K and Mg:Ca ratios at both cellular and whole-body levels.³⁴ Dietary magnesium is directly proportional to dietary calcium. Magnesium deficiency can alter calcium metabolism even when calcium intake is adequate, resulting in a state of high intracellular calcium, low serum calcium, and low urinary calcium states. High intracellular calcium and high cellular Na:K ratio both occur when cellular magnesium ratio becomes too low and the Mg-ATP-driven sodium-potassium pump and calcium pump become functionally impaired. As discussed earlier, high intracellular calcium has several vasoconstrictor effects that lead to hypertension (an indirect result of low-magnesium status).

Hypertension occurs when cellular Na:K ratios become too high, a consequence of a high-sodium/low-potassium diet. Magnesium deficiency can precipitate a pseudo potassium deficit.³⁴ In addition, magnesium status has a direct relationship with the relaxation capability of vascular smooth muscle cells and cellular $\text{Na}^+:\text{K}^+$ ratio. As a result, nutritional magnesium has both direct and indirect impacts on the regulation of BP and hypertension. Magnesium supplementation above 15 mmol per day is required to normalize high BP in unmedicated hypertensive patients, while 15 mmol per day will lower high BP in patients treated with antihypertensive medications. The knowledge that low magnesium (impact of the Mg:Ca ratio) causes imbalance in both cellular and physiological calcium points toward the conclusion that hypertensives may have abnormal calcium metabolism.³⁴

Even though metabolic and experimental studies suggest that magnesium may have a role in the regulation of BP, epidemiological evidence on the effects of magnesium on BP is inconsistent. A recently published Cochrane review evaluated 12 randomized control trials (RCTs) on the effects of magnesium supplementation as treatment for primary hypertension in adults.³⁵ The results of the individual trials were heterogeneous. Combining all trials, participants receiving magnesium supplements as compared to control did not significantly reduce systolic BP but did have a statistically significant reduction in diastolic BP. Due to the poor quality of trials and the heterogeneity among trials, the evidence in favor of a causal association between magnesium supplementation and BP reduction was weak.

DIETARY CHANGES FOR OPTIMAL ELECTROLYTE INTAKE

A transition toward modern diets has led to a substantial decline of K^+ intake compared with traditional (natural) food habits, and a large fraction of the population might now have suboptimal K^+ intake. A high K^+ intake has been reported to have protective effects against several conditions affecting the cardiovascular system, kidneys, and bones.³⁶ The levels of sodium, potassium, calcium, and magnesium provided by the typical current diet are significantly different in amounts and ratios than the natural diet. If a daily energy need of 2,100 kcal is satisfied by a natural diet composition, the daily intake of sodium is approximately 500 mg, that of potassium about 7,400 mg, that of calcium approximately 1,100 mg, and that of magnesium about 800 mg.

It is reported that in the average U.S. diet the energy-standardized intake (per 2,100 kcal) of sodium was about 3,000 mg a day (that is, approximately sixfold compared with the genetically programmed diet). The potassium intake was as low as 1,750 mg, which is only 24% of the amount provided by the natural diet. Further, the daily intake of calcium (about 440 mg) from modern diet is remarkably lower than that from the natural diet (approximately 40% only). Even the usual intake of magnesium (approximately 180 mg) is also very low (approximately 23% of the optimal requirement) compared with the amount provided by the natural diet.

The recommended dietary reference intake (DRI) for sodium is 1,500 mg a day, whereas 2,500 mg has been given as the maximum level of daily intake likely to pose no risk of adverse effects. The average current sodium intake of 3,000 to 4,500 mg a day in various westernized communities exceeds clearly even the highest sodium intake level, which has been estimated to be safe. The recommended intake of potassium for adolescents and adults is 4,700 mg/day. Recommended intake of potassium for children 1 to 3 years of age is 3,000 mg/day, for 4 to 8 years of age 3,800 mg/day, and for 9 to 13 years of age 4,500 mg/day. The DRI for calcium is 1,000 to 1,300 mg per day. The magnesium intake recommendation is 420 mg for adult men.^{20,37}

SUMMARY

Electrolytes play an important role in determining the BP levels of both normotensive and hypertensive subjects. The mechanisms by which they influence BP are complex

and involve the interplay of several factors. Simple alterations in the diet to enhance potassium intake and reduce sodium levels are extremely useful measures in reducing BP in individuals with hypertension and in maintaining “normotension” among individuals with normal BP.

Chapter
41Alcohol Intake and
Blood Pressure

Ian B. Puddey and Lawrence J. Beilin

Key Findings

- The regular consumption of alcohol directly elevates blood pressure. The effect is predominantly on systolic blood pressure with a predicted increase of approximately 1 mmHg for each 10 g of alcohol consumed per day.
- Precise mechanisms have not been elucidated but several aetiological factors have been implicated both centrally (altered sympatho-vagal balance, impaired arterial baroreceptor responses) and peripherally (effects on vascular membrane ion handling and reactivity).
- In communities that regularly consume alcohol, the population-attributable risk from alcohol consumption may be as high as 20 to 30%. The consumption of 3 to 5 drinks per day results in a twofold increase in the incidence of hypertension.
- Alcohol-related increases in blood pressure have implications for incidence of cerebral thrombosis, cerebral hemorrhage, left ventricular hypertrophy, and coronary artery disease.

Astute clinicians have noted an association between excessive alcohol intake and an increase in blood pressure since at least 1877, when Frederick Akbar Mahomed (using his sphygmograph) reported a high-tension pulse in so-called “alcoholists.”¹ The relationship between regular alcohol consumption and an increase in blood pressure lay largely unexplored thereafter until Lian² (Figure 41–1) observed in 1915 among 150 42- to 43-year-old French soldiers serving on the Western front that there was a linear increase in the prevalence of hypertension with increasing alcohol consumption, with very heavy drinkers (“tres grand buveurs,” >3 L of wine per day) having fourfold the prevalence of hypertension compared to those drinking 1 L of wine per day (intriguingly labeled “les sobres”). Subsequent reports were scattered and infrequent and relied on observations from case control comparisons of higher levels of blood pressure in alcoholics that fell upon detoxification and increased in those who resumed drinking.³

Heavy alcohol consumption was thought responsible for a number of early reports of an increase in the prevalence of abnormal liver function tests among hypertensives. In a Swedish study of patients with established hypertension, heavy drinking was also thought to underlie resistance to antihypertensive drug therapy, although poor

compliance with treatment rather than alcohol *per se* was thought to be the major contributing factor.⁴ Further circumstantial evidence for an association between heavy alcohol intake and blood pressure was implied from the observation of a positive association between death rates from stroke and cirrhosis in England and Wales.⁵ A considerable body of epidemiological literature since these early studies has confirmed that in drinking communities alcohol consumption is a major lifestyle factor responsible for an increased prevalence and incidence of hypertension.

EPIDEMIOLOGY

Cross-sectional studies

The first large-scale cross-sectional definition of the relationship between alcohol consumption and the prevalence of hypertension was established by Klatsky and colleagues in 1977⁶ in an analysis of the Kaiser Permanente Insurance data from over 80,000 contributors to a health insurance plan. This data showed a threshold relationship between alcohol and increased level of blood pressure in men, but a J-shaped relationship in women, with a clearcut increase in blood pressure in both from three or more drinks per day. These relationships were consistent in the three ethnic groups studied: whites, African Americans, and those of Asian origin (Figure 41–2). They were also similar in either smokers or nonsmokers or in obese compared to nonobese subjects. Those drinking three or more drinks a day had twice the prevalence of hypertension (defined as >160/90 mmHg) when compared to nondrinkers. Ex-drinkers had similar levels of blood pressure to abstainers, suggesting reversibility of any blood-pressure-elevating effect of alcohol.

Since this groundbreaking study, more than 100 cross-sectional population studies from nations on all five continents have confirmed the positive relationship between alcohol, increased blood pressure, and prevalence of hypertension. In the worldwide Intersalt study,⁷ of the 48 centers in which some people reported consuming at least 240 g/week of alcohol (~3 or more drinks per day) 35 had positive regression coefficients linking heavy alcohol consumption to blood pressure. After account was taken of key confounders, men who drank 240 to 400 g alcohol/week had systolic/diastolic blood pressure on average 2.7/1.6 mmHg higher than nondrinkers, and men who drank ≥400 g alcohol/week had pressures of 4.6/3.0 mmHg higher. For women, heavy drinkers (≥240 g alcohol/week)

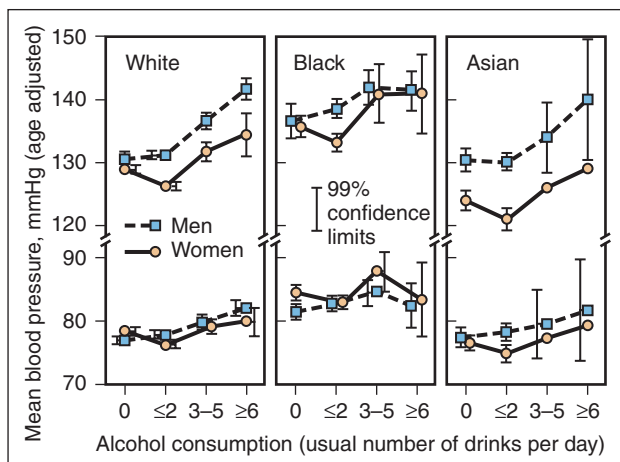

Figure 41-2. Mean systolic blood pressures (upper half of figure) and mean diastolic blood pressures (lower half of figure) of white, black, or Asian men and women with known drinking habits. Small circles represent data based on less than 30 persons. (Reproduced with permission from Klatsky et al.⁶)

had blood pressures 3.9/3.1 mmHg higher than nondrinkers. In a recent systematic review of all studies from 1988 to 1999 of moderate alcohol consumption (<40 g/day) in relation to blood pressure, Burger et al.⁸ concluded that there were linear blood pressure elevations at drinking levels of >20 g per day for women and >30 g per day for men.

These studies, however, have not clearly defined the effects of alcohol consumption on blood pressure at intakes below three drinks per day (30 g alcohol). Subsequent reports in which there has been more stringent evaluation of alcohol intake have since shown continuous positive relationships,^{9,10} whereas a second Kaiser Permanente report nearly a decade after the first¹¹ (utilizing a more comprehensive alcohol database) found that even at 1 to 2 drinks per day there was a slight but significant increase in blood pressure in men. However, the curvilinear relationship observed in the original study in female participants with lower blood pressures at 1 to 2 drinks per day was still seen. However, there are many potential factors that could result in J-shaped or U-shaped relationships. These include differences among nondrinkers, light drinkers, and heavier drinkers in dietary habits, level of physical activity, prevalence of overweight, smoking habit, and socioeconomic background. They also include misclassification bias, with subjects underreporting their alcohol intake and being inappropriately included in a non or light drinker category or past heavy drinkers who have now given up drinking being mistakenly categorized as nondrinkers. In some studies, when these confounding influences have been carefully taken into account curvilinearity of the alcohol/blood-pressure relationship has been attenuated.

A consistent pattern of a stronger association of alcohol and blood pressure with aging has been reported in several cross-sectional studies, with the association of alcohol with blood pressure increasing with age at least up to the seventh decade.¹² In one study of elderly men and women 60 to 87 years of age,¹³ alcohol intake was associated with higher blood pressure even when the mean background intake in men was only 12.5 g per day and in the women 5 g per day. At the other end of the spectrum, the alcohol/blood-pressure relationship has also been demonstrated surprisingly in teenage Argentinians¹⁴ and Italian schoolchildren.¹⁵

Ambulatory blood pressure measurements have provided further insights into the relative effects of alcohol on blood pressure. The Harvest study¹⁶ of 1100 Italians used ambulatory blood pressure to examine factors influencing the daily variation of blood pressure in hypertensive subjects aged 18 to 45 years. Alcohol intake was linearly

related to daytime blood pressure, and heavier drinkers showed greater blood pressure variability. Alcohol intake influenced ambulatory blood pressures to a greater extent than its effect on office pressures.

Insights from more recent cross-sectional studies have concentrated on the relative effects on hypertension subtypes, the effects of drinking alcohol with or without food, and possible effects of individual alcoholic beverage preference. With respect to hypertension subtype, alcohol has generally been more strongly associated with increases in systolic rather than diastolic blood pressures. However, in a recent cross-sectional study that examined *a priori* the associations between alcohol intake and isolated systolic, combined systolic and diastolic and isolated diastolic hypertension in 5317 Chinese men it was found that those in the highest alcohol intake category (≥ 30 drinks/week) were twice as likely as nondrinkers to have any of these hypertensive subtypes—with population attributable risks of 13.9%, 13.4%, and 12.0%, respectively.¹⁷ The consumption of alcohol with or without food was examined in a study of 2609 white men and women from western New York.¹⁸ It was found that compared with lifetime abstainers participants reporting drinking mostly without food exhibited a 64% higher risk of hypertension.

When analyses were restricted to current drinkers, those consuming alcohol without food had a 41% higher risk of hypertension even after adjustment for the amount of alcohol consumed in the past 30 days. The relative effects of different types of alcoholic beverage on blood pressure remain controversial. The older Kaiser Permanente study⁶ and a study from western New York¹⁸ found no consistent beverage-specific associations with hypertension risk in North Americans drinking beer, wine, or spirits. On the other hand, in a recent Chinese study liquor drinking was associated with a higher odds ratio of isolated systolic hypertension, whereas combined systolic-diastolic hypertension and isolated diastolic hypertension did not differ by type of alcoholic beverage.¹⁷ However, in that study liquor drinkers generally drank more alcohol. It is likely that this was the explanation for such findings given the results of a similar study in 4335 Japanese male workers,¹⁹ which grouped subjects on the basis of their total consumption of beer, sake, shochu (traditional Japanese spirits), whiskey, or wine. Blood pressure was highest in the shochu group, but an analysis adjusting for total alcohol consumption resulted in disappearance of this difference.

There have also been consistent suggestions that wine drinking (especially red wine) is associated with smaller effects on blood pressure, an outcome attributed to its high content of potentially vasodilator flavonoids. In the Lipid Clinics Prevalence Study²⁰ there were significant positive regression coefficients for beer and spirits drinkers in relation to blood pressure but no significant relationship for wine drinkers. The PRIME study also found a weaker association for wine and blood pressure compared with beer.²¹ Neither of these studies adjusted for diet, and given the now well recognized dietary differences among wine, beer, and spirits drinkers²² this and other dissimilarities in lifestyle (as well as differences in the relative amounts and patterns of drinking) may account for such

observations. This would appear a more likely explanation given the results of a 4-week crossover trial from Western Australia that compared effects of wine, dealcoholized red wine, beer, and water on 24-hour ambulatory blood pressure in 26 men. Similar increases in blood pressure were observed with either red wine or beer.²³ The effect of both of these alcoholic beverages was predominantly on awake systolic blood pressure, with increases of 2.9 mmHg for red wine and 1.9 mmHg for beer when compared to water (Figure 41–3).

Interaction with other lifestyle factors

If there is to be a balanced assessment of the overall clinical implications of alcohol-related hypertension, alcohol consumption cannot be considered in isolation from the effects on blood pressure of other lifestyle risk factors. Another study from Western Australia⁹ focused on a younger population of working men, specifically evaluating the relative importance of the effects of alcohol on blood pressure in relation to other lifestyle factors. Careful evaluation of alcohol consumption in these 491 men aged 20 to 44 years revealed it to be linearly related to the prevalence of hypertension (>140 mmHg systolic and/or 90 mmHg diastolic) (Figure 41–4). The association was independent of smoking, physical activity, and tea and coffee consumption but additive to that of body mass index. The 50% of the men who averaged 3 or more standard drinks per day (1 standard drink equivalent to 10 g ethanol), principally as beer, had 3 to 4 times the prevalence of systolic hypertension (140 mmHg or more) compared with current nondrinkers. In multivariate analysis, alcohol consumption equated with body mass index in the magnitude of its contribution to the variance in blood pressure level, a reflection of the relatively high levels of alcohol drinking in this young to middle-age male population. In a recent meta-analysis, however (which quantified the contributions of body weight, physical inactivity, and dietary factors to the prevalence of hypertension in Finland, Italy, the Netherlands, the United Kingdom, and the USA),²⁴ the major impacts on population-attributable risk for hypertension were overweight, physical inactivity, high sodium intake, and low potassium intake—with the impact of alcohol consumption relatively small (2 to 3%).

Interactions of alcohol with other lifestyle effects on blood pressure also need to be considered. In one study,²⁵ salt intake was only found to be associated with increased blood pressure in subjects who consumed larger amounts of alcohol and simultaneously were characterized by a low calcium intake. However, an alcohol-salt interaction was not confirmed in a two-way factorial intervention study in which treated hypertensive drinkers reduced their alcohol intake, sodium intake, or both.²⁶ In this study, only alcohol restriction resulted in a fall in blood pressure. Population studies also indicate a potential interaction of physical activity and alcohol intake to determine level of blood pressure, with weaker alcohol/blood-pressure relationships in more active subjects.²⁷ In an intervention study in which sedentary drinkers were randomized to vigorous exercise, alcohol restriction, or both only alcohol restriction resulted in a fall in blood pressure.²⁸

Figure 41-3. Top: 24-hour profile of systolic blood pressure following the four interventions. Compared to control/abstinence, both red wine and beer increased 24-hour and daytime systolic blood pressure ($p < 0.05$). Bottom: 24-hour profile of heart rate (HR) following the four interventions. Compared to the control/abstinence, both red wine and beer increased HR for 8 to 10 hours after drinking ($p < 0.001$). (Reproduced with permission from Zilkens et al.²³)

In contrast, the results from both population studies^{6,9} and an intervention study²⁹ have been consistent in finding an additive effect of alcohol and obesity on blood pressure. In the intervention study, overweight drinkers who decreased their alcohol intake from approximately 5 to 1 standard drink per day and simultaneously followed a calorie-restricted diet decreased their weight by nearly 10 kg and experienced falls in systolic blood pressure of 10 to 14 mmHg after 16 weeks (Figure 41-5). Other reported interactions have been between alcohol and smoking (wherein those who both smoked and drank had the highest blood pressures)³⁰ and between alcohol and job strain, where regular heavy drinkers in high-strain jobs had higher blood pressure than those with low-strain jobs.³¹

Prospective studies

Prospective population studies have added strong support to the cross-sectional data implicating alcohol as a major risk factor for subsequent development of hypertension in both men and women. In 1999, a meta-analysis of the three prospective studies then available reported a 40% increase in the relative risk of developing hypertension in those drinking more than 25 g alcohol/day and over a fourfold increase in risk in those drinking more than 100 g a day.³² Subsequently, large-scale prospective studies from Japan³³ and the USA³⁴ have reported up to a twofold increase in risk of hypertension with intakes of 30 to 50 g a day or more. In the ARIC study it was estimated that in subjects drinking 30 g/day or more one in five cases of hypertension could be attributed to alcohol consumption.³⁴ An effect with even lower levels of alcohol consumption has been reported in a native American population³⁵ in which in light to moderate drinkers (occasional drink up to 1 to 2 drinks a day) there were 1.24-fold and 1.53-fold increases in the incidence of hypertension in men and women, respectively. Similarly, in young middle-age Swedish males within a 6-year period of follow-up alcohol intake emerged as an important determinant of the development of hypertension.³⁶

Randomized controlled trials

There have now been more than a dozen randomized controlled trials of the effects of alcohol on blood pressure. The consistent finding has been that that regular alcohol consumption directly elevates blood pressure. The first trial was carried out in community-based ambulatory subjects in Western Australia,³⁷ where normotensive drinkers reduced their alcohol consumption by drinking a low alcohol beer (0.9% ethanol) for 6 weeks before switching back to their

usual alcohol intake, consuming a normal alcohol beer (5% ethanol) from which the low-alcohol beer had been distilled. This reduced their alcohol consumption by approximately 80% and was accompanied by a corresponding fall in blood pressure, increasing once again when normal intake was resumed. The main fall in blood pressure occurred within the first 1 to 2 weeks of switching to the low-alcohol beer but was still declining at 6 weeks (Figure 41-6). Similar effects of regular drinking have subsequently been shown to occur in both treated³⁸ (Figure 41-7) and untreated³⁹ hypertensives.

The first meta-analysis of all randomized controlled trials to 2000 of the effects of alcohol reduction on blood pressure⁴⁰ included 15 trials. The majority of these trials involved men, with three of the studies having included a

Figure 41-4. Percentage of each drinking category with systolic or diastolic hypertension. Numbers in columns refer to total in the population subgroup. The trend for systolic hypertension and alcohol consumption = 8.09, $p < 0.005$; for diastolic hypertension, trend = 5.84, $p < 0.025$. (Reproduced with permission from Arkwright et al.⁹)

small number of women only. Seven studies included only hypertensive subjects: 6 normotensive subjects and 2 either normotensives or hypertensives. The hypertensives in six of these trials were taking blood-pressure-lowering medication. Subjects were studied for a median 8 weeks and reduced their alcohol consumption by a median 76% from baseline intakes of 3 to 6 standard drinks per day. The pooled effect estimates for the fall in systolic and diastolic blood pressure were 3.31 and 2.04 mmHg, respectively (Figure 41-8). These changes were similar in hypertensives and normotensives, and in treated versus untreated hypertensive subjects, with a dose response relationship between the falls in blood pressure and the drop in alcohol intake.

A further systematic review⁴¹ focused primarily on studies that directly administered alcohol rather than the approach of Xin et al.,⁴⁰ which utilized randomized clinical trial data. It came to similar conclusions with estimates of a significant effect of alcohol restriction to reduce systolic and diastolic blood pressure by 2.7 mmHg and 1.4 mmHg, respectively. This meta-analytic review also compared data from studies that utilized conventional clinic or office review of blood pressure with those that incorporated ambulatory or home blood pressure monitoring and was able to highlight biphasic effects of alcohol on blood

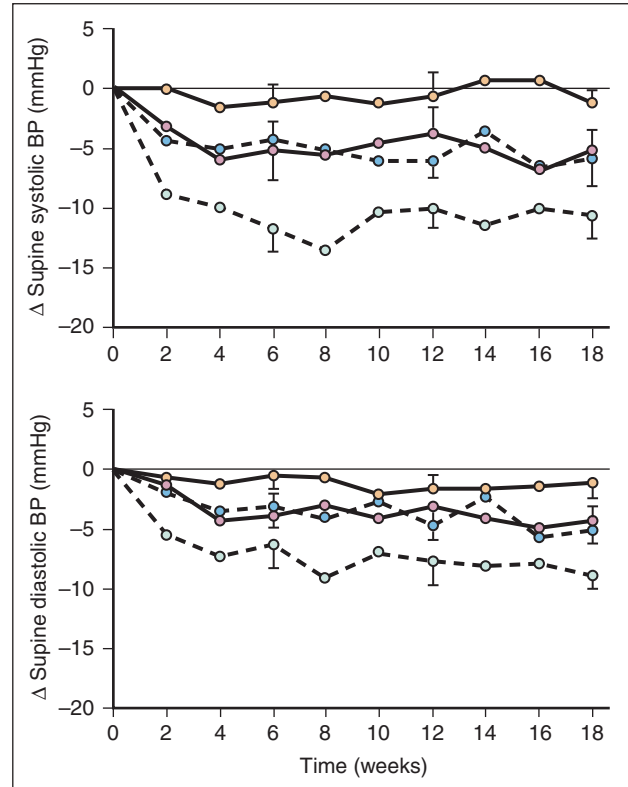

Figure 41-5. Line graphs show change in mean \pm SEM systolic (top) and diastolic (bottom) blood pressure in four study groups. \bullet — \bullet , normal alcohol intake/normal caloric intake ($n=20$); \circ — \circ , normal alcohol intake/low caloric intake ($n=22$); \square — \square , low alcohol intake/normal caloric intake ($n=21$); and \triangle — \triangle , low alcohol intake/low caloric intake ($n=23$). (Reproduced with permission from Puddey et al.²⁹)

pressure with an early presumably vasodilator effect of alcohol leading to a reduction in blood pressure (in the immediate hours after exposure) and a later effect (the next day) of raising blood pressure.

Gender effects

As discussed previously, cross-sectional studies have indicated that (similar to men) heavier drinking is associated with a higher prevalence of hypertension in women. However, with light to moderate drinking the nature of the relationship has been more controversial. First has been the persistent suggestion that the effects of alcohol on blood pressure may not be as substantial in women, with the NHANES III study⁴² (which included over 9000 women) finding that associations between alcohol intake and blood pressure and pulse pressure were weaker in women than in men. This contrasts with a smaller Brazilian study,¹⁰ which showed exactly the opposite. Second has been the suggestion that low-level alcohol intake may actually lower blood pressure in women, with the majority of cross-sectional studies suggesting lower blood pressures at lower levels of alcohol intake in women.^{6,43} Moreover, in a meta-analysis of 11 population studies up to 1993⁴⁴ it was concluded that there was a decreased risk of hypertension in women with low-level alcohol intake.

Figure 41-6. Line graphs show group systolic and diastolic blood pressure after 6 minutes of supine rest. Values are means \pm SEM. Group 1 (closed squares) = low alcohol intake in period 1 (dotted line), normal alcohol intake in period 2 (solid line); group 2 (closed diamonds) = normal alcohol intake in period 1 (solid line), low alcohol intake in period 2 (dotted line). (Reproduced with permission from Puddey et al.³⁷)

These results need to be interpreted, however, against those studies that have demonstrated a dose response relationship in women across the continuum of alcohol intake^{10,45} that suggests unmeasured confounding as an explanation for the inconsistencies. They may, at least to some extent, be a consequence of gender-related differences in the accuracy of self-reporting of alcohol intake. In a cross-sectional survey of 19,000 subjects in the USA, women who reported a prior diagnosis of hypertension also reported drinking less alcohol than those not reporting hypertension,⁴⁶ whereas the opposite was true of hypertensive men. Other confounders may also be playing a role with differences in diet, drinking patterns, and other lifestyle parameters rarely or inadequately assessed in most studies. In this regard, a UK-based study of 14,000 female employees of the firm Marks and Spencer⁴⁷ noted that a finding of a decreased prevalence of hypertension with consumption of up to 14 drinks a week was no longer seen after accounting for age, BMI, physical activity, and family history of premature coronary artery disease.

The more stringent prospective population studies have also not been able to resolve the uncertainty as to gender differences in the alcohol/blood-pressure relationship. The

largest was the Nurses Health Study⁴⁸ in women aged 25 to 42 at baseline. This found a biphasic effect of alcohol, with a 14% decrease in risk of developing hypertension in those consuming 2 to 3 drinks per week compared with nondrinkers and a 20% increase risk in those drinking more than 14 drinks a week. However, in the Atherosclerosis Risk in Communities Study³⁴ the relative risks for those drinking more than 210 g alcohol per week were increased similarly in men and women. As mentioned previously, randomized controlled trials have so far either been confined to men or contained too few women for assessment of a gender effect of alcohol on blood pressure.

A recently completed trial,⁴⁹ however, focused specifically on the blood pressure effects of alcohol in pre-menopausal women. Twenty-four normotensive women aged 25 to 49 were randomized to a three-period crossover study in which each evening they consumed either higher-volume red wine (146 to 218 g alcohol per week) or a lower-volume red wine (42 to 73 g ethanol/week) titrated against their alcohol intake at entry to the study. Dealcoholized red wine was consumed as a control for an identical period of 4 weeks.

Ambulatory blood pressure and heart rate were monitored every 30 minutes for 24 hours at the end of each study period. With the higher-volume red wine there was a significant increase in 24-hour systolic and diastolic blood pressure relative to the dealcoholized red wine but no significant effect on blood pressure of the lower-volume red wine. The magnitude of the blood pressure elevation was similar to that reported in previous intervention studies in men (by 2.0/1.2 mmHg) but evident at even lower levels of intake, with no evidence provided for the contention that low levels of alcohol will lower blood pressure in women.

GENETICS

Given that there is already a wide acknowledgement of the genetic basis of both hypertension and predisposition to excessive alcohol consumption it should not be surprising if there is also a substantial genetic predisposition to alcohol-related hypertension. Research in this area is at an early stage, with the focus to date having been predominantly on a few functionally significant polymorphisms of genes integral to either alcohol metabolism or blood pressure regulation. A point mutation at -357 of the promoter region of the gene coding for the aldehyde

Figure 41–7. Line graphs show group systolic and diastolic blood pressure after 6 minutes of supine rest. Values are means \pm SEM. Group 1 (closed squares) = low alcohol intake in period 1 (dotted line), normal alcohol intake in period 2 (solid line); group 2 (closed diamonds) = normal alcohol intake in period 1 (solid line), low alcohol intake in period 2 (dotted line). (Reproduced with permission from Puddey et al.³⁸ with permission from Elsevier.)

Figure 41–8. Average net change in systolic blood pressure (left) and diastolic blood pressure (right) and corresponding 95% CIs related to alcohol reduction intervention in 15 randomized controlled trials. Net change was calculated as the difference of the baseline minus follow-up levels of blood pressure for the intervention and control groups (parallel trials) or the difference in blood pressure levels at the end of the intervention and control treatment periods (crossover trials). The overall effect represents a pooled estimate obtained by summing the average net change for each trial, weighted by the inverse of its variance. (Reprinted with permission from Xin et al.⁴⁰)

dehydrogenase isozyme leads to a deficiency in metabolism of the major metabolite of ethanol (acetaldehyde), resulting in higher levels and a characteristic flushing and tachycardia after alcohol ingestion. This polymorphism has been well described in Japanese, Chinese, and Scandinavian populations, with speculation that it may predispose to alcohol-related hypertension.

The major problem in testing this hypothesis, however, is that those with the ALDH*2/2 genotype consume less alcohol because of the unpleasant symptoms and are therefore significantly less likely to be at risk of alcohol-related hypertension.⁵⁰ In one study in Japanese men and women,⁵¹ after allowing for such lower levels of alcohol intake no causal relation between this mutation and the prevalence of hypertension could be seen. Another study, however (which included only subjects who consumed >300 g ethanol per week),⁵² found increased odds for higher systolic blood pressure in those with the ALDH*2/2 genotype even after adjustment for alcohol consumption as well as other potential demographic and lifestyle confounders.

Polymorphisms of another important alcohol metabolizing enzyme, alcohol dehydrogenase, have been evaluated in the context of the alcohol/blood-pressure relationship. The wild-type ADH2¹/2¹ genotype has a substantially lower ethanol-oxidizing capacity compared to the mutant ADH2¹/2² and ADH2²/2² genotypes, and is again more commonly seen in Japanese populations. Results have been inconsistent, however. This polymorphism has in one Japanese study⁵³ not predicted hypertension risk with alcohol, whereas in another after adjustment for alcohol consumption a significantly stronger alcohol blood pressure relationship was seen in men with the wild-type ADH2¹/2¹ genotype. Slow metabolism of alcohol due to presence of the alcohol dehydrogenase type 3 polymorphism has been associated with a decrease in risk of myocardial infarction in the Physicians' Health Study,⁵⁴ probably because of higher HDL-cholesterol levels. However, the implications of this polymorphism for alcohol-related hypertension have not yet been investigated. Alcohol metabolism also occurs through the hepatic mitochondrial cytochrome P450 oxidase pathway, especially following enzyme induction in high alcohol consumers. There is evidence that a genetic polymorphism of CYP2E1, the c2 allele, predisposes to higher blood pressure—possibly as a consequence of higher acetaldehyde levels.⁵³

Apolipoprotein E polymorphisms have been proposed as determinants of alcohol-related hypertension in Finnish subjects.⁵⁵ Those with the E2/E3 and E3/E3 genotypes had a stronger alcohol/blood-pressure relationship than the E4/E3 genotype. However, in a Western Australian intervention study in regular drinkers no relationship between the apolipoprotein E genotype and the magnitude of the falls in blood pressure following alcohol restriction was seen.⁵⁶ In male Japanese workers, alcohol drinking has been associated with increased prevalence of high normal blood pressure in M allele carriers of angiotensinogen gene T174M polymorphism.⁵⁷ Other investigators have examined a possible role for polymorphisms in the beta-adrenoceptor (beta-AR)-stimu-

latory guanine nucleotide-binding (Gs) protein system.⁵⁸ They reported an interaction between the T393C polymorphism of the gene encoding the alpha-subunit of Gs proteins (GNAS1) and drinking status in the association with hypertension. The T allele carriers had a higher probability of hypertension than CC homozygotes in nondrinkers and light drinkers, whereas CC homozygotes had a higher probability of hypertension than T allele carriers in moderate to heavy drinkers. There was also a significant association between the T393C polymorphism and pulse pressure in moderate to heavy drinkers.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Studies in animals

By far the majority of animal studies into the phenomenon of alcohol-related hypertension have been carried out in rats. The results have been inconsistent in relation to blood pressure outcomes, largely because of the use of different rat strains, the utilization of a variety of alcohol doses, and different routes of alcohol administration. The first such study surprisingly demonstrated no significant effects on blood pressure after chronic alcohol feeding to either normotensive Wistar Kyoto rats (WKY) or spontaneously hypertensive rats (SHR).⁵⁹ In fact, hypotensive effects of high-dose alcohol have been the usual finding in the SHR, stroke-prone SHR, and WKY rats. In these latter studies, falls in blood pressure were seen after feeding SHR rats 20% alcohol solutions for 16 weeks⁶⁰ (or there was a retardation of the rise in blood pressure normally seen with aging in both the SHR and the stroke-prone SHR).^{61,62} In contrast, in the Wistar rat⁶³⁻⁶⁵ and in experiments in WKY rats that used only low doses of alcohol (1, 5, and 10% alcohol v/v)⁶⁶⁻⁶⁹ increases in blood pressure with alcohol have been consistently reported.

The unexpected finding of lower blood pressures following alcohol may have been due to depression of cardiac performance, a phenomenon known to be enhanced by alcohol in hypertensive rat strains.⁷⁰ The falls in blood pressure have occurred, however, despite enhanced vascular contractility⁷¹ or heightened heart rate responses to stress.⁷² Some of the differences between rat models may also have related to the timing of blood pressure measurement in relation to the last intake of alcohol. In the SHR, an increase in blood pressure lasting several days after sudden withdrawal of alcohol has been seen,⁶¹ and similarly in Sprague-Dawley rats a hypertensive response has been reported 24 hours after cessation of alcohol feeding.⁷³ Such an acute increase in blood pressure is also characteristic of the alcohol withdrawal syndrome in man.

Utilizing radiotelemetry, hemodynamic effects of alcohol have once again been assessed more recently during chronic low-dose alcohol administration to SHRs and WKY controls (5% v/v for 12 weeks).⁷⁴ The advantage of such an approach is that it eliminates the potential stressful effects of other conventional techniques that attempt to measure rat-tail blood pressure after initial warming of the animals or the monitoring of intra-arterial

blood pressure after anaesthesia. Again, alcohol had no effect on blood pressure in WKY rats but caused falls in blood pressure in the SHR, reaching a maximum at week 5 and remaining low thereafter.⁷⁴ Alcohol also caused reductions in the blood pressure variability and the circadian fluctuations in blood pressure in the SHR but not in WKY rats. Plasma norepinephrine levels were elevated by alcohol in WKY rats, but not in the SHR. The authors speculated that the absence of a fall in blood pressure in the WKY rats may have been related, at least in part, to the associated sympatho-excitation. Utilizing an identical telemetric approach, effects of alcohol on circadian haemodynamic rhythms were subsequently assessed. Alcohol resulted in a fall in blood pressure during both the day and night in the SHR. However, effects of alcohol to increase HR and decrease HR variability (consistent with inhibition of vagal tone) were only seen during the night.⁷⁵

Some pathogenic insights into the mechanism of the pressor response to alcohol have been provided by those rat models that have consistently identified an increase in blood pressure with chronic alcohol feeding. In these studies alcohol was administered in the drinking water, gradually increased from 5 to 10% and then 20% v/v over 12 weeks.⁶³⁻⁶⁵ Both a slight increase in calcium pump activity and a decrease in cell membrane cholesterol content were seen in association with the increase in blood pressure.⁶⁴ These changes were thought secondary to the known acute fluidizing effects of alcohol on cell membranes, with compensatory changes in lipid composition resulting in increased $\text{Ca}^{2+}/\text{Mg}^{2+}$ -ATPase activity. Such an interpretation has been supported by observations in the same rat model of changes in the polyunsaturated to saturated fatty acid ratio in red cell membranes that were proportional to the magnitude of the alcohol-related rise in blood pressure.⁷⁶

Increases in vascular smooth muscle calcium uptake together with an increase in blood pressure have also been seen in WKY rats chronically fed lower doses of alcohol (10% v/v in the drinking water).⁶⁶ After lowering the dose of alcohol even further to 5% v/v, renal vascular changes and increases in intracellular calcium in alcohol-fed rats have still been seen and could be reversed by either the calcium entry blocker verapamil⁶⁷ or by n-acetyl cysteine,⁶⁸ the latter suggesting a possible role for the metabolism of alcohol to acetaldehyde in the pathogenesis of alcohol-related hypertension. A pressor response to alcohol has even been seen with as little as 1% alcohol v/v in the drinking water over 14 weeks.⁶⁹ In that experiment, the administration of dietary vitamin B6 (which augments methionine metabolism to cysteine) decreased tissue acetaldehyde conjugates, prevented an increase in intracellular calcium levels, and counteracted both an increase in blood pressure and any renal arteriolar changes. Magnesium supplementation has also been reported to counteract the development of hypertension in Wistar rats chronically fed alcohol,⁷⁷ with the mechanism proposed that it possibly prevents an alcohol-induced increase in intracellular calcium and consequent suppression of sodium pump activity.

In combination, these studies highlight the potential for peripheral effects of alcohol on vascular membrane structure and function to ultimately influence resting vasomotor tone and vascular reactivity. In contrast, chronic alcohol administration to Sprague-Dawley rats raises the equally plausible possibility of centrally mediated effects. In these studies, alcohol attenuated acutely induced clonidine hypotension but augmented acutely induced hydralazine hypotension, suggesting opposite effects on centrally versus peripherally mediated hypotension.⁷⁸ This clonidine-alcohol interaction has only been seen with acute but not chronic clonidine administration.⁷⁹ Further experiments⁸⁰ indicate that acute hypotensive effects of rilmenidine or alpha-methyl dopa are also significantly attenuated by ethanol feeding (2.5 or 5%) in a concentration-dependent manner. These findings have been interpreted as evidence that chronic ethanol attenuates both imidazoline I¹ receptor and alpha (2)-adrenoceptor-mediated hypotension.

Chronic alcohol administration to male Sprague-Dawley rats impaired arterial baroreceptor responses,⁸¹ with the suggestion that such an effect could be an important prelude to subsequent increase in blood pressure. After 12 weeks of alcohol administration, this mechanism was also identified in Wistar rats,⁸² although associated with only modest increases in blood pressure. Subsequent studies point to a centrally mediated action of alcohol in impairment of the arterial baro-receptor response. For example, acute exposure to ethanol decreased the sensitivity of the baroreceptor reflex, an effect seen in association with gamma-aminobutyric acid depletion in the brain stem.⁸³ Acute alcohol exposure has also been shown to exert a marked inhibitory action on glutamatergic pathways within the rostral ventrolateral medulla, leading to reduced baroreflex sensitivity.⁸⁴ A central effect has also been suggested by the observation in ethanol-fed rats (6.7% volume/volume for 28 days) that arterial blood pressure increased by 21% relative to pair-fed controls in association with simultaneous changes in the levels of both vasopressin and neuropeptide Y neurotransmitters in the neuronal pathways related to control of blood pressure.⁸⁵

Studies in humans

Given the rapid onset and offset of alcohol-related hypertension evident in human intervention studies, effects of alcohol to elevate blood pressure are likely to be mediated at least in part by neuro-humoral mechanisms or by reversible effects on vascular tone, heart rate, or cardiac output. However, chronic effects of alcohol to alter vascular or cardiac structure are also implied from those studies where hypertension has persisted for months after alcohol cessation by alcoholics⁸⁶ and by evidence that suggests a link between at least heavy alcohol intake and hypertensive end-organ disease. This includes increased cardiovascular disease outcomes such as stroke⁸⁷ and myocardial infarction⁸⁸ together with surrogate markers such as increased intimal-medial thickness of carotid arteries,⁸⁹ increased vascular stiffness,⁹⁰ and increased left ventricular hypertrophy.⁹¹ However, the contribution of alcohol-related hypertension to each of these endpoints

has been largely undefined. Moreover, the precise mechanism for alcohol-related hypertension itself has not been characterized but is highly likely to be a multifactorial phenomenon.

In alcoholic subjects studied during detoxification, there is a relationship between level of blood pressure and the severity of alcohol withdrawal.⁹² This has led to conjecture that the broader alcohol/blood-pressure relationship identified in population studies could also be caused by alcohol withdrawal. In some of these studies, level of blood pressure has been linked more closely to recent alcohol intake rather than to longer-term intake.^{20,93} However, these comparative measures of recent and longer-term intake have been constructed from the same 7-day retrospective alcohol diary, raising the possibility that such results were influenced by recall bias, with more accurate recall of intake in the preceding 24 to 72 hours. Where longer-term and recent intake have been assessed with separate instruments, the relationship between longer-term intake and blood pressure has been predominant.⁹⁴

In a Brazilian study¹⁰ that measured the exact time since the last drink, blood pressure was lower in men who had consumed alcohol less than 3 hours before blood pressure measurement but higher in those who consumed alcohol 13 to 23 hours before measurement. As discussed previously, a number of intervention studies that used ambulatory blood pressure monitoring have reported a similar biphasic pattern following the acute ingestion of alcohol.⁹⁵ The early fall in blood pressure may reflect an initial vasodilator effect of alcohol, but the subsequent increase in blood pressure was not evident in one study until 7 days⁹⁵ and was therefore unlikely to have been due to alcohol withdrawal. Furthermore, the finding of an alcohol/blood-pressure association in population-based studies at relatively low levels (2 to 3 drinks per day) is also inconsistent with an alcohol withdrawal effect as the only explanation for a pressor effect of alcohol.

There is support, however, for a contribution of effects of alcohol withdrawal in heavier drinkers. In the British Heart Survey⁹⁶ of 7735 middle-age men, hypertension was more likely to be diagnosed on a Monday than on a Friday—the assumption being that heavy drinkers were exhibiting withdrawal pressor effects after heavy weekend drinking. Further support is provided by a comparative study of drinking and weekday blood pressure relationships in men from Northern Ireland versus France.⁹⁷ The Irishmen were characterized not only by weekend drinking but by blood pressures that were highest on Monday, whereas no weekday effect was seen in the French (whose alcohol consumption was more uniform throughout the week).

To shed further light on the relative effects of regular and intermittent drinking patterns on blood pressure, a randomized controlled crossover trial was conducted in Western Australia in 55 men, 14 of whom drank more than 60% of their alcohol on weekends (whereas the remainder were regular daily drinkers).⁹⁸ Baseline 24-hour blood pressures were higher on Mondays than on Thursdays in weekend but not daily drinkers, an effect lost after switching to low-alcohol beer. However, both

groups showed a fall in 24-hour ambulatory blood pressure when changing from normal to low-alcohol beer—an effect evident after one week in the weekend drinkers but not until the fourth week in daily drinkers. This study indicated that there are contributing elements from both acute alcohol withdrawal and more sustained blood pressure elevation in weekend drinkers, whereas those who drink throughout the week show only a more sustained pressor response. Overall, the evidence suggests that consumption of alcohol averaged over a week or more is more important than pattern of intake with regard to alcohol-related blood pressure elevation.^{94,99}

Hypertension is often part of a metabolic syndrome differentiated not only by an increase in blood pressure but by reduced insulin sensitivity, central adiposity, and a characteristic dyslipidaemia with a low HDL-cholesterol and high triglyceride levels and elevated uric acid. Alcohol has been linked not only to the increase in blood pressure but to several discrete elements of this syndrome, in particular the increase in triglyceride levels, central adiposity, and elevated uric acid. However, alcohol simultaneously acts to increase HDL-cholesterol levels¹⁰⁰ and thus whether it makes any significant contribution to the metabolic syndrome has remained controversial. This was highlighted in the 1998 Korean National Health and Nutrition Examination Survey,¹⁰¹ in which drinking more than 30 g alcohol/day was associated with an increase in blood pressure in men, a high blood glucose in women, and higher triglycerides in both men and women. In addition, for both sexes and across all alcohol consumption categories there was a significant increase in HDL-cholesterol. Despite these contrasting effects on different components, overall there was a dose-response relationship between increasing alcohol intake and the odds of having the metabolic syndrome.

In contrast, another Korean study¹⁰² found that although heavy consumption increased blood pressure and waist circumference there was no significant relationship between alcohol intake and the metabolic syndrome. This finding was thought to be a consequence of the corresponding higher HDL-C seen with increasing alcohol consumption. Similarly, in the smaller Alcohol and Insulin Resistance Study from Sweden¹⁰³ alcohol intake was positively related to triglyceride levels and blood pressure in men, but simultaneously linked to improved insulin sensitivity and higher HDL cholesterol levels so that overall there was no evidence of a significant difference in alcohol intake in those subjects with the metabolic syndrome compared to those without. These results contrast with those from a U.S. study on data from participants in the Third National Health and Nutrition Examination Survey,¹⁰⁴ in which alcohol consumption was significantly and inversely associated with the prevalence of at least three components of the metabolic syndrome: low serum HDL cholesterol, elevated serum triglycerides, and high waist circumference. It was also associated with hyperinsulinemia, leading to the conclusion that mild to moderate alcohol consumption was associated with a lower prevalence of the metabolic syndrome—a finding strongest among whites and among beer and wine drinkers.

The National Heart, Lung, and Blood Institute Family Heart Study has also indicated that alcohol consumption is associated with a lower prevalence of the metabolic syndrome but emphasised that this was irrespective of the type of beverage consumed.¹⁰⁵ Recent meta-analyses of the relationship between alcohol intake and incidence of new-onset diabetes mellitus in prospective population studies^{106,107} have identified a biphasic relationship with a decrease in risk with low alcohol intake and an increase with heavy alcohol intake. The contrasting results from several different population studies therefore suggest that any overall effects of alcohol on the metabolic syndrome appear to be determined by a number of competing influences, including the volume and type of alcohol consumed, gender, race, and ethnicity. An effect of alcohol to impair insulin resistance as a primary pathogenic pathway for alcohol-induced hypertension therefore appears unlikely.

This conclusion is further supported by an intervention study from Western Australia,¹⁰⁸ in which a controlled decrease in alcohol intake by approximately 60 g per day had no effect on several indices of peripheral insulin sensitivity despite effects to decrease systolic and diastolic blood pressure by 5/4 mmHg and to decrease weight by 0.9 kg. An alternative causative pathway has been suggested by the finding in postmenopausal women that the ingestion of 15 to 30 g of alcohol per day increases serum leptin levels, suggesting that further investigations of the interrelationships among alcohol, central adiposity, and the metabolic syndrome need to consider a possible pathophysiologic role for leptin in alcohol-related hypertension—an increase in blood pressure now recognized as a correlate of chronic elevations of this hormone.¹⁰⁹

There is some evidence that enhanced blood pressure sensitivity to sodium may participate in the pathogenesis of alcohol-related hypertension, at least in alcoholics. In a study of 30 alcoholics during detoxification¹¹⁰ there was an abnormal response of both blood pressure and plasma renin activity to variations in salt intake, which was similar to that seen in sodium-sensitive hypertension. A subsequent study in 18 chronic alcoholics¹¹¹ demonstrated a persistence of this sodium sensitivity even after 1 year of abstinence, with the postulate that such sensitivity may be integral to the hypertensive response of alcoholics during withdrawal. These results contrast with those from an intervention study in moderately drinking ambulatory subjects who were all placed on a fixed intake of 160 mmol/day.²⁶ During a subsequent 4-week period of either a decrease in sodium intake or a decrease in alcohol intake (or both) only an effect of alcohol restriction to reduce blood pressure was seen. The absence of a fall in blood pressure with sodium restriction argues against enhanced sodium sensitivity to blood pressure in moderately drinking subjects.

Abnormal salt handling by the kidney has also been postulated to contribute to alcohol-related hypertension. In 6-week intervention studies in normotensive and treated hypertensive subjects from Western Australia no differences have been observed in 24-hour urinary excretion of sodium during periods of low versus high alcohol

intake.^{37,38} In contrast, in chronic alcoholics admitted for detoxification¹¹² there was evidence of altered renal sodium handling with lower fractional urinary sodium excretion in those subjects whose blood pressure was >160/95 mmHg upon admission. A study in Japanese males with hypertension, however, specifically investigated the effects of repeated alcohol intake (1 ml/kg per day) on blood pressure and sodium metabolism over 7 days.¹¹³ Blood pressure, although falling initially, increased toward the end of the alcohol period. This corresponded with initial sodium retention and a subsequent return to baseline, with restoration of sodium balance after 7 days. The sodium retention during the early phase was thought secondary to the corresponding initial fall in blood pressure but could possibly have contributed to the subsequent increase in blood pressure.

It has been proposed that alcohol-related hypertension results from cellular magnesium deficiency in drinkers with inactivation of the sodium pump, an increase in intracellular sodium, and an increase in vascular tone. Such magnesium deficiency with chronic alcohol consumption may be secondary to reduced dietary magnesium intake or result from the combined effects of alcohol to induce both hypomagnesaemia and magnesiumuria.¹¹⁴ Support for this mechanism comes from the results of a Japanese study in hypertensive drinkers,¹¹⁵ in which a fall in blood pressure during 4 weeks of alcohol restriction correlated with an increase in intra-erythrocyte magnesium and a decrease in intra-erythrocyte sodium. It has also been argued that intracellular free Mg^{2+} can act to maintain low resting levels of intracellular free Ca^{2+} and trigger muscle contraction or relaxation by competing with Ca^{2+} for membrane binding sites and by modulating Ca binding and release from the sarcoplasmic reticular membranes.¹¹⁶ Decreasing Mg^{2+} levels may therefore increase resting vascular tone and level of blood pressure, and such a mechanism has been linked to alcohol-induced cerebrovascular spasm.¹¹⁷

Effects of alcohol on sympatho-vagal balance with either augmentation of sympathetic nervous system activity or dampening of parasympathetic tone (or both) have long been implicated in the genesis of alcohol-related hypertension. Effects on heart rate variability have been utilized as a surrogate for such effects, but reports of alcohol as an independent determinant of heart rate variability in cross-sectional population studies have not been consistent.^{118,119} However, they appear likely given results from an intervention study in which 3 weeks of alcohol restriction in Japanese male drinkers produced reductions in ambulatory systolic blood pressure and heart rate and an index of sympatho-vagal balance with augmentations of parasympathetic indices of heart rate variability.¹²⁰ These findings suggest that drinking dampens vagal tone, with a corresponding relative increase in sympathetic tone.

An acute effect of alcohol to increase sympathetic tone has been demonstrated during skeletal muscle microneurography,¹²¹ although in that study there was only an increase in heart rate but not blood pressure because of an initial acute vasodilator effect of alcohol. Acute intra-

venous infusion of alcohol rather than oral administration also caused sympathetic nerve activation as monitored by skeletal muscle microneurography,¹²² but in this setting caused an increase in blood pressure that could be blocked by prior administration of dexamethasone. This was interpreted as evidence that alcohol was inducing a centrally mediated sympatho-excitatory effect mediated by release of corticotropin releasing hormone. Central autonomic effects of alcohol influencing blood pressure control have also been implied from the observation that acute ethanol ingestion leads to impaired baroreceptor function,¹²³ as well as from the finding in a cross-sectional study in healthy subjects that alcohol was an independent predictor of reduced baroreflex activity.¹²⁴

Endothelial function is impaired in hypertensive subjects, and such impairment has been seen as an indication of subsequent risk for hypertension and vascular disease. An effect of alcohol to impair endothelial function has therefore been postulated to contribute to alcohol-related hypertension and the pathophysiological evidence for such an effect has been extensively reviewed.¹²⁵ The recent observation of increased plasma levels of asymmetric dimethylarginine, an endogenous nitric oxide synthase inhibitor, in male and female drinkers compared to abstainers¹²⁶ would be consistent with such a postulate. Furthermore, in a case control study in chronic alcohol abusers there was decreased flow mediated dilation (FMD) in the brachial artery after 3 months of abstinence as compared to non-drinking controls.¹²⁷ In contrast, in a study in Japanese males with coronary artery disease endothelial function of the brachial artery was less impaired in drinkers despite a worse coronary risk factor profile.¹²⁸

The possibility of unaccounted confounding to account for these disparate results is likely given the finding in a randomized controlled crossover trial of reducing alcohol consumption from beer from 72.4 to 7.9 g/day in 16 healthy male drinkers of no changes in either FMD of the brachial artery or biomarkers of endothelial function.¹²⁹ This finding has since been repeated using a similar paradigm but with male subjects also drinking either red wine or dealcoholized red wine and again with no discernible effects on FMD.²³ Interestingly, in that study urinary endothelin-1 excretion was higher during alcohol administration, suggesting that this endothelially derived potent vasoconstrictor may have contributed to the blood pressure elevation seen with either red wine or beer consumption.

An impact of alcohol intake on not just endothelial function but on stiffness of the arterial wall may be relevant to the genesis of alcohol-related hypertension. Compliance and distensibility of arterial walls may play a role in subsequent genesis of hypertension, especially isolated systolic hypertension (which is characterized by a widened pulse pressure closely linked to the presence of stiff arteries). The overall effect of alcohol intake on arterial stiffness remains controversial. In an Irish study,⁹⁰ male heavy drinkers had higher aortic stiffness and aortic systolic blood pressure compared to lighter drinkers. However, the same authors found that when red wine containing alcohol (0.8 g/kg) was ingested it acutely

reduced arterial stiffness.⁹⁰ In a study of Japanese male office workers where the development of aortic stiffness was studied prospectively over 9 years,¹³⁰ aortic stiffness was observed to increase progressively with increasing alcohol intake. Another more recent Japanese study (131) of 1682 middle-age male workers with normal blood pressure also found that high alcohol intake (>60 g of ethanol/day) was associated with increased arterial stiffening, as reflected in an elevated brachial-ankle pulse wave velocity (an increase that remained significant after controlling for conventional cardiovascular risk factors).

A further recent report from the Atherosclerosis Risk in Young Adults study found that the heaviest drinkers (>3 glasses/day) had a significantly higher augmentation index, consistent with increased arterial stiffness.¹³² In contrast to these reports, a Dutch study utilizing pulse wave velocity as a measure of arterial stiffness suggested a J-shaped relationship with alcohol intake, with a reduction in arterial stiffness with mild to moderate alcohol intake but a loss of this potential protective effect at higher intakes (>3 to 8 drinks per day).¹³³ This same group of authors reported a similar J-shaped relationship in a separate study in 371 healthy postmenopausal women aged 50 to 74 years.¹³⁴ More recently, in a cross-sectional analysis of data from a cohort study in men and women aged 28 years (240 men and 283 women) the same authors suggested that a moderate intake of alcohol may favorably affect vascular stiffness at a relatively early age, notably in women.¹³⁵

A similar favorable association was reported in the Baltimore Longitudinal Study of Aging, in which a U-shaped relation was found between alcohol intake and stiffness index for the common carotid artery in those subjects >55 years old in 774 community-based subjects.¹³⁶ In contrast, the Atherosclerosis Risk in Community (ARIC) study did not find any effects of regular alcohol intake on arterial stiffness in subjects aged 45 to 64 years,¹³⁷ a finding similar to the finding in subjects <55 years old in the Baltimore Longitudinal Study of Ageing.¹³⁶ In summary, the more consistent observation appears to be of increased vascular stiffness with heavier drinking, whereas the improvements in compliance reported with lighter drinking have been dependent on age and gender. The question as to whether the increase in arterial stiffness with heavier drinking is a prelude to alcohol-related hypertension or a consequence requires further study.

Finally, given that in many different tissues the disease consequences of chronic and excessive alcohol consumption have been ascribed to its ability to increase oxidative stress the possibility that alcohol-related hypertension may also arise at least in part from such an effect needs to be discussed. By monitoring isoprostane levels (an *in vivo* marker of oxidative stress), alcohol has been shown to induce oxidative stress acutely¹³⁸ and is associated with other biomarkers of oxidative stress in population-based studies,^{139,140} including gamma-glutamyl transpeptidase (γ GT).¹³⁹ γ GT is essential for the uptake of extracellular glutathione, which helps maintain intracellular glutathione levels and therefore oxidative balance. γ GT has been consistently related to level of blood pressure in cross-

sectional studies,¹⁴¹ and to incidence of hypertension in longitudinal studies.¹⁴² Higher γ GT levels have also been related to poor blood pressure control in treated hypertensive drinkers.⁴ Thus, an increase in γ GT with increasing alcohol intake may indicate those subjects who develop increased oxidative stress with alcohol resulting in vascular wall nitric oxide depletion and increased susceptibility to development of alcohol-related hypertension. The finding in an intervention study that falls in blood pressure following a 4-week period of reduced alcohol intake were greatest in subjects who initially had the highest γ GT levels¹⁴³ supports such a proposition.

CLINICAL IMPLICATIONS AND PERSPECTIVES

The mean 4/2 mmHg fall in systolic and diastolic blood pressure (respectively) predicted from a reduction in alcohol intake by the meta-analysis of Xin et al.⁴⁰ should translate into an 18% decrease in the incidence of death from stroke and a 12% decrease in that from coronary heart disease. However, the complicated and often biphasic effects of alcohol on multiple cardiovascular risk factors means that this simple equation has no correlate in epidemiologic reality. At the same time as increasing blood pressure, alcohol has a dose-dependent action to increase HDL-cholesterol, decrease fibrinogen levels, and reduce platelet adhesiveness. Effects to enhance fibrinolysis and decrease lipoprotein-a may also be relevant. At high levels of consumption, however, disadvantageous influences on cardiovascular risk are mediated not only by the increase in blood pressure but by higher triglyceride levels, increased plasma homocysteine, and increased risk of type 2 diabetes mellitus. These contrasting effects translate into complex relationships of alcohol to stroke and coronary heart disease outcomes.

The relationships of alcohol to stroke, for example, have recently been described as an epidemiological labyrinth¹⁴⁴—predominantly due to the contrasting effects of light versus heavy alcohol consumption on the myriad of stroke outcomes (ischemic stroke, cardio-embolic stroke, hemorrhagic stroke, and so on). A comprehensive systematic review of the association between alcohol and stroke¹⁴⁵ suggests that for ischemic stroke there is a J-shaped relationship with a decrease in risk at light drinking and an increase in risk with heavier drinking. The evidence linking light drinking with a reduction in risk was considered inconsistent, whereas that linking increased consumption (especially recent consumption and binge drinking)⁸⁷ to increased risk of ischemic stroke was considered strong. Alcohol-induced hypertension is probably a mediator of this increase in ischemic stroke risk, although in some studies the increase in risk remains even after adjustment for level of blood pressure. Important further considerations may therefore be cardioembolic stroke in the setting of alcohol-related atrial fibrillation or after acute binge drinking a combination of dehydration, hypotension, and perhaps impaired fibrinolytic activity. For hemorrhagic stroke, systematic review¹⁴⁵ reveals only an increase in risk with increasing

consumption—an outcome possibly dictated by an alcohol-related increase in blood pressure in combination with the antithrombotic actions of alcohol.

A recent meta-analysis of the risks for coronary artery disease with increasing alcohol consumption suggested a biphasic J-shaped curve similar to the relationship seen for ischemic stroke. The nadir of the curve was seen at 20 g ethanol per day, with a mean decrease in relative risk of 20%.¹⁴⁶ At the level of 72 g per day, any protective effect was lost. At intakes greater than 89 g per day there was a mean 5% increase in relative coronary risk. Loss of the protective effect and the increase in risk with heavy alcohol consumption may reflect, at least in part, an effect from alcohol-related hypertension—as well as the increased risk of cardiac arrhythmia (both atrial fibrillation and ventricular fibrillation) and sudden cardiovascular death known to attend heavy drinking. Several studies suggest that any protective effects for coronary artery disease and ischemic stroke are likely to be confined not only to older subjects but to those with other established risk factors for cardiovascular disease such as increased LDL-cholesterol,¹⁴⁷ smoking,¹⁴⁸ or preexisting vascular disease or with specific genetic predisposition (e.g., apoE4 polymorphism¹⁴⁹ or the ADH3 genotype⁵⁴).

Any benefits of alcohol for protection against ischemic heart disease will also be correspondingly less in populations with a low risk of atherosclerosis. In this regard, an analysis from the landmark World Health Organization Global Burden of Disease 2000 Comparative Risk Analysis study¹⁵⁰ (which looked carefully at risks and benefits of alcohol by region and then globally) attributed 16% of all hypertensive disease to alcohol, as well as 10% of hemorrhagic stroke and 2% of coronary artery disease events. Any promulgation of alcohol drinking as a means of reducing coronary artery disease risk in specific populations needs to carefully consider a balance of risks and benefits that is highly dependent on the background prevalence of other cardiovascular risk factors or genetic predisposition to atherosclerotic vascular disease.

What are the implications of these interrelationships for those with established hypertension? There is evidence that hypertension and heavy drinking may act synergistically to increase the risk of both cerebral hemorrhage and infarction two- and threefold, respectively.¹⁵¹ However, other studies (such as a British study of 10,000 attendees at a hypertension clinic)¹⁵² found a 40% decrease in relative risk of stroke in drinkers, with the lowest risk of stroke mortality at intakes of 8 to 80 g alcohol per week. Similarly, a decrease in risk of ischemic heart disease mortality was seen, but this finding was confined to males only. The population, however, included few heavy drinkers and the beneficial effects of alcohol were offset at intakes >21 units/week by an increasing incidence of noncirculatory causes of death.

Age may be an important consideration in such studies, with any overall survival benefits being restricted to predominantly older subjects.¹⁵³ In the Physicians' Health Study cohort¹⁰⁴ a group of 14,125 men with a history of current or past treatment for hypertension who were free of myocardial infarction or stroke at baseline were

assessed for incidence of cardiovascular disease mortality at follow-up. Among men with a systolic blood pressure of 140 mmHg or higher or a diastolic blood pressure of 90 mm Hg or higher (when compared with individuals who rarely or never drank alcoholic beverages), those who reported monthly, weekly, and daily alcohol consumption had multivariate adjusted relative risks for cardiovascular disease mortality of 0.82, 0.64, and 0.56, respectively. These results also suggested that light to moderate alcohol consumption might be associated with a reduction in risk of cardiovascular disease mortality in hypertensive men.¹⁵⁴ However, the mean age of participants was 60 years at baseline, alcohol intake and blood pressure measurement were both self-reported, there was only a single baseline measure of alcohol intake, and no measure of the pattern of alcohol intake.

More worryingly, the finding that consumption of as little as a single alcoholic drink monthly could reduce overall cardiovascular risk by 18% strongly suggests confounding from an unmeasured effect modifier with nondrinkers probably an inappropriate comparison group in this study. In this regard, results from the recent Behavioural Risk Factor Surveillance System Survey, a telephone survey of over 200,000 adults in the USA,¹⁵⁵ revealed that 27 of 30 cardiovascular-associated risk factors or groups of factors (demographic, behavioral, socioeconomic, health related) were significantly more prevalent in nondrinkers than in light to moderate drinkers. Such observations suggest caution in extrapolating risk estimates from population-based studies in which nondrinkers have been the only reference group, with the chances of confounding from unmeasured effect modifiers very likely to account for much of the observed cardiovascular protective effects.

Similar questions need to be asked of the results from a prospective cohort study of French middle-age men who attended the Center for Preventive Medicine.¹⁵⁶ In that study, in moderate wine drinkers (those who consumed <60 g alcohol/day and no beer) there was a decreased risk of cardiovascular death by 24% compared to abstainers. However, this was not observed in heavier wine drinkers or drinkers of beer and spirits. When broken down by quartiles of systolic blood pressure, it was also concluded that moderate wine drinkers who were hypertensive also had a decreased risk of mortality from all causes. The study ignored major dietary and drinking pattern differences that have been consistently reported in relation to predominant beverage choice (wine drinkers less likely to binge drink, more likely to drink with meals, and more likely to make healthier diet choices).^{22,157} The most recent study measuring cardiovascular outcomes in drink-

ing hypertensives compared to abstainers was in a cohort of subjects with not only hypertension but documented left ventricular hypertrophy: the LIFE study.¹⁵⁸ In that study, in drinkers (>8 drinks per week) there was no decrease in composite cardiovascular risk while being treated with losartan compared to atenolol because a decrease in the incidence of myocardial infarction in the drinkers was offset by an increase in the risk of stroke.

SUMMARY

Alcohol-related hypertension is now established as a distinct clinical entity. Similar to essential hypertension, its pathophysiologic basis is multifactorial and complex, with a high likelihood of a significant contribution from genetic predisposition. Unlike essential hypertension, there is a substantial degree of reversibility, with intervention studies suggesting that the majority of any fall in blood pressure will occur within 2 to 4 weeks of a reduction in alcohol intake. Therefore, given global estimates that the contribution of alcohol to the attributable risk of hypertension is 16% moderation of consumption must remain a major public health priority for prevention of hypertensive disease. The links between chronic heavy drinking, especially binge drinking, and adverse cardiovascular outcomes such as ischemic and hemorrhagic stroke are clear (although the role of alcohol-related hypertension in the causal pathway is not always as well defined).

Any benefits of alcohol for protection against ischemic heart disease and stroke appear confined to low levels of consumption and to individuals and populations at increased risk of atherosclerotic vascular disease. Subjects with established hypertension may similarly anticipate a decrease in risk with light drinking, although the magnitude of any benefit has probably been overestimated because of inability to control for important confounders. This has been recently reemphasized by Jackson et al.,¹⁵⁹ who hold that any benefits are likely to be outweighed by harmful effects (with the conclusion that there was "probably no free lunch"). In hypertensive subjects, from the point of view of cardiovascular benefits an intake averaging about 1 to 2 standard drinks a day in men (10 to 20 g alcohol) and up to one a day in women (10 g alcohol) would appear to offer the optimal level of consumption in terms of relative benefits and risks. In normotensive subjects, similar upper levels of intake would appear a sensible recommendation in terms of prevention of alcohol-related hypertension and its sequelae. Binge drinking (which poses a particularly high risk scenario for stroke, coronary events, arrhythmia, and sudden death) should be discouraged in all subjects.

Chapter
42Psychosocial Stress
and Hypertension*Michael W. Brands and Dexter L. Lee***Key Findings**

- A psychosocial stressor is a culturally or socially based situation to which an individual attaches enough meaning so that it is perceived as a challenge.
- Once perceived as a challenge, the sympathetic nervous system and the hypothalamic-pituitary-adrenocortical axis are activated, varying in relative strength depending on coping strategy. An active response to control the stressor drives the sympathetic system.
- Sympathetic-mediated hypertension is augmented, particularly with chronic stress, by components of the HPA-axis and is linked to angiotensin II and cytokines.
- Sustained exposure to a psychosocial stressor causes sustained hypertension in susceptible individuals, and such a response should be considered a risk factor for essential hypertension.

It is interesting, if not perplexing, that even though psychological factors have been implicated as causes of essential hypertension since at least the 1930s¹ (and there is current scientific acceptance²⁻¹⁴ and a general perception in the lay public that psychological factors can increase blood pressure), proof that there can be a psychological basis for chronic hypertension is elusive.¹⁰ One explanation for this may be that the studies in mice in the 1960s and 1970s by Henry et al.¹⁵⁻¹⁷ that began to strengthen the case for psychosocial stress-induced hypertension were not readily reproducible in rats,¹⁸ and it often is difficult to make the association between results from animal and human studies. Another factor, to be discussed later, is the time frame in which the hypertension is studied or defined. In addition, evidence from the Western Collaborative Group Study^{19,20} and Framingham that began linking stress to coronary artery disease (CAD) may have caused a shift in emphasis in the cardiovascular literature.^{21,22} Indeed, much of the clinical interest in stress-induced increases in blood pressure lies in its predictive value for CAD,^{3,21-24} although the deleterious effects of hypertension on other aspects of the circulation are well established. However, regardless of the perception there is evidence that psychosocial stress can cause hypertension in humans.^{11,14}

An extensive study by Schnall et al.²⁵ revealed a significant effect of job stress in increasing blood pressure, and that group later confirmed those findings using ambulatory blood pressure monitoring.²⁶ However, the effect of job stress in causing hypertension has not been demonstrated consis-

tently,^{27,28} with analyses from the same patient studies even yielding conflicting results.^{8,29} Inconsistent results linking job stress to hypertension have been attributed to methods for measuring blood pressure and to considerations of what factors interact with job stress.^{10,30} For example, low socioeconomic status has been associated with higher blood pressure in several studies (including large clinical trials³¹⁻³⁵) but the effect of job stress in increasing blood pressure has been linked to both low^{35,36} and high^{8,37} socioeconomic status. The contrasting findings may be because the ability of job stress to increase blood pressure has been linked to the workers' perception of their control over their job,^{10,11,30,38} and workers of higher socioeconomic status may be more stressed by low job control compared to workers of lower socioeconomic status.^{8,30,38}

The issue of control and the attempt to gain or maintain control is a fundamental concept in evaluating not only the blood pressure response to stress but in determining whether a given event or condition is even defined as a stressor. The next section, therefore, defines a stressor and what makes it capable of inducing a physiological response such as increased blood pressure.

ANATOMY OF A PSYCHOSOCIAL STRESSOR

We will define psychosocial stress as psychological stress in which the meaning attached to the stressor is dependent on the cultural context and social environment (e.g., socioeconomic status). A logical assumption would be that psychosocial stress is a subset of a more generalized umbrella or syndrome of stress, and with regard to hypertension has unique characteristics that define its effect on blood pressure versus the blood pressure effects of other stress subtypes. This is true to a great extent, but it implies a framework in which a well-defined syndrome of stress is neatly subdivided into various subtypes (each of which has its own characteristic causes and effects). However, perhaps the most uniform observation when delving into the stress-hypertension literature is the frustration authors express at the outset in attempting just to define "stress."

This frustration can be traced back even to the person recognized as the originator of the modern concept of stress, Hans Selye. Selye began writing in 1936 about what he called the General Adaptation Syndrome, which was the nonspecific response of the body to any demand.³⁹⁻⁴¹ Thus, his focus was on the response, and Dr. Selye has been noted as saying that he would have been remembered as the father

of the “strain” concept had his knowledge of English been more precise at the time of his early writings.⁴² The reference was to Hooke’s law, in which stress is an external force that produces strain in a malleable metal, and Dr. Selye’s comment serves to highlight the importance of distinguishing between the challenge versus the stress response.

Challenges, or stressors, range from physical (e.g., heat or infection) to emotional or psychological. Responses also cover the same range, with seemingly infinite possibilities for combinations and overlap depending on the stressor and other factors. For example, being hot can provide a psychological challenge in addition to its physical challenge, leading to emotional and/or physiological stress responses (and different stressors may activate the same neural or hormonal response systems). Therefore, we will not attempt an all-inclusive discussion of stress and cardiovascular disease, but will extract from this complex mosaic of causes and responses a specific challenge: psychosocial stress. We will first attempt to define psychosocial stress and illustrate the characteristics that identify it as a unique subtype of stress challenge. We then will describe the overall cardiovascular-related response to psychosocial stress and draw some parallels to what is observed in response to other stress challenges. The focus, however, will move to the blood pressure component of the response, and the remainder of our discussion will therefore be devoted to psychosocial-stress-induced hypertension.

Psychosocial stress challenge

A particularly appealing global definition of a stressor is an event, or challenge, that threatens the maintenance of homeostasis of an organism.^{6,43} This defines stress in the combined contexts of Claude Bernard’s description of the need for constancy of the internal environment⁴⁴ and Walter B. Cannon’s description of the coordinated physical processes (or control systems) that maintain the steady state (i.e., homeostasis).⁴⁵ In this model, organisms are always under conditions of some stress and the issue really becomes one of how these stressors are recognized and handled. In fact, stress is not necessarily a bad thing even if there is a threat to homeostasis.⁷ Stressors that threaten homeostasis can be physical (such as temperature challenges or infection, as noted previously) or perceived, which means that the significance attached to the stressor rather than the stressor itself causes the response.^{46–48} One of the earliest examples of this can be found in the conclusion by Cannon, in 1914, that the “emergency function” of the adrenal medulla was to prepare the body for “flight” or “fight” responses through actions of adrenalin to ensure adequate glucose and blood flow for skeletal muscle, heart, lungs, and brain.⁴⁹ That, and his discussions in that same paper of the fear response of a cat to a barking dog, illustrate that the cause of the stress response under fight-or-flight conditions, in general, is the perceived threat.

Psychosocial stress builds on that principle, because the stressor is still external and the stress response also is dependent on the meaning attached to the stressor. Psychosocial stress can be viewed as a type of psychological stress, but it is important to understand the subtle distinction between the two—especially with regard to psychological

stress typified by the “Type A” nomenclature so often linked to risk for coronary artery disease. Friedman and Rosenman in 1959 reported on the increased coronary risk in patients in Group A in their study. Those patients exhibited a “behavior pattern primarily characterized by intense ambition, competitive drive, constant preoccupation with occupational deadlines, and a sense of time urgency.”⁵⁰ Follow-up prospective studies confirmed the increased cardiovascular risk in persons they later labeled Type A,^{19–21,51–53} and the stress in those individuals (although not universally linked to CAD^{21,22,54}) has been attributed to their attempt to control uncontrollable events.^{55,56} Thus, the ultimate cause of the stress response in both is the psychological meaning attached to an event. However, a key distinction between classic Type A psychological stress and psychosocial stress is that the meaning in the latter is derived from a cultural context and dependent on the social environment.

Attributing psychosocial stress to the meaning attached to a socially dependent stressor may not seem to fit with our working definition of a stressor as a threat to homeostasis, because the meaning attached to the way a person is treated based on social status may not evoke in the reader the same image as the meaning a cat might attach to a barking dog. However, the studies of Henry et al.^{15–17} in mice provide clear evidence that challenges to social status can indeed provoke an intense fight-or-flight response. Thus, the stressor in psychosocial stress is the challenge to an individual’s real or perceived social position. However, the stress response is dependent on the meaning the individual places on that challenge.^{46–48}

Psychosocial stress response: when is a challenge sufficient to elicit a response?

A comprehensive presentation of stress response and coping patterns is not feasible in the context of this chapter, and indeed would require considerably more space to be fairly discussed. There are, of course, many conflicting theories. However, even when considering theories with similar fundamental roots there are a multitude of variations. We will propose, therefore, a general framework that is reasonably inclusive and that also will help us focus more specifically on the hypertensive psychosocial stress response.

With that as our goal, there is an urge to jump immediately to a discussion of the measurable cardiovascular responses to a psychosocial stressor (such as changes in sympathetic nervous system activity or blood pressure). However, it is essential to understand first that the meaning attached to the stressor determines whether there actually will be a stress response.^{46–48} Thus, just as there is a threshold in a pain receptor that determines when an external stimulus will activate it and initiate a response, there also may be a psychological threshold that determines when the individual will consider the external stressor a significant threat.^{12,13} Lazarus, Folkman, and colleagues used the terms *cognitive appraisal* for the process through which an encounter with the environment is evaluated to determine its relative threat to well-being or homeostasis.^{46–48}

There can be considerable variation in cognitive appraisal with psychosocial stressors. Thus, although there would be fair uniformity in the psychological appraisal of the stressor

potential (or perceived threat) of a fire alarm by most people the appraisal of a racial slur may not be as uniform. A mature individual with high self-esteem and secure in their social environment may, for example, be able to attribute the slur to problems within the person making the comment. The slur would therefore not reach the “threshold” to generate a stress response. The same situation may trigger a stress response in other individuals, which indicates that they have attached a level of significance to the event so as to make it a psychosocial stressor. The first step in triggering a psychosocial stress response, therefore, is the individual attaching significant meaning to the event.

Psychosocial stress response: How coping determines the response pattern

Once the cognitive appraisal has reached the “psychological threshold” to identify an event as a psychosocial challenge or stressor, the second step is how the organism or individual copes with the challenge.^{4,38,46–48,57,58} This will have a major impact, in conjunction with the magnitude of the stressor, on determining which physiologic processes are initiated and by what mechanism. Cannon’s fight-or-flight response describes the sympathetic-adrenal medullary system activation in response to an identified threat.^{45,49} This initial rapid-onset response was termed the “alarm reaction” stage within the universal framework of coping that Selye later developed.^{40,41} Sympathetic-driven acute increases in blood pressure were part of that response in both models, but during the maintained response to a continued stressor in Selye’s scheme (termed the *resistance stage*) the hypothalamic-pituitary-adrenocortical (HPA) axis dominated the stress response and adrenal corticoids were thought to be responsible for sustained hypertension.^{40,41}

Henry later hypothesized that these two systems were not linked in such a serial fashion, but that a perceived stimulus activated one of two coping patterns that alternatively activated one or the other system.^{17,59,60} Active coping was focused on gaining control of the stressor and was driven by the sympathetic-adrenal medullary system, whereas passive coping was associated with defeat (or loss of control) and was driven by the HPA axis. Thus, the coping pattern was determined in part by the success of the animal or person in meeting the challenge to homeostasis. There could be genetic predisposition to respond immediately to a perceived threat with active or passive coping. Alternatively, continued challenge to control could eventually lead to a transition from active coping to the defeat reaction. Hypertension in that model was due to persistent, or repeated, activation of the sympathetic system during active coping in the attempt to retain or gain control.

There remains strong support for dual roles of the sympathetic and HPA mechanisms in coping with perceived psychosocial stimuli,^{4,6,57,61–63} but Sapolsky⁶⁴ and others^{61,63,65} have shown that the HPA axis (although not a direct cause or mediator of increased blood pressure) may be required for maximal sympathetic effectiveness during a stress response. Thus, a more integrated action of these two systems may occur even during the initial response to a perceived psychosocial challenge. Figure 42–1 depicts the framework we will use to explain how these systems are

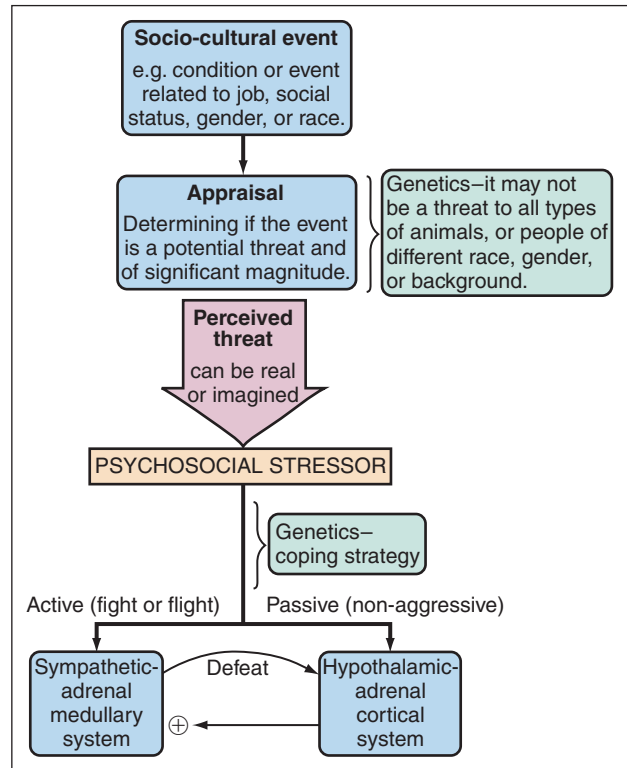

Figure 42–1. The framework to explain how the sympathetic-adrenal medullary and hypothalamic-adrenal cortical systems may be stimulated by psychosocial stress, and the potential different mechanisms for influence of genetic background on the response to a stress challenge.

stimulated by psychosocial stress. The figure also indicates the potential different mechanisms for influence of genetic background on the response to a stress challenge.

GENETICS

The role of genetics in psychosocial stress hypertension seems first to have been considered as an explanation for why the phenomenon appeared to be unique to mice, because there was difficulty in establishing the response consistently in rat studies.^{18,66} However, psychosocial stress hypertension is not a uniform occurrence even in mice,⁶⁷ and the studies that have been done in rats actually can be used to support hypotheses for how genetics might help identify human subpopulations susceptible to psychosocial stress hypertension.¹³

Henry and colleagues reported that male mice housed in complex cage systems (which forced repeated exposure to challenges to social dominance) demonstrated sustained hypertension that was maintained even after removal from the social conflict caging system.^{15–17} Later, Henry speculated that genetics and environmental factors must be coupled to the appropriate stress challenge to induce hypertension, and he tested that hypothesis in rats.⁶⁸ Although studies in the borderline hypertensive rat⁶⁹ and SHR⁷⁰ demonstrated the ability of the appropriate genetic background to enable acute stress to cause hypertension in rats, Henry and others showed that the ability of psychosocial stress to induce

hypertension in rats was also significantly dependent on genetic background and propensity for fighting.^{4,68}

However, the issue of genetics is not as simple as whether a given genetic background will or will not lead to hypertension under stressful conditions, and here it is important to define the time frame under which hypertension is considered. First, it must be established whether one is describing the ability of an acute stressor to cause an acute hypertensive response, the ability of repeated exposure to stress to cause sustained hypertension, or the establishment of chronic hypertension that is maintained even when the stress is removed. Rats, for example, can have significant acute increases in blood pressure caused by stress. However, strain differences appear to determine whether they do^{4,68} or do not develop sustained hypertension.^{18,66,70} Sustained stress-induced hypertension has been shown to lead to irreversible hypertension in mice,^{16,71} but similar data are lacking in rats. On the other hand, Landbergis et al. reported inconsistent evidence that job strain caused rapid onset of significant sustained hypertension in humans and yet it was life-long job strain that was associated with higher blood pressure.⁷² Most stress-hypertension data from human studies correlate baseline blood pressure with some measure of psychosocial stress derived from a survey or interview, often accompanied by measurement of the acute blood pressure response (or “reactivity”) to a laboratory or real-life stressor. However, the predictive value of this acute blood pressure reactivity on long-term blood pressure is variable. The inconsistent results may be due to failure to consider positive family history of hypertension (i.e., genetics, along with environment and the acute stressor^{12,13,17,68,73}).

Thus, whether one is considering the acute increase in blood pressure in response to a stressor or the ability of sustained stress to cause sustained hypertension, there can be a genetic component⁷³, and the tendency would be to explore genetic variation in blood pressure control systems. Although that has been a valid and fruitful approach,⁷³ it also is important to consider the role of genetics in determining whether the individual even considers a given psychosocial condition a stress challenge. Animals of different genetic backgrounds respond to the same psychosocial stimulus in a variety of ways, ranging from aggression, to fear, to nonresponsiveness—and even that can be modified by the animal’s current social rank.^{2,7,17,57} Therefore, when determining why there is a blunted or absent acute increase in blood pressure in response to a stressful event it is important to consider whether the subject even considers the event stressful before probing for physiologic explanations.

PHYSIOLOGY AND PATHOPHYSIOLOGY

As noted previously, most hypotheses for the integrated response to psychosocial stress continue to invoke activation of the sympathetic nervous system and the HPA axis—with responses that include increases in body temperature, blood pressure, heart rate, and plasma glucocorticoid concentration (interference with either system compromises the body’s ability to respond to the stressor).^{4,6,17,57,61,62,64,73–76} The HPA axis describes in general the stimulation of

corticotrophin-releasing hormone (CRH) synthesis and secretion from the paraventricular nucleus (PVN) of the hypothalamus, its stimulation of adrenocorticotropin hormone (ACTH) release from the anterior pituitary, and the effect of ACTH to increase glucocorticoid synthesis and secretion by the adrenal gland.^{6,63,64,77–79} There are variations among hypotheses regarding how social rank and cognitive appraisal affect the time course and magnitude of activation of the sympathetic system and the HPA axis,^{2,4,7,17,57,62,73,80} but this general paradigm is sound (Figure 42–2). However, there are important caveats to understand.

First, the long-standing belief that activation of the sympathetic nervous system was a global all-or-none response to stress^{40,49} has given way to understanding that there is specific activation of selective sympathetic efferent pathways depending on the stimulus.⁸¹ In addition, the classic negative feedback control of CRH and ACTH release by adrenal glucocorticoids now incorporates dose- and time-dependent interactions such as an effect of glucocorticoids under chronic stress to stimulate (or augment) CRH release.^{63,64,77,79,82} There is also not a sharp distinction between the sympathetic system and the HPA axis centrally because CRH stimulates the locus ceruleus/norepinephrine nuclei of the brain stem and norepinephrine stimulates the PVN.^{6,63,77,79,83} Moreover, there are more central mediators involved than just the prototypical CRH and norepinephrine. Arginine vasopressin, for example, is secreted by the PVN along with CRH, and it acts synergistically with CRH to increase ACTH release and stimulates norepinephrine release from the locus ceruleus.^{63,64,74,84,85}

ACTH is interesting because it is formed along with β -endorphin and α -melanocyte-stimulating hormone (α -MSH) from proopiomelanocortin (POMC) in the anterior pituitary.^{74,86} Thus, in addition to the effects of glucocorticoids on food intake and metabolic rate, the interplay of melanocortins, insulin, and other central-acting satiety/metabolic regulators provides a link among stress, insulin resistance, and obesity.^{79,82,87,88}

Mechanisms of hypertension

The considerable emphasis on the dual activation of the sympathetic nervous system and the HPA axis might seem misplaced given that increased blood pressure during stress is mediated by the sympathetic nervous system. Two points must be made in that regard. First is that hypertension is not necessarily a required or “programmed” response to all psychosocial stressors by animals or people of varied genetic backgrounds in various environments. For example, the defeat response (the perception of loss or lack of control that is not accompanied by attempts to regain or gain it) to long-term psychosocial stress is associated with long-term HPA-axis stimulation without hypertension, and we have just noted the multiple links between chronic activation of that system with regulation of food intake and metabolism that point to mechanisms linking psychosocial stress to obesity.^{79,82,87,88} Responses of other animals or people (depending on the particular psychosocial stressor, the environment, and their genetic makeup) may be active and call upon the sympathetic nervous system,

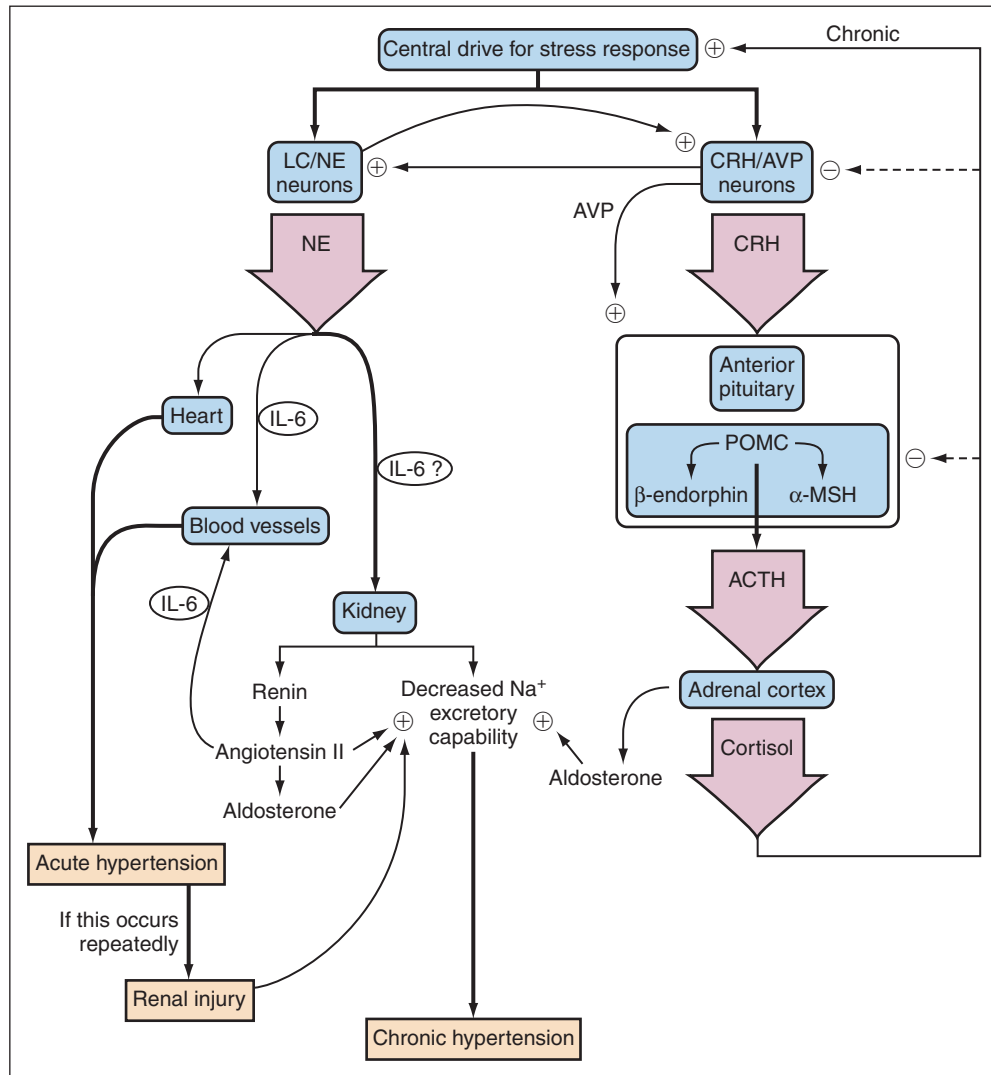

Figure 42-2. Potential mechanisms for how central activation of the sympathetic-adrenomedullary and hypothalamic-adrenal cortical systems may cause both acute and chronic hypertension.

acutely and perhaps long term. Thus, the second point to be made is to recall the previous discussion regarding the role of the HPA-axis (particularly with chronic stress) to amplify the stimulation and action of the sympathetic nervous system.^{61,64}

Sympathetic nervous system: Renin angiotensin system

The sympathetic nervous system has well-described effects to increase blood pressure through vascular and cardiac actions, and Chapter 27 of this book covers those mechanisms in detail. We will explore its interaction with the renin-angiotensin system, because it is an important component of the integrated hypertensive effect of sympathetic activation that will also enable us to clarify the role of time in understanding psychosocial stress hypertension. In addition, the link between the sympathetic nervous system and angiotensin II provides a sound physiologic basis for understanding the potential role of inflammation in stress-induced hypertension.

The sympathetic nervous system stimulates renin secretion primarily through direct actions on juxtaglomerular cell beta-1 adrenoreceptors, but also through its effect on proximal tubular sodium reabsorption to decrease sodium delivery to the macula densa.⁸⁹⁻⁹¹ Angiotensin II, in turn, has rapid and direct vasoconstrictor actions^{92,93} that enable it to contribute to the pressor response to activation of the sympathetic nervous system.⁹⁴ We recently tested the role of these two systems in the acute hypertensive response to a new model of psychosocial stress in mice.⁹⁵ The psychosocial stressor is a variation of cage-switch stress, in which a male mouse is placed into a cage that had been occupied by another mouse for 3 days. As shown in Figure 42-3, telemetry-measured mean arterial pressure (MAP) increases rapidly by approximately 40 mmHg and remains increased for over 90 minutes. Alpha-1-receptor blockade markedly blunted the initial increase in MAP with little effect after 20 minutes, whereas beta-receptor blockade had no effect on the initial increase in MAP but essentially eliminated the response after 20 minutes.

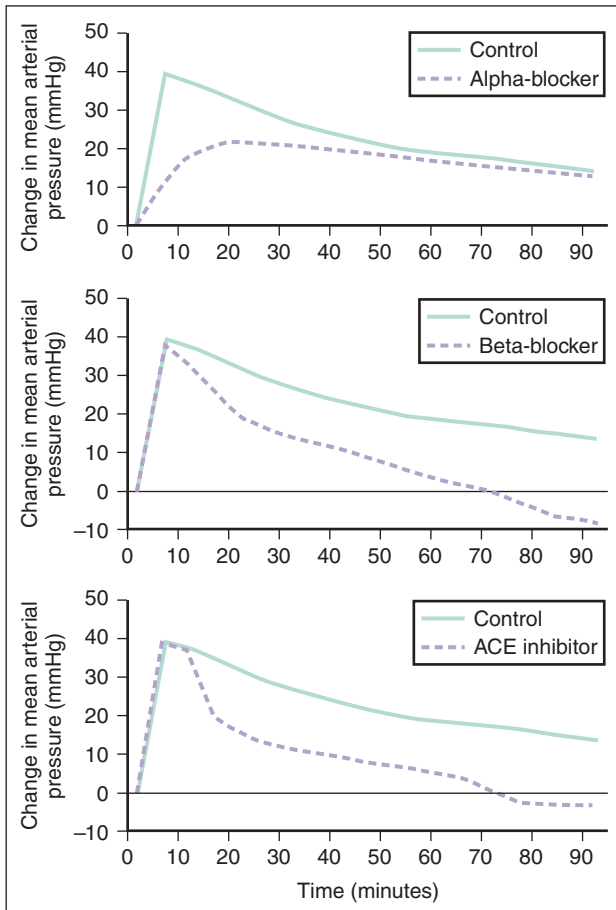

Figure 42-3. The roles of the sympathetic and renin-angiotensin systems in mediating the acute hypertensive response to psychosocial stress, as determined by administration of alpha blockers, beta blockers, and ACE inhibitors to mice undergoing cage-switch stress testing.

It was interesting that the beta-mediated effect was independent of an effect on heart rate, and we found in a third experiment that an ACE-inhibitor affected the MAP response virtually identically to that of the beta blocker. Not only does that provide evidence for a powerful role for AngII in the acute hypertensive response to psychosocial stress but suggests that the mechanism is through sympathetic beta-receptor-mediated stimulation of renin secretion. Plasma renin activity also is increased chronically in mice with sustained psychosocial hypertension,⁹⁶ and the hypertension is prevented by ACE inhibition.⁹⁷

Stress and inflammation

It is an important new observation that both the sympathetic nervous system⁹⁸⁻¹⁰⁶ and AngII¹⁰⁷⁻¹¹³ have been shown to increase production of the inflammatory cytokine interleukin-6 (IL-6). Approximately 25 years ago it became established that immunoregulatory cytokines, theretofore believed to be primarily autocrine/paracrine factors, had a powerful stimulatory effect on the HPA axis.^{76,114,115} The stimulatory effect of cytokines on this system provided an important mechanism to link local inflammatory events with stress and stimulation of the HPA axis,^{76,116,117} and the glucocorticoids in turn have been shown to have an important

function to prevent overshoot of the immune/inflammatory response and preserve the local specificity of the response.^{74,76,118,119} An important consequence of the discovery and description of these negative feedback interrelationships between cytokines and the HPA axis is that classical hormonal modes of action, rather than only autocrine/paracrine functions, became increasingly ascribed to cytokines.

Armed with an appreciation for a physiologic role for circulating cytokines, new evidence that psychosocial stress triggers an inflammatory response^{74,120-123} has raised the possibility that inflammatory mediators may mechanistically link stress to cardiovascular disease. This is bolstered by recent findings by Alexander et al.¹²⁴ that a twofold elevation in the plasma levels of tumor necrosis factor α (TNF- α) caused a significant increase in arterial pressure in pregnant rats (and by Orshal et al.,¹²⁵ who followed with a report infusing IL-6 in pregnant rats). IL-6 is particularly intriguing for the fact that of the three inflammatory cytokines IL-1 β , TNF- α , and IL-6 only IL-6 typically increases significantly in the circulation, where it can act to stimulate CRH and ACTH release in addition to serving as the key trigger for the hepatic acute phase response and release of acute phase proteins such as C-reactive protein.^{74,76,116,126,127} All three can act centrally to stimulate the HPA axis, but IL-6 inhibits production of IL-1 β and TNF- α and is least sensitive to inhibition by the rise in glucocorticoids they stimulate.^{74,76,116,127,128} Therefore, we tested the role of inflammatory cytokines in mediating psychosocial stress hypertension by subjecting IL-6 knockout mice to our cage-switch model.

Figure 42-4 shows the significant decrease in area under the MAP curve during stress in the IL-6 knockout versus wild-type mice. This was all the more interesting because there were no differences in the heart rate or activity responses, suggesting that the effect of IL-6 was not via central control of sympathetic outflow but perhaps at the level of the vasculature. The mechanism through which IL-6 may contribute to increased blood pressure during stress-induced activation of the sympathetic nervous system is

Figure 42-4. Changes in MAP during stress in the IL-6 knockout versus wild-type mice.

not known. Acute IL-6 infusion was shown not to increase blood pressure in dogs,¹²⁹ and the increased IL-6 that occurs with endotoxin shock, cirrhosis, or septic shock is associated with decreased blood pressure.^{130–133} It appears, therefore, that IL-6 is not uniformly a vasoconstrictor or hypertensive factor, but because the sympathetic nervous system can increase IL-6 release from vascular smooth muscle cells^{107–109} these observations together suggest that IL-6 (and perhaps other inflammatory cytokines) plays a role as permissive factor or amplifier of psychosocial stress hypertension.

CLINICAL IMPLICATIONS AND PERSPECTIVES

We raised the issue of time briefly in our discussion of genetics. Time is seldom addressed in reviews of the stress hypertension literature, and for that reason may be the biggest contributor to the confused perception of how stress affects blood pressure. When questioning whether a psychological stressor can cause hypertension, is the focus on the potential for an acute stress challenge to increase blood pressure acutely, on the ability of continued exposure to that stress to cause sustained increases in blood pressure, or on the establishment of permanent hypertension even after the stress has been removed? This may be apparent for a given experiment, but becomes a problem when attempting to reach a conclusion about whether stress causes hypertension: What is the time frame being considered?

By far, most of the experimental evidence in animals and humans for hypertension caused by psychosocial stress is for an acute increase in blood pressure when exposed to the stress challenge. In humans, this is most often expressed as blood pressure reactivity (i.e., the acute increase in blood pressure in response to stress). However, the acute stress actually might not be psychosocial in nature. Instead, chronic psychosocial stress (as determined by interview, for example) may be studied through its effect on blood pressure reactivity to other acute stressors. Nonetheless, overall there is strong support in animal and human studies that acute exposure to psychosocial stress can cause an acute sympathetic-mediated increase in blood pressure. The only other point to make regarding acute pressor responses to acute psychosocial challenges is that not all stress is bad or causes blood pressure to rise. This is noted again to bring in the term *allostasis*, which was coined to avoid the negative connotation that accompanies the term *stress* and to describe the normal responses of the body to daily challenges to homeostasis.^{80,134,135} In this context, the evolutionary value and benefit of increased blood pressure in response to an acute stressor (e.g., the flight-or-fight response) may be more evident.

To describe the negative consequences of a stress response, McEwen et al. developed the concept of allostatic load to quantify the impact of these responses, particularly with prolonged response to a given stressor.^{7,80,135} Thus, although the activation of the sympathetic nervous system and increase in glucocorticoids (and perhaps inflammatory cytokines) are important in helping the animal or person meet and overcome what they have perceived as a significant stress

challenge, continuing to respond to a stress challenge (e.g., loss of job and social position with no end in sight) in this manner can have pathologic consequences. Here is where the gray area regarding psychosocial stress hypertension develops.

From the literature reviewed here, there is good support for the hypothesis that psychosocial stress leads to (or at least contributes to) sustained irreversible hypertension in humans. The human data are correlational in that populations that score high on indexes of psychosocial stress tend to have higher baseline blood pressure. The attempts to use acute blood pressure reactivity as a predictor or gauge of this have yielded mixed results, but as noted previously this might be due to failure to consider genetic background and environment.¹² Thus, psychosocial stress could be viewed as a risk factor for essential hypertension.¹⁰ The difficulty in making this link stronger is the lack of solid experimental evidence for mechanisms from animal studies. Animal studies have shown that sustained psychosocial stress can cause sustained hypertension as long as the stress is maintained in animals of certain genetic backgrounds. The two key questions are: What is the mechanism for the sustained hypertension and what mechanisms would be required for the hypertension to be maintained after the stimulus is removed?

The answer to these questions is rooted in hypotheses developed by Starling,¹³⁶ Borst,¹³⁷ and Guyton and Coleman¹³⁸ that the kidneys' ability to excrete sodium must be decreased in order for hypertension to be sustained chronically. This concept is discussed in detail in Chapter 23, but there is evidence for this mechanism to operate in psychosocial stress hypertension. First, if a person takes an active response to a psychosocial stressor the sympathetic nervous system will be activated. However, in addition to the acute effects on the heart and on blood vessels (also due in part to the stimulation of the renin-angiotensin system), continued high activity of the sympathetic system in a continued attempt to confront the stressor actively can shift the kidneys into a sodium-retaining state through effects on tubular sodium reabsorption, renal vascular resistance, and stimulation of the renin-angiotensin system.⁷³

In fact, psychosocial stress has been shown to decrease urinary sodium excretion in dogs¹³⁹ and humans.¹⁴⁰ However, how could psychosocial stress cause a change in kidney function that would be maintained even after the stress is removed? This most likely would be related to some degree of glomerular injury, as seen with the mechanism for hypertension with progression of diabetic nephropathy, and studies in mice have shown that irreversible hypertension from psychosocial stress is associated with renal injury.^{16,71} The probable mechanism would be repeated transmission of high systemic pressure to the glomeruli over many years due to the wide swings and high peaks in blood pressure associated with repeated sympathetic activation in response to repeated stress.^{141–143} The difficulty in firmly linking psychosocial stress to sustained hypertension through that, or any quantifiable, mechanism is the basis for persistent questions about the “validity” of psychosocial stress hypertension.

SUMMARY

A psychosocial stressor is a culturally or socially based situation to which an individual attaches enough meaning so that it is perceived as a challenge. Once that has happened, there is activation of the sympathetic nervous system and the HPA axis. If the person chooses to confront the challenge directly and attempt to control it, the sympathetic nervous system predominates and causes an acute increase in blood pressure. Elements of the HPA axis and inflammatory cytokines may act centrally and at peripheral target tissues to augment the hypertensive actions of the sympathetic system.

Whether or not a person responds to a psychosocial stressor in this way is dependent not only on the stressor

but on the environment and the family history of hypertension, and those factors also will determine whether sustained exposure to the stressor will cause a sustained hypertensive response. If that occurs, the focus must be on how the individual perceives the challenge and copes with it to prevent the hypertension—unless, of course, the stressor can be eliminated. Although there is no direct experimental support that long-term hypertensive responses to repeated psychosocial stressors can cause essential hypertension, correlational data from human populations and evidence that high blood pressure variability can lead to permanent renal injury suggest that acute psychosocial stress hypertension should be considered a risk factor for essential hypertension.

Overview of Assessment and Investigation of Hypertension: A Pragmatic Practical Approach

Judith A. Whitworth

Key Findings

- Focus on hypertension is shifting to focus on elevation of blood pressure as a risk for cardiovascular disease.
- “Hypertension should be defined in terms of blood pressure level above which investigation and treatment do more good than harm” (Evans and Rose 1971).
- Blood pressure levels at which treatment is recommended depend on overall cardiovascular risk.
- Evaluation of the hypertensive patient aims to confirm elevation of blood pressure, identify secondary causes, evaluate target organ damage, and identify other cardiovascular risks.
- A comprehensive clinical history is essential both for the information it elicits and establishment of the doctor/patient relationship, which is critical to ongoing management.
- Full physical examination is required.
- Routine investigation should include urinalysis and urine microscopy, measurement of potassium, creatinine, fasting glucose and total cholesterol, and electrocardiography.
- A WHO-CVD-Risk Management Package has been designed for feasible and affordable assessment in low- and medium-resource settings.

We are rapidly moving from a paradigm of dichotomous normotension and hypertension to one of blood pressure as a cardiovascular disease (CVD) risk factor.¹ To quote the 2002 WHO Report: “Increasingly, the very terms *hypertension*, *hyperglycemia*, and *hypercholesterolemia*

will probably disappear, as the focus moves from treating a theoretically decided cut-off point, towards managing continuous distributions of risks that intersect and interact with each other: blood pressure, blood sugar and blood cholesterol should be the focus of control.”²

Nonetheless, the words of Evans and Rose remain valid: “Hypertension should be defined in terms of blood pressure level above which investigation and treatment do more good than harm.”³ It follows that any assessment of the hypertensive patient, or the patient in whom blood pressure is contributing to risk, must start with careful blood pressure measurement. This topic, and its extension ambulatory blood pressure monitoring, are covered in Chapters 44 and 45.

Once blood pressure is known, it is essential to assess target organ damage because its presence will determine the extent of overall CVD risk (Table 43–1)⁴ and thus modify the blood pressure levels at which treatment is recommended. This section on clinical assessment and approaches is followed by an extensive section on target organ damage and assessment of heart, vessels, eye, and kidney. According to the 1999 WHO/ISH Guidelines,⁵ “The clinical and laboratory evaluation of the hypertensive patient should be conducted with four aims in mind:

- To confirm a chronic elevation of blood pressure and determine its level.
- To exclude or identify secondary causes of hypertension.
- To determine the presence of target-organ damage and to quantify its extent.
- To search for other cardiovascular risk factors and clinical conditions that may influence prognosis and treatment.”

WHO/ISH STRATIFICATION OF RISK			
BP (mmHg)	Grade 1	Grade 2	Grade 3
	140–159/90–99	160–179/100–109	≥180/≥110
Other risks			
Nil	Low	Medium	High
1–2	Medium	Medium	High
≥3 TOD/ACC	High	High	High
TOD (target organ damage); ACC (associated clinical conditions). From World Health Organization (WHO)/International Society of Hypertension (ISH) statement on management of hypertension. <i>J Hypertens</i> 2003;21:1983–92.			

Table 43–1. WHO/ISH Stratification of Risk

This chapter focuses on basic investigations for the hypertensive patient in both developed and developing countries. More specialized cardiologic investigations are considered in Chapter 46 and in various chapters under the topic “secondary hypertension.” Thus, this chapter should be considered in this broader context of clinical history, physical examination, and core investigations in different global settings.

CLINICAL HISTORY

According to the 1999 WHO/ISH Guidelines,⁵ “A comprehensive clinical history is essential and should include:

- family history of hypertension, diabetes, dyslipidemia, CHD, stroke or renal disease;
- duration and previous levels of high blood pressure, and results and side effects of previous antihypertensive therapy;
- past history or current symptoms of CHD and heart failure, cerebrovascular disease, peripheral vascular disease, diabetes, gout, dyslipidemia, bronchospasm, sexual dysfunction, renal disease, other significant illnesses and information on the drugs used to treat those conditions;
- symptoms suggestive of secondary causes of hypertension;
- careful assessment of lifestyle factors including dietary intake of fat, sodium and alcohol, quantitation of smoking and physical activity, and enquiry of weight gain since early adult life as a useful index of excess body fat;
- detailed enquiry of intake of drugs or substances that can raise blood pressure, including oral contraceptives, nonsteroidal anti-inflammatory drugs, liquorice, cocaine and amphetamines, and attention should be paid to the use of erythropoietin, cyclosporins or steroids for concomitant disorders; and
- personal, psychosocial and environmental factors that could influence the course and outcome of antihypertensive care, including family situation, work environment and education background.”

In eliciting a history of high blood pressure, it is useful to enquire specifically whether blood pressure has been measured in the past (e.g., for a life insurance examination or preoperatively) and whether any comment was made or advice given at the time.⁶ It is also useful to ascertain the patient’s understanding of hypertension and cardiovascular risk, and in the light of increasing knowledge of the deleterious effects of obstructive sleep apnea specific enquiry should be made for sleep disturbance.⁶

Analgesic abuse is now a rarity in many countries where it was formerly a scourge, but the possibility should not be forgotten when a drug history is being elicited. The specific symptoms of underlying causes of hypertension are protean, which are considered under specific chapters later in this book. Symptoms that may suggest underlying causes include anxiety, tremor, sweating and palpitations (pheochromocytoma), muscle cramps or weakness (Conn’s syndrome), daytime somnolence, obesity, snoring (sleep apnea), polyuria, nocturia, and thirst (diabetes or chronic

renal disease) or hematuria or frothy urine (kidney disease). Comprehensive history taking is not only valuable for the information it elicits but for the establishment of a doctor/patient relationship, which is so critical in the ongoing effective management of a chronic asymptomatic condition.

PHYSICAL EXAMINATION

The 1999 WHO/ISH Guidelines⁵ state that “A full physical examination is essential and will include careful measurement of blood pressure. Other important elements of the physical examination include:

- measurement of height and weight, and calculation of BMI (weight in kilograms divided by height in meters squared);
- examination of the cardiovascular system, particularly for heart size, for evidence of heart failure, for evidence of arterial disease in the carotid, renal and peripheral arteries for coarctation of the aorta;
- examination of the lungs for rales and bronchospasm and of the abdomen for bruits, enlarged kidneys and other masses; and
- examination of the optic fundi and of the nervous system for evidence of cerebrovascular damage.”

Findings that may suggest an underlying cause include truncal obesity and striae (Cushing syndrome), tachycardia (pheochromocytoma or thyrotoxicosis), diminished femoral pulses (coarctation), renal bruit (renovascular disease), or palpable kidneys (polycystic disease).

LABORATORY INVESTIGATIONS

The 1999 WHO/ISH Guidelines⁵ state that “In all regions of the world, routine investigations should include urinalysis for blood, protein and glucose, and microscopic examination of urine. Blood chemistry should include measurements of potassium, creatinine, fasting glucose and total cholesterol. An ECG should also be performed. In some regions of the world this list of routine investigations is frequently expanded. . . . The cost of investigations should be considered in the context of the needs of the individual patient and the availability of resources in the particular health system or region.” Canadian recommendations for routine laboratory tests also include complete blood cell count, plasma sodium, HDL and LDL cholesterol, and triglycerides.⁷ The Heart Foundation of Australia⁸ adds hemoglobin, plasma sodium, uric acid, LDL and HDL cholesterol, and triglycerides.

Urinalysis and urine microscopy are particularly valuable in the diagnosis of renal disease, the most common cause of secondary hypertension. Proteinuria found on dipstick testing should be quantified by 24-hour urine collection. According to the Caring for Australians with Renal Impairment (CARI) guidelines, some proteins are normally excreted in the urine (about 80 mg/day). These include filtered plasma proteins (albumin and low-molecular-weight immunoglobulin) and secreted tubular proteins. The cutoff for abnormal is laboratory dependent, between 150 and 300 mg/day. Urine albumin excretion is normally

some 10 mg/day. It is increased during exercise, fever, standing, and pregnancy. Microalbuminuria is 30 to 300 mg/day, and macroalbuminuria >300 mg/day. Urine protein/albumin can be assessed in “spot” urine samples by measuring urine concentration or the albumin/ creatinine ratio.

CARI suggestions for clinical care based on levels III and IV sources state that testing for proteinuria is preferred in patients with hypertension or known vascular disease, whereas in diabetes initial testing for albuminuria is preferred because it allows detection of early nephropathy. Microscopy may reveal excess numbers of red or white cells or casts. Urine abnormalities will usually precede significant renal functional impairment. Red cell casts signify glomerulonephritis, whereas white cell casts indicate pyelonephritis. Granular casts represent degenerated cellular casts and are indicative of renal disease. Waxy casts are a feature of chronic renal disease. Hyaline casts may be present in small numbers in normal urine, but large numbers indicate renal disease. Increased red cell excretion raises the possibility of glomerulonephritis, and excess white cells (with or without bacteria) suggest renal infection. Using phase-contrast microscopy, dysmorphic (i.e., morphologically variable) red blood cells are suggestive of glomerular bleeding (glomerulonephritis), whereas isomorphic (i.e., morphologically uniform) erythrocytes in the urine indicate nonglomerular bleeding.¹⁰

Box 43–1**Essential Investigations****To investigate cause:**

- Urinalysis
- Urine microscopy
- Serum potassium
- Serum creatinine

To assess target organ damage and CVD risk factors:

- Urinalysis
- Serum creatinine
- Serum cholesterol
- Blood glucose
- ECG

Hyperkalemia is suggestive of primary or secondary hyperaldosteronism, but a normal serum potassium does not by any means exclude these diagnoses. Normokalemic hyperaldosteronism is well recognized.¹¹ Serum potassium concentration is also useful as a baseline prior to diuretic therapy. Creatinine is a crude measure of renal function

Modified from Lever and Swales.¹²

Table 43–2. Prevalence (%) of Secondary Hypertension

because it is not elevated until creatinine glomerular filtration rate is significantly decreased, but creatinine remains the best simple measure of renal function.

Fasting glucose is an important investigation because diabetes is a major CVD risk factor, mandating aggressive blood pressure lowering.⁴ Electrocardiography is important in detection of left ventricular hypertrophy (LVH), of itself a major risk factor, as well as evidence of ischemia. It is less sensitive than echocardiography in detecting LVH but is much less expensive and thus more appropriate for routine use. Essential investigations are listed in Box 43–1.

It should be remembered that secondary hypertension is relatively uncommon. Hypertension is so prevalent that even in resource-rich settings investigation for secondary causes should be targeted to those most likely to benefit, e.g., younger people with suggestive symptoms or signs of severe or treatment-resistant hypertension.

The goals are to find a surgically curable cause or a condition for which a particular therapy is indicated (e.g., aldosterone antagonist for aldosteronism consequent on bilateral adrenal hyperplasia), to determine associated risk factors and target organ disease (which would influence therapy), to provide a baseline for assessing progress, and to identify conditions that of themselves require management (e.g., polycystic kidney disease). Lever and Swales¹² compared prevalence of secondary hypertension in referred patients and population studies and found that although it was more common (about twofold) in referred patients it was exceptional in both groups (Table 43–2). In population studies, renovascular disease was by far the most common secondary cause, followed by renovascular disease. Other causes were rare. In referred patients the pattern was similar, although the prevalence of renovascular disease was higher. It should also be remembered that identifying secondary hypertension does not necessarily influence management, and where hypertension is long-standing even removal of the primary cause may not cure or even improve the elevated blood pressure.

Investigation should always be tailored to the likely clinical benefit to the patient, but often even basic tests are ignored. In a U.S. study of 249 patients with newly diagnosed hypertension in community-based primary care clinics, hypertension was staged initially on a single blood pressure recording in 85% of patients. No electrocardiogram was ordered for 89%, and other mandatory laboratory tests were ordered for about 50%.²¹

A group from the Italian Society of Hypertension studied 228 consecutive patients with recently diagnosed hypertension from six outpatient hypertension centers throughout Italy. A complete clinical and laboratory evaluation according to the minimum work-up suggested by the 1999 WHO/ISH guidelines had been carried out in only 10% of patients. A full physical examination had been performed in 60% of the patients, electrocardiogram in 54%, serum total cholesterol in 53%, glucose in 49%, creatinine in 49%, urine analysis in 46%, potassium in 42%, and fundus oculi in 19%.²²

Box 43–2

WHO CVD-Risk Management Package

Scenario One: Protocol for CVD-Risk Assessment and Management

Resource availability

Human resources: Non physician health worker

Equipment: Stethoscope; Blood pressure measuring device; Measuring tape or weighing scale; Optional: test tubes, holder, burner, solution or test strips for checking urine glucose

Other facilities: Referral facilities; Maintenance and calibration of blood pressure measurement devices

Measure SBP in all adults

Take history of heart attack, angina, stroke, TIA, diabetes

Check urine sugar if facilities available

Scenario Two: Protocol for CVD-Risk Assessment

Resource availability

Human resources: Medical doctor or specially trained nurse

Equipment: Stethoscope; Blood pressure measurement device; Measuring tape or weighing scale; Test tubes, holder, burner, solutions or test strips for checking urine glucose and albumin

Other facilities: Referral facilities; Maintenance and calibration of equipment

If BP ≥ 140 or ≥ 90 after 5–10 minutes rest

Take history of heart attack/angina, stroke/TIA, cardiac failure, peripheral vascular disease, family history of premature CVD (first degree relatives <50 years), tobacco use, alcohol intake

Examine for heaving apex, evidence of cardiac failure

Measure BMI or waist circumference

Look for features of secondary hypertension by history and physical examination

Check urine sugar and urine albumin

Scenario Three: Protocol for CVD-Risk Assessment

Resource availability

Human resources: Medical doctor with access to full specialist care

Equipment: Stethoscope; Blood pressure measurement device; Measuring tape and weighing scale; Electrocardiograph; Ophthalmoscope; Urine analysis; Blood analysis: fasting blood sugar, electrolytes, creatinine, cholesterol and lipoproteins

Other facilities: Access to full specialist care; Maintenance and calibration of equipment

Measure BP in all adults

If BP ≥ 140 or ≥ 90 after 5–10 minutes rest

Take history of heart attack/angina, stroke/TIA, cardiac failure, peripheral vascular disease, family history of premature CVD (first degree relatives <50), tobacco use, alcohol intake

Examine for heaving apex, evidence of cardiac failure

Measure BMI or waist circumference

Look for features of secondary hypertension by history and physical examination

Examine fundus for hypertensive retinopathy (if BP >180 or >110)

Check urine albumin, serum creatinine and electrolytes, fasting blood sugar, ECG, Total cholesterol or LDL and HDL

Adapted from WHO, 2002.²⁴

An interesting study from Brazil²³ looked at 145 patients in a general outpatient clinic and found that hypertension was not associated with a higher number of abnormal laboratory tests than normotension (hemoglobin, blood sugar, plasma uric acid, potassium, total and LDL cholesterol, triglycerides, calcium, and creatinine), but both hypertensives and normotensives who were obese had more diabetes and hyperlipidemia.

ASSESSMENT FOR LOW- AND MEDIUM-RESOURCE SETTINGS

The WHO CVD Risk Management Package was designed to make the assessment and management of cardiovascular risk feasible and affordable in low- and medium-resource settings. The package provides clinical protocols that can be applied in three scenarios,²⁴ with hierarchical resource levels adapted to diverse health care facilities. These characteristics are outlined in Box 43–2. The package focuses on treatment but does include initial assessment (as shown in Box 43–2) and a questionnaire for the presence of CVD (Box 43–3).

Barriers to management of CVD risk in a low-resource setting in Nigeria, using hypertension as an entry point, were examined by Mendis and colleagues from WHO.²⁵ They interviewed 1000 consecutive hypertensives and their health care providers across a range of facilities. Laboratory and other investigations to exclude secondary hypertension or assess target organ damage were not available in the majority of facilities. They concluded that if the absolute risk approach for assessment of risk and effective management of hypertension is to be implemented in low-resource settings appropriate policy measures need to be taken to improve the competency of health-care providers, to provide basic laboratory facilities, and to develop affordable financing mechanisms.

Questionnaire to Determine Probable Angina, Heart Attack, Stroke, and TIA

- Have you ever had any pain or discomfort or any pressure or heaviness in your chest?
 Yes No
- If no go to Q8, if yes proceed to the next question:**
- Do you get the pain in the center of the chest or left chest or left arm?
 Yes No
- If no, got to Q8, if yes proceed to next question:**
- Do you get it when you walk at an ordinary pace on level or when you walk uphill or hurry?
 Yes No
 - Do you slow down if you get the pain while walking?
 Yes No
 - Does the pain go away if you stand still or if you take a tablet under the tongue?
 Yes No
 - Does the pain go away in less than 10 minutes?
 Yes No
 - Have you ever had a severe chest pain across the front of your chest lasting for half an hour or more?
 Yes No
- If the answer to questions 3 or 4 or 5 or 6 or 7 is yes patient may have angina or heart attack and needs referral.**
- Stroke and TIA**
- Have you ever had any of the following: difficulty in talking, weakness of arm and/or leg on one side of the body or numbness on one side of the body?
 Yes No

If the answer to question 8 is yes the patient may have had a TIA or stroke and needs referral.

Blood Pressure Measurement

Thomas G. Pickering

Key Findings

- With the demise of the mercury sphygmomanometer, the oscillometric method of blood pressure measurement is becoming the most widely used method.
- Hybrid sphygmomanometers, in which an electronic transducer replaces the mercury column, have promise.
- Measurement from the upper arm is the preferred location, although wrist measurement may be appropriate in patients with very obese arms.
- Applanation tonometry is a promising technique for measuring the central aortic pressure, which may give a better prediction of risk than the brachial artery pressure.
- The traditional clinic or office measurement of blood pressure often significantly over- or underestimates the true blood pressure, which is conceived as the average blood pressure over time.
- When automated monitors are used, only validated devices should be chosen.
- It is important to choose cuffs of the appropriate size, particularly in children and obese subjects.

Although hypertension can only be identified by measuring the blood pressure, the conventionally used methods for its detection are notoriously unreliable. There are three main reasons for this: inaccuracies in the methods, some of which are avoidable; the inherent variability of blood pressure; and the tendency for blood pressure to increase in the presence of a physician (the so-called white-coat effect). For clinical practice, the gold standard has for many years been measurements made with the Korotkoff sound technique by a physician using a mercury sphygmomanometer. However, there is increasing evidence that this may lead to the misclassification of large numbers of individuals as hypertensive. In addition, mercury is being banned in many countries and there is still uncertainty as to what will replace it. Neither the distribution of blood pressure in the population nor the relationship between blood pressure and cardiovascular morbidity provide any justification for a rigid separation between normotension and hypertension,¹ but for clinical purposes a threshold level of blood pressure above which antihypertensive treatment is recommended needs to be established. Thus, the accurate measurement of blood pressure is of extreme importance.

There are two general reasons for measuring blood pressure. The first is as a “vital sign” when evaluating a critically ill patient, in which case the blood pressure at the time of measurement is of critical interest. Is it too high, normal, or too low? For the vast majority of measurements, however, we are not interested in the pressure at the time of measurement so much as its ability to estimate the average (or “true”) level of blood pressure—which is generally assumed to be responsible for the adverse effects of high blood pressure on the circulation and for which the clinic or office blood pressure is taken as a surrogate measure.

CLASSIFICATION/SUBTYPES OF HYPERTENSION

JNC 7 Classification

The latest report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC 7)² has classified hypertension as outlined in Table 44–1. For adults age 18 or older, the cutoff point for defining hypertension continues to be 140/90 mmHg. The classification is based on the average of two or more seated blood pressures, properly measured with well-maintained equipment, at each of two or more visits to the office or clinic.

For patients with diabetes or chronic kidney disease, the cutoff point is 130/80 mmHg. The category of prehypertension has created some confusion, in that a “normal” blood pressure is defined as being less than 120/80 mmHg, leading many people to think that this is the target level of drug treatment. The intent of introducing the concept of prehypertension was to emphasize that people with this level of blood pressure are at increased risk of developing hypertension over the years and that lifestyle changes may help to modify this process.

Isolated systolic hypertension

After the age of 50, the systolic pressure tends to increase with age, and the diastolic to fall. An elevation of systolic pressure (>140 mmHg) together with a normal diastolic pressure (<90 mmHg) is defined as systolic hypertension. The primary mechanism underlying this is increased stiffness of the central arteries. Patients with systolic hypertension over the age of 50 are at increased risk of cardiovascular disease. In the Framingham study, predictors of isolated systolic hypertension (ISH) included older age,

CLASSIFICATION OF HYPERTENSION (JNC7)		
BP Classification	SBP (mmHg) ^a	DBP (mmHg) ^a
Normal	<120	<80
Prehypertension	120–139	80–89
Stage 1 hypertension	140–159	90–99
Stage 2 hypertension	≥160	≥100

a. Classification determined by highest blood pressure category.

Table 44-1. Classification of Hypertension (JNC7)

female sex, and increased body mass index (BMI) during follow-up.³

Isolated systolic hypertension of the young

Although it has been recognized for many years that elevation of systolic pressure with a normal diastolic may also occur in young people (below the age of 30), it is only recently that the phenomenon has been given recognition as a distinct entity. The mechanism is unclear, and has been attributed to a high stroke volume (it is common in athletes) and increased amplification of the pressure waveform in the peripheral circulation.^{4,5} The prognosis is unknown.

Isolated diastolic hypertension

Isolated diastolic hypertension (IDH) is a condition that is also not uncommon in young people, and is defined as a diastolic pressure >90 mmHg together with a normal systolic (<140 mmHg). In some cases this may be the result of early disappearance of the Korotkoff sounds, such that the true diastolic pressure is lower.⁶ Its prognostic significance remains uncertain,^{7,8} but it may be a precursor of systolic and diastolic hypertension and has been related to weight gain in the Framingham Heart Study.³

Pseudohypertension

In some elderly people, the noninvasive methods using a sphygmomanometer cuff compressing the brachial artery may give a very exaggerated estimate of the blood pressure because the artery may be so stiff that it becomes incompressible. The only accurate known method of confirming the diagnosis is to record the pressure intra-arterially, but this is rarely done in practice. Osler's maneuver (the ability to palpate the brachial or radial artery when the cuff is inflated to above systolic pressure) is sometimes positive, but is not a very reliable guide.⁹

Orthostatic (postural) hypotension

Orthostatic (postural) hypotension is defined as a reduction of systolic blood pressure of at least 20 mmHg or 10 mmHg in diastolic blood pressure within three minutes of quiet standing.¹⁰ It is common in elderly patients, and is typically the result of impaired autonomic control. Blood pressure measurement is a major issue because of the increased variability (the pressure may be very low when the patient is upright and high when supine, particularly during the night).

Situational hypertension

In some patients, the blood pressure may be high or low depending on the situation or circumstances of measurement. Although measurements taken in a medical setting are the gold standard for defining hypertension, there is increasing evidence that they may not be representative of the blood pressure levels prevailing at other times. There is also consensus that the overall average blood pressure level is what ultimately determines risk. These types of hypertension are discussed in greater detail in Chapter 45.

White-coat hypertension

White-coat hypertension is defined as a persistently high blood pressure taken in the clinic setting (>140/90 mmHg) together with a normal pressure occurring at other times, away from the clinic. To allow for the white-coat effect, the upper limit of normal (whether measured by home or ambulatory monitoring) is typically taken as 135/85 mmHg. Note that some patients can be normotensive and have white-coat hypertension when attending the doctor, whereas some known hypertensives who are normally well controlled with drug treatment can have raised blood pressures when attending the clinic (due to a white-coat effect).

Masked hypertension

Masked hypertension is the converse of white-coat hypertension, being defined as a persistently normal blood pressure in the clinic but an elevated pressure (>135/85 mmHg) outside it.

TECHNIQUES

The methods currently available for blood pressure measurement in clinical practice are listed in Box 44-1. There are two basic techniques: the auscultatory and oscillometric methods. The former can be done with mercury or aneroid sphygmomanometers, or the more recently introduced hybrid technique. Measurements are preferably taken from the upper arm, although the wrist and finger are alternative sites. In addition, measurements can be taken in the office, at home, or over 24 hours with ambulatory monitoring. The use of all three methods has been endorsed by the JNC 7 recommendations.² This chapter reviews the techniques of blood pressure measurement and their use in the clinic or office setting. Chapter 45 reviews the applications of measurement outside the clinic with home and ambulatory monitoring. Applanation tonometry is a new technique that enables the central aortic pressure to be estimated from recordings made in the peripheral arteries.

The auscultatory technique

It is surprising that nearly 100 years after it was first discovered, and the subsequent recognition of its limited accuracy, the Korotkoff technique for measuring blood pressure has continued to be used without any substantial improvement. The Korotkoff sound method tends to give values for systolic pressure that are lower than the intra-

arterial pressure, and diastolic values that are higher, but there is no obvious superiority for phase 5 over phase 4.^{11–13} The range of discrepancies is quite striking: one author commented that the difference between the two methods might be as much as 25 mmHg in some individuals.¹⁴

There is still no universal agreement as to which phase of the Korotkoff sounds should be used for recording diastolic pressure. The official recommendation of organizations such as the American Heart Association^{15,16} and British Hypertension Society¹⁷ is to use the fifth phase, except in children or other situations in which the disappearance of sounds cannot reliably be determined.¹⁵ Most of the large-scale clinical trials that have evaluated the benefits of treating hypertension have used the fifth phase.

The oscillometric technique

This was first demonstrated by Marey in 1876,¹⁸ and it was subsequently shown that when the oscillations of pressure in a sphygmomanometer cuff are recorded during gradual deflation the point of maximal oscillation corresponds to the mean intra-arterial pressure.^{19,20} The oscillations begin well above systolic pressure and continue below diastolic (Figure 44–1), so that systolic and diastolic pressure can only be estimated indirectly according to some empirically derived algorithm.

One advantage of the method is that no transducer need be placed over the brachial artery, so that placement of the cuff is not critical. Other potential advantages of the oscillometric method for ambulatory monitoring (see Chapter 45) are that it is less susceptible to external noise (but not to low-frequency mechanical vibration) and that the cuff can be removed and replaced by the patient (for example, to take a shower). The main disadvantage is that

such recorders do not work well during physical activity, when there may be considerable movement artifact.

The oscillometric technique has been used successfully in ambulatory blood pressure monitors and home monitors. It should be pointed out that different brands of oscillometric recorders use different algorithms, and there is no generic oscillometric technique. However, comparisons of several different commercial models with intra-arterial and Korotkoff sound measurements have shown generally good agreement.^{21–23}

Ultrasound techniques

Some devices use an ultrasound transmitter and receiver placed over the brachial artery under a sphygmomanometer cuff. As the cuff is deflated, the movement of the arterial wall at systolic pressure causes a Doppler phase shift in the reflected ultrasound, and diastolic pressure is recorded as the point at which diminution of arterial motion occurs.²⁴ Another variation of this method detects the onset of blood flow at systolic pressure, which has been found to be of particular value for measuring pressure in infants and children.²⁵ Such devices are rarely used in clinical practice, having been supplanted by oscillometric monitors.

In patients with very faint Korotkoff sounds (for example, those with muscular atrophy), placing a Doppler probe over the brachial artery may help to detect the systolic pressure (by the appearance of pulsatile sounds as the cuff is deflated). The same technique can be used for measuring the ankle/arm index, in which the systolic pressures in the brachial artery and the posterior tibial artery are compared to obtain an index of peripheral arterial disease.

The finger cuff method of Penaz

This method, developed by Penaz,²⁶ works on the principle of the “unloaded arterial wall.” Arterial pulsation in a finger is detected by a photoplethysmograph under a pressure cuff. The output of the plethysmograph is used to drive a servo-loop which rapidly changes the cuff pressure to keep the output constant, so that the artery is held in a partially opened state. The oscillations of pressure in the cuff are measured, and have been found to resemble the intra-arterial pressure wave in most subjects.

This method gives an accurate estimate of the changes of systolic and diastolic pressure, although both may be underestimated (or overestimated in some subjects) when compared to brachial artery pressures²⁶ (the cuff can be kept inflated for up to two hours). It is now commercially available as the Finometer (formerly Finapres) and Portapres recorders, and has been validated in several studies against intra-arterial pressures.^{27,28} The Portapres enables readings to be taken over 24 hours while the subjects are ambulatory, although it is somewhat cumbersome.²⁹

Applanation tonometry

This is a technique rapidly gaining in popularity that enables the shape of the arterial pressure waveform to be recorded noninvasively from a handheld probe, usually at the wrist (Figure 44–2). The principle of this technique is

Figure 44-1. Changes occurring distal to a sphygmomanometer cuff during deflation. Upper trace (ECG), second trace (auscultatory marker when Korotkoff sounds were first and last heard), third trace (oscillations under cuff detected by foil electret sensor), fourth trace (Korotkoff sounds), and fifth trace (cuff pressure and arterial pressure, recorded noninvasively from other arm).

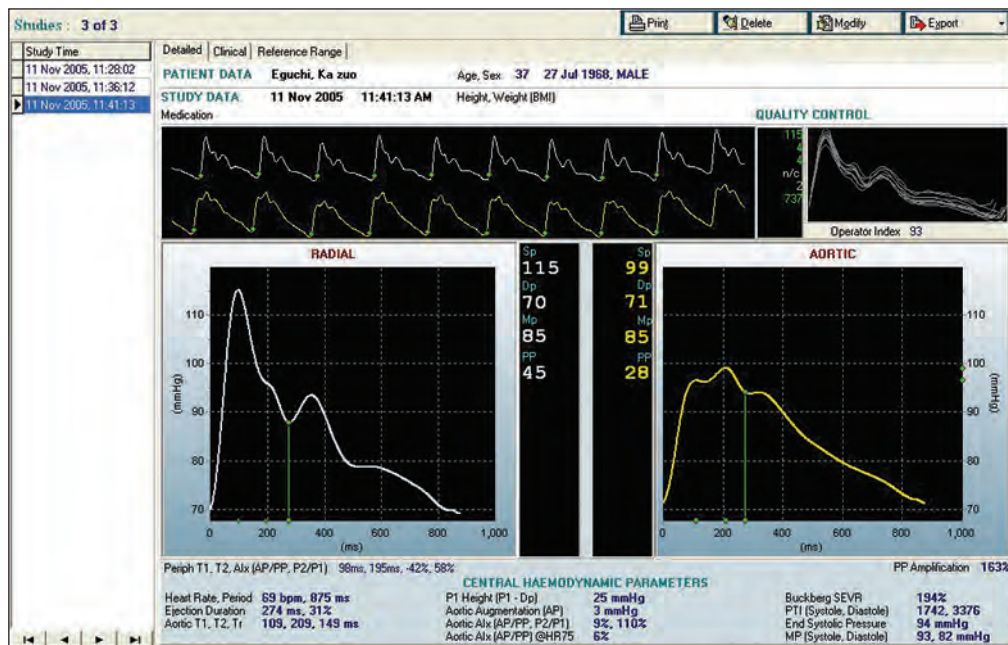

Figure 44-2. Applanation tonometry (Sphygmocor device). Upper left trace shows recordings of radial artery trace (10 pressure waves superimposed) made from a probe held on the radial artery. Upper right trace shows estimated central aortic pressure. Bottom right trace shows augmentation index.

that when an artery is partially compressed or splinted against a bone the pulsations are proportional to the intra-arterial pressure.³⁰ The objective of the technique is to be able to derive central aortic pressure, which is done by Fourier analysis of the waveform. This requires calibration of the recorded wave by taking the brachial artery pressure by the auscultatory or oscillometric technique. The rationale for performing the tests is that cardiovascular events and target organ damage may be more closely related to the central aortic pressure than to the peripheral pressure (as has been confirmed, for example, in the ASCOT CAFÉ study).³¹

Location of measurement

The standard location for noninvasive blood pressure measurement is the brachial artery, although there are several other sites where it can be done. Monitors that measure pressure at the wrist and fingers have become popular, but it is important to realize that the systolic and diastolic pressures vary substantially in different parts of the arterial tree. In general, the systolic pressure increases in more distal arteries, whereas the diastolic decreases. There is currently great interest in measuring the central aortic pressure, which can be derived indirectly from analyses of the blood pressure waveform recorded at more peripheral sites such as the radial artery using applanation tonometry (see material following). The rationale is that the central pressure may be more important in causing target organ damage.

Technical issues with measurement from the upper arm

There are important potential sources of error with measurements from the upper arm. These are discussed in the sections that follow.

Effects of posture

There is no consensus as to whether blood pressure should be routinely measured sitting or supine, although most guidelines recommend sitting.^{15,32} In a survey of 245 subjects of different ages, Netea et al.³³ found that systolic pressures were the same in both positions, but there was a systematic age-related discrepancy for diastolic pressure

such that at the age of 30 the sitting diastolic was about 10 mmHg higher than the supine reading, whereas at the age of 70 the difference was only 2 mmHg.

Body position

Blood pressure measurements are also influenced by the position of the arm in relation to the position of the chest.^{34,35} There is a progressive increase in the pressure of about 5 to 6 mmHg as the arm is moved down from the horizontal to vertical position. These changes are exactly what would be expected from the changes of hydrostatic pressure, and are even more pronounced when recording is made from the wrist (see material following). It is also important that the patient's back be supported during the measurement. If the patient is sitting bolt upright, the diastolic pressure may be 6.5 mmHg higher than if sitting back.³⁶ These differences are of critical importance for monitors that record blood pressure at the wrist (see Chapter 45).

Cuff size

The size of the cuff relative to the diameter of the arm is critical. The most common mistake is to use a cuff that is too small, which will result in an overestimation of the pressure.³⁷⁻³⁹ In general, the error can be reduced by using a large adult-size cuff for all except the skinniest arms. The British Hypertension Society¹⁷ recommends that if the arm circumference exceeds 33 cm a large adult cuff should be used (width 12.5 to 13 cm, length 35 cm). In the United States, the most widely advocated protocol for the selection of the appropriate cuff size is the one recommended by the American Heart Association (AHA),¹⁶ outlined in Table 44-2.

There has been some controversy concerning the width of the largest cuff for use in very obese people (arm circumference more than 45 cm). The older guidelines recommended a maximum width of 22 cm, whereas the most recent AHA guidelines proposed a 16-cm-wide cuff (Table 44-2). The rationale for this was that 22 cm is longer than the upper arm in most people. Very few studies have systematically compared blood pressure measured with the two widths of cuffs in obese people, and where they have there is no consistent difference.⁴⁰

1993 AND 2005 AMERICAN HEART ASSOCIATION RECOMMENDATIONS FOR CUFF SIZES IN OBESE AND OVERWEIGHT SUBJECTS				
Arm Circumference	Cuff	Year	Bladder Width	Bladder Length
22-26 cm	Small adult	1993/2005	10 cm	24 cm
27-34 cm	Adult	1993/2005	13 cm	30 cm
35-44 cm	Large adult	1993	16 cm	38 cm
		2005	16 cm	36 cm
45-52 cm	Adult thigh	1993	20 cm	42 cm
		2005	16 cm	42 cm

Table 44-2. 1993 and 2005 American Heart Association Recommendations for Cuff Sizes in Obese and Overweight Subjects

Blood pressure differences between the two arms

The standard recommendation in all guidelines is to measure the blood pressure in both arms when the patient is first seen, and then to use the arm with the higher pressure for subsequent measurements. In some studies of inter-arm differences, an average difference of more than 10 mmHg has been reported in as many as 20% of patients.⁴¹ What is not clear from these studies is the extent to which the observed differences are reproducible, as opposed to random error. More recent work has shown that genuine differences that are clinically meaningful are very rare, and in the small number of patients who have such differences clinically overt vascular disease is usually present. There is, however, a consistent but small difference in the majority of patients, with the right arm being about 2 mmHg higher than the left arm.⁴² This difference is more noticeable when the auscultatory technique is used, but is still detectable with oscillometric devices. To what extent it is due to handedness is not clear.

DEVICES

Devices for clinic and hospital measurement

Despite the increasing use and acceptance of out-of-office blood pressure measurement, readings taken in a clinic setting are still regarded as the standard by which blood pressure control is assessed. Traditionally, this was done using mercury sphygmomanometers, but these are rapidly disappearing from the clinical scene. They are being replaced by aneroid or hybrid devices (both of which use the auscultatory technique) and by oscillometric devices. As clinical measures of blood pressure and other variables become more widely used for the evaluation of physicians' performance and reimbursement, it is likely that there will be an increasing need for objective measures of clinic blood pressure that can be downloaded into electronic medical records (which at present can only be done with oscillometric devices).

Mercury sphygmomanometers

The mercury sphygmomanometer has always been regarded as the gold standard for clinical measurement of blood pressure, but this situation is rapidly changing (as discussed in material following). The design of mercury sphygmomanometers has changed little over the past 50 years, except that modern versions are less likely to spill mercury if dropped. In principle, there is less to go wrong with mercury sphygmomanometers than other devices, but this should not be any cause for complacency. One hospital survey found that 21% of devices had technical problems that would limit their accuracy,⁴³ whereas another found more than 50% to be defective.⁴⁴

The future of mercury

A growing trend throughout the world is the removal of mercury-containing devices from hospitals. This has already happened with thermometers, and is now starting to happen with sphygmomanometers. The reason is not

because any more accurate device has been developed but because there are concerns about the safety of mercury. In some European countries mercury has already been banned, and there is a growing tendency in the United States to replace mercury devices, although this is being resisted by organizations such as the Council for High Blood Pressure Research and the AHA.⁴⁵ The unresolved issue is what should replace mercury. Currently, the two alternatives are aneroid or electronic (oscillometric) devices, but neither is regarded as satisfactory. Hybrid devices (see material following) are another alternative.

Aneroid devices

The incipient demise of the mercury sphygmomanometer has placed new interest in alternative methods, of which aneroid devices are the leading contenders. Three surveys conducted in hospitals in the past 10 years have examined the accuracy of the aneroid dials. One was conducted in the University of Missouri hospitals, which found that 35% of monitors were in error. A second survey in the Hospital of the University of Sao Paulo in Brazil found 44% in error,⁴³ and the third in the Mayo Clinic Hospitals found only 1%.⁴⁶

Hybrid devices

These devices combine the main advantages of the mercury technique while avoiding the use of mercury, by using an electronic transducer in place of the mercury column or aneroid scale (Figure 44-3). The blood pressure is recorded using the auscultatory technique.⁴⁷

Automated devices for clinic use

The decline in the use of mercury, coupled with the ascendance of the oscillometric technique, has led to the introduction of automated oscillometric devices that can take a series of readings (typically three to five) in the clinic setting. These are usually lower than readings taken

Figure 44-3. A hybrid sphygmomanometer (Accoson), which functions like an aneroid device except that the pressure is measured by an electronic transducer.

by physicians (and to a lesser extent nurses) and hence reduce but do not completely eliminate the white-coat effect.⁴⁸ Their use is likely to increase in the future.

Electronic monitors for clinic and home measurement of blood pressure

When home monitoring was first used, the majority of studies used aneroid sphygmomanometers.⁴⁹ Although inexpensive, such devices require a certain degree of training and dexterity on the part of the patient, and the dials are not always accurate. In one survey, 30% of aneroid dials had errors greater than 4 mmHg.⁵⁰ The mercury sphygmomanometer has never been considered very suitable for home use, partly because of its expense but also because of concerns about the toxicity of mercury.⁵¹ In the past few years, automatic electronic devices have become increasingly popular.

Arm monitors

The standard type of monitor for home use is now an oscillometric device that records pressure from the brachial artery. Oscillometric monitors have the advantage of being easy to use because cuff placement is not as critical as with devices that use a Korotkoff sound microphone, and the oscillometric method has in practice been found to be as reliable as the Korotkoff sound method. The early versions were largely inaccurate,^{52,53} but those currently available are often satisfactory.^{54,55} Unfortunately, only a few have been subjected to proper validation tests such as the Association for the Advancement of Medical Instrumentation (AAMI) and British Hypertension Society (BHS) protocols.

The advantages of electronic monitors have begun to be appreciated by epidemiologists,⁵⁶ who have always been greatly concerned about the accuracy of clinical blood pressure measurement and who have paid much attention to the problems of observer error, digit preference, and the other causes of inaccuracy described previously. Cooper et al. have made the case that the ease of use of the electronic devices and the relative insensitivity to who is actually taking the reading can outweigh any inherent inaccuracy compared to the traditional sphygmomanometer method.⁵⁶ Electronic devices are now available that will take blood pressure from the upper arm, wrist, or finger. Although the use of the more distal sites may be more convenient, measurement of blood pressure from the arm (brachial artery) has always been the standard method and is likely to remain so for the foreseeable future.

Wrist monitors

Wrist monitors have the advantage of being smaller than arm devices, and they can be used in obese people because the wrist diameter is little affected by obesity. A potential problem with wrist monitors is the systematic error introduced by the hydrostatic effect of differences in the position of the wrist relative to the heart,³⁴ as shown in Figure 44–4. This can be avoided if the wrist is always at heart level when the readings are taken, but there is no way of knowing retrospectively whether this was complied with when a series of readings are reviewed.

Figure 44–4. The effects of changes in the position of the forearm on the blood pressure recorded by a wrist monitor. Ten readings were taken in each of three positions: vertically down, horizontal, and vertically up. The average values are shown at the top of each bar.

Wrist monitors have potential, but need to be evaluated further.^{57,58}

Finger monitors

Finger monitors are convenient, but so far have been found inaccurate. The pressure waveform in the finger is different from the brachial artery trace because of the effects of wave reflection. Thus, the systolic peak is shorter and higher, and hence finger monitors would be expected to overestimate the brachial artery systolic pressure by about 4 mmHg.⁵⁹ In practice, there may be little systematic disagreement between finger blood pressure measurement and conventional sphygmomanometry. However, the scatter of individual readings is excessively high.⁶⁰

Choice of monitors

The standard recommendation for the use of automated monitors (whether they will be used for measurement in the clinic, for epidemiological studies, or by the patient at home) is for a device that records blood pressure from the upper arm and that has passed the standard validation tests. The results of validation studies that have been conducted according to these protocols are posted on two web sites: the dabl Educational Trust (<http://www.dableducational.org/>) and the British Hypertension Society (http://www.bhsoc.org/blood_pressure_list.htm). Both of these sites are updated on a regular basis. One of the problems in choosing a monitor is that the manufacturers may change the brand number, making it difficult to know if the accuracy is the same as a similar model that has been validated. Manufacturers are being asked to post statements on these sites as to whether there has been any change in the measurement algorithm.

Ambulatory monitors

First developed more than 40 years ago, ambulatory blood pressure monitoring is only now beginning to find accep-

tance as a clinically useful technique. Technologic advances over the past few years have led to the introduction of monitors that are small, relatively quiet, and can take up to 100 readings of blood pressure over 24 hours while patients go about their normal activities. They are reasonably accurate while the patient is at rest, but less so during physical activity. The accuracy of the various devices can be found on the dabl and BHS web sites. The use of ambulatory and home monitors is discussed in Chapter 45.

Validation of monitors

The increasing use of electronic monitors for both self- and ambulatory monitoring has necessitated the development of standard protocols for testing them. The original two protocols that gained the widest acceptance were developed in the United States by the AAMI in 1987 and the BHS in 1990, with revisions to both in 1993. These required testing of a device against two trained human observers in 85 subjects, which made validation studies difficult to perform. One consequence of this has been that there are still many devices on the market that have never been adequately validated.

More recently, an international group of experts who are members of the European Society of Hypertension Working Group on Blood Pressure Monitoring have produced an international protocol⁶¹ that should replace the two earlier versions and that is easier to perform. Briefly, it requires comparison of the device readings (four in all) alternating with five mercury readings taken by two trained observers. Devices are recommended for approval if both systolic and diastolic readings taken are at least within 5 mmHg of each other for at least 50% of readings.

One of the limitations of the validation procedures is that they analyze the data on a population basis, and pay no attention to individual factors. Thus, it is possible that a monitor will pass the validation criteria and still be consistently in error in a substantial number of individuals. For these reasons it is recommended that when large numbers of readings are going to be taken with an automated device in a particular patient (e.g., with an ambulatory or home monitor) the device be calibrated against a mercury sphygmomanometer.

Applanation tonometry

Devices using this technique are currently used mainly to record the arterial pressure wave at the radial artery, which is the most readily accessible peripheral artery. They may be handheld (using a pencil-shaped probe that is pressed onto the radial artery) or strapped around the wrist, with an array of transducers that ensures that at least one of them is optimally placed over the artery to record the pressure waveform. The basis of the technique is to identify the incident and reflected waves, and hence the augmentation index (a measure of the relative height of the reflected wave).⁶² The results are expressed either as the augmentation index or the central aortic pressure. These devices are relatively expensive, and require some skill in their use.

MEASUREMENT OF BLOOD PRESSURE IN THE CLINIC

Although the mercury method is still considered the gold standard for measurement in the clinic, there is a huge gulf between the ideal measurements and those made in real life. The recent interest in alternative methods of measuring blood pressure has served to emphasize some of the potentially correctable deficiencies of its routine clinic measurement. By increasing the number of readings taken per visit, and the number of visits, as well as by attempting to eliminate sources of error such as terminal digit preference, the reliability of clinic pressure for estimating the true blood pressure and its consequences can be greatly increased. However, a number of factors relating to the physician, the patient, or their interaction may lead to either over- or under-estimation of the true blood pressure.

Patient preparation

The patient should be asked to remove all clothing that covers the location of cuff placement, and should be seated comfortably, with the legs uncrossed, and the back and arm supported, such that the middle of the cuff on the upper arm is at the level of the right atrium (the midpoint of the sternum). These requirements mean that blood pressure should not be measured while the patient is sitting on an exam table. The patient should be instructed to relax as much as possible, and not to talk during the measurement procedure; ideally 5 minutes should elapse before the first reading is taken. At the initial visit, blood pressure should be measured in both arms.

Sources of error with the auscultatory method

Some of the major causes of a discrepancy between the conventional clinical measurement of blood pressure and the true blood pressure are listed in Table 44–1. These include factors that apply whichever method of measurement is used, e.g., cuff size and posture of the patient (see Section IV), and those that are specifically prominent with the auscultatory method, which are described below. The measurement of blood pressure typically involves an interaction between the patient and the physician (or whoever is taking the reading), and factors related to both may lead to a tendency to either overestimate or underestimate the true blood pressure, or to act as a source of bi-directional error, as shown in Table 44–3. There may also be activities which precede or accompany the measurement that make it unrepresentative of the patient's "true" pressure. These include exercise and smoking before the measurement, and talking during it.

Observer error and observer bias are important sources of error when conventional sphygmomanometers are used. Differences of auditory acuity between observers may lead to consistent errors, and terminal digit preference is very common, with most observers recording a disproportionate number of readings ending in 5 or 0.⁶³ The average values of blood pressure recorded by trained individual observers have been found to vary by as much as 5–10 mmHg.⁶⁴ The level of pressure that is recorded

Table 44-3. Patient- and Physician-related Factors That Lead to a Discrepancy Between the Clinic and True Blood Pressure

may also be profoundly influenced by behavioral factors related to the effects of the observer on the subject, the best known of which is the presence of a physician. It has been known for more than 60 years that blood pressures recorded by a physician can be as much as 30 mmHg higher than pressures taken by the patient at home, using the same technique and in the same position.⁶⁵ Physicians also record higher pressures than nurses or technicians.^{66,67} In a population of patients with mild hypertension (diastolic pressures between 90 and 104 mmHg), that approximately 20% may be expected to have “white-coat” hypertension, that is, pressures that are persistently high when in the presence of a physician, but normal at other times.⁶⁷ Other factors that influence the pressure that is recorded may include both the race and sex of the observer.^{68,69} The extent to which inter-observer differences in blood pressure are due to differences in technique as opposed to the white-coat effect can be assessed by having two observers take simultaneous readings with a double-headed stethoscope.

The white-coat effect

One of the main reasons for the growing emphasis on blood pressure readings taken outside the physician’s office or clinic is the white-coat effect, which is conceived as the increase of blood pressure that occurs at the time of a clinic visit, and dissipates soon thereafter. The mechanisms underlying the white-coat effect are not well understood, but may include anxiety, a hyperactive alerting response, or a conditioned response.⁷⁰ Recent evidence supports the idea that it is a conditioned anxiety response. Patients with a large white-coat effect do not appear to be more anxious than others in general, but do record higher levels during the actual blood pressure measurements,⁷¹ and are much more likely to have been previously diagnosed as being hypertensive. The white-coat effect is seen to a greater or lesser extent in most if not all hypertensive patients, but is much smaller or absent in normotensive individuals. It has usually been defined as the difference between the clinic and daytime ambulatory pressure, which is certainly a convenient method of measurement, if not very precise scientifically.⁷² A closely linked but discrete entity is white-coat hypertension, which refers

to a subset of patients who are hypertensive according to their clinic blood pressures, but normotensive at other times. Thus white-coat hypertension is a measure of blood pressure levels, while the white-coat effect is a measure of blood pressure change. What distinguishes patients with white-coat hypertension from those with true or sustained hypertension is not that they have an exaggerated white-coat effect, but that their blood pressure is within the normal range when they are outside the clinic setting. White-coat hypertension is discussed in Chapter 45.

Stethoscope head

Some official recommendations have suggested that the bell of the stethoscope should be used rather than the diaphragm for taking blood pressure, but when it was systematically tested no difference was found between the readings taken with the bell or the diaphragm.³⁶

Rate of cuff inflation and deflation

The rate of inflation has no significant effect on the blood pressure,⁷³ but with very slow rates (2 mmHg/sec or less) the intensity of the Korotkoff sounds is diminished, resulting in slightly higher diastolic pressures. This effect has been attributed to venous congestion reducing the rate of blood flow during very slow deflation.⁷⁴ The generally recommended deflation rate is 2 to 3 mmHg/sec.

Auscultatory gap

This can be defined as the loss and reappearance of Korotkoff sounds that occur between systolic and diastolic pressures during cuff deflation, in the absence of cardiac arrhythmias. Thus, if its presence is not recognized it may lead to the registration of spuriously high diastolic or low systolic pressures. It may occur because of phasic changes of arterial pressure or in patients who have faint Korotkoff sounds. The auscultatory gap may pose a problem for automatic recorders (which operate by the Korotkoff sound technique) and result in gross errors in the measurement of diastolic pressure.⁷⁵ Oscillometric devices are less susceptible to this problem.⁷⁵ Its presence is of clinical significance, because it is associated with an increased prevalence of target organ damage.⁷⁶

Technical sources of error

There are also technical sources of error with the auscultatory method, although these are usually much less when a mercury column is used than with many of the semi-automatic methods (see material following). The mercury should read zero when no pressure is applied, and it should fall freely when the pressure is reduced (this may not occur if the mercury is not clean or if the pinhole connecting the mercury column to the atmosphere is blocked). It is essential that aneroid meters be checked against a mercury column both at zero pressure and when pressure is applied to the cuff. Surveys of such devices used in clinical practice have shown them to be frequently inaccurate.⁵⁰

Training of observers

For the accurate measurement of blood pressure in the clinic setting, adequate training of the observers who will be taking the blood pressure is essential. This applies not only to the traditional auscultatory method but to the use of automated methods. Items such as the proper positioning of the patient (seated comfortably with the back supported, legs uncrossed, and not on an examination table) and the selection of the proper cuff size apply whichever method of measurement is used. When the auscultatory method is used, however, it is critical that the observers be trained in the detection of the Korotkoff sounds. The accuracy of observers' technique can be checked by the use of video recordings of a mercury column and Korotkoff sounds during cuff deflation. The training and certification of observers is described in more detail in the American Heart Association Guidelines.¹⁶

Measurement with automated devices

Although the standard method of clinic blood pressure measurement continues to be a physician or nurse using the auscultatory method, there is a trend to use automated devices, of which several models are now available. All are oscillometric devices that can be programmed to take a number of readings without a human observer present.

MEASUREMENT OF BLOOD PRESSURE IN SPECIAL POPULATIONS AND CIRCUMSTANCES

Infants and children

The Korotkoff sound technique is recommended as the standard for children above the age of one year, although it may give systematic errors in infants (where the sounds are very difficult to hear and the true systolic pressure may be underestimated).²⁵ In infants, the best indirect measurement technique is an ultrasonic flow detector.⁷⁷ A particular problem associated with blood pressure measurement in children of different ages is knowing which size of cuff to choose.

The recommended technique is to choose a cuff that has a bladder width that is approximately 40% of the upper arm circumference. This will usually be a cuff bladder with a length that will cover 80 to 100% of the circumference

of the arm. The equipment necessary to measure blood pressure in children three years of age through adolescence includes pediatric cuffs of different sizes: for newborn/premature infants a cuff size of 4 × 8 cm is recommended; for infants, 6 × 12 cm; and for older children, 9 × 18 cm. A standard adult cuff, a large adult cuff, and a thigh cuff for leg blood pressure measurement and for use in children with very large arms (obese, muscular) should also be available. In children, particularly preadolescents, a difference of several millimeters of mercury is frequently present between the fourth Korotkoff sound, the muffling of Korotkoff sounds, and K5.⁷⁸ In some children, the Korotkoff sounds can be heard to 0 mmHg, which has limited physiologic meaning.

Blood pressure changes markedly with age, and the interpretation of blood pressure in children is very dependent on the child's height and weight. Tables are available that give the 95th percentile for age, sex, and height.⁷⁹

White-coat hypertension (see Chapter 45) is well described in children, and may be diagnosed if either home or ambulatory monitoring shows normal daytime blood pressure values. Normal ranges for both types of monitoring have been published.^{80,81} The use of both types of monitoring in children is increasing rapidly.

Pregnant subjects

In normal pregnancy there is a fall of blood pressure, together with an increase of cardiac output and a large decrease of peripheral resistance. As a result of this hyperkinetic state, Korotkoff-like sounds may occasionally be heard over the brachial artery without any pressure being applied to the cuff. These sounds are most probably due to turbulent flow in the artery. Consequently, the use of phase 4 has frequently been recommended for registering diastolic pressure in pregnant women, which may be 12 mmHg higher than phase 5.⁸² The National High Blood Pressure Education Program (NHBPEP) Working Group report recommends recording both phases 4 and 5 throughout pregnancy.⁸³ However, in one study of 85 pregnant women phase 5 never approached zero, and phase 4 could be identified in only half, leading the authors to recommend phase 5.⁸⁴

The International Society for the Study of Hypertension in Pregnancy currently recommends using K5 for the measurement of diastolic blood pressure in pregnancy.⁸⁵ Because blood pressure changes throughout the course of pregnancy, and the early detection of an increase may herald preeclampsia, a good case can be made for the wider use of home monitoring during pregnancy.⁸⁶

Elderly subjects

In many older people there is an increase of systolic pressure without a corresponding increase of diastolic (systolic hypertension), which has been attributed to a diminished distensibility of the arteries with increasing age. They are also more likely than younger people to have white-coat hypertension (see Chapter 45) and pseudohypertension (see above—page 2 of this chapter).

Care should be taken to measure the seated blood pressure properly, two or more times at each visit, averag-

ing the data. Blood pressure should be taken in the standing position routinely, because the elderly may have postural hypotension. Hypotension is more common in diabetic patients. It is frequently noticed by patients upon rising in the morning, after meals, and when standing quietly.

Obese subjects

It is well known that the accurate estimation of blood pressure using the auscultatory method requires an appropriate match between cuff size and arm diameter. In obese subjects, the regular adult cuff (12 × 23 cm) may seriously overestimate blood pressure.⁸⁷ The effects of arm circumference on the cuff method of measuring blood pressure were studied systematically by King.³⁸ Thus, it is essential to use a large cuff to obtain accurate readings (see Table 44–2). In very obese patients it may be difficult to wrap the cuff around the arm, and measurement at the wrist may be appropriate, either using an oscillometric device or with a stethoscope placed over the radial artery.

Exercise

During dynamic exercise, the auscultatory method may underestimate systolic pressure by up to 15 mmHg, whereas during recovery it may be overestimated by 30 mmHg.^{88,89} Errors in diastolic pressure are unlikely to be as large, except during the recovery period, when falsely low readings may be recorded.⁸⁹ This is the reason the AHA recommends taking the fourth phase of the Korotkoff sound after exercise.¹⁵

Arrhythmias

When the cardiac rhythm is very irregular, such as in atrial fibrillation, the blood pressure varies greatly from

beat to beat, leading to considerable error when the auscultatory method is used to measure blood pressure.⁹⁰ The best that can be done is to record blood pressure several times and use the average value. Automated devices using the oscillometric method are also often inaccurate, for example, in the presence of atrial fibrillation and should be validated in each subject before use.⁹¹ However, ambulatory monitors have been found to provide data similar to that in subjects with normal cardiac rhythm.⁹²

SUMMARY AND PERSPECTIVES

There is increasing attention being paid to small elevations of blood pressure, such as prehypertension, and to the poor state of hypertension control throughout the world. Both of these require that blood pressure be measured accurately and frequently. The traditional auscultatory method using a mercury sphygmomanometer or aneroid device has provided the basis for almost all of our knowledge about blood pressure in human subjects, but is prone to numerous errors (and mercury is being banned in most countries). It is being replaced by automated oscillometric devices, which while not as accurate in principle are less susceptible to faulty technique and can provide multiple readings.

For the foreseeable future, it is likely that measurements made in the clinic or office will continue to be the standard by which blood pressure control is judged. However, this is increasingly being done using automated devices, and there will continue to be greater reliance on out-of-office measurements for making clinical decisions.

Out-of-Office Blood Pressure Monitoring

Thomas G. Pickering

Key Findings

- Self- (home) and ambulatory blood pressure (BP) monitoring are useful adjuncts to clinic or office measurements.
- BPs taken with these techniques are greatly influenced by the diurnal rhythm of BP and by the effects of physical and mental activity.
- In some patients, the normal dipping pattern of BP during sleep is lost or reversed, a phenomenon that can only be evaluated with ambulatory monitoring. The clinical significance of non-dipping is not clear.
- Two conditions detected by home and ambulatory monitoring are white coat hypertension (WCH; in which the clinic pressure is raised but the out-of-office BP is normal) and masked hypertension, which is the opposite situation. Thus, the clinic pressure overestimates risk in WCH and underestimates it in masked hypertension.
- Ambulatory monitoring provides the most reliable estimate of an individual patient's risk of cardiovascular events.
- The upper limit for normal daytime BP for both home and ambulatory monitoring is usually taken as 135/85 mmHg (to correspond with a clinic pressure of 140/90).
- Home monitoring is particularly well suited for monitoring changes of BP over time.

INTRODUCTION

The techniques for measuring BP in order to decide whether or not a patient is hypertensive have undergone considerable change in the past 20 years. Despite the fact that the bulk of our knowledge about the risks of hypertension and the benefits of treating it is based on the traditional method of taking a small number of readings using the auscultatory technique in a medical setting, there is increasing recognition that such measurements (while of enormous value on a population basis) may give a poor estimate of risk in an individual patient.

There are several reasons for this, which include poor observer technique such as terminal digit preference (the tendency to read to the nearest 10 mmHg), the white coat effect (the transient but variable elevation of BP in a medical setting), and the inherent variability of BP. Any clinical measurement of BP may be regarded as a surrogate measure for the patient's "true" BP, which may be conceived as the average level over prolonged periods of time.

Two techniques have been developed to improve the estimate of the true BP/ambulatory-BP monitoring (ABPM) and home (or self-) monitoring (HBPM), which may be subsumed under the title of "out-of-office monitoring" because they avoid many of the limitations of traditional clinic or office measurements described previously. The use of both techniques has been endorsed by national and international guidelines such as JNC 7¹ and the International Society of Hypertension (ISH).²

The first ambulatory monitor was developed by Dr. Maurice Sokolow in the 1960s.³ This monitor required the patient to inflate the cuff manually, and thus only daytime readings could be obtained. Studies with this procedure established a number of important findings. First, there was enormous variability of BP during a normal day. Second, the agreement between the conventionally measured BP and the daytime average was relatively poor. Third, the relationships with the adverse effects of hypertension were stronger for the ambulatory measured BP. These early findings have been substantiated by numerous later studies, and form the basis for establishing ABPM as the gold standard for estimating BP-related risk in an individual patient.

Home (or self-) monitoring is much more widely used than ambulatory monitoring, and is gradually finding its way into routine care. Virtually all home monitors work on the oscillometric technique, and are valuable both for the initial diagnosis of hypertension and for monitoring the response to treatment.

Out-of-office monitoring has some distinct advantages over clinic BP measurement. These are (1) the ability to take larger numbers of readings, (2) the ability to make a better evaluation of "situational hypertension" (i.e., hypertension whose diagnosis depends on the circumstances of measurement, such as white coat and masked hypertension), and (3) the ability to assess nighttime BP, which at present can only be made with ABPM.

The relative values of the three methods of measuring BP are summarized in Table 45-1, and are described in more detail in material following. For the diagnosis of hypertension and the prediction of clinical outcomes, ABPM is usually regarded as the gold standard, although it has been suggested that any elevation of BP (whether measured in the office, at home, or by ABPM) carries an adverse prognosis.⁴ It is important to recognize that the upper limits of "normal" BP are set lower for out-of-office measurements, to allow for the white coat effect. Home monitoring is particularly useful for assessing the

VALUE OF DIFFERENT METHODS OF BLOOD PRESSURE MEASUREMENT IN CLINICAL PRACTICE			
Utility	Method of Blood Pressure Measurement		
	Office	Self	Ambulatory
Predicts outcome	+	+	++
Diagnostic use	+	+	++
"Normal" limit	140/90	135/85	135/85 (day)
Evaluation of treatment	+	++	+
Improves adherence	–	+	–

Table 45–1. Value of Different Methods of Blood Pressure Measurement in Clinical Practice

effects of antihypertensive treatment, and for improving adherence. The major factor that distinguishes out-of-office BP measurements (both home and ambulatory) is that they are taken at different times of day and under different circumstances, and thus it is important to understand the effects of these on BP (as described in sections following).

FACTORS AFFECTING BLOOD PRESSURE DURING DAILY LIFE

Most biologic variables show a diurnal rhythm, and BP is no exception. This is determined by a combination of a built-in biologic clock and external influences such as the light/dark cycle. There are also changes of longer periodicity, such as the day of the week and the season of the year.

TEMPORAL INFLUENCES ON BLOOD PRESSURE

The diurnal rhythm of blood pressure

Evaluation of the time course of BP over 24 hours can only be achieved using ABPM. In normotensive subjects, there is a pronounced diurnal rhythm of BP⁵ that falls to its lowest level during the first few hours of sleep. There is a marked surge in the morning hours coinciding with waking and getting out of bed. The average difference between the waking and sleeping BP is 10 to 20%.

Hypertensive patients usually show the same pattern, but the diurnal profile of BP is set at a higher level.⁵ In some subjects, whether normotensive or hypertensive, the normal nocturnal fall of BP is diminished (<10%). This pattern is referred to as non-dipping, in contrast to the normal dipping pattern. A further classification that some authors have used is to identify people who show an excessive fall of pressure (the extreme dippers, whose nocturnal pressure falls more than 20%) or an actual increase (risers).⁶

Time of day

Studies using ABPM have generally shown that the highest BP is seen in the first few hours after waking. This is the so-called morning surge of BP, which is also the time of highest cardiovascular risk.^{7,8} This can be attributed to the

process of waking up and to increased physical activity.⁹ However, this pattern is less readily discernible with self-monitoring. In studies where morning and evening measurements were both taken, the evening readings often tend to be higher for systolic pressure (by about 3 mmHg), although there are less consistent differences for diastolic pressure.^{10,11} These differences may be more pronounced in hypertensive patients. In one study of untreated hypertensives,¹² the average home BP was 147/86 mmHg at 8 AM, 145/82 mmHg at 1 PM, and 152/86 mmHg at 10 PM. The differences between morning and evening pressures may be higher in men and in smokers.¹¹ The reason for the apparent discrepancy between morning and evening BP with the two techniques may be that self-monitored readings are taken under more standardized conditions.

The pattern of BP change over the day may vary considerably from one patient to another, depending on their daily routine. Antihypertensive treatment may also have a major influence.¹¹ For these reasons, it is generally recommended that patients should take readings in the early morning and at night.

Day of the week

There is relatively little information as to whether pressures recorded on non-workdays are the same as on workdays. In a study using ambulatory monitoring of BP, we found that the pressures in the middle of the day are higher if the subject is at work rather than at home, and the evening readings are also higher at home if the patient had gone to work earlier in the day.¹³

Season of the year

Home and ambulatory BP tend to be up to 5 mmHg higher in the winter than in the summer, at least in temperate climates.^{14–16}

DEMOGRAPHIC FACTORS INFLUENCING HOME AND AMBULATORY BLOOD PRESSURE LEVELS

Gender

Home and ambulatory BP are generally lower in premenopausal women than men, as is true for office BP. This

has been well documented by large epidemiologic studies.¹⁷⁻²⁰ However, the office/home differences are generally the same in men and women.

Age

Age influences out-of-office BP, with most studies that evaluated this (at least those in industrialized societies) showing an increase. Many non-industrialized societies (e.g., primitive societies that have almost no obesity and low sodium intakes) have little or no increase in BP with aging.²¹ In the largest population study to investigate this (conducted in Ohasama, Japan), the increase with age was surprisingly small. The average home BP was 118/71 mmHg for men aged 20 to 29 and 127/76 mmHg for men over 60.¹⁹ The increase of ambulatory BP with age is also much smaller than the increase of office BP.²²

The published results almost certainly underestimate the true changes, because subjects on antihypertensive medications were usually excluded and the prevalence of hypertension increases with age. Another age-related change is the increase of BP variability, as shown by the Ohasama study. The day-to-day variability of systolic pressure increases markedly with age in both men and women, whereas diastolic pressure is little affected and the variability of heart rate actually decreases.

ENVIRONMENTAL FACTORS INFLUENCING HOME AND AMBULATORY BLOOD PRESSURE LEVELS

As with any other measure of BP, the level of pressure recorded during out-of-office monitoring shows considerable variability and is likely to be influenced by several factors. These are summarized in the sections that follow.

Meals

In younger subjects, there is typically an increase of heart rate, a decrease of diastolic pressure, and little change of systolic pressure for up to three hours after a meal.²³ In older subjects, there may be a pronounced fall of both systolic and diastolic pressure after food. Thus, one study compared the effects of a breakfast of two eggs, two slices of toast, and orange juice in healthy elderly subjects (mean age 82 years) and controls aged 35 years.²⁴ The average fall of BP between 30 and 60 minutes after the meal was 16/10 mmHg in the elderly, but only 4/3 mmHg (not significant) in the young.

Alcohol

In people who drink alcohol regularly, it has been reported that evening BP is lowered by 7/6 mmHg and that there is also a smaller increase of morning BP (5/2 mmHg) that is only seen after a delay of two weeks.²⁵

Caffeine

Drinking coffee increases BP, but not heart rate. The increase of BP begins within 15 minutes of drinking coffee, and is maximal in about one hour and may last for as much as three hours. Typical increases are between 5/9

and 14/10 mmHg.^{26,27} Drinking decaffeinated coffee produces little or no change.²⁶ These changes are dependent on the level of habitual caffeine intake. BP changes are much greater in people who do not use caffeine regularly than in habitual users (12/10 versus 4/2 mmHg, respectively). Older subjects show greater increases of pressure than younger ones.²⁸ Caffeine also has an additive effect on the BP response to mental stress: higher absolute levels of pressure are achieved after caffeine, but the rise of pressure during the stressor is not affected.²⁹

Smoking

Smoking a cigarette raises both heart rate and BP. In patients who were studied smoking in their natural environment during intra-arterial ambulatory BP monitoring, it was found that the BP increased by about 11/5 mmHg,³⁰ sometimes preceded by a transient fall of pressure. Changes were quantitatively similar in normotensives and hypertensives. The effect on BP is seen within a few minutes, and lasts about 15 minutes. Coffee and cigarettes are often taken together, and a study by Freestone and Ramsay showed that they may have an interactive effect,³¹ which may raise BP for as long as two hours. Home BPs are usually lower than office BPs, but this difference is less in smokers,³² presumably because they are likely to have smoked before taking the home readings.

ABP readings are typically higher during the day in smokers than in non-smokers, although office and nighttime BPs tend to be the same. This can be explained by the fact that patients are unlikely to be smoking in the latter two situations.

Talking

Talking is a potent pressor stimulus that has both physical and psychological components. Reading aloud produces an immediate increase of both systolic and diastolic pressure (by about 10/7 mmHg in normotensive individuals) and of heart rate, with an immediate return to baseline levels once silence is resumed.³³ Reading silently, however, does not affect the pressure. Speaking fast produces a bigger increase than speaking slowly.³⁴

Stress

Emotional stress can produce marked elevations of BP that can outlast the stimulus. In a study in which people were asked to recall a situation that made them angry, we found that the BP could increase by more than 20 mmHg, and was still elevated by more than 10 mmHg 15 minutes later.³⁵ In a survey of hypertensives who were monitoring their BP at the time of the Hanshin-Awaji earthquake in Japan in 1995, it was found that those who lived within 50 km of the epicenter showed an increase of BP of 11/6 mmHg (which took a week to wear off) on the day following the quake, whereas those living further away showed no change.³⁶

After the terrorist attacks on the World Trade Towers in New York on 9/11/2001, we observed a 30-mmHg increase of home systolic pressure (which persisted for several days) in a patient whose office was immediately

opposite one of the towers.³⁷ In a larger series of subjects monitoring their pressure using a teletransmission device (described in material following), in the months before and after 9/11/2001 in four sites in the United States we observed a 2-mmHg increase of systolic pressure.³⁸ This was not a seasonal effect, because comparable data were available for the same time during the previous year. Chronic stress, such as job strain, may elevate the BP throughout the 24 hours, thus resetting the diurnal profile of BP at a higher level.³⁹

Exercise

Although BP rises markedly during physical exercise, it rapidly returns to its baseline level when the exercise is completed, and there may be a period of several hours after a bout of heavy exercise when the pressure may remain below the pre-exercise level (a phenomenon described as post-exercise hypotension).⁴⁰

Bathing

Within about an hour after taking a bath, there is a modest fall of BP of 2 to 3 mmHg.⁴¹

AMBULATORY MONITORING

First developed more than 40 years ago, ambulatory BP monitoring is only now beginning to find acceptance as a clinically useful technique. Technological advances over the past few years have led to the introduction of monitors that are small, relatively quiet, and can take up to 100 readings of BP over 24 hours while patients go about their normal activities. They are reasonably accurate while the patient is at rest, but less so during physical activity. They can in theory provide information about the three main measures of BP: the average level, the diurnal variation, and short-term variability.

Because the currently available monitors take readings intermittently rather than continually, and are unreliable during exercise, they can only give a very crude estimate of the short-term variability of BP. Recordings in hypertensive patients show that in the majority of patients the average ambulatory pressure is lower than the office BP, and in some cases may be within the normal range, leading to a diagnosis of WCH (described in material following).

TECHNIQUES OF ABPM

The currently available ambulatory monitors are fully automatic, and can record BP for 24 hours or longer while patients go about their normal daily activities. Most use the oscillometric technique. The monitors measure about $4 \times 3 \times 1$ inches and weigh 4 pounds. They can be worn on a belt or in a pouch, and are connected to a sphygmomanometer cuff on the upper arm by a plastic tube (Figure 45-1). They are typically programmed to take readings every 15 to 30 minutes throughout the day and night.

At the end of the recording period, the readings are downloaded into a computer. Subjects are asked to keep

Figure 45-1. An ABPM device.

their arm still while the cuff is inflating, and to avoid excessive physical exertion. There are standard protocols for evaluating the accuracy of the monitors, and approved devices are usually accurate to within 5 mmHg of readings taken with a mercury sphygmomanometer. Some devices have been developed that can record 24-hour ECG, but they have not been widely used.

ADVANTAGES AND LIMITATIONS OF AMBULATORY MONITORING

ABPM can provide three types of information that is of potential value in the clinical field (Table 45-2). The first is an estimate of the true or average BP level, the second is the diurnal rhythm of BP, and the third is its variability. At the present time, there are clinical guidelines for only the first of these, and in principle the same information could be obtained by multiple office or home BP measurements. However, in many patients the white coat effect will lead to a distorted estimate. Evaluation of the time course of BP over 24 hours can of course only be achieved using ABPM. This may be of value in several ways. First, non-dippers may be at higher risk of cardiovascular events than dippers. Second, patients with an excessive morning surge of BP may also be at increased risk. Third, it is important to know if the patient's antihypertensive therapy is controlling BP throughout the 24 hours. The issue of BP variability is more complex.

It has frequently been suggested that increased variability of BP may be an independent risk factor for vascular damage, and there is some evidence that transient increases of BP provoked by mental or physical stress may trigger acute coronary events. There are many different ways of measuring variability, ranging from beat-to-beat variations to changes over weeks and months.

COMPARISON OF AMBULATORY AND OFFICE BLOOD PRESSURES

The correlation coefficient between ABP and office BP is usually about 0.5 to 0.7, but the slope is less than unity, such that at low levels of office BP the ABP is higher and at high levels the ABP is lower.⁴² The daytime level of ABP

BLOOD PRESSURE PATTERN DATA THAT CAN BE OBTAINED BY ABPM AND OTHER METHODS			
Variable	ABPM	Office BP	Home BP
Average or true BP	Yes	Questionable	Yes
Diurnal BP rhythm	Yes	No	No
– Dipping status	Yes	No	No
– Morning surge	Yes	No	Questionable
– Duration of drug effects	Yes	No	Yes
BP variability	Yes	No	Questionable

Table 45–2. Blood Pressure Pattern Data That Can Be Obtained by ABPM and Other Methods

that corresponds to a office BP of 140/90 mmHg is usually taken to be 135/85 mmHg.⁴³

REPRODUCIBILITY OF AMBULATORY READINGS

It was established many years ago that office BP may vary by as much as 25 mmHg between successive visits without any intervention, a finding attributed to the small number of readings that could be taken.⁴⁴ Not surprisingly, therefore, both ambulatory and home BP levels are more stable when repeated over short periods of time such as two weeks.⁴⁵ It would be expected that longer time intervals between repeated measurements would give less agreement because there may be temporal trends related to the change of seasons, for example,¹⁶ and this is indeed observed. However, the superiority of ABP over office BP in this respect is still seen.

In one study with an eight-month interval between measurements, the potential error (random change between the two occasions) was estimated to be as high as 38 mmHg for clinic pressure and 18 mmHg for ambulatory pressure.⁴⁶ A commonly used measure of the stability of a measure is the standard deviation of the difference (SDD) between successive readings. When a measure is reproducible, this number is low. In one study estimating the reproducibility over an interval of two years, this was reported to be 17/10 mmHg (systolic/diastolic) for clinic pressure and 10/5 mmHg for 24-hour pressure.⁴⁷

AMBULATORY BLOOD PRESSURE IN NORMAL SUBJECTS

Because the distribution of BP in the population is continuous, with no natural separation between a normotensive and hypertensive group (and because the relationship between BP and risk of morbidity is also continuous), any division between “normal” and “abnormal” or “healthy” and “unhealthy” levels of BP must be arbitrary. This statement applies whichever measure of BP is used (office, ambulatory, or home readings). Both the JNC 7 and the WHO-ISH recommendations have accepted a clinic pressure of 140/90 mmHg as the threshold level for drug treatment in the majority of patients, and 130/85 mmHg for diabetics or patients with renal disease. They diverge

significantly, however, when it comes to ambulatory pressure.

JNC 7 is the same as the American Society of Hypertension (ASH) recommendations⁴⁸ for a daytime pressure of 135–140/85–90 mmHg, and a 24 hour pressure of 130–135/80–85 mmHg, whereas WHO-ISH recommends 125/80 mmHg as the upper limit of normal 24-hour pressure. The difference may seem small, but there are many millions of people who have pressures between these levels. In fact, using data obtained from population surveys of clinically normotensive people who underwent ambulatory monitoring it has been estimated that 45% of the population would be classified as being hypertensive by these criteria.⁴⁹ The JNC 7 and ASH criteria are closer to the levels identified in prospective studies as being associated with an increased risk of cardiovascular morbidity.

DIPPING AND NON-DIPPING

The normal pattern of the diurnal rhythm of BP is a decrease of about 10 to 20% during the night, which coincides with the hours of sleep, and is commonly referred to as dipping. This pattern is not universal, however, and in some people (about 25% of hypertensives) a non-dipping pattern is seen in which the normal nocturnal fall of pressure is absent. A further classification some authors have used is to identify people who show an excessive fall of pressure (the extreme dippers, whose nocturnal pressure falls more than 20%) or an actual increase (risers).

A major question at the present time is the pathologic significance of the differences in these patterns, and whether identification of them has clinical relevance. Several studies have indicated that non-dippers may be at higher risk of cardiovascular events than dippers. It is therefore worth discussing what factors influence dipping status. Of note, “reverse dipping” has also been reported (with high nocturnal BPs) in situations such as preeclampsia.⁵⁰

Causes of non-dipping

Because all definitions of dipping and non-dipping rely on some measure of the differences between daytime and nighttime pressures, it is clear that both components will influence the classification. The nocturnal BP is mainly

influenced by two factors: assuming the horizontal posture and going to sleep. Another factor that will affect nocturnal pressure is body position. When the patient is lying on one side, the BP recorded in the two arms will be different because of the effects of the hydrostatic pressure differences between the arm and the right atrium.

These differences can be 10 mmHg or more.⁵¹ It is possible to record body position during ambulatory BP monitoring, and it has been reported that the non-dipping status may be influenced by the body position during sleep.⁵¹ Changes of body position could thus be one reason for the relatively low reproducibility of dipping. The depth and quality of sleep may also affect dipping. Thus, in subjects who are kept awake during the first part of the night the BP remains high until they are allowed to go to sleep.⁵² Normally, BP is at its lowest during the first few hours of sleep, when stage 4 sleep predominates. Therefore, one possible reason for non-dipping may be a diminished amount of stage 4 sleep.

One study found that non-dippers had a worse sleep profile than dippers (less stage 4 and less REM, and more micro-arousals).⁵³ In addition, non-dippers are likely to have some degree of sleep-disordered breathing (snoring and apnea), but the association between dipping and sleep apnea is not close.^{54,55} Another factor affecting the dipping pattern is the volume and electrolyte status: sodium-sensitive subjects are more likely to be non-dippers than sodium-resistant subjects, and when the former are put on a low-sodium diet their BP tends to shift to a dipper pattern.⁵⁶

Likewise, the daytime BP level will depend on posture and activity. This has been well illustrated in a two-day study combining activity monitoring and BP monitoring, when subjects were relatively active during one day and inactive during the other.⁵⁷ As expected, both the recorded activity levels and the daytime BPs were higher on the active day, and subjects were consequently more likely to be classified as dippers on the active day than on the inactive day.

Several studies have reported that African Americans are more likely to be non-dippers than whites. A recent meta-analysis of 18 such studies looked at American and non-American blacks separately and concluded that American blacks are more likely to be non-dippers than American whites, whereas this trend is not apparent in blacks studied outside the United States,⁵⁸ raising the possibility that the difference is of psychosocial rather than genetic origin.

The prevalence of the non-dipping pattern is increased in several disease states. These include diabetes, chronic kidney disease, congestive heart failure, and Cushing's disease.⁵⁹ Other conditions with "non-dipping" status include obesity, malignant hypertension, and preeclampsia.

Reliability of dipping status

If a classification such as dipping and non-dipping is to be clinically useful, it should be statistically reliable from one occasion to another. There has been considerable debate on this point, which is still unresolved. Thus, one study that performed three ABPM recordings in 79 untreated

hypertensive and normotensive subjects at intervals of six months⁶⁰ found that only 54% of subjects were classified as dippers on all three occasions, leading the authors to conclude that the phenomenon was not a reliable one.

Others have obtained similar results.^{61,62} Thus, the reproducibility of dipping status is limited, which means that it would be wrong to expect very close correlations between dipping and measures of target organ damage or clinical outcomes. It has been suggested that to get an accurate estimate of a patient's dipping status two ABP recordings should be made. This obviously is not practical for the majority of patients.

Does non-dipping predict clinical outcomes?

The big question here is whether the non-dipping pattern is related to a higher risk of cardiovascular events than dipping, independently of the 24-hour BP level. Although there have been several claims for this, the evidence is mixed. Three large-scale prospective studies have found that non-dipping is associated with a higher risk than dipping. The first was the Ohasama study, a population-based prognostic study of 1,542 Japanese who were followed for nine years, which found that dipping and BP level were independent predictors of the risk of cardiovascular mortality. Compared with normotensive dippers, the relative risk in normotensive non-dippers was 2.35. In hypertensive dippers it was 2.67, and in hypertensive non-dippers it was 5.37.⁶³

It is important to note that in both the normotensive and hypertensive groups the 24-hour average levels were the same in the dippers and non-dippers. The second study was the Italian PIUMA study, in which it was found that men and women who were non-dippers (defined in this case as the highest third of the distribution of the night/day ratio of BP) were at approximately double the risk of events as the dippers.⁶⁴ This was the case after controlling for the 24-hour level and diabetes. The third was the Syst-Eur study, a placebo controlled study of the treatment of isolated systolic hypertension, in which a subgroup were evaluated with 24-hour monitoring.⁶⁵ Office BP had a weak predictive value, but the 24-hour readings gave a much broader spread of risk because there were some patients at low risk (the white coat hypertensives) and others at much higher risk than predicted from the clinic pressures. The best predictor of risk was the night/day ratio, which was independent of BP level.

These three studies provide the strongest evidence for risk from the non-dipping pattern. Two other recent studies did not confirm these findings, however. One was a Japanese study of elderly patients, which reported that an exaggerated morning surge of BP (greater than 55 mmHg increase of systolic pressure from the lowest sleep level to the first two hours after waking) predicted risk independently of the BP level.⁶⁶ The people at the highest risk were thus those who showed a pronounced dipping pattern, and the non-dippers had a relatively small morning surge.

Another study by Bjorklund et al. performed in 872 elderly Swedish men found that nighttime BP and dipping were no better at predicting risk than the daytime

pressure.⁶⁷ Another prospective study of treated hypertensives confirmed earlier reports that the ambulatory pressure was a better predictor of risk than the clinic pressure, but did not find any superior prediction of nighttime over daytime pressures.⁶⁸ One explanation for this finding may be the fact that the patients were on antihypertensive treatment when first studied, and it is well recognized that drug treatment may change the dipping pattern.

It has been proposed that the non-dipping pattern may be an independent risk factor for progression of renal damage. This is supported by results of a study by Timio and colleagues,⁶⁹ who conducted a three-year longitudinal study to test the hypothesis that an association exists between a reduced or absent nighttime fall in BP and a future decline of kidney function in renal hypertensive patients. After three years, non-dippers had a faster rate of decline in creatinine clearance compared with dippers (0.37 versus 0.27 mL/min/month). In addition, non-dippers had greater increases in proteinuria compared with dippers (993 versus 438 mg/24 h).

The authors recommended that proper nocturnal BP control should be an additional aim of antihypertensive therapy. In a second study of 95 patients with nondiabetic kidney disease, non-dipping at baseline was also associated with a faster rate of progression of renal disease during three years of follow-up.⁷⁰ However, in this study non-dipping was associated with a higher creatinine and greater proteinuria at baseline as well, making it difficult to determine what role, if any, non-dipping played in the progression of renal disease. Finally, in a study by Tripepi et al.⁷¹ 168 dialysis patients without a history of diabetes, cardiovascular disease, or clinical evidence of heart failure were followed for 38 months. In a multiregression analysis model not including left ventricular hypertrophy (LVH), an association between the highest night/day BP tertile and increased cardiovascular and all-cause mortality was found.⁷¹ In contrast, the pre-dialysis BP averaged over one month did not predict events.

MORNING SURGE OF BLOOD PRESSURE

Most cardiovascular events show a peak incidence during the morning hours, between 6 AM and noon,⁷² and this coincides with the morning surge of BP. The increase of BP can be attributed both to waking up and to getting out of bed. Often these coincide, but when they are separated there is a rise of BP occurring with each of them.⁹ The most direct evidence that there is a causal connection between the rise of BP and the occurrence of events comes from a study showing that patients with the greatest morning surge (defined as the difference in BP between the lowest level during sleep and the average during the first two hours after waking) were at increased risk of having a stroke during a four-year follow-up.⁶⁶

Another prospective study concluded that this applied to hemorrhagic but not ischemic strokes.⁷³ Most antihypertensive medications have relatively little effect on the rate of rise of BP even if they are fully active throughout the 24 hours, although alpha-adrenergic blockade

may reduce it.⁷⁴ The morning surge can only be evaluated by 24-hour ambulatory monitoring, although comparisons of morning and evening BP measured by home monitoring have been proposed as a surrogate measure.⁷⁵

AMBULATORY BLOOD PRESSURES, TARGET ORGAN DAMAGE, AND PROGNOSIS

The rationale for believing that ABPM gives a more valid estimate of an individual's true BP level than office measurements is that many studies have found that it correlates more closely with measures of BP-related target organ damage. More importantly, several prospective studies have shown that it predicts long-term clinical outcomes better. These are reviewed in material following.

Ambulatory blood pressure and target organ damage

A large number of predominantly cross-sectional studies have examined the correlations between ABP and target organ damage. Many of these compared office BP and ABP, but others have also looked to see which component of ABP (e.g., daytime versus nighttime BP) correlates best with target organ damage. The target organs that have been looked at include the heart (LVH), the kidney (microalbuminuria), the brain (magnetic resonance imaging, MRI), and the arteries (carotid ultrasound and measures of arterial stiffness).

LVH is the most frequently measured marker of hypertensive target organ damage. Even in asymptomatic hypertensive patients, those with LVH have a worse cardiovascular prognosis than those without it.^{76,77} Although BP is certainly one of the major determinants of LVH, there is disagreement as to whether the daytime or nighttime pressure is more important. Some studies have shown that LVH is more pronounced in non-dippers,^{20,78–80} whereas others have found no difference.^{81–83}

In view of the fact that dipping has a relatively low reproducibility, the most rigorous test of the role of dipping on target organ damage is to look at the relationships in patients whose dipping status is derived by averaging the daytime and nighttime BPs measured on two separate occasions. This was done by Cuspidi et al., who compared left ventricular (LV) mass in 238 dippers with 117 non-dippers⁸⁴ and found an insignificantly higher LV mass in the non-dippers but a significantly higher prevalence of LVH. The overall (48-hour) average BP level was the same in the two groups, suggesting that there is indeed a modest effect of the non-dipping pattern on LVH.

Silent lacunar infarction can be detected by brain MRI in approximately 30 to 50% of asymptomatic elderly hypertensives,^{85,86} and is a strong predictor of clinically overt stroke.⁸⁷ Its major determinants are aging and hypertension, but an abnormal diurnal BP pattern is also a factor and in elderly hypertensive patients non-dippers have more frequent lacunar infarcts than dippers.⁸⁵

Microalbuminuria is thought to reflect the glomerular capillary leak, which is a consequence of endothelial cell dysfunction and increased intraglomerular pressure, both of which are partly determined by the systemic BP level.

The 24-hour ambulatory BP level is more closely related to microalbuminuria than office BP,^{88,89} and thus white coat hypertensive patients are less likely to have microalbuminuria than patients with sustained hypertension.⁹⁰

The arteries bear the brunt of the damage resulting from hypertension, and show major changes in their structure and function, which help to maintain the hypertension but also set in motion the processes that lead to its adverse consequences. Noninvasive measurements of arterial structure and stiffness are becoming very popular. Several studies have used carotid ultrasound and have shown that ABP relates more closely than office BP to carotid artery intimal-medial thickness.^{90,91}

Ambulatory blood pressure and prognosis

A number of studies have compared conventional office BP measurements with ABPM for the prediction of cardiovascular events, and all have used some measure of the average level of ABP as the predictor variable.^{63,65,67,68,92-98} These are summarized in Table 45-3. Most have included patients whose hypertension was untreated at the time of the initial measurements but who were treated during the follow-up period, in all cases according to the office BP. One trial included treated patients.⁶⁸ The follow-up period ranged from two to eight years.

There are now 12 major prospective studies comparing the prediction of cardiovascular events using office or ambulatory BP, and the overwhelming consensus is that ambulatory pressure is a better predictor of risk than office BP.⁹⁹ Thus, when the ambulatory pressure is low in comparison to the office BP (WCH) the prognosis is benign. This body of data was what led to the decision by the CMS (The Centers for Medicare and Medicaid Services) to approve ABPM for reimbursement in patients with suspected WCH, on the grounds that they are a low-risk group who do not necessarily need antihypertensive drug treatment.

One study looked at patients with refractory hypertension, defined as a diastolic pressure above 100 mmHg while on three or more antihypertensive medications.¹⁰⁰ Patients were classified in three groups according to their daytime ambulatory pressure. Those in the lowest tertile (below 88 mmHg) had a significantly lower rate of morbidity over the next four years, despite similar office BPs. An important study in this series was Syst-Eur, a large placebo-controlled study of the effects on cardiovascular morbidity of treating systolic hypertension of the elderly with a calcium channel blocker.

A sub-study of 808 patients used ABPM, and found that ABP was a much more potent predictor of risk than office BP.⁶⁵ This study is the only one that has examined the effects of treating patients with WCH, because there was a placebo group as well as an active treatment group. There was a significant reduction of events in the active treatment group in patients with sustained hypertension, but not in the group with WCH.

Which component of the 24-hour BP gives the best prediction of risk?

Although there is consensus that ABP is the best predictor of risk, it is uncertain which component of the diurnal pattern of BP is most important. The leading candidates are shown in Figure 45-2. The most widely used has been the average 24-hour level. There has been great interest in the role of the diurnal rhythm of BP, and many studies have compared the predictive value of the daytime versus the nighttime pressure. Many have found no difference,^{67,96} although some recent studies have reported that the best prediction of risk comes from the nighttime BP.^{65,94,97,98} A related method of analysis is to look at the dipping patterns, and there have been claims that non-dippers are at higher risk than dippers.⁶³ In addition, patients with an excessive morning surge of BP may also be at increased risk.⁶⁶

Table 45-3. Prospective Studies Comparing Clinic and Ambulatory Blood Pressure for Predicting Clinical Events

Figure 45-2. A 24-hour BP recording in a hypertensive patient. Yellow lines show systolic and diastolic pressure, and the gray zones indicate normal ranges. Light blue = day; dark blue = night. Boxes show various components of blood pressure that could be related to risk of events.

One study, using continuous intra-arterial BP monitoring,¹⁰¹ found that BP variability was an independent predictor of increased LV mass seven years later, even after controlling for BP level. Another prospective study, using noninvasive monitoring, found that increased BP variability during the day did not predict cardiovascular events after controlling for factors known to be associated with increased variability (age, BP level, and diabetes).¹⁰² It is quite conceivable that there is no single answer to this question, and that different components of the BP have different effects on risk. Nevertheless, the issue is important because antihypertensive drugs have different effects on different components of the diurnal BP profile and thus there is the possibility of more targeted treatment.

HOME MONITORING

The potential utility of hypertensive patients having their BPs measured at home, either by using self-monitoring or by having a family member make the measurements, was first demonstrated in 1940 by Ayman and Goldshine.¹⁰³ They found that home BPs could be 30 or 40 mmHg lower than the physicians' readings, and that these differences might persist over a period of six months. Home monitoring has the theoretical advantage of being able to overcome the two main limitations of office readings: the small number of readings that can be taken and the white coat effect. It provides a simple and cost-effective means of obtaining large numbers of readings, which are at least representative of the natural environment in which patients spend a major part of their day. Home monitoring has four practical advantages: it is helpful for distinguishing sustained from WCH, it can assess the response to anti-hypertensive medication, it may improve patient compliance, and it may reduce costs.

Home monitoring is now performed almost exclusively with automated oscillometric monitors, which are easy to use, relatively inexpensive, and readily available in drug-stores and elsewhere. The latest generation of monitors

has incorporated memory and the ability to calculate average levels of BP. A typical monitor is shown in Figure 45-3.

The limitations of home monitoring also need to be specified. First, readings tend to be taken in a relatively relaxed setting and thus may not reflect the BP occurring during stress. Second, patients may misrepresent their readings. Third, some patients may become more anxious as a result of home monitoring.

Although the technique has been readily available for many years, it is taking a surprisingly long time to find its way into general clinical practice. There has been a recent explosion in the sale of devices for home monitoring, few of which have been properly validated. Physicians are also endorsing the more widespread use of home monitoring, and national guidelines (such as produced by the American Society of Hypertension⁴⁸) are beginning to appear. Patients are enthusiastic about home monitoring. In a survey of 855 treated hypertensive patients attending specialized clinics, 75% were using it regularly.¹⁰⁴

COMPARISON OF HOME AND CLINIC PRESSURES

The original observation of Ayman and Goldshine¹⁰³ that home BPs are usually much lower than office BPs has been confirmed in a number of studies,^{105,106} including the population surveys described previously (in which the vast majority of subjects were normotensive). In the Didima study of 562 normotensive subjects, home and office BPs were very similar (clinic SBP was 1 mm lower and DBP 1 mm higher).¹⁰ Home BP was higher on day 1 of monitoring than on subsequent days. These differences may be more marked in older subjects.¹⁰⁷ The correlations between the office and home BP readings in the population studies were quite close, ranging from 0.73/0.64 (for systolic and diastolic pressures, respectively) in the PAMELA study¹⁰⁸ to 0.84/0.77 in PURAS.¹⁰⁷

Figure 45-3. A typical digital home monitor.

In hypertensive subjects, the differences between office and home BPs are greater than in normotensive subjects, as shown in Figure 45-4. A notable exception to this was the HOT study, which included a sub-study of 926 treated hypertensives who had their BP evaluated by both office and home measurements using a semiautomatic device in both cases.¹⁰⁹ There were no differences between the two (the average levels of BP were 137/83 mmHg in the office and 137/83 at home). The probable explanation for this is that the readings were largely within the normal range, where differences are slight.

In patients with severe hypertension, office BPs may be 20/10 mmHg higher than home readings, and these clinic readings are also higher than readings taken in a hospital by a nurse.¹¹⁰ The Ohasama study found that the correlations between home and office BP were stronger in untreated ($r = 0.57$ and 0.54 for SBP and DBP) than treated hypertensive subjects ($r = 0.30$ and 0.38).¹¹

In some cases, home BPs may show a progressive decline with repeated measurement,¹¹¹ but this is by no means always seen.^{106,112} Kenny et al. measured BP by four different techniques on three occasions separated by intervals of two weeks in 19 patients with borderline hypertension.¹¹² The techniques included conventional office measurement, basal BP (measured after lying for 30 minutes in a quiet room), daytime ambulatory pressure, and self-recorded home BP. None of the four measures showed any consistent change over the three study days, although there was an insignificant downward trend in all of them. For all three days, the office BPs were consistently higher than any of the other measures, but there were no significant differences between any of the other three measures. The average difference between office and home BPs was 9/4 mmHg.

That the office/home difference is due to the setting rather than the technique of BP measurement can be demonstrated by having patients take readings both at home and in the office. In the office, it may be found that the patients' and the physicians' readings are very similar and in both cases higher than the home readings. In 30 treated hypertensives who were evaluated with both

Figure 45-4. Plot of the difference between home and office BP as a function of BP level. Data from 18 studies published since 1992.

office and home BP, clinic BPs were taken either by the physician or the patient using an electronic device and the BPs were the same.¹¹³

The discrepancy between home and office BPs raises the question of which is closer to the true pressure. As shown in Figure 45-5, the home BPs are closer to the 24-hour average than the office BPs.¹⁰⁶ Figure 45-5 also demonstrates the phenomenon seen in Figure 45-4; namely, that there is a progressively greater discrepancy between the clinic and the true pressure at higher levels of BP. Other studies have also found that the correlation between home and ambulatory pressure is closer than for either of them with clinic pressure.¹¹⁴

REPRODUCIBILITY OF HOME READINGS

Relatively little has been published on this issue, but it is important. In a study we performed some years ago comparing the reproducibility of home, clinic, and ambulatory readings (all measured twice separated by an interval of two weeks), we found that in hypertensive patients there was a significant decline of systolic pressure in the clinic over this period but the home and ambulatory pressures showed no significant change.⁴⁵ In normoten-

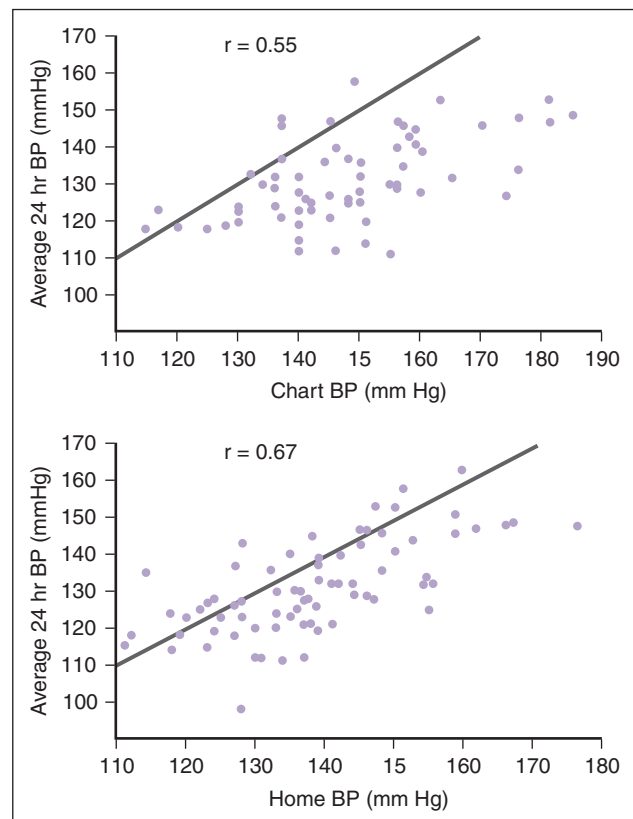

Figure 45-5. Top: chart (office) systolic BP versus average 24-hour BP. Bottom: home systolic pressure versus 24-hour average pressure. The lines are lines of identity. (Redrawn from Ayman P, Goldshine AD. Blood pressure determinations by patients with essential hypertension I: The difference between clinic and home readings before treatment. *Am J Med Sci* 1940;200:465-74.)

sive subjects, there was no consistent change in any of the three measures of BP.

In another study, Jyothinagaram et al. measured clinic and home BPs three times over a four-week interval in 17 hypertensive patients.¹¹⁵ The clinic pressure fell from 181/97 to 162/93 mmHg, whereas the home BP showed no change (153/89 to 154/89 mmHg). The superior reproducibility of home and ambulatory measurements may be partly explained by the greater number of readings. These findings support the notion that the fall of office BP on successive visits is primarily due to habituation to the office setting or to regression to the mean.

In a typical study comparing the short-term reproducibility of the three measures of BP, the SDD for the home readings was 5.6/4.6 mmHg, which was similar to the SDD for ambulatory readings (5.3/5.4) and lower than for office readings (9.7/6.7).⁴⁵ The correlation coefficients for all three sets of measurements were very close (0.96/0.94 for home systolic and diastolic pressures, 0.93/0.87 for ambulatory, and 0.94/0.87 for office readings). Another study of 133 hypertensive subjects found that home BP gave the lowest SDD for systolic and diastolic pressures (6.9/4.7 mmHg), compared with 8.3/5/6 for ABP and 11.0/6.6 for office BP.¹¹⁶ These studies thus show that the greater numbers of readings taken with home and ambulatory monitoring than with office measurement mean that the estimate of the true BP is much better.

The studies described previously investigated the reproducibility of home BPs over a period of weeks, and it might be expected that over longer periods of time the reproducibility would be lower. This is not necessarily the case, however. In the Ohasama study, 136 untreated subjects measured home BP for three days on two occasions one year apart.¹¹⁷ The correlations between the two were high ($r = 0.84$ and 0.83 for SBP and DBP), and there were no consistent change over the year. In contrast, the office BPs declined 4/3 mmHg over the same period, and were less closely correlated ($r = .69$ for SBP and 0.57 for DBP). Thus, home BP appears to be relatively stable.

HOME BLOOD PRESSURE IN NORMAL SUBJECTS

As with ambulatory pressure, there is no universally agreed on upper limit of normal home BP, but there are several studies that have compared home and office levels of BP, and others which have described average levels in normal populations. There have been seven large epidemiologic studies of home BP, which have attempted to define normal ranges. These were the Tecumseh study,¹¹⁸ the Dubendorf study,¹⁸ the Ohasama study,¹⁹ the Limbourg study,¹¹⁹ the Didima study,¹⁰ the PURAS study,¹⁰⁷ and PAMELA.^{120,121} All seven studies found that home BPs were higher in men than in women (as has been shown for ambulatory pressures), and five of six studies (the Tecumseh Study could not evaluate this) found that home BPs increased with age.

The distribution of BP in the population is in the form of a skewed Gaussian or bell-shaped curve, which tails off at the higher end. Any division into “normal” and “high”

BP is thus arbitrary, and this applies whichever measure of BP is used. In practice, the need for such a dividing line is that it can be used as a treatment threshold. One common technique used to define the upper limit of a variable such as BP that is continuously distributed in the population is to take the 95th percentile, which defines the upper 5% as being “abnormal.” A variation of this method is to use the mean plus 2 SD, which is very similar to the 95th percentile.

An obvious problem with this is that hypertension affects more than 5% of the population. Another is that hypertensive individuals are often excluded from population surveys. Thus, if in the population studies described previously the upper limit of normal home BP were defined as the 95th percentile the values would range from 137/86 to 152/99 mmHg, which are clearly too high. In a meta-analysis of 17 studies of home BPs in normotensive subjects, Thijs et al.¹²² used a number of techniques to define the upper limit of normal. One was to use the 95th percentile, which gave a level of 135/86 mmHg. The mean plus 2 SD gave 137/89 mmHg.

An alternative method of defining the upper limit of normal home BP is to estimate the home BP equivalent to an office BP of 140/90 mmHg, as has also been done for ambulatory pressure. In the Thijs meta-analysis, two techniques were used to derive the home BP equivalent to 140/90 mmHg.¹²² The first was to compute the linear regression between office and home readings, which gave a value for the home BP of 125/79 mmHg. The second was the percentile method, which calculated the percentile in the distribution of office BPs that corresponded to 140/90 mmHg, and used the same percentile for the distribution of the home BP. This gave a value of 129/84 mmHg. In the PAMELA study, the home BP equivalent to an office BP of 140/90 was 132/83 mmHg (calculated by the linear regression method).¹²³ The average values for home BP and the home BP estimated to be equivalent to 140/90 in the office for four of the studies are outlined in Table 45-4.

The ASH recommended that an appropriate level for the upper limit of normal home BP should be 135/85 mmHg.⁴⁸ This was based on the fact that home BPs tend to be somewhat lower than office BPs, and is in accord with the findings of several studies (as described previously). It is also consistent with the prospective findings of the Ohasama study, where home BPs above 138/83 mmHg were found to be associated with increased mortality.¹²⁴ The same value has been adopted by the JNC 7 recommendations¹ and by the American Heart Association.¹²⁵ As with office BP, a lower home BP goal is advisable for certain patients, including diabetics, pregnant women, and patients with renal failure. No specific limits have been set for these patients, however.

HOME BLOOD PRESSURES, TARGET ORGAN DAMAGE, AND PROGNOSIS

One of the factors that has limited the acceptance of home BP for clinical decision making has been the lack of prognostic data, but there are increasing numbers of

AVERAGE VALUES AND PROPOSED UPPER LIMITS OF NORMAL HOME BLOOD PRESSURE FROM POPULATION STUDIES					
Study	N	Average Values		Home BP Equivalent to 140/90 in Office	
		Clinic BP	Home BP	Percentile	Regression
PAMELA	1438	127/82	119/74	–	132/83
Didima	562	118/73	120/72	140/86	137/83
Dubendorf	503	130/82	123/77	133/86	–
PURAS	989	126/76	118/71	134/84	131/82

Table 45–4. Average Values and Proposed Upper Limits of Normal Home Blood Pressure from Population Studies

studies showing that self-measured BP predicts target organ damage and clinical outcomes better than traditional office BP. These are reviewed in material following.

Home blood pressure and target organ damage

In one of the first studies using home monitoring, it was reported that regression of LVH evaluated by the ECG correlated more closely with changes of home BP than with office BP following the initiation of antihypertensive treatment.¹²⁶ Several other studies have indicated that the correlation between echocardiographically determined LVH and BP is better for home than for office readings.^{106,127,128} However, in one study of 84 previously untreated hypertensive patients home BP and clinic BP gave similar correlations with LVH ($r = 0.31$ and 0.32), but not as good as the correlation between ABP and LVH ($r = 0.51$).¹² In a study of treated hypertensives, home BP correlated with LVH but office BP did not.¹²⁹

Home BP has also been related to other measures of target organ damage. It has been reported to correlate more closely than office BP with microalbuminuria^{128,130} and with carotid artery intima-media thickness.^{130,131}

Home blood pressure and prognosis

There are four studies that have compared the predictive value of office and home measurements, and all have shown that home measurements are potentially superior (see Table 45–4). In the first (conducted as a population survey in Ohasama, Japan), 1,789 people were evaluated with home, office, and 24-hour BP measurements.¹³² Over a five-year follow-up it was found that the home BP predicted risk better than the office readings. For each measure of BP, the subjects were divided into quintiles. The survival rate was significantly lower for people whose initial home BP was above 138 mmHg systolic and 83 mmHg diastolic pressure.¹³³

As also shown Figure 45–5, the consequences of a high clinic pressure were less clear. There was some suggestion from these data of a J-shaped curve, representing a paradoxical increase of mortality at low home BPs. The actual numbers were too small to be sure of this, however, and it was not observed for the screening BPs. A subsequent analysis over 10 years¹³⁴ found that the prediction of risk

became stronger with more home readings, up to a maximum of 25 measurements. There was no evidence of a threshold number. The second study (conducted in France) recruited 4,939 elderly hypertensives currently on treatment and found that morbid events observed over a 3.2-year follow-up period were predicted by the home BP at baseline but not by the clinic pressure.¹³⁵

One particularly interesting aspect of this study was that patients who had normal office BPs but high home BPs were at increased risk, a phenomenon known as masked hypertension (see material following). It is not known if the variability of home BP readings is an independent predictor of events, although there is some evidence that the variability of daytime readings measured with ABPM may be.¹³⁶ The third study was an Italian population-based study⁹⁴ of 2,051 subjects who had one set of three clinic BP readings and two home BP readings (one in the morning and one in the evening) and who were followed for 11 years. Adding the data from a second office visit on the following day did not improve the prediction of cardiovascular events, whereas adding the home readings did. In the fourth study, Fagard et al. measured BP in the office, at home, and by ABPM in 391 elderly patients registered in family practices and followed them for 10 years. Office BP did not predict cardiovascular events, whereas home BP did⁹⁸ (Table 45–5).

A not uncommon finding is isolated diastolic hypertension, in which the systolic pressure is normal and the diastolic pressure is raised. There has been some controversy as to its prognosis, but the only report using home monitoring (the Ohasama study) concluded that it is benign.¹³⁷ The threshold values for defining it were a home systolic pressure <138 mmHg and a diastolic pressure >85 mmHg. In contrast, patients with isolated systolic hypertension were at increased risk.

There is also some evidence that self-monitored BP may predict the change of BP over time, as well as the decline of renal function in diabetics. In the Tecumseh study of 735 healthy young adults (mean age 32), home BP predicted future BP over three years better than clinic BP.¹³⁸ A prospective study of 77 hypertensive diabetic patients whose clinical course was followed over a six-year period using both clinic and home monitoring found that home BP predicted the loss of renal function (decrease of GFR) better than the office BP.¹³⁹

PROSPECTIVE STUDIES COMPARING OFFICE AND HOME BLOOD PRESSURE FOR PREDICTING CLINICAL EVENTS				
Author	Year (ref)	Population	N	Results

Fagard	2005	Population	391	HBP better than OBP

Table 45–5. Prospective Studies Comparing Office and Home Blood Pressure for Predicting Clinical Events

CLINICAL APPLICATIONS OF OUT-OF-OFFICE MONITORING

In clinical practice, a patient's BP is typically characterized by a single value of the systolic and diastolic pressures, to denote the average level. Such readings are normally taken in an office setting, but there is extensive evidence that in hypertensive patients office BPs are consistently higher than the average 24-hour pressures recorded with ambulatory monitors.¹⁴⁰ This overestimation by office readings of the true pressure at high levels of pressure and underestimation at low levels has been referred to as the regression dilution bias, which refers to the fact that the slope of the line relating BP and cardiovascular morbidity should be steeper for the true BP than for the office BP.¹⁴¹

Thus, hypertension can be regarded as a disturbance of the set point or tonic level of BP with normal short-term regulation. Antihypertensive treatment reverses these changes, again by resetting the set point toward normal, with little effect on short-term variability. The normal diurnal rhythm of BP is disturbed in some hypertensive individuals, with loss of the normal nocturnal fall of pressure. This has been observed in a variety of conditions, including malignant hypertension, chronic renal failure, several types of secondary hypertension, preeclampsia, and conditions associated with autonomic neuropathy.¹⁴¹

For the foreseeable future, measurement of office BP by conventional sphygmomanometry will continue to be the principal method of clinical evaluation. A cardinal rule is that the closer the BP is to the threshold level at which treatment will be started the more readings should be taken over more visits before the decision is made. In patients who have persistently elevated office BP and evidence of BP-related target organ damage, it is usually unnecessary to supplement the office readings with other types of measurement before reaching a therapeutic decision.

When an elevated BP is the only detectable abnormality, however, the possibility that the office BP may overestimate the true pressure should be considered. This can be done either by home or ambulatory monitoring. A schema for the use of the different procedures for measuring BP when evaluating a newly diagnosed hypertensive patient is shown in Figure 45–6. If home monitoring is chosen and reveals pressures comparable to the office value, treatment may be appropriate. However, if the home readings are much lower than the office read-

ings it does not rule out the possibility that the BP may be elevated at work. This is the advantage of ambulatory monitoring, which gives the best estimate of the full range of BP experienced during everyday life.

CLASSIFICATION OF HYPERTENSION USING OUT-OF-OFFICE MONITORING

With the combined use of BP measurement in and out of the office, BP status can be classified differently from the traditional unidimensional method based solely on office BPs. As shown in Figure 45–7, the cutoff points for clinic and daytime ambulatory BPs are different: 140/90 mmHg for the former and 135/85 for the latter. There are four cells: true normotension (normotensive by both criteria), true hypertension (hypertensive by both), WCH (hypertensive by office criteria, normotensive by ambulatory), and masked hypertension (normotensive in the office and hypertensive during ambulatory monitoring). As also shown in the figure, current evidence indicates that the degree of cardiovascular risk goes with the ambulatory rather than the office BP.

There are several clinical situations in which out-of-office monitoring may help to establish the diagnosis of hypertension, as outlined in Table 45–6. These include suspected WCH, masked hypertension, or nocturnal hypertension (none of which can be diagnosed by exclusive reliance on office measurement), and others (labile

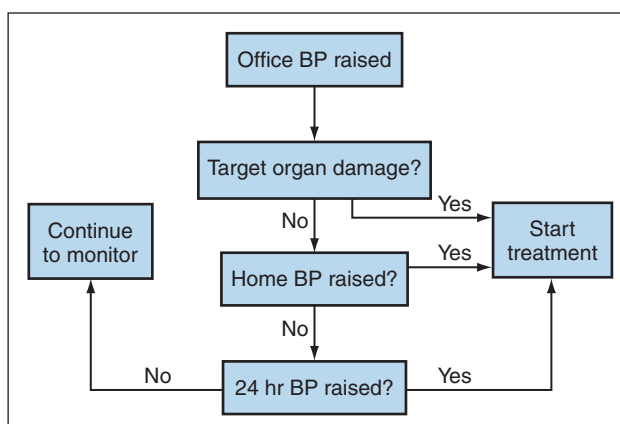

Figure 45–6. Schema for the evaluation of hypertensive patients using office and out-of-office measurement.

Figure 45-7. Classification of BP status according to office and out-of-office measurements.

CLINICAL SITUATIONS IN WHICH OUT-OF-OFFICE MEASUREMENT IS HELPFUL		
Clinical Situation	Home BP	ABP
White coat hypertension	+	++
Masked hypertension	+	++
Nocturnal hypertension	–	++
Labile blood pressure	+	+
Resistant hypertension	+	+
Autonomic insufficiency	+	++
Hypertension of pregnancy	++	+

Table 45-6. Clinical Situations in Which Out-of-Office Measurement Is Helpful

BP, resistant hypertension, autonomic insufficiency, and hypertension of pregnancy) in which out-of-office measurement greatly adds to the precision of the diagnosis.

White coat hypertension

This is the only indication that has been approved for reimbursement by the CMS in the United States. Suspected WCH is defined as a clinic BP above 140/90 mmHg on at least three occasions, with at least two sets of measurements below 140/90 mmHg out of the office plus an absence of target organ damage. The reason this diagnosis is important is that it is generally accepted that WCH is a relatively low-risk condition and that antihypertensive drug treatment is likely to be of no benefit.

There are two reasons for thinking this. First, several studies have shown that drug treatment of WCH reduces the clinic BP but has negligible effect on the ambulatory pressure, which by definition is normal to begin with.¹⁴² Second, the only study to investigate the effects of treating WCH on morbid events found no significant benefit.¹⁴³ It is possible that some patients with WCH may go on to develop sustained hypertension¹⁴⁴ or masked

hypertension,¹⁴⁵ and there may be an increase in the risk of stroke after six years.¹⁴⁶ Therefore, long-term follow-up with repeated ABPM or home monitoring is essential.

WCH is defined as a persistently elevated clinic pressure (above 140/90 mmHg together with a normal daytime ambulatory pressure of 135/85 or less). It is important to emphasize that it requires several office visits to establish the diagnosis, because there may be a spontaneous decline of office BP with multiple visits. WCH is not a discrete entity because most hypertensive patients show a white coat effect. What distinguishes patients with WCH from those with true or sustained hypertension is not that they have an exaggerated white coat effect but that their BP is within the normal range when they are outside the office setting. Patients with WCH do not necessarily look anxious or have a tachycardia while in the office. Thus, it can only be diagnosed reliably by ambulatory monitoring. If patients with WCH are treated with antihypertensive drugs, there is typically a decline of office BP but little or no change of ambulatory pressure, which by definition is normal to start with.

The phenomenon of WCH (elevated office BP and normal out-of-office BP) is also observed in patients who are on antihypertensive treatment. In a survey of 3,303 treated Japanese patients, its prevalence was 19%.¹⁴⁷

Masked hypertension

In the past few years there has been growing interest in the phenomenon of masked hypertension, defined as a normal office BP and high ambulatory BP (the obverse of WCH). The important point is that these are patients in whom the office BP underestimates the risk of cardiovascular events. A study of treated hypertensive patients¹⁴⁸ found that about a third of treated patients seen in a hypertension clinic had masked hypertension, and over a five-year follow-up their relative risk for cardiovascular events was 2.28 when compared with patients controlled by both office BP and ABP criteria.

Other studies have shown that masked hypertension in untreated and often undiagnosed patients is associated with an increase of target organ damage¹⁴⁹ and an adverse prognosis.⁶⁷ As with WCH, the condition may be suspected on the basis of high home BPs. One study has shown that masked hypertension diagnosed solely by home recordings is associated with increased mortality.¹³⁵ Not surprisingly, patients diagnosed with masked hypertension do not show complete concordance with those diagnosed using ABPM.¹⁵⁰

The prevalence of masked hypertension may be as much as 10% in the general population, based on data from population studies in several countries.^{67,151–153} As with WCH, masked hypertension is seen in treated hypertensive patients, and in one study its prevalence was 19%.¹⁴⁷

Nocturnal hypertension

As described previously, BP may remain high or even increase during the night. At the present time there are no clear clinical indications for assessing this, but there are

several conditions in which it is common, and in which its recognition might alter treatment regimens. These include diabetes, chronic kidney disease, and sleep apnea. There are also some studies (see previous material) that suggest that the nocturnal BP may give the best prediction of risk, but this is still controversial. Nevertheless, it has been clearly established that antihypertensive treatment can selectively lower nocturnal BP.

Labile hypertension

This title is something of a misnomer because all hypertension is labile. However, there are some patients who give a history of paroxysmal hypertension in whom ABPM may prove helpful. Pheochromocytoma may be suspected in some of these patients, but the hypertension in this condition is not always particularly labile.¹⁵⁴ A much more common cause of labile hypertension is panic attacks, which have been shown to be accompanied by surges of both BP and heart rate¹⁵⁵ and which may be detected by out-of-office monitoring. There are at present no norms for deciding if BP variability over 24 hours is greater than normal.

Resistant hypertension

In some patients whose clinic BP remains high despite being on three or more antihypertensive drugs, an exaggerated white coat effect may be suspected. Two prospective studies have shown that there is a subgroup of patients who have resistant hypertension by office BP criteria but whose ambulatory BP is normal and whose prognosis is benign.^{100,148} However, it is probable that the two categories of resistant hypertension could be separated by home monitoring.

Autonomic insufficiency

This is a not uncommon finding in elderly patients who complain of dizziness when standing for long periods of time, and who may also have syncopal episodes. When they are supine, the BP may be quite high, particularly during the night.¹⁵⁶ Thus, their BP is unusually labile, depending on their body position. Treatment with pressor drugs and antigravity stockings is always a compromise between letting the BP go too low and making it go too high, and therefore ABPM is essential for evaluating the optimal BP control in these patients.

Hypertension of pregnancy

Hypertension of pregnancy is still one of the leading causes of maternal death, and is potentially preventable.¹⁵⁷ Close monitoring of BP is therefore essential. WCH is a significant problem, and can lead to unnecessary early terminations of pregnancy. There have been several attempts to detect preeclampsia in its early stages using ambulatory monitoring, and it was suggested that a loss of dipping might be an early sign. However, this has not been well substantiated. Home monitoring has more potential because it is well suited to detecting trends over time.¹⁵⁸ However, it has not been used very widely.¹⁵⁹

EVALUATION OF THE BLOOD PRESSURE RESPONSE TO ANTIHYPERTENSIVE TREATMENT

Although still the gold standard for clinical practice and trials, the traditional method of evaluating the effects of antihypertensive treatment by the changes of office BP suffers from several major defects, which have become more apparent with the introduction of out-of-office monitoring. First is the well-known fact that the small number of readings that can be taken at a clinic visit may not be representative because of the inherent variability of BP. Second, readings are only taken at one time of day, and the effects of antihypertensive drugs are often not the same over 24 hours. In clinical trials, BP is typically measured at trough (just before the next dose is due), but this is rarely achieved in clinical practice. Third, there are variable changes in the white coat effect and thus the changes in office BP do not parallel the changes in the out-of-office BP. In principle, both methods of out-of-office monitoring can avoid these pitfalls.

ABPM is not commonly used in routine clinical practice for this purpose, mainly because of the cost and inconvenience of performing multiple ABP recordings. However, changes in ABP correlate more closely than changes of office BP with regression of LVH during antihypertensive treatment.¹⁶⁰ Home BP monitoring is more practical. On the grounds that hypertension is usually characterized by a sustained increase of BP throughout the day and night, it seems reasonable to propose that the goal of antihypertensive drug treatment should be to lower the BP to the same extent during the day and night. Whether treatment should be directed to convert hypertensive non-dippers to normotensive dippers with treatment is unresolved, but certainly feasible.

Diuretics normalize the non-dipper pattern by lowering the nocturnal more than the daytime pressure.¹⁶¹ In an analysis of the effects of doxazosin on dipping status, we found that non-dippers were likely to become dippers following treatment. The best explanation for this was that the effects of the drug on BP were proportional to the pretreatment level, such that the nighttime pressure is lowered more in non-dippers than dippers.⁶ Similarly, studies with calcium channel blockers have found that the drugs lower daytime BP in both dippers and non-dippers, but nighttime BP more in non-dippers.¹⁶²

The timing of antihypertensive drug dosing may also be a factor. In patients with renal disease who were predominantly non-dippers, evening dosing of a calcium channel blocker (isradipine) lowered the nighttime pressure more than morning dosing.¹⁶³ However, it must be admitted that at the present time there is no evidence that selectively lowering the nighttime BP has any impact on clinical outcome.

Performing multiple ABP recordings to evaluate the effects of antihypertensive treatment may not be practical, but home monitoring is ideally suited to this task because it is easy to obtain serial measurements over long periods of time. Despite the general parallelism between office and home BPs during treatment, there may be considerable discrepancy between the two in indi-

vidual patients. Other studies have shown that drug treatment lowers clinic BP more than home BP. In a study of 760 hypertensives treated with diltiazem 300 mg, the clinic BP fell by 20/13 mmHg and the home BP by 11/8 mmHg.¹⁶⁴

In another study,¹⁶⁵ losartan lowered office BP by 17/13 mmHg and home BP by 7/5. Trandolapril lowered office BP by 17/13 and home BP by 7/5. Changes of ABP were closer to the changes of home BP. It is well recognized that drug treatment also lowers ambulatory BP less than office BP.¹⁶⁶ One study has looked at the effects of exercise training on office and home BP. Office BP fell by 13/8 in the experimental group and 6/1 mmHg in the controls, whereas home BPs fell by 6/3 and 1/-1, respectively.¹⁶⁷

SELF-MONITORING FOR IMPROVING ADHERENCE TO ANTIHYPERTENSIVE TREATMENT

There is considerable interest in the use of home monitoring for improving BP control. The rationale is that patients who monitor their BP regularly are more likely to take their medications. A recent review of the effects of HBPM on adherence found 11 randomized trials, most of which used some additional interventions other than simple monitoring (such as counseling by nurses) to improve adherence.¹⁶⁸ The conclusion was that there was a modest improvement. There has also been a review of the effects of HBPM on BP control,¹⁶⁹ which found 18 randomized controlled trials and concluded that there was a 4/2 mmHg lower BP in the groups randomized to home monitoring as opposed to usual care.

ECONOMIC ISSUES AND REIMBURSEMENT

ABPM is not widely used at the present time in clinical practice, mainly because it is often not reimbursed by insurance companies. Medicare pays between \$56 and \$122 in different regions, but only for suspected WCH (defined as a high clinic BP, an absence of target organ damage, and evidence of normal BP outside the clinic). On the grounds that WCH does not warrant antihypertensive drug treatment, but that patients diagnosed with it undergo annual ABPM, it has been estimated that if all newly diagnosed hypertensive patients underwent ABPM

there would be a net saving of costs of managing hypertension if the average cost of drug treatment were \$300 or higher.¹⁷⁰

USE OF OUT-OF-OFFICE MONITORING IN CLINICAL TRIALS

ABPM is widely used for clinical trials of antihypertensive drugs, and to lesser extent for non-drug forms of treatment. The reduction of BP is almost always smaller for ABPM than for clinic BP.¹⁶⁶ The potential advantages of ABPM for evaluating treatment effects in clinical trials include the evaluation of duration of action, analysis of the effects on nighttime BP, absence of a placebo effect, smaller sample size, and better correlation with clinical outcomes.¹⁷¹ One of the goals of major outcome trials that have compared the effects of different drugs on cardiovascular morbidity has been to determine if there are effects on cardiovascular events that are independent of the drugs' effects on BP. Unfortunately, ABPM has often not been included. However, in one instance of it being included (the HOPE trial¹⁷²) the BP changes recorded by ABPM were very different from the changes reported by office measurement.¹⁷³

SUMMARY AND PERSPECTIVES

At the present time, ABPM is used only in the minority of patients but its use is gradually increasing. The monitors are reliable, reasonably convenient to wear, and generally accurate. ABPM can be regarded as the gold standard for BP measurement on the basis of prognostic studies showing that it predicts clinical outcome better than conventional measurements. Thus, a good case can be made for using it in all newly diagnosed hypertensive patients.

The procedure is relatively expensive in comparison with other methods of measuring BP, and many of the studies documenting its value were done without home monitoring. In contrast to ABPM, home monitoring has seen a dramatic growth in its clinical use over the past few years, and it remains to be seen to what extent it will be able to replace ABPM. It is likely that in the near future there will be a further decline in reliance on clinic BP measurements and an increased emphasis on out-of-office monitoring for the diagnosis and treatment of hypertensive patients.

Chapter
46

Cardiologic Investigation of the Hypertensive Patient

Robert J. MacFadyen

Key Findings

- Cardiologic investigation in hypertension supplements blood pressure definition and management but does not supplant it.
- The sensitivity and specificity of many standard cardiologic investigations are fundamentally altered in hypertension.
- Although hypertension overlaps profoundly with coronary disease, not all patients with cardiac symptoms have coronary disease.
- Definitive assessment of cardiac status is critical in the definition and management of the risk of future occlusive vascular events in individual hypertensive patients and relies heavily on an integrated approach to cardiac test strategies.

The cardiologic investigation of a patient with hypertension is an important clinical topic with many relevant clinical lessons and a large amount of research to be considered, but this tends to get confused with the definition of a “new” disease (for example, coronary artery disease or valvular heart disease). This can lead to a misplaced focus on these linked pathologies at the expense of continuing emphasis on the definition and management of hypertension. Losing track of the importance of hypertension care while embarking on relevant cardiac investigation is a critical mistake that can nullify any benefits in subsequent cardiac management—whether by percutaneous interventional treatments or cardiac surgery.

Epidemiologic study reveals many independent statistical associations between hypertension and the evolution of a range of cardiac disease processes. Although it has been widely demonstrated that treating blood pressure alone can reduce the relative risk of future cardiac events,¹ it is essential that the many well-described aspects of cardiac structural and functional investigation are applied correctly in clinical practice. There is the necessity for individual physicians to appreciate the changes in sensitivity and specificity of cardiologic testing procedures that are applicable to the hypertensive patient. Indeed, it is important to apply appropriate testing patterns adjusted to the hypertensive patient wisely and without the need to apply every known test to every patient nor to over- or underinterpret the results obtained during these work-ups.

Myocardial ischemia

The relationship between coronary disease and hypertension is a complex one. The pathology of atherosclerosis and vascular degeneration is accelerated in the process of symptomatic and asymptomatic coronary artery disease, providing the link to both fatal and nonfatal coronary occlusive events. The definition of symptomatic coronary disease is confounded by the recognition of hypertension, which may have been present in the asymptomatic patient for some years. Thus, the diagnosis (or rather, recognition) of hypertension has a confounding association with the onset of symptomatic coronary artery disease. In a proportion of cases, death from a fatal first coronary occlusion can occur before hypertension is diagnosed or recognized as a primary factor in the development of coronary atherosclerosis in the index case. This is not a new association,² and the temporal sequence of these critical events has long been a source of concern.³ Alternatively, the onset of ischemic symptoms in patients with hypertension is generally associated with fairly prompt testing to try to define the presence of myocardial ischemia and/or to exclude coronary disease.

Valvular function

It is generally appreciated that there are associations between hypertension and degenerative valvular heart disease. Specifically, these relate to left heart valve function and the aortic valve in particular. As with coronary artery atheroma, the coming together of degenerative changes in valve structure along with changes in vascular compliance and structure create increased pressure after load in the arterial system (a well-accepted detrimental phenomenon associated both with valvular stenosis and regurgitation in the aortic position). Valvular function in the mitral position can equally be affected by secondary myocardial remodeling of the left ventricle, which is common and may be severe in some hypertensive patients (see material following).

Restrictive myocardial changes and ventricular hypertrophy

Restrictive cardiac-filling abnormalities (primarily due to the myocardial hypertrophy associated with hypertension) are features that are often confused and that are to an increasing extent seen to overlap with hypertrophic myogenic or infiltrative cardiac disease. The range of hypertrophic cardiomyopathies in particular can be difficult to differentiate from hypertensive disease (e.g., clinically with restrictive changes in the pericardium). Definition of the

myocardial geometry and the contractile and relaxing functions of the heart in hypertension is therefore essential. The linkage of these myogenic responses to the appearance of exercise limitation is important.

Ventricular function assessment

Net systolic contractility of the left ventricle is of great prognostic value and powerfully defines cardiac event rates in hypertensive patients. The evolution of hypertensive heart disease from the state of hypertrophic changes (with generally well-preserved systolic contractility) is a complex process (see other chapters), with progressive change through to a phase of ventricular dilatation and systolic impairment. These patients tend to have unrecognized, untreated, or persistently uncontrolled hypertension, and the progression to systolic impairment of the heart is not often recognized short of acute presentation of pulmonary edema. The widely cited but poorly analyzed association of arterial hypertension to systolic left ventricular impairment suggests the presence of such a progressive change regardless of the definition or recognition of intervening coronary occlusion and ventricular infarction.

Rhythm assessment

The primary changes in cardiac structure in hypertensive heart disease are also associated with changes in cardiac conduction and instability of cardiac rhythm. Similar to the situation with systolic ventricular impairment, these changes can occur with or without the impact of intervening intermittent cardiac ischemia or prior myocardial infarction. Much of the rhythm instability of hypertensive heart disease is asymptomatic until late in the disease, where there are major myocardial changes linked to hypertensive left ventricular hypertrophy and or ventricular infarction. Both resting conduction and ambulatory cardiac rhythm need to be considered.

SYMPTOMATIC STATE: SYMPTOMS IN HYPERTENSION

The investigation of the heart in hypertensive patients starts either at the detection of asymptomatic hypertension at chance screening or upon the presentation of linked or unlinked cardiac or general symptoms. The presence of symptomatic complaints among patients with hypertension is commonly the subject of population investigation. These do not often indicate a causal link, and separating these on the basis of clinical presentation alone can often be problematic.⁴ In the interpretation of cardiac symptoms in hypertensive patients, similar problems apply.

A good example is the association between hypertension and headache. Although the association may be more direct in the case of patients with severe uncontrolled or untreated hypertension, most studies have conclusively shown that mild hypertension and headache are *not* causally associated. In a large sample of 1763 hypertensive patients, for example, intermittent headache was present in 903 subjects (51.3% of entire sample), and from these 378 of the patients (21.4%) were classified as having moderate to severe hypertension (stage III of the JNC-VI

classification system). However, the diagnosis of moderate to severe hypertension was clearly not independently associated with headache (OR 1.02, 95% CI from 0.79 to 1.30) and arterial pulse pressure and headache were in fact *inversely* associated (OR 0.91, 95% CI from 0.86 to 0.97, for 10 mmHg).⁵

Many studies are directed at the impact of concomitant drug therapy on the symptomatic state of hypertensive patients. In this regard, the quality of life of untreated patients with hypertension is complex (dealt with elsewhere in this textbook). However, some symptoms due to treatment are of the orthostatic variety (dizziness, postural light-headedness, presyncope). Syncope is relatively rare, but among those with a documented episode of true syncope hypertension is a common co-morbidity, occurring in about 25% of patients.⁶ There are simple biological links among syncope, hypertensive vascular disease, and cardiac function. For example, syncope is common among elderly hypertensive patients with preexisting or co-existent sinus node disease⁷ and/or carotid sinus disease.⁸ Furthermore, orthostatic symptoms are likely to be more common where patients have a white coat response yet normal ambulatory blood pressure (BP) and receive inappropriate hypotensive drug treatment. In addition, patients with neurodegenerative diseases affecting the dentato-rubro-spinthalamic pathways (which produce a spectrum of disorders from primary autonomic failure through to more mixed effects characterized by supine hypertension and orthostatic hypotension) are often grouped as neurocardiogenic syncope. The individual composition and origin of BP effects in these often elderly patients can be complex and require detailed assessment to define autonomic, arterial vasodilator, and/or cardiogenic (largely a vagal dromotropic response) elements.⁹

The link between chest pain symptoms and hypertension is probably the most important one for the average hypertensive patient and the responsible clinician. There is clearly a worsening outcome in terms of emergent cardiac events in patients with undiagnosed chest pain who have hypertension, and this is explained by the greater prevalence of coronary disease and underlying myocardial ischemia. There is a clear-cut profile of elevated risk of an acute cardiac event associated with an acute symptom onset¹⁰ as opposed to patterns of undifferentiated chronic symptoms. In this regard, symptomatic presentation *alone* (regardless of its detailed characteristics) is a parameter neither sensitive nor specific enough to define the emergence of coronary disease in the hypertensive patient. For example, the electrocardiograph can contain many valuable observations but is at the same time inherently a very limited test strategy in the hypertensive patient.

THE INVESTIGATION OF THE HEART IN HYPERTENSIVE PATIENTS

The surface electrocardiograph (ECG/EKG) has been a fundamental part of basic cardiac assessment for over a century. Its utility comes from the ease of documentation and technical simplicity. Its value is amplified by repeated recordings made in a consistent fashion, and in particular where performed during a symptomatic episode (whether

of pain, palpitation, or breathlessness). In hypertensive patients (as in other patient groups) its primary drawback (used at rest, continuously, or during exercise stress) is its demonstrably low sensitivity (failing to identify cardiac disease where this is present) and low specificity (suggesting cardiac disease when in fact none is present) to define even simple and common cardiac processes such as regional myocardial ischemia or global or regional ventricular hypertrophy. As the key aspects in the diagnostic management of hypertension are to assess reversible ischemia, evolving infarction, or patterns of cardiac hypertrophy, the ECG is clearly limited.

Rest ECG

The utility of the baseline electrocardiogram (ECG) has been defined in large population surveys. The prevalence of *any* electrocardiographic abnormality (regardless of significance) is increased in patients with hypertension compared to normotensive controls.

For example, in 1190 hypertensive patients from the WHO Community control program for Hypertension in Italy,¹¹ the overall prevalence of any 12-lead electrocardiographic abnormalities (i.e., all Minnesota codes) was 40.8%, with a slightly higher prevalence in males than in females (at 42.4 versus 39.4%). Electrocardiographic LVH (ECG-LVH; see material following) was more frequent in males (21.2%) than in females (14.5%), but not for ECG changes indicative of ischaemia (4:1 to 4:3 or 5:1 to 5:3). The prevalence of ECG abnormalities increased with age, with the exception of ECG-LVH. Predictably, younger males in the age class 20 to 29 years showed these more often (11.1 to 17.5% of the subjects, where these findings will often represent a false positive finding) than the oldest age group (60 to 64 years) where the prevalence of ECG-LVH ranged from 12.4–15.2%.

The prevalence of electrocardiographic abnormalities is in part due to the high rate of nonspecific false positive results (such as T wave changes or conduction defects) interpreted as evidence of ischemia, infarction, or hypertrophy without supporting evidence from more definitive studies (see material following).

P-wave changes in hypertension

P-wave morphology can in part clearly reflect atrial dimensions and structure.¹² It can therefore readily be seen as a reasonable point of interest on the surface ECG in hypertension—whether in sustained sinus rhythm or recorded in the phase before persistent atrial fibrillation is established in susceptible hypertensive patients. Studies in hypertension in general show a complex link between P-wave morphology on the rest ECG and cardiac structure. In several surveys of hypertensive patients, the most frequent rest ECG abnormality is an abnormal P-wave (duration or voltage; 23%). This compares with the much lesser prevalence of abnormal repolarization (10%), increased limb lead or chest lead QRS voltage (5.4%), and patterns of abnormal intraventricular conduction (10%).¹³ In general, there is no simple correlation between abnormal P-wave and other ECG abnormalities, although patients with an abnormal P-wave are often shown to have higher systolic

blood pressure (SBP) and heart rate. The electrocardiographic findings are in general unresponsive to BP treatment, although this may simply be due to lack of sensitivity rather than to underlying structural change.

Genovesiebert et al.¹⁴ explored the link between abnormal P-waves and structure in 53 untreated hypertensive patients. Although abnormal P-wave conformation was predictably common in their sample, they could not relate simple P-wave morphology (duration and voltage) to left atrial size or estimated LA volume as measured by echocardiography. However, they did show some relationship between abnormal P-wave morphology and trans-mitral Doppler indices of LV filling (see material following).¹⁴ Thus, in patients with hypertension they suggest that simple P-wave changes indicative of LA abnormality were perhaps more likely to be indicative of increased left atrial work and mechanics, possibly secondary to an impaired ventricular filling rather than due to more simple left atrial enlargement.

To further address this lack of sensitivity of the P-wave in hypertension, some investigators have turned to the use of signal-averaging technology. This is similar in principle to the technology employed for many years in the assessment of ventricular conduction, defining the presence of after-potentials on repeatedly averaged and combined high-sensitivity ECG recordings and linking this to susceptibility to ventricular arrhythmia. In this setting studying a P-wave signal, averaged ECG (P-SAECG) has been analyzed in patients with hypertension. In 234 normotensive, 84 white hypertensive, and 34 black hypertensive patients undergoing P-SAECG analysis, Madu and colleagues¹⁵ found that mean filtered P-wave duration and total P-wave time-voltage area for normotensives of either ethnic group were similar. However, hypertensive black patients had greater increase in P-wave duration (138 ± 16 versus 132 ± 12 ms; $p < 0.01$) and total P-wave time-voltage area (922 ± 285 versus 764 ± 198 $\mu\text{V}\cdot\text{ms}$; $p < 0.001$) than white hypertensive patients. In addition, the P-wave duration and total P-wave voltage integral increased with severity of hypertension.

Thus, the early stages of hypertension are associated with prolonged atrial conduction as defined using a resting P-SAECG and this index may better reflect the electrical remodeling of the atria. The changes seen in African American black hypertensive patients seem to be greater than those in white patients with hypertension and may link in with the greater cardiac structural changes seen in hypertension in black patients (see material following).

The role of the PR interval as an index of general autonomic tone reflecting atrial electrical conduction velocity has been confirmed in hypertensive patients.¹⁶ However, the role of this simple measure in predicting (for example) the degeneration of sinus rhythm to either atrial fibrillation or atrioventricular block (both common features of electrophysiologic change in hypertension) has not yet been tested prospectively.

QT intervals and QT dispersion

Heart-rate-corrected QT interval is another important and well-studied general ECG marker of ventricular repolarization. It is generally susceptible to the prevailing level of autonomic tone, which is also the case in hypertensive

patients. Prior to treatment, prolonged heart-rate-corrected QT interval is associated with higher risk of mortality in patients with coronary heart disease (CHD) and in the general population. Although unaffected by age, there is possibly a confounding effect of female gender¹⁷ on the prognostic value of QT interval—and as with many ECG measures there is also some variance among patients of African descent (e.g., African American or Afro Caribbean).¹⁸ Xiao and colleagues in a detailed, if small, cohort of hypertensive patients with pathologic ventricular hypertrophy (14/42 being due to the effects of hypertension, whereas the others had aortic valve disease or hypertrophic cardiomyopathy) suggested that QRS duration had a bimodal distribution and correlated with measured left ventricular mass only if the QRS duration was less than 135 msec.¹⁹ In this study, the association of QRS duration and left ventricular mass was lost above a QTd figure of 135 msec, and perhaps predictably at these greater values correlated more with the onset of a proximal left bundle branch block and associated uncoordinated LV activation/contraction.

The presence of electrocardiographic intraventricular conduction delay and broad QRS duration are well documented in patients with hypertension. Although these are often automatically associated with the presence of epicardial coronary artery disease and prior infarction equally, they have been shown to have a strong association with hypertension *in the absence of CAD*²⁰ and more often reflect the impact of ventricular hypertrophy on intraventricular conduction.²¹ Thus, the interpretation of these findings becomes more complex in separating structural change (hypertrophy) from functional changes (ischemia/infarction or intrinsic conduction disease), both of which obviously coexist in the hypertensive population (making conclusions from the individual ECG tracing of reduced value in the hypertensive population).

QT prolongation in the form of an analysis of the spatial dispersion of the QT interval (QT dispersion, corrected QT dispersion, or QT dispersion index) across the heart (most commonly a simple subtraction of maximal and minimal measured QT interval in msec across standard chest ECG leads) is a marker of adverse cardiac risk in hypertension,^{22,23} in systolic heart failure,²⁴ in coronary artery disease, and even in the asymptomatic well general population.^{25,26} The changes in QT dispersion again appear to track with changes in ventricular hypertrophy in hypertension (being elevated in untreated hypertrophy and at least in part reversed by management of ventricular hypertrophy), in the pressure overload of aortic stenosis, and in endurance athletes with exercise-related ventricular hypertrophy (the latter group being regarded as physiologic).²⁷ However, QT dispersion indices appear to be no better than simple voltage criteria at detecting left ventricular hypertrophy in the hypertensive patient.²⁸

The relationship of variability in QT dispersion, as with RR interval, may be linked in part to autonomic tone in hypertension and in cases of pathological hypertrophic cardiomyopathy.²⁹ A recent small pilot study³⁰ has suggested that a minor adjustment to record QT interval to the peak T-wave voltage—rather than the asymptote of the T-wave

and the isoelectric line (a strategy previously well defined in the clinical pharmacology of antiarrhythmic drugs nearly 30 years previously)—should improve the sensitivity of QT interval measures to predict LVH calculations. Similarly, the use of time voltage area measures for the QRS complex in hypertension, particularly that derived from all 12 leads, might equally produce better sensitivity for the definition of LVH from the simple ECG.³¹

Ventricular hypertrophy definition using electrocardiography in hypertension

The electrocardiographic definition of ventricular hypertrophy has been well established for many decades and has been examined closely in population studies due to its ease of use, albeit with many and variable definitions.³² Unfortunately, the patterns seen in hypertensive patients in the absence of other confounding disease are neither easily nor reliably distinguished from patients with coronary artery disease on the basis of the ECG appearance alone. This can be readily appreciated from studies completed in patients with normal coronary angiographic imaging yet marked LVH and strain patterns on the rest ECG.³³ Notwithstanding this difficulty in interpretation, there is no doubt about its linkage of electrocardiographic LVH to future vascular events in hypertensive patients.³⁴

Electrocardiographic LVH as defined by the most widely used criteria (e.g., Sokolow Lyon = $SV1 + RV5$ or $RV6 > \text{or} = 35$ mm) have been reliably and independently related to untreated clinically measured BP levels, male gender, and Afro Caribbean racial origin and *inversely* associated with body mass index.³⁵ This latter relationship to generalized obesity, reducing the sensitivity of ECG detection of LVH in hypertension, is commonly ignored yet paradoxically becoming increasingly relevant to Westernized populations in which with each year there is evidence of a dramatically increased prevalence of obesity. Put simply, the ECG voltage is damped markedly by subcutaneous fat in the same way that this relationship is used to define body fat mass by bioimpedance frequency measures.

It is accepted that echocardiography and the rest ECG give different information with respect to the presence or absence of LVH. Their diagnostic reliability (sensitivity and specificity) is fundamentally different whether they are positive or negative. It is clear that ECG-defined LVH is significantly *less* sensitive than echocardiographic assessment of LV mass.³⁶ ECG-defined LVH is prone to being less specific, particularly in younger patients, and perhaps more importantly in nonwhite patients. In both of these settings, false positive results are more common.³⁷ Where increased body fat (in particular, subcutaneous fat, paradoxically less associated with increased cardiovascular risk) is associated with high electrical resistance, obesity markedly confounds the accuracy of surface ECG voltage and limits the ability of voltage-based criteria to reliably identify LVH.³⁸ A lack of specificity can be particularly problematic where a treatment decision is being made on the basis of elevated clinic BP readings and ECG-LVH might in many instances be taken as the sole confirmation of end-organ damage used to make a pharmacologic treatment decision.

A key finding is that the prevalence of ECG-LVH may be up to six times higher in African American patients with hypertension than in white patients, depending on the criteria used (given a range of 6 to 24% in blacks versus 1 to 7% in whites). However, this observation is due in part to a lack of specificity as the estimated difference in the prevalence of *echocardiographic* LVH appears less striking (26% in blacks versus 20% in whites; $p>0.2$). As can be seen, this is largely due to the underreporting of LVH (at least as defined by echocardiography) when defined by ECG in white patients with hypertension. However, the overall sensitivity of the rest ECG (generally low; range, 3 to 17%) does not appear to differ significantly between African American and white patients for any of the conventional ECG-LVH criteria (Sokolow Lyon; Cornell adjusted score, and so on). Specificity indeed is lower in blacks for all criteria (range 73 to 94% versus 95 to 100% for whites; $p=.0001$ to $.09$). The predictive value of an ECG positive for LVH is therefore consistently lower in black subjects, even outside the U.S. African American population.³⁹ Black ethnic groups are indeed associated with the strongest independent predictor of a *decreased* ECG specificity in multiple logistic regression analysis factoring for age, gender, body mass index, left ventricular mass index, and smoking.³⁷

Several attempts have been made to adjust the criteria used to define LVH on the basis of rest electrocardiography by modifying the voltage criteria⁴⁰ to account for the impact of obesity⁴¹ and/or age.⁴² In general, these can help improve sensitivity but still leave unacceptably low rates (missing cases affected by generally echocardiographically but occasionally MRI-defined LVH)—particularly in elderly or female patients.

In the CASTEL study of 447 subjects, the sensitivity, specificity, and positive and negative predictive values of the most commonly used ECG tests of LVH were calculated and compared. All ECG calculations and modifications or adjustments thereof had a very low sensitivity in the elderly.⁴³ Furthermore, except for the Cornell index and the Minnesota code, they were unable to demonstrate the higher prevalence of echocardiographic LVH in elderly females in comparison with males. In contrast, the predictive value of the rest ECG for echocardiographic LV mass appears consistently better in elderly males compared with females (whether negative or positive). Some criteria are more predictive in males, some more predictive in females, and others equally predictive in both sexes. Overall, Casiglia and colleagues reaffirmed general consensus that a rest ECG, regardless of how the voltage LVH calculation is derived, is *not* a reliable method for screening LVH in the elderly.

Exercise-based studies in hypertension

In the hypertensive population, diagnostic exercise stress testing gives important information from both the BP and electrocardiographic as well as symptomatic aspects of the response to exercise. The cardiac prognostic significance of exercise BP rise in the hypertensive population has been recognized for a long time.⁴⁴ Most recent exercise packages now incorporate automated or semiautomated oscillometric BP cuffs. To some extent this has helped reduce inadequate

operator technique and number bias in the definition of exercise BP responses. Inadequate BP measurements in hypertensive patients off or on therapy are a totally unacceptable standard of practice whether as part of a screening test or part of a specific work-up for potential ischemia, which is directed more at the ECG and symptomatic response to exercise in routine practice.

Simplified submaximal exercises using step tests have been used in the assessment of hypertensive patients.⁴⁵ These have the value of added safety where an exercise-associated BP overshoot (occasionally of dramatic proportions) and may cause anxiety for patients or technicians supervising exercise tests and indeed appear to have some value in demonstrating associations with the presence of endothelial dysfunction⁴⁶ and levels of ambulatory blood pressure⁴⁷ and in predicting maximal QT interval dispersion on the rest ECG (see previous discussion). However, they are not predictive of echocardiographically or MRI-derived LV mass.⁴⁸ In one small study of maximal treadmill exercise testing, Gottdeiner and colleagues⁴⁹ from Washington suggested that they could demonstrate a correlation between echocardiographic LV mass and a BP overshoot on exercise testing (defined as measured SBP >210 mmHg) in normotensive male subjects. In all of the current studies of exercise BP response, there is a pathologic relationship to exercise BP loads for the heart both in persistent hypertension and in some prehypertensive states.⁴⁹ This alone underlines the general utility of exercise-based protocols and careful BP as well as other measurements in the hypertensive patient.

Many tests in hypertensive patients are performed to assess the possibility of myocardial ischemia in a hypertensive patient with either suspicious symptoms and/or minor non-specific ECG changes on their rest ECG. With respect to the definition of myocardial ischemia in unselected subjects with a BP overshoot during a maximal exercise perfusion scintigram, Campbell and colleagues⁵⁰ found that their subjects with BP overshoot (peak systolic BP greater than or equal to 210 mmHg in men and greater than or equal to 190 mmHg in women) were in fact *less likely* to have a scintigraphic perfusion defect (transient, fixed, or reversible) rather than more likely. Importantly, over a 6-year prospective follow-up there were 283 deaths in this subset and reassuringly no association between the exercise BP overshoot and risk of mortality regardless of the BP ECG or symptomatic response. Thus, an exercise-induced BP rise was associated with a lower likelihood of myocardial perfusion abnormalities, and this was not associated with any increased mortality rate.

The limitations of exercise stress electrocardiography for the definition of myocardial ischemia in unselected patients are well recognized, and like the rest ECG is summarized as low sensitivity (false negative rates of $>30\%$) and low specificity (false positive rates of $>30\%$) in specific groups such as the elderly, women, and patients with diabetes. However, these figures are somewhat confounded by a requirement to exercise fully (which is essential in the interpretation of results and a valid definition of receiver operating characteristics for exercise stress). Notwithstanding this, there may be some value in submaximal exercise testing

applied to the correct parameters (as discussed previously). There may be additional value derived from exercise tests and other aspects such as achieved work, cardiac rhythm, heart rate, and BP response. However, the key issue for most subjects remains the electrocardiographic response and whether this is indicative of myocardial ischemia.

In the hypertensive patient, the presence of electrocardiographic changes at rest (the strain pattern) would be expected to influence the predictive capacity of an exercise ECG test. However, Marwick et al. saw little impact (either positive or negative) on the *sensitivity* of exercise electrocardiography, although specificity was slightly reduced in the presence of ECG-LVH (74 versus 69%) in a group of 68 hypertensive patients.⁵¹ Given the frequency of normal epicardial coronary angiographic studies in patients with a positive noninvasive testing for ischemia, it is often suggested that hypertension by its association with a poor coronary flow reserve (independent of epicardial coronary artery disease), left ventricular hypertrophy, and possibly microvascular coronary disease would indicate that different diagnostic strategies are required to define tissue ischemia in these patients compared to those with ischemia through epicardial flow-limiting stenoses.⁵² Although stress-induced (physical, mental, or pharmacological) cardiac wall motion abnormalities (for example, detected at echocardiography) are generally highly specific for angiographic epicardial coronary disease, ST segment depression and/or scintigraphic myocardial perfusion abnormalities are often found in the presence of angiographically normal coronary arteries where there is coexistent hypertensive left ventricular hypertrophy and/or microvascular disease.

Given these findings, the value of exercise stress electrocardiography in hypertensive patients has been portrayed by some as its negative predictive value. This appears to be comparable in both normotensive and hypertensive patients. That is where the test is negative for inducible ischemia (it reliably defines an absence of epicardial coronary disease). Unfortunately, the overall negative predictive value of exercise electrocardiography in hypertensive patients remains poor, providing false negative rates in the region of 50% (low sensitivity) even with effective BP control.⁶⁹ Thus, whether an exercise-electrocardiography stress test is positive or negative or is uninterpretable or ambiguous generally another imaging stress test is warranted if there is a genuine high level of clinical suspicion of coronary artery disease, to suggesting a significant flow-limiting epicardial coronary disease and to justify targeted ischemia-guided revascularization.

Continuous ambulatory ECG studies in the definition of ischemia in hypertension

Despite its general utility in the definition of ambulatory ischaemia,⁵³ continuous ST segment monitoring has not been studied greatly in the assessment of patients with hypertension. Pringle et al. reported a detailed assessment of 90 hypertensive patients with left ventricular hypertrophy and abnormal 48-hour ambulatory ECG studies suggestive of ischemia.⁵⁴ From 68 men and 22 women (mean age 57; range 25 to 79) they completed 48-hour ambulatory ST segment monitoring (in all patients)—and addi-

tional exercise electrocardiography (n=79), stress thallium scintigraphy (n= 80), and coronary arteriography (n= 35)—to finalize diagnoses. They found that 48% of their sample (43 patients) had at least one episode of ST segment depression on ambulatory electrocardiographic monitoring. These were frequent (median number of episodes 16, range 1 to 84) and protracted (median duration of 8.6, range 2 to 17 minutes), but were in the vast majority *asymptomatic*. Twenty-six of the patients went on to show positive exercise electrocardiography, and 48 patients showed reversible stress thallium perfusion defects despite chest pain having occurred in only five of the patients during exercise. Eighteen of the 35 patients (20%) who progressed to coronary arteriography had clinically significant epicardial coronary artery disease. Of these, seven had no history of chest pain at any time.

Thus, symptomatic and asymptomatic myocardial ischemia are common in hypertensive patients with left ventricular hypertrophy, even in the absence of epicardial coronary artery disease. These patients could be reliably detected on Holter monitoring and continuous ECG analysis, yet this simple and effective technique remains poorly applied in the routine assessment of hypertensive patients. Unfortunately, this study did not define the false negative rate of this technique.

Similar studies by Asmar et al. studied unselected hypertensive patients for ambulatory ischemic changes, as defined by electrocardiographic criteria (a horizontal or down-sloping ST depression; >1 mm and >60 seconds). They found ST-segment depression together with concomitant BP and heart rate variations to be common and to follow a diurnal variation.⁵⁵ In 100 hypertensive patients (male/female ratio 1:1), 23 patients (15 men and 8 women) had 72 episodes of ST depression with 2 peaks: upon awakening and in the late afternoon periods. The mean ambulatory BP load was greater in the patients with than without ST-segment depression for both systolic and diastolic BP (135 +/- 14 versus 129 +/- 15 and 84 +/- 8 versus 79 +/- 10 mmHg, respectively; $p<0.01$). Plasma glucose (5.83 +/- 0.70 versus 5.46 +/- 0.71 mmol/L; $p=0.04$) and self-rated work-related stress levels (22% versus 13%; $p=0.03$) were also higher in patients with ambulatory ST-segment depression, regardless of symptoms suggestive of ischemia. There was no difference between the patient groups with or without ambulatory electrocardiographic ischemia on the basis of clinical parameters, left ventricular mass index, and other general cardiovascular risk factors (gender, smoking, lipids, and so on). This second study also suggested that 24-hour ambulatory ECG monitoring might have utility in defining ischemia in unselected hypertensive patients. They extended the analysis by suggesting that those hypertensive patients showing ambulatory ST depression episodes had a higher ambulatory BP load—and again by this technology electrocardiographic ischemic changes were common regardless of symptoms or the presence of LVH.

Finally, given the suggested role of potassium balance in ST segment interpretation Siegel and colleagues studied the role of diuretic-induced potassium depletion in the diagnostic utility of ambulatory ECG studies in 186 male hyper-

tensive subjects. They treated their patients to ensure repletion of potassium following control of blood pressure using diuretic therapy. Siegel et al. found a 27% prevalence of silent ambulatory ST segment depression compatible with ischemia.⁵⁶ The episodes followed a pattern similar to that seen in the studies of both Asmar and Pringle, with peaks in the early morning hours between 0000 hr and 0600 hrs.

In summary, ambulatory ECG studies appear distinct from rest or exercise ECG testing in the hypertensive population and probably have a better diagnostic profile in the assessment of both symptomatic or asymptomatic hypertensive patients, regardless of the presence of either electrocardiographic or echocardiographic LVH. Why such simple and reliable technology remains generally infrequently applied in the routine assessment of hypertensive patients is unclear, but this may simply relate to the time and effort required to complete detailed analyses that cannot be easily automated.

Stress myocardial perfusion studies

As an initial investigation to supplement symptomatic clinical assessment, nuclear cardiac studies are generally accepted as more sensitive and specific than exercise electrocardiography in the definition of significant epicardial coronary artery disease. Symptom-limited bicycle exercise stress test in conjunction with technetium,⁹⁹ sestamibi, or tetrafosmin SPECT imaging provides similar levels of diagnostic accuracy; sensitivity, and specificity whether or not the patient is normotensive or hypertensive for the detection of fixed or reversible perfusion defects.⁵⁷ Abnormal cardiac function in patients with positive exercise electrocardiography yet normal coronary angiography is well recognized, and hypertension is a common finding.⁵⁸ Neither hypertension *per se* nor hypertensive left ventricular hypertrophy⁵⁹ (in the absence of coronary disease) increases the likelihood of perfusion abnormalities with a given level of cardiovascular risk.⁶⁰

Comparative studies in hypertension generally show that the sensitivity of pharmacological stress perfusion is greater than that achieved by exercise stress electrocardiography and the specificity of results is improved.⁶¹ The features of a false positive test (a perfusion study suggesting ischemia yet with a normal coronary angiography) may relate to the presence of small vessel coronary disease visualized as a slow angiographic runoff. Unfortunately, an optimal agent to provide flow/vasodilator or rate stress or the best perfusion tracer is not specifically identified for the assessment of hypertensive patients.

Stress echocardiography

In some studies of patients with hypertension there is evidence to suggest that the incidence of coronary artery disease can be overestimated not only by exercise stress electrocardiography (ECG) but by stress perfusion scintigraphy (symptomatic patients who have test results suggestive of epicardial coronary disease yet have unequivocally normal coronary angiography). Stress echocardiography has been suggested to be a more sensitive and specific technique than the previously cited testing modalities.

This strategy is particularly useful in patients who have limited exercise capacity or in those who cannot (or alternatively will not tolerate an adequate exercise stress work load) reach adequate levels of exercise stress to achieve a diagnostic outcome. Exercise echocardiographic technique is clearly more operator and subject dependent than electrocardiography or nuclear scintigraphy. This is because it is influenced by the echocardiographic image quality of the patient studied in order to achieve sufficient image quality for accurate definition of segmental ventricular wall motion.

A range of techniques similar to those used in nuclear cardiac scintigraphy can be used to place the heart under stress. The key differences are that imaging is generally completed at baseline and immediately after completion of physical exercise and that graded assessments during exercise are generally not possible. The exercise protocols used are generally similar to those used in exercise electrocardiography. Pharmacologic stress commonly using either dobutamine (with or without atropine), adenosine, dipyridamole, or a range of less commonly used agents has advantages in that patients are not physically moving and thus during these protocols graded imaging can be achieved during the infusion protocol.

The endpoint of analysis is the detection of stress-induced reversible wall motion impairment of contractility. Unlike exercise ECG studies, segmental wall motion analysis generally allows broad anatomical location of the ischemic response and the definition of these wall motion abnormalities has good prognostic validity in reliably predicting subsequent coronary events in that territory. Thus, anterior/LAD abnormalities are associated with a significantly increased risk of cardiac death and nonfatal infarction. This added prognostic risk of events is independent of the resting baseline LV ejection fraction and the perceived extent of wall motion abnormalities identified during stress echocardiography in hypertension.⁶²

Echocardiographic imaging is normally acquired by the transthoracic route but can also be completed by the transesophageal route, where either a direct pacing stress or pharmacologic stress can be employed with reasonable comparability to pharmacologic transthoracic stress echocardiography.⁶³ Although pharmacological stress is generally preferred to minimize motion artifact during echocardiography, this is associated with some adverse effects on the patients studied. In some early studies, safety was a concern particularly for hypertensive patients for whom an abrupt pressor response is more often seen during pharmacologic stress protocols.^{64,65} As with exercise electrocardiography, there are composite endpoints for the test (including symptoms, concomitant electrocardiographic changes, and most centrally the definition of reversible regional wall motion abnormalities), suggestive of flow-limiting myocardial ischemia.

Using an exercise echo technique (without electrocardiographic LVH) in hypertensive patients who had already undergone coronary angiography, Senior and colleagues from London showed improved sensitivity and specificity even in a relatively small sample of 43 patients (of whom only 29 had coronary disease).⁶⁶ Maltagliati et al. tested the role of exercise echocardiography as an alternative to exer-

cise electrocardiography for the detection of epicardial coronary disease in hypertension, before and after adequate BP control.⁶⁷ In a parallel group case control study of 59 hypertensive and normotensive patients undergoing coronary angiography for chest pain, these investigators defined both upright bicycle exercise ECG and post-exercise stress echocardiographic results for each group. The hypertensive patients had repeated testing following BP control (in this study using sublingual nifedipine). Coronary artery disease (defined as >1 angiographic luminal narrowing >50%) was found in 22 hypertensive and 41 normotensive patients. The sensitivity, specificity, and diagnostic accuracy of the two techniques were not statistically different (95%, 94%, 94%) in hypertensives or (82%, 77%, 83%) normotensives, but were significantly better than those seen on the bicycle exercise ECG test (68%, 70%, and 69%). BP lowering had little impact on exercise echocardiography, slightly decreasing sensitivity (91%)—whereas the sensitivity of exercise ECG decreased even more markedly (45%).

Elhendy et al. evaluated in 1164 hypertensive patients the hemodynamic profile, safety, and feasibility of combined dobutamine (up to 40 µg/kg per minute) and atropine (up to 1 mg) stress echocardiography in patients with “limited exercise capacity” (age, 60 +/- 12 years; 761 men). In this large study, 446 of the patients were known to have treated hypertension. The test protocol was defined using a limit of achieving 85% of age-predicted maximal heart rate and/or an ischemic endpoint (new or worsened wall motion abnormalities, ST segment depression, or angina). Predictably, dobutamine induced a significant increase of heart rate in patients with and without the presence of hypertension (59 +/- 25 and 63 +/- 23 beats per minute, respectively). A hypotensive response (>40 mmHg SBP drop) was more frequent in older hypertensive patients with higher baseline BP treated with calcium channel blockers (7% versus 4%). Protocol-related ventricular tachycardia occurred at a small but significant rate (4.1%) but was similar in normotensive or hypertensive patients and could be terminated promptly by intravenous metoprolol administration. This form of testing proved feasible in 91% of patients with and 92% of patients without hypertension. Therefore, they could reasonably conclude that this technology and protocol was safe, effective, and reliable in the assessment of hypertensive patients where evaluation for myocardial ischemia was indicated.

Perfusion imaging has been directly compared to stress echocardiography in other reports. Astarita et al. studied 53 patients with hypertension (29 males, aged 58 +/- 10 years) and with normal left ventricular systolic function and a positive exercise ECG test suggestive of ischemia. They further investigated these patients with dipyridamole-atropine stress echocardiography (DASE) and thallium-201 stress/rest myocardial single-photon emission computed tomography (SPECT).⁶⁸ All patients had additional coronary angiography. Coronary angiography was used to define the occurrence of >1 epicardial stenosis (>50%), which was present in 23 of the 53 patients (43%) who had a positive exercise ECG. The calculated sensitivity for detection of angiographic coronary artery disease was significantly higher

for perfusion scintigraphy compared to echocardiography (DASE = 78% versus SPECT = 100%, $p < 0.05$), whereas specificity was higher for echo (DASE = 100% versus SPECT = 47%, $p < 0.00001$). Diagnostic accuracy was also higher for echo (DASE = 91% versus SPECT = 70%, $p < 0.01$). Thus, this group felt that in the further assessment of hypertensive patients with chest pain symptoms suggestive of ischemia and an exercise-induced ST segment depression both dipyridamole/atropine stress echo and SPECT perfusion scintigraphy were good diagnostic options. Dobutamine-atropine stress echo was characterized by a higher specificity but slightly lower sensitivity than stress perfusion SPECT.

In a later study, Elhendy et al. compared their pharmacologic stress echocardiography protocol with stress perfusion scintigraphy (this time using a sestamibi SPECT protocol and coronary angiography) in hypertensive patients with or without LVH (where the presence of coronary stenoses at angiography was defined as more than one >50% lesion). From a sample of 88 patients where epicardial coronary disease was defined in 66, these two techniques were largely comparable without statistically significant differences in either sensitivity or specificity.⁶⁹ Both appeared to lack sensitivity compared with an angiographic standard (63% and 51%, respectively, for echocardiography and scintigraphy), but the presence of echocardiographic LVH had no impact on either technique.

Flow dilatation using dipyridamole in combination with echocardiography has similar value in the assessment of hypertensive patients with undiagnosed chest pain symptoms and appears to give reliable prognostic information. In a relatively small prospective study of 257 hypertensive patients with chest pain (110 men; age, 63 +/- 9 years), Cortigiani et al.⁷⁰ had no major complications with a stepped dipyridamole infusion protocol successfully completed in 98% of hypertensive patients symptomatic with chest pain. A positive echocardiographic response suggestive of ischemia was found in 72 patients: 27 during the low-dose (less than or equal to 0.56 mg/kg) and 45 during the high-dose (>0.56 mg/kg) dipyridamole infusion. During follow-up (32 ± 18 months), 27 cardiac events had occurred comprising 3 deaths, 8 myocardial infarctions, and 16 cases of admission with unstable symptoms. Twenty-seven patients underwent coronary revascularization. At multivariate analysis, the positive stress echocardiographic result [odds ratio (OR) = 5.5; 95% CI, 1.4 to 16.6] was the only predictor of subsequent major cardiac events (cardiac death or infarction). A positive stress echocardiographic study (OR, 4.2; 95% CI, 1.8 to 9.6) and family history of coronary disease (OR, 4.2; 95% CI, 1.5 to 6.9) were both independently associated with prognosis. The 5-year survival rates for the negative stress echo and the positive stress echo populations were, respectively, 97% and 87% ($p = 0.0019$) for cardiac events.

In a more recent study, the same group assessed the relative value of dipyridamole stress echo or exercise electrocardiography in hypertensive patients with right-bundle branch block (35) or patients with right-bundle branch block and normal blood pressure (36). In this group (with right-bundle branch block) they found less concordance of

testing in hypertension (69% cf 92%) compared to the normotensive patients, although overall the sensitivity of both techniques was similar. The accuracy of positive and negative predictive values was much higher with dipyridamole stress echocardiography (66, 61, and 75%, respectively, for exercise electrocardiography and 86, 87, and 84%, respectively, for dipyridamole stress echocardiography).⁷¹

However, this comparability of performance was not found in a further study in 101 patients with hypertension, chest pain, and positive exercise ECG.⁷² This group completed an extensive comparison in their patient group using stress/rest SPECT with Tc^{99m}-MIBI, dipyridamole, and dobutamine stress echocardiography and coronary angiography in their patients, all of whom had normal global ventricular function (57 had preserved systolic function but echocardiographic LVH). They observed no side effects during perfusion scintigraphy but dose-limiting side effects in 5 patients during dipyridamole and 7 patients during dobutamine stress echo. The sensitivity, specificity, accuracy, and positive and negative predictive values for angiographic coronary disease were, respectively, 98%, 36%, 71%, 67%, and 94% for perfusion scintigraphy; 61%, 91%, 74%, 90%, and 64% for dipyridamole; and 88%, 80%, 84%, 85%, and 83% for dobutamine stress echocardiography. Thus, dipyridamole stress performed significantly less well in this series than dobutamine stress applied to symptomatic hypertensive patients for the definition of angiographic coronary disease.

In contrast to these isolated comparisons of the diagnostic performance of single-test strategies, Marwick et al.⁷⁵ published an important and more realistic stepwise analytical approach to define the added diagnostic value of stress echocardiographic assessment from a substantial study of 2363 hypertensive patients followed up for 10 years. Although the majority of their cohort had normal studies (63%), ischemia identified by stress echocardiography independently predicted mortality in those able to complete a treadmill exercise echo protocol (hazard ratio 2.21, 95% confidence intervals 1.10 to 4.43, $p=0.0001$) as well as those undergoing dobutamine echo (hazard ratio 2.39, 95% confidence intervals 1.53 to 3.75, $p=0.0001$). The other major predictors of events were age, the presence of resting LV systolic dysfunction, heart failure symptoms (regardless of systolic function), and the clinically derived Duke treadmill score. Using a stepwise model to replicate the sequence of clinical evaluation (applied after screening exercise electrocardiography), stress echocardiography added prognostic power to predictive models based on clinical and/or stress-testing variables. Thus, stress echocardiography (exercise or pharmacologic) were an independent predictor of cardiac death in hypertensive patients with known or suspected coronary artery disease, incremental to clinical risks and exercise ECG test results alone.⁷³

Whether or not conduction defects influence stress echocardiography is not quite as straightforward as with stress perfusion scintigraphy. Hypertensive patients with resting conduction defects who undergo stress echocardiography and do not have studies indicative of ischemia (no regional wall motion abnormalities) are associated with low excess mortality. However, the specific combination of

right-bundle branch block and anterior hemiblock has been associated with adverse outcomes, even where the stress echocardiographic study does not suggest coronary ischemia is present.⁷⁴ In a small sample of 161 hypertensive patients stratified on the basis of ventricular geometry, Yuda et al. suggested that the accuracy of dobutamine stress echocardiography is reduced in patients with concentric remodeling (61%) compared to hypertensive patients with normal geometry (85%, $p<0.05$) or concentric hypertrophy (86%, $p<0.05$). Accuracy with eccentric hypertrophy (64%, $p<0.05$) was lower than with concentric hypertrophy and similar to that found with concentric remodeling.⁷⁵

Patients with chest pain symptoms and completely normal angiography often remain symptomatic and cause concern. However, Zouridalkis et al.⁷⁶ examined 33 such patients with exertional anginal chest pain, a positive exercise stress ECG, and a completely normal coronary arteriogram. All patients had normal left ventricular systolic function at rest and none fulfilled echocardiographic criteria for LVH, whereas 8 of the normotensive patients and 10 of the hypertensive patients had perfusion abnormalities on thallium SPECT ($p=0.61$). Dobutamine infusion reproduced anginal pain and ST segment changes in some patients, but none developed regional wall motion abnormalities indicative of ischemia. They concluded that the high prevalence of scintigraphic perfusion defects in both normotensive and hypertensive groups were probably false positive results or less likely that dobutamine stress echocardiography is insensitive to ischemia caused by microvascular dysfunction.

Coronary angiography

Coronary angiography is frequently performed in patients with hypertension due to the presence of equivocal or positive noninvasive testing for myocardial ischemia to define the nature of epicardial coronary flow. It is particularly appropriate in hypertension, where the implications of the presence (or indeed absence) of epicardial coronary disease are prognostically important.

Although the appearance at angiography is not equivalent to the absence of sub-intimal coronary atherosclerosis and does not guarantee absence of future coronary disease, there is general agreement that the presence of unequivocally normal coronary arteries is a useful prognostic indicator even in the presence of hypertension and or hypertensive LVH.⁷⁷ Although the morbidity of patients remains high (many have symptoms of chest pain both typical and atypical of inducible ischemia) mortality (in the absence of a documented myocardial infarction at any point⁷⁸) is consistently low.

The prognostic significance of *nonobstructive* coronary disease seen at coronary angiography in hypertensive patients is less easy to predict. In unselected patients with noncritical lesions there is a significantly lower (albeit only slightly) 10-year survival rate (85.8%) than those with unequivocally normal coronary arteries (90.1%). The difference in survival rate in population studies of nonobstructive coronary atheroma detected at angiography is generally attributed to more advanced age, male gender, and a higher prevalence of cigarette smoking, diabetes, mellitus,

and hypertension. However, it is also clear that the presence of noncritical coronary stenoses is *not* a statistically significant independent determinant of survival. Long-term survival rates of the patients with one or more critical lesions were in fact largely equivalent to those seen in patients with critical stenoses plus one or more noncritical lesions.⁷⁹ Thus, noncritical stenoses appear to be important only if they occur in conjunction with a critical flow-limiting stenosis.

In a relatively small comparative case control study using a positive treadmill exercise test involving 320 patients with hypertension and 320 patients without hypertension, De Cesare et al.⁸⁰ showed that *only in the sixth and seventh decade* did the patients with hypertension have a greater prevalence of triple vessel coronary disease (40 and 50% cf. 25 and 31%) than the normotensive comparator group. This appeared unrelated to standard cardiovascular risk factor distribution (age, gender, smoking, lipids, and so on) demographics. Thus, “diagnostic” exercise treadmill results suggestive or indicative of ischemia should be treated with some caution in patients with hypertension, as they need not reflect epicardial coronary stenoses with its attendant prognostic implications.

Vascular calcification and electron beam studies in hypertension

In the last 10 years, the long-standing association of vascular calcification with the process of endo-luminal stenoses⁸¹ has been explored using noninvasive electron beam tomography. The measurements have been applied to a variety of sites, but the most relevant to the heart of the hypertensive patient is in the assessment of the calcification occurring in the coronary circulation (CAC). The improving resolution and data interpretation of this noninvasive technology gives the technique some future potential. It has been suggested to provide independent predictive information on vascular occlusive event rates at least over and above that provided by a traditional demographic cardiovascular risk factor analysis.⁸²

Although the technique appears to show an independent relationship to the severity of coronary stenosis, there are confounding associations with age, hyperlipidaemia, diabetes, smoking status, and gender. For example, African American ethnicity (and, interestingly, hypertension) does not appear to link coronary disease well with the appearance of coronary calcification using EBCT.⁸³ However, in the largest study so far (completed in 30,908 asymptomatic individuals undergoing EBCT), Hoff et al. report that for both men and women all conventional risk factors (including hypertension) were significantly associated with the presence of any detectable CAC, and the mean CAC score increased in proportion to the number of CAD risk factors. In age-adjusted (multivariable) logistic regression analysis, cigarette use, histories of hypercholesterolemia, diabetes, and hypertension were each significantly associated with mild to extensive CAC scores (greater than or equal to 10.0). Thus, they felt that CAC scores were associated with *presumed* higher atherosclerotic plaque burden in both men and women. Unfortunately, this association with risk factor scores is not an adequate definition of the presence or absence

of coronary stenoses in these individuals, all of whom were ostensibly well.

In a relatively small early case control study, there was a relationship between the extent of coronary calcification scoring to the duration of high BP in a sample of 73 male hypertensive patients.⁸⁴ They found no association with the extent of BP elevation in this cohort but were able to suggest a weak link of CAC scores to age that was also demonstrable in asymptomatic normotensive subjects.⁸³ However, in some studies⁸⁵ and not in others⁸⁶ in angiographic coronary artery disease hypertension is less strongly linked to the extent of coronary calcification or stenosis scoring than are other generalized atherosclerosis risk factors.

Turner et al. have recently reexamined the relationship of BP to CAC in a sample of 298 hypertensive patients (male and female) using ambulatory BP recordings⁸⁷ and have found a link between ambulatory diastolic BP and CAC scoring. In a logistic regression analysis of CAC in the presence of hypertensive LVH, Altunkan et al. have suggested that body mass index and age were the main independent factors affecting the presence and amount of coronary calcification in patients with left ventricular hypertrophy.⁸⁸

CARDIAC STRUCTURE AND FUNCTION IN HYPERTENSION

Valvular associations and hypertension

There are known associations between cardiac valvular dysfunction and hypertension, but these are confounded by the presence of concomitant disease. For example, secondary valvular dysfunction following ischemia or infarction with or without dilatation of the heart would be a well-accepted but separate pathologic process.

The coexistence of hypertension and stenosis of the aortic valve is well recognized and is a common clinical association in surveys of symptomatic aortic stenosis (32% of symptomatic cases of aortic stenosis in some series⁸⁹). For example, hypertension is coexistent in 21% of patients with any grade of aortic stenosis, and aortic stenosis affects 1.1% of hypertensive patients.⁹⁰ Theoretically, the increased valve shear stress caused by hypertension may be a possible mediator (or at the very least an accelerating factor) in the development of aortic valve stenosis. However, the exact interrelationship of these two conditions is less clear.

Degenerative aortic valve disease is common in the elderly where hypertension is more prevalent. For example, in the 5201 subjects over 65 years of age enrolled in the Cardiovascular Health Study echocardiographic aortic valve sclerosis was evident in 26% and aortic valve stenosis in 2% of subjects. In those over 75 years of age, the prevalence of aortic sclerosis rose to 37% and aortic stenosis rose slightly (to 2.6%). Upon multiple logistic regression analysis, the independent predictors of this change somewhat predictably included age (twofold increased risk for each 10-year increase in age), male gender (twofold excess risk), smoking (35% increase in risk), and a history of hypertension (20% increase in risk).⁹¹ Despite this association, hypertension does not appear to independently influence the natural course of aortic valve disease.⁹² Although a

higher left ventricular outflow tract velocity (common in hypertension in response to the changes associated with the hypertrophy remodeling of the hypertensive heart⁹³) is associated with more rapid degeneration in aortic valvular stenosis, it is not a statistically independent predictor of progression.⁹⁴

Studies in patients with both hypertension and aortic stenosis are limited, but recent reports suggest no significant differences between hypertensive and normotensive aortic stenosis patients with respect to age, gender, symptom class, ventricular function, or remodeling patterns. In hypertensive patients, symptoms tend to present with larger aortic valve areas and lower stroke work (i.e., less valvular stenosis).⁹¹ This may be because of the additional overload due to hypertension or more practically due to simple earlier recognition by chance physical examination.

Data on the *spontaneous* detection of echocardiographic valvular regurgitation in patients with hypertension are not extensive, and examination of potential causal associations with arterial hypertension is scant. In the normal population, the presence of regurgitation at the mitral position has been shown to have a weak association with coexistent hypertension in the Framingham study. In 1696 men and 1893 women (preselected by those who had acceptable echocardiographic imaging), a multiple logistic regression analysis was used to define the association of clinical variables to mitral (MR) or tricuspid regurgitation (TR; more than or equal to mild severity) and aortic regurgitation (more than or equal to trace severity). MR of more than mild severity was seen in 19.0% of men and 19.1% of women, with AR of more than or equal to trace severity in 13.0% of men and 8.5% of women. The demographic associations with the finding of echocardiographic MR were increased age (OR = 1.3/9.9 years, 95% CI 1.2 to 1.5), hypertension (OR 1.6; 95% CI 1.2 to 2.0), and body mass index [OR 0.8/4.3 kg/m²; 95% CI 0.7 to 0.9; i.e., less likely]. The determinants of AR were only age (OR 2.3/9.9 years; 95% CI 2.0 to 2.7) and male gender (OR 1.6; 95% CI 1.2 to 2.1).

In the hypertension genetic epidemiology study⁹⁵ conducted in 1496 hypertensive patients free of diabetes the occurrence of aortic and mitral regurgitation was 246/1496 (16.5%) and 75/1496 (5%), respectively. In short, the role of hypertension in the evolution of echocardiographic or symptomatic valvular regurgitation seems to be dependent on factors other than hypertension *per se*.

Ventricular function assessment *Role of rest echocardiography in routine management (asymptomatic)*

Left ventricular function assessment is a crucial aspect of hypertension care. There are two key areas of interest: the definition of ventricular hypertrophy and the functional assessment of ventricular contraction and to some extent relaxation. By far the most widespread mode of diagnostic assessment is by use of transthoracic echocardiography. The definition of ischemia as a cause of symptoms or in the asymptomatic hypertensive patient can also be addressed (at least in part) by use of an echocardiographic technique (see previous material). There is little evidence to suggest

that ventricular function can be adequately addressed in isolation by a process of structured symptomatic enquiry (whether alone or supplemented by examination) or by employing basic tests such as electrocardiography or chest radiography⁹⁶ (which is *less likely* in hypertension given the more subtle nature of the changes involved in these patients, many of whom do not voice symptoms of any form).⁹⁷

The use of a variety of technical assessments in hypertension is the subject of several regional and/or national guideline statements. In virtually all of these, echocardiography is not routinely recommended for all hypertensive subjects to stratify cardiovascular risk. However, the application of this technology *clearly* allows more precise definition of ventricular hypertrophy than would be possible on the basis of examination and routine chest X-ray and electrocardiography (see previous material).

For example, Cuspidi et al.⁹⁸ combined echocardiography with ultrasonographic carotid media thickness assessments (a similarly unclear clinical risk stratifier in hypertension) in 1074 hypertensive patients and were able to show reclassification of hypertensive patients as defined by population risk scoring alone. The proportion of patients (originally defined as low risk) decreased to 11.1%, and that of medium-risk patients also fell (to 35.7%). The largest change was that more than 50% of the patients previously classified at low or medium risk were deemed to be at high risk of subsequent vascular events following the addition of data from the use of these two ultrasonographic technologies (assessing LVH and IMT). A similar conclusion was reached by Schillaci et al. in their reclassification of 792 untreated adult hypertensive patients with and without echocardiographic data.⁹⁹ Again, the main change in classification they saw was that a significant proportion of low-risk subjects that were reclassified as at higher vascular event risk and were now candidates for antihypertensive drug therapy (as opposed to BP monitoring or lifestyle interventions). Thus, although echocardiography appears to have a valuable role in the routine and *initial* assessment of hypertension it is clear that this data has not yet been incorporated into current national and international guidelines.

As indicated by Schillaci et al., echocardiographic assessments performed at the diagnostic phase of hypertension assessment may be of value in the classification of a white coat response and in the significance of white coat hypertension by putting blood pressure changes in the context of accurate end-organ assessments of the heart. Furthermore, the spectrum of ventricular change (which can be defined in hypertensive patients) can extend to the period *before* the appearance of fixed BP elevation. For example, echocardiographic indices of diastolic function appear to become abnormal when measured BP is within the normal range in the offspring of parents with hypertension. Indeed, Aeschbacher et al.¹⁰⁰ performed serial echocardiographic assessments in normotensive male offspring of hypertensive and normotensive parents. Over a 5-year period, although BP had not altered overall 5 offspring of hypertensive parents went on to develop mild sustained hypertension. Although overall LV mass was

not different between the two groups at follow-up (92 ± 17 versus 92 ± 14 g/m²) and diastolic assessments had been similar at baseline, at follow-up mitral E-wave deceleration time and pulmonary vein reverse A-wave duration were both prolonged.

These changes were associated with significantly higher trans-mitral A-wave velocities (54 ± 7 versus 44 ± 9 cm/sec, hypertensives versus normotensives, $p < 0.05$), lower E/A ratio (1.31 ± 0.14 versus 1.82 ± 0.48 , $p < 0.05$), increased systolic-to-diastolic pulmonary vein flow ratio (1.11 ± 0.3 versus 0.81 ± 0.16 , $p < 0.005$), longer myocardial isovolumic relaxation times (157 ± 7 versus 46 ± 12 msec, $p < 0.05$), and smaller myocardial E-wave velocity (10 ± 1 versus 13 ± 2 cm/sec, $p < 0.05$) and E/A ratio (1.29 ± 0.25 versus 1.78 ± 0.43 , $p < 0.05$) despite similar LV mass (91 ± 16 versus 93 ± 18 g/m²). Thus, normotensive men with a moderate genetic risk for hypertension develop echocardiographic alterations of LV diastolic function before any appreciable rise in LV mass.

There is still some debate as to the best means of echocardiographic definition of diastolic relaxation in hypertension. Trans-mitral Doppler filling indices are commonly abnormal, but the independent relationship of these changes to hypertension and or ventricular remodeling (independent of aging) is not absolutely clear. It is clear that the aging process and the response to hypertension are different, dependent on gender. There is well-documented interest in the impact of hypertension on the systolic performance of the mid-wall of the left ventricle. Again distinct from symptoms, this echocardiographic analysis of LV systolic strain is suggested to be associated with a poorer cardiovascular event rate. How this translates to overall systolic function defined by a volume technique such as MR or radionuclide ventriculography is less clear.

Recent investigations of the utility of ultrasonic tissue backscatter have shown some linkage to structure *in vivo* and have suggested that these relate to the abnormal restrictive filling patterns seen in hypertensive heart disease. Maceira et al.¹⁰¹ defined real-time integrated backscatter analysis in 109 patients with essential hypertension. Backscatter cyclic variation and maximal intensity measured in 6 regions throughout the left ventricle were compared to trans-mitral filling patterns and subjects classified as showing normal BP and normal diastolic function (group 1, 29), hypertension with normal diastolic function (18, group 2) or hypertension with a delayed relaxation pattern (47, group 3). In addition, they found 11 hypertensives with a pseudo-normal filling pattern (group 4), and 4 hypertensives with a restrictive filling pattern (group 5). The highest cyclic variation was found in groups 1 and 2, the lowest in groups 4 and 5 (5.7 ± 0.2 dB in group 1 and 5.7 ± 0.2 dB in group 2 versus 2.9 ± 0.3 dB in group 4 and 2.1 ± 0.4 dB in group 5; $p < 0.001$), with intermediate values within group 3 (5.2 ± 0.2 dB). In correlation studies, left ventricular chamber stiffness was inversely related to the cyclic variation of backscatter signals ($p < 0.05$) and directly correlated with mid-wall fractional shortening ($p < 0.02$) in all patients with HBP. These results suggest a link between backscatter indices and diastolic function in hypertensive heart disease.

As an alternative, left atrial chamber dimensions or volume estimates can be readily defined using echocardiography.¹⁰² As indicated previously, electrocardiographic indices of atrial conduction tend to link in best with simple diastolic filling parameters. Thus, atrial echocardiographic assessment might also hold useful indirect indices of diastolic function. Tsang et al. have shown that an echocardiographic atrial volume index has additional value in the retrospective cardiovascular event rate of elderly subjects referred within the Olmstead County survey.¹⁰³ A separate report from 140 subjects showed left atrial volume to correlate closely with age, ventricular dimensions, and mass in patients without evidence of atrial arrhythmia or valvular heart disease.¹⁰⁴ Thus left atrial volume appeared to be closely associated with the severity of a range of echocardiographic indices of diastolic dysfunction in these patients.

The white coat effect has little relationship to the structure or function of the left ventricle.¹⁰⁵ Although there are changes to trans-mitral flow reported in some series,¹⁰⁶ these are of uncertain clinical significance in the absence of ventricular hypertrophy or changes in systolic function despite signs of vascular dysfunction in these subjects.¹⁰⁷

Studies in normotensive subjects also show small declines in resting LV systolic function and mid-wall contractility with aging. In a cross-sectional study of 272 asymptomatic adults (aged 25 to 80 years old) with untreated hypertension, Slotwiner et al.¹⁰⁸ found no change in endocardial or mid-wall stress-corrected left ventricular fractional shortening. Neither cardiac index nor total peripheral resistance changed with age in either gender because age-related increases in systolic pressure were offset by increased concentric remodeling in the female patients or enhanced systolic contractility in the males. Thus, in mild hypertension although cardiac index and peripheral resistance change with respect to age alone there are age-related increases in concentricity of ventricular geometry in women and increased ventricular performance indexes in hypertensive men.

Systolic function in patients with hypertension may also need more detailed assessment in hypertensive patients than in more straightforward studies designed to define contractility following infarction. Occult ischemia is a common cause of both systolic and diastolic impairment and may often be a cause of symptoms in the hypertensive population. Long-axis contraction of the left ventricle can be analyzed using a variety of echocardiographic techniques either using simple M-mode mitral annular movements alone or in conjunction with trans-mitral color flow studies or by tissue Doppler analyses.¹⁰⁹ The more recent application of myocardial tissue Doppler imaging can reveal subtle long-axis systolic ventricular impairment in patients previously presumed to have diastolic dysfunction.¹¹¹ The impact of hypertension is to change long-axis measures of contractility and these appear more sensitive in hypertensive patients than indices based on trans-mitral filling.¹¹⁰ Clearly overall systolic contraction by a volume method might better appreciate such changes, but these are not often compared to purely echocardiographic indices.

The geometric pattern of ventricular remodeling seen in individual patients with hypertension can have an impact

on cardiac function by influencing both systolic and diastolic mechanics differently at rest or during exercise. Stroke volume is higher in patients with eccentric hypertrophy (83 mL/beat) and lower in patients with concentric LVH (68 mL/beat) compared to matched normotensive adults (73 mL/beat).¹¹¹ In keeping with these changes, obviously cardiac output will then be higher in hypertensive patients with eccentric LV hypertrophy and lower in concentric LVH. These changes occur independently of achieved BP, although in multivariate analysis LV mass is predictably independently related to higher systolic pressure, older age, stroke volume, male gender, and body mass index. Stroke volume and cardiac output are lower in hypertensive patients with low stress-corrected mid-wall shortening.¹¹²

Role in symptomatic assessment

Although echocardiographic technology and image quality are constantly improving, the role of this investigation (echocardiography) in the routine assessment of symptomatic hypertensive patients has not been addressed in detail. It is feasible to complete rapid assessment at least of overall systolic function using portable machines. Using a handheld device and comparing this with a standard fully functional echocardiography platform, Senior and colleagues found a sensitivity of only 72% and positive and negative predictive values of 73 and 90% in 183 patients reviewed within a community systolic heart failure screening project.

Assessment of diastolic function in symptomatic patients

The subject of diastolic ventricular impairment in hypertension has been debated for many years. It has been marred largely by confusion over clinical definitions and importantly a failure to link many measurements to demonstrable exercise impairment in patients who voice heart failure symptoms. These are typically breathlessness upon exertion and/or undue fatigue, and they occur in patients who have normal systolic (generally short-axis contraction defined by echocardiography) ventricular function.

There is now general agreement that in the routine assessment of patients with heart failure symptoms (of whatever origin) many patients will have no demonstrable abnormality of systolic function, however this is assessed. Some may be accounted for by abnormal long-axis systolic function (although the significance of this phenomenon is as yet unclear where global volume ejection methods of stroke work are normal),¹¹¹ by valvular disease, by pulmonary hypertension, by intermittent occult arrhythmia (such as PAF common in conjunction with hypertension), or by parenchymal lung disease. Often the diagnosis of diastolic heart failure is arrived at by exclusion of other causes and the presence of indicators of impaired ventricular relaxation. A substantial proportion of these patients are female, many are overweight, and specifically there is often a clear association with hypertension and echocardiographic left ventricular hypertrophy.

In the Olmsted County survey, those patients (n=83) with a new clinical diagnosis of heart failure (i.e., a presentation of heart failure symptoms) and subsequent normal

systolic function were generally very elderly (mean age 79 years) females (76%) who had defined histories of hypertension and/or coronary disease (85%).¹¹³ Given the age range, it is perhaps not surprising therefore that the three-year mortality rate was high (60%). However, only half of these patients met broader ESC echocardiographic criteria for an association of the presenting symptoms with a diagnosis of *diastolic* heart failure.

Symptomatic heart failure without systolic contractile dysfunction remains an important, and for some observers even a dominant, form of heart failure presentation (particularly in the elderly).¹¹⁴ The knowledge base regarding the epidemiology, pathophysiology, natural history, and therapy of these patients is still remarkably limited. There is a complex interaction with a number of age-related changes in the heart and vascular system that predispose to clinical presentation. Some population-based observational studies suggest that >50% of persons over 65 years who have heart failure symptoms will have normal LV systolic function. Of these, roughly half will have no other confounding variables (coronary, valvular, or pulmonary disease) and could meet suggested criteria for isolated DHF. This is substantially more common in older women than in men, and hypertension with echocardiographic left ventricular hypertrophy is almost invariably present. Although short-term mortality rates are about 50% lower than in systolic heart failure in stable patients, in acutely hospitalized or very elderly patients the mortality rate is similar in both systolic and potential diastolic heart failure. Furthermore, due to its higher prevalence the total mortality in the older population attributable to DHF in fact exceeds that of SHF. In the chronic setting, DHF patients can have severe exercise intolerance related to failure of the Frank-Starling mechanism with reduced peak cardiac output, heart rate, and stroke volume and increased LV filling pressure. DHF patients also appear to have increased vascular stiffness, accelerated systolic blood pressure response to exercise, neuro-endocrine activation, and reduced quality of life.

It is possible (and may be essential) to define diastolic heart failure by showing either impaired weight-corrected exercise capacity using expired gas analysis at cardio-pulmonary testing,¹¹⁵ or even elevated pulmonary wedge pressures at rest or during exercise in patients with symptomatic patients with echocardiographically normal systolic ventricular function.¹¹⁶ Stress echocardiographic studies of potential diastolic filling abnormalities in hypertension (the difference between color tissue Doppler of myocardial segments at baseline and during pharmacological stress) show that hypertensive LVH is associated with reduced flow. In one survey of 30 patients free of epicardial coronary disease, and after adjusting for the LV mass and body mass, trans-mitral filling indices remained independently associated with impaired coronary flow reserve.¹¹⁷ This may translate to impaired diastolic filling during subclinical (asymptomatic) myocardial ischaemia.

The role of transesophageal echocardiography (TOE) in the definition of diastolic relaxation is generally complementary to other techniques. Klein et al. have reported a large sample (n=181) from their practice where TEE was

used primarily to assess for potential cause of diastolic dysfunction.¹¹⁸ A large number in this selected group were found to have unsuspected restrictive cardiomyopathy (n=71), and a further substantial number (n=54) had features consistent with constrictive pericarditis, subsequently confirmed at surgery. Only a minority in this series (32%) had idiopathic diastolic dysfunction, and surprisingly only a very small number were found in association with hypertension (which would not be a general feature of these cases in most series).

There is no doubt that the technical assessment of diastolic filling has progressed rapidly in recent years since the clinical concept and significance of symptomatic isolated diastolic heart failure emerged. The population prevalence of this patient group is underrepresented by studies in hospital populations, which tend to be dominated by systolic ventricular dysfunction. In community-based surveys, prevalence figures as high as 15 to 20% are common in the elderly. Using only an echocardiographic point of analysis, Fischer et al. (examining the MONICA cohort in Augsburg) used the ESC definitions for diastolic heart failure, which are based on an age-dependent impairment of ventricular isovolumic relaxation time (95 to 105 ms) and early and late ventricular filling wave reversal (1 to 0.5). On this basis, they found a 15.8% prevalence of these characteristics in patients over 65 years of age from a sample of 1274 individuals. In this study, these echocardiographic abnormalities were more common in men than women, but were typically associated with hypertension, left ventricular hypertrophy, coronary artery disease, high body fat mass versus BMI, and diabetes. Abnormalities of diastolic filling were in fact rare (only 1 to 4% prevalence) in the absence of these features.¹¹⁹

Despite such surveys and prospective follow-up studies, there remains some debate as to the validity of diastolic filling abnormalities as the cause of heart failure symptoms in patients with normal systolic left ventricular ejection fraction, whether hypertensive or normotensive. The optimal means of the contribution of diastolic filling assessment to the definition of these patients remains somewhat controversial.

As with the assessment of coronary involvement and ischemia, invasive measures calculating the rate of decline in ventricular pressures in early diastole are often regarded as a gold standard by some cardiologists but in reality these can only reliably evaluate the active process of diastolic relaxation.¹²⁰ Changes in the more detailed end diastolic pressure volume filling loop are the most detailed physiological measure, but these are generally approximated in clinical practice rather than measured directly.

Estimates of ventricular stiffness can be used as a surrogate for a pressure volume study, but this parameter is affected by any condition that will increase ventricular filling pressure. In addition, the assumption that ventricular hypertrophy is related to changes in passive diastolic filling is not entirely valid. For example, an acute ischemic stress will cause the upward shift in EDPV (end diastolic pressure volume) relationships, as will pericardial constriction and abnormal mechanical ventricular interaction. In some surveys of diastolic heart failure, EDPV curves are normal

both at rest and during exercise.¹²¹ In others they are abnormal. This divergence of findings has further fueled questions as to the true nature of the abnormality in patients with heart failure symptoms and yet a preserved LV systolic ejection fraction.¹²² The key issue is in the clinical definition of the patients themselves, and there is no doubt in almost every published survey in community or hospital clinic setting that these patients are predominantly older, female, hypertensive patients with echocardiographic ventricular hypertrophy.¹²³ The concomitant presence of obesity and hypertensive ventricular hypertrophy is common in many surveys. This simple association alone would seem logical, and many clinicians look to a cardiac cause for their symptoms, but it is still unclear if the linkage that so many feel is intuitive is indeed causal.

There is no doubt that echocardiographic parameters of diastolic filling and altered wall tension or echo backscatter are different between physiologic and pathologic hypertrophy. The latter is what is associated with isolated diastolic heart failure, whereas the former is associated with enhanced physical capacity and well being. In this respect, there is a lot of concern that the eccentric (predominantly septal) hypertrophic remodeling pattern of hypertensive heart disease should be differentiated from that seen with variants of genetic hypertrophic cardiomyopathy (HOCM). Although hypertensive eccentric hypertrophy is generally a less severe pattern than concentric remodeling in terms of its prognostic impact,¹²⁴ clearly HOCM has separate prognostic implications and differing molecular mechanisms that are not responsive to measures lowering BP that will predominantly reverse eccentric or concentric hypertensive ventricular remodeling.¹²⁵ The coexistence of hypertension and HOCM predictably causes confusion unless based on a molecular analysis. This is generally not available in routine practice, and it is clear that the linkage of many of these polymorphisms to outcome is still too complex to apply. The default position of some opinions is of course that all septal hypertrophy should be regarded as potentially malignant.¹²⁶

Recent useful data looking at the value of BNP measurements confirm that this parameter (commonly seen as of diagnostic value in the definition of systolic dysfunction) is not in itself a good enough marker to allow reliable triage (at least of echocardiographic indices of diastolic ventricular function). In 72 hypertensive patients with heart failure symptoms, Mottram et al.¹²⁷ found that although BNP did relate independently to ventricular and atrial systolic parameters it was normally only within the high normal range in patients with echocardiographic diastolic dysfunction and therefore has limited positive diagnostic value in patients.

Contractile function and nonechocardiographic methods

MRI studies

The role of magnetic resonance and positron emission tomography studies in the assessment of the hypertensive patient continues to emerge. For example, Akinboboye et al. defined that myocardial oxygen demand in the hypertensive hypertrophied ventricle is best calculated using

carbon-11 labeled acetate, and found that hypertensive LVH was most closely related to the physical wall stress as approximated by the stress mass heart rate product.¹²⁸

The analysis of diastolic function by cardiovascular magnetic resonance can be completed to combine estimates of three-dimensional chamber volume, filling velocity, and flow, as well as myocardial strain and energy content.¹²⁹ These technologies can focus on specific regions of the myocardium (for example, a hypertrophied septum) and provide a real-time analysis of function applicable in clinical practice. Lamb and colleagues¹³⁰ from Leiden, using phosphorus³¹ magnetic resonance spectroscopy, were able to readily define impaired LV filling in hypertension by an analysis of wall thinning (peak filling rates with normal systolic contractility). In association with these changes, atropine dobutamine stress levels of myocardial phosphocreatinine/ATP ratios were lowered from those values seen in normotensive controls. Although not all studies agree with these observations,¹³¹ the accuracy of the technology and its ability to link energy metabolism with contractile function (as well as much more accurate morphological data than are possible with echocardiography)¹³² might mean that this is the key area where the origins and significance of diastolic filling abnormalities in hypertension will finally be defined. Although echocardiographic measures are strongly correlated with MRI studies in selected echogenic patients, MR protocols still allow more accurate planimetry and variance in LV mass measurements are reduced about 40% (21% to 13%).¹³³ This reproducibility of assessment upon repeated measures is now widely accepted.

PET can similarly accurately map fatty acid oxidation and turnover in the heart. From a group based in St. Louis, data have been derived across a range of ventricular remodeling showing that myocardial fatty acid uptake, oxidation, and metabolism can be directly correlated to left ventricular mass in hypertension (as well as in other states such as ischemic cardiomyopathy).¹³⁴

Coronary blood flow reserve (the maximal rise in coronary blood flow above its resting autoregulated values for a given perfusion pressure) can be accurately measured using N¹⁵-labeled ammonia in hypertensive patients.¹³⁵ For example, the impact of BP-lowering therapy on the rest or stressed CFR of individual patients can be seen to be improved in response to treatment.¹³⁶ This type of study is regarded by some as the only truly quantitative noninvasive technique for the definition of coronary flow. These studies do not underestimate flow, as occurs with coronary sinus sampling.

PET studies

Gimelli et al.¹³⁷ used the flexibility of PET studies of N¹⁵ ammonia labeling (both at rest and following dipyridamole flow stress) to study the influence of ventricular hypertrophy on regional perfusion patterns in 50 hypertensive patients. Using this technology, they were able to show that patients with regional defects in perfusion were more likely to have ventricular hypertrophy but that overall myocardial blood flow was not simply related to total ventricular mass estimates. During pharmacologic stress, hypertensive patients who preserved a homogenous pattern of perfusion showed reduced coronary flow.

In the same way as MRI techniques have differentiated the stricture of the septum in HOCM from asymmetrical septal hypertrophy of hypertension, PET studies of glucose uptake show altered metabolism. F¹⁸(2)-deoxy-glucose fractional uptake ratios for the septum and posterior LV wall are similar in patients with HOCM or hypertensive heart disease but that the regional uptake is more heterogeneous in HOCM.¹³⁸

CARDIAC RHYTHM IN HYPERTENSION

Assessment and relevance of arrhythmia in hypertension

The definition of cardiac arrhythmia in asymptomatic and symptomatic patients with hypertension is facilitated by ambulatory recordings either of a continuous or intermittent (where patients are symptomatic) nature. This allows a basic link to be made between patient symptoms (generally of palpitation but more realistically variably described) and rhythm. The key factor in hypertensive heart disease is an assessment of ventricular structure (generally echocardiographic) allowing both systolic and diastolic contractility; intercurrent valve function, and hypertrophy to be established. Although the presence of baseline conduction abnormalities has been alluded to previously, investigation of these generally relates to the linked processes of defining hypertrophy, ischemia, and valve function described previously. Two major areas require specific mention in the analysis of cardiac rhythm in hypertensive patients: atrial fibrillation and ventricular arrhythmia. Management of these conditions in hypertension is dealt with elsewhere in the text.

Atrial flutter-fibrillation

The etiological links among atrial fibrillation, hypertension, and stroke disease are important. As is now well appreciated, nonrheumatic atrial fibrillation is associated with an approximately fivefold increase in the risk of ischemic stroke and a 5 to 7% yearly increase in risk that increases with age. In addition, atrial fibrillation is associated with an increased incidence of clinically silent cerebral infarction and increased mortality. Treating hypertensive patients' stroke risk must take into account the definition of atrial fibrillation (and to a lesser extent atrial flutter coexistent with hypertension).

Unfortunately, few specific studies of atrial flutter and its association to hypertension have been completed. In patients with atrial flutter, there is a lesser prevalence of thromboembolic events. However, atrial flutter does *not* have a benign association where it occurs with concomitant hypertension. Using multivariate analysis, Seidl et al. (following only 191 patients with atrial flutter) found that the only independent risk factor on multivariate analysis for predicting thromboembolic events was a history of hypertension (OR = 6.5; 95% confidence intervals 1.5 to 45).¹³⁹ Atrial flutter cannot be ignored in the hypertensive patient, even if it is asymptomatic, and in contrast to many other clinical presentations should not be regarded as a benign feature.

In population studies, the relative risk ratio for acute atrial fibrillation is strongest at the onset of defined ischemic heart disease but diminishes in these patients over time. In contrast, the rate of atrial fibrillation is approximately 1.42 times increased in hypertensive men compared to normotensive men—and although congestive heart failure, valvular heart disease, and cardiomyopathy are important risk factors for the development of AF they are relatively uncommon in *known* AF patients.¹⁴⁰ Again, atrial fibrillation and hypertension are prevalent, and frequently coexistent, conditions in the elderly. The incidence of both *increases* with advancing age and independently they can both create significant burden of morbidity and mortality.¹⁴¹ Although the interrelationship of these two conditions is long established,¹⁴² the etiological details of this linkage are not yet well separated.

Hypertension is associated with left ventricular hypertrophy, impaired ventricular filling, left atrial enlargement, and a slowing of atrial conduction velocity. Such simple independent changes in cardiac structure clearly favor the loss of sinus rhythm and the development of atrial fibrillation. They also increase the risk of thromboembolic complications in both states. However, left atrial diameter (for example) determined by M-mode echocardiography does not predict stroke in patients with AF.¹⁴³ The pathological linkage of atrial fibrillation to hypertension is strong and simple, although dependent on a progression of several factors. Many factors contribute to changes in left atrial size, which in turn alters left atrial conduction and contributes to the promotion of paroxysmal atrial fibrillation. This links directly to the presence of increased left ventricular mass in hypertensive atrial fibrillation,¹⁴⁴ and as with ventricular arrhythmia is generally *unrelated* to concomitant epicardial coronary disease.¹⁵⁵ Thus, the important investigational issue is that in the hypertensive patient there should not be an immediate assumption that atrial fibrillation is a marker of coronary disease when in point of fact this is true only in the minority.

Verdecchia et al.¹⁴⁵ followed up 2482 hypertensive patients, all of whom were in sinus rhythm at presentation. Excluded were subjects with known valvular heart disease, CAD, ventricular arrhythmia, and thyroid or lung disease. This investigation reported that the incidence of a first episode of atrial fibrillation was 0.46 per 100 person-years (n=61). These affected patients at entry were older (59 versus 51 years), had higher office and 24-hour mean SBP (165 and 144 versus 157 and 137 mmHg, respectively), had a greater left ventricular mass {58 versus 49g/height[m](2.7)}, and echocardiographic left atrial diameter (3.89 versus 3.56 cm). In a multivariate logistic regression analysis, only age and left ventricular mass predicted the evolution of a first episode of atrial fibrillation in hypertension. They calculated that for every 1 standard deviation increase in left ventricular mass the risk of atrial fibrillation was increased 1.20 times (95% CI, 1.07 to 1.34). Interestingly, atrial fibrillation became chronic in only 33% of the subjects in the study during the follow-up period. Similarly, age, left ventricular mass, and left atrial diameter were independent predictors of chronic atrial fibrillation. The ischemic stroke rate was 2.7% and 4.6% per year for paroxysmal

and chronic atrial fibrillation, respectively. The interesting aspect of this study was that increased left atrial size predisposed to the degeneration of PAF to chronic or persistent AF. Thus, echocardiographic assessment may play a role in this hypertensive patient subgroup.

The general population prevalence of atrial fibrillation in the elderly is associated with clear structural changes in the heart definable at echocardiography. In the Framingham study, subjects routinely evaluated with M-mode echocardiography (n=1924 aged 59 to 90 years) provided data for analyzing the association of echocardiographic features with atrial fibrillation risk after adjustment for age, sex, hypertension, coronary heart disease, congestive heart failure, diabetes, and valvular heart disease.¹⁴⁶ Over a mean follow-up of 7.2 years, 154 subjects (8.0%) developed atrial fibrillation. Multivariable stepwise analysis identified left atrial size (hazard ratio [HR] per 5-mm increment, 1.39; 95% confidence interval [CI], 1.14 to 1.68), left ventricular fractional shortening (HR per 5% decrement, 1.34; 95% CI, 1.08 to 1.66), and sum of septal and left ventricular posterior wall thickness (HR per 4-mm increment, 1.28; 95% CI, 1.03 to 1.60) as independent echocardiographic predictors of atrial fibrillation. The likelihood of atrial fibrillation grew markedly when these changes occurred together, giving cumulative 8-year age-adjusted atrial fibrillation rates of 7.3 and 17.0%, respectively, when one and two or more highest-risk-quartile features were present compared with 3.7% when none was present. These echocardiographic precursors offer prognostic information beyond that provided by traditional clinical atrial fibrillation risk factors.

Although conventional therapy of atrial fibrillation has focused on interventions to control heart rate and/or rhythm and the prevention of stroke through the use of antithrombotic anticoagulant medications, in patients with hypertension and atrial fibrillation aggressive management of BP by reversing structural change in the heart can reduce the likelihood of thromboembolic complications and can retard or prevent the occurrence of atrial fibrillation.

The restoration of sinus rhythm by DC cardioversion is feasible in hypertensive atrial fibrillation, but the maintenance of sinus rhythm is lowest in patients with ventricular hypertrophy or concomitant ventricular dysfunction.¹⁴⁷ Such former strategies are currently being reevaluated because the benefits of rhythm control seem limited and the risks may outweigh benefit. The management issues will be dealt with elsewhere, but the key features for the development of atrial fibrillation are clear. The integrated risk of stroke in the hypertensive patient with atrial fibrillation is such that anticoagulation should be a priority.¹⁴⁸

Ventricular arrhythmia

The presence of significant ventricular arrhythmia in hypertension is well established, as is the increased incidence of sudden death frequently assumed to represent serious ventricular arrhythmia. The key mediators are the involvement of ischemia (which can be clinically silent or symptomatic), prior infarction or left ventricular hypertrophy, and more rarely left ventricular systolic dysfunction.^{149,150} However, there is often confusion over the sequence of

events and the primary mediator in individual hypertensive patients. The links among serious arrhythmia, ventricular structural changes, arterial pressure/wall stress, ischemia, and sudden death are clearly complex and interdependent. The coincident occurrence of silent ischemia and LVH is a particularly powerful but independent (on population analyses) combination in hypertensive patients for future ventricular arrhythmia.¹⁵¹

Holter studies of the prevalence of ventricular arrhythmia show simple ectopy to be common (>70%), but this is confounded by age and many other factors—leading this feature to have little prognostic validity whether applied to uncomplicated or even symptomatic patients with hypertension. Complex ventricular arrhythmia is less frequent, is age and pressure dependent, and appears responsive in part to BP control.¹⁵² Some studies suggest that the frequency of arrhythmia is graded and is related to the severity of LVH even in the absence of angiographic coronary disease.¹⁵³ In terms of prognosis for future cardiac or vascular events, the electrocardiographic definition of arrhythmia is perhaps less significant than the value of defining ventricular structure and/or the presence of inducible ischemia or systolic contractile function.

Prospective studies of arrhythmia and sudden death restricted to cases where hypertensive heart disease has been defined in detail are rare indeed. From the limited information available, there seems to be little evidence of a link between markers such as abnormal QT dispersion in LVH and the risk of serious arrhythmia in cases of hypertension.¹⁵⁴ This is despite well-documented investigation of the utility of QT dispersion in predicting sudden death or arrhythmia in unselected ischemic cardiomyopathy.¹⁵⁵ The impact and linkage of QT_c dispersion to ventricular arrhythmia may be stronger in nonischemic *dilated* cardiomyopathy than in hypertensive LVH.¹⁵⁶ The lack of association to LVH is similar to some studies in hypertension. Saadeh and Vann Jones prospectively found only LVH and documented Holter complex arrhythmia associated with sudden (presumed arrhythmic) death in a small cohort of hypertensive patients. They found only 6 sudden deaths from a long-term study of 54 hypertensive patients over nearly 10 years. Despite this, it remains a valuable if limited observation.

SUMMARY

There is little doubt that patients with hypertension present a particular challenge to completing effective diagnostic

cardiac evaluation of symptoms or signs. Assessment must extend beyond the definition of BP alone, particularly in symptomatic patients. Although there is neither an excuse nor a justification for “scattergun” testing of asymptomatic patients, equally there is evidence that initial assessment of even asymptomatic hypertensive patients should encompass some routine cardiac assessment beyond the simplistic traditions of rest electrocardiography and chest radiology. A variety of factors affecting the hypertensive population (the impact of age, obesity, concomitant diabetes and vascular disease, drug therapy, and ethnicity) complicate coherent cardiac diagnostic evaluation by simple techniques alone. Although hypertensive patients are traditionally viewed as asymptomatic, sophisticated investigational assessment using both stress and rest studies are required to obtain a true overall cardiac risk assessment.

When hypertensive patients do start to present cardiac symptoms, their investigation is not often well served by relying solely on noninvasive or static evaluation techniques applied in an isolated fashion. As a good example, the definition of symptoms due to impaired diastolic relaxation are focused very clearly in the elderly hypertensive population in the community where purely echocardiographic definitions have little meaning unless accompanied by some reasonable quantification of what is often predictably poor exercise capacity and functional activity. The complexity of this patient group may be better analyzed using evolving MR-based technology even more so than invasive physiological measurements of intraventricular diastolic pressure wave forms applicable only to a tiny minority. Similarly, in the definition of myocardial ischemia the confounding impact of hypertension means that noninvasive testing protocols lag well behind a conventional approach of progressing rapidly toward invasive angiographic risk stratification, provided of course that BP control has been correctly achieved and that functional cardiac assessment is not ignored.

The investigation of the cardiac status of hypertensive patients remains a crucial aspect of clinical management in hypertension and cannot be abridged to simplistic BP control issues. Ultimately, many hypertensive patients pass on to be labeled “coronary” or “stroke” patients after surviving critical vascular events often where their systemic arterial BP cannot be sustained (through myocardial loss).

The Effects of Hypertension on the Structure of Human Resistance Vessels

Enrico Agabiti Rosei and Damiano Rizzoni

Key Findings

- Hypertension is associated with changes in the structure of small arteries; namely, eutrophic remodeling (rearrangement of otherwise normal material around a narrowed lumen) or hypertrophic remodeling (vascular smooth muscle cell hypertrophy or hyperplasia).
- Essential hypertension is associated with eutrophic remodeling, whereas hypertrophic remodeling may be present in renovascular hypertension, acromegaly, and non-insulin-dependent diabetes mellitus.
- In arterioles and capillaries of patients with essential hypertension, a functional rarefaction (vessels temporarily not perfused) or a structural rarefaction (vessels actually missing) may be present.
- The presence of an increased media-to-lumen ratio of small-resistance arteries may amplify the effects of hypertensive stimuli, and may reduce organ flow reserve at maximum dilatation.
- In the genesis of eutrophic remodeling, changes in the extracellular matrix may play an important role. In the genesis of hypertrophic remodeling, growth factors, changes in wall stress, and impairment of myogenic response may have more relevant roles.
- Structural alterations in the microcirculation may possess a prognostic significance, in that they may predict the subsequent occurrence of cardiovascular events independently of other known risk factors.
- Hypertrophic remodeling seems to be associated with an even worse prognosis compared to eutrophic remodeling.
- Hypertensive treatment may induce a regression of vascular structural alterations in hypertensive patients. Some drugs (ACE inhibitors, angiotensin II receptor blockers, and calcium antagonists) may be more effective than others (β -blockers, diuretics) in this regard. It is possible that the beneficial effect is due to intrinsic properties of the drugs, more than to blood pressure reduction.
- It is not presently known whether regression of structural alterations of small arteries may improve prognosis *per se* in hypertensive patients, independently of blood pressure reduction.
- To answer this important question, the clinical application of noninvasive techniques of evaluation of vascular structure (presently under investigation) is needed.

Essential hypertension is often characterized by increased peripheral vascular resistance to blood flow, which occurs largely as a result of energy dissipation in arteries with a lumen diameter of 100 to 350 μm^2 and in smaller

arterioles.¹⁴ According to Poiseuille's law, flow resistance is inversely related to the fourth power of the vessel radius. Therefore, minor decreases in the lumen of resistance arteries may induce significant increase in resistance. It has therefore been proposed that this segment of the arterial tree may play an important role in the development of hypertension, and may contribute to its complications.

Vascular changes in resistance arteries may be structural, mechanical, or functional. In any case, a decrease in lumen size occurs.¹ It is now widely accepted that structural abnormalities of microvessels are common alterations associated with chronic hypertension.^{4,5} An increase in arterial wall thickness together with a reduced lumen may play an important role in the increase of vascular resistance, and may be an adaptive response to an increased hemodynamic load. Alterations in the capillary structure and distribution may also be observed.

If structural changes in the resistance arteries are of hemodynamic importance, we have to face several issues, including the problem of how to appropriately measure vascular structure, how to meaningfully quantify or describe structural changes in hypertension, how to properly assess their pathologic role in terms of association with organ damage or cardiovascular events, and how to correct them. We address these issues in this chapter.

VASCULAR STRUCTURAL ALTERATIONS IN HYPERTENSION

Small resistance arteries

Resistance vessel structure is a difficult quantity to measure. *In vivo* studies of vascular resistance measured under conditions of complete relaxation provide a sensitive comparison of apparent resistance vessel diameter but are difficult to interpret because any difference could be due to alterations in vascular architecture rather than structure of the individual vessels.⁴ *In vitro* studies of isolated resistance vessels have the advantage of precise measurements of vascular dimensions without fixation artifacts but suffer from the difficulty that there is no clear agreement as to the length to which vessels should be set.⁴ Histologic studies have the advantage of allowing global analysis but may be compromised by unintended activation of vessels during fixation and lack of knowledge of the intravascular pressure during the process. Therefore, none of the

methods is perfect, and it is unwise to draw strong conclusions on the basis of results from one method alone. Nevertheless, if measurements are confined to a comparison of the ratio of the wall thickness to the lumen diameter (wall:lumen ratio; or with measurements of tunica media thickness, the media:lumen, M/L, ratio)—ratios at a given lumen—there is general agreement that this parameter is increased in hypertension, at least in the more proximal resistance vessels.⁴

In the last two decades, the presence of structural alterations in subcutaneous and omental small resistance arteries dissected from biopsies performed in essential hypertensive patients has been confirmed with a direct investigation using the micromyographic method.^{6–8} Patients with essential hypertension present an increased M/L ratio, without any relevant increase in the total amount of wall tissue as indicated by a media cross-sectional area similar to that observed in normotensive controls. Therefore, most of the structural changes observed in essential hypertension are the consequence of eutrophic remodeling (rearrangement of the same amount of wall material around a narrowed lumen)^{9–12} without net cell growth (Figure 47–1). On the contrary, in patients with some forms of secondary hypertension (renovascular hypertension, primary aldosteronism) a more evident contribution of cell growth—leading to the development of hypertrophic remodeling (vascular smooth muscle cell hypertrophy or hyperplasia)—has been observed^{13,14} (Figure 47–1).

In the development of hypertrophic remodeling, a relevant role is played by growth factors, especially endothelin-1 and angiotensin II (Figure 47–2). The mechanisms leading to eutrophic remodeling are less clear. The equivalence in media volume between hypertensive and normotensive blood vessels may be the result of media growth toward the lumen combined with enhanced apoptosis in the periphery of the vessel (Figure 47–2). According to Laplace's law, a smaller lumen decreases circumferential tension. Media stress diminishes due to increased media width, which protects the vessel wall from the effects of elevated

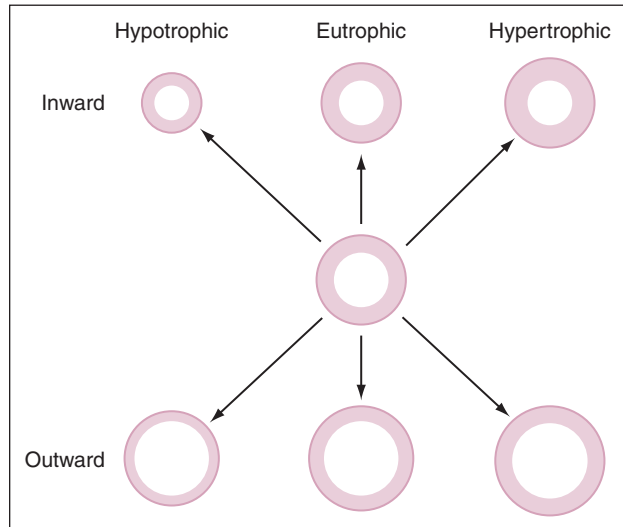

Figure 47–1. Types of vascular remodeling in hypertension. (Redrawn from Mulvany MJ, Aalkjaer C. Structure and function of small arteries. *Physiol Rev* 1990;70:921–71.)

blood pressure.² If hypertension is long-standing or severe, smooth muscle cell growth (in number or size) may predominate over apoptosis, and remodeling may be hypertrophic. As a consequence, this process leads to an increase in media cross-sectional area and in the M/L ratio. Both eutrophic and hypertrophic remodeling may be present to varying degrees and in different vascular beds in the same animal model or human beings.² It has also been suggested that the connections between vascular smooth muscle cells and the extracellular matrix proteins may be labile, allowing the vascular wall components to move relative to each other through a process that may be integrin mediated. It therefore seems likely that the remodeling process may be intimately connected with extracellular matrix protein activity, integrin α , V,¹⁶ and tissue-type transglutaminase.¹⁷

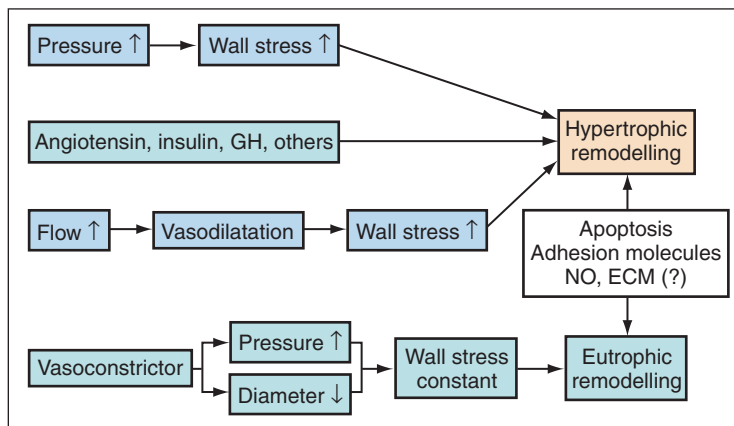

Figure 47–2. Some determinants of small artery remodeling. (Redrawn with modification from Mulvany MJ. Small artery remodeling and significance in the development of hypertension. *News Physiol Sci* 2002;17:105–109, and Mulvany MJ. Small artery remodeling in hypertension. *Curr Hypertens Rep* 2000;4:49–55.)

Among extracellular matrix proteins, matrix metalloproteinases (MMPs) may have a prominent role in modulating remodeling of small arteries. MMPs are catabolic enzymes involved in the degradation of extracellular matrix proteins, and may be divided into three main groups: interstitial collagenases (MMP-1), which degrade type I and II native collagen; gelatinases (MMP-9, MMP-2), which act on elastin and type IV collagen; and stromelysins (MMP-3), which have specific proteolytic action toward proteoglycans, fibronectin, and laminin. The accumulation of collagen and other interstitial proteins in resistance arteries may be facilitated by diminished MMP activity. Changes in extracellular matrix are critically important to vascular remodeling (Figure 47–2). With chronic vasoconstriction (due to the influence of neurohumoral factors, the renin-angiotensin system, catecholamines, and other growth factors), vessels may become embedded in the remodeled extracellular matrix and not return to their more dilated state.¹⁷ Some degree of cell migration, secretion of fibrillar and nonfibrillar components, and rearrangement of extracellular matrix/cell interactions may be involved. Collagen deposition is significantly enhanced in small arteries of spontaneously hypertensive rats (SHRs)¹⁸ and in patients

with essential hypertension¹⁹ (Figure 47–3) and may account for changes in compliance and stiffness.

Cell growth and extracellular matrix deposition may result from blood pressure elevation or from growth-promoting factors such as endothelin-1,²⁰ angiotensin II,²¹ and catecholamines acting through α -adrenoreceptors.²² Deposit of proteins (e.g., collagen) contributes to media thickening (in hypertrophic remodeling) and to the reorganization of vessel wall components, embedding the vessels in the chronically vasoconstricted state (in eutrophic remodeling). Increased extracellular matrix may also result from diminished activity of MMPs. Changes in MMP activity are particularly implicated in the accumulation of types IV and V collagen and of fibronectin in the extracellular matrix of resistance arteries. In hypertensive patients with augmented vascular type I collagen, serum concentrations of MMP-1 are reduced.²³ Finally, a possible stimulus for hypertrophic remodeling may be in increased wall stress, as a consequence of an impaired myogenic response (Figure 47–2). Myogenic response is a pressure-induced vasoconstriction, which is the key component in blood flow autoregulation and in the stabilization of capillary pressure. The loss of such a myogenic response

Figure 47–3. Cellular effects in the vascular wall associated with increased oxidative stress lead to cell growth and migration, upregulation of adhesion molecules, inflammation, endothelial dysfunction, and vascular damage. AP, activator protein; ET, endothelin; ICAM, intracellular adhesion molecule; MCP, monocyte chemoattractant protein; NADH, reduced nicotinamide adenine dinucleotide; NADPH, reduced nicotinamide adenine dinucleotide phosphate; NFκB, nuclear factor κB; NO, nitric oxide; NOS, NO synthase; PAI-1, plasminogen activator inhibitor-1; SMC, smooth muscle cell; TGF, transforming growth factor; and VCAM, vascular adhesion molecule. was previously observed in patients showing the presence of hypertrophic remodeling of small arteries.²⁴

Time course of vascular structural alterations and blood pressure

The time course of the vascular structural changes in hypertension is not clear; nor is their role in promoting hypertension. Early detection of increased wall thickness, even in the pre-hypertensive phase of SHR, may point toward a predominantly genetic mechanism for vascular structural changes. However, it is not clear whether vascular structural changes are an important factor in initiating hypertension in the SHR. If this is the case, the late increase of blood pressure (after the development of vascular structural changes) might be hypothetically explained by additional events such as a progressive increase of adrenergic activity or a progressive reduction of total vascular bed. In fact, it has been demonstrated that vascular structural abnormalities may act as an amplifier, able to increase the effect of any hypertensive stimulus (Figure 47-4).²⁵⁻²⁷

On the other hand, at least two findings would suggest that the influence of vascular structural changes on blood pressure is of minor importance at best: (1) the presence of an increased M/L ratio in 4-week-old pre-hypertensive SHR as compared to Wistar-Kyoto normotensive controls²⁸ and (2) the persistence of a significant regression of vascular alterations in SHR treated for a short period of time with nitrendipine from week 8 to week 12 (even at 38 weeks of age) in the presence of high pressure levels almost indistinguishable from those of untreated SHR of the same age.²⁹ Similar dissociations between vascular structural alterations and blood pressure values were previously observed in one-kidney/one-clip rats after unclipping of the renal artery and in SHR after withdrawal of a prolonged angiotensin II infusion. Both models showed a rapid decrease in blood pressure despite a persistent increase of the M/L ratio.³⁰

Therefore, there is no clear evidence for the possible role of vascular structural changes in initiating hypertension. Neurohumoral or functional factors would play an important role, and the presence of a vascular amplifier of hypertensive stimuli is not enough for the induction of

Figure 47-4. Relationships between percentage of contraction of vascular smooth muscle cells and lumen diameter in normotensive controls (NT) and in hypertensive patients (EH) with an increased media-to-lumen ratio. Structural alterations amplify vasoconstrictor stimuli (for any level of vascular contraction the lumen is smaller in hypertensive patients) and reduces flow reserve at maximum vasodilatation.

hypertension if the stimulus is lacking. Therefore, a complex interplay between vascular structure and function as well as neurohumoral factors may be postulated, and even the rebound effect of the increased hemodynamic load on vascular structure should be taken into account (Figure 47-5).^{5,31} Figure 47-6 shows the evolution in time of the various changes that may occur in the vascular wall in hypertension, as suggested by Schiffrin.²

Arterioles and capillaries

Not only the diameter of individual vessels but the absolute number of perfused vessels contributes to total vascular resistance. Vascular rarefaction may be defined either as a functional rarefaction (when the vessels are temporarily not perfused or “recruited”) or an anatomical rarefaction, when vessels are actually missing.^{32,33} Many studies have reported microvascular rarefaction in some, but not all, vascular beds in hypertensive animals. Data available for humans are relatively scanty.^{34,35} Greene et al.³⁶ calculated

Figure 47-5. Role of resistance vessel structure in the control of blood pressure. Solid lines show fast processes; dashed lines show slow processes. ChrW(61636), multiplier. Increased blood pressure will tend to increase wall thickness; increased cardiac output (flow) will tend to increase vessel diameter. (Redrawn from Mulvany MJ. Small artery remodeling and significance in the development of hypertension. *News Physiol Sci* 2002;17:105-09, and Mulvany MJ. Small artery remodeling in hypertension. *Curr Hypertens Rep* 2000;4:49-55.)

Remodeling of resistance arteries in essential hypertension and effects of antihypertensive treatment. *Am J Hypertens* 2004;17:1192–1200.)

that a rarefaction of about 42% of third-order arterioles would increase tissue flow resistance by 21%.

A reduction of arteriolar [vessels smaller than 100 μm] and capillary number in skeletal muscle and other vascular beds of spontaneously hypertensive rats has been observed, together with a rarefaction of small vessels in the cremasteric muscle of renal hypertensive rats.^{32,33} A reduction of arteriolar and capillary density in conjunctival microcirculation of hypertensive patients has been also detected by direct visualization *in vivo*.³⁷ In addition, Gasser et al.³⁸ observed a 20% reduction of capillary density in the nailfold capillaries using capillary microscopy *in vivo*.

A capillary rarefaction in the intestinal circulation,³⁹ in skeletal muscle,⁴⁰ in the myocardium, and in the stomach has been observed. However, because these are necropsy-derived data a main problem is a lack of healthy control data—the controls often being subjects with diseases that may impact on the microcirculation. Recently, some studies from Antonios et al.^{34,35} using a direct technique have demonstrated the presence of capillary rarefaction in the skin of the fingers of patients with essential hypertension or borderline hypertension, and of normotensive offspring of patients with essential hypertension.

3-VASCULAR STRUCTURAL ALTERATIONS AND END-ORGAN DAMAGE

It has been proposed that structural alterations in the resistance vasculature may act as a “vascular amplifier” able to enhance the effects of any hypertensive stimulus^{25,27} (Figure 47-4), but there is also some disagreement about this “amplifier hypothesis.”^{41,42} In any case, an important consequence of the presence of structural alterations in small resistance arteries and arterioles may be an impairment of vasodilator reserve.^{43,44} In fact, remodeling of small resistance arteries is characterized by a narrowing of the lumen, which leads to an increase of flow resistance even at full dilatation (i.e., in the absence of vascular tone).

A significant correlation between coronary flow reserve and subcutaneous small resistance artery remodeling has been detected in hypertensive patients, suggesting that structural alterations in small resistance arteries may be present at the same time in different vascular districts (reflecting even clinically more important alterations in other vascular beds, including the coronary circulation).⁴⁵ A correlation between flow reserve in the forearm and M/L ratio of subcutaneous vessels has been also observed.⁸

The extent of structural alterations in small resistance vessels is more pronounced in patients with both diabetes mellitus and hypertension, suggesting that clustering of risk factors may have synergistic deleterious effects on the vasculature.^{24,46} Some data suggest that alterations in small resistance artery morphology may represent the most prevalent, and perhaps earliest, form of preclinical target organ damage in essential hypertension.⁴⁷ In addition, structural alterations in resistance arteries may be closely related to target organ damage, especially at the cardiac level. In fact, a linear relation between M/L ratio of subcutaneous small resistance arteries and left ventricular mass index or relative wall thickness has been detected in hypertensive patients. This relation with left ventricular geometry was more evident in patients with activation of the renin-angiotensin-aldosterone system.⁴⁸ Therefore, alterations in the microcirculation may play an important role in the development of target organ damage in hypertension.⁴⁹

VASCULAR STRUCTURAL ALTERATIONS AND PROGNOSIS

It has been proposed that cardiovascular events are the consequence of vascular damage at both the macro- and microcirculatory level. Hence, the presence of structural alterations in the microcirculation may represent an important link between hypertension and ischemic heart disease, stroke, or renal failure. To evaluate the possible presence of a relationship between structural alterations in the subcutaneous small resistance arteries and the occurrence of cardiovascular events, 151 hypertensive and/or diabetic patients (together with some normal subjects) in whom a basal evaluation of small arteries morphology was available were evaluated.⁵⁰ All subjects were submitted to a biopsy of subcutaneous fat, and small resistance arteries were dissected and mounted on an isometric myograph. The tunica media to internal lumen ratio was measured. The subjects were reevaluated after an average follow-up time of 5.6 years. Thirty-seven subjects had a documented fatal or nonfatal cardiovascular event (5.32 events/100 patients/year), in that they suffered from ischemic heart disease, heart failure, cerebral ischemic attacks, and renal failure. Then, the subjects were subdivided according to the presence of an M/L ratio of small arteries greater or smaller than the mean and median value observed in the entire population.

Life table analyses showed a significant difference in event-free survival between the subgroups (Figure 47-7). Cox’s proportional hazard model, considering all known cardiovascular risk factors, indicated that only pulse pressure ($p=0.009$) and M/L ratio ($p<0.0001$) were significantly associated with the occurrence of cardiovascular

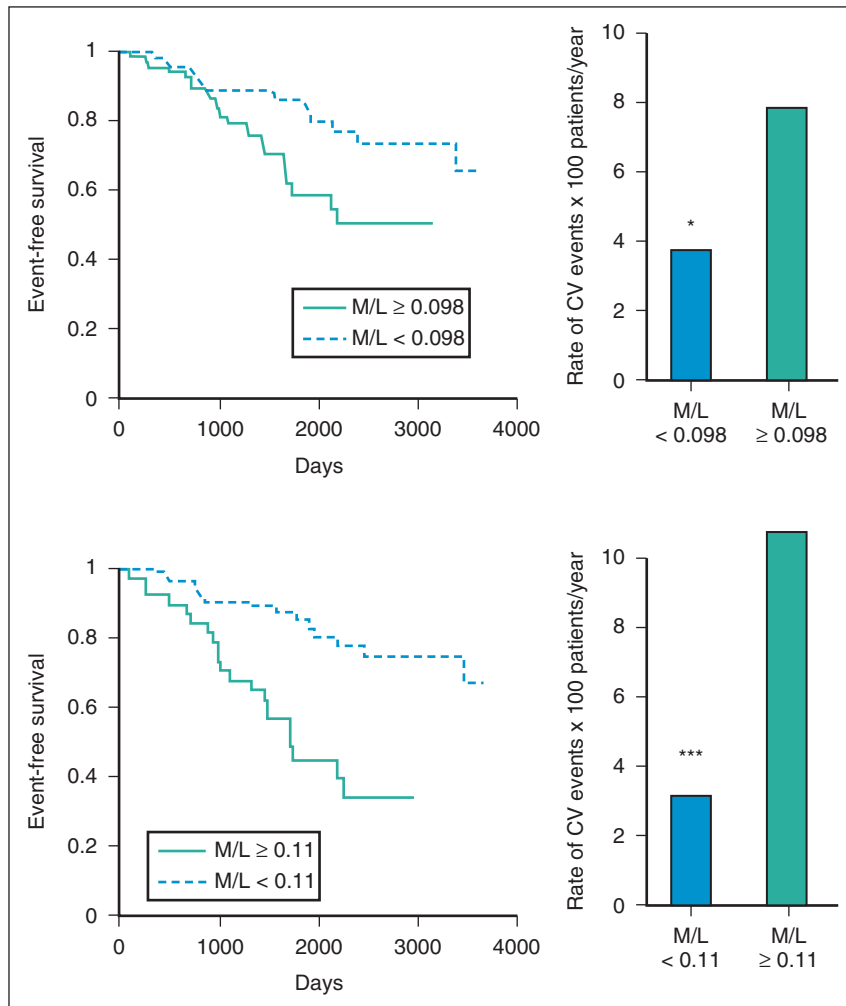

Figure 47-7. Top left: Event-free survival (Kaplan-Meier method) in group of patients with a media:lumen (M/L) ratio of subcutaneous small arteries ≥ 0.098 (mean and median values observed in whole population) ($n=64$, solid line) or < 0.098 ($n=64$, dotted line). Mantel-Cox test between curves, $p=0.015$; Breslow test between curves, $p=0.036$. Bottom left: Event-free survival in group of patients with an M/L ratio of subcutaneous small arteries ≥ 0.11 (2 SD above mean value of our normal reference subjects) ($n=36$, solid line) or < 0.11 ($n=92$, dotted line). Mantel-Cox test and Breslow test between curves, $p=0.00001$. Top and bottom right: Incidence of cardiovascular (CV) events in subgroups of patients. (Redrawn from Rizzoni D, Porteri E, Boari GEM, et al. Prognostic significance of small artery structure in hypertension. *Circulation* 2003;108:2230-35.)

events.⁵⁰ These results strongly indicate a relevant prognostic role of small resistance artery structural alterations in a high-risk population. More recently, we have reevaluated these data taking into account the characteristics of the vascular remodeling. For the same values of internal diameter, those subjects who suffered cardiovascular events had a greater media cross-sectional area in comparison to those without cardiovascular events⁴⁹ (Figure 47-8). Therefore, it seems that for the same size of vessels a more consistent cell growth (hypertrophic remodeling) means a worse prognosis. It has also been suggested that an impairment of myogenic response may have a relevant role in the development of hypertrophic remodeling in patients at high cardiovascular risk.^{46,49}

The prognostic relevance of vascular structural alterations in the microcirculation has been partly confirmed in a different vascular territory (i.e., the retinal circulation). In fact, Wong et al.⁵¹ observed that in a population-based cohort study of 9648 subjects [the Atherosclerosis Risk in Communities Study (ARIC) Study] retinal arteriolar narrowing (as evaluated by retinal photographs) was associated with a higher risk of coronary artery disease in women but not in men. In particular, for each decrease of one standard deviation of the retinal arteriole to venule ratio (AVR) a greater relative risk of coronary artery disease (1.37) and of myocardial infarction (1.50) occurs.

A similar evaluation was performed in another general population cohort of 4926 subjects in Wisconsin (Beaver

Figure 47-8. Medial cross-sectional area (MCSA) plotted against lumen diameter of the small arteries of patients with hypertension who have subsequently had a cardiovascular event (full squares) or who were event free (full circles) at the time of follow-up. The slopes of the two regression lines are significantly different ($p=0.00009$). (Redrawn from Izzard AS, Rizzoni D, Agabiti-Rosei E, Heagerty AM. Small artery structure and hypertension: Adaptive changes and target organ damage. *J Hypertens* 2005;23:247–50.)

Dam Study). In this study, no relation between smaller AVR and 10-year mortality was observed.⁵² However, in the same cohort the presence of retinal disease (retinal microaneurysms, blot hemorrhages, cotton wool spots, hard exudates, venous beading, new vessels on the disk, and preretinal or vitreous hemorrhages) was associated with increased cardiovascular mortality, with an odds ratio of 1.8⁵³ and with a higher prevalence of cerebral white-matter lesions and stroke.⁵⁴ However, in another study lower grades of hypertensive retinopathy were not associated with a more prominent cardiac or extracardiac target organ damage.⁵⁵ Narrowed retinal arterioles, at least in women, may predict cardiovascular outcome. Therefore, data available suggest a prognostic role of structural changes of the subcutaneous microcirculation in patients with hypertension and other cardiovascular risk factors, probably because they are associated with similar changes in the coronary, renal, and cerebral microcirculation.

EFFECT OF ANTIHYPERTENSIVE TREATMENT

According to the previously mentioned observations, the possible regression of vascular alterations in small resistance arteries is an appealing goal of antihypertensive treatment. However, some years ago the first study employing a direct and reliable technique for the evaluation of structural alterations in the subcutaneous vascular bed^{56,57} failed to observe a complete normalization of the vasculature during long-term antihypertensive treatment. In these studies, the patients were given diuretics, blockers, calcium antagonists, and angiotensin receptor blockers.

More recently, some studies have demonstrated an almost complete normalization of the structure of subcutaneous small resistance arteries with ACE inhibitors (cilazapril, perindopril).⁵⁸⁻⁶¹ On the contrary, the β blocker atenolol

was devoid of effects on resistance vessels, despite a blood pressure reduction similar to that observed with ACE inhibitors.⁵⁸⁻⁶¹

We have also investigated the effects on vascular structure of treatment with the ACE inhibitor lisinopril for 3 years.⁶² The M/L ratio in subcutaneous small resistance arteries was significantly lower in treated hypertensives than in well-matched untreated hypertensives. However, M/L ratio remained significantly higher than that observed in normotensive subjects. Because blood pressure values also remained higher in treated hypertensives than in normotensives, our data suggest that a persistent and complete normalization of blood pressure is probably mandatory in order to obtain a normalization of vascular structure.⁶² A complete normalization of vascular structure of subcutaneous small resistance arteries was, however, also observed after effective treatment with the calcium antagonist nifedipine in an extended-release formulation.⁶³ It seems therefore probable that calcium entry blockers could share with ACE inhibitors the beneficial effect on vascular structure² (Figure 47-9).

On the contrary, diuretics seem to be less effective in terms of regression of vascular structural alterations.⁶⁴ Recently it has been demonstrated that the angiotensin II receptor blockers losartan and irbesartan are also quite effective in normalizing subcutaneous small resistance artery structure in hypertensive patients^{65,66} (Figure 47-10).

The improved structure and function of resistance arteries during renin-angiotensin system blockade may be explained by several mechanisms, including vasodilation. Because angiotensin II induces oxidative stress and promotes inflammation as well as smooth muscle cell growth and migration, blockade of these actions (Figure 47-3) may also play a significant role.² Renin-angiotensin system blockade decreases reactive oxygen species and increases the bioavailability of nitric oxide, improving endothelial

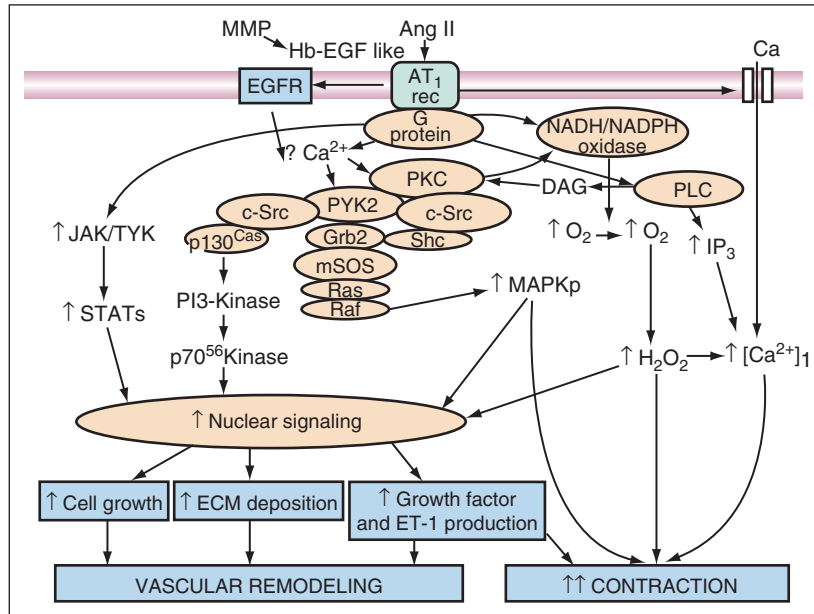

Figure 47–9. Signaling pathways of the AT₁ receptor and Ca²⁺ that participate in vascular remodeling. Blockade of these pathways explains some of the improvement in remodeling and endothelial dysfunction seen with antihypertensive treatment in hypertension. Ang II, angiotensin II; c-Src, normoreceptor tyrosine kinase; [Ca²⁺]_i, intracellular (cytosolic) calcium; DAG, diacylglycerol; ECM, extracellular matrix; EGFR, epidermal growth factor receptor; ET-1, endothelin 1; Grb2, mSOS, Shc, adaptor proteins acting as scaffolding for signaling complex; Hb-EGF-like, heparin binding epidermal growth factor-like growth factor; IP₃, inositol triphosphate; JAK/TYK, Janus family kinases; MAPKp, mitogen-activated protein kinase; MMP, matrix metalloproteinase; NADH, reduced nicotinamide adenine dinucleotide; NADPH, reduced nicotinamide adenine dinucleotide phosphate; p130^{cas}, docking protein; PKC, protein kinase C; PI3, phosphoinositide 3; PLC, phospholipase C; PYK2, calcium-dependent praline-rich tyrosine kinase-2; RAS, Raf, a mitogen-activated protein kinase kinase; and STATs, signal transducers and activators of transcription. Remodeling of resistance arteries in essential hypertension and effects of antihypertensive treatment. *Am J Hypertens* 2004;17:1192–1200 with permission from *The American Journal of Hypertension*.)

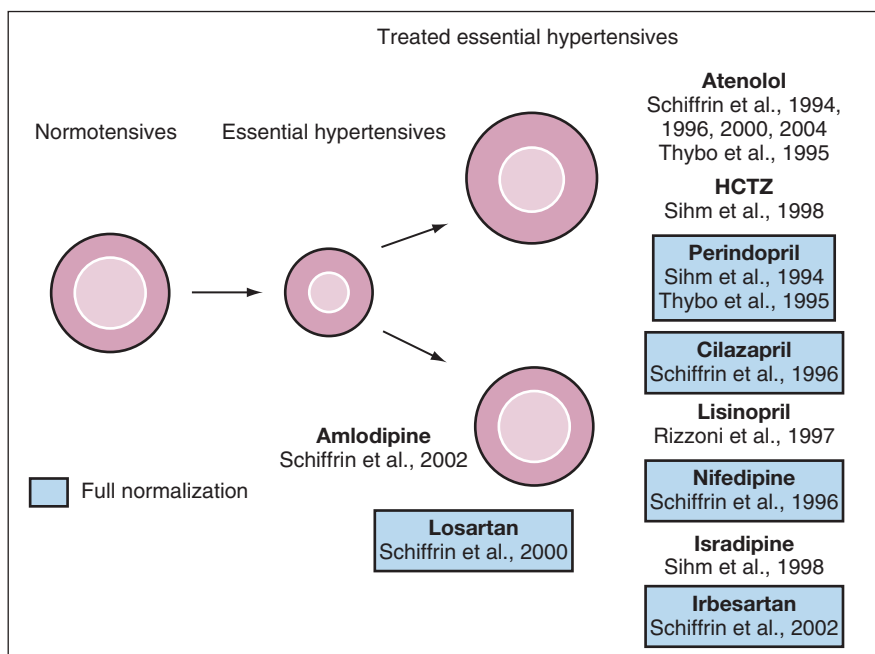

Figure 47–10. Effects of antihypertensive treatment on vascular structure.

function. Blockade of the renin-angiotensin system may also reduce collagen deposition and extracellular matrix remodeling induced by angiotensin II.^{67,68}

Shargorodsky and co-workers⁶⁹ reported a significant increase in small artery elasticity ($p < 0.01$) with valsartan during long-term treatment. Blood pressure was rapidly lowered, suggesting that improved elasticity was not directly related to the acute blood pressure effect of the drug. Treatment with perindopril also improved coronary reserve and significantly reduced pericoronary fibrosis in small vessels of hypertensive subjects.⁷⁰

These findings may have clinical relevance. In fact, recently at least three studies (the LIFE, PROGRESS, and HOPE studies) have demonstrated that drugs able to inhibit the renin-angiotensin-aldosterone system (such as losartan, perindopril, and ramipril) may have some advantage over other drugs, beyond the decrease in blood pressure, in terms of reduced morbidity and mortality in high-risk hypertensive patients.⁷¹ It is possible that their favorable effect on small resistance artery structure may partially explain the additional benefits observed. However, it should be emphasized that the prognostic impact of the regression of vascular structural alterations per se is still unknown, and prospective studies are needed to clarify whether structural alterations in small resistance arteries may be considered an “intermediate” endpoint in the evaluation of the effects of antihypertensive treatment.

CONCLUSIONS

Essential hypertension is associated with alterations in the resistance vasculature. In particular, an increased M/L ratio is almost uniformly detected. However, some methodologic problems in the evaluation of vascular structure in humans remain. In addition, it is not clearly established whether structural alterations in the microcirculation precede

or are a consequence of hypertension. In particular, the causative role of vessel structure in hypertension is still a matter of debate, although vascular alterations may act as an amplifier of hypertensive stimuli.

Structural alterations in the microcirculation are associated with increased cardiovascular risk in hypertensive patients, perhaps as a consequence of an impaired vascular reserve in several vascular beds, including the coronary circulation. Structural alterations in different vascular regions are probably interrelated. It has been observed that the presence of an increase in wall:lumen ratio in the subcutaneous resistance arteries is associated with a worse prognosis in hypertensive patients, and that structural alteration in the microcirculation is probably the most potent predictor of cardiovascular events, together with pulse pressure. The characteristics of vascular remodeling might also be relevant in this context, in that hypertrophic remodeling seems to be associated with a worse prognosis.

The presence of structural alterations in the microcirculation may have an important role in the development of ischemic heart disease, heart failure, stroke, and renal failure. It is conceivable that vascular structural changes in small resistance arteries may be considered, in the future, as an important intermediate endpoint for evaluating the benefits of antihypertensive therapy, although this point needs to be demonstrated by specific intervention studies.

The current method for the evaluation of subcutaneous small artery structure is minimally invasive. Nevertheless, its invasiveness limits its application to large populations. It is possible that noninvasive techniques for investigation of the microcirculation presently under evaluation and validation (such as acoustic, confocal, fluorescence, and intravital microscopy) may in the near future provide important information in achieving a better diagnostic and therapeutic approach in hypertensive patients.

Key Findings

- Raised blood pressure (BP) has adverse consequences in causing brain diseases, including stroke and cognitive impairment/dementia.
- Lowering high BP will help protect the brain from developing these conditions, although optimal protection requires all relevant risk factors to be addressed in a holistic manner.
- Intervening to manage raised BP in mid-life may reduce the risk of cerebrovascular damage and cognitive impairment in later life.
- More than half of all strokes could be avoided if BP were optimized in all persons, as would a reduction in the development of dementias.

Hypertension is the most prevalent modifiable risk factor for both ischemic and hemorrhagic stroke, which is often associated with vascular cognitive impairment and dementia. Importantly, stroke and dementia are significant predictors of reduced total and disability-free life expectancy.¹ This chapter focuses on aspects of these clinical manifestations of hypertension-related brain target organ damage.

ANATOMY AND PATHOLOGY

Although the brain accounts for 2% of the body's weight, it receives 15% of the cardiac output at rest. The blood supply is via two pairs of arteries: the internal carotid arteries and the vertebral arteries (the latter joining to form the basilar artery). The arterial inflow joins in an anastomotic ring (the circle of Willis), from which three pairs of arteries arise on the external surface of the corresponding region of the cerebral cortex (Figure 48–1). Thereafter, these anterior, middle, and posterior cerebral arteries progressively divide into smaller perforating vessels to supply specific brain regions.

Hypertension is an important risk factor for the development of atherosclerotic changes in these vessels. The progression of atherosclerotic plaques in the larger extracerebral vessels (particularly at the carotid bifurcation) and in the medium-sized intracranial vessels (through a process of necrosis, ulceration, and thrombosis with complete or partial vessel occlusion or distal embolization) has been discussed in previous chapters. Furthermore, at the level of smaller arteries (such as the single deep-perforating end-arteries of the deep cerebral white matter) the process of vessel

occlusion by microatheroma and hypertensive lipohyalinosis has also been discussed.

The brain has important adaptive mechanisms to reduced inflow. The circle of Willis acts as a shunt, predominantly anterior to posterior, but also side to side. However, reduced collateral reserve (particularly in association with hypotension) will lead to border-zone or watershed infarction (for example, between anterior and middle, or middle and posterior, cerebral artery territories). There are also physiologic mechanisms to maintain cerebral blood flow (the process of cerebrovascular autoregulation, discussed in a later section). Nonetheless, the brain remains highly sensitive to changes in its blood supply. Loss or reduction of blood flow in a specific vascular territory results in stroke, producing specific pathologic changes related to the duration and degree of ischemia. Importantly, the time interval required to trigger irreversible injury (ischemic sensitivity) varies markedly among different regions. Nonetheless, focal ischemia of 30 to 60 minutes will result in a pannecrosis of all cell types (neuronal, glial, endothelial) within a vascular territory, surrounded by a transition zone of irreversibly injured neurones but preserved glial and endothelial cells (and then normal brain tissue).

Where stroke-related loss of brain tissue exceeds 50 to 100 mLs, dementia may result.² Vascular dementia (the cerebrovascular or cardiovascular-related loss of cognitive function secondary to ischemic, hypoperfusive, or hemorrhagic brain lesions) is the second most common cause of elderly dementia, after Alzheimer's disease. The term encompasses several clinico-pathologic subtypes. First, large-vessel disease may result in multiple large-vessel cortico-subcortical thrombotic or embolic strokes (multi-infarct) or in a single "strategic" stroke. Second, chronic, diffuse, partial, or occlusive small-vessel disease may result in predominantly subcortical white matter ischemia (Binswanger's disease) or frank lacunar infarction(s).³

PATHOPHYSIOLOGY

The pathophysiologic effects of hypertension on cerebral hemodynamics are considered in the following, as are changes in systemic and cerebral hemodynamics that occur in the most common hypertension-related brain injury (acute stroke).

Cerebral blood flow and cerebral autoregulation

The brain arterial blood supply has a low impedance, resulting in a high cerebral blood flow (CBF) of approximately

Figure 48–1. Anatomy of the blood supply to the brain. (From Instructor's Resource CD-ROM to accompany *Porth's Pathophysiology: Concepts of Altered Health States, Seventh Edition*. Philadelphia: Lippincott Williams & Wilkins, 2005, with permission.)

50 mL per 100 g per minute. The brain receives blood during both systole and diastole. In comparison to myocardium, which receives blood during diastole only, brain tissue may be more susceptible to the adverse effects of long-term changes in systolic and pulsatile pressure. CBF is closely coupled to the metabolic needs of brain tissue. For example, CBF is globally increased in epilepsy, anemia, and acidotic states and globally decreased in comatose states. Focal cerebral activation results in regional increases in CBF and oxygen consumption. The absolute level of CBF decreases with age but is similar in uncomplicated hypertensives and age-matched normotensive individuals. However, both aging and hypertension profoundly influence CBF regulation.

CBF is usually maintained at a near-constant level in the face of fluctuations in arterial BP levels across the physiological range by a process of cerebral autoregulation. This is mediated by changes in cerebrovascular resistance resulting from vasomotor changes at the arteriolar level. The mechanisms underlying cerebral autoregulation are as yet incompletely understood, but myogenic, metabolic, and neurogenic mechanisms have been postulated (including roles for nitric oxide, calcitonin gene-related peptide, endothelial-cell potassium channels, and the autonomic nervous system).⁴ Cerebral autoregulation may be described in both static and dynamic terms. The ability of the brain to maintain CBF in response to a steady-state change in

cerebral perfusion pressure is described as *static* cerebral autoregulation (SCA), whereas the maintenance of CBF in response to transient changes in cerebral perfusion pressure (defined as >15 mmHg in <20 seconds) is the *dynamic* component (DCA). Noninvasive methods of measuring cerebral autoregulatory capacity in humans are described in a later section.

In normotensive subjects, when mean arterial pressure falls below approximately 60 mmHg (considered the lower limit of SCA) CBF decreases proportionally with BP (Figure 48–2). The upper limit in normotensive humans, above which CBF increases proportionally with BP, is untested but in primate models is between 120 and 150 mmHg. Chronic hypertension and aging result in a shift in the limits of SCA toward higher pressures in humans, through the induction of structural and functional changes in cerebral arteriolar walls. However, DCA appears to be unaffected by either chronic hypertension or aging.⁵ Moderate BP reduction in chronic hypertension does not precipitate cerebral ischemia due to there being sufficient scope on the autoregulatory plateau to lower arterial pressure without affecting CBF and due to the ability of neuronal tissue to increase oxygen consumption.

In the longer term, sustained BP reduction results in a shift of the SCA curve to the left. Both SCA and DCA are impaired following stroke, in accelerated (malignant) hypertension, and following head injury, resulting in a pressure-

Figure 48–2. Curves depicting static autoregulation in normotensive young (NY), hypertensive young (HY), hypertensive elderly (HE), and hypertensive stroke (HS) subjects. Autoregulation is defined from the relationship between cerebral blood flow and mean arterial pressure.

passive relationship between BP levels and CBF.^{6,7} BP reduction, particularly where this is rapid, may be deleterious in these situations. In addition, where there are established and widespread areas of small-vessel cerebrovascular disease (particularly in the very elderly patient in whom CBF is generally reduced and autoregulation impaired) BP reduction to usual target levels may in theory result in impairment of cerebral perfusion (although this has yet to be addressed by a randomized clinical trial).

The ischemic penumbra following acute stroke

During the first few hours following occlusion of a cerebral artery (and surrounding the dense core of infarcted tissue) is a zone of variable extent and distribution (the ischemic penumbra). The blood supply to the ischemic penumbra is reduced, abolishing electrical activity but not to sufficient levels to induce cell death. Neuronal cells appear to pass through two thresholds as CBF declines. Studies in humans have shown suppression of electrical activity to occur as flow falls below approximately 20 mL per 100 g/minute and irreversible loss of energy-dependent cellular ion gradients to occur at flow rates of approximately 10 mL per 100 g/minute, leading to cytotoxic edema and cell death. In theory, cells that have lost capacity for electrical activity but remain in a hibernated state have the capacity to be fully restored to normal with an increase in blood flow. The distribution and potential viability of the ischemic penumbra following a stroke is influenced by local metabolic activity, vascular anatomy, and the extent of collateral blood flow. The acute stroke phase presents additional challenges to penumbral viability due to relative oxygen deficiency, excitatory amino acid release, spreading waves of electrical depolarization, impaired autoregulation, and

increased BP variability. Methods of imaging the ischemic penumbra in the acute stroke phase are discussed later in the chapter.

Cardiovascular changes in the acute stroke phase

Although approximately two-thirds of the global stroke burden can be attributed to poorly controlled BP levels, a greater proportion of patients present with elevated BP levels immediately following a stroke. Over 80% of patients present with SBP >140 mmHg and 30% with SBP >180 mmHg within the first 48 hours of ischemic stroke, with levels even higher following hemorrhagic stroke. The mechanisms underlying the stroke-associated rise in BP levels are incompletely understood but include the stress of removal to hospital and alterations in autonomic nervous system activity with associated catecholamine, glucocorticoid, and mineralocorticoid release.

Many studies report a strong and independent relationship between the BP level in the acute stroke phase and short- and long-term outcomes, with most reporting a U-shaped relationship. For example, in the International Stroke Trial⁸ for every 10 mmHg rise in SBP above 150 mmHg the risk of early death (by day 14) increased by 4%, and for each 10 mmHg decrease below this level the risk increased by 18%. In primary intracerebral hemorrhage, both the degree of hematoma expansion during the first few hours and patient outcome are related to the SBP level. The natural history of BP levels following stroke is for a spontaneous reduction to occur over a period of 4 to 10 days, with the greatest falls being associated with the highest baseline BP levels. However, no consistent data have emerged regarding the relationship between the magnitude or direction of the BP change in the acute stroke phase and stroke outcome. In addition to the absolute BP level, other abnormalities of cardiovascular function confer independent prognostic information in the acute stroke phase. For example, increases in beat-to-beat BP variability and decreases in cardiac baroreceptor sensitivity, coupled with impairment of autonomic reflexes, independently predict outcome in the short and longer terms.⁹

CLINICAL PRESENTATIONS

Some common clinical presentations of hypertension-related brain injury are considered in the following, with examples of stroke and dementia. Comprehensive details of acute and secondary stroke management are presented later in the chapter.

A case of lacunar stroke

History

An 80-year-old right-handed man presented to the emergency room with a speech disturbance and left arm and leg weakness. He awoke with these deficits and was last known to be symptom free when retiring to bed the previous evening 10 hours earlier. His past medical history was significant for hypertension and hyperlipidemia. He had no known history of myocardial infarction or stroke and no history of calf claudication. He was a life-long nonsmoker. His

hypertension was being treated with a beta blocker and a diuretic, and his hypercholesterolemia with an HMG CoA-reductase inhibitor (statin). He had no known drug allergies. He had no family history of ischemic heart disease or stroke.

Physical examination

BP in both arms was elevated at 180/100, with a regular pulse of 90 bpm. Cardiovascular examination revealed a normally situated cardiac apex; a soft nonradiating systolic murmur at the cardiac base; no carotid, femoral, or supraclavicular bruits; and palpable foot pulses. Respiratory examination was normal. Abdominal examination was normal without organomegaly or abdominal bruits.

Neurological examination

The patient was alert. He had dysarthria, but with no word-forming difficulties, neologisms, or paraphrasias. He was able to follow complex verbal instructions. Cognitive evaluation revealed a Mini-Mental State Examination score of 24/30. Cranial nerve examination confirmed a mild left lower facial paresis. Pupillary light reflexes, the visual fields, and the remainder of the cranial nerves were normal to examination. Fundoscopic examination showed arteriolar narrowing, with arteriolar-venous nicking. Upon examination of the peripheral nervous system, there was diminished tone in the left arm and leg, 2/5 proximal and 2/5 distal strength in the left arm and leg, deep tendon reflex diminishment, and extensor left plantar response. Sensation to light touch was intact in the left arm and leg and there was a coordination deficit consistent with the level of motor weakness. Gait was not tested.

Initial investigations

The blood count, electrolytes, blood glucose, and renal function were normal. The activated partial thromboplastin and prothrombin times were normal. ECG fulfilled voltage criteria for left ventricular hypertrophy. An MRI brain scan was obtained (Figure 48–3, A).

Management

A diagnosis of right lacunar stroke was made using the OSCP classification (Table 48–1). Thrombolysis was not considered due to the onset of symptoms being beyond the 3-hour time window. The acute event was managed initially with aspirin, paracetamol, intravenous saline, and graduated compression stockings to reduce the venous thromboembolism risk. Early assessment and mobilization was initiated by the multidisciplinary team. Secondary preventative measures included the addition of dipyridamole, lipid-lowering therapy, and (2 weeks following the event) BP-lowering therapy with a combination of an ACE inhibitor and a thiazide diuretic. With a combination of hospital and community-based rehabilitation, the patient made a full recovery at 6 months (being independent in daily activities, with mild weakness of the left hand remaining).

Discussion

Classifying stroke events into stroke subtypes on the basis of clinical, neuroradiologic, and cardiovascular criteria confers several advantages (i.e., stratification of the possible etiologies of a stroke and associated risk factors, targeted and efficient use of appropriate investigations, and improved prognostication for survival and functional outcome). Classification systems are based on clinical, cardiovascular,

Table 48–1. The Oxfordshire Community Stroke Project Classification

or neuroradiologic criteria or a combination of these. The TOAST classification of ischemic stroke, designed originally for use in a clinical trial,¹⁰ organizes ischemic stroke according to origin: large-artery atherosclerosis, small-artery disease (lacunar) origin, and cardioembolic or other etiologies (e.g., carotid artery dissection, vasculitis, migraine). However, accuracy of the TOAST classification is dependent on comprehensive pre- and post-stroke investigations, which may not always be obtainable. Even when this information is available, approximately 40% of patients remain unclassified using this system. As a tool for predicting outcome (and with value in the acute stroke phase), most experience has been gained with the Oxford Community Stroke Project (OCSP) classification,¹¹ a system based solely on neurologic examination (Table 48–1)—with neuroimaging distinguishing between infarct and hemorrhage.

Lacunar stroke accounts for approximately 25% of acute ischemic stroke cases in Western populations and is most commonly caused by an occlusion of a deep perforating end artery, commonly through complex small-vessel disease and microatheroma. Embolism is an uncommon cause. Predisposing risk factors include hypertension, age, smoking, and diabetes. The risk of recurrent stroke is lower compared to other stroke subtypes (9% at one year compared to 17%

for PACI), and subsequent cardiovascular events may be reduced further with a combination of antiplatelet, anti-hypertensive, and lipid-lowering therapy.

A case of total anterior circulation infarction (TACI)

History

A 70-year-old right-handed woman was brought to the hospital with drowsiness, inability to speak, and weakness of the right arm and leg. She was accompanied by her husband, who reported that this had happened at breakfast (some 60 minutes earlier). Prior to this she had been symptom free. Her past medical history was significant for hypertension, hypercholesterolemia, myocardial infarction 2 years previously, and peripheral vascular disease giving rise to bilateral calf claudication. She had stopped smoking at the time of the myocardial infarction, having been a 20-cigarette-per-day smoker prior to this for most of her adult life. Her hypertension was being treated with a combination of an angiotensin-converting enzyme inhibitor and a diuretic. She was also receiving aspirin 75 mg daily and an HMG CoA-reductase inhibitor (statin). There was a family history of ischemic heart disease after the age of 50.

Physical examination

BP was 160/90 in both arms, and the pulse was 80 bpm and irregular. Her lungs were clear to auscultation. Cardiovascular examination showed a laterally displaced cardiac apex with irregular impulse and no added sounds. There were soft bilateral anterior cervical and femoral bruits. Femoral pulses were present, but dorsalis pedis and posterior tibial pulses were impalpable. Abdominal examination revealed no organomegaly or abdominal bruits.

Neurological examination

The patient was drowsy but rousable to voice. She spoke in abbreviated syllables insufficient to form words. She was unable to follow simple verbal commands. Further cognitive evaluation could not be performed because of the extent of the dysphasia. Cranial nerve examination revealed a right homonymous hemianopia, a preference for gaze to the right, a right lower facial paresis, a diminished right corneal reflex, and tongue deviation to the right. Pupillary light reflexes were normal. Fundoscopic examination revealed arteriolar narrowing and tortuosity. Upon examination of the peripheral nervous system, there was hemiparesis of the right arm and leg (power 0/5 all groups), with hypotonia, diminished deep tendon reflexes, and an extensor right plantar response. Sensory examination was limited by language disturbance, but there appeared to be right-sided deficits to pinprick and light touch sensation.

Initial investigations

Full blood count, electrolytes, blood glucose, renal function, and clotting studies were unremarkable. ECG showed atrial fibrillation and evidence of an established anterior myocardial infarction. Neuroimaging showed early signs of infarction in the territory of the left MCA (Figure 48–4, A).

Management

A diagnosis of total anterior circulation infarction (TACI) was made (Table 48–1). The patient was considered for intravenous thrombolysis. Following discussion with the family, including explanation of the potential risks and benefits of treatment, she received intravenous r-tPA 120 minutes following symptom onset. During administration of the drug, stroke severity scores improved. She was admitted to the stroke unit. At discharge from the hospital on day 21 there was a partial right hemianopia but no sensory neglect, and although mild weakness of the right arm remained she returned home to an independent existence with help from her husband. Appropriate attention was paid to secondary prevention strategies, which included introduction of anticoagulation for permanent atrial fibrillation.

Discussion

TACI accounts for approximately 17% of acute ischemic strokes and is commonly caused by MCA occlusion by local disease or embolism from proximal arteries or the heart, or as a result of internal carotid artery occlusion. The risk of death or severe disability following TACI is high (Table 48–1). Intravenous thrombolysis with rtPA administered

within 3 hours of the development of symptoms of ischemic stroke has been shown to reduce the risk of the combined endpoint of death or dependency at follow-up in all ischemic stroke subtypes (discussed further later in the chapter).

A case of cognitive decline due to cerebrovascular disease

History

An 80-year-old man was referred to his general practitioner by his wife, who had noticed he had become progressively more forgetful over the previous year. Initially, he had begun to lose his way while driving his car along previously familiar routes. He had become neglectful of his usual hobbies, and more recently had developed difficulty in

A
Figure 48–4. (A) CT of acute cerebral infarct (i) showing effacement of sylvian fissure “insular ribbon sign” and (ii) showing “dense MCA sign.” (B) MR image showing an acute left middle cerebral artery infarct on T2-weighted imaging, apparent diffusion coefficient (ADC), and diffusion-weighted imaging (DWI) scans.

B
Figure 48-4.—cont'd

remembering the names of family members or close friends. Sleep had become fitful, and more recently he had developed periods of depression. His past medical history was significant for type II diabetes mellitus and hypertension, both diagnosed 12 years previously. His diabetes was treated with a combination of an oral biguanide and a sulphonyl-urea and his hypertension with a diuretic. The last glycated hemoglobin (HbA1c) level one year previously had been 9.0%.

Physical examination

BP was 170/100 in both arms, and the pulse was 70 bpm and regular. Cardiorespiratory examination revealed clear lung

fields, a soft nonradiating systolic murmur at the cardiac base, no vascular bruits, and impalpable posterior tibial and dorsalis pedis pulses bilaterally. Bilateral corneal arcus was present. Abdominal examination was normal.

Neurological examination

The patient was alert but spoke with occasional paraphrasias. He was able to follow 3-step verbal instructions. A score of 16/30 was obtained on Mini-Mental State Examination. Cranial nerve examination revealed no abnormality, visual fields were intact, pupillary light reflexes were normal, and there was arteriolar narrowing and tortuosity upon funduscopy. Arm and leg tone were mildly

increased, and there was global exaggeration of all deep tendon reflexes in the limbs (with no asymmetry). Both plantar responses were extensor. Sensory and cerebellar examinations were normal.

Investigations

Complete blood count, electrolytes, renal function, and clotting studies were normal. Random plasma glucose level was 11.0 mmol/L. An ECG fulfilled the voltage criteria for left ventricular hypertrophy. Referral was made to the memory clinic at the local hospital. There, detailed neuropsychologic testing was conducted—revealing deficits in episodic, semantic, and working memory (with relative preservation of personality). An MRI brain scan was performed (Figure 48–3, B). A diagnosis of vascular dementia was made. With liaison with primary care, a strategy for better control of his diabetes and BP was devised, aspirin commenced, and community mental health support accessed with appropriate caregiver support. A 3-month trial of an antidepressant was also commenced.

Discussion

Cognitive decline due to cerebrovascular disease encompasses a spectrum of underlying causes ranging from multiple cortical or subcortical infarcts to a single strategic infarct (e.g., genu of the internal capsule, thalamus) to ischemic demyelination of the white matter. Typical cases of vascular dementia have preexisting vascular risk factors, symptoms, and signs of cerebrovascular disease; undergo a step-wise deterioration; and unlike other forms of dementia usually preserve personality and insight until late in the disease. However, distinguishing vascular from other types of dementia is often not possible because (1) vascular risk factors are being increasingly recognized as independent risk factors for Alzheimer's pathology, (2) the classical step-wise deterioration in cognitive function with associated focal symptoms or signs of neurological disease does not always occur in vascular cases, and (3) frequently there is evidence of both vascular and Alzheimer's pathology. The evidence of vascular risk reduction on the progression of cognitive decline is discussed later in the chapter. Such a strategy may also reduce the incidence of subsequent macrovascular disease in these individuals.

DIAGNOSTIC TECHNIQUES

The discussion of investigational techniques for evaluating cerebrovascular disease will be limited to brain imaging techniques because these are of direct relevance to this chapter. Various imaging modalities have advanced the understanding of cerebrovascular disease (both acute and chronic) and the effect of BP and changes in blood flow on cerebral function. Indeed, results of imaging studies make a major contribution to the diagnosis and management of both chronic and acute cerebrovascular diseases.

Acute cerebrovascular disease

Computerized tomography (CT) remains the most commonly used imaging tool for the evaluation of suspected acute stroke. It can readily detect early hemorrhage, but

not all early infarcts. Magnetic resonance imaging (MRI) is becoming more commonly used in the investigation of acute stroke. It allows detection of intracranial hemorrhage within hours of stroke onset,¹² and unlike CT the presence of previous microhemorrhage (due to its breakdown product hemosiderin remaining) is easily visible. MR diffusion-weighted imaging readily reveals ischemic or infarcted tissue (within minutes of stroke onset) with better sensitivity and accuracy than CT¹³ (Figure 48–4, B). Multimodal CT (perfusion CT and CT angiography) and multimodal MR imaging—diffusion-weighted imaging (DWI), perfusion-weighted imaging (PWI), fluid-attenuated inversion recovery (FLAIR), and MR angiography (MRA)—provide significantly more information useful in patient management. For example, abnormalities on DWI represent bioenergetic compromise and PWI abnormalities show areas of hemodynamic compromise. In an area of infarction, the diffusion abnormality has been taken to represent irreversibly damaged tissue and the surrounding region with abnormal perfusion represents damaged but potentially viable tissue (i.e., the penumbra). However, positron emission scanning studies reveal that the mismatch zone is only an approximation of the penumbra.¹⁴ More sophisticated modeling allows more accurate representation of the penumbra, allowing patients with salvageable tissue to be selected for stroke treatments (e.g., thrombolysis).¹⁵

Cognitive impairment and dementia

Neuroimaging is recommended in the initial assessment of patients with dementia. CT and MRI can delineate structural brain changes associated with dementia (e.g., cortical atrophy with widening of cortical sulci and ventricular enlargement). Dementia type can be assessed from various imaging modalities. Indeed, guidelines for diagnosing vascular dementia include brain imaging to detect the presence of cerebrovascular disease. Compared to CT, white matter lesions are shown with greater sensitivity using MR techniques. Single-photon emission CT (SPECT) and positron emission tomography (PET) scanning (see material following) have been used to diagnose and differentiate dementias.¹⁶

Other techniques

Cerebral blood flow assessment

Numerous techniques are available for assessing cerebral blood flow and its abnormalities. These have recently been reviewed by Wintermark.¹⁷

Positron emission tomography

This is a noninvasive technique that can, using various positron emitting radioisotopes, measure not only regional cerebral blood flow, blood volume, metabolic rate of oxygen use, and oxygen extraction fraction (using ¹⁵O₂) but glucose consumption (using ¹⁸F fluorodeoxyglucose) and neurotransmitter activity (using the appropriate isotope). PET can only be used in chronic conditions (e.g., chronic cerebrovascular disease and dementia). A further major drawback is the cost and requirement for a cyclotron to produce the very short-lived radiopharmaceuticals.

Single-photon emission CT

This uses radiopharmaceuticals that are more easily available (for example, based on 99 technetium or 133 xenon). Unlike PET scanning, this technique can be used in acute and chronic cerebrovascular disease and at the bedside. SPECT can determine relative changes in regional cerebral blood flow but does not provide quantitative data. It has clinical application in acute stroke and differential diagnosis of dementia.

Xenon-enhanced CT

Nonradioactive xenon is inhaled and rapidly dissolves in blood, acting as a contrast agent detected by the CT scanner. CT brain images allow blood flow data to be related to anatomy with a high degree of resolution, and quantitative assessment of regional cerebral blood flow to be undertaken. This technique can be used in acute and chronic cerebrovascular disease and can predict groups at high risk of stroke. Various CT and MR techniques with exogenous contrast and endogenous tracer using the patient's own blood (arterial spin labeling) allow investigation of perfusion abnormalities in acute and chronic stroke.

Doppler ultrasound

Doppler ultrasound techniques have long been able to measure blood flow velocity in the internal carotid artery and middle cerebral artery, but more recent developments (pulse wave digital doppler and dual-beam flow technology) allow estimation of blood flow volume. Differences in hemispheric blood flow can be compared, but although spatial resolution is limited temporal resolution is good and repeated measurements can follow dynamic blood flow changes.

MANAGEMENT

Stroke

Acute stroke is a medical emergency. Active management in the initial hours after stroke onset may save the ischemic brain from infarction (i.e., "time is brain"). A combination of public education and patient triage—by the use of the Face Arm Speech Test (FAST)¹⁸ or Los Angeles Prehospital Stroke Screen (LAPSS)¹⁹ by paramedical staff or the Recognition of Stroke In the Emergency Room (ROSIER) scale [Ford, Unpublished data] by Emergency Department Staff (Box 48–1)—can facilitate rapid access to stroke specialist care. Such organized care should be provided in a geographically identified unit by a coordinated multidisciplinary team with specialist expertise in stroke and rehabilitation,²⁰ supported by access to diagnostic services as outlined in the preceding section (although subsequently rehabilitation may be provided effectively by early supported discharge services).²¹ The management of acute stroke is supported by a plethora of international and national guidelines established by such organizations as the American Stroke Association,²² the European Stroke Initiative,²³ and the Royal College of Physicians.²⁴ Specific and general measures of acute ischemic and hemorrhagic stroke management drawn from these guidelines are summarized in the following.

Box 48–1

Pre-hospital Assessment Stroke Scales

Face Arm Speech Test (FAST)

- Speech impairment? Yes/No
- Facial palsy? Yes/No (affected side)
- Arm weakness? Yes/No (affected side)

Los Angeles Prehospital Stroke Screen (LAPSS)

- Age >45
- History of seizures or epilepsy absent
- Symptom duration less than 24 hours
- At baseline, patient is not wheelchair bound or bedridden
- Blood glucose between 60 and 400
- Examination: Look for obvious asymmetry
- Face smile/grimace (normal/droop)
- Grip (normal/weak grip/no grip)
- Arm strength (normal/drifts down/falls rapidly)

Recognition of Stroke in the Emergency Room (ROSIER) Scale

- Loss of consciousness or syncope?
 - Yes (-1)/No (0)
- Seizure activity?
 - Yes (-1)/No (0)
- New acute onset (or on awakening from sleep):
 - Asymmetric facial weakness: Yes (+1)/No (0)
 - Asymmetric arm weakness: Yes (+1)/No (0)
 - Asymmetric leg weakness: Yes (+1)/No (0)
 - Speech disturbance: Yes (+1)/No (0)
 - Visual field defect: Yes (+1)/No (0)

Stroke is likely if total score is >0

Specific measures

Major intracranial arterial thromboembolic occlusion is demonstrable in the majority of stroke patients, and therefore urgent reperfusion strategies are important. To date, only intravenous thrombolysis with recombinant tissue plasminogen activator (alteplase) has been approved for administration within 3 hours of acute ischemic stroke onset.²⁵ However, intra-arterial thrombolysis and mechanical clot disruption techniques continue to be studied.²⁶ Nonetheless, the short therapeutic window, the need to exclude hemorrhagic stroke, and the risk of precipitating hemorrhagic transformation limit the generalizability of this therapeutic modality (although the International Stroke Trial-3 aims to provide robust evidence of risks and benefits over a time window up to 6 hours to define more precisely which patients are most likely to benefit). (See www.dcn.ed.ac.uk/ist3/.) On the contrary, neuroprotection (the process of preventing ischemia and reperfusion-induced excitatory neurotransmitter, calcium channel, inflammatory, and free-radical-mediated cell death) might

be more universally applicable. Unfortunately, no agent to date has proved efficacious, including multimodal physiologic magnesium.²⁷

The use of anticoagulation in acute ischemic stroke has been studied for both unfractionated²⁸ and low-molecular-weight heparins.²⁹ There is no evidence to favor its routine use and it is associated with high risk of serious intracranial bleeding.^{22,30} The early use of aspirin, however, is effective in reducing recurrent ischemic stroke, death, or dependency—with a small (but significant) risk of hemorrhagic transformation—but should be administered as soon as possible after the onset of stroke symptoms once a diagnosis of primary hemorrhage has been excluded at an initial dose of 300 mg.³¹

Specific treatments for patients with primary intracerebral hemorrhage are few. Although surgical intervention should be considered in patients with posterior fossa or cerebellar hemorrhage (and indeed infarction) without formal randomized trial evidence, its use in the management of supratentorial hemorrhage has been assessed in the Surgical Trial in Intra-Cerebral Hemorrhage (STICH). This trial compared immediate neurosurgical intervention within 72 hours (predominantly via craniotomy) with initial conservative management (although 26% progressed to neurosurgical intervention) and reported no significant benefit in favor of immediate intervention.³² Medical treatment with recombinant activated factor VII has also been assessed within 3 hours of onset of intracerebral hemorrhage (in the Phase II NovoSeven Trial) and has been found to be associated with a significant reduction in hematoma expansion (although at the risk of increased thromboembolic complications).³³ Further trials are therefore needed.

General measures

Although early neuronal loss following acute stroke onset does occur, most patients have potentially viable “penumbra tissue” and measures that optimize perfusion and metabolism can be brought to bear and are important. As previously discussed, the process by which cerebral blood flow is maintained across a range of systemic BPs (cerebral autoregulation) is impaired following acute stroke, and flow becomes pressure dependent. Acute stroke is most commonly complicated by hypertension, although extremes of BP are associated with adverse prognosis (with a reported nadir of 150 mmHg).⁸ Acute stroke BP management is an area of active clinical research, with few randomized controlled trials to inform the management of this common problem. Preliminary evidence supported the further assessment of angiotensin receptor blockade, combined alpha and beta-adrenergic blockade, or nitrates for hypertensive patients—and volume expansion and phenylephrine or norepinephrine for relatively hypotensive patients.³⁴ Nonetheless, current consensus recommends the acute use of antihypertensive therapy for associated cardiac (acute myocardial infarction, severe left ventricular failure) or vascular urgencies (aortic dissection), hypertensive encephalopathy, acute renal failure, concurrent coagulant therapy (thrombolysis, intravenous heparin), or persistent BP elevation (with a threshold of >200/120 mmHg for

ischemic and >180/105 mmHg for hemorrhagic stroke).^{22,23} For relatively hypotensive patients, the same guidelines recommend the exclusion of potential causes (for example, myocardial ischemia, cardiac failure, and sepsis). Thereafter, BP can be raised by adequate patient rehydration and due consideration to pressor therapy.^{22,23}

However, a number of other general measures are also important. Maintaining adequate tissue oxygenation is vital—by maintaining the airway, monitoring respiration, preventing and treating aspiration pneumonia, and the empirical administration of supplemental oxygen. Acute coronary syndromes and arrhythmias are potential complications, and should be sought and appropriately managed. Pyrexia is associated with increased metabolic demand, enhanced neurotransmitter release, and increased free radical production. Therefore, infection should be sourced and actively managed—and antipyretics such as paracetamol considered,³⁵ although the use of therapeutic hypothermia is associated with serious adverse effects and lacks efficacy from clinical trials.³⁶ Abnormalities of glucose control are also common, and should be measured and treated. Hypoglycemia is an important stroke mimic, and untreated may lead to irreversible brain injury.

Hyperglycemia promotes increased tissue acidosis and blood/brain barrier permeability, and can be safely managed by a glucose-potassium-insulin infusion³⁷ (although the recently completed phase III Glucose Insulin in Stroke Trial (GIST) will further inform the efficacy of this approach). Under-nutrition is common in hospitalized stroke patients, being associated with increased risk of infection, greater difficulty with rehabilitation, and poor outcome. However, the FOOD trials (albeit underpowered) do not support a policy of routine oral supplementation in nondysphagic stroke patients,³⁸ report that early tube feeding in dysphagic patients may reduce case fatality at the expense of increasing the proportion of patients surviving with poor outcome, and do not support a policy of early percutaneous endoscopic gastrostomy (PEG) tube feeding.³⁹

Finally, venothromboembolism presenting as deep vein thrombosis or pulmonary embolism is a complication of advanced age, immobility, severe or lower extremity paralysis, and atrial fibrillation (all common in acute stroke). Early mobilization is important. The effectiveness of graduated compression stockings is being assessed in the Clots in Legs or TEDs after Stroke (CLOTS) Trial (www.clotstrial.com), although routine use of prophylactic anticoagulation is associated with significant risk (as previously discussed).

Secondary prevention

Stroke patients remain at increased risk of recurrent stroke, and this may be as high as 15% within the first month for patients with transient ischemic attack (TIA). Therefore, a high priority should be attached to the delivery of an individualized strategy of evidence-based secondary prevention. First, the acute use of aspirin therapy has already been discussed, and this agent should be continued at a dose of 50 to 300 mg daily. However, it is also important to consider the role of other antiplatelet agents alone or

in combination with aspirin. Dipyridamole acts to inhibit adenosine uptake into blood and vascular cells, and has both antiplatelet and vasodilator properties. The European Stroke Prevention Study 2 of modified-release dipyridamole reported risk reductions in recurrent vascular events when used in combination with aspirin compared to aspirin alone,⁴⁰ and the United Kingdom's National Institute for Health and Clinical Excellence recently recommended that patients following ischemic stroke or TIA be treated with combination therapy for a 2-year period before reverting to standard care.

Clopidogrel inhibits binding of adenosine phosphate to its platelet receptor. The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) study reported a significant reduction in composite vascular outcome with clopidogrel compared to aspirin, although this effect was not significant when only stroke patients were considered in an underpowered post-hoc analysis.⁴¹ The Management of Atherothrombosis with Clopidogrel in High-Risk Patients with Recent Transient Ischemic Attack or Ischemic Stroke (MATCH) study also reported a significant reduction in composite vascular outcome with clopidogrel in combination with aspirin compared to clopidogrel alone, but at the expense of significant major bleeding complications.⁴² Clopidogrel alone is therefore reserved for aspirin-intolerant stroke patients. However, there are a number of recently completed and ongoing trials (including CHARISMA, ESPRIT, and ProFESS) that will provide further information regarding which antiplatelet agent or combination is most effective. However, the recently published CHARISMA trial[G1]^{42a} suggested that clopidogrel plus aspirin was not significantly more effective than aspirin alone in reducing the rate of myocardial infarction, stroke, or death from cardiovascular causes (in 15,603 patients with either clinically evident cardiovascular disease or multiple risk factors). In subgroup analyses, benefit was found with clopidogrel treatment in patients with symptomatic atherothrombosis and a suggestion of harm in patients with multiple risk factors.

Second, statin treatment should be given to ischemic stroke and TIA patients with a total cholesterol >3.5 mmol/L unless contraindicated,²⁴ the subgroup of stroke patients treated with statin therapy within the Heart Protection Study having a significant reduction in subsequent major vascular events.⁴³ Finally, all patients should receive appropriate lifestyle advice on smoking cessation, regular exercise, appropriate diet, and the avoidance of excess alcohol.²⁴

Two stroke patient subgroups demand specific treatment. Persistent or paroxysmal atrial fibrillation (valvular or nonvalvular) patients (following brain imaging to exclude hemorrhagic stroke and usually not until 14 days after stroke onset) should receive anticoagulation with a target International Normalized Ratio (INR) of 2.5 (range 2.0 to 3.0).⁴⁴ Carotid endarterectomy is highly beneficial in patients with 70% or more stenosis without near-occlusion, and of some benefit for 50 to 69% stenosis.⁴⁵ Benefit also depends on other clinical characteristics, including delay to surgery (which should ideally be undertaken within 2 weeks of last symptoms).⁴⁶

Blood pressure and secondary stroke prevention

The reported association of BP or hypertension with recurrent stroke has not been consistent, some studies showing no association or a J-shaped relationship. However, data from the UK TIA Aspirin Trial (in which BP was measured prior to randomization in 2435 subjects with a history of minor stroke or TIA) demonstrated that a 10-mmHg lower systolic BP (SBP) was associated with a 28% lower risk of recurrent stroke.⁴⁷ This relationship between BP and stroke is similar to that seen in populations with no history of previous stroke.

Pharmacologic lowering of BP has long been known to be effective in the primary prevention of stroke. Other than a few small studies in hypertensive stroke survivors, there was little firm evidence on which to base clinical practice until 1995 (when the Chinese Post-Stroke Anti-hypertensive Treatment Study reported).⁴⁸ More than a month after episode, the diuretic Indapamide was compared to placebo in 5665 normotensive and hypertensive patients who had sustained a TIA, ischemic, or hemorrhagic stroke. Significant reductions in stroke recurrence (29%) and major cardiovascular events (23%) were reported. Since 2000, three further studies have reported on the effects of anti-hypertensive therapy in patients having had a history of stroke. The Heart Outcomes Prevention Evaluation (HOPE) study reported separately on 1013 subjects who had a history of stroke or TIA for which there was a nonsignificant 15% reduction in total stroke recurrence.⁴⁹ In the PROGRESS Trial, another ACE inhibitor (Perindopril, with or without Indapamide) was compared to placebo in 6105 normotensive and hypertensive patients with a history of ischemic or hemorrhagic stroke or TIA.⁵⁰ Active intervention reduced recurrent stroke by a significant 28%, and major vascular events by 26%, during 4 years of follow-up. The bulk of the benefit was seen in those patients who received both an ACE inhibitor and Indapamide where the BP reduction was the greatest. In those taking Perindopril only, compared to placebo only a 6% reduction in the risk of recurrent stroke was seen. The Perindopril and Indapamide combination, however, provided a 45% reduction. More recently, the Morbidity and Mortality after Stroke Eprosartan Study (MOSES) compared in hypertensive stroke survivors Eprosartan (an angiotensin receptor blocker) with Nitrendipine (a dihydropyridine calcium channel blocker).⁵¹ For a similar fall in BP, there was a 21% risk reduction in the primary endpoint of all cardio and cerebrovascular events and a 25% reduction in recurrent cerebrovascular events in patients randomized to the Eprosartan-based regimen. The results from the PATS, HOPE, PROGRESS, and MOSES trials allow a number of issues to be considered.

Initial BP level

The initial BP level determines the need for commencing antihypertensive therapy in patients with a history of stroke. In the PATS, HOPE, and PROGRESS studies, a similar benefit in stroke recurrence was seen regardless of BP level at entry (i.e., both normotensive and hypertensive patients appear to benefit from a further reduction in BP). However, whether all patients with cerebrovascular disease would benefit from a further reduction in BP regardless of their

initial level is unclear. Concerns have been raised in two areas. First, it is unclear whether stroke survivors with severe carotid occlusion will develop impaired cerebral perfusion if BP is lowered too aggressively. In patients with bilateral carotid stenosis, Rothwell⁵² found from a review of carotid endarterectomy studies an altered relationship between BP and stroke risk, suggesting that lowering BP in such patients aggressively may reduce cerebral perfusion and increase the risk of stroke. However, such severe bilateral carotid stenosis is uncommon and such concerns may be lessened following revascularization. The second area of concern is the effect on cognitive function of aggressive BP reduction in people with established cerebrovascular disease. This may be particularly relevant to those patients with cerebral small-vessel disease where cerebral blood flow is reduced (see material following). Further BP reduction may compromise cerebral perfusion, increasing the risk of cognitive decline and cerebrovascular disease progression.

Target BP level

No studies have addressed the issue of optimal BP to be attained, but in the PROGRESS Study a greater reduction in BP from baseline (even in normotensives) was associated with a greater reduction in stroke recurrence.

Effect of therapy in patients with different stroke subtype

In the PROGRESS Study, those with a hemorrhagic stroke had a relative risk reduction about twice as great as that for those with an ischemic stroke (49% versus 26%).⁵³ In the HOPE and PROGRESS studies, all ischemic stroke subtypes benefited from therapy to a similar extent. Overall, intervention with antihypertensive therapy reduced stroke recurrence regardless of stroke type.

Effect of type of antihypertensive therapy on outcome

Results of primary and secondary prevention trials suggest that for a similar reduction in BP different antihypertensive therapies vary in their effects on stroke outcome. In the MOSES Study, for a similar reduction in BP the angiotensin receptor blocker produced greater benefits in terms of stroke reduction than a calcium channel blocker. Primary prevention trials using an angiotensin receptor blocker have also suggested a preferential effect of angiotensin receptor blockers on stroke reduction compared to other therapies (e.g., β -blockers).⁵⁴ The ACE inhibitor Perindopril in PROGRESS reduced BP to an extent similar to that of Indapamide in PATS (5/2 mmHg), yet the latter reduced stroke incidence by 29% compared to no significant effect from Perindopril. It may not only be the extent to which BP is lowered but how it is lowered that achieves optimal benefits for stroke prevention.

Hypertension and cognitive impairment

Classification of cognitive impairment

Cognitive impairment spans the spectrum from mild cognitive impairment to dementia. Dementia affects about 3% of persons aged 65 to 74, but 28% of those over 85.

Traditionally, three main subtypes of dementia have been recognized: Alzheimer's disease (the most common; >50% of dementias), followed by vascular dementia (approximately 30% of dementias), and a small minority related to others such as Lewy Body disease. Alzheimer's disease, a neurodegenerative disorder characterized histologically by extracellular amyloid plaques and intracellular neurofibrillary tangles, has until recently been considered a separate entity from vascular dementia. More recently, evidence has accumulated to show associations between these two dementia subtypes; for example, with regard to shared risk factors (hypertension, diabetes mellitus, smoking, hypercholesterolemia) and proposed common pathologies.⁵⁵ Reduced cerebral blood flow and brain hypoperfusion secondary to atherosclerosis have also been associated with Alzheimer's disease.⁵⁶ Autopsy studies in patients with dementia frequently show features of both vascular dementia and Alzheimer's disease occurring together. These considerations have led to the concept of mixed dementia, perhaps the most common of all forms of dementia.⁵⁷

Vascular cognitive impairment (VCI)

The narrow concept of vascular dementia caused by multiple infarcts has expanded to emphasize the role of cerebrovascular disease in general on cognitive function. Causes of VCI include post-stroke dementia, strategic infarcts, silent infarcts, and subcortical ischemic vascular dementia. Cerebrovascular damage leading to cognitive impairment can occur not only from atherothrombosis but through cerebral hemorrhage, hypoperfusion, and other arteriopathies. Hypertension, usually in the presence of other cardiovascular risk factors, plays a major role in promoting these pathologies.

Post-stroke dementia or cognitive decline occurs in up to one-third of patients within a year of stroke. Having a stroke may double the risk of dementia.⁵⁸ Patients with stroke may also have an earlier onset of Alzheimer's disease. In the presence of stroke, a smaller burden of Alzheimer's pathology is required to produce dementia. It is unclear whether stroke predisposes to Alzheimer's or both occur independently with additive effects.

Subcortical ischemic vascular disease primarily involves small-vessel disease, leading to lacunar infarcts and/or ischemia of the deep white matter (see Figure 48–3). The main cause of the small-vessel disease is hypertension, although other vascular risk factors play an important role (e.g., smoking, diabetes mellitus, and older age). The hypertensive arteriopathy leads to thrombotic occlusion or microaneurysm formation and hypertensive cerebral hemorrhage. Subcortical ischemic vascular dementia probably forms the bulk of vascular dementia subtypes. Major features include loss of executive functioning (attention, working memory, organization and constructional skills), motivation, and effects on mood and behavior. Gait disturbances (i.e., short stepped and wide based) and urinary problems are also common. White matter lesions are commonly seen on MRI brain scans in middle-age individuals but are not necessarily benign⁵⁹ and increase dramatically in the elderly where more than 70% of 70-year-olds are affected.⁶⁰

Relationship of blood pressure to cognitive impairment

Epidemiological studies can broadly be divided into cross-sectional (which limit causal inference) and longitudinal, which if of sufficient follow-up allow the temporal relations between BP and cognition to be examined and causality inferred.

Cross-sectional studies

Cross-sectional studies have reported that low BP in older subjects is related to the prevalence of dementia.^{61,62} In contrast, cognitive impairment (without dementia) has more commonly been associated with high BP. In the Atherosclerosis Risk in Communities study of 1384 persons aged 45 to 69, BP >160/95 mmHg was related to lower cognitive test scores.⁶³ Other smaller studies in young⁶⁴ and older subjects have shown similar associations.⁶⁵⁻⁶⁷ An association of low BP with cognitive impairment, largely in studies of elderly groups (>75 years), has been reported in the Helsinki Aging Study, Honolulu-Asia aging study, and the Kungsholmen Project.⁶⁸⁻⁷⁰ Overall, there is some indication that high BP is related to cognitive impairments. In older subjects a sufficient BP level is required to maintain cerebral perfusion to preserve optimum cognitive functioning.⁷¹

Longitudinal studies

High BP in middle age without or with other vascular risk factors has consistently been associated with cognitive decline and dementia of both vascular and Alzheimer type when assessed after follow-up periods of 10 to 25 years.^{69,72,73} In contrast to studies undertaken in middle-age persons, follow-up of elderly cohorts has shown no consistent association of BP with cognition or dementia. As in younger groups, high BP in the elderly has been related to decline in cognitive performance.^{71,74} However, in distinction from younger cohorts in the elderly low BP has in some studies been associated with the development of dementia.^{75,76} Overall, these longitudinal studies strongly suggest an adverse effect of high BP in middle age (and perhaps also older age) on cognitive functioning. There is also an adverse effect of low BP in the elderly for the development of dementia. Follow-up studies examining the effect of BP on brain structural changes provide further evidence for the adverse effect of high BP on cognitive performance.^{69,77}

Effect of treating hypertension on cognition and dementia

Several randomized controlled trials had as secondary objectives the assessment of antihypertensive therapy on changes in cognition or the development of dementia. These studies have mainly involved older participants followed up for a relatively short duration of 2 to 4 years.

The Medical Research Council Trial in older persons aged 65 to 74 years⁷⁸ and the Systolic Hypertension in the Elderly Programme (SHEP), using thiazide-based regimens, found no effect of active treatment on cognition (SHEP). The Study on Cognition and Prognosis in the Elderly (SCOPE) of hypertensives aged 70 to 89 years (whether

analyzed with all participants or restricted to the subgroup randomized to candesartan versus placebo) found no difference on the Mini-Mental State Exam (MMSE).⁷⁹ In all of these studies, active therapy significantly reduced BP (and vascular events), with no apparent adverse effect on cognition.

The SYST-EUR Study of Nitrendipine versus placebo in subjects with systolic hypertension reported a 50% reduction in dementia incidence after 2 years, although the number of dementia cases was small.⁸⁰ Follow-up occurred for another 2 years, with all participants receiving active treatment. Compared to the original placebo group, the “active” treatment group (i.e., those treated the longest) had dementia risk reduced by half. In contrast to the previously cited studies, the HOPE Trial included normotensives randomized to Ramipril or placebo. Subjects who went on to develop stroke had less of a reduction in cognitive performance if they were taking Ramipril.⁴⁹

Two studies have reported on the effect of antihypertensive therapy on cognitive function in patients who have previously suffered a stroke. In the PROGRESS study, therapy with an ACE inhibitor and Indapamide attenuated the decline in the MMSE and significantly reduced the risk of dementia with recurrent stroke by 34% and the risk of severe cognitive decline. In the MOSES study of two active treatments, Eprosartan and Nitrendipine, a similar and significant BP fall occurred in both groups without any change from baseline in MMSE or between active therapies.

So far, the controlled randomized intervention studies suggest no deterioration in cognitive performance with antihypertensive therapy in well elderly hypertensive patients, in those normotensive patients with vascular disease, or in hypertensive patients with a history of stroke. There is limited evidence from one study that antihypertensive therapy may reduce the incidence of dementia, although further confirmation of this effect is required.

PROGNOSIS

About a quarter of the world's population, or almost one billion, have hypertension. Two-thirds of these people are in the economically developing world and one-third in the developed world. In 20 years' time, over one-and-a-half billion people are expected to have hypertension. It will then be the most common risk factor for death and disability.

Stroke is the second leading cause of death worldwide, causing up to five million deaths per year. Another fifteen million stroke survivors add to the global burden of disability. By 2020, it is estimated that cerebrovascular diseases will become the second most prevalent cause of death and disability in developed countries, and will be ranked fifth in developing countries.

Dementia is also predicted to be in the top eight leading causes of death and disability in developed regions. Dementia is also one of the leading causes of death and disability in the older population. By 2020, it is predicted that worldwide there will be nearly 29 million people with dementia.⁸¹

SUMMARY

BP, as discussed earlier in this chapter, has a close relationship with stroke (especially in Asian populations). Over 50% of stroke deaths can be attributed to increased BP levels. A modest population-wide reduction in BP of 2% and a targeted approach in hypertensives could annually prevent about 20% of stroke deaths worldwide. Although high BP is the greatest population-attributable risk for stroke, other factors (e.g., high cholesterol,

smoking, poor diet, and inactivity) also contribute. Removal of all of these risks could reduce global stroke burden by approximately 70%. Beneficial effects of modest BP reduction would also be seen not only in reduction of stroke-related dementia but likely in other dementia types (e.g., vascular, mixed, and Alzheimer's). Again, multiple vascular risk factor reductions could have greater benefits. Global management of hypertension has the potential for making a significant impact on reducing the burden from brain diseases.

Chapter
49**Kidney Disease
and Hypertension***Panteleimon A. Sarafidis and George L. Bakris***Key Findings**

- People with chronic kidney disease have a higher risk for cardiovascular events independent of elevated blood pressure.
- Presence of microalbuminuria (>30<300 mg/day) is a cardiovascular risk marker.
- Presence of macroalbuminuria (proteinuria) \geq 300 mg/day indicates presence of kidney disease.
- Individuals with proteinuria and kidney disease must have both their blood pressure lowered to <130/80 mmHg and proteinuria reduced by at least 30%.
- Reductions in proteinuria of more than 50% following 6 months of treatment yields a 70% risk reduction for progression to end-stage renal disease at 5 years in nondiabetic kidney disease.
- Agents that block the renin-angiotensin system, either alone or combined, yield the greatest slowing of kidney disease progression (assuming blood pressure is reduced) in those with advanced disease and proteinuria.
- Combinations of ACE inhibitors with angiotensin receptor blockers or aldosterone receptor blockers may provide additional reductions in proteinuria independent of further blood pressure reductions.

Chronic kidney disease (CKD) is defined either as kidney damage, which is confirmed by kidney biopsy or markers of damage, or as the presence of glomerular filtration rate (GFR) under the level of 60 mL/min/1.73 m² for a period greater than 3 months.¹ The stage of CKD is based on the level of GFR, irrespective of the cause of kidney disease (Table 49–1). Decreased kidney function starts at a GFR

below 89 mL/min/1.73 m² and is considered to be pronounced if the GFR is less than 60 mL/min/1.73 m² for more than 3 months.¹ In clinical terms, the latter is reflected in an elevation of serum creatinine levels above the normal range [=1.5 mg/dL (133 μ mol/L) in men and =1.3 mg/dL (115 μ mol/L) in women]. This decrease in renal function along with an increase in the presence of microalbuminuria (>30 mg/dL or <300 mg/dL) or development of albuminuria (>300 mg/dL) is a clear indication of the presence of renal dysfunction. Apart from the stage, diagnosis of the type of CKD based on etiology is also very important (Table 49–2). A definitive diagnosis could be assigned after biopsy or imaging studies, but in most patients well-defined clinical presentations and causal factors provide sufficient basis for a diagnosis without these procedures.¹

During the past decades, CKD has grown to a worldwide public health problem. In the United States, about 20 million individuals are currently suffering from CKD.² Both the incidence and prevalence of kidney failure treated by dialysis and transplantation continue to increase, as shown in Figure 49–1.³ In 2002, the number of patients with kidney failure rose to more than 430,000, and the incident rate of kidney failure has increased to 333 new cases per million people—a number almost four times higher than that in 1980.³ The United States Renal Data System, taking into consideration the enormous growth of both the elderly and type 2 diabetic populations, estimates that by the year 2030 more than 2.2 million individuals will require treatment for end-stage renal disease (ESRD).² Among patients on dialysis, 5-year survival rates are extremely low (about 32%)—largely due to the parallel high prevalence of cardiovascular disease (CVD).² Moreover, the cost of treatment for ESRD is enormous and is expected to rise

STAGES AND PREVALENCE OF CKD IN 2002				
Stage	Description	GFR (mL/min/1.73m ²)	Prevalence	
			N (1,000's)	(%)
1	Kidney damage with normal or \uparrow GFR	\geq 90	5,900	3.3
2	Kidney damage with mild \downarrow GFR	60–89	5,300	3.0
3	Moderate \downarrow GFR	30–59	7,600	4.3
4	Severe \downarrow GFR	15–29	400	0.2
5	Kidney failure	<15 of dialysis	300	0.1

steeply. For example, Medicare costs associated with ESRD are projected to have increased from \$12.7 billion in 1999 to \$28.0 billion by the year 2010.⁴ In contrast to this, several lines of evidence indicate that both establishment and progression of CKD as well as cardiovascular events can be delayed or avoided by several measures, among which achievement of hypertension control is the most important.

Goals of antihypertensive treatment in kidney disease

As shown in Table 49–2, hypertension represents an important cause of CKD but is also a consequence of it.¹ Several lines of evidence support the role of hypertension as a renal risk factor. In the Third National Health and Nutrition Examination Survey (NHANES III), 3% of the civilian

population has been estimated to have elevated serum creatinine levels [=1.6 mg/dL (141 μ mol/L) for men and =1.4 mg/dL (124 μ mol/L) for women], and among those 70% also had hypertension.⁵ In the Multiple Risk Factor Intervention Trial (MRFIT), which included 332,544 middle-age men, blood pressure was a strong predictor of the development of ESRD during the 16 years of follow-up.⁶ In practical terms, the second most common cause of ESRD after diabetic nephropathy is hypertensive nephrosclerosis, which is typically represented by hyalinization and sclerosis of the walls of the afferent arterioles. On the other hand, many of the abnormalities present in an individual with CKD or certain agents used in the treatment of ESRD patients or graft recipients could be responsible for blood pressure elevation (Box 49–1).⁷

Apart from sex- and body-size-related variability, GFR varies according to age. Normally, age-related declines in GFR begin at about 50 years of age, at a rate of approximately 1 mL/min per year. However, this age-related loss of renal function is directly proportional to blood pressure level, and the rate of GFR decline can rise up to 4 to 8 mL/min per year if systolic blood pressure is elevated to a hypertensive level.⁸ Interventions that lower blood pressure levels in patients with kidney disease have been consistently shown to slow down the progression of it. An analysis of long-term clinical trials in patients with diabetic or nondiabetic kidney disease clearly showed that lower blood pressures result in greater preservation of kidney function (Figure 49–2).⁹

Although GFR declines in varying rates depending on the type of underlying kidney disease, the impact of earlier blood pressure reduction is far more significant compared to later intervention, and therefore early treatment is invariably preferred.^{10,11} Apart from the foregoing, hypertension has long been identified as one of the major independent risk factors for CVD,^{12,13} and patients with kidney disease are at increased risk for cardiovascular events compared with patients with normal kidney function.^{14–16} Therefore, according to the National Kidney Foundation (NKF)-Kidney Disease Outcomes Quality Initiative (KDOQI) Working Group guidelines, the goals of antihypertensive therapy in patients with CKD are to lower blood pressure, reduce the

Box 49-1**Possible Mechanisms for BP Elevation
in CKD**

- Preexisting essential hypertension
- Extracellular fluid volume expansion
- Renin-angiotensin-aldosterone system stimulation
- Increased sympathetic activity
- Endogenous digitalis-like factors
- Prostaglandins/bradykinins
- Alterations in endothelium-derived factors (nitric oxide/endothelin)
- Increased body weight
- Erythropoietin administration
- Parathyroid hormone secretion/increased intracellular calcium/hypercalcemia
- Calcification of arterial tree
- Renal artery disease
- Chronic allograft dysfunction
- Cadaver allografts, especially from a donor with family history of hypertension
- Cyclosporine/tacrolimus/other immunosuppressive and corticosteroid therapy

risk of CVD in patients with or without hypertension, and slow the progression of kidney disease in patients with or without hypertension.¹

Blood pressure goal

According to the Seventh Report of the Joint National Committee (JNC) 7, the blood pressure goal for a patient with hypertension is less than 140/90 mmHg.¹⁷ Two multicenter outcome trials that randomized to different levels of blood pressure—the Hypertension Optimal Treatment

(HOT) trial¹⁸ and the United Kingdom Prospective Diabetes Study (UKPDS) 38¹⁹—have shown a significant reduction in cardiovascular mortality in the groups of diabetic patients that achieved the lower levels of blood pressure and were the main reasons for setting a blood pressure goal of <130/80 for patients with diabetes in the JNC 7 report.¹⁷ In particular, in the HOT trial (which included almost 19,000 hypertensive patients) the subgroup of diabetic patients randomized to the lowest diastolic blood pressure group (<80 mmHg) had the most significant reductions in cardiovascular events. This was not true, however, for the study as a whole. The same was found in the UKPDS 38 trial, which randomized 1148 patients with hypertension and type 2 diabetes to “tight blood pressure control” (<150/85 mmHg) and to “less tight control” (<180/105 mmHg). After 9 years of follow-up, those at the “tight blood pressure control” group (mean blood pressure achieved 144/82 mmHg) had far fewer cardiovascular events than those at the “less tight control” group (mean blood pressure achieved 154/87 mmHg) and medication selection did not affect clinical outcome.¹⁹

If CKD is present, JNC 7 also recommends a blood pressure goal of <130/80 mmHg.¹⁷ The JNC 7 guidelines, however, are not the only to recommend this blood pressure goal. The evidence in favor of such a tight blood pressure control in order to reduce the rates of both kidney disease progression and cardiovascular events is so strong that all important international guidelines released during the past few years—including those from the JNC 7,¹⁷ the European Society of Hypertension-European Society of Cardiology committee,²⁰ the NKF-KDOQI working group,¹ and the American Diabetes Association¹¹—recommend a goal of <130/80 mmHg for patients with CKD and/or diabetes. Long-term clinical trials with primary renal outcomes in patients with or without diabetes, including those comparing intensive with regular blood pressure control, are summarized in Table 49-3.

The first trial to randomize individuals with advanced nephropathy to two different levels of blood pressure was the Modification of Diet in Renal Disease (MDRD) Study. In this study, patients with chronic kidney disease and high rates of protein excretion were randomly assigned to a low blood pressure group with a goal mean arterial pressure (MAP) <92 mmHg and a high blood pressure group (goal MAP <107 mmHg) for 4 years. At the end of the study, patients in the low target blood pressure group had a significantly slower reduction in GFR decline compared to patients assigned to the high target blood pressure group.²¹ Moreover, an analysis of data obtained about 7 years after the end of the randomization trial revealed that the risks for kidney failure and the composite outcome of kidney failure and all-cause mortality were significantly lower in the low target blood pressure group.²² In a meta-analysis of studies in nondiabetic kidney disease by the ACE Inhibition in Progressive Renal Disease (AIPRD) Study Group, a systolic blood pressure range of 110 to 129 mmHg was that associated with the lowest risk of kidney disease progression in patients with urine protein excretion >1 g/day (Figure 49-3).²³

In patients with lower levels of urine protein excretion (i.e., <1 g/day), however, the evidence from the MDRD

Figure 49-2. Relationship between achieved blood pressure control and declines in GFR in clinical trials of diabetic and nondiabetic kidney disease. (Adapted from Bakris GL, Williams M, Dworkin L, et al. Preserving renal function in adults with hypertension and diabetes: A consensus approach. National Kidney Foundation Hypertension and Diabetes Executive Committees Working Group. *Am J Kidney Dis* 2000;36(3):646-61.)

LONG-TERM OUTCOME STUDIES WITH PRIMARY RENAL ENDPOINTS					
No Diabetes		No. Patients	Baseline GFR	Follow-up	Favorable Therapy
MDRD, 1993 (21)	Usual vs low blood pressure goal	840	40	2.2 years	Low blood pressure goal in patients with proteinuria

Table 49-3. Long-Term Outcome Studies with Primary Renal Endpoints

trial in favor of such a low blood pressure goal is not as strong.²¹ Another trial that did not show a benefit to a low blood pressure goal in patients with lower levels of proteinuria was the African-American Study of Kidney Disease and Hypertension (AASK), in which African-American patients with hypertensive kidney disease (GFR between 20 and 65 mL/min/1.73 m²) and an average urine protein excretion <1 g/day were randomized to a low blood pressure goal (MAP=92 mmHg) or a usual one (MAP 102 to 107 mmHg). At the end of the study, no benefit of the lower blood pressure goal in reducing the decline in GFR compared to the usual goal was noted.²⁴ The mentioned above meta-analysis of the AIPRD Study Group further supports these findings, in that no significant relation between the level of systolic blood pressure and risk of kidney disease progression in patients with proteinuria <1 g/day was found (Figure 49-3).²³

The percentage of hypertensive patients achieving the current blood pressure goals is rather disappointing. In the United States, estimates suggest that about 34% of the general hypertensive population and 36% of patients with diabetes manage to keep their blood pressure within recommended limits.^{17,25} Data from NHANES III demonstrates that blood pressure control rates in patients with CKD are even lower, as only 11% of hypertensives with elevated serum creatinine levels had a blood pressure of less than 130/85 mmHg.⁵ In clinical trials, the proportion of participants achieving such goals is roughly double that in routine clinical practice. However, in either setting no more than 75% of the total group achieve target blood pressure goal. In the Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart

Attack Trial (ALLHAT), the mean number of medications needed to achieve the mean blood pressure (135/75 mmHg) in patients with stage 1 or 2 hypertension was 2.²⁶ In patients with kidney disease, achievement of blood pressure goals is more difficult and requires even more antihypertensive agents. In particular, to achieve these lower levels of blood pressure in people with renal insufficiency will require an average of 3.5 to 4.2 different antihypertensive agents in moderate to high doses, as shown in Figure 49-4.^{24,27} For example, in the Irbesartan Diabetic Nephropathy Trial (IDNT)—which included subjects with diabetic nephropathy (median urine protein excretion of 2.9 g/day) and renal insufficiency (mean creatinine 1.65 to 1.69 mg/dL)—an average of 4.0 different antihypertensive medications (including the study medication) were required to reduce mean blood pressure from 159/87 mmHg at baseline to 140/70 mmHg at the end of the study.²⁸

All agents that lower blood pressure are known to reduce cardiovascular risk, but certain antihypertensive compounds may have an advantage in reducing the rate of kidney disease progression in the presence of advanced nephropathy. Both JNC 7 and the KDOQI-blood pressure guidelines clearly state that there are compelling and specific indications for the use of ACE inhibitors or angiotensin receptor blockers (ARBs) in the armamentarium to lower blood pressure in individuals with either diabetes or kidney disease.^{1,17} However, these reports also emphasize the fact that arterial pressure in such patients should be reduced to <130/80 mmHg, especially in the presence of proteinuria. It is therefore clear that once a person has established nephropathy the main factor that will slow its progression

Figure 49-3. Relative risk for kidney disease progression based on current level of systolic blood pressure and urine protein excretion. Results based on a meta-analysis of 11 randomized controlled trials. The reference group for each is defined at a systolic blood pressure of 110 to 119 mmHg. (Adapted from Jafar TH, Stark PC, Schmid CH, et al. Progression of chronic kidney disease: The role of blood pressure control, proteinuria, and angiotensin-converting enzyme inhibition. A patient-level meta-analysis. *Ann Intern Med* 2003;139(4):244-52.)

is aggressive blood pressure reduction and that this will require multiple drug treatment.

Microalbuminuria

According to the NKF-KDOQI guidelines, microalbuminuria is defined as urine albumin excretion (UAE) between 30 and 300 mg/day if measured in a 24-hour urine collection or as 30 to 300 mg/g if measured by the preferred method of spot albumin to creatinine (Table 49-4).¹ The appearance of microalbuminuria is the earliest clinical sign of diabetic and hypertensive nephropathy.¹ A diabetic patient with microalbuminuria is considered to have incipient nephropathy, whereas the progression to UAE >300 mg/day or >300 mg/g is considered a sign of overt nephropathy.

Without specific interventions, about 80% of patients with type 1 and 20 to 40% of patients with type 2 diabetes and microalbuminuria will progress to overt nephropathy.

After the onset of overt nephropathy, about 75% of type 1 and 20% of type 2 diabetic patients will develop ESRD in a period of 20 years.¹¹ In addition to the previous, in several studies (either in the general population²⁹ or in individuals with other cardiovascular risk factors^{5,30,31}) the presence of microalbuminuria was associated with an increased risk for cardiovascular events. As shown in Figure 49-5, higher levels of urinary albumin excretion are associated with increased risk for CVD outcomes.^{5,29} Thus, in the JNC 7 guidelines microalbuminuria has been identified as an independent cardiovascular risk factor.¹⁷

Several lines of evidence support that reduction of microalbuminuria is best achieved with agents that block the renin-angiotensin-aldosterone (RAAS) system. In a previous study, Lebovitz et al. randomized patients with hypertension, type 2 diabetes, and GFR between 30 and 100 mL/min to enalapril or control treatment (not including an ACE-inhibitor) and followed them for 3 years. The change in UAE and rate of decline in GFR in both the albuminuria group and in the total study population favored use of the ACE inhibitor, but it did not reach statistical significance. In the group of patients with UAE <300 mg/day, significantly fewer patients progressed to overt nephropathy (7% versus 21%), and the rate of GFR decline was 0.20 versus -0.33 mL/min/1.73 m²/month in the enalapril and the control group (respectively). However, these findings could not be conclusive, as mean blood pressure was 4.9 mmHg lower in the enalapril group.³²

In the Irbesartan Microalbuminuria (IRMA 2) study, 590 patients with hypertension, type 2 diabetes, and GFR microalbuminuria (average range of UAE between 53.4 and 58.3 μg/min) were randomly

Figure 49-4. Number of blood pressure medications needed to achieve systolic blood pressure in large clinical trials ([^] denotes trials with renal endpoints).

DEFINITIONS OF PROTEINURIA AND ALBUMINURIA				
	Urine Collection Method	Normal	Microalbuminuria	Albuminuria or Clinical Proteinuria
Total protein	24-hour excretion	<300 mg/d	NA	>300 mg/d
	Spot urine dipstick	<30 mg/dL	NA	>30 mg/dL
	Spot urine protein-to-creatinine ratio	<200 mg/g	NA	>200 mg/g
Albumin	24-hour excretion	<30 mg/d	30-300 mg/d	>300 mg/d
	Spot urine albumin-specific dipstick	<3 mg/dL	>3 mg/dL	NA
	Spot urine albumin-to-creatinine ratio	<30 mg/g	30-300 mg/g	>300 mg/g
	Spot urine albumin-to-creatinine ratio (gender-specific definition)	<17 mg/g (men)	17-250 mg/g (men)	>250 mg/g (men)
		<25 mg/g (women)	25-355 mg/g (women)	>355 mg/g (women)

assigned to receive placebo or irbesartan 150 mg or 300 mg daily. The primary endpoint was the appearance of clinical nephropathy (i.e., albuminuria >200 μ g/min) and at least a 30% increase from the baseline level. After 24 months of follow-up, the approach of the three groups to the endpoint was 14.9%, 9.7%, and 5.2% (respectively), which translates to a significant 68% reduction in progression to albuminuria between irbesartan 300 mg daily and placebo groups.³³ Whether reduction of microalbuminuria is linked with a reduction in cardiovascular endpoints is still uncertain. The LIFE trial, the only trial that prospectively measured microalbuminuria in a group of hypertensive patients with high CVD risk, demonstrated that the group with lowest cardiovascular event rate had the greatest reduction in microalbuminuria from baseline.³⁴

The adjusted effect of urinary albumin concentration (UAC) on hazard function in the Prevention of Renal and Vascular End Stage Disease (PREVEND) Study. (Adapted from Hillege HL, Fidler V, Diercks GF, et al. Urinary albumin excretion predicts cardiovascular and noncardiovascular mortality in general population. *Circulation* 2002;106(14):1777-82.)

In the Prevention of Renal and Vascular Endstage Disease Intervention Trial (PREVEND IT), 864 inhabitants of the city of Groningen in the Netherlands with microalbuminuria (UAE between 15 and 300 mg/day) were randomized to fosinopril 20 mg/day or matching placebo and pravastatin 40 mg/day or matching placebo.³⁵ Fosinopril reduced UAE by 26% during the mean follow-up of 46 months, but the reduction in cardiovascular mortality or cardiovascular hospitalization in patients treated with this agent showed only a trend toward statistical significance.³⁵ This study, however, was limited by the low overall number of cardiovascular events and by submaximal doses of ACE inhibitors.

In the IRMA 2 study, the higher dose of irbesartan (300 mg versus 150 mg/day) was clearly associated with improved kidney protection³³—a finding indicating that the use of adequate dosages of agents that block the RAAS is necessary to provide maximal kidney protective effects. Recent studies support that ultra-high doses of ARBs can have even better renoprotective results. In one of these studies, 52 type 2 diabetic patients with microalbuminuria were randomized to 300, 600, and 900 mg of irbesartan daily for 2 months. All doses of irbesartan significantly reduced UAE, ambulatory blood pressure, and GFR from baseline, but the 900-mg dose provided an additional 15% reduction in UAE compared to the 300-mg dose. Reductions in ambulatory blood pressure were similar across the three groups.³⁶ Likewise, in a study in proteinuric subjects (mean protein excretion rate between 1 and 10 g/day), the use of 64 mg of candesartan daily for 4 weeks in patients already on 16 mg was associated with a 29% reduction in protein excretion. The use of 32 mg had no significant effect. Moreover, after down-titration of candesartan to 16 mg daily again in both groups proteinuria increased in patients formerly receiving 64 mg but remained stable in those formerly on 32 mg.³⁷ In view of these findings, further studies are necessary to delineate the optimal renal protective doses of ARBs.

Intervention with a RAAS blocker has been also shown to protect against the development of microalbuminuria in hypertensive patients with type 2 diabetes. In particular, in the Bergamo Nephrologic Diabetes Complications Trial

(BENEDICT) 1204 patients with hypertension, type 2 diabetes, and normal UAE (median between 5.02 and 5.91 $\mu\text{g}/\text{min}$) were randomized to the non-dihydropyridine calcium-channel blocker (CCB) verapamil (240 mg per day), the ACE inhibitor trandolapril (2 mg per day), the combination of verapamil (180 mg per day), and trandolapril (2 mg per day) or to placebo.³⁸ After a median follow-up of 3.6 years, progression to microalbuminuria was significantly lower in the subjects treated with trandolapril or the combination (6.0 and 5.7%, respectively) compared to the subjects receiving verapamil or placebo (11.9 and 10.0%, respectively).³⁸

Proteinuria

The NKF-KDOQI guidelines define albuminuria or clinical proteinuria as urinary albumin or protein excretion >300 mg/day if measured in a 24-hour urine collection (Table 49–5).¹ The presence of proteinuria and increased stage of kidney disease are associated with faster progression to kidney failure and increased risk of CVD.^{1,14,15,39,40} Therefore, the goal of therapy in patients with proteinuria is to reduce rate of kidney disease progression and the risk of CVD.^{1,40} Data from the MDRD study and the meta-analysis by the AIPRD Study Group show that reduction of blood pressure in patients with proteinuria slows the progression to kidney failure.^{21,23} In addition, reductions in proteinuria correlate with preservation of kidney function, as well as with reductions in cardiovascular mortality.⁴¹ It is interesting that the classes of drugs that fail to reduce proteinuria (i.e., dihydropyridine CCBs, alpha blockers, hydralazine, and minoxidil) have also failed to either slow progression of kidney disease or reduce mortality in the absence agents that reduce proteinuria.⁴²

ACE inhibitors and ARBs are the antihypertensive agents that have most consistently been found to reduce proteinuria and the rate of renal function deterioration in diabetic and nondiabetic kidney disease. In a previous study, that of the Collaborative Study Group, 409 type 1 diabetic patients with overt nephropathy (UAE=0.5 g/day) and mild renal insufficiency (serum creatinine=2.5 mg/dL) were randomized to captopril or placebo. In the captopril-treated

group, a mean decrease of UAE of 0.3 g/day versus baseline was observed after a median follow-up of 3 years. In addition, patients treated with captopril had a 43% reduction in the primary endpoint of doubling of serum creatinine and a 50% reduction in the combined endpoints of death, need for dialysis, and transplantation in comparison with the placebo group.⁴³ The use of ACE inhibitors to reduce proteinuria in nondiabetic kidney disease is supported by the original REIN Study, the AASK trial, and the meta-analysis by the AIPRD Study Group. In the REIN study, nondiabetic patients with an average creatinine of 2.4 mg/dL and 24-hour urine protein excretion >3 g/day were randomized to ramipril 5 mg/day or placebo. The ramipril group presented a 55% reduction in median urine protein excretion from baseline and significant reductions in urine protein excretion and GFR decline compared to placebo.⁴⁴ In the AASK trial, African-American patients with hypertensive kidney disease, mean serum creatinine of 2.2 mg/dL, and 24-hour urine protein excretion of 0.6 g/day were randomized to ramipril, amlodipine, or metoprolol. Patients treated with ramipril had a 36% reduction in the secondary composite outcome of 50% reduction of GFR, ESRD, or death compared to amlodipine, and a 22% reduction compared to metoprolol.²⁴ The meta-analysis by the AIPRD Study Group in nondiabetic CKD showed that regimens including an ACE inhibitor were associated with a 31% reduction in progression to ESRD and a 30% reduction in the combined endpoint in doubling of serum creatinine or progression to ESRD.⁴⁵

Two randomized controlled trials have shown that ARBs are effective in reducing proteinuria and in slowing the progression to kidney failure in nephropathy due to type 2 diabetes. In the Reduction in Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) Study, 1513 type 2 diabetic patients with nephropathy (mean creatinine 1.9 mg/dL and median urine albumin-to-creatinine ratio 1237 mg/g) were randomized to losartan or placebo. Patients treated with losartan had a 35% reduction in the urinary albumin-to-creatinine ratio, whereas patients in the placebo group tended to have an increase. In addition, treatment with losartan resulted in a 16% reduction in

RECOMMENDATIONS ON HYPERTENSION AND ANTIHYPERTENSIVE AGENTS IN CHRONIC KIDNEY DISEASE			
Type of Kidney Disease	Blood Pressure Target (mmHg)	Preferred Agents for CKD, with (or Without) Hypertension	Other Agents to Reduce CVD Risk and Reach Blood Pressure Target
Diabetic kidney disease	<130/80	ACE inhibitor or ARB	Diuretic preferred, then BB or CCB
Nondiabetic kidney disease with spot urine total protein-to-creatinine ratio ≥ 200 mg/g	<130/80	ACE inhibitor or ARB	Diuretic preferred, then BB or CCB
Nondiabetic kidney disease with spot urine total protein-to-creatinine ratio <200 mg/g	<130/80	None preferred	Diuretic preferred, then ACE inhibitor, ARB, BB, or CCB

Adapted from K/DOQI clinical practice guidelines on hypertension and antihypertensive agents in chronic kidney disease. *Am J Kidney Dis* 2004;43(5 Suppl 2):1–290 with permission from The National Kidney Foundation, Inc.

Table 49–5. Recommendations on Hypertension and Antihypertensive Agents in Chronic Kidney Disease

the primary endpoint of doubling of baseline serum creatinine, progression to ESRD, or death. The median rate of decline in estimated clearance was 4.4 and 5.2 mL/min/1.73 m²/per year in the losartan and placebo groups, respectively.²⁷

In the previously mentioned IDNT study, 1715 patients with diabetic nephropathy (mean creatinine 1.65 to 1.69 mg/dL and median urinary protein excretion 2.9 g/day) were randomized to 300 mg of irbesartan, 10 mg of amlodipine, or placebo. After a mean follow-up of 2.6 years, proteinuria was decreased by 33% in the irbesartan group versus 6% in the amlodipine group and 10% in the placebo group. Treatment with irbesartan also resulted in a 20% reduction compared to placebo and 23% reduction compared to amlodipine in the primary composite outcome of doubling of baseline serum creatinine, onset of ESRD, or death from any cause. The risk of a doubling of the serum creatinine concentration was 33% lower in the irbesartan group than in the placebo group, and 37% lower in the irbesartan group than in the amlodipine group. The mean rate of decline of creatinine clearance was -5.5, -6.8, and -6.5 mL/min/1.73 m² per year in the irbesartan, placebo, and amlodipine groups (respectively).²⁸

The Diabetics Exposed to Telmisartan And enalapril (DETAIL) study more recently compared the long-term renoprotective effects of enalapril 10 to 20 mg and telmisartan 40 to 80 mg in 250 patients with type 2 diabetes, hypertension, and UAE between 11 and 999 µg/min.⁴⁶ After 5 years of follow-up, the change in the glomerular filtration rate (which was the primary endpoint) was -17.5 mL/min/1.73 m² in the telmisartan-treated subjects and -15.0/min/1.73 m² in the enalapril-treated subjects. The treatment difference was thus -2.6 mL/min/1.73 m², with 95 confidence interval (-7.1 to 2.0 mL/min/1.73 m²). Because the lower boundary of the confidence interval in favor of enalapril was greater than the predefined margin of -10.0 mL/min/1.73 m², statistical analysis revealed that telmisartan was not inferior to enalapril in preserving renal function. The effects of the two agents on the secondary endpoints of the annual changes in the glomerular filtration rate, serum creatinine level, UAE, blood pressure, end-stage renal disease, and cardiovascular events and the rate of death from all causes were not significantly different.⁴⁶

Although kidney protection with dual blockade of the RAAS with the combined use of ACE inhibitors and ARBs has not been as extensively studied, preliminary data indicate that dual RAAS blockade can reduce proteinuria and slow kidney disease progression more effectively than either using ACE inhibitors or ARBs alone. In the COOPERATE trial, patients with nondiabetic kidney disease and mean urinary protein excretion of 2.5 g per day were randomized to trandolapril 3 mg daily, losartan 100 mg daily, or a combination of the two drugs at the same dosages.⁴⁷ After 3 years of follow-up, urinary protein excretion was reduced significantly more with combined therapy (75.6%) compared to trandolapril (44.3%) or losartan (44.1%) alone. Moreover, the group of patients treated with the combined therapy had a 60 to 62% reduction in the primary endpoint of time to doubling of serum creatinine concentration or ESRD compared to either trandolapril- or losartan-

treated group.⁴⁷ It is important to note that these findings were independent of blood pressure differences, as both the office and ambulatory blood pressure reductions were similar across all three groups.⁴⁸ However, because this trial included only 263 patients larger studies are needed to confirm these findings.

In addition, it has to be noted that recently published data from several of the previously cited renal outcome trials clearly show that the reported benefit on kidney disease progression with the use of an ACE inhibitor or an ARB could not be explained by blood pressure lowering alone and that reduction of proteinuria *per se* is a particularly important factor in retardation of kidney disease progression.⁴⁹⁻⁵¹ In particular, retrospective analyses of the AASK, RENAAL, and IDNT studies showed that a reduction in proteinuria of more than 35% with the use of an ACE inhibitor or an ARB resulted in a range of 39 to 72% risk reduction for dialysis at 3 to 5 years, identifying the change in the level of proteinuria as a strong predictor of subsequent progression of CKD.⁴⁹⁻⁵¹

Further blockade of the RAAS with aldosterone receptor antagonists such as spironolactone and eplerenone in patients already on an ACE inhibitor or an ARB may also be beneficial. It has been shown that blockade of the RAAS with ACE inhibitors does not necessarily result in a maintained decrease in plasma aldosterone levels, which can either remain high or increase in the long run (aldosterone escape).^{52,53} As far as ARBs are concerned, a preliminary study showed that hypertensive patients treated with losartan for 12 months had no change in plasma aldosterone levels.⁵⁴ Even in studies in which plasma aldosterone was decreased with RAAS blocking agents,⁵⁵ the reductions were small and therefore the action of this hormone was not fully suppressed. Plasma aldosterone levels are elevated in patients with chronic renal insufficiency and could play a role in kidney injury.^{56,57} Several studies suggest that the addition of spironolactone in patients with proteinuric nephropathy receiving an ACE or an ARB results in a reduction of urine protein excretion.⁵⁸⁻⁶² Eplerenone, the newer aldosterone receptor antagonist that lacks the side effect of gynecomastia,⁶³ has also been shown to further reduce urine albumin excretion in patients with hypertension and left ventricular hypertrophy when combined with an ACE inhibitor.⁶⁴ Future studies combining aldosterone blockade with the use of an ACE inhibitor or an ARB in larger populations of CKD patients are necessary to determine the effect of these combinations on kidney function preservation.

Cardiovascular disease

As mentioned previously, patients with decreased GFR have markedly increased risk of cardiovascular events compared to patients with normal kidney function, and this risk of cardiovascular events progressively increases as GFR declines.¹⁴⁻¹⁶ Among patients in the Medicare database, 80% of those with CKD submitted CVD claims over a 2-year period compared with 45% of those without CKD and the prevalence of heart failure was four times higher in CKD patients compared to those without CKD.² In ESRD patients treated by dialysis, the risk of cardiovascular death increases further, with cardiovascular mortality rates approxi-

mately 5 to 500 times higher than age- and sex-matched controls in the general population.^{1,65} This elevation of the risk for cardiovascular events and cardiovascular mortality with the progressive decrease of GFR has also been demonstrated in patients after a myocardial infarction.⁶⁶ Based on the NKF-KDOQI guidelines, patients with CKD can be considered in the highest risk category for CVD.¹

Hypertension is one of the major independent risk factors for CVD,^{12,13} and pharmacologic treatment of high blood pressure in hypertensive individuals has been shown beyond doubt to decrease the risk of a range of cardiovascular events.^{67–69} Because of the slow rate of decline of kidney function and the high cardiovascular death rate associated with CKD, most individuals with CKD will not develop ESRD but instead die from an intercurrent cardiovascular event. Therefore, blood pressure control is imperative in the treatment of CKD not only to slow down the progression to ESRD but (perhaps most importantly) to deter cardiovascular morbidity and mortality. Apart from hypertension, there is a substantial overlap in the rest of the traditional risk factors for CVD and CKD.^{8,70} Thus, the optimal therapeutic approach for CVD in patients with CKD requires a multi-intervention strategy with a coordinated effort by practitioners and apart from aggressive blood pressure control includes smoking cessation, management of diabetes, and lipid lowering with pharmacologic and lifestyle measures—as well as other interventions, from antiplatelet therapy (low-dose aspirin) to correction of anemia if present.^{1,8}

Management of hypertension in kidney disease

As mentioned previously, the achievement of a goal blood pressure less than 130/80 mmHg in patients with kidney disease has been proven quite difficult and requires both lifestyle modifications (most important of which is sodium restriction due to the impaired salt excretion in CKD⁷) and multiple antihypertensive medications.^{1,17} The selection of antihypertensive agents in CKD should be based on the pathophysiology of hypertension in kidney disease, which includes sodium and water retention and increased vasoconstriction due to activation of the RAAS and the sympathetic nervous system.⁷ The combined use of agents that affect these mechanisms will counteract the effects of these pathophysiologic mechanisms, thereby helping blood pressure levels return to optimum and consequently providing a reduction in organ injury.

Several lines of evidence indicate that in various stages and types of CKD agents that block the RAAS should be the drugs of choice. Based on the results of IRMA 2 and PREVENT IT trials, adequate doses of an ARB or an ACE inhibitor should be preferentially used in patients with microalbuminuria in order to reduce UAE and to prevent the onset of overt nephropathy.^{33,35} In patients with kidney disease and proteinuria, agents that block the RAAS (such as ACE inhibitors and ARBs) are also preferred as part of a regimen to achieve blood pressure control.¹ Based on the results of Captopril in Diabetic Nephropathy trial, ACE inhibitors should be the agents of choice in patients with proteinuria due to type 1 diabetes.⁴³ Patients with overt

nephropathy due to type 2 diabetes should be preferably treated with an ARB, based on the evidence from clinical trials such as IDNT and RENAAL—which both showed a regression in the decline in GFR as well as the onset of kidney failure with the use of ARBs.^{27,28} However, the results of the DETAIL trial⁴⁶ suggest and the NKF-KDOQI guidelines indicate that either ACE inhibitors or ARBs can be used to manage blood pressure in people with type 2 diabetes to preserve kidney function.¹

On the other hand, in patients with nondiabetic kidney disease and proteinuria ACE inhibitors should be preferred based on results from the REIN and AASK trials.^{24,44} In addition to these quite similar renoprotective properties, ARBs and ACE inhibitors present other beneficial properties (i.e., they reduce the risk for new-onset diabetes⁷¹ and reduce the incidence of recurrent stroke).^{72,73} It must be noted, however, that ARBs are generally better tolerated than ACE inhibitors because they are associated with a lower incidence of cough, angioedema, and hyperkalemia.⁷⁴ Based on the previous, the NKF-KDOQI guidelines recommend the use of either an ACE inhibitor or an ARB (regardless of blood pressure) in all patients with diabetic kidney disease and in patients with nondiabetic kidney disease with a spot urine total protein-to-creatinine ratio ≥ 200 mg/g, as shown in Table 49–5.¹ In addition, the guidelines suggest that moderate to high doses (rather than low doses) of RAS-blocking agents be used to achieve additional benefits—according to the evidence that the use of higher doses of RAS-blocking agents may achieve greater reductions in microalbuminuria and proteinuria.

In spite of substantial evidence from long-term clinical trials demonstrating the renal protective effects of ACE inhibitors and ARBs for patients with CKD, there is general hesitancy among clinicians to prescribe these agents in patients with serum creatinine >1.4 mg/dL because serum creatinine often rises after an ACE inhibitor or an ARB is given. The most common cause of increased creatinine following blockade of the RAAS is from preexisting decreased arterial blood volume, often due to volume depletion or low cardiac output. With kidney dysfunction, the autoregulatory ability of the kidney to maintain intrarenal arterial pressure diminishes. This results in a direct relationship between systematic blood pressure and GFR. Therefore, an abrupt decrease in blood pressure often results in a pressure-related drop in GFR, manifesting itself with an increase in serum creatinine levels. Analysis of long-term clinical trials has confirmed that ACE inhibitor induced reduction in kidney function plateaus within 2 months.⁹

If serum creatinine increases by $>30\%$ or continues to rise after 3 months of therapy with a RAAS-blocking agent, volume depletion, unsuspected left ventricular dysfunction, or bilateral renal artery stenosis should be considered.⁹ In general, according to the JNC 7 and the NKF-KDOQI guidelines at serum creatinine values of <3.0 mg/dL and age <65 years a 30 to 35% increase in serum creatinine above the starting point is acceptable within the first 3 to 4 months of starting blood pressure treatment—as long as creatinine does not continue to rise and hyperkalemia does not occur.^{1,17} Apart from this, ACE inhibitors and ARBs are often discontinued due to rises in serum potassium levels.

This should be worrisome only if serum potassium rises ≥ 0.5 mEq/L and the baseline level is already greater than 5 mEq/L. Otherwise, elevations in serum potassium can often be addressed by increasing the dose of appropriate diuretics, stopping agents known to increase potassium (such as nonsteroidal anti-inflammatory agents that decrease renal perfusion), and providing dietary education of potassium-containing foods.

In the COOPERATE trial, only 8% (7 out of 88 patients) of the patients on combination treatment with an ACE inhibitor and ARB developed hyperkalemia and were all successfully treated for it with dietary education or potassium binders.⁴⁷ Therefore, ACE inhibitors or ARBs should be withdrawn only when the rise of serum creatinine exceeds 30 to 35% above baseline within the first 3 to 4 months of therapy or when hyperkalemia (serum potassium >5.6 mEq/L) occurs.

Due to increased salt and water retention with kidney function deterioration, diuretics often need to be included in the antihypertensive regimen in patients with kidney disease. However, thiazide diuretics become less effective when GFR falls below 30 mL/min/1.73 m², because of the reduced renal blood flow and the accumulation of organic acid end products of metabolism that antagonize diuretics at the level of the secretion in the tubular fluid—which will require high doses of the drugs for an adequate amount to reach the tubular sites of action.⁷⁵ An adequate blood pressure control in patients with renal insufficiency is thus very likely to need a loop diuretic (furosemide, torsemide, bumetanide, and so on) as part of the blood-pressure-lowering regimen because these compounds have higher intrinsic efficacy compared to thiazides.⁷⁵ Potassium-sparing diuretics should be avoided in patients with preexisting hyperkalemia; that is, serum potassium more than 5.5 mEq/L from either diabetes or renal disease of other etiologies.

According to the previously cited data on the ability of aldosterone blockade to further reduce proteinuria in patients already receiving an RAAS blocking agent,^{58–62} use of aldosterone receptor antagonists such as spironolactone and eplerenone in low doses may be indicated in patients with proteinuric CKD, especially if heart failure is present.⁷⁶ However, when using spironolactone or eplerenone serum potassium must be followed closely because levels rise in a dose-dependent fashion and a dose adjustment of the concomitant conventional diuretic therapy should always be considered.

It also has to be noted that although moderate to high doses of diuretics worsen insulin resistance and increase the risk for new onset diabetes, when currently recommended low doses of diuretics are taken in combination with an ACE inhibitor or ARB their effects on insulin sensitivity and other metabolic parameters are negligible.⁷⁷ Based on NKF/KDOQI guidelines, because combination of two or more antihypertensive agents are imperative to achieve the current blood pressure goal in most patients with CKD a diuretic should be the first agent added to the ACE inhibitor or the ARB regimen if necessary in all patients with diabetic kidney disease and in patients with nondiabetic kidney disease with spot urine total protein-to-creatinine ratio ≥ 200 mg/g (Table 49–5).¹ In addition, in patients with

nondiabetic kidney disease with spot urine total protein-to-creatinine ratio <200 mg/g a diuretic should be one of the initial choices to achieve blood pressure goal.¹

The antihypertensive effects of conventional β -blockers, as well as their capability to reduce cardiovascular mortality in high-risk patients, have been well established.^{69,78} However, there is no direct evidence that these agents provide additional renoprotective effects. Data regarding whether β -blockers are associated with increased risk of progression of kidney disease are conflicting. In a former study, type 2 diabetic patients with proteinuria were titrated to atenolol 100 mg/day versus sustained-release verapamil 480 mg/day. After 54 months of follow-up, patients treated with the non-dihydropyridine CCB had a significant reduction in creatinine rise and proteinuria compared to patients in the β -blocker group.⁷⁹ In the UKPDS 39 study, comparison of the effectiveness of captopril and atenolol as basic therapy in patients with type 2 diabetes with incipient nephropathy took place. Both study groups achieved the same levels of blood pressure with similar percentage of additional non-study drugs. The progress to overt nephropathy was 5% in the captopril group and 9% in the atenolol group at the end of the study, with no statistically significant difference between them. There was also no difference in the rate of plasma creatinine doubling or in plasma creatinine concentration between the two groups.⁸⁰

These findings suggest that any renoprotective effect is due to lowering of blood pressure. It has to be noted, however, that a newer β -blocker with vasodilating properties (carvedilol) has a much better metabolic effect profile than conventional β -blockers⁸¹ and has been shown to reduce the risk of microalbuminuria in patients with hypertension and diabetes⁸² and mortality in people with ESRD.⁸³ Therefore, based on the NKF-KDOQI guidelines β -blockers should be normally used in patients with CKD when a combination of proper doses of an ACE inhibitor or an ARB regimen with a diuretic is not enough to low blood pressure levels below the goal of 130/80 mmHg.¹ The beneficial metabolic profile of carvedilol is an indication for preferable use of this β -blocker in such high-risk patients, whereas future studies should investigate the effect of this agent on renal function in patients with CKD.

Calcium channel blockers are effective antihypertensive agents in patients with kidney disease. However, within the class of CCBs the various agents have different effects on proteinuria beyond their blood-pressure-lowering effects due to differences in glomerular permeability.^{84,85} As shown in Table 49–3, non-dihydropyridine CCBs (verapamil, diltiazem) have been shown to reduce proteinuria,^{79,86} whereas dihydropyridine CCBs do not unless used in the presence of a RAAS blocker.^{87,88} In addition, dihydropyridine CCBs are less efficacious in slowing kidney disease progression. As mentioned previously, the IDNT patients with proteinuria due to type 2 diabetes who were treated with irbesartan had a 23% reduction compared to amlodipine in the primary composite outcome of doubling of baseline serum creatinine, onset of ESRD, or death from any cause—as well as a significant reduction in urine protein excretion compared to amlodipine.²⁸ Similar findings with dihydropyridine CCBs have been observed in nondiabetic kidney disease with

proteinuria. In the AASK trial, African-American patients with hypertensive nephrosclerosis treated with ramipril had a 36% reduction in the composite outcome of 50% reduction of GFR, ESRD, or death compared to patients treated with amlodipine.²⁴ Based on the previous, although dihydropyridine CCBs are effective in lowering blood pressure in patients with CKD they should not be used as monotherapy in diabetic or nondiabetic kidney disease with proteinuria but always in combination with an ACE inhibitor or an ARB if blood pressure is not adequately controlled.¹

Recently published data from the second part of the Ramipril Efficacy in Nephropathy (REIN-2) study question the ability of dihydropyridine CCBs to help prevent renal function deterioration in proteinuric kidney disease even by means of blood pressure lowering. In this study, 335 patients with nondiabetic nephropathy and urine protein excretion >1 g/day who were already receiving background treatment with the ACE inhibitor ramipril (2.5 to 5 mg/day) were assigned to either conventional (diastolic blood pressure <90 mmHg) or intensified (systolic/diastolic blood pressure <130/80 mmHg)—with the addition of the dihydropyridine CCB felodipine (5 to 10 mg/day). After a median follow-up of 19 months and in spite of a difference of 4.1/2.8 mmHg in blood pressure levels throughout the study in favor of the intensified regimen, the cumulative incidence of end-stage renal disease, rate of GFR decline, and residual proteinuria were similar in the two arms.⁸⁹ These findings argue against the use of dihydropyridine CCBs in proteinuric nephropathies, but have to be further confirmed from other studies with longer follow-up periods.

Although combining effective blood pressure reduction⁹⁰ and a beneficial metabolic profile,^{91,92} α -blockers have not

been shown to slow renal disease progression or to reduce UAE in patients with type 2 diabetes and albuminuria.⁹³ Moreover, this class of agents also failed to reduce cardiovascular events in patients who have or develop heart failure—as evidenced by the results of the long-acting α -blocker arm of ALLHAT (which was stopped early due to increased incidence of heart failure⁹⁴). Hence, this class should not be preferred as an initial or even secondary treatment for hypertension in patients with CKD but as third-line treatment, especially in older men with benign prostatic hypertrophy and urine flow problems.⁹⁵

SUMMARY

As the prevalence of chronic kidney disease has grown dramatically during the past decades, slowing the decline in renal function to prevent kidney failure has become a therapeutic target of major importance. The goals of therapy in patients with CKD are to control blood pressure, reduce the risk of CVD, and slow the progression of renal dysfunction. There is now strong evidence that blood pressure levels should be reduced to less than 130/80 mmHg in patients with kidney disease, especially if proteinuria is present. There is also evidence that ACE inhibitors and ARBs are effective in reducing proteinuria and in slowing the progression of renal dysfunction. Based on these observations, hypertension in patients with CKD and proteinuria should be initially managed with an ACE inhibitor or an ARB, and if more antihypertensive agents are necessary to reach goal blood pressure initially a diuretic and then compounds from the other antihypertensive classes should be added.

Hypertensive Heart Disease

Javier Díez

Definition

Hypertensive heart disease can be defined as the cardiomyopathy that results from the response of the myocardium to the biomechanical stress imposed on the left ventricle by progressively increasing arterial pressure.

Key Features

- Hypertensive heart disease is characterized by the presence of left ventricular hypertrophy in the absence of a cause other than arterial hypertension.
- Beyond macroscopic hypertrophy, complex changes in myocardial histological composition (which are responsible for the structural remodeling of the myocardium) develop in hypertensive heart disease.
- Hypertensive myocardial remodeling is the consequence of several pathologic processes mediated by mechanical, neurohormonal, and cytokine routes and occurring in the cardiomyocyte and the noncardiomyocyte compartments of the heart.

Clinical Implications

- Left ventricular hypertrophy represents not only an adaptation to increased pressure load but an independent risk factor and a marker of risk of cardiovascular complications in hypertensive patients.
- Hypertensive left ventricular hypertrophy is often associated with disturbances of cardiac function and electric activity, as well as with cardiac ischemia, heart failure, cardiac arrhythmias, and a higher incidence of stroke and sudden death.
- Concurrent atherosclerotic coronary disease and left ventricular hypertrophy in hypertensive patients increase the risk of all cardiovascular events.
- Left ventricular hypertrophy may be detected early and accurately in hypertensive patients by electrocardiography or echocardiography.

Therapy

- Effective long-term antihypertensive treatment is associated with regression of left ventricular hypertrophy.
- Regression of left ventricular hypertrophy by antihypertensive treatment is associated with improvement in outcome and with the decrease of the risk of cardiovascular morbidity and mortality.

In general, the cardiac complications of arterial hypertension can be considered as either atherosclerotic or hypertensive. The former have multiple causes and the latter are more directly caused by the increased blood

pressure *per se*. In fact, because increased blood pressure is one of the major risk factors that facilitates atherosclerotic coronary artery disease, the prevalence of arterial hypertension is >60% in patients with chronic ischemic heart disease. On the other hand, hypertensive heart disease (HHD) can be defined as the response of the heart to the afterload imposed on the left ventricle by the progressively increasing arterial pressure and total peripheral resistance.¹

HHD is characterized by increased left ventricular (LV) mass associated with left ventricular hypertrophy (LVH). Hypertension-induced LVH consists of a constellation of genetic, structural, and functional abnormalities of cardiac tissue that allow its differentiation as a separate entity, which has been recently referred to as a so-called “hypertensive cardiomyopathy.”² LVH is associated with alterations of cardiac function, abnormalities of myocardial perfusion, and disturbances of cardiac rhythm in hypertensive patients. In addition, LVH is an independent risk factor associated with cardiovascular complications in these patients. The diagnostic methods such as electrocardiography and echocardiography that are used to define LVH are discussed elsewhere in this book. A number of studies have established that reduction of LV mass is achieved with effective antihypertensive treatment and that reversal of LVH by blood pressure control is associated with decreases in cardiovascular event rates in hypertensive patients. Therefore, there is an important need for physicians to recognize this entity, to understand its pathophysiology, and to become fluent in treatment options available.

STRUCTURAL AND MOLECULAR BASIS**The hypertrophy of the left ventricle**

The essential anatomic criterion in defining HHD is the presence of LVH in the absence of a cause other than arterial hypertension. LV cavity dimension remains normal but LV mass is considerably increased due to increased wall thickness. Thus, HHD is generally characterized by a geometric pattern of concentric LVH (Figure 50–1).

LVH is mainly the result of cardiomyocyte growth in conjunction with changes in extracellular matrix and provides the adaptive response of the heart to pressure overload in an attempt to normalize systolic wall stress (as predicted by Laplace’s law). The degree of cardiomyocyte hypertrophy to mechanical stress imposed by pressure overload is, however, inappropriate and the increase in LV mass is out of proportion to the hemodynamic stimulus.

Figure 50–1. Macroscopic view of the typical geometric pattern of concentric left ventricular hypertrophy seen in hypertensive patients.

Recent data suggest that this exaggerated cardiomyocyte response is the result of the interaction between genetic (e.g., polymorphisms of the angiotensin-converting enzyme, ACE, gene) and environmental factors (e.g., obesity, excessive sodium intake). The growth of cardiomyocytes that follows mechanical loading of the LV is a true hypertrophic response (i.e., cardiomyocyte mass increases in the absence of an increase in cardiomyocyte number).

The hypertrophic response of cardiomyocytes can be categorized into several components:³ (1) an increase in the transverse or longitudinal size (Figure 50–2) of the cell, (2) enhanced protein synthesis leading to the formation of new (sarcomeres that are added in parallel or in series) resulting in cardiomyocyte thickening and/or elongation, respectively, and (3) altered profile of gene expression linked to overexpression of several proto-oncogenes (i.e., *c-fos*, *c-jun*, and *c-myc*), mediating the expression of a range of gene transcripts that occur most often in embryonic but not adult ventricular myocardium

(i.e., skeletal α -actin and atrial natriuretic factor). A number of ultrastructural changes are also present in the hypertrophied cardiomyocyte, including polyploidization of nuclei with increased DNA content, decrease in the mitochondrial volume fraction with reduction of the ratio of mitochondrial to myofibrillar volume, increase of free polyribosomes, increase in the surface area of the T-tubules and smooth endoplasmic reticulum, and accumulation of Z-band material (which may serve as the locus of new sarcomere formation).

The remodeling of the myocardium

Beyond macroscopic and microscopic hypertrophy, however, complex changes in myocardial histological composition (responsible for the structural remodeling of the myocardium) develop in HHD (Box 50–1). Structural remodeling is the consequence of a number of pathologic processes mediated by mechanical, neurohormonal, and cytokine routes and occurring in the cardiomyocyte and the noncardiomyocyte compartments of the heart.

Cardiomyocyte apoptosis appears to be abnormally stimulated in the hypertrophied heart of hypertensive patients.⁴ In addition, moderate cardiomyocyte loss has been demonstrated in long-term systemic hypertension. Interestingly, an association between increased apoptosis and diminished cardiomyocyte density has been reported in the human hypertensive heart; namely, when heart failure (HF) develops. Cardiomyocyte apoptosis has been proposed to occur as an excess of those factors that induce apoptotic cell death. Alternatively, it is possible that apoptosis reflects some abnormalities in those survival factors that act to determine the resistance of the cell to apoptosis.

Myocardial fibrosis secondary to an exaggerated accumulation of collagen type I and type III fibers within the interstitium and surrounding intramural coronary arteries and arterioles (Figure 50–3) is one of the key features of structural remodeling of the hypertensive left ventricle.⁵ In fact, various studies performed in human heart post-mortem specimens and endomyocardial human biopsy samples have shown that the fraction of myocardial volume occupied by collagen fibers (i.e., collagen volume fraction or CVF) is significantly increased in the heart of patients with HHD compared with that in normotensive popula-

Figure 50–2. Microscopic view of the two patterns of cardiomyocyte growth present in the human hypertensive hypertrophied left ventricle. Left panel, transversal hypertrophy; right panel, longitudinal hypertrophy. (Sections were stained with hematoxylin-eosin.) (With permission from The American College of Cardiology Foundation.)

Figure 50-3. Microscopic view of the two topographical patterns of collagen deposition leading to myocardial fibrosis in the human hypertensive hypertrophied left ventricle. Left panel, interstitial fibrosis; right panel, perivascular fibrosis. (Sections were stained with picosirius red and collagen fibers were identified in red.)

Box 50-1

Histologic Components of Structural Remodeling of the Myocardium in Hypertensive Heart Disease

At the parenchymal level:

- Cardiomyocytes: hypertrophy, increased apoptosis
- Fibroblasts: hyperplasia, phenotypic transformation to myofibroblasts
- Other cells: infiltration by monocytes/macrophages, proliferation of mast cells
- ECM: increased deposition of fibrillar collagen types I and III, increased deposition of fibronectin

At the microvascular level:

- Small arteries and arterioles: hypertrophy and/or hyperplasia of smooth muscle cells
- Disruption of the endothelial layer
- Increased wall deposition of ECM components
- Capillaries: diminished number

ECM means extracellular matrix.

tions. Excess of ventricular collagen seen in hypertension is suggested to be the result of both increased collagen synthesis by fibroblasts and phenotypically transformed fibroblast-like cells or myofibroblasts, as well as unchanged or decreased collagen degradation by matrix metalloproteinases. Hypertensive fibrosis is now considered to be the consequence of the loss of reciprocal regulation that normally exists at the myocardial level between profibrotic and antifibrotic molecules (Box 50-2).

Hypertensive patients with LVH present different structural alterations in the small coronary vessels.⁶ On the one hand, hyperplasia and/or hypertrophy (and altered alignment of vascular smooth muscle cells leading to encroachment of the tunica media into the lumen) cause both an increase in the medial thickness/lumen ratio and

a reduction in the maximal cross-sectional area of intramyocardial arteries (Figure 50-4). In addition to mechanical factors, a number of local growth factors and vasoactive substances may directly stimulate proliferation and hyperplasia of vascular smooth muscle cells in the hypertensive heart. On the other hand, if the density of arterioles and capillaries is estimated as the vessel number per unit area there is a relative decrease in arteriolar and capillary density in LVH. This can be due to both capillary rarefaction (i.e., the vessels are actually missing or temporarily not perfused or “recruited”) and inadequate vascular growth (i.e., impaired angiogenesis) in response to increasing muscle mass.

Box 50-2

Molecules That Regulate the Metabolism of Fibrillar Collagen in the Heart

Molecules favoring synthesis over degradation:

- Growth factors: transforming growth factor beta, connective tissue growth factor
- Cytokines: interleukin-6, cardiotrophin-1, osteopontin, thrombospondin
- Vasoactive substances: angiotensin II, norepinephrine, endothelin-1
- Adrenal steroids: aldosterone, deoxycorticosterone
- Other molecules: reactive oxygen species, plasminogen activator inhibitor 1

Molecules favoring degradation over synthesis:

- Cytokines: tumor necrosis factor alpha, interleukin-1 beta
- Vasoactive substances: bradykinin, prostaglandins, nitric oxide, natriuretic peptides
- Adrenal steroids: glucocorticoids
- Other molecules: N-acetyl-seryl-aspartyl-lysyl-proline, endogenous ligands of PPAR alpha, peroxisome proliferator-activated receptor

Figure 50–4. Microscopic view of an intramyocardial artery presenting thickening of the wall and narrowing of the lumen in a human hypertensive hypertrophied left ventricle.

PATHOPHYSIOLOGY

Mechanisms of LVH

It is well known that hypertension is the major factor involved in the development of LVH, but nevertheless the relationship is complex and simple linear correlation between the magnitude of the hypertrophy and measured arterial pressure is poor. In fact, in untreated patients with mild hypertension blood pressure levels (as assessed with clinical and ambulatory monitoring) explain at most approximately 40% of LV mass variability independent of demographics, nutrition, and lifestyle.⁷ Thus, although hemodynamic mechanisms play a leading role in the development of LVH in hypertension this process reflects more than simple pressure or volume overload and other factors should be considered (Box 50–3).⁸

The occurrence of the different geometric forms of LVH is variable and is dependent on the hemodynamic and demographic characteristics of the population.^{9–11} The prevalence of concentric hypertrophy is increased by greater severity of hypertension, advancing age, and higher peripheral resistance with normal intravascular volume. Eccentric hypertrophy is more common in young patients and in those with relative volume overload. The evolution of eccentric to concentric hypertrophy may be caused by the increase in peripheral resistance that occurs with aging. Ethnic differences in myocardial response to hypertension are clearly evident. Studies performed both in the United States and in the United Kingdom, comparing blacks and whites, concluded that African-American or Afro-Caribbean patients tend to have a greater prevalence of concentric LVH. Ventricular geometry and responses may also be influenced by gender. In the Framingham community survey, LV hypertrophy in the context of hypertension tended to be more often concentric in women and eccentric in men.

Whatever are the factors potentially responsible for the increase in LV mass in patients with hypertension, the signals for cardiomyocyte growth are multiple (generated both locally and systemically).¹² Such mediators include (1) mechanical stretch itself (which is communicated to both cardiomyocytes and non-cardiomyocytes) that may directly activate cell signaling, (2) autocrine factors (released by cardiomyocytes in response to stretch or growth factors), (3) paracrine factors (produced by cardiomyocytes or non-cardiomyocytes) that may be diffusible, matrix-bound, or mediated through cell-cell contact, and (4) endocrine factors (released in response to baroreceptor activation or renal hypoperfusion). Identification of specific growth signals involved in different types of hypertrophy, however, still remains an elusive goal and will probably require complex integrative systems for resolution.

Impact of myocardial remodeling on cardiac function

Myocardial fibrosis might contribute to the increased risk of HF and other adverse cardiac events in patients with HHD through different pathways (Figure 50–5). First, a linkage between fibrosis and LV systolic dysfunction may evolve over time.¹³ Initially, the accumulation of collagen fibers compromises the rate of relaxation, diastolic suction, and passive stiffness, contributing to impaired diastolic function. This phase is often not recognized and may be asymptomatic. Continued accumulation of fibrotic tissue, accompanied by changes in the spatial orientation

Box 50–3

Factors with a Causal Role in Left Ventricular Hypertrophy

Factors with very strong supporting evidence:

- Increased blood pressure
- Obesity
- Excessive sodium intake

Factors with strong supporting evidence:

- Heritability
- Gender
- Black race
- Advanced age
- Stimulation of angiotensin II
- Insulin resistance
- Alterations of the GH/IGF-1 axis

Factors that need confirmation:

- Alcohol abuse
- Increased blood viscosity
- Excess of aldosterone
- Excess of parathormone
- Genetic polymorphisms

GH means growth hormone, IGF-1 insulin-like growth factor 1.

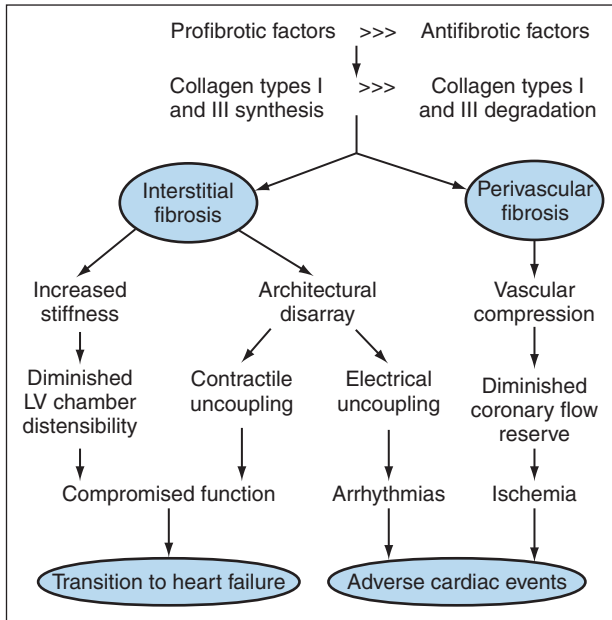

Figure 50–5. Potential consequences of myocardial fibrosis in hypertensive heart disease. (LV means left ventricle.)

of collagen fibers, further impairs diastolic filling and may compromise transduction of cardiomyocyte contraction into myocardial force development. Thus, systolic performance may eventually be reduced. Second, impaired coronary flow reserve associated with HHD might be related to several factors, including perivascular fibrosis.¹⁴ In fact, it has been demonstrated that perivascular CVF correlates inversely with coronary flow reserve in patients with HHD. Third, fibrosis may also contribute to the emergence of significant ventricular arrhythmia in patients with HHD.¹⁵ It has been reported that patients with arrhythmia exhibit higher values of LV mass and CVF than patients without arrhythmia. The LV systolic ejection fraction (EF) and the frequency of coronary vessels with significant epicardial stenosis are similar in the two groups of patients. Perivascular and interstitial fibrosis induce conduction abnormalities to promote local reentry, and thereby cardiac arrhythmias.

Several observations suggest that apoptosis of cardiomyocytes may contribute to the transition from LVH to LV dilatation and failure of systolic contractions (Figure 50–6).¹⁶ First, an association of increased cardiomyocyte apoptosis with diminished cardiomyocyte number has been found in the failing heart of hypertensive patients.⁴ Thus, apoptosis may be one of the mechanisms involved in the loss of contractile mass and systolic contractile function in hypertensive cardiomyopathy. Second, impaired myocardial contractile function may reflect not only a decrease in the number of viable fully functional cardiomyocytes but a decrement in the function of viable cardiomyocytes, or a combination of these mechanisms. It has been reported recently that caspase-3 cleaved cardiac myofibrillar proteins resulted in an impaired force/ Ca^{2+} relationship and myofibrillar ATPase activity.¹⁷ Third, cytochrome c plays a major role in ATP production through

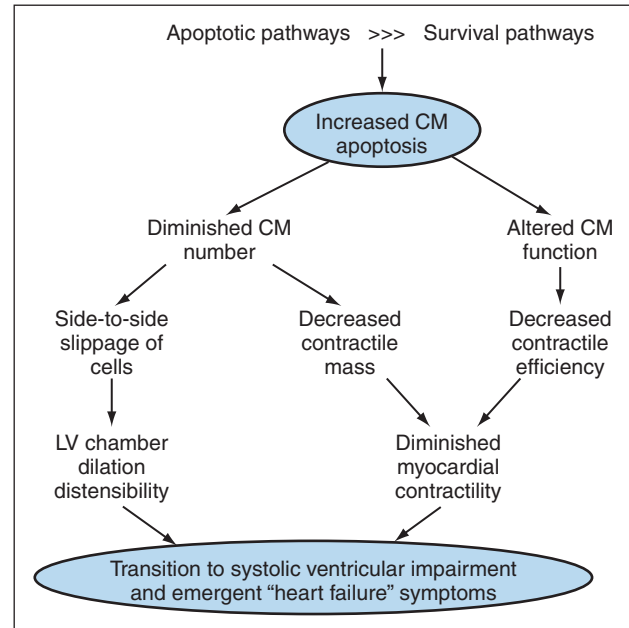

Figure 50–6. Potential consequences of cardiomyocyte apoptosis in hypertensive heart disease. (CM means cardiomyocyte, LV left ventricle.)

mitochondrial oxidative phosphorylation. Thus, it has been hypothesized that release of cytochrome c from mitochondria during the occurrence of the apoptotic process may interfere with cardiomyocyte energy production and lead to functional impairment.¹⁸ Finally, severe cardiomyocyte apoptosis may lead to side-to-side slippage of cells, mural thinning, and chamber dilation.¹⁹ Indeed, wall restructuring secondary to severe cardiomyocyte apoptosis may create an irreversible state of the myocardium, conditioning progressive dilatation and the continuous deterioration of cardiac hemodynamics and ventricular performance with time.

Alterations of coronary flow

As in other end organs of the hypertensive process, local regulation of blood flow is compromised in the heart. Thus, hypertensive LVH is associated with a profound impairment of coronary autoregulation.²⁰ In hypertensives with LVH, a shift of the pressure-flow autoregulatory relationship is evident, and coronary flow decreases progressively as coronary perfusion decreases below 90 mmHg. In hypertensives without LVH and in normotensive individuals, coronary flow is maintained down to a perfusion pressure of 60 mmHg.

On the other hand, hypertensive patients have frequently impaired coronary flow reserve (as estimated by the maximal increase in coronary flow above its resting level when the coronary vasculature is maximally dilated), even in the absence of LVH.²¹ The decrease in coronary vasodilator response present in patients with HHD is accounted for by several changes in myocardial structure (perivascular fibrosis) and function (increase in left wall tension and oxygen consumption), as well as by structural alterations of intramyocardial arteries and/or changes in

myocardial angiogenesis together with increased arteriolar tone, endothelial dysfunction, and extravascular systolic compression.

CLINICAL MANIFESTATIONS

Alterations of cardiac function

Epidemiological studies, such as the Framingham Heart Study, have suggested that hypertension is the most common etiological factor for congestive HF and is present in 50% of cases.²² In addition to alterations of LV myocardium characteristic of HHD, hypertension may itself promote a systolic HF presentation linked to underlying coronary artery disease, as well as the evolution of arrhythmia (most commonly uncontrolled atrial fibrillation). Unlike HF presentations associated with coronary artery disease, in which systolic impairment may decline after a discrete event (myocardial necrosis and infarction) that damages the heart muscle, LV dysfunction/failure in the patient with HHD may evolve through several stages (Figure 50–7).

Alterations of diastolic function

The clinical presentation of diastolic dysfunction (an echocardiographic entity) in HHD is variable. It can be viewed as progressing from asymptomatic echocardiographic findings to symptomatic HF presentation, to congestive HF with generally normal systolic function (i.e., preserved radial systolic EF), to ultimately evolving systolic ventricular impairment. The prevalence of asymptomatic LV filling abnormalities in adults without hypertrophy and with ambulatory awake blood pressure greater than 130/85 mmHg may be as high as 33%.²² These asymptomatic abnormalities may translate to a decrease in exercise EF when hemodynamically challenged by exercise or stress. In this regard, patients who had acute pulmonary edema and marked systolic hypertension were submitted to echocardiographic examination during the acute episode and after lowering treatment, and diastolic dysfunction was found to contribute to pulmonary edema in these hypertensive patients.²³ It has been estimated that 30 to 45% of hypertensive patients with chronic congestive HF symptoms present have diastolic dysfunction, with relatively normal normal systolic function.²⁴ Overall, the prognosis for patients with diastolic HF is poor, with survival rate at 3 months being 86%, at 1 year 76%, and at 5 years 48%.²⁵

Figure 50–7. Stages in the clinical evolution of the heart in arterial hypertension (LVH means left ventricular hypertrophy.)

Alterations of systolic function

Most hypertensive patients have normal or supranormal conventional measures of LV systolic function, such as endocardial fractional shortening and EF. LV midwall shortening, in relation to stress, provides a different impression of the integrity of systolic performance. In fact, midwall shortening may be impaired in hypertensives with normal or supranormal EF and depressed midwall shortening has been shown to predict an adverse outcome in hypertensives, especially in the subgroup with LVH.²⁶

However, depressed LV systolic function is the most potent risk factor for the development of overt congestive HF. In asymptomatic patients with abnormal LV systolic function, progression to ventricular dilatation appears to be slower—and clinical events, including death, are less common.²⁷ Nonetheless, in these patients survival at 2 years is significantly reduced (15 to 18%), compared with patients who have normal systolic function.

Development of LV dilatation is an indication of increased risk of major cardiac events and death.²⁸ In the hypertensive patient, the presence of LVH may lessen LV wall stress. However, at the expense of diastolic function systolic function is often preserved. However, the development of ventricular dilatation in the hypertensive patient with LVH, even if asymptomatic, is an ominous sign indicating that LVH is no longer able to maintain normal wall stresses. It may be hypothesized that with loss of the mechanical advantage conferred by LVH ventricular dilatation is the next compensatory response (through the Frank-Starling mechanism), which is invoked in an effort to restore normal LV systolic function. Any functional benefit derived, however, is at the cost of increased myocardial oxygen consumption, greater LV wall stress, and afterload mismatch.

Ischemic syndromes

Hypertensive patients with LVH frequently have signs and symptoms of myocardial ischemia due to a combination of microvascular disease, diminished coronary reserve, and atherosclerosis of epicardial vessels.²⁰ The reduction in dilating capacity of coronary flow is greater during exercise, when oxygen demand increases. In fact, under resting conditions the reduction in coronary flow reserve seen in hypertensive LVH may not have important consequences. However, in the presence of an exercise-induced increase in oxygen requirements it may become clinically relevant, producing the manifestations of myocardial ischemia and favoring the progression to LV systolic dysfunction.

There is a close relationship between hypertension and risk of coronary atherosclerotic disease. The risk for development of a cardiac ischemic event is approximately doubled in the hypertensive patient, and this is irrespective of sex or age, or whether systolic or diastolic blood pressure is increased.²⁹ Indeed, there is almost a “dose-response” relationship between coronary heart disease risk and increasing blood pressure, greater blood pressures being associated with greater risk. In patients with chronic angina pectoris, more than 50% have history of hypertension.³⁰ Furthermore, patients with hypertension have an increased incidence of unrecognized myocardial infarction, a greater likelihood of complications from acute

coronary syndromes, and compared with normotensive patients worse acute and 5-year survival after myocardial infarction.³¹ However, many epidemiological reports of “silent” infarction in patients with hypertension are confounded by overinterpretation of nonspecific isolated ECG abnormalities (see Chapter 46).

Disturbances of cardiac rhythm

Hypertension is an important risk factor for the development of atrial and ventricular arrhythmias and sudden cardiac death.³² Hypertension may play a direct part in the development of these rhythm disturbances by contributing to the development of LVH and myocardial remodeling, atherosclerotic disease, and microvascular abnormalities. The risk of arrhythmias is greatest with evidence of LVH and/or left atrial abnormality on echocardiography and electrocardiogram, even in patients with no clearly documented coronary artery disease.

Premature ventricular ectopy and complex ventricular tachyarrhythmias are more prevalent in patients with hypertension and LVH than in those without hypertrophy or in normotensive individuals.³³ However, electrophysiologic testing does not reveal an increased frequency of sustained ventricular tachycardia.

Atrial fibrillation is the most common and most serious of the atrial tachyarrhythmias, because of its association with fatal and nonfatal stroke and pulmonary edema. Indeed, hypertension and LVH account for more atrial fibrillation in the population than any other risk factor (Table 50–1).³⁴ In addition, hypertension is the only cardiovascular risk factor that independently predicts the development of atrial fibrillation, even after adjustment for age and associated co-morbidity.

Alterations of the aortic valve

Aortic valve sclerosis is defined by echocardiography as focal areas of increased echogenicity on aortic cusps not inducing stenosis. The prevalence of aortic sclerosis in hypertensive patients increases with age and with the presence of concentric LVH, and is associated with com-

promised diastolic function and mitral annular calcification.^{35,36} The attention to this condition has been increased by the observation that aortic sclerosis is a marker for increased risk of cardiovascular events, even when the baseline cardiovascular factors are taken into account.³⁷

It is known that hypertension predisposes to aortic root dilatation at sinuses of Valsalva and consequent aortic regurgitation. In fact, aortic root dilatation has been reported to be associated with higher LV mass (namely, eccentric LVH) and with lower systolic function in hypertensives.^{38,39}

DIAGNOSTIC PROCEDURES

Physical examination

Hypertensive LVH may be associated with an absence of symptoms for many years before the development of congestive HF or unexpected sudden death. Nevertheless, physical examination may reveal some clues. One of the most important signs of LVH is a localized, sustained, and forceful apical impulse. This is best appreciated with the patient in the left lateral decubitus position. If the apical impulse in the supine position is laterally displaced, LV dilatation should be suspected.

The incidence of a fourth sound (S_4) in hypertensive patients has been estimated to be between 50 and 70%, especially in the presence of LVH. An S_4 is the auscultatory counterpart of a vigorous atrial contraction into a relatively noncompliant left ventricle. An S_4 may be associated with a palpable presystolic impulse or A-wave. The S_4 is best appreciated when the patient is in the left lateral decubitus and the stethoscope is gently placed directly on the point of maximal apical impulse.

A systolic murmur can frequently be heard in hypertensive patients with LVH. This murmur is usually ejection in type, early in timing, and of low intensity (grade 1 or 2). This murmur can be heard at both the apex and the base. It most often represents aortic outflow turbulence related to a sclerotic aortic valve. An early diastolic

murmur of aortic regurgitation (secondary to dilatation of the aortic ring), which may be variable in intensity and duration, may occasionally be found in patients with HHD.

PROGNOSIS

LVH is an independent cardiovascular risk factor related to cardiovascular complications in hypertensive patients. In fact, considered as a categorical variable LVH significantly increases the risk of coronary artery disease, congestive HF, stroke, cardiac arrhythmia, and sudden death.⁴⁰ In addition, when LV mass is considered as a continuous variable a direct and progressive relationship exists between cardiovascular risk and the absolute amount of LV mass. During 4 years of follow-up in the Framingham Heart Study,⁴¹ each 50-g/m² increase in LV mass was associated with a 1.49 increase in relative risk of cardiovascular disease for men and a 1.57 increase for women. The effect on cardiovascular mortality was even more striking, with a 1.73 and 2.12 relative risk for each 50 g/m² for men and women, respectively. More recently, it has been reported that the continuous relation between LV mass and cardiovascular risk in patients with essential hypertension remains significant after control for cardiovascular risk factors, including ambulatory blood pressure.⁴²

The different patterns of ventricular shape and geometry are associated with markedly different risks for cardiovascular disease. A study performed with hypertensive patients followed up for 10 years reported that the incidence of cardiovascular events was 30% in subjects with concentric LVH, 25% in those with eccentric LVH, 15% in those with concentric remodeling, and 9% in those with normal LV mass.⁴³ Other reports have described associations between LV geometric pattern and extracardiac organ damage in essential hypertension, with hypertensives with concentric LVH having the most advanced fundoscopic abnormalities, the greatest renal dysfunction,⁴⁴ and the most severe abnormalities of carotid artery structure and function.⁴⁵

MANAGEMENT

Specific therapies

Antihypertensive therapy is effective in reducing LV mass. In fact, Mosterd et al.⁴⁶ analyzed data from 10,333 participants in the Framingham Heart Study and reported that

the increasing use of effective antihypertensive therapy has caused a decrease in the prevalence of both high blood pressure and LVH in the general population. A large number trials and meta-analyses have attempted to compare the effects of different antihypertensive agents on LV mass, but flawed study designs and methodologic problems have limited the utility of these studies. Nevertheless, a recent meta-analysis by Kingbeil et al.⁴⁷—including 80 double-blind randomized controlled trials with 146 active treatment arms (n=3767 patients) and 17 placebo arms (n=346 patients)—showed that after adjustment for treatment duration and change in diastolic blood pressure there was a significant difference ($p=0.004$) among medication classes. In fact, the decrease in LV mass indexed by surface area induced by the different classes was as follows: angiotensin II receptor antagonists > calcium antagonists > ACE inhibitors > diuretics > beta blockers (Table 50–2). In pairwise comparisons, angiotensin II receptor antagonists, calcium antagonists, and ACE inhibitors were more effective at reducing LV mass than were beta blockers and diuretics (all $p<0.05$ with Bonferroni correction).

A new generation of recent large well-designed trials support the notion that antihypertensive drugs need to be judged on their individual effects on LV mass in well-designed and adequately sized studies. In addition, extrapolation of the results of these studies in terms of class effects could be misleading and should be made with caution.

Outcomes

Different studies have examined the potential clinical prognostic benefit obtained from regression of LVH. Levy et al.⁴⁸ analyzed the data from 524 participants studied in the Framingham Heart Study, where LVH was measured according to electrocardiographic criteria. They reported that the decrease in electrocardiographic LVH toward normal, assessed using biannual serial examinations over a mean follow-up of 5 years, was associated with a reduction in cardiovascular risk. Recent data from the LIFE study have shown that a greater reduction of electrocardiographic LVH, after more than 4 years of treatment, with losartan than with atenolol was associated with higher reduction in the frequency of cardiovascular death, stroke, and myocardial infarction (Figure 50–8). Interestingly, there was substantial blood pressure reduction with both drugs with no significant differences between the two treatment groups (Figure 50–8).⁴⁹

REDUCTION OF LEFT VENTRICULAR MASS INDEXED BY SURFACE AREA WITH DIFFERENT ANTIHYPERTENSIVE DRUGS					
	Angiotensin Receptor Antagonists	Calcium Antagonists	Angiotensin-converting Enzyme Inhibitors	Diuretics	Beta Blockers

Table 50–2. Reduction of Left Ventricular Mass Indexed by Surface Area with Different Antihypertensive Drugs

Figure 50-8. Despite a similar reduction in systolic and diastolic blood pressure (SBP and DBP, respectively) from baseline, the diminution in Sokolow-Lyon (SL) index and the Cornell voltage-duration product (CVD) from baseline was higher in hypertensive patients from the LIFE study treated with losartan than in hypertensive patients treated with atenolol. In addition, the primary composite endpoint (cardiovascular mortality, stroke, and myocardial infarction) occurred in fewer losartan-treated patients than atenolol-treated patients. (Adapted from Dahlöf B, Devereux RB, Kjeldsen SE, et al. Cardiovascular morbidity and mortality in the losartan intervention for endpoint reduction in hypertension study (LIFE): A randomised trial against atenolol. *Lancet* 2002;359:995–1003 with permission from Elsevier.)

Other studies have analyzed LV mass changes using echocardiography. In the study by Yurenev et al.,⁵⁰ 304 patients who all had LVH or high-normal LV mass at baseline echocardiographic examination were followed for 4 years and retrospectively divided into two groups, according to the presence or absence of cardiovascular complications. They reported that there was a strong relationship between LVH progression or regression and the probability of morbid events. In fact, there was only a significant reduction in LV mass in the group of patients without cardiac complications. Recently, Devereux et al.⁵¹ published a substudy of the LIFE trial showing significant relative risk reductions in all-cause mortality, cardiovascular mortality, and the composite between those patients in whom LVH regressed by at least 25.3 g/m² compared with those who did not. These beneficial effects were independent of blood pressure lowering and other potential confounding factors, including age, smoking, diabetes, prior stroke, prior myocardial infarction, and baseline HF.

Collectively, these studies suggest that it is possible that treatment-induced LVH regression provides cardiovascular protection beyond blood pressure reduction. This can be related to the fact that reversing LVH has been shown to exert a beneficial influence on associated cardiac complications (i.e., improvement of diastolic and systolic function, amelioration of coronary reserve, and reduction of the incidence of cardiac arrhythmias).⁵²

Preventive strategies

Although in most studies and meta-analyses the relationship between changes in blood pressure and LV mass was relatively weak ($r < 0.50$), emerging evidence indicate that 24-hour monitoring of blood pressure may help to

identify those hypertensive patients predisposed to develop LVH (i.e., patients with early morning rise in blood pressure and/or patients with a non-dipping profile) and more prone to benefit from the ability of some antihypertensive drugs to prevent LV growth.

LV mass is a complex phenotype influenced by the interacting effects of multiple genetic and environmental factors. Genetic variation probably contributes to inter-individual differences in the LV mass by virtue of effects on blood pressure level as well as via pathways that are not captured by measurements of blood pressure. It is possible that identification of genes that influence LV mass may enhance the ability to detect those patients who deserve early treatment to prevent the development of LVH. In this regard, a recent meta-analysis of case-control studies and association studies has shown that the D allele of the insertion/deletion (I/D) polymorphism of the ACE gene behaved as a marker for LVH in untreated hypertensive patients.⁵³

Nonpharmacologic therapy may have some impact on the evolution of LVH, as some conditions that cause an increase in volume load (such as obesity and dietary sodium intake) also increase on LV mass. Results from the Treatment of Mild Hypertension Study (TOMHS)⁵⁴ reported that nutritional-lifestyle intervention with emphasis on weight reduction, restriction of salt, and alcohol intake and a physical exercise program was highly effective in both blood pressure and LV mass reduction.

Future perspectives

LVH that occurs as a consequence of pressure overload is termed *compensatory* on the premise that it facilitates ejection performance by normalizing systolic wall stress.

Recent experimental results, however, call into question the necessity of normalization of wall stress that results from hypertrophic growth of the heart. These findings, largely from studies in genetically engineered mice, raise the prospect of modulating hypertrophic growth of the myocardium to afford clinical benefit without provoking hemodynamic compromise.

To accomplish this goal, it is essential to identify molecular events involved in the hypertrophic process, and to identify commonalities and differences in the signaling systems that promote pathological hypertrophy versus physiological hypertrophy. Especially critical is elucidation of mechanisms underlying the maladaptive features of LVH, such as arrhythmogenicity, facilitation of ischemia, and transformation to HF. Observations from animal models and clinical trials identify signaling cascades that hold promise as potential targets for therapeutic interventions (Box 50–4).⁵⁵

SUMMARY

HHD can be defined as the cardiomyopathy that results from the response of the heart to the stress imposed on the left ventricle by the progressively increasing arterial pressure. Clinically, HHD is characterized by LVH and its associated alterations, including disturbances of cardiac function and electric activity and coronary flow abnormalities. As a consequence, LVH is an independent cardiovascular risk factor related to cardiovascular complications in hypertensive patients. Therefore, early detection of LVH is mandatory in the clinical evaluation and risk stratification of these patients. In addition, LVH has become a validated surrogated endpoint for the treatment of hypertension and a decrease in LV mass is now considered a therapeutic goal in hypertensive patients. Most studies designed to evaluate the effect of treatment on patients with HHD conclude that if blood pressure decreases significantly there is LV mass reduction with most antihypertensive agents usually prescribed. Furthermore, a large number of studies have established that reversal of LVH decreases

the occurrence of adverse cardiovascular events in hypertensive patients.

Nevertheless, the time has come to revisit the current management of HHD simply focused on controlling blood pressure and reducing LV mass. In fact, it is necessary to develop new approaches aimed to repair myocardial structure and protect myocardial perfusion and function—and in so doing reduce in a more effective manner adverse risk associated with HHD. The development of noninvasive methods to assess those changes in the composition of myocardial tissue leading to structural remodeling of the myocardium, and the knowledge of those genes involved in both the process of LVH and its response to therapy, may be critical to advance in the development of these new approaches.

The Eye in Hypertension

Tien Yin Wong and Paul Mitchell

Key Findings

- Hypertensive retinopathy refers to a spectrum of microvascular signs in the retina pathophysiologically related to elevated blood pressure.
- Hypertensive retinopathy can be classified as mild (generalized and/or focal arteriolar narrowing, arterio-venous nicking, and arteriolar wall opacification), moderate (mild plus microaneurysms, hemorrhages, cotton wool spots, or hard exudates, in people without diabetes) or malignant (moderate plus optic disc swelling).
- Hypertensive retinopathy signs are strongly associated with elevated blood pressure, but inconsistently associated with cholesterol and other atherosclerosis risk factors.
- Data from recent prospective studies demonstrate that moderate hypertensive retinopathy predicts incident clinical stroke, congestive heart failure, and cardiovascular mortality, independent of blood pressure levels and other traditional vascular risk factors.
- A clinical assessment of retinopathy signs may provide information for risk stratification in persons with hypertension.
- Hypertension is also a known risk factor for other retinal vascular diseases, including diabetic retinopathy, retinal vein occlusion, artery occlusion, arteriolar emboli, and macroaneurysm.

Hypertension affects the eye in several ways. The retinal circulation undergoes a series of pathophysiologic changes in response to elevated blood pressure, resulting in a spectrum of clinical signs traditionally known as hypertensive retinopathy.¹ These signs include generalized arteriolar narrowing, focal arteriolar narrowing, arteriovenous (AV) nicking, retinal hemorrhages, microaneurysms, hard exudates, cotton wool spots, and rarely optic disc swelling.² With the exception of disc swelling, these signs can be detected frequently in adult persons, even in those without a known history of hypertension.³

In addition to hypertensive retinopathy, elevated blood pressure is also an important risk factor for the development of several retinal vascular diseases, such as retinal vein occlusion, artery occlusion, arteriolar emboli, and macroaneurysms (together with typical retinopathy in diabetes). These conditions, although less commonly seen than hypertensive retinopathy, are potentially blinding. Finally, elevated blood pressure has been implicated as a possible risk factor

for nonvascular conditions in the eye, such as glaucoma and age-related maculopathy.^{4,5} This chapter focuses on hypertensive retinopathy and the common retinal vascular diseases associated with hypertension.

HYPERTENSIVE RETINOPATHY

Pathophysiology

Elevated blood pressure affects the retinal, optic nerve head, and choroidal circulations to produce three distinct manifestations: hypertensive retinopathy, hypertensive optic neuropathy, and hypertensive choroidopathy.² The initial response of the retinal circulation to a rise in blood pressure is vasospasm and an increase in vasomotor tone.² This response is reflected clinically as generalized retinal arteriolar narrowing. Persistently elevated blood pressure leads to more chronic “arteriosclerotic” changes, including intimal thickening, media wall hyperplasia, and hyaline degeneration. This is seen as more severe generalized arteriolar narrowing, arteriolar wall opacification, and focal areas of narrowing. Thickening of the retinal arteriolar wall by these arteriosclerotic processes may compress the venules at their common adventitial sheath, resulting in the clinical sign of AV nicking.

In the presence of more acute elevations in blood pressure, an “exudative” stage may develop, in which there is a breakdown of the blood/retinal barrier with necrosis of vascular smooth muscles and endothelial cells, exudation of blood and lipids, and retinal ischemia. These changes manifest as microaneurysms, hemorrhages, hard exudates, and cotton wool spots. Optic disc swelling and macular edema may occur at this stage, usually in the setting of severely elevated blood pressure, and represents malignant retinopathy. Optic disc swelling is believed to result from either elevated intracranial pressure from hypertensive encephalopathy or from ischemia to the optic nerve head.² The stages of hypertensive retinopathy so described are frequently not sequential, and retinopathy signs reflecting the “exudative” stage (e.g., retinal hemorrhages or microaneurysms) may be seen in eyes without features of the “arteriosclerotic” stage (e.g., AV nicking).

Classification and diagnosis

Marcus Gunn provided the first description of hypertensive retinopathy signs based on a series of patients with renal and cerebrovascular disease in the late nineteenth century.^{6,7} The traditional classification of hypertensive retinopathy

was developed based on work by Wagner and Barker in 1939.⁸ Although many modern variations of this classification system bear their name, the original work was not an attempt to classify retinopathy signs but to show that severity of hypertension itself was predictive of mortality.⁸ This classification typically includes four grades of retinopathy. “Mild” generalized retinal arteriolar narrowing is considered grade 1 retinopathy; “more severe” generalized narrowing, focal narrowing, and AV nicking are considered grade 2 retinopathy; the presence of retinal hemorrhages, microaneurysms, hard exudates, and cotton wool spots is considered grade 3 retinopathy; and grade 4 retinopathy, usually referred to as malignant retinopathy, consists of optic disc swelling and macular edema in the presence of signs in the preceding three grades.

Although widely used, one of the major limitations of this classification system is the difficulty in clinically distinguishing early retinopathy grades (e.g., grade 1 from grade 2).^{2,3} Based on more recent data from prospective population-based studies, we propose a simple three-grade classification system (Table 51–1). Mild retinopathy consists of retinal arteriolar signs only, including generalized and focal arteriolar narrowing, arteriolar wall opacification, and AV nicking (Figure 51–1, A). Moderate retinopathy includes mild retinopathy changes plus the presence of microaneurysms, flame- or blot-shaped hemorrhages, cotton wool spots, and hard exudates (Figure 51–1, B). Malignant retinopathy includes moderate retinopathy changes plus optic disc and macular swelling.

It is important for the physician to be aware that some of these signs (particularly microaneurysms, hemorrhages and cotton wool spots) may also be found in many other systemic and ocular conditions (e.g., diabetic retinopathy, radiation retinopathy, retinopathy associated with anemia, leukemia, and other blood disorders, as well as trauma and human immunodeficiency virus and other infections). Thus, in atypical scenarios appropriate investigations may be necessary to rule out other important diseases.

Epidemiology

Until recently, there were few epidemiologic data on the prevalence of hypertensive retinopathy signs in the general population. In the Framingham Eye Study, only 0.8% of participants who had a dilated screening ophthalmoscopic

examination were observed to have retinal hemorrhages or microaneurysms.⁹ Prevalence of AV nicking and focal arteriolar narrowing were not reported.

Since the 1990s, there have been several population-based studies that have provided data on the prevalence and incidence of various hypertensive retinopathy signs as detected from retinal photographs.^{10–17} These studies, summarized in Table 51–2, include the Beaver Dam Eye Study in Wisconsin,^{10,11} the Blue Mountains Eye Study in Australia,^{15,17} the Rotterdam Eye Study in Holland,¹⁴ and two multicentered cohort studies of cardiovascular diseases in the United States [the Atherosclerosis Risk In Communities (ARIC) study¹² and the Cardiovascular Health Study].¹⁶ Data from these studies have contributed to a greater understanding of the epidemiology, risk factors, and systemic associations of hypertensive retinopathy and other retinal vascular conditions.

In general, the prevalence of various hypertensive retinopathy signs, as detected from retinal photographs, ranges from 2 to 14% in the general adult population 40 years and older.^{10–17} Data from the Beaver Dam Eye Study showed that the prevalence of focal arteriolar narrowing was 14%, AV nicking 2%, and retinal hemorrhages and microaneurysms 8%.¹¹ There are fewer studies on the incidence of new hypertensive retinopathy signs. In the Beaver Dam Eye Study, the 5-year incidence of focal arteriolar narrowing was 10%, AV nicking 7%, and retinal haemorrhages and microaneurysms 6%.¹⁰

Most of the studies to date have been conducted in white populations, and there are fewer data on the epidemiology of hypertensive retinopathy signs in non-white populations.¹³ In the ARIC study, the prevalence of retinopathy signs was twice as high in blacks compared to whites.¹⁸ However, after controlling for blood pressure levels and the severity of left ventricular hypertrophy the excess prevalence in blacks was reduced by 40%, suggesting that the higher frequency of these retinopathy signs in blacks may be related in part to poorer hypertension control.

Relationship with blood pressure

An abundance of data from clinical and population-based studies show a strong graded and consistent association of hypertensive retinopathy signs with blood pressure.^{10–13,15–17} Figure 51–2 shows the strong relationship of blood pres-

CLASSIFICATION OF HYPERTENSIVE RETINOPATHY		
Retinopathy Grade	Description	Systemic Associations
Mild	One or more of the following signs: generalized arteriolar narrowing, focal arteriolar narrowing, arteriovenous nicking, arteriolar wall opacity (silver-wiring)	Weak associations with stroke, coronary heart disease, and cardiovascular mortality
Moderate	Mild retinopathy with one or more of the following signs: retinal hemorrhage (blot, dot, or flame-shaped), microaneurysms, cotton wool spot, hard exudates	Strong association with stroke, congestive heart failure, renal dysfunction, and cardiovascular mortality
Malignant	Moderate retinopathy signs plus optic disc swelling and macular edema	Associated with mortality

Table 51–1. Classification of Hypertensive Retinopathy

PREVALENCE OF HYPERTENSIVE RETINOPATHY: SUMMARY OF POPULATION-BASED STUDIES				
Study	Population	Prevalence of Retinopathy Signs ^a		
		All Persons	Hypertensive Persons	References
Beaver Dam Eye Study (BDES)	4926 persons aged 43 to 86 years, white ethnicity, Wisconsin	7.8 to 13.5%	2.8 to 19.4%	11
Blue Mountains Eye Study (BMES)	3654 persons aged 49 and older, white ethnicity, Australia	7.9 to 9.9%	6.8 to 15.4%	15,17
Atherosclerosis Risk in Communities (ARIC) Study	10,000+ persons aged 51 to 72 yrs, white and black ethnicity, four communities: North Carolina, Mississippi, Minneapolis, and Maryland	3.3 to 7.3%	5.0 to 11.9%	12
Cardiovascular Health Study (CHS)	2,400+ persons aged 69 to 97 yrs, white and black ethnicity, four communities: North Carolina, Pennsylvania, California, and Maryland	8.3 to 9.6%	9.0 to 12.3%	16
Rotterdam Eye Study	5674 persons aged 55 and older, white ethnicity, Holland	5%	—	14

a. Includes focal arteriolar narrowing, arteriovenous nicking, and retinal hemorrhages/microaneurysms/cotton wool spots in nondiabetic persons.

Table 51–2. Prevalence of Hypertensive Retinopathy: Summary of Population-based Studies

sure with focal arteriolar narrowing, AV nicking, and retinal hemorrhages/microaneurysms in the Cardiovascular Health Study.

In the Beaver Dam Eye Study, both the prevalence¹¹ and incidence of new hypertensive retinopathy signs¹⁰ were strongly related to hypertension and elevated blood pressure. In that study, hypertensive individuals were 50 to 70% more likely to have retinal hemorrhages and microaneurysms, 30 to 40% more likely to have focal arteriolar narrowing, and 70 to 80% more likely to have AV nicking than normotensive people.¹¹ In addition, hypertensive persons whose blood pressure was still elevated despite use of antihypertensive medications (an indication of “poorer” control) were more likely to develop retinopathy than individuals whose blood pressure was controlled with medications. These findings were mirrored in data from the Blue Mountains Eye Study.^{15,17}

To quantify generalized retinal arteriolar narrowing, recent population-based studies have employed computer-based imaging methods to measure retinal vascular diameters from photographs. These studies demonstrate that generalized retinal arteriolar narrowing, as indicated by narrower arteriolar diameters, is strongly associated with elevated blood pressure.^{19–23}

The pattern of associations of blood pressure with specific hypertensive retinopathy signs varies. For example, generalized retinal arteriolar narrowing and AV nicking appear to be persistent markers of long-term hypertensive damage, and are independently associated with blood pressure levels measured up to 8 years prior to the retinal assessment.^{21,22} In contrast, focal arteriolar narrowing, retinal hemorrhages, microaneurysms, and cotton wool spots appear to reflect more transient blood pressure changes and are associated only with concurrent blood pressure measured at the time of the retinal assessment.^{21,22}

A new observation from recent studies was that generalized retinal arteriolar narrowing may predict the development of incident hypertension.^{24–26} In the ARIC study, normotensive participants who had generalized arteriolar narrowing were 60% more likely to be diagnosed with hypertension within a 3-year period than those without arteriolar narrowing.²⁴ Thus, generalized retinal arteriolar narrowing, possibly reflecting systemic peripheral vasoconstriction, may be a preclinical marker of hypertension or moderate hypertension.²⁶

Relationship with stroke

Because the retinal circulation is essentially an extension of the cerebral circulation (sharing similar anatomical, physiologic and embryological characteristics), numerous investigators have attempted to correlate retinal vascular changes with cerebrovascular diseases in both hypertensive and nonhypertensive populations.^{27–32} As early as the 1970s, autopsy studies demonstrate similar histopathology changes in the retinal and cerebral arterioles among stroke decedents.²⁷ Functional studies show that retinal microcirculatory flow is reduced in persons with white matter lesions and lacunar infarction.³⁰

The strongest evidence is based on the ARIC study, which showed that individuals with moderate hypertensive retinopathy signs (microaneurysms, retinal hemorrhages, cotton wool spots) were two to four times more likely to develop an incident clinical stroke event within three years—while controlling for the effects of age, gender, long-term blood pressure levels, cigarette smoking, lipids, and other risk factors.³³ Weaker associations with mild hypertensive retinopathy were also seen. In a related analysis, among the ARIC study participants without clinical stroke or transient ischaemic attacks hypertensive retinopathy signs were significantly related to changes in cognitive impairment (as defined from standardized neuropsychologic tests).³⁴ In a smaller subset of participants who also underwent cranial MRI, the study showed that hypertensive retinopathy signs were associated with presence and severity of cerebral white matter hyperintensity lesions³⁵ and cerebral atrophy.³⁶

Relationship with coronary heart disease and heart failure

In contrast to stroke, there are fewer data on the association of hypertensive retinopathy signs with coronary heart disease and congestive heart failure. There have been reports of association of retinopathy signs with ischemic changes on electrocardiogram,³⁷ severity of coronary artery stenosis on angiography,³⁸ and with incident coronary heart disease and myocardial infarction in men³⁹ and women.⁴⁰

In the ARIC study, controlling for predisposing risk factors persons with moderate hypertensive retinopathy were two times as likely to develop congestive heart failure as compared to those without retinopathy.⁴¹ Even in low-risk individuals without preexisting heart disease, diabetes, or hypertension the presence of moderate hypertensive retinopathy predicted a threefold increased risk of congestive heart failure events. This may suggest that microvascular damage to the myocardium from hypertensive processes may play an important etiologic role in the development of heart failure.

Relationship with other systemic diseases and risk factors

In addition to stroke and heart disease, hypertensive retinopathy signs have been linked with a variety of systemic conditions and vascular risk factors. Hypertensive retinopathy signs have not been consistently associated with direct measures of subclinical atherosclerosis. In the ARIC study, while controlling for blood pressure generalized arteriolar narrowing was associated with carotid artery plaque but not intima-media thickness, AV nicking was associated with carotid artery intima-media thickness but not carotid artery plaque, and focal arteriolar narrowing was not related to either carotid artery measure.¹² In both the Rotterdam Eye Study and Cardiovascular Health Study, hypertensive retinopathy signs were not related to carotid artery disease.^{16,18}

Similarly, most studies have not been able to demonstrate clear associations of hypertensive retinopathy with

traditional atherosclerosis risk factors, including hyperlipidemia, cigarette smoking, or obesity.^{19,42,43} There are several recent studies investigating associations with novel risk markers, such as biomarkers of inflammation (C-reactive protein, fibrinogen),^{12,16,19} endothelial cell activation (von-Willebrand factor),¹² and angiogenesis (vascular growth endothelial factor,⁴⁴ adiponectin,⁴⁵ and leptin⁴⁶). The significance of these associations remains to be determined.

Renal impairment is another marker of target organ damage in individuals with hypertension. The presence of microalbuminuria and renal impairment is often associated with concomitant hypertensive retinopathy.^{47,48} In the ARIC study, individuals who developed renal dysfunction were more likely to have moderate retinopathy as compared to those without renal dysfunction.⁴⁹ This association was independent of the shared risk factors and was seen in persons without diabetes or hypertension.

Cardiovascular mortality

Previous studies, largely conducted in the 1950s and 1960s, have shown that persons with hypertension and retinopathy are at increased risk of mortality.^{8,50–52} However, inferences from many of these older studies are limited by the lack of data on the specific association between retinopathy severity and mortality, as well as inadequate control for potential confounders such as blood pressure and diabetes.

More recent studies provide stronger evidence that hypertensive retinopathy signs are independent predictors of mortality. In a nested case-control analysis of the Beaver Dam Eye Study, individuals who died from cardiovascular events were two times as likely to have hypertensive retinopathy sign controls after adjustment for age, gender, blood pressure, and other risk factors.⁵³

Management

Data from recent studies support the hypertension guidelines regarding the prognostic significance of retinopathy signs.^{54,55} These guidelines emphasize that retinopathy, along with left ventricular hypertrophy and renal impairment, may be considered an indicator of target organ damage and thus may represent a useful indication for physicians to consider a more aggressive approach in managing blood pressure in these patients.⁷ Further, the information obtained from an assessment of the retinopathy status may be qualitatively different from that of measuring blood pressure, as the presence of retinopathy signs indicates susceptibility and the onset of preclinical systemic vascular disease.

Based on the simple three-grade classification system for hypertensive retinopathy shown in Table 51–1, a suggested management plan for patients with various retinopathy grades is shown in Figure 51–3. Patients with mild retinopathy signs will likely require routine care according to established guidelines. Patients with moderate retinopathy signs may benefit from further assessment of vascular risk (e.g., assessment of cholesterol levels), and if clinically indicated from appropriate risk reduction therapy (e.g., cholesterol lowering agents). Patients with malignant retinopathy will need urgent antihypertensive management.

There is, however, no convincing evidence that treatment of hypertension would reverse retinopathy changes, or that such reversal would result in a reduction in cardiovascular risk. A small number of experimental studies in animals^{56,57} and clinical case series^{58,59} have observed regression of some retinopathy signs (hemorrhages, cotton wool spots) but not others (AV nicking) with control of blood pressure. It is also unclear if specific antihypertensive medications such as those reported to have direct beneficial effects on microvascular structure (e.g., angiotension

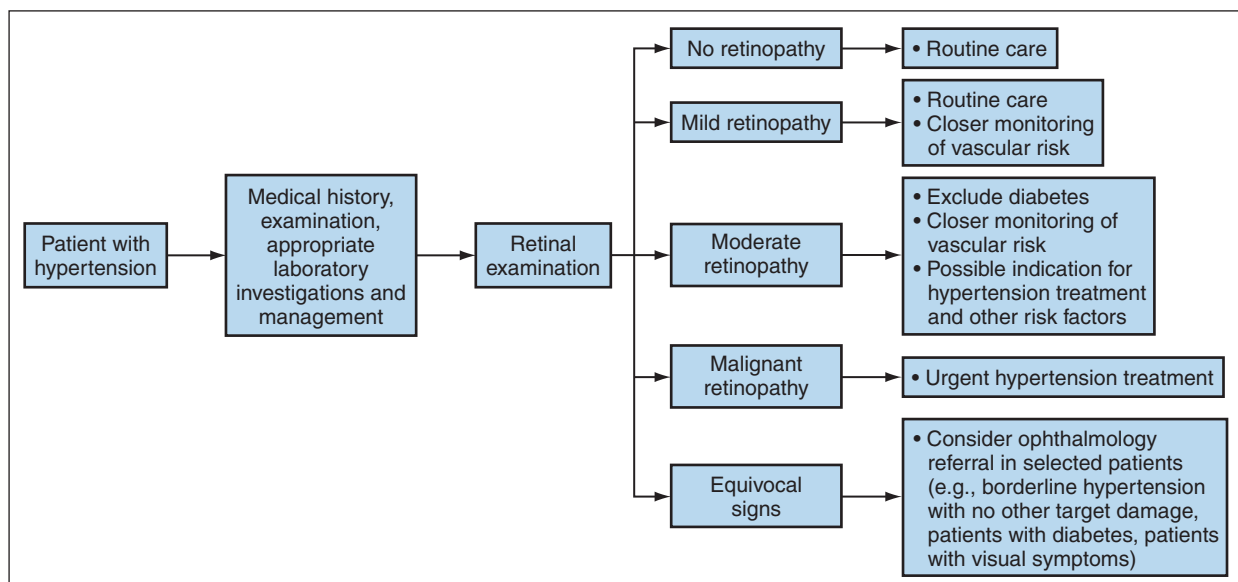

Figure 51–3. Evaluation and management of patients with hypertensive retinopathy.

converting enzyme inhibitors) would reduce retinopathy damage beyond the effects of lowered blood pressure alone. However, such agents may have added therapeutic value in preventing and treating cardiovascular diseases.

RETINAL VASCULAR CONDITIONS ASSOCIATED WITH HYPERTENSION

Retinal vein occlusion

Retinal vein occlusions are common potentially sight-threatening conditions frequently associated with hypertension. They are characterized clinically by dilated and tortuous retinal veins and the presence of retinal hemorrhages, cotton wool spots, and macular and optic disc edema. In central retinal vein occlusion (CRVO), these findings appear in all four quadrants, whereas branch retinal vein occlusion (BRVO) will manifest these findings in only one quadrant. Branch vein occlusion occurs at an arteriovenous crossing, typically affected by AV nicking. Approximately one-third of CRVOs are ischemic in nature and two-thirds nonischemic. Ischemic CRVO is typically associated with much poorer vision and visual prognosis.

There have been few population-based studies on the epidemiology and risk factors for retinal vein occlusions.⁶⁰⁻⁶² The Blue Mountains Eye Study reported the prevalence of BRVO at 1.1% and CRVO at 0.4%.⁶² Slightly lower prevalence was found in the Beaver Dam Eye Study, with both prevalence and 5-year incidence of BRVO at 0.6%. For CRVO, the prevalence was 0.1% and 5-year incidence was 0.2%.⁶⁰ Most studies show a clear relationship between hypertension and risk of both CRVO and BRVO.⁶⁰⁻⁶³ Hemispherical retinal vein occlusion typically involves an arteriovenous crossing at the optic disc rim, and is strongly associated with hypertension as well as glaucoma.⁶² In both the Blue Mountains Eye Study and ARIC study, after adjusting for age retinal vein occlusion was associated with hypertension status, higher systolic blood pressure, and higher diastolic blood pressure.^{62,63}

Management of patients with retinal vein occlusion should include a systemic evaluation and ophthalmologic follow-up to diagnose and prevent the two main complications: neovascularization and macular edema (both of which are potentially sight threatening). In relation to the prevention of neovascularization, randomized clinical trials have shown that prophylactic pan-retinal laser photocoagulation does not necessarily prevent neovascularization in ischemic vein occlusions, and that laser may be withheld until the patient develops ocular neovascularization.^{64,65} Focal laser photocoagulation is useful in preventing visual loss in selected patients with macular edema from BRVO,⁶⁶ although this treatment does not appear to benefit macular edema associated with CRVO.⁶⁷

Retinal arteriolar emboli

Hypertension is a risk factor for retinal arteriolar emboli, which are discrete plaque-like lesions lodged in the lumen of retinal arterioles.⁶⁸ Retinal emboli are pathologically heterogeneous, and are composed of cholesterol crystals

(reflective or refractile emboli) or fibrin, platelets, calcium, and other materials (nonreflective emboli).

Data from epidemiologic studies suggest that retinal arteriolar emboli are seen in over 1% of adult persons 50 years and older.^{69,70} Almost identical prevalences (1.3%, 1.4%) were reported from these two studies, and were strongly age related. The Beaver Dam Eye Study showed that the 5-year incidence of retinal emboli was 0.9%, but that up to 90% of eyes with retinal emboli at baseline were not present 5 years later (in keeping with observations that these emboli are transient retinal phenomena).⁷¹ Indeed, it is likely that reported prevalences are underestimates.

Retinal emboli are associated with hypertension and other vascular risk factors, such as cigarette smoking and diabetes.^{62,69,70} In both the Beaver Dam and Blue Mountains Eye studies, retinal emboli were associated with hypertension and cigarette smoking.^{69,70} Furthermore, in the Blue Mountains Eye study population hypertensive persons who were cigarette smokers were six times as likely to have retinal emboli as normotensive persons who were not cigarette smokers.⁶⁹

Like hypertensive retinopathy, the presence of retinal emboli is a poor prognostic marker.⁷² In the ARIC study, participants with retinal arteriolar emboli were two times as likely to have prevalent coronary heart disease and four times as likely to have carotid artery plaque as those without emboli.⁶² In the Beaver Dam Eye Study, retinal emboli at baseline was associated with a twofold higher risk of stroke mortality than persons without emboli (controlling for blood pressure and other risk factors).⁷⁰

Management of patients with retinal emboli should include a thorough systemic evaluation, concentrating on modifiable risk factors such as the control of hypertension, dyslipidemia, and diabetes. Routine carotid ultrasonography for patients with asymptomatic retinal emboli detected incidentally remains controversial. Some studies suggest that between 60 and 80% of people with asymptomatic retinal emboli do not have significant carotid stenosis.⁷³ Furthermore, the benefits of carotid endarterectomy in asymptomatic patients with retinal emboli and significant carotid artery stenosis are unclear because this has not been systematically assessed.

Retinal artery occlusion

Elevated blood pressure is also a risk factor for retinal artery occlusion.^{74,75} A central retinal artery occlusion (CRAO) is associated with a sudden painless unilateral loss of vision. A retinal embolus may be visible in the vessels at the optic disc, or downstream in branch retinal arterioles. A branch retinal artery occlusion (BRAO) is associated with a visual field defect, and central visual loss may be minimal—or when present have a good prognosis for recovery. CRAO is usually considered an ocular emergency, and attempts to dislodge the embolus within 3 hours after an occlusion has been suggested to restore ocular circulation and preserve vision. However, these methods (such as digital massage of the eyeball, paracentesis of anterior chamber fluid, breathing into a paper bag to induce carbon dioxide related vasodilation, and use of intraocular pressure-lowering agents) have

not been proven to be effective in restoring vision, except in anecdotal cases.⁷⁶

Retinal macroaneurysm

Retinal macroaneurysm, a fusiform or saccular lesion of the retinal arterioles, is a fairly common vascular condition seen almost always in patients with hypertension.⁷⁷⁻⁷⁹ Approximately 20% of macroaneurysms are bilateral, and in 10% of cases multiple macroaneurysms can be found.⁷⁹ Macroaneurysms may be incidental findings in asymptomatic patients, but can present acutely with visual loss secondary to hemorrhage or exudation. Visual recovery occurs usually spontaneously with thrombosis of the macroaneurysm and resolution of the hemorrhage and exudate. Laser photocoagulation is useful in selected cases, particularly when exudation threatens or involves the macula.

CONCLUSIONS

Individuals with hypertension frequently develop typical retinal signs (termed *hypertensive retinopathy*) as well as other retinal vascular complications. Moderate hypertensive retinopathy (retinal hemorrhages, microaneurysms, and cotton wool spots) is associated with an increased risk of subclinical and clinical stroke, congestive heart failure, and cardiovascular mortality independent of traditional risk factors. Mild hypertensive retinopathy (generalized retinal arteriolar narrowing, focal arteriolar narrowing, and AV nicking) is less strongly associated with systemic outcomes. An assessment of hypertensive retinopathy signs may provide important information for prognostication and risk stratification. Conversely, patients with retinal vascular signs may need a careful review of their blood pressure and other cardiovascular risk factors.

Chapter
52**Hypertension in Children
and Adolescents***Joseph T. Flynn***Definition**

- Hypertension in children and adolescents is defined as blood pressure persistently above the 95th percentile for age, gender, and height. New normative values and recommendations for evaluation and management have recently been published by the National High Blood Pressure Education Program.

Key Findings

- Less than 2% of children and adolescents have hypertension; however, the incidence is much greater in obese children.
- Hypertensive target-organ damage, including left ventricular hypertrophy and increased carotid intima-media thickness, occurs commonly in hypertensive children and adolescents.
- Causes of hypertension in children and adolescents are age-dependent, with secondary causes predominant in infants and younger children, and primary hypertension most common in adolescents.

Clinical Implications

- Treatment should include nonpharmacologic approaches in all patients, and antihypertensive medications if hypertensive target-organ damage, secondary hypertension or other compelling conditions are present.
- The special cases of hypertensive emergencies in children and adolescents and neonatal hypertension are addressed.

The lack of cardiovascular endpoints such as stroke and myocardial infarction in childhood means that definitions of normal and elevated blood pressure (BP) must be based upon statistical analyses of large-scale, cross-sectional studies of BP in normal children. Such analyses have been conducted under the auspices of the National Heart, Lung and Blood Institute, which has issued consensus guidelines with recommendations for identification and management of elevated BP in childhood have on four occasions over approximately the past 30 years. The most recent of these, “The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents”¹ is notable for its adaptation of terminology and staging criteria utilized in recent consensus guidelines for adult hypertension² to the problem of childhood hypertension, and for its emphasis on prevention of adult cardiovascular disease by early intervention in children and adolescents with elevated BP.

According to the Fourth Report,¹ normal BP in childhood is defined as systolic and diastolic BP below the 90th percentile for age, gender, and height, and hypertension is defined as systolic and/or diastolic BP equal to or higher than the 95th percentile on repeated measurement. BP percentile values for boys and girls aged 1 to 17 years can be found in Tables 52–1 and 52–2. Children with systolic or diastolic BP between the 90th and 95th percentiles, who in prior reports had previously been classified as having “high-normal” BP,³ are now classified as “prehypertensive,” in keeping with the terminology used for adults in the Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7)². Recognizing that the prehypertension cut-point of 120/80 used in adults begins to appear as the 90th percentile in children by the age of 12, the Fourth Report also recommends that adolescents with BP =120/80 be classified as having pre-hypertension.

The Fourth Report additionally provides guidelines for staging the severity of hypertension in children and adolescents, which can then be used clinically to guide evaluation and management¹ (Table 52–3). Stage 1 hypertension is defined as BP equal to or higher than the 95th percentile for age, gender, and height up to the 99th percentile plus 5 mmHg. This level of BP elevation is roughly similar to stage 1 hypertension in adults.² Stage 2 hypertension is any BP reading above the 99th percentile plus 5 mmHg. As will be discussed later, children or adolescents with stage 2 hypertension should be evaluated and treated more quickly and/or aggressively than those with less significant BP elevation.

PREVALENCE

Traditionally, hypertension has been considered to be an uncommon problem in childhood and adolescence. For example, a BP screening study conducted in Dallas in the late 1970s revealed that just 1.2% of eighth graders had persistent systolic hypertension and 0.37% diastolic hypertension.⁴ Similarly, Sinaiko et al.⁵ determined that the prevalence of hypertension in Minneapolis students aged 10 to 15 years was 0.3% for systolic and 0.8% for diastolic hypertension. A recent reanalysis of the Minneapolis data applying the normative values from the 1996 Working Group Report⁶ resulted in a combined prevalence of systolic and diastolic hypertension of 1.2%.⁷ These screening programs also demonstrated the importance of performing repeated measures of BP before labeling a child as hyper-

BLOOD PRESSURE LEVELS FOR BOYS BY AGE AND HEIGHT PERCENTILE

From National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. *Pediatrics* 2004;114:555–76.
BP, blood pressure.
Note: To use the table, first plot the child's height on a standard growth curve (www.cdc.gov/growthcharts). The child's measured systolic BP and diastolic BP are compared with the numbers provided in the table according to the child's age and height percentile.

Table 52-1. Blood Pressure Levels for Boys by Age and Height Percentile

tensive: studies that used just one BP determination found significantly higher “prevalence” of hypertension than studies in which repeated screenings were performed^{4,5,7–12} (Table 52-4).

Other studies, however, have suggested that this may be changing. Sorof et al.^{12,13} conducted a screening study in the Houston public schools and found that 13% of adolescents had blood pressures persistently elevated above the 95th percentile for age, gender, and height, a significantly greater percentage than in the studies cited above. The children in this study also tended to be obese, with a mean BMI of 24 ± 6 kg/m², and hypertension was significantly more common among obese children. This reflects the increasing prevalence of obesity among American children over the past decade: analyses of the 1999–2000 National Health and Nutrition Examination Survey (NHANES) data demonstrate a significantly greater prevalence of obesity in children of all ages and ethnic backgrounds compared to the NHANES III data from 1988 to 1994.¹⁴

ETIOLOGIES

In infants and preadolescent children, primary hypertension is exceedingly rare. In these age groups, secondary forms of hypertension are much more common (Table 52-5), with renal disease being the most common underlying cause. Especially in the young school-age child, the differential diagnosis of hypertension can be vast, necessitating a careful and thorough evaluation, as specific treatment of the underlying cause may result in “cure” of the child's hypertension. The reader interested in a detailed discussion of the causes of hypertension in infants and young children is encouraged to consult one of the recent comprehensive texts on pediatric hypertension.^{15,16}

In adolescents, however, primary hypertension accounts for the majority of cases. An example of this can be seen in a 1992 study by Wyszynska et al.¹⁷ of 1025 children referred to a Polish children's hospital for evaluation of hypertension (defined as blood pressure greater than the 95th percentile for age). Overall, 45% of their population had primary hypertension and 55% secondary hypertension. Adolescents (aged 15–18 years) comprised 60% of the study population, and 75% of the subjects in this age group had primary hypertension. The breakdown of causes of secondary hypertension (regardless of age) was comparable to the list of causes for younger children in Table 52-5.

Certain groups of children are at increased risk of developing primary hypertension in childhood, including children of hypertensive parents and obese children.^{18–20} Along these lines, the recent increase in the prevalence of obesity among children in the United States will most likely be followed by an increased incidence of childhood hypertension in the next one to two decades.²¹ The high frequency of obesity among children with primary hypertension is highlighted by two recent referral series, one consisting of primarily Caucasian children,²² and the other consisting of primarily minority children.²³ In both of these series, primary hypertension was diagnosed after standardized evaluations for identifiable causes of hypertension. The mean age of the subjects in both series was approximately 14 years, and most had BMI's at or above the 95th percentile for age and gender. Isolated systolic hypertension was a common feature in both reports, and most of the adolescents had relatively mild hypertension, averaging 5% to 25% above the 95th percentile.^{22,23} It is reasonable to assume, therefore, that most adolescents found to have sustained hypertension will have primary hypertension,

BP, blood pressure.
Note: To use the table, first plot the child's height on a standard growth curve (www.cdc.gov/growthcharts). The child's measured systolic BP and diastolic BP are compared with the numbers provided in the table according to the child's age and height percentile.

Table 52–2. Blood Pressure Levels for Girls by Age and Height Percentile

CLASSIFICATION OF HYPERTENSION IN CHILDREN AND ADOLESCENTS, WITH MEASUREMENT FREQUENCY AND THERAPY RECOMMENDATIONS				
Classification	SBP or DBP Percentile ^a	Frequency of BP Measurement	Therapeutic Lifestyle Changes	Pharmacologic Therapy
Normal	<90th	Recheck at next scheduled physical examination.	Encourage healthy diet, sleep, and physical activity.	—
Prehypertension	90th to <95th or if BP exceeds 120/80 even if below 90th percentile up to <95th percentile ^b	Recheck in 6 months.	Counsel for weight management if overweight, and introduce physical activity and diet management.	Do not initiate therapy unless compelling indications exist, such as CKD, diabetes mellitus, heart failure, LVH.
Stage 1 hypertension	95th percentile to the 99th percentile plus 5 mmHg	Recheck in 1–2 weeks or sooner if the patient is symptomatic; if persistently elevated on two additional occasions, evaluate or refer to source of care within 1 month.	Counsel for weight management if overweight, and introduce physical activity and diet management.	Initiate therapy based on indications in Table 52–6 or if compelling indications as above.
Stage 2 hypertension	>99th percentile plus 5 mmHg	Evaluate or refer to source of care within 1 week or immediately if the patient is symptomatic.	Counsel for weight management if overweight, and introduce physical activity and diet management.	Initiate therapy.

From National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. *Pediatrics* 2004;114:555–76.
BP, blood pressure; CKD, chronic kidney disease; DBP, diastolic blood pressure; LVH, left ventricular hypertrophy; SBP, systolic blood pressure.
^aFor sex, age, and height measured on at least three separate occasions; if systolic and diastolic categories are different, categorize by the higher value.
^bThis occurs typically at age 12 years for SBP and at 16 years for DBP.

especially if the blood pressure elevation is not severe, or if diastolic hypertension is absent.

CONSEQUENCES OF CHILDHOOD HYPERTENSION

As noted previously, the long-term cardiovascular sequelae of hypertension seen in adults such as stroke and myocardial infarction do not occur in children. However, a large body of evidence has accumulated over the years documenting that persistent blood pressure elevation in children

and adolescents can produce other target-organ effects that may be important to consider, especially when making treatment decisions.

Left ventricular hypertrophy (LVH) is probably the most common and most easily identified target-organ effect of hypertension in children and adolescents. It has been recognized as occurring commonly, even with mild blood pressure elevation, since the early 1980s.²⁴ More recent studies have established a prevalence of LVH in hypertensive children and adolescents of between 23% to 30%.^{22,23,25} Abnormal left ventricular geometry has also been demonstrated, especially in those with more severe blood pressure elevation.²⁶ Although the adverse effects of LVH seen in adults such as sudden cardiac death²⁷ have not been proven to occur in hypertensive children, LVH is still considered an important cardiovascular risk factor in hypertensive children,²⁶ and treatment recommendations from consensus organizations have emphasized that if LVH is present, the child or adolescent should be aggressively treated with antihypertensive medications.¹

Other vascular effects of hypertension have also been demonstrated in hypertensive children and adolescents, including retinal changes^{28,29} and increased carotid intima-media thickness (cIMT).³⁰ Retinal changes, when systematically looked for, occur in a large number of hypertensive children and adolescents,²⁸ and in one study appeared more often in those with higher diastolic blood pressure.²⁹ Increased cIMT, which is well established as a correlate of atherosclerosis and increased cardiovascular risk in adults,^{31,32} has recently been found to also occur in hypertensive children.^{30,33,34} As in hypertensive adults, increased cIMT in the young is correlated with obesity³³ and left ventricular

hypertrophy,³⁴ suggesting that this may someday be used as a marker of increased cardiovascular risk in hypertensive children and adolescents.

The other major target organ in hypertension is the kidney. In adults, hypertension is one of the most common causes of chronic kidney disease (CKD). According to the 2004 U.S. Renal Data Systems (USRDS) Annual Data Report, hypertension was the second leading cause of end-stage renal disease (ESRD) in adults in 2002, affecting approximately 125,000 individuals, or 24.4% of the entire ESRD population.³⁵ In children, on the other hand, it is not so clear if hypertension alone may result in ESRD. The North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) dialysis, transplant, and chronic renal insufficiency registries do not list hypertension among the causes of CKD/ESRD in children.³⁶ However, close analysis of the USRDS data reveals that hypertension was reported as the cause of ESRD in over 150 children in 2002.³⁵ Hypertension was reported much less often than other forms of kidney disease in children, and was primarily reported as a cause of ESRD in children aged 10 years and older. Reconciling these two databases is difficult as they are derived from significantly different sources. Since hypertension was reported as a cause of ESRD mostly in older children, it is tempting to speculate that perhaps long-standing hypertension may indeed lead to CKD/ESRD in adolescents, adding further weight to recent recommendations advocating earlier use of antihypertensive medications in some children and adolescents.¹

It is possible that hypertension may also have significant effects on mental function in children. In adults, it is well known that long-standing blood pressure elevation may cause impaired performance on neuropsychological testing,³⁷ with at least one study demonstrating an inverse relationship between blood pressure level and measures of attention and memory.³⁸ In children, only one study has examined the effects of elevated blood pressure on cognition. Lande et al.³⁹ examined data from the NHANES III, which included information on blood pressure as well as results of standardized neuropsychological testing (including tests of short-term memory, attention, concentration, and constructional skills). They found that children with blood pressure above the 90th percentile for age, gender, and height had decreased performance on the neuropsychological tests compared to control children with normal blood pressure. These findings are especially provocative given that only a single blood pressure measurement was made in the NHANES III. Further studies are clearly needed to examine the effects of sustained blood pressure elevation in childhood on mental function, as well as the potential effects of treatment on neuropsychological function in hypertensive children.

The final and perhaps most intriguing consequence of elevated childhood blood pressure is that it may predict the development of adult hypertension. This phenomenon, known as blood pressure “tracking,” has been the subject of much study, with the overall conclusion in the literature being that BP does indeed track into adulthood,⁴⁰ especially in children with what used to be termed “high normal” blood pressure. Perhaps the most convincing of the avail-

able studies is the Muscatine study,⁴¹ which enrolled schoolchildren aged 7 to 18 years in Muscatine, Iowa between 1971 and 1978. A subgroup (the “longitudinal cohort”) was then recalled as young adults (aged 23–28 years). Subjects with systolic blood pressure in childhood higher than the 90th percentile were 3.9 times more likely than expected to develop adult hypertension, and subjects with diastolic blood pressure in childhood higher than the 90th percentile were 1.9 times more likely than expected to develop adult hypertension. The likelihood of developing adult hypertension increased with increasing numbers of childhood readings greater than the 90th percentile. In addition, the absence of abnormal readings in childhood was associated with a reduced risk of developing adult hypertension. Other important influences on adult blood pressure were ponderosity, change in ponderosity, and a positive family history of hypertension, which are all characteristics of primary hypertension in the young.²² This phenomenon underscores the importance of detection and treatment of hypertension in childhood.

EVALUATION

Perhaps the most important step in evaluating a child or adolescent with elevated blood pressure is to confirm that the blood pressure is being measured correctly. As has been emphasized elsewhere,^{1,42} proper cuff size is of paramount importance in accurately measuring blood pressure in the young. The bladder of the cuff should be long enough to encircle 80% to 100% of the arm circumference. If the cuff bladder has a 1:2 ratio of width:length, the cuff should be wide enough to obtain an accurate reading.¹ If the cuff dimensions differ from this standard, a larger/wider cuff may be needed for adolescents with long upper arms in order to avoid a falsely elevated reading due to a narrow cuff.

The method of blood pressure measurement is also important. While the use of oscillometric measurement devices has become widespread in pediatric settings,⁴³ these devices have inherent inaccuracies that make them suspect for diagnosing a child or adolescent with hypertension.^{44,45} Furthermore, the normative blood pressure values published by the National Heart, Lung and Blood Institute are based on auscultated blood pressures.¹ Therefore, it is recommended that elevated BP readings obtained using oscillometric devices should be confirmed by auscultation. It is additionally recommended that the child or adolescent with elevated BP have this finding confirmed on at least three occasions before making a “diagnosis” of hypertension and embarking on a diagnostic evaluation.¹

Once the child or adolescent has been confirmed to have hypertension, a diagnostic evaluation should be conducted to determine if an underlying cause can be identified. As discussed previously and as illustrated in Table 52–5, secondary causes of hypertension are common in younger children, so a comprehensive evaluation will need to be conducted in order to determine if there is an underlying cause. On the other hand, adolescents are likely to have primary hypertension, especially if obese and if there is a family history of hypertension,²² so a less extensive work-up may suffice. The history and physical examination should

focus on eliciting signs and symptoms of an underlying disorder; for example, a history of recurrent urinary tract infections in early childhood would be a clue to reflux nephropathy, while multiple café-au-lait spots and an epigastric bruit would be signs of renal artery stenosis in the setting of neurofibromatosis. Detailed discussions of the diagnostic approach to the hypertensive child or adolescent, including comprehensive tables of typical symptoms and physical exam findings, can be found elsewhere.^{15,16,46}

In addition to determining whether the child or adolescent has an identifiable underlying cause for hypertension, evaluation should also include whether hypertensive target-organ damage is present, and whether any additional risk factors/comorbidities are present. As discussed earlier, many forms of hypertensive target organ damage have been shown to occur in children and adolescents. Since hypertension-related events such as stroke and myocardial infarction occur extremely rarely before adulthood, these other signs of hypertensive damage can be considered “surrogate endpoints” and if present, prompt aggressive treatment in order to prevent progression to more significant cardiovascular disease. Since left ventricular hypertrophy occurs commonly and is relatively easy to detect, it is recommended that echocardiography be performed at the time of diagnosis of hypertension and periodically thereafter in those with persistent hypertension.¹ Other examinations that may be considered include formal ophthalmologic exams to detect retinopathy, and urine testing for microalbuminuria (however, it must be stated that no clear recommendations currently exist for urine microalbumin testing in childhood).

Screening for the presence of other cardiovascular risk factors/comorbidities should also be performed as part of the evaluation of hypertensive children, particularly in obese adolescents. Currently, the best evidence supports testing for dyslipidemia and impaired glucose tolerance, both of which clearly increase cardiovascular risk in adults. It has long been known that dyslipidemia occurs commonly in children with elevated BP,⁴⁷ and recent case series confirm this association.²² Impaired glucose tolerance also occurs frequently in obese hypertensive children, typically as part of the metabolic syndrome.⁴⁸ Other studies have demonstrated that these cardiovascular risk factors may be associated with the early development of atherosclerosis in the young.⁴⁹ It is therefore reasonable, as recommended by the Fourth Report,¹ to screen for these risk factors/comorbidities when evaluating hypertensive children and adolescents. Identification of multiple cardiovascular risk factors at an early age may in turn permit institution of measures aimed at prevention of adult cardiovascular disease.

THERAPY

In contrast to management of hypertension in adults, which is guided by evidence derived from the results of large-scale clinical trials, the management of hypertensive children and adolescents is still largely empiric. This is largely due to the lack of long-term outcome data regarding nonpharmacologic and pharmacologic approaches to treatment of hypertension in children and adolescents.⁵⁰ However, as

some hypertensive children and adolescents will either have secondary hypertension or hypertensive target-organ damage, the practitioner caring for these patients should be familiar with appropriate treatment strategies, both pharmacologic and nonpharmacologic.

As discussed earlier, the Fourth Report from the National High Blood Pressure Education Program¹ recommends that, as in adults, elevated BP in children and adolescents be staged in order to help guide evaluation and management. Intervention is recommended even for children or adolescents with BPs that fall into the “prehypertension” range (Table 52–3). Such children should be counseled regarding lifestyle changes and should be seen within 6 months for a repeat BP measurement and assessment of how well they are adhering to the recommended lifestyle measures. At the other end of the scale, children or adolescents with stage 2 hypertension are candidates for immediate institution of pharmacologic therapy.

Nonpharmacologic management

Although the magnitude of change in BP may be modest, weight loss, aerobic exercise, and dietary modifications have all been shown to successfully reduce BP in children and adolescents, at least in research settings.

Studies in obese adolescents have demonstrated that modest weight loss not only decreases BP but also improves other cardiovascular risk factors such as dyslipidemia and insulin resistance.^{51–54} In studies where a reduction in body mass index of about 10% was achieved, short-term reductions in BP were in the range of 8 to 12 mmHg. Unfortunately, weight loss is notoriously difficult and usually unsuccessful, especially in the primary care setting.⁵⁵ Additionally, even intensive efforts at weight loss in childhood may be followed by recidivism and an increased prevalence of adverse consequences of obesity in adulthood.⁵⁶ However, identifying a medical complication of obesity such as hypertension can perhaps provide the necessary motivation for patients and families to make the appropriate lifestyle changes.

Similarly, exercise training over 3 to 6 months has been shown to result in a reduction of 6 to 12 mmHg for systolic BP and 3 to 5 mmHg for diastolic BP.⁵⁷ However, cessation of regular exercise is generally promptly followed by a rise in BP to pre-exercise levels.⁵⁸ Aerobic exercise activities such as running, walking, or cycling are usually preferred to static forms of exercise in the management of hypertension.⁵⁹ Many children may already be participating in one or more appropriate activities, and may only need to increase the frequency and/or intensity of these activities to produce a reduction in their BP. Exercise should probably be combined with dietary changes such as those discussed later in this chapter for best results in terms of BP reduction.⁶⁰ The combination of dietary changes and exercise training may also restore vascular function in addition to reducing BP.⁶¹

Dietary modification in the management of hypertension in children and adolescents has received a fair amount of attention over the years. Nutrients that have been examined include the obvious, such as sodium, potassium, and calcium, as well as folate, caffeine, and other substances. Manipula-

tion of sodium intake has received extensive study. Although it is controversial whether excessive sodium intake may cause hypertension,^{62–64} once hypertension has been established, “salt sensitivity” becomes more common, and reduction in sodium intake is likely to be of benefit.^{62,64–66} Trials of dietary sodium restriction in hypertensive children and adolescents have had mixed results, with some controlled studies showing no benefit,⁶⁷ and others showing a modest reduction in BP in obese adolescents but not lean adolescents.⁶⁸ Many authors have noted that the usual dietary sodium intakes of children and adolescents, at least in the United States, far exceed any nutritional requirement for sodium.^{62,67} This suggests that dietary sodium restriction may have a role in those children with established hypertension, a substantial proportion of whom are likely to be salt-sensitive.

Other nutrients that have been examined in patients with hypertension include potassium and calcium, both of which have been shown to have antihypertensive effects.^{66,67,69,70} A recent 2-year trial of potassium and calcium supplementation in hypertensive, salt-sensitive children demonstrated that this combination significantly reduced systolic BP.⁷⁰ Therefore, a diet that is low in sodium and enriched in potassium and calcium may be more effective in reducing BP than a diet that restricts sodium only. An example of such a diet is the so-called DASH (Dietary Approaches to Stop Hypertension) diet, which has been shown to have an antihypertensive effect in adults with hypertension, even in those receiving antihypertensive medication.⁷¹ Although this diet has not been specifically studied in children or adolescents, the basic elements of the DASH eating plan are logical to apply the treatment of hypertensive children, especially if accompanied by counseling from a pediatric dietitian. The DASH diet also incorporates higher intake of such micronutrients as folate, which may have an antihypertensive effect,⁷² as well as measures designed to reduce dietary fat intake, an important strategy given the frequent presence of both hypertension and elevated lipids in children and adolescents and the imperative to begin prevention of adult cardiovascular disease at as early an age as possible.^{47,53,73}

Pharmacologic management

For many years, drug therapy of childhood hypertension relied upon either on trial-and-error, or on adapting efficacy data from studies conducted in adults.⁷⁴ Fortunately, this situation has changed because the number of antihypertensive medications that have been systematically studied in children has increased markedly over the past 7 to 8 years due to incentives provided to the pharmaceutical industry by the 1997 Food and Drug Modernization Act (FDAMA) and the 2002 Best Pharmaceuticals for Children Act (BPCA).^{75,76} Thus, while the 2000 *Physicians Desk Reference* contained Food and Drug Administration (FDA)–approved pediatric dosing information for a minority of antihypertensive medications commonly used in children,⁷⁴ the 2004 Fourth Report¹ indicates that FDA-approved dosing information is now available for at least a dozen medications, including seven drugs for which pediatric trials have been conducted since 1999.

Experience in adults indicates that although some hypertensive patients may experience a decline in BP without treatment, in most it will likely persist and even progress over time.⁷⁷ This implies that once a hypertensive patient is started on medication, he or she is likely to remain on medication for the rest of his or her life. This is readily accepted for adults given the known long-term adverse consequences of untreated or undertreated hypertension.^{2,79} However, since the long-term consequences of untreated hypertension in an asymptomatic, otherwise healthy child or adolescent remain unknown,⁵⁰ the decision to prescribe antihypertensive medications in a child or adolescent should not be made lightly. Furthermore, even the open-label extensions to pediatric clinical trials of antihypertensive medications will be insufficient to fully elucidate the long-term effects of antihypertensive medications on the growth and development of children. Therefore, a clear-cut indication for initiating pharmacologic therapy should be determined before a prescription is written.

Indications for use of antihypertensive medications in children and adolescents are listed in Box 52–1. These have been recommended by consensus organizations¹ because pharmacologic reduction of BP for hypertensive children who fall into one of these categories is likely to result in health benefit. This is especially true for children with secondary hypertension and diabetes, in whom the underlying/accompanying condition will probably be benefited by BP reduction. Not to be overlooked are children who fail a trial of nonpharmacologic measures; no matter whether the child’s lifestyle has successfully been changed, if their BP remains persistently elevated, then pharmacologic treatment should be initiated. Since the long-term health consequences (both good and bad) of using antihypertensive medications in childhood remain unknown, it is of paramount importance to ensure that there will be a potential health benefit before a prescription is written.

In hypertensive adults, recommendations for which antihypertensive medication to prescribe are based on the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) and similar large-scale studies of hypertension treatment.^{2,79} Many of these studies have compared the effects of various classes of antihypertensive agents on cardiovascular endpoints such as myocardial infarction and stroke. Since these events are exceedingly rare in the pediatric age group, it is unlikely that comparable studies will ever be conducted in children. Given this, the choice of

Box 52–1

Indications for Antihypertensive Medications in Children and Adolescents

- Stage 2 hypertension
- Symptomatic hypertension
- Secondary hypertension
- Hypertensive target-organ damage
- Type 1 or 2 diabetes
- Persistent hypertension despite nonpharmacologic measures

initial antihypertensive agent for use in children still remains up to the preference of the individual practitioner.

Diuretics and beta-adrenergic blockers, which were recommended as initial therapy in the First and Second Task Force Reports,^{80,81} have a long track record of use in hypertensive children and are still appropriate choices. Newer classes of agents, including ACE inhibitors, calcium channel blockers, and angiotensin receptor blockers, have been shown to be safe and well tolerated (at least for short-term use) in hypertensive children in recent industry-sponsored trials.⁸²⁻⁸⁶ A recent survey of current prescribing practices of North American pediatric nephrologists has demonstrated that these newer agents, particularly calcium channel blockers and ACE inhibitors, have become the most widely used initial agents in the pediatric age group, with diuretics and beta-adrenergic blockers being primarily used as add-on

therapy when a second or third agent is required.⁴³ Current dosing recommendations for oral antihypertensive agents are given in Table 52-6.

Specific classes of antihypertensive medications should be prescribed in certain hypertensive children and adolescents with specific underlying or concurrent medical conditions. The best example of this would be the use of ACE inhibitors or angiotensin receptor antagonists in children with diabetes or proteinuric renal diseases, something that is already being done by many physicians who treat hypertensive children.⁴³ This parallels the approach outlined in the seventh report of the Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7), which recommends that specific classes of antihypertensive agents be used in adults if compelling indications are present,² and is consistent with

RECOMMENDED DOSES FOR SELECTED ANTIHYPERTENSIVE AGENTS FOR USE IN HYPERTENSIVE CHILDREN AND ADOLESCENTS

Class	Drug	Starting Dose	Interval	Maximum Dose ^a	Adverse Effects/Other Comments
Angiotensin-converting enzyme (ACE) inhibitors	Benazepril ^b	0.2 mg/kg/day up to 10 mg/day	QD	0.6 mg/kg/day up to 40 mg QD	<ol style="list-style-type: none"> 1. Monitor serum chemistries shortly after initiating therapy and periodically thereafter. 2. Contraindicated in patients with bilateral RAS or RAS in single kidney, and in pregnancy. 3. May cause cough and angioedema. 4. Many ACEI are available in combination preparations containing a diuretic.
	Captopril ^b	0.3-0.5 mg/kg/dose	BID-TID	6 mg/kg/day up to 450 mg/day	
	Enalapril ^b	0.08 mg/kg/day	QD	0.6 mg/kg/day up to 40 mg/day	
	Fosinopril	0.1 mg/kg/day up to 10 mg/day	QD	0.6 mg/kg/day up to 40 mg/day	
	Lisinopril ^b	0.07 mg/kg/day up to 5 mg/day	QD	0.6 mg/kg/day up to 40 mg/day	
Angiotensin-receptor blockers	Quinapril	5-10 mg/day	QD	80 mg/day	<ol style="list-style-type: none"> 1. Monitor serum chemistries shortly after initiating therapy and periodically thereafter. 2. Contraindicated in patients with bilateral RAS or RAS in single kidney, and in pregnancy. 3. Many ARB are available in combination preparations containing a diuretic.
	Candesartan	4 mg/day	QD	32 mg QD	
	Irbesartan Losartan ^b	75-150 mg/day 0.75 mg/kg/day up to 50 mg/day	QD QD	300 mg/day 1.4 mg/kg/day up to 100 mg/day	
α- and β-adrenergic antagonists	Labetalol ^b	2-3 mg/kg/day	BID	10-12 mg/kg/day up to 1.2 g/day	<ol style="list-style-type: none"> 1. Contraindicated in asthma, heart failure (labetalol only), and diabetes. 2. Heart rate is dose-limiting. 3. May impair athletic performance. 4. Carvedilol beneficial in heart failure.
	Carvedilol	0.1 mg/kg/dose up to 12.5 mg BID	BID	0.5 mg/kg/dose up to 25 mg BID	
β-adrenergic antagonists	Atenolol	0.5-1 mg/kg/day	QD-BID	2 mg/kg/day up to 100 mg/day	<ol style="list-style-type: none"> 1. Propranolol contraindicated in asthma and heart failure. 2. Heart rate is dose-limiting. 3. May impair athletic performance. 4. Should not be used in insulin-dependent diabetics. 5. Sustained-release formulations of propranolol and metoprolol are available that are dosed once daily.
	Bisoprolol/HCTZ	2.5/6.25 mg/day	QD	10/6.25 mg qd	
	Metoprolol	1-2 mg/kg/day	BID	6 mg/kg/day up to 200 mg/day	
	Propranolol	1 mg/kg/day	BID-TID	16 mg/kg/day up to 640 mg/day	

RECOMMENDED DOSES FOR SELECTED ANTIHYPERTENSIVE AGENTS FOR USE IN HYPERTENSIVE CHILDREN AND ADOLESCENTS—cont'd					
Class	Drug	Starting Dose	Interval	Maximum Dose ^a	Adverse Effects/Other Comments
Calcium channel blockers	Amlodipine ^b	0.06 mg/kg/day	QD	0.6 mg/kg/day up to 10 mg/day	<ol style="list-style-type: none"> 1. Felodipine and extended-release nifedipine tablets must be swallowed whole. 2. May cause mild tachycardia, flushing, and headache. 3. Gingival hyperplasia may occur with prolonged use, especially in combination with calcineurin inhibitors.
	Felodipine	2.5 mg/day	QD	10 mg/day	
	Isradipine ^b	0.05–0.15 mg/kg/dose	TID–QID	0.8 mg/kg/day up to 20 mg/day	
	Extended-release nifedipine	0.25–0.5 mg/kg/day	QD–BID	3 mg/kg/day up to 120 mg/day	
Central α -agonists	Clonidine ^b	5–10 mcg/kg/day	BID–TID	25 mcg/kg/day up to 0.9 mg/day	<ol style="list-style-type: none"> 1. May cause dry mouth and sedation. 2. Clonidine also available in a transdermal preparation. 3. Sudden withdrawal of clonidine may cause severe rebound hypertension.
	Methyldopa ^b	5 mg/kg/day	BID–QID	40 mg/kg/day up to 3 g/day	
Diuretics	Amiloride	5–10 mg/day	QD	20 mg/day	<ol style="list-style-type: none"> 1. Electrolytes should be monitored shortly after initiating therapy and periodically thereafter. 2. All diuretics are best used as add-on therapy in combination with other classes of antihypertensives. 3. Chlorothiazide and furosemide are commercially available as suspensions.
	Chlorothiazide	10 mg/kg/day	BID	20 mg/kg/day up to 1.0 gram/day	
	Chlorthalidone	0.3 mg/kg/day	QD	2 mg/kg/day up to 50 mg/day	
	Furosemide	0.5–2.0 mg/kg/dose	QD–BID	6 mg/kg/day	
	HCTZ	0.5–1 mg/kg/day	QD	3 mg/kg/day up to 50 mg/day	
	Spironolactone ^b	1 mg/kg/day	QD–BID	3.3 mg/kg/day up to 100 mg/day	
Peripheral α -antagonists	Triamterene	1–2 mg/kg/day	BID	3–4 mg/kg/day up to 300 mg/day	<ol style="list-style-type: none"> 1. All may cause first-dose hypotension.
	Doxazosin	1 mg/day	QD	4 mg/day	
	Prazosin	0.05–0.1 mg/kg/day	TID	0.5 mg/kg/day	
Vasodilators	Terazosin	1 mg/day	QD	20 mg/day	<ol style="list-style-type: none"> 1. Tachycardia and fluid retention are common side effects. 2. Hydralazine can cause a lupus-like syndrome in slow acetylators. 3. Prolonged use of minoxidil can cause hypertrichosis.
	Hydralazine	0.25 mg/kg/dose	TID–QID	7.5 mg/kg/day up to 200 mg/day	
	Minoxidil	0.1–0.2 mg/kg/day	BID–TID	1 mg/kg/day up to 50 mg/day	

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin receptor blocker; BID, twice daily; HCTZ, hydrochlorothiazide; QD, once daily; QID, four times daily; RAS, renal artery stenosis; TID, three times daily.
^aThe maximum recommended adult dose should never be exceeded.
^bInformation on preparation of a stable extemporaneous suspension is available for these agents.

Table 52-6. Recommended Doses for Selected Antihypertensive Agents for Use in Hypertensive Children and Adolescents

prior expert recommendations that the therapy of childhood hypertension should be tailored to the specific clinical status of the individual patient.⁸⁷

For children with uncomplicated primary hypertension and no hypertensive target-organ damage, goal BP should be less than 95th percentile for age, gender, and height, whereas for children with secondary hypertension, diabetes, or hypertensive target-organ damage, goal BP should be less than 90th percentile for age, gender, and height.¹ These treatment goals are akin to current recommendations for therapy of hypertension in adults,² which are designed to

achieve lower BPs in certain groups of patients in order to slow the progression of underlying renal disease, or reverse hypertensive target-organ damage.

Long-term issues in hypertension treatment

As in adults, treatment of hypertension in children and adolescents is a long-term proposition. Initially, medication doses should be adjusted until the desired goal BP is reached. After that, there should be ongoing monitoring of BP, surveillance for medication side effects, periodic moni-

RECOMMENDED DOSES FOR ANTIHYPERTENSIVE AGENTS USED FOR HYPERTENSIVE EMERGENCIES AND URGENCIES IN CHILDREN AND ADOLESCENTS				
Drug	Class	Dose	Route	Comments
Clonidine	Central α -agonist	0.05–0.1 mg/dose, may be repeated up to 0.8 mg total dose	Oral	Side effects include dry mouth and sedation.
Enalaprilat	ACE inhibitor	0.05–0.10 mg/kg/dose up to 1.25 mg/dose	IV bolus	May cause prolonged hypotension and acute renal failure.
Esmolol	β -blocker	100–500 mcg/kg/min	IV infusion	Very short-acting. May cause profound bradycardia.
Fenoldopam	Dopamine receptor agonist	0.2–0.8 mcg/kg/min	IV infusion	Less potent than nicardipine but may improve renal bloodflow in patients with acute renal failure.
Hydralazine	Vasodilator	0.2–0.6 mg/kg/dose	IV, IM	Should be given q 4 hours when given IV bolus.
Isradipine	Calcium channel blocker	0.05–0.1 mg/kg/dose	Oral	Stable suspension can be compounded.
Labetalol	α - and β -blocker	Bolus: 0.20–1.0 mg/kg/dose up to 40 mg/dose Infusion: 0.25–3.0 mg/kg/hr	IV bolus or infusion	Asthma and overt heart failure are relative contraindications.
Minoxidil	Vasodilator	0.1–0.2 mg/kg/dose	Oral	This drug is long-acting; most potent form is oral vasodilator.
Nicardipine	Calcium channel blocker	1–4 mcg/kg/min	IV infusion	May cause reflex tachycardia.
Sodium nitroprusside	Vasodilator	0.5–10 mcg/kg/min	IV infusion	Monitor cyanide levels with prolonged (>72 hours) use or in renal failure; or co-administer with sodium thiosulfate.

ACE, angiotensin-converting enzyme; IM, intramuscular; IV, intravenous.

Table 52–7. Recommended Doses for Antihypertensive Agents Used for Hypertensive Emergencies and Urgencies in Children and Adolescents

INTRAVENOUS ANTIHYPERTENSIVES FOR SEVERE HYPERTENSION IN INFANTS			
Drug	Dose/Interval	Route	Comments
Alpha- and Beta-Adrenergic Blocker			
Labetalol	Bolus: 0.2–1.0 mg/kg/dose, q 6–12 hours Infusion: 0.25–3.0 mg/kg/hr	Bolus injection or continuous infusion	Heart failure and lung disease are relative contraindications.
Angiotensin-Converting Enzyme Inhibitor			
Enalaprilat	15 \pm 5 mcg/kg/dose, q 8–24 hours	Bolus injection	Use with extreme caution. May cause prolonged hypotension and acute renal insufficiency.
Beta-Adrenergic Blocker			
Esmolol	100–500 mcg/kg/min	Continuous infusion	Very short-acting; continuous infusion is necessary.
Calcium Channel Blocker			
Nicardipine	0.5–4 mcg/kg/min	Continuous infusion	May cause reflex tachycardia.
Vasodilators			
Hydralazine	0.15–0.6 mg/kg/dose q 4 hours	Bolus injection	Tachycardia is a common side effect. May also be given intramuscularly.
Sodium nitroprusside	0.3–10 mcg/kg/min	Continuous infusion	Thiocyanate toxicity can occur with prolonged (>72 hours) use or in renal failure.

Table 52–8. Intravenous Antihypertensives for Severe Hypertension in Infants

toring of electrolytes (in children treated with angiotensin-converting enzyme inhibitors or diuretics), counseling regarding other cardiovascular risk factors, and continued emphasis on nonpharmacologic measures, particularly weight loss and exercise. Home BP measurement has been found to be helpful in ensuring that BP control has been achieved.⁴³ Alternatively, repeat ambulatory BP monitoring may need to be performed in some patients, particularly if “resistant hypertension” appears to be present based on office BP measurements.⁸⁸ Hypertensive target organ damage such as left ventricular hypertrophy, if present, should be reassessed periodically.¹

Withdrawal of antihypertensive medications may be considered in selected children and adolescents with hypertension. This involves an attempt at gradual reduction in medication after an extended course of good BP control, with the eventual goal of completely discontinuing drug therapy. Although no comparable studies have been performed in children, experience in adults suggests that a significant percentage of patients may remain normotensive, at least in the short-term, after withdrawal of

active treatment.⁷⁷ Children with uncomplicated primary hypertension, especially obese adolescents who have successfully lost weight and remain compliant with recommendations for dietary modification and exercise, are probably the best candidates for medication withdrawal. These children should receive continued BP monitoring after drug therapy is withdrawn, as well as continued nonpharmacologic treatment.

HYPERTENSIVE EMERGENCIES AND URGENCIES IN CHILDREN AND ADOLESCENTS

The pathophysiology, management, and outcome of severe hypertension in children and adolescents have been comprehensively reviewed elsewhere.⁸⁹ Many aspects are similar to hypertensive emergencies and urgencies in adults as covered in Chapter 63. However, a few unique aspects merit consideration.

Underlying conditions that may produce a hypertensive emergency or urgency in a child or adolescent may

ORAL ANTIHYPERTENSIVES FOR CHRONIC HYPERTENSION IN INFANTS			
Drug	Dose	Frequency	Comments
Aldosterone Antagonist			
Spironolactone	0.5–1.5 mg/kg/dose Maximum 3.3 mg/kg/day	BID	This drug is potassium “sparing”; monitor electrolytes. It takes several days to achieve maximum effectiveness.
Angiotensin-Converting Enzyme Inhibitors			
Captopril	<3 months: 0.01–0.5 mg/kg/dose Maximum 2 mg/kg/day >3 months: 0.15–0.3 mg/kg/dose Maximum 6 mg/kg/day	TID	First dose in pre-term infants may cause rapid drop in BP; monitor serum creatinine and potassium.
Enalapril	0.08–0.6 mg/kg/day	QD or BID	Monitor serum creatinine and potassium.
Alpha- and Beta-Adrenergic Blocker			
Labetalol	0.5–1.0 mg/kg/dose Maximum 10 mg/kg/day	BID or TID	Monitor heart rate; avoid in infants with BPD or congestive heart failure.
Beta-Adrenergic Blocker			
Propranolol	0.5–1.0 mg/kg/dose Maximum 8–10 mg/kg/day	TID	Maximal dose depends on heart rate; avoid in infants with BPD or congestive heart failure.
Calcium Channel Blocker			
Amlodipine	0.05–0.17 mg/kg/dose Maximum 0.6 mg/kg/day	QD or BID	This drug is less likely to cause sudden hypotension than isradipine.
Isradipine	0.05–0.15 mg/kg/dose Maximum 0.8 mg/kg/day	TID or QID	In suspension, drug may be compounded; useful for both acute and chronic hypertension.
Central Alpha Agonist			
Clonidine	5–10 mcg/kg/day Maximum 25 mcg/kg/day	BID or TID	Rebound hypertension may occur with abrupt discontinuation.
Thiazide Diuretics			
Chlorothiazide	10–30 mg/kg/day	BID	Monitor electrolytes; in patients with renal disease, thiazides may precipitate azotemia.
Hydrochlorothiazide	1–3 mg/kg/dose	QD	
Vasodilators			
Hydralazine	0.25–1.0 mg/kg/dose Maximum 7.5 mg/kg/day	TID or QID	Suspension only stable for 1 week; tachycardia and fluid retention are common side effects.
Minoxidil	0.1–0.2 mg/kg/dose	BID or TID	Usually reserved for refractory hypertension.

BID, twice daily; BPD, bronchopulmonary dysplasia; QD, once daily; QID, four times daily; RAS, renal artery stenosis; TID, three times daily.

Table 52-9. Oral Antihypertensives for Chronic Hypertension in Infants

include acute or chronic renal disease, organ transplantation, renal artery stenosis, or congenital renal disease such as autosomal recessive polycystic kidney disease. Hypertensive encephalopathy is frequent, particularly in younger children with severe hypertension, emphasizing the need for slow, controlled reduction in BP to prevent complications arising through loss of normal autoregulatory processes.^{89,90} Less severe symptoms may include nausea, vomiting, or unusual irritability; since these are somewhat nonspecific, a high degree of clinical suspicion must be maintained when evaluating such children.

Although evidence-based recommendations are lacking, the usual goal in treatment of a hypertensive emergency is to reduce the BP by no more than 25% over the first 8 hours, with a gradual return to normal/goal BP over 24 to 48 hours.^{89,90} Treatment of most hypertensive emergencies in children should begin with a continuous infusion of an intravenous antihypertensive, with nicardipine and labetalol finding the greatest popularity in many centers.^{89,91} The dopamine receptor agonist fenoldopam has also been reported effective,⁹² although it is less potent than alternative agents, particularly nicardipine. For many hypertensive urgencies, or if the child's symptoms permit, oral antihypertensive agents can be administered. Recommended doses for intravenous and oral drugs used to treat severe hypertension in children and adolescents can be found in Table 52–7.

HYPERTENSION IN INFANTS

Neonatal hypertension is a problem primarily confined to infants admitted to neonatal intensive care units. Overall, the incidence of neonatal hypertension is low—from 0.2% in healthy newborns to 0.7% to 2.5% in high-risk infants. Those with indwelling umbilical catheters and those with chronic lung disease are at greatest risk.⁹³ Moreover, many of these infants have acute hypertension that resolves as the underlying condition improves. Those requiring chronic treatment generally have underlying renal disorders or persistent lung disease. The differential diagnosis for neonatal hypertension covers a wide spectrum of conditions, many of which are acute and resolve after prompt intervention (Box 52–2).

Proper identification of infants with hypertension can be problematic due to problems with BP measurement in the nursery, and also due to changes in BP that occur with maturation, especially in pre-term infants.⁹⁴ This topic is complex and beyond the scope of this chapter; the interested reader should consult other sources for detailed discussion of these issues.^{93,95} Evaluation of infants with elevated BP, on the other hand, is usually fairly straightforward, and should begin with a targeted physical exam looking for signs of underlying renal disease or other easily identifiable conditions, followed by appropriate laboratory and imaging studies. Renal ultrasonography is the most important imaging modality as it will uncover a variety of the possible causes of elevated BP (Box 52–2); other techniques such as nuclear scans and angiography should only be performed in selected cases.⁹⁶

Box 52–2

Causes of Hypertension in Infants

Renovascular

- Thromboembolism
- Renal artery stenosis
- Aortic coarctation
- Renal venous thrombosis
- Compression of renal artery
- Idiopathic arterial calcification
- Congenital rubella syndrome

Renal Parenchymal Disease

Congenital

- ARPKD
- ADPKD
- Multicystic-dysplastic kidney disease
- Tuberous sclerosis
- Ureteropelvic junction obstruction

Acquired

- Acute tubular necrosis
- Cortical necrosis
- Hemolytic-uremic syndrome
- Obstruction (stones, tumors)

Pulmonary

- Bronchopulmonary dysplasia
- Pneumothorax

Genetic

Single-gene disorders

- Glucocorticoid-remediable aldosteronism
- Liddle syndrome
- Pseudohypoaldosteronism type II

Malformation syndromes

- Williams syndrome
- Turner syndrome
- Neurofibromatosis
- Cockayne syndrome

Endocrine

- Congenital adrenal hyperplasia
- Hyperaldosteronism
- Hyperthyroidism

Medications/Intoxications

Infant

- Dexamethasone, corticosteroids
- Adrenergic agents
- Vitamin D intoxication
- Theophylline, aminophylline
- Caffeine
- Pancuronium
- Phenylephrine eye drops

Maternal

- Cocaine
- Heroin

Neoplasia

- Wilms' tumor
- Mesoblastic nephroma
- Neuroblastoma

Neurologic

- Pain
- Intracranial hypertension
- Seizures
- Opiate withdrawal

Box 52-2—cont'd**Causes of Hypertension in Infants—cont'd****Miscellaneous**

Fluid overload
 Closure of abdominal wall defect
 Adrenal hemorrhage
 Hypercalcemia
 Traction
 Birth asphyxia
 Idiopathic

ADPKD, autosomal dominant polycystic kidney disease;
 ARPKD, autosomal recessive polycystic kidney disease.

While an overriding priority in hypertensive neonates would seem to be quick, effective, and safe BP reduction, this is difficult because data regarding the use of antihypertensive agents in neonates are inadequate. Therefore, most treatment recommendations are empiric and based on expert opinion. Agents currently in use for acute, severe hypertension in infants are listed in Table 52-8, and oral agents for less severe neonatal hypertension are listed in Table 52-9. The management of neonatal hypertension

requires experience and knowledge regarding the unique characteristics of neonatal renal physiology. For example, ACE inhibitors should be used with extreme caution in this age group due to the dependence of renal development on an intact renin-angiotensin system. The intravenous ACE inhibitor enalaprilat in particular may cause severe hypotension and persistent oliguric renal failure.

SUMMARY

Hypertension is an important pediatric problem that is growing in importance as a result of the childhood obesity epidemic. Cardiovascular risk factors, including hypertension, should be identified in children so that adult cardiovascular disease may be prevented. Evaluation and treatment of hypertension in children and adolescents should be guided by the likely etiology and should include evaluation for hypertensive target-organ damage and coexisting risk factors. Although the amount of information on antihypertensive agents for children and adolescents has increased, significant deficits remain, including data in neonates and data regarding the long-term risks and benefits of these drugs in this age group. Further research is needed to better define the optimal approach to the management of hypertensive children and adolescents.

Chapter
53**Hypertension in the Elderly***Stanley S. Franklin***Key Findings**

- The elderly, defined as 65 years of age and older, have a 90% lifetime risk of developing hypertension.
- Isolated systolic hypertension (ISH), once considered only an inconsequential part of the aging process, has become the predominant form of hypertension in the elderly.
- ISH—wide pulse pressure hypertension by definition—is a surrogate risk marker for increased arterial stiffness.
- ISH in the elderly is an independent risk factor for the development of coronary heart disease, heart failure, stroke, dementia, peripheral vascular disease, and renal failure.

Clinical Implications

- There is overwhelming evidence that effective pharmacologic treatment of both systolic–diastolic hypertension and ISH reduces cardiovascular events in the elderly.
- Treatment benefits of hypertension are greater in the old than in the young, but paradoxically, ISH in the elderly has the lowest rates of control; this occurs because ISH in the old is more difficult to treat to goal than diastolic hypertension in the young.
- The barriers to control of hypertension in the elderly can be overcome in part by an aggressive polytherapeutic approach to management that includes the use of a diuretic.

Approximately 65 million individuals in the United States and 1 billion worldwide are affected by hypertension.¹ With the aging of the population and the advent of effective antihypertensive therapy, there has been a shift toward a more slowly evolving form of hypertension that is predominately systolic in nature and affects middle-aged and older persons (Figure 53–1).² Indeed, the elderly, defined as persons 65 years of age and older, represent the fastest growing segment of the United States population with a 90% lifetime risk of developing hypertension.³

An age-associated rise in systolic blood pressure (SBP), occurring as a consequence of increased arterial stiffness, was once considered an inconsequential part of the aging process. Hypertension was largely defined using only the criterion of elevated diastolic blood pressure (DBP) until the 1990s. This slowly rising SBP with aging, out of proportion to the rise in DBP, is referred to as *isolated*

systolic hypertension (ISH). Previously, ISH was defined as an SBP ≥ 160 mmHg and a diastolic blood pressure (DBP) of < 95 or < 90 mmHg. With the recognition of its true cardiovascular risk, ISH was redefined as an SBP ≥ 140 and DBP < 90 mmHg. Elderly individuals with ISH have at least a twofold increase in risk for cardiovascular disease events compared with younger individuals with systolic–diastolic hypertension. ISH is frequently associated with coronary heart disease (CHD), thrombotic and hemorrhagic stroke, dementia, peripheral vascular disease, and slowly progressive heart and renal failure; it has become the most common and the most difficult form of hypertension to treat successfully and hence a public health problem of major proportion. The purpose of this chapter is to provide a better understanding of hypertension in the elderly and how to treat it effectively.

EPIDEMIOLOGY

The U.S. Fourth National Health and Nutrition Examination Survey⁴ (NHANES) recently showed an overall prevalence of hypertension (≥ 140 mmHg SBP or ≥ 90 mmHg DBP, or on antihypertensive medication) of 28.7% in 1999–2000, which varied from 7.2% in those aged 18 to 39 to 65.4% in those aged 60 and over, and which was greater in women (30.1%) than in men (27.1%). Noteworthy is the fact that since 1988–1991 the prevalence of hypertension has increased significantly in women and in all age groups, although most dramatically in those aged 60 and over who experienced an increase in prevalence from 57.9% in 1988–1991 to 65.4% in 1999–2000. Moreover, in the United States, prevalence of hypertension in the elderly is greatest among non-Hispanic blacks and lowest among Mexican Americans.⁴ Compared to the United States, the prevalence of hypertension is similar in Canada, but is markedly higher in European countries (44% overall), being as high as 55% in Germany.⁵

ANATOMY AND PATHOLOGY

The elastic behavior of the arterial wall of the central blood vessels—the thoracic aorta and its branches—are profoundly affected by aging.^{6,7} This process depends primarily on the composition and arrangement of the materials that make up the media of the arterial tree. In the media of the thoracic aorta and its immediate branches are large attachments of elastic lamellae to smooth muscle cells, constituting the contractile-elastic unit and

Figure 53-1. Frequency distribution of untreated hypertensive individuals by age and hypertension subtype. Numbers at the tops of bars represent the overall percentage distribution of all subtypes of untreated hypertension in the age group (National Health and Nutrition Examination Survey III [NHANES III], 1988 to 1994). IDH, isolated diastolic hypertension (SBP \leq 140 mm Hg and DBP $>$ 90 mm Hg); ISH, isolated systolic hypertension (SBP $>$ 140 mm Hg and DBP \leq 90 mm Hg); SDH, systolic–diastolic hypertension (SBP \geq 140 mm Hg and DBP \geq 90 mm Hg). (Adapted from Franklin SS, Jacobs MJ, Wong ND, et al. *Hypertension* 2001;37:869–74.)

arranged in an alternating oblique pattern, that exert maximum force in a circumferential direction. This arrangement is important for the balance of normal changes in intraluminal pressure and tension that occur during systole and diastole. The medial fibrous elements of the thoracic aorta contain a predominance of elastin over collagen, but as one proceeds distally along the arterial tree there is a rapid reversal favoring collagen over elastin in the peripheral, largely muscular arteries. Thus, the thoracic aorta and its immediate branches (such as carotid arteries) show maximum elasticity while more distal vessels become progressively stiffer.

Hypertension can produce arterial stiffness by both functional and structural mechanisms.^{6,7} With the development of hypertension and increased distending pressure, the load-bearing elastic lamellae stretch and become stiffer on a functional basis. There are also longstanding struc-

tural changes with aging that cause increased stiffness of the thoracic aorta and its branches, but spare the more peripheral muscular arteries. Elastin, with a half-life of 40 years, is one of the most stable proteins in the body. Despite this stability, fatigue of elastin fibers and lamellae can occur by the sixth decade of life from the accumulated cyclic stress of more than 2 billion aorta expansions during ventricular contraction. Longstanding cyclic stress in the media of elastic-containing arteries produces fatigue and eventual fracturing of elastin along with structural changes of the extracellular matrix that include proliferation of collagen and deposition of calcium. This degenerative process, termed arteriosclerosis, is the pathologic process that results in increased central elastic arterial stiffness and the development of ISH in older age groups. Furthermore, hypertension left untreated may accelerate the rate of development of elastic artery stiffness; this, in turn, can perpetuate a vicious cycle of accelerated hypertension and further increases in stiffness.⁶⁻⁸ Similarly, other disease processes such as type 1 and type 2 diabetes, obesity, hypercholesterolemia, generalized atherosclerosis, smoking, and chronic renal failure, can accelerate aging of central elastic arteries with earlier development of arterial stiffness and ISH.^{6,7}

PATHOPHYSIOLOGY

Pulse pressure (PP) is determined not only by arterial stiffness, but also by stroke volume and to a lesser extent by the ejection rate of the left ventricle. In contrast, mean arterial pressure (MAP) is determined by cardiac output and total peripheral resistance. By definition, ISH is characterized by an increase in PP, but not necessarily by an increase in MAP, stroke volume, or ejection rate. Thus, in older subjects brachial PP is regarded as a surrogate measure of arterial stiffness.^{6,7}

Both cross-sectional and longitudinal population studies show that SBP rises from adolescence, whereas DBP, although initially increasing with age, levels off at about age 50 and decreases after age 60.^{8,9} Thus, PP begins to increase after age 50. The rise in SBP and DBP up to age 50 can best be explained by the dominance of peripheral vascular resistance (Table 53-1). The transition age of 50-60 years when DBP levels off constitutes a near balancing of increased resistance and increased thoracic aortic stiffness. By contrast, after age 60, the fall in DBP

HEMODYNAMIC PATTERNS OF AGE-RELATED CHANGES IN BLOOD PRESSURE					
Age (Years)	DBP (mmHg)	SBP (mmHg)	MAP (mmHg)	PP (mmHg)	Hemodynamics
30-49	↑	↑	↑	→↑	R>S
50-59	→	↑	→	↑↑	R=S
≥60	↓	↑	→↓	↑↑↑	S>R

and the rapid widening of PP become surrogate indicators of central elastic arterial stiffening. Indeed, after age 60, central arterial stiffness, rather than peripheral vascular resistance, becomes the dominant hemodynamic factor in both normotensive and hypertensive individuals.

Arterial stiffness is also accompanied by the phenomenon of early wave reflection.^{6,7} The central pressure waveform is produced by two major components: a forward-traveling wave generated by ventricular ejection, and a backward wave reflecting off of distal arteries at the branching origins of arterioles. In young subjects the reflected pressure waves return to the ascending aorta in diastole and serve to elevate mean DBP, thus boosting coronary artery perfusion. The summation of the incident pressure wave with the reflected wave in young adults produces a normal phenomenon of pressure amplification of PP and SBP from the aorta to the brachial artery. Between the ages of 20 and 70 years, as arteries stiffen, the pulse wave velocity doubles. In older individuals, the reflected pressure wave returns to the ascending aorta earlier during late systole and increases or “augments” the central SBP and PP, thus decreasing pressure amplification and simultaneously contributing to increased cardiac afterload.^{6,7}

Paradoxically, the heart only “sees” SBP in the ascending aorta, and pressure wave amplification distorts the relationship between central and peripheral SBP, as measured at the brachial artery by the sphygmomanometer. Therefore, central and not peripheral SBP, regardless of age, determines cardiac afterload and hence cardiac risk. The changing pattern of age-related brachial artery blood pressure (BP) components that predict CHD risk results from altered peripheral resistance, aortic stiffness, and early wave reflection, all acting in concert to raise SBP, decrease DBP, and abolish pressure amplification; this leads to an age-related shift from sphygmomanometric-determined DBP to SBP and ultimately to ISH with wide PP as the predictors of cardiac risk (Figure 53–2).¹⁰ These findings represent a significant paradigm

shift in our understanding of how we use brachial artery cuff BP components to predict cardiovascular risk.

In addition to arterial stiffening, the left ventricle itself becomes stiff, perhaps as an adaptation to facilitate cardiac ejection and maintain matched coupling of heart to arteries. This is particularly notable in hearts that develop left ventricular hypertrophy, a common occurrence in the elderly and particularly in those individuals with ISH. A stiffer left ventricular coupled to a stiffer arterial system can contribute to increased cardiovascular risk in several ways, as has been shown by the studies of Kass.¹¹ First, there is increased late-systolic wall stress, and the cardiac energy costs imposed on the heart. Second, the imposition of high late-systolic load that often rises markedly during stress demand slows cardiac relaxation rates, potentially leading to incomplete diastolic relaxation, elevated diastolic pressures, and compromised cardiac reserve. This appears to be a factor in patients with heart failure symptoms who have apparent preservation of left ventricular function. Third, loss of arterial distensibility appears to alter vascular mechano-signaling, so the normal augmentations of nitric oxide release and vasoprotective mechanisms are compromised. Lastly, increased pulsatile stress, secondary to the loss of the conduit artery cushioning function, can contribute to endothelial dysfunction, increased coronary atherosclerosis, rupture of unstable atherosclerotic plaques, and acute coronary heart syndromes.¹² Many of these disturbances in cardiovascular function characterize the elderly person with longstanding ISH and markedly elevated PP.

The conventional wisdom is that the reduction DBP that accompanies ventricular–arterial stiffening results in compromised coronary perfusion. Whereas reflected waves normally return during early diastole and thereby enhance coronary perfusion, this increased boost is absent in elderly persons with ISH^{6,7}; the decline in DBP, however, rarely falls to the critical level (~50–60 mmHg) required to disturb coronary flow autoregulation.^{13,14} Furthermore, cardiac ejection into the stiff arterial system results in more coronary perfusion during systole. This suggests that the frequent reduction in DBP that accompanies increased PP does not compromise coronary perfusion significantly. It is more likely that the reduction in DBP that occurs in most individuals with ISH is primarily a surrogate risk marker for ventricular–arterial stiffness.

In summary, *coupling disease* results from stiffness of both the heart and arteries interacting to produce diastolic dysfunction and heart failure; this results from the combination of an elevated cardiac afterload presented to a compromised left ventricle, which is unable to handle the load. Thus, cardiovascular risk of an increased PP is defined by (1) increased SBP, a marker of cardiac afterload, and by (2) discordant decreased DBP in association with an increased SBP, a marker of increased stiffness of the left ventricle and the proximal aorta.

As suggested by their age-dependent divergent patterns of onset, diastolic hypertension and ISH may be two distinct disorders with significant overlap. The conversion from diastolic hypertension to ISH in the older age group has been attributed to “burned-out” diastolic hypertension.

Figure 53–2. Difference in coronary heart disease prediction between SBP and DBP as function of age. Difference in β coefficients (from Cox proportional hazards regression) between SBP and DBP is plotted as function of age, obtaining the following regression line: $\beta(\text{SBP}) - \beta(\text{DBP}) = -1.49848 + 0.0290 \times \text{age}$ ($p=0.008$). DBP, diastolic blood pressure; SBP, systolic blood pressure. (Adapted from Franklin SS, Larson MG, Khan SA, et al. *Circulation* 2001;103:1245–9.)

While some people who have had untreated or poorly treated diastolic hypertension at a younger age develop ISH as they become older, data from the Framingham Study suggest that only about 40% of patients acquire ISH in this manner.¹⁵ The majority of people who developed ISH do not go through a stage of diastolic hypertension (Figure 53–3).¹⁵ The bias toward DBP over SBP by earlier generations of physicians may be, in part, due to the emphasis on hypertension as a young person's condition. However, with the aging of the population during the past half-century, hypertension has become largely a condition affecting older persons, that is, those with the ISH subtype.

Contrary to the conclusion of the Prospective Studies Collaboration (PSC)¹⁶ and the Asian Pacific Cohort Studies Collaboration (APCSC)¹⁷ that MAP is superior to PP as a predictor of future cardiovascular events in the elderly, the preponderance of evidence supports the opposite conclusion. PP is a surrogate risk marker for ventricular–arterial stiffness in the elderly, although at times an imperfect one. Moreover, PP is an independent risk factor for cardiovascular disease. Clearly, these findings call into question the belief that elevation of SBP and DBP contribute equally to cardiovascular risk in all age groups. However, there is as yet no evidence supporting the reduction of PP instead of SBP as a therapeutic goal. In addition, we have little information on the utility of using PP and SBP together, rather than SBP alone, to classify hypertensive risk. Since the majority of people with systolic hypertension are over 55 years of age and have ISH, the focus should be on high-risk systolic hypertension. From a practical viewpoint, effective antihypertensive therapy most often simultaneously lowers both SBP and PP. On the basis of prevailing data, it would be premature to modify current treatment guidelines that focus primarily on lowering SBP in middle-aged and the elderly for the prevention of cardiovascular events.

Figure 53–3. Average maximum DBP reached prior to the development of isolated SBP for those who reached a DBP of <90 mmHg, from 90 to 94 mmHg, and ≥95 mmHg, respectively. DBP, diastolic blood pressure; SBP, systolic blood pressure. (Adapted from Franklin SS, Pio JR, Wong ND, et al. *Circulation* 2005;111:1121–7.)

CLINICAL PRESENTATION AND EVALUATION

Hypertension in the elderly differs from younger individuals with essential hypertension in a number of ways (Table 53–2). Blood pressure fluctuates physiologically in response to changes in emotion, physical activity, and wakefulness. Furthermore, subjects with hypertension have more lability than do normotensive individuals. The higher the BP, the greater is the extent of lability. Aging is associated with disruption of normal baroreceptor reflex activity. In the absence of this stabilizing influence, it is not surprising that BP lability increases with age. Therefore, multiple measurements of BP on at least two separate visits may be necessary before labeling a patient as having hypertension.

The incidence of postural hypotension appears to increase with aging and especially after a meal. Indeed, orthostatic hypotension has been shown to be a powerful predictor of cardiovascular mortality in the Honolulu Heart Study.¹⁸ Furthermore, the occurrence of postural hypotension may limit a person's ability to control supine and sitting SBP. Since BP recordings in the standing position disclose the presence and severity of orthostasis, it is imperative that these BP levels be used for defining pre-treatment levels and for determining the endpoint of therapy.

In patients with hypertension, a silent interval called the “auscultatory gap” may occur between the end of the first and the beginning of the third phases of Korotkoff sounds. In patients with geriatric hypertension, there appears to be a greater incidence and severity of an auscultatory gap.¹⁹ Since the gap occurs only with auscultation, preliminary determination of SBP by palpation ensures the proper amount of cuff compression for the auscultatory technique and avoids the pitfall of beginning the evaluation of the Korotkoff sounds during the auscultatory gap. Without this maneuver, the auscultatory gap is not appreciated and erroneously low values of SBP can be recorded.

How well do indirect cuff blood pressure numbers correlate with direct intra-arterial BP values? With the most careful cuff measurements, true DBP is overestimated by 5 to 15 mmHg or more and true SBP is underestimated

SPECIFIC CHARACTERISTICS OF HYPERTENSION IN ELDERLY AND CLINICAL ASSESSMENT	
Characteristics	Assessment
Increased BP lability	Multiple measurements
Orthostatic hypotension	Sitting and standing BP
Post-prandial hypotension	Pre- and post-prandial BP
Auscultatory gap	Palpate radial pulse
Pseudohypertension	Pertains to DBP only
Increased % of RVHBP	Elevation of both SBP and DBP

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

Table 53–2. Specific Characteristics of Hypertension in Elderly and Clinical Assessment

by 0 to 5 mmHg or more compared with simultaneous intra-arterial pressure recordings.²⁰ Although the DBP artifact may be present regardless of age or BP level, this entity is found more frequently in elderly hypertensives with large artery stiffness. Moreover, correlation of pulse wave velocity with DBP cuff artifact suggests that increasing wall stiffness is responsible for erroneously high diastolic cuff values. The clinical importance of falsely overestimating DBP in the geriatric hypertensive patient is that many elderly hypertensives who were previously classified with systolic–diastolic hypertension have, in reality, ISH or pseudo-diastolic hypertension. In contrast, the entity of pseudo-systolic hypertension in the elderly is a rare occurrence.

Although atherosclerotic renovascular hypertension is more common and often unrecognized in the elderly as compared to the younger person with hypertension, it is seldom cured and often not improved by angioplasty with stenting or by surgical intervention. Therefore, one can make a case for avoiding excessive evaluation, other than to assess other potential cardiovascular risk factors that coexist with hypertension. However, in the presence of severe systolic–diastolic hypertension in an elderly patient, one can be alerted to possible underlying renal artery stenosis. Other indications for proceeding with a workup for renal artery stenosis would be spontaneous or ACE inhibitor/angiotensin II inhibitor induced worsening of renal function, flash pulmonary edema, or drug-resistant hypertension.²¹

MANAGEMENT

Benefits of medical therapy

During the past few decades, the therapeutic approach in elderly hypertensive patients has changed markedly. In the early 1970s, prevailing wisdom questioned the benefit of antihypertensive agents in patients over 65 years of age. Beginning in the early 1990s, the publication of three major placebo-controlled studies that specifically addressed the treatment of ISH in older patients changed the perception of the significance of SBP control. In 1991, the landmark Systolic Hypertension in the Elderly Program (SHEP) study first established that older patients with ISH benefited from treatment.²² The Syst-Eur²³ and the Syst-China²⁴ trials corroborated these findings.

Staessen et al.²⁵ conducted a meta-analysis of the 11,825 patients aged 60 years or older who participated in these three major trials (Figure 53–4). This analysis found that antihypertensive treatment significantly reduced fatal and nonfatal coronary events by 25%, fatal and nonfatal strokes by 37%, all cardiovascular events by 32%, cardiovascular mortality by 25%, and total mortality by 17%.²⁵ Additionally, a highly significant 49% reduction in fatal and nonfatal heart failure was reported from the SHEP study.²² These studies negate prior assumptions that age-related changes in BP are benign, and reinforce the emerging paradigm that treatment will benefit patients with elevated SBP, even when they have normal or low DBP. Further-

Figure 53–4. Effect of antihypertensive drug treatment on fatal and nonfatal cardiovascular endpoints in three outcome trials in older patients with isolated systolic hypertension. more, the benefit-to-risk ratio of antihypertensive therapy is higher in the elderly than in younger or middle-aged patients.

Currently life expectancy in the United States is 77 years, raising the question of the benefit of antihypertensive agents in patients over this age. A meta-analysis of six major trials that included 1670 patients aged 80 years or older suggested that even the very old may benefit from antihypertensive treatment (Figure 53–5).²⁶ In these patients, active treatment produced a 34% reduction in stroke ($p=0.014$), a 39% reduction in heart failure ($p=0.01$), and a 22% reduction in major cardiovascular events ($p=0.01$). The reduction in coronary events was not statistically significant and a nonsignificant 6% increase in mortality was observed.²⁶ Evidence from this meta-analysis was strong for older patients with SBP of at least 160 mmHg (stage 2 ISH); current data are weaker for treatment of stage 1 hypertension in the absence of target-organ damage.²⁷ Indeed, there is disagreement as to whether nonsustained systolic hypertension is innocuous compared with true normotension in the elderly patient. The Hypertension in the Very Elderly Trial,²⁸ a more definitive intervention study of the very old (age 80 or older) utilizing a randomized, double-blind, placebo-controlled protocol in 2100 subjects with ISH, is nearing completion. Until the results of this study are known, it would be inappropriate to withhold antihypertensive treatment in this age group. Even though we may not extend the lives of octogenarians, effective treatment of ISH may enhance the quality of their remaining years through prevention of strokes, heart failure, and major cardiovascular complications.

Therapeutic target goals

There are Joint National Committee (JNC-7)²⁹ and World Health Organization (WHO)³⁰ guidelines for the optimal reduction of BP to achieve maximum benefit from antihypertensive therapy that make no distinction between young and older adults. These guidelines, based on obser-

Figure 53–5. Effect of antihypertensive drug treatment in the very old (aged over 80 years) on cardiovascular endpoints in 1670 participants from five trials. CHD, coronary heart disease; CHF, congestive heart failure. (Adapted from Gueyffier F, Bulpitt C, Boissel J-P, et al. *Lancet* 1999;353:793–6, with permission from Elsevier.)

vational as well as on outcome data, suggest that low-risk patients be treated to a target goal of <140 SBP mmHg and <90 DBP mmHg. For high-risk subjects with diabetes, renal impairment, or heart failure, the therapeutic target goal is <130 SBP mmHg and <80 DBP mmHg. In patients with renal disease and at least 1 g of proteinuria per 24 hours, BP guidelines suggest that the BP treatment goal is <125/75.

Value of lifestyle intervention

A variety of lifestyle interventions have been shown to lower BP, with the most effective being successful weight reduction in overweight and obese hypertensives.³¹ Reducing weight is of special importance if the elderly hypertensive has diabetes. Even a reduction of 10 to 15 pounds can have a significant benefit in lowering BP. Unfortunately, most patients are refractory to successful weight reduction, and even when partially successful, tend to have a high percentage of recidivism within a year of losing weight.

The older hypertensive patients are usually more salt-sensitive than the young, especially in persons with ISH.³² However, successful salt restriction depends to a large extent on limiting milk, bread, and a variety of high salt-containing processed foods and substituting fruits, vegetables, and nuts. The more recent use of the Dietary Approaches to Stop Hypertension (DASH) diet,³³ rich in fruits, vegetables, high-calcium but low animal-fat foods, has been successful in reducing BP in older hypertensives even when they consume average salt intakes. Heavy alcoholic intake can precipitate or worsen hypertension in older patients, and is frequently refractory to usual drug therapy. Except for the unusual patient, lifestyle intervention is generally unsuccessful in correcting ISH fully. However, in addition to partial reduction in BP, lifestyle intervention may reduce the need for extensive antihypertensive therapy and minimize associated cardiovascular risk factors. It should be emphasized that lifestyle intervention is more likely to be successful in preventing rather than in reversing hypertension when initiated early at the high-normal BP level.²⁹

Selection of antihypertensive drug therapy

The Blood Pressure Treatment Trialists Collaboration,³⁴ a meta-analysis of 29 trials involving 162,341 persons with a mean age of 65 years, concluded that all classes of commonly used antihypertensive agents were equally successful in reducing the risk of ischemic heart disease and stroke events. Moreover, the reduction in risk was directly proportional to the reduction in SBP. These conclusions were supported by the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),³⁵ an outcome trial of over 42,000 high-risk subjects with a mean age of 67 years. The ALLHAT study showed that a thiazide-type diuretic (chlorthalidone) was equally effective in reducing the primary endpoints of nonfatal myocardial infarction and CHD deaths when compared to the calcium channel blocker amlodipine or the ACE inhibitor lisinopril.

Perhaps beta-blockers represent an exception to the dictum that the benefit of an antihypertensive agent is directly proportional to its blood pressure lowering capability. This was shown in the Losartan Intervention for Endpoint Reduction (LIFE),³⁶ a trial of patients with hypertension and left ventricular hypertrophy, in which losartan (an angiotensin II receptor blocker [ARB]) was superior to atenolol (a beta-blocker) in preventing fatal and nonfatal strokes, independent of any significant difference in BP lowering between the two arms.³⁶ However, central BP may be more adversely affected by beta-blockade as compared to blockade of renin-angiotensin system.³⁷ It should be noted also that a diuretic was an add-on drug in more than 77% of both therapeutic arms, suggesting that the combination of a diuretic and ARB was an effective modality of treatment for stroke prevention in this high-risk group of older hypertensive patients. The LIFE study reinforces an earlier meta-analysis of 10 geriatric hypertension outcome studies that showed the inferiority of beta-blockers as compared to diuretics in reducing cardiovascular events.³⁸

The question of which drug class is best suited to start first in patients with ISH may be a moot point. Although diuretics and calcium channel blockers have been shown to be most effective in decreasing BP and reducing cardiovascular events in the major geriatric hypertension intervention trials,²²⁻²⁴ it should be remembered that reaching goal therapy is generally more difficult in geriatric ISH than in younger persons with systolic–diastolic hypertension. In practice, a combination of two or more drug classes will be necessary for BP control in the majority of patients with ISH.³⁹ The use of combination therapy generally increases BP reduction at lower doses of the component agents and often reduces adverse events when compared to higher-dose monotherapy.⁴⁰ Elevations in SBP by ≥ 20 mmHg and DBP by ≥ 10 mmHg above goal (the “20/10” rule)²⁹ will often require combination therapy from the start in order to achieve goal therapy within a relatively short time and thereby minimize cardiovascular events.⁴¹ Low-dose diuretics should almost always be part of combination therapy because of their efficacy in BP reduction, minimal adverse events, and low cost.

There are always potential dangers in reducing BP in the elderly, but the available evidence would suggest that adverse events are no more frequent in the elderly than in younger hypertensive subjects. However, it may be appropriate to start with lower doses of medication in the elderly and then titrate against response and symptoms. In addition, there are some potential hazards of combination therapy in the elderly. The combination of a beta-blocker and a nondihydropyridine calcium channel blockers may cause bradyarrhythmias. Alpha-blockers and calcium channel blockers may cause or exacerbate orthostatic hypotension. ACE inhibitors and potassium-sparing diuretics may cause or exacerbate hyperkalemia.

Optimal treatment of ISH should not only reduce peripheral vascular resistance, but also reduce large artery stiffness and the early wave reflection generated by that stiffness. Treatment approaches with the capability of minimizing arterial stiffness include a variety of approved

agents. Most conventional antihypertensive drugs, however, fall short of optimally reducing age-related increases in PP.⁴² Therapeutic benefit may result from at least five different mechanisms. First, reduction of peripheral resistance downstream will decrease large-artery stiffness upstream by a reduction in distending pressure that decreases the stretch on elastic arteries; a variety of antihypertensive agents that dilate arterials work in this manner.^{6,7} Second, vasodilatation of small arteries and arterioles will shorten the artery reflection sites, decrease early wave reflection, decrease aortic late SBP peaking and hence decrease cardiac afterload without a structural decrease in arterial stiffness.^{6,7} Nitrates, in doses that do not affect peripheral vascular resistance, have been shown to decrease early wave reflection, decrease central pulse pressure and hence lower left ventricular afterload—all without a significant change in arterial stiffness.⁴³ Third, long-term reduction in cardiac afterload will eventually result in regression of left ventricular hypertrophy, regression of vascular smooth muscle hypertrophy and remodeling of small blood vessels toward a normal wall to lumen ratio.⁴⁴ Indeed, the ability of angiotensin converting enzyme inhibitors and angiotensin receptor blockers to promote regression of LVH and arterial remodeling may have important long-term benefits in reducing arterial stiffness.⁴⁵ Fourth, therapy that blocks excessive aldosterone at the tissue level may over time result in regression of fibrosis in the heart, renal mesangium, and large blood vessels. Indeed, spironolactone and eplerenone may prove to be of value in reversing the stiffness of arteries in persons with ISH.⁴⁵ Fifth, some antihypertensive agents appear to possess properties that specifically influence arterial stiffness without affecting peripheral vascular resistance. In animal models, advanced glycation end product (AGE) cross-linking breakers have been shown to prevent arterial stiffening.⁴⁶ Although poorly understood, reduced-sodium diets to achieve negative salt balance, with or without the use of diuretics, can reduce arterial stiffness.³² Other possible destiffening strategies include aerobic exercise, 3-hydroxy-methylglutaryl-coenzyme A reductase inhibitors (statins), antioxidants, and inhibiting of PDE5a with sildenafil.¹¹

The optimal strategy in treating ISH is to maximize SBP reduction while minimizing the reduction in DBP. As was demonstrated by Koch-Weser in 1973⁴⁷ and recently confirmed by Wang et al.,⁴⁸ the higher the PP (in part, age related), the greater will be the fall in SBP as compared to the fall in DBP with conventional antihypertensive agents. Therefore, antihypertensive therapy will maximize the decrease in PP and minimize the further reduction in DBP, in direct proportion to the age of the patient and the extent of large artery stiffness.⁴⁸

Achieving therapeutic goals

The realization that antihypertensive treatment of patients over age 60 to 65 correlates with improved outcomes makes awareness of hypertension and access to treatment important factors in achieving therapeutic goals. In recent decades awareness of hypertension has steadily increased. However, in the most recent U.S. NHANES survey

(1999–2000), awareness was approximately 70%, the same as in the previous NHANES survey, conducted approximately 5 years previously. Thus, a substantial proportion (30%) of hypertensive persons in the United States continue to be unaware of having hypertension, with nearly one-half of these persons over age 65.⁴⁹

Furthermore, of the patients treated, many remain above recommended BP goals. Nearly 60% of hypertensive patients receive antihypertensive therapy, but a little more than 50% of those patients on therapy achieve the recommended SBP of 140 mmHg.⁴ Not unexpectedly, the vast majority of treatment failures occur in patients over age 50 and especially in older women.⁵⁰ Only 14% of failures in NHANES III² occurred in patients under age 50, while 86% of treatment failures occurred in older individuals, most of whom had ISH, access to health care, and relatively frequent contact with physicians.⁵¹ Analyzing treatment failures by age reveals the age-related discrepancy in the successful control of both SBP and DBP. Approximately 50% of younger patients who failed treatment had concordant SBP and DBP that were not at target goals. In contrast, older patients who failed to achieve treatment goals had discordant failure. Only 17% of patients aged 50 or over were above their DBP goal, but fully 82% were above their SBP target goal.²

The tendency toward failure to reach SBP treatment goal becomes more apparent with aging, as shown in the Framingham Heart Study by Lloyd-Jones et al.⁵² More patients aged over 75 than under the age of 60 achieved their DBP goal (92% vs. 85%, respectively). In contrast, the SBP target progressively became more difficult to obtain: in patients aged less than 60, 69% reached their SBP target goal; in those aged 61 to 75 years, 48% of patients reached goal; and in those over the age of 75 years, only 34% reached goal.

That target SBP becomes more difficult to achieve with aging is best explained by age-related increasing arterial stiffness. Physician inertia and errors contribute greatly to inadequate control of ISH. In the past, treatment guidelines focused on the DBP, relegating the control of SBP to minimal importance. Some clinicians feared reaching excessively low DBP and, therefore, were fearful of lowering the SBP even at pressures above 150 or 140 mmHg as long as the DBP remained at or below its target. This fear of excessive therapeutic lowering of DBP—the so called “J curve phenomenon”—has been exaggerated. If there is any significant risk of precipitating an ischemic cardiac event with therapy-induced low BP, it would occur only with DBP reduction below 60 mmHg, as indicated in a

post-hoc analysis of the SHEP study.¹⁴ Failure to titrate medications upward, failure to use optimal polypharmacy, and, in particular, failure to incorporate diuretics as part of polypharmacy, may hamper the ability to control ISH. In addition, not treating to the lower target goals in high-risk patients with diabetes and with kidney disease likely further contributed to the disappointingly high incidence of treatment failures.

Patient noncompliance with antihypertensive medication contributes greatly to poor control of BP. Indeed, as many as 50% of individuals who start medications for hypertension discontinue their treatment within the first year. Achieving goal therapy is greatly facilitated by enlisting active patient participation in their care. This would include establishing treatment goals, home monitoring of blood pressure, simplifying treatment regimens, reviewing medications and refills on each visit, discussing realistic objectives for lifestyle modifications, and addressing potential drug side effects and cost issues.⁵³

While several aspects involving treatment approaches may explain the failure to optimally control ISH overall, one must conclude that there exists a substantial number of patients with systolic hypertension that are truly resistant to currently available medications, even when used properly. Unrecognized conditions in the elderly that lead to poor BP control are the use of non steroidal anti-inflammatory agents for arthritis (especially with coexisting impaired renal function), occult alcoholism, undiagnosed sleep apnea, hypothyroidism, atherosclerotic renal artery disease, and recently described hyperaldosteronism associated with morbid obesity.⁵⁴

SUMMARY

Once considered an inconsequential part of the aging process, the development of ISH represents a late manifestation of increased arterial stiffness in the middle-aged and elderly population. Its inherent increased risk for vascular events highlights the importance of its control. Furthermore, there is overwhelming evidence that pharmacologic treatment of ISH reduces cardiovascular events in the elderly. Paradoxically, ISH remains more difficult to control than diastolic hypertension and most middle-aged and elderly hypertensive patients fail to achieve recommended targets. Reaching target systolic pressure levels may require the use of polypharmacy that includes a diuretic, and perhaps includes future new agents that specifically and effectively target arterial stiffness.

Hypertension in Pregnancy

Jason G. Umans

Definitions

- Hypertension in pregnancy can be due to one of several distinct disorders, including pre-existing chronic hypertension, gestational hypertension, pre-eclampsia or pre-eclampsia superimposed on chronic hypertension.
- Pre-eclampsia is a multisystem disorder that may present without proteinuria, and more severe phenotypes include central nervous system, hematologic, hepatic, and renal manifestations.

Clinical Implications

- There are no formally established blood pressure (BP) targets in pregnancy, although BP is always controlled to less than 170/110, using drugs other than angiotensin-converting enzyme inhibitors or angiotensin II-receptor blockers.
- Magnesium sulfate is the preferred agent for eclamptic seizures.

Hypertension is the most common medical complication of pregnancy, affecting 10% to 15% of all pregnancies in the developed world, where it is the second leading cause of maternal death and markedly increases the incidence of preterm birth, intrauterine growth restriction, placental abruption, and perinatal mortality. Its impact on maternal morbidity and mortality are even greater in the developing world. Hypertension in pregnancy includes several distinct disorders, whose differential diagnosis, although often difficult, is important because they differ in etiology and apparent mechanism, hemodynamics, clinical evolution, risks to mother and fetus, and long-term cardiovascular consequences. In addition, clinicians often fail to appreciate the presence or evolution of underlying hypertension as it may be obscured by the normal hemodynamic, renal, and biochemical adaptations to pregnancy.

In 2006, we are still without any evidence-based blood pressure (BP) treatment targets for hypertensive gravidas. Defining BP targets is even more difficult, because guidelines were developed using mercury sphygmomanometry, while practice has largely shifted to use of automated oscillometric BP devices, even though they often yield erroneous results in hypertensive pregnant women. Tight BP control appears not to benefit women without target-organ damage. Indeed, it is unclear which, if any of the morbid complications of hypertensive pregnancy are prevented by varying degrees of BP control. However, all

agree that BP should not exceed either 170 mmHg systolic or 110 mmHg diastolic, since these high levels may lead to cerebrovascular catastrophe. Further, it remains important to recognize when hypertension is due to pre-eclampsia, as this disorder may evolve rapidly and unpredictably toward multiorgan failure and life-threatening complications. Antihypertensive therapy is limited by contraindications to the use of angiotensin-converting enzyme (ACE) inhibitors and AT₁ receptor blockers late in pregnancy and by a striking paucity of well-designed and adequately-powered studies to assess risks and benefits of other antihypertensive agents.

HEMODYNAMICS IN NORMAL AND HYPERTENSIVE PREGNANCY

Normal pregnancy strikingly alters systemic hemodynamics and renal function so as to impact our recognition of and approach to hypertension. Gestational decrements in systemic vascular resistance (SVR) are so profound that, despite an increase in cardiac output (CO) of nearly 50%, BP falls early in the first trimester.^{1,2} Along with this microvascular vasodilation, there is a parallel adaptation of large artery function, with increased total arterial compliance early in pregnancy.³ Paradoxically, the gestational hypotension is even more striking in women with underlying chronic hypertension, so that BP may fall by 30/15 mmHg, masking the recognition of pregestational hypertension when the patient is examined at her first prenatal visit.⁴ Thus, a thorough history, review of records, fundoscopic examination, and evidence of target-organ damage may be the only clues to chronic hypertension in the early phase of pregnancy; BP values of 120/80 during the first trimester may be abnormal and should lead to suspicion of underlying hypertension. The mechanisms of gestational vasodilation in women remain uncertain, but appear not to depend on either vasodilator prostaglandins or nitric oxide (NO).

Pregnancy alters every aspect of the renin-angiotensin-aldosterone system, markedly increasing levels of angiotensinogen, plasma renin activity, angiotensin II, Ang 1–7, and aldosterone.^{5,6} However, there is a specific refractoriness to the AT₁ receptor-mediated effects of angiotensin, which manifests as decreased pressor response to infused angiotensin II and to blunted constriction of human resistance arteries *in vitro*. In addition, progesterone antagonizes the effects of aldosterone at mineralocorticoid receptors.^{5,7}

Not only is there generalized systemic vasodilation, but pregnancy causes specific renal vasodilation and hyperfiltration. Afferent and efferent arteriolar vasodilation is balanced, so that renal plasma flow and glomerular filtration rate (GFR) increase in parallel.² In the same way that pregnancy may obscure the recognition of underlying essential hypertension, this gestational hyperfiltration may mask underlying renal insufficiency. A serum creatinine concentration of more than 0.8 mg/dL early in pregnancy should be viewed with suspicion. The mechanisms leading to gestational renal vasodilation have been elucidated in the rat and depend on a signaling cascade in which the ovarian hormone relaxin acts via gelatinase to cleave big endothelin (ET), resulting in ET_B receptor-mediated activation of NO synthase.⁸ It appears that relaxin also underlies the increased arterial compliance and many of the systemic vascular changes of pregnancy in the rat; whether similar mechanisms occur in women is yet to be determined.⁹

Measuring blood pressure in pregnant women

Diagnosis of hypertension in pregnancy, defined as a BP greater than 140 mmHg systolic or greater than 90 mmHg diastolic occurring at any time during gestation,¹⁰ depends, of course, on accurate BP measurement using standardized and validated techniques. Unfortunately, these validated techniques are rarely used in typical clinical practice. When possible, BP should be measured in the sitting position, with the arm supported, using an appropriately sized cuff, a mercury sphygmomanometer (or a recently calibrated aneroid device), and with diastolic BP defined by the fifth Korotkoff sound.¹¹ In bed-bound patients, many clinicians measure BP in the left lateral decubitus position so as to avoid spurious elevations, especially in late pregnancy, due to the mass effect of the gravid uterus when supine. This is a reasonable strategy as long as the clinician accounts for the artifactual lowering of BP if it is recorded from the right arm (inadvertently elevated relative to the heart). Most of the oscillometric devices now used routinely for home BP monitoring as well as for BP measurement in hospital clinics, on labor and delivery units, and even those devices which are integral to fetal monitoring devices, have not been validated in hypertensive pregnant women; nearly all depend on algorithms that provide erroneous values for diastolic BP. Because most guidelines for treatment of severe hypertension focus on diastolic values, all automated readings should be confirmed by auscultation when they might alter therapy.

Despite the possible inaccuracy of oscillometric devices in hypertensive gravidas, home BP monitoring can markedly improve the care of women at high risk for pre-eclampsia or with more severe underlying hypertension by detecting significant changes in systolic pressure, thus leading to earlier diagnosis of pre-eclampsia or to more careful titration of antihypertensive medications.¹² Similarly, there may be a role for ambulatory BP monitoring for risk assessment in pregnancy, although confirmatory and outcomes data remain lacking.¹³

DIAGNOSIS AND CLASSIFICATION OF HYPERTENSION IN PREGNANCY

Using a nomenclature endorsed by the International Society for the Study of Hypertension in Pregnancy, several national and international obstetrics groups, and by the National High Blood Pressure Education Program (NHBPEP) Working Group on Hypertension in Pregnancy,^{10,11} we recognized four major hypertensive disorders of pregnancy. First, chronic hypertension (antepartum pregnancy) may be either essential or secondary. Two disorders, gestational hypertension and pre-eclampsia, occur only in pregnancy. Finally, pre-eclampsia may be superimposed upon underlying chronic hypertension. Terms such as pregnancy-induced hypertension (PIH) may include a mix of disorders, with differing pathophysiology and risks, and should be abandoned.

Chronic hypertension

This is the most rapidly growing cause of hypertension in pregnancy, perhaps the combined result of several factors, including postponement of childbearing to more advanced age, and the epidemic of essential hypertension, often coupled with obesity and insulin resistance. Although less common than essential hypertension, three forms of secondary hypertension that affect young women deserve specific mention: pheochromocytoma, renovascular hypertension, and primary hyperaldosteronism.⁴ Clinicians should have a low threshold for suspecting pheochromocytoma, despite its rarity, when hypertension is associated with classic signs and symptoms, since it may lead to hypertensive crisis during labor. Appropriate management, as in nonpregnant women, would include α -adrenoreceptor blockade and confirmatory measurements of catecholamines and their metabolites. There are several case reports of life-saving surgical management with proper pharmacologic blockade of pheochromocytoma during pregnancy.¹⁴ Renovascular hypertension, most likely due to fibromuscular dysplasia or arteritis in women of childbearing age, so often leads to superimposed pre-eclampsia and poor pregnancy outcome that it should be corrected before or even during pregnancy. Diagnosis is difficult because usual measurements of renin activity are of little to no diagnostic utility during pregnancy; Doppler ultrasound measurements are often misleading, and radionuclide renal scans are avoided in pregnancy. Further, radiologists are often hesitant to perform magnetic resonance (MR) imaging or interventional procedures, even when indicated. Notwithstanding these obstacles, there are well-documented cases in which diagnosis by MR angiography and correction by angioplasty during pregnancy led to good maternal and neonatal outcomes.¹⁵ Finally, hypertension due to primary hyperaldosteronism may have a variable and often mild course during pregnancy because high levels of progesterone during pregnancy can antagonize mineralocorticoid effects at the aldosterone receptor.^{5,7} It is important to realize that serum and urinary aldosterone during normal pregnancy far exceeds levels usually observed in patients with a proven aldosteronoma.

In these cases, severe hypertension, hypokalemia, and suppression of endogenous plasma renin activity may only be unmasked postpartum.

Importantly, many apparently healthy young women have never had BP measurement (or any routine medical care) before conception. Normal gestational vasodilation and relative hypotension may then mask their underlying chronic hypertension, which can then be mistaken for either gestational hypertension or pre-eclampsia if it worsens later in pregnancy.

Gestational hypertension

Gestational hypertension is hypertension that occurs *de novo*, usually during the latter half of pregnancy in the absence of proteinuria and other signs or symptoms of pre-eclampsia (see below) and resolves postpartum. Although it may result in severe hypertension requiring treatment, its course is usually more benign than that of pre-eclampsia. It may recur in subsequent pregnancies and often predicts essential hypertension or, like pre-eclampsia, increased cardiovascular risk later in life.

Pre-eclampsia

Pre-eclampsia is characterized by *de novo* hypertension, usually during the latter half of pregnancy, although well-characterized cases have been reported as early as 16 weeks. However, it is a multisystem disorder, usually defined by proteinuria (>300 mg/day) and resolving postpartum. It occurs in ~6% of (usually primigravid) pregnancies. Its incidence falls dramatically in subsequent pregnancies, except when risk is increased by a persisting underlying medical disorder (see below), or when the subsequent pregnancy involves a new father. Risk factors, listed in Box 54–1, include a family history of pre-eclampsia, multifetal gestation, diabetes mellitus, renal or autoimmune diseases, and obesity with insulin resistance.

In addition, a variety of unrelated genetic abnormalities, including mutations of angiotensinogen or NO synthase genes, seem to increase the risk of pre-eclampsia in some populations. Whereas clinically evident target-organ damage characterizes more severe disease, subtle symptoms or laboratory evidence of target-organ damage, including hyperuricemia, thrombocytopenia, and abnormalities of liver function or coagulation tests, are common. Because pre-eclampsia can have a variable course and explosive clinical evolution,¹⁶ with real risks of maternal morbidity and mortality, one should err toward diagnosing pre-eclampsia, even in the absence of proteinuria (which can occur later in the evolution of the disorder), when hypertension is accompanied by abdominal pain, neurologic symptoms such as headache or blurred vision, or any evidence of thrombocytopenia or liver function or coagulation abnormalities.¹¹ Indeed, criteria advocated by the Australasian Society for the Study of Hypertension in Pregnancy (ASSHP) favor the diagnosis of pre-eclampsia, even in the absence of proteinuria, when hypertension is accompanied either by fetal growth restriction or by evidence of renal, hepatic, neurologic, or hematologic involvement.¹⁷ This approach, which differs from the other consensus guidelines,¹⁸ better identifies women at low risk for subsequent complications, labeling them as gestational hypertensives.

Pre-eclampsia can evolve rapidly to a convulsive and life-threatening phase, termed eclampsia. An especially threatening variant of pre-eclampsia is the HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome, which may seem mild in its initial presentation, and then evolves over hours to microangiopathic hemolysis, severe thrombocytopenia, and hepatic necrosis with rupture.

It can be surprisingly difficult to distinguish pre-eclampsia from gestational hypertension by the detection of proteinuria or by hemodynamic assessment. Obstetricians in the United States typically screen for proteinuria using urine dipsticks, confirming positive (1+) results by 24-hour urine collection (using methods for quantitation of 24-hour urine protein that often vary from hospital to hospital, although with a fixed diagnostic threshold value of 300 mg/day). This “gold standard” case definition is based on historical studies of clearly defined cases before the availability of sensitive and specific methods for assessment of albuminuria, excretion of other specific urine proteins, or recent advances in our understanding of the pathophysiology of this disorder. Indeed, it is likely that these advances will eventually lead to new case definitions and diagnostic strategies that will then replace this “tarnished” standard. Many gravidas with proteinuria exceeding the 300 mg/day threshold will prove to have no glomerular protein leak; 500 mg/day proteinuria or some new definition of pathologic albuminuria may better predict morbid maternal and fetal outcomes.¹⁹ Due mostly to variation in urinary concentration, the sensitivity of urine dipsticks and their prediction of 24-hour urine protein are both poor. This limitation may be overcome, in part, by efforts to standardize screening techniques based on measurement of albumin:creatinine ratios, correction

Box 54–1

Risk Factors for Pre-eclampsia

- Primigravida
- First pregnancy with this partner
- Family history of pre-eclampsia
- Multifetal pregnancy
- Pre-eclampsia in prior pregnancy
- IUGR, placental abruption, or fetal demise in prior pregnancy
- Obesity
- Renal disease of any cause or severity (including microhematuria or microproteinuria without specific etiologic diagnosis)
- Diabetes mellitus
- Chronic hypertension
- Connective tissue disease

for urine specific gravity, or use of automated point-of-care devices.^{20,21} Beyond these minor technical considerations, it is now clear that the onset of proteinuria may lag, in some cases by many weeks, behind that of hypertension.²² This asynchrony would lead to misdiagnosis of pre-eclamptic women as gestational hypertensives and would then support the notion that gestational hypertension could transform (or evolve) into pre-eclampsia in a subset of patients.

It is likely that markers such as sFlt-1 or AT₁ receptor autoantibodies or convenient noninvasive hemodynamic measurements may, in the future, allow for more certain differential diagnosis during pregnancy. While we await adequately powered prospective studies that link these markers to outcomes in women at normal and elevated risk for pre-eclampsia or superimposed pre-eclampsia,²³ the diagnosis of pre-eclampsia can only be made with real certainty in retrospect.

Superimposed pre-eclampsia

“Pure” pre-eclampsia complicates ~6% of (usually primigravid) pregnancies. It can, in addition, be superimposed on 20% to 40% of pregnancies in women with underlying chronic hypertension or other predisposing medical diseases, including even minor renal disease of any cause, such as early diabetic nephropathy, autoimmune disease, or even microscopic hematuria.^{24,25} Superimposed pre-eclampsia tends to be more severe than pre-eclampsia without underlying medical disorders. Likewise, given the persistence of the underlying risk factor, it is not surprising that it is more apt to recur in subsequent pregnancies. Indeed, pre-eclampsia occurring in other than a first pregnancy with the same partner should lead the clinician to search for an underlying medical predisposition. Superimposed pre-eclampsia and progression to more severe hypertension represent the two major risks of chronic hypertension in pregnancy.

It is often difficult to decide when an already hypertensive or already proteinuric woman's course has worsened due to the onset of superimposed pre-eclampsia. Indeed, in a classic study using renal biopsies to verify diagnosis, while clinical diagnosis of pure pre-eclampsia was quite accurate in previously healthy primigravidae, a nephrologist and obstetrician were only able to correctly diagnose pre-eclampsia and distinguish it from competing disorders in 58% of parous women.²⁶ Since it is now known that sFlt-1 accounts for the typical renal lesion of “glomerular endotheliosis,”²⁷ we suspect that its diagnostic accuracy would be similarly discordant in parous women or in those with underlying disease, although this remains to be determined. Diagnosis of pre-eclampsia can be even more difficult in women with preeclamptic glomerular disease whose proteinuria usually worsens during pregnancy, often to nephrotic levels. In such complicated cases, we currently advocate a strategy of close monitoring, repeatedly re-establishing baseline data in order to detect interval changes in BP, proteinuria or albuminuria, symptoms, or blood test results that might suggest superimposed pre-eclampsia. This cumbersome strategy might be streamlined if ongoing studies of high-

risk pregnancies confirm a role for routine diagnostic or predictive testing based on measurement of sFlt-1 or related proteins.²⁸

PATHOPHYSIOLOGY OF PRE-ECLAMPSIA AND ECLAMPSIA

Molecular pathophysiology

Because pre-eclampsia may occur in molar pregnancy (i.e., without a fetus), resolves following delivery of the placenta, and seems uniformly associated with typical defects in placentation when it occurs in primigravid women without underlying risk factors, much attention has been focused on a pathophysiologic role of the placenta. It is widely believed that early defects in trophoblastic invasion and remodeling of spiral arteries may fail to decrease placental resistance appropriately, leading to focal ischemia in the placenta and elaboration of factors that may act on the maternal vasculature to result in pre-eclampsia. While it is unclear whether these placental abnormalities are specific to pre-eclampsia or occur similarly in pre-eclamptic women with either underlying risk factors or with later clinical onset of disease (i.e., nearer to term), a large literature seems to support this construct by demonstrating that experimental uteroplacental hypoperfusion leads to hypertension in pregnant laboratory animals and, more recently, in primates.^{29,30} In pre-eclamptic women, the placenta elaborates soluble fms-like tyrosine kinase-1 (sFlt-1), a soluble receptor for (and functional antagonist of) vascular endothelial growth factor (VEGF) and placental growth factor (PlGF).^{8,27} Abnormalities of another angiogenic factor, angiopoietin-1 and its receptor, tie-2, are also evident in pre-eclampsia.³¹ Abnormalities in the availability of these angiogenic factors may increase BP and almost certainly lead to proteinuria and to the renal biopsy lesion of glomerular endotheliosis, which is typical of pre-eclampsia.

The pre-eclamptic placenta also sheds soluble fragments of endoglin, a TGF_β co-receptor, which appears to act in concert with sFlt-1 to produce several of the more severe disease phenotypes, such as severe hypertension, nephrotic-range proteinuria, fetal growth restriction, and the HELLP syndrome.³² In addition to their roles in the molecular pathophysiology of pre-eclampsia, these antiangiogenic proteins may have an important role in diagnosis or disease prediction,²⁸ their actual utility will depend on the results of adequately powered prospective studies, such as that being undertaken by the World Health Organization.

Sympathetic outflow is increased in women with pre-eclampsia, perhaps contributing to hypertension,³³ and preceding the onset of clinically evident disease.³⁴ Several studies have also demonstrated changes in angiotensin receptor expression and activity³⁵ or the occurrence of autoantibodies that activate AT₁ receptors in women with pre-eclampsia.^{8,36} The former report noted the occurrence of (bradykinin) B₂-AT₁ receptor heterodimers in maternal resistance arteries from pre-eclamptic women; it is unknown whether these heterodimeric receptors reveal antigenic epitopes that then lead to the agonistic auto-

antibodies. The autoantibodies, which clear soon after delivery, may underlie not only vasoconstriction and hypertension, but also the oxidative stress (via AT₁ receptor activation of superoxide synthesis by NAD(P)H oxidase) and endothelial dysfunction that are characteristic of pre-eclampsia. The effect of these autoantibodies is inhibited *in vitro* by angiotensin receptor blockers (ARBs), but use of these agents, along with use of ACE inhibitors, is contraindicated in late pregnancy due to fetal toxicity.³⁷

SYSTEMIC AND RENAL HEMODYNAMICS IN PRE-ECLAMPSIA

Pulmonary artery catheterization of untreated pre-eclamptic women reveals that hypertension in this disorder is due to systemic vasoconstriction associated with decreased CO and left ventricular filling pressures.³⁸ Paradoxically, early in pregnancy, prior to the onset of hypertension, CO is increased more in women who subsequently develop either gestational hypertension or pre-eclampsia than in those who go on to uneventful normotensive pregnancies, although not so reliably as to allow prediction of these disorders. Hemodynamics of these two disorders diverge when hypertension becomes manifest, with further increments of CO (and low SVR) in women with gestational hypertension and a “switch” to systemic vasoconstriction and low CO in women with pre-eclampsia.³⁹ Pre-eclampsia appears to reverse the increments in large-artery compliance that characterize normotensive pregnancy.⁴⁰ In addition, pulse wave analysis reveals marked increments of systolic augmentation index, determined by applanation tonometry, in women with pre-eclampsia. By contrast, the augmentation index is usually negative in normal gravidas and only modestly elevated in gravidas with chronic or gestational hypertension.^{40–42}

Pre-eclampsia decreases GFR by ~33% and effective renal plasma flow by ~25%, consistent with selective afferent arteriolar renal vasoconstriction, and usually decreases renal uric acid clearance, elevating serum levels above the norms for pregnancy (2.8 to 3.2 mg/dL).² An older literature demonstrated striking parallels between the severity of hyperuricemia and either renal biopsy or clinical manifestations of pre-eclampsia.⁴³ Recent studies have revisited the clinical value of hyperuricemia, demonstrating that uric acid increases progressively before the onset of hypertension in women with pre-eclampsia and that hyperuricemia predicts fetal morbidity even in the absence of pre-eclampsia.^{44,45} The proteinuria that characterizes pre-eclampsia is nonselective, with increased excretion of both albumin and nonalbumin proteins. Pre-eclampsia is the major cause of nephrotic-range proteinuria during pregnancy. The occurrence of edema (which is common even in normal pregnancy) is quite variable in pre-eclampsia; indeed, many women who present with eclamptic seizures may be free of edema.

Platelet abnormalities

Platelet activation is present in the hypertensive disorders of pregnancy, and platelets play a major role in the disease

process.^{46,47} In normal pregnancy, there is an increased platelet activation *in vivo*, which is usually accompanied by a limited decline in platelet numbers.^{3,4} In pre-eclampsia, there is platelet consumption secondary to unchecked intravascular platelet activation and fibrin deposition, resulting in a progressive and marked decline in circulating platelets. Abnormal platelet activation and adhesion have also been shown.⁴⁸

CEREBROVASCULAR ABNORMALITIES IN PRE-ECLAMPSIA

There has been long-standing controversy regarding the mechanisms that lead to eclamptic seizures and other central nervous system complications in pre-eclampsia. Some have viewed these as a form of hypertensive encephalopathy, while others, citing autopsy findings of hemorrhage and petechiae,⁴⁹ have suggested that brain injury is caused by focal ischemia due to vasoconstriction. The preponderance of recent studies, many using non-invasive Doppler and MR techniques, suggest a role for increased cerebral perfusion pressure or defective local autoregulation in most cases, supporting the former pathophysiologic construct.⁵⁰ Further, MR evidence associates cerebral edema and reversible posterior leukoencephalopathy syndrome with even “minor” neurologic symptoms such as headache and blurred vision in pre-eclampsia. It is intriguing that anti-VEGF antibodies, which can mimic the effects of sFlt-1 on BP and proteinuria, also may lead to reversible posterior leukoencephalopathy.^{51,52} This cerebrovascular pathophysiologic construct leads to specific therapeutic strategies regarding selection of antihypertensive agents in pre-eclamptic women, since labetalol and magnesium (but not calcium channel blockers or other vasodilators) appear to decrease elevated cerebral perfusion pressure in these patients.^{53,54}

PRE-ECLAMPSIA PREVENTION

Antihypertensive treatment and BP lowering *per se* fail to prevent pre-eclampsia.^{55,56} Similarly, neither salt restriction nor prophylactic diuretics prevents pre-eclampsia, despite earlier claims to the contrary.⁵⁷ An extremely controversial literature has suggested that genetic thrombophilias, including the factor V Leiden and prothrombin gene mutations, may increase the risk of pre-eclampsia. Most recent studies appear to refute this association⁵⁸; however, we are without a well-designed randomized trial of low-molecular-weight heparin in women at risk. Observations of hypocalciuria in pre-eclamptic women led to several large studies of calcium supplementation, which, however, failed to prevent pre-eclampsia.⁵⁹ By contrast, while there was still no effect on the incidence of pre-eclampsia, a randomized trial of calcium supplementation in 8325 nulliparous women with extremely low baseline dietary calcium decreased the incidence of eclampsia, severe gestational hypertension, and several composite measures of maternal morbidity.⁶⁰

Observations consistent with an imbalance in arachidonic acid metabolism in pre-eclampsia that favored vaso-

constrictor thromboxanes over prostacyclin led to many primary prevention studies using low-dose (60 to 100 mg/day) aspirin. Many early small studies were extraordinarily promising; unfortunately, these results have not been confirmed in subsequent well-designed large trials that have included more than 25,000 women, demonstrating only trivial effects on maternal or fetal outcome or on the occurrence of pre-eclampsia.^{61,62} Additional studies of women at high risk for recurrent or superimposed pre-eclampsia also failed to demonstrate meaningful prevention of proteinuric hypertension with aspirin. Although meta-analyses of trials that included more than 36,000 women have suggested some benefit (relative risk 0.81, confidence interval 0.75–0.88) of aspirin prophylaxis, this conclusion is not supported by any of the larger well-designed trials included within the meta-analysis and have failed to identify any aspirin-sensitive subgroups of women at risk.⁶³

Evidence of placental, vascular, and systemic oxidative stress in pre-eclampsia along with plausible pathophysiologic schema relating oxidative stress to hypertension, renal dysfunction, and organ damage led to several large prophylactic studies using the antioxidant vitamins C and E. The Vitamins in Pre-eclampsia (VIP) trial showed no benefit in 2395 women at high risk for pre-eclampsia.⁶⁴ Indeed, vitamin supplementation in this study was surprisingly associated with more severe and earlier-onset pre-eclampsia, more severe hypertension, lower birth weight, and increased neonatal morbidity.^{64,65} Vitamin supplementation resulted in neither benefit nor harm in a similarly large and well-conducted study of 1877 low-risk nulliparas (the Australian Collaborative Trial of Supplements).⁶⁶ An even larger trial is still ongoing in the United States.⁶⁵

RISKS OF HYPERTENSION IN PREGNANCY AND GUIDELINES FOR EVALUATION AND MANAGEMENT

Chronic hypertension increases risks of several morbid pregnancy outcomes, including superimposed pre-eclampsia, preterm birth, intrauterine growth restriction, placental abruption, perinatal death, and accelerated hypertension threatening the mother.^{67–69} Antihypertensive treatment fails to prevent these outcomes, except for the occurrence of more severe hypertension later in pregnancy. This remains important because adverse perinatal outcomes seem closely related to severity of maternal hypertension and because severe hypertension may be a major cause of both hospitalization and early delivery. Recognition of these risks and of clinical uncertainty regarding evaluation and treatment of hypertensive gravidas has led to updated guidelines by consensus groups in the United States, Canada, and Australia.^{11,17,70}

All of the consensus groups agree, even without clear outcomes data, that BPs as low as 170/110 mmHg can lead to cerebrovascular hemorrhage during pregnancy, making control of such pressures a medical emergency. At the opposite extreme, it has been suggested, but not proven, that tight BP control may impair fetal growth.⁷¹

The ASSHP suggests maintaining BPs at less than 140/90 mmHg.¹⁷ The Canadian Hypertension Society suggests similarly tight control only for some groups of women.⁷⁰ By contrast, the NHBPEP Working Group on Hypertension in Pregnancy suggests (re)instituting drug therapy at pressures of 150 to 160/100 to 110, targeting lower pressures in selected patients with target-organ damage or underlying renal disease.¹¹ Not only is there disagreement among national groups, but disagreement occurs even within a single system: a survey of Canadian practitioners with experience in the care of hypertensive pregnant women revealed no consensus regarding appropriate BP targets.⁷² These uncertainties provide both the equipoise and impetus for adequately powered prospective trials to guide therapy, several of which are now planned or underway.

EVALUATION AND MANAGEMENT OF HYPERTENSION IN PREGNANCY

Ideally, evaluation of women with chronic hypertension or with a history of hypertension in a previous pregnancy should begin before conception. The clinician should focus on the possibility of secondary hypertension, assessment of renal function and hypertensive target-organ damage, detecting underlying diabetes or renal disease, and eliciting a family history of pregnancy complications. Proteinuria, *per se*, appears to increase pregnancy risk in hypertensive women. In addition, the obstetric history should focus on both maternal and neonatal outcome that includes premature birth, intrauterine growth restriction leading to small-for-gestational-age infants, placental abruption, fetal demise, neonatal morbidity and mortality, and the severity and timing of superimposed pre-eclampsia, because severe early-onset disease is more apt to recur.

Most women whose hypertension is well controlled using two or fewer antihypertensive drugs before conception will be able to discontinue therapy, due to the physiologic BP control effected by gestational vasodilation. Often, no antihypertensives will be required until later in pregnancy, obviating most concerns regarding drug safety in the first trimester. Women should have a baseline laboratory evaluation that includes urinalysis and urine culture, 24-hour urine for evaluation of creatinine clearance, protein and albumin excretion, comprehensive chemistry panel including measurement of hepatic transaminases, uric acid, and electrolytes, and complete blood count with platelets. Most clinicians would repeat these studies each trimester, in order to establish a new baseline to aid in the recognition of superimposed pre-eclampsia, although there are no prospective studies demonstrating benefit from this strategy. Women should then be seen every 2 to 3 weeks for measurement of BP and urine protein, and for fetal assessment as indicated.

Higher-risk chronic hypertensive women include those with advanced maternal age, long-standing hypertension, or any evidence of target-organ damage, diabetes mellitus, renal disease of any cause or severity, any connective tissue disease, cardiomyopathy, vascular malformation, previous history of fetal or perinatal loss, or worsened hyper-

tension early in pregnancy. These women require closer observation, collaborative care with appropriate subspecialists, and probably tighter BP control to avoid progressive target-organ damage during pregnancy. Despite general agreement, there have been no studies that show benefit of tighter BP control in hypertensive gravidas with renal disease or other underlying medical disorders. Worsened hypertension or suspicion of superimposed pre-eclampsia will commonly lead to inpatient evaluation in order to ensure maternal and fetal well-being and titrate antihypertensive therapy, and to decide whether pregnancy may be prolonged safely with close monitoring.

Antihypertensive therapy remote from delivery

With some small differences, the American, Canadian, and Australasian consensus statements make note of the wealth of clinical experience that led to recognizing methyldopa as a preferred antihypertensive for use during pregnancy.^{11,17,70} It is well tolerated, does not alter uteroplacental or fetal hemodynamics, and has the best long-term follow-up of childhood development following exposure *in utero*, albeit in an underpowered study.⁷³ Methyldopa-induced hepatitis is a rare adverse effect, and Coombs-positive hemolytic anemia is rare with short-term treatment. Many women are, however, unable to tolerate its more common adverse effects of drowsiness or dry mouth. A recent meta-analysis suggesting excess perinatal morbidity and mortality with methyldopa when compared with other antihypertensive drugs⁵⁶ should serve as impetus for further prospective studies rather than for abandonment of the long clinical experience and consensus support for use of methyldopa in pregnancy.

Beta-blockers are also widely used in pregnancy, have been assessed in several randomized trials, and are the subject of a Cochrane meta-analysis.⁵⁵ Early preclinical and clinical observations raised concerns of impaired uteroplacental perfusion, fetal growth restriction, and harmful cardiovascular effects on the fetus. Atenolol use early in pregnancy in one small trial led to striking fetal growth restriction, a conclusion supported by several reviews, retrospective series, and meta-analyses.^{74–77} However, most prospective studies, focusing instead on β -blocker use during the third trimester, have shown effective BP control, prevention of more severe hypertension, and an absence of significant adverse effects, including bradycardia, on the fetus. A large single-center case series has noted superior perinatal outcome with β -blockers (primarily atenolol) compared with other agents (primarily nifedipine or methyldopa).⁶⁷ Further, a meta-analysis of several small trials suggested that β -blockers might decrease (and calcium channel blockers increase) the incidence of proteinuria or superimposed pre-eclampsia, perhaps by limiting abnormal elevations in cardiac output.^{56,79} While many older studies focused on agents such as atenolol, the NHBPEP Working Group advocates labetalol (a combined α - and β -blocker) as an alternative to methyldopa, and the Australasian group advocates use of β -blockers with intrinsic sympathomimetic activity, such as oxprenolol or pindolol.^{11,17}

Calcium channel blockers, principally extended-release nifedipine, are widely used, apparently safe, and effective in pregnancy.¹¹ Although data are limited, nifedipine is widely viewed as an acceptable alternative to methyldopa or β -blockers for chronic use during pregnancy. In the past, hydralazine was the most commonly used second-line agent, although its popularity has probably been exceeded by the calcium channel blockers. It is generally used in combination with either a β -blocker or methyldopa to limit reflex tachycardia. Alpha-adrenergic blockers are used seldom during pregnancy, although they remain first-choice agents in the rare setting of suspected pheochromocytoma. Diuretic use during pregnancy is controversial since they limit normal gestational volume expansion, and can decrease amniotic fluid volume and lead to electrolyte abnormalities. However, they do not seem to compromise fetal outcome.⁵⁷ Diuretics may be continued if they are crucial to BP control before conception, and may be combined with other agents, especially in patients with renal insufficiency or heart disease, or when clinical volume overload is a problem.¹¹ Diuretics are not used when pre-eclampsia is suspected, because its hemodynamics are characterized by decreased CO and primary systemic vasoconstriction.^{1,38,39}

Increased circulating elements of the renin-angiotensin system during pregnancy and evidence for AT₁ receptor activation in pre-eclampsia might seem to support use of ACE inhibitors or ARBs in hypertensive gravidas. Indeed, many young women of childbearing age with either underlying diabetic nephropathy or proteinuric renal disease will be receiving these drugs for “renal protection” before conception. They are, however, frankly contraindicated during the latter half of pregnancy due to a specific fetopathy (including renal dysgenesis and calvarial hypoplasia) and the risk of (fatal) neonatal acute renal failure.^{37,80,81} In addition, first trimester exposure now appears to convey some teratogenic risk as well. Using information from a Tennessee Medicaid database, Cooper et al.⁸² identified 18 major congenital malformations in babies exposed to ACE inhibitors only during the first trimester. The risk of major malformation was ~2.7-fold greater than in unexposed infants and due primarily to a mixture of cardiovascular and central nervous system anomalies. It should be noted that many of these abnormalities were patent ductus arteriosus or septal defects that did not require surgical correction and that a previous unpublished study of first-trimester captopril exposure had failed to identify these risks.⁸³ Taken together, it would seem prudent to avoid ACE inhibitors and ARBs in women of childbearing potential for whom the only indication is essential hypertension that is easily controlled with other agents. By contrast, for women such as those with refractory hypertension, diabetes mellitus, or proteinuric renal disease, whose care may depend on these drugs, it would seem prudent to counsel them regarding these risks, discontinue their use when pregnancy is confirmed, and review fetal well-being with a detailed ultrasound examination at 18 weeks gestational age. Table 54–1 summarizes the agents most commonly used for chronic BP control in pregnancy.

ORAL ANTIHYPERTENSIVES USED COMMONLY IN PREGNANCY		
Drug (FDA risk ^{1,2})	Dose	Concerns or Comments
Most Commonly Used First Line Agents		
Methyldopa (B)	0.5-3.0g/d in 2-3 divided doses	Preferred agent of the NHBPEP working group; maternal side effects sometimes limit use.
Labetalol (C) or other β receptor antagonists	200-2400mg/d in 2-3 divided doses	Labetalol is preferred by NHBPEP working group as alternative to methyldopa. Atenolol most commonly used in Canada and β blockers with intrinsic sympathomimetic activity are preferred by some in Australia. May cause fetal growth restriction when started early
Nifedipine (C)	30-120mg/d of a slow-release preparation	Less experience with other calcium entry blockers.
Adjunctive Agents		
Hydralazine (C)	50-300mg/d in 2-4 divided doses	Few controlled trials, long experience; used only in combination with sympatholytic agent (eg methyldopa or a β blocker) to prevent reflex tachycardia.
Thiazide diuretics (C)	depends on specific agent	Most studies in normotensive gravidas.
Contraindicated		
ACE inhibitors and AT1 receptor antagonists (D ⁴)		Use after first trimester can lead to fetopathy, oligohydramnios, growth retardation, and neonatal anuric renal failure, which may be fatal.
¹ No antihypertensive has been proven safe for use during the first trimester (ie, FDA Category A).		
² US Food and Drug Administrations classifies risk for most agents as C: either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal effects or other) and there are no controlled studies in women, or studies in women and animals are not available. Drugs should only be given if the potential benefit justifies the potential risk to the fetus. This nearly useless classification unfortunately still applies to most drugs used during pregnancy.		

Table 54-1. Oral Antihypertensives Used Commonly in Pregnancy

Antihypertensive therapy of more severe hypertension

Table 54-2 lists the antihypertensives most commonly used for urgent control of severe hypertension late in pregnancy. Parenteral labetalol, by continuous intravenous infusion or in repeated boluses, has replaced hydralazine at many centers and appears to have similar safety and efficacy, although comparative studies are few.⁸⁴⁻⁸⁶ Hydralazine is used either in small (5 to 10 mg) repeated doses or as a continuous infusion, because larger doses or frequent dosing may lead to precipitous maternal hypotension and fetal distress. Despite its lack of approval by the U.S. Food and Drug Administration for the treatment of hypertension, the NHBPEP Working Group advocates oral (or sublingual) nifedipine as an acceptable alternative to hydralazine or labetalol for urgent BP control during pregnancy.¹¹ Its efficacy and safety, as well as that of parenteral nicardipine infused at 3 to 9 mg/h⁸⁷ appear similar to the other agents, while diazoxide and ketanserin seem inferior.⁸⁴ Concerns that dihydropyridine calcium channel blockers might accentuate adverse effects of magnesium sulfate in pre-eclamptic women seem unfounded.⁸⁸ Sodium nitroprusside remains a relatively contraindicated agent of last resort.⁸⁹ Finally, while there have been reports of ACE inhibitor use as “salvage therapy” during pregnancy,⁹⁰ there seems to be no justification for use of these agents or of angiotensin receptor blockers during the second or third trimester.

CLINICAL AND ADJUNCTIVE MANAGEMENT OF PRE-ECLAMPSIA

Suspicion of pre-eclampsia should lead to hospitalization and inpatient evaluation, although this might be undertaken in a day hospital or short-stay unit if available. Despite common practice, we still do not know if hypertensive gravidas benefit from bedrest.⁹¹ Near to term (>34 weeks), if fetal maturity can be ensured, delivery is the preferred and definitive treatment for pre-eclampsia. Earlier in pregnancy, it may seem desirable to temporize, attempting to control BP, administer glucocorticoids to hasten fetal lung maturation, and monitor laboratory and clinical status closely so as to prolong pregnancy. The obstetric literature on such temporizing strategies often appears confusing and contradictory. Expectant management may result in a few days to, rarely, several weeks of additional fetal maturation; however, such strategies are best reserved to tertiary centers. Regardless of gestational age, consensus opinion currently suggests that any of the ominous signs or symptoms noted in Box 54-2 should lead to immediate delivery. Despite this widespread agreement, we caution that there are no prospective data to support the notion that our clinical definition of “severe” pre-eclampsia actually predicts morbid outcomes. Indeed, an ongoing multicenter prospective observational study in Canada, the United Kingdom, and New Zealand thus far suggests that only severe hypertension, throm-

ANTIHYPERTENSIVES USED COMMONLY FOR URGENT BP CONTROL		
Drug (FDA risk ¹)	Dose and Route	Concerns or Comments ²
Hydralazine (C)	5mg, iv or im, then 5-10mg every 20-40 min; or constant infusion of 0.5-10mg/hr	Higher doses or more frequent administration often precipitate maternal or fetal distress, which appear more common than with other agents.
Labetalol (C)	20mg iv, then 20-80 mg every 20-30 min, up to maximum of 300mg; or constant infusion of 1-2mg/min	Probably less risk of tachycardia and arrhythmia than with other vasodilators, likely less BP control than hydralazine.
Nifedipine (C)	5-10mg po, repeat in 30 min if needed, then 10-20mg every 2-6 hr	Oral and sublingual dosing are equivalent; neither is FDA-approved for hypertension treatment.
Nicardipine (C)	3-9 mg/h, iv, titrated to effect	Tachycardia more common than with labetalol.

¹ US Food and Drug Administration Class C, as noted in footnote to Table 54-1.

² Adverse effects for all agents, except as noted, may include headache flushing, nausea, and tachycardia (primarily due to precipitous hypotension and reflex sympathetic activation).

Table 54-2. Antihypertensives Used Commonly for Urgent BP Control

Box 54-2

Ominous Signs and Symptoms in Pre-eclampsia Suggesting Prompt Delivery

- Inability to control BP (systolic <160 mmHg or diastolic <105)
- Any evidence of acute renal failure or progressive oliguria
- Falling platelets or thrombocytopenia <105/mm³
- Any evidence of microangiopathic hemolysis or coagulopathy
- Upper abdominal (epigastric or right upper quadrant) pain
- Headache, visual disturbance, or any CNS signs
- Retinal hemorrhage or papilledema
- Acute congestive heart failure or pulmonary edema

bocytopenia, elevated liver enzymes, chest pain, dyspnea, or right upper-quadrant abdominal pain might predict morbid outcomes strongly enough to justify delivery for maternal indications.⁹² As noted earlier, accelerated hypertension should be treated at systolic levels of greater than 160 mmHg or diastolic of greater than 100 to 105 mmHg (Korotkoff 5), to avoid the cerebrovascular catastrophes that can occur at pressures of $\geq 170/110$. We advocate treatment at these somewhat lower pressures due to increased BP lability and uncertainty in BP measurement in women with pre-eclampsia. Central nervous system signs or symptoms, including headache or blurred vision, should provoke treatment at even lower pressures. Despite findings from invasive hemodynamic studies, there appears to be no benefit from therapeutic volume expansion in addition to BP control.⁹³

Parenteral magnesium sulfate has long been favored by North American clinicians for prevention or treatment of

eclamptic seizures, which can occur antepartum (38% to 53% of cases), intrapartum (18% to 36% of cases), or postpartum (11% to 36% of cases).⁹⁴ Magnesium is superior to either phenytoin or diazepam in preventing recurrent seizures in women with eclampsia.^{95,96} Several primary prevention trials in women with pre-eclampsia, including a placebo-controlled, double-blind study in over 10,000 women, demonstrated the efficacy of magnesium, without significant short-term adverse effects to mother or baby.^{93,97} It remains unclear, however, which women with pre-eclampsia should be offered magnesium and how long treatment should continue if delivery is postponed. In most centers, treatment usually entails a loading dose of 4 to 6 g of MgSO₄ (infused over 10 minutes, never as a bolus), followed by continuous infusion of 1 to 2 g/h to achieve plasma levels of 5 to 9 mg/dL. Magnesium is then usually continued until the patient stabilizes or for 24 hours following delivery. Lower doses should be used, without continuous infusion, guided by serum levels, in women with any degree of renal insufficiency, as magnesium is excreted renally. Finally, a vial of calcium gluconate should always be kept at the bedside in case of magnesium toxicity.

Overall, our clinical approach to evaluation, management, and treatment of pregnant women with underlying hypertension is in accord with recommendations made by the NHBPEP Working Group,¹¹ although, as noted above, we favor the classification scheme of the Australasian group.¹⁷ Our key objectives, to be carried out in close coordination with experienced high-risk obstetric colleagues, are to achieve BP control adequate to ensure maternal safety, to carefully and serially monitor maternal BP, well-being, and laboratory data in order to facilitate early recognition of superimposed pre-eclampsia, and to proceed to expeditious delivery (with or without magnesium prophylaxis) in the face of pre-eclampsia or accelerated hypertension when it presents a threat to maternal safety.

Chapter
55Insulin Resistance and Diabetes
in HypertensionMaryann N. Mugo, Daniel Link, Craig S. Stump,
and James R. Sowers

Key Findings

- In the United States, diabetes mellitus currently affects 18.2 million individuals and is the sixth leading cause of death.
- Coexistent hypertension contributes significantly to the development of cardiovascular disease and associated premature morbidity in these patients.
- “Prediabetic” states should be evaluated for hypertension as they are at increased risk for hypertension and cardiovascular disease.
- Genetic predisposition and acquired factors such as obesity and sedentary lifestyle result in insulin resistance, which is strongly associated with hypertension.
- The renin-angiotensin-aldosterone system plays a crucial role in the pathogenesis of both diabetes and hypertension and associated cardiovascular and renal disease.

Clinical Implications

- Several antihypertensive medications, including angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, have beneficial effects in diabetes mellitus beyond blood pressure control, including reducing renal dysfunction, cardiovascular disease, and stroke.
- Some antihypertensive medications have been shown to decrease onset of diabetes mellitus when compared with placebo and others.

The rise in the prevalence of diabetes mellitus (DM) is a global phenomenon that is approaching epidemic proportions. It is currently estimated that approximately 300 million adults will be affected worldwide in the next few decades. In the United States alone, DM currently affects 6.3% of the adult population, or approximately 18.2 million individuals, and is the sixth leading cause of death.¹ Among adults over 60 years of age, 8.6 million are affected, representing 18.3% of this age group. The prevalence of DM is highest in persons above 65 years of age but adults under 45 years of age have shown the most striking rise in DM prevalence in the last decade.² Furthermore, ethnic groups other than Caucasians such as Hispanics, African Americans, and Native Americans are affected by DM at a rate two to four times that for Caucasian Americans.³

A notable rise in the prevalence of DM has occurred in children and adolescents primarily due to the rise in the prevalence of type 2 DM. The leading cause of premature

mortality in adults with DM is cardiovascular disease (CVD). Additionally, DM is now the leading cause of end-stage renal disease (ESRD) and nontraumatic amputations, both of which contribute to the higher rates of premature mortality. Coexistent hypertension contributes significantly to the development of CVD and renal disease in these patients.⁴ In this chapter we review the pathophysiology of hypertension in DM—particularly type 2—clinical presentation, and treatment.

SPECTRUM OF INSULIN RESISTANCE,
IMPAIRED GLUCOSE TOLERANCE,
AND OVERT DIABETES MELLITUS TYPES 1
AND 2

Recently the recognition of “prediabetic” states such as impaired fasting glucose (IFG), impaired glucose tolerance (IGT), and the metabolic syndrome have expanded the spectrum of patients to be considered when approaching the management of hypertension in the DM population (Table 55–1).

First, it is important to make the distinction between type 1 (DM1) and type 2 diabetes mellitus (DM2) when tackling hypertension management. The most notable

State	Characteristics
Normal	FPG <100 mg/dL; 2-hour P <140 mg/dL (5.5 mmol/L)
“Prediabetes”	Impaired fasting glucose (IFG): ≥100 and <126 mg/dL (5.5–7.0 mmol/L) Impaired glucose tolerance (IGT): 2-hour post-75-g anhydrous glucose plasma glucose ≥140 mg/dL and <200 mg/dL (7.0–11.1 mmol/L)
Diabetes	FPG ≥126 mg/dL (7.0 mmol/L); fasting = no caloric intake for at least 8 hours Random glucose ≥200 mg/dL (11.1 mmol/L) without symptoms on two occasions or once with symptoms (<i>random glucose</i> means without regard to previous meal) 2-hour post-75-g anhydrous glucose plasma glucose ≥200 mg/dL (11.1 mmol/L)
FPG, fasting plasma glucose.	

Table 55–1. Definitions and Diagnosis

differences are that DM1 patients form only 6% to 8% of the total population diagnosed with DM, are usually younger, and typically develop hypertension only after the onset of renal disease.⁵ The onset of hypertension (HTN), however, accelerates the course of microvascular and macrovascular disease in this subgroup of patients.⁴

Most diabetic patients are in the DM2 group, and only a fraction of the population estimated to have DM2 have actually been diagnosed and treated despite more stringent diagnostic criteria. Many of these patients manifest the clustering of CVD risk factors described in the Framingham study and are at risk of developing DM2 and its attendant CVD complications.⁶ In this subgroup of patients, HTN may precede the onset of DM2 or be present at the time of diagnosis, thus underscoring the importance of evaluating associated risk factors collectively in these patients.

The National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) defined the metabolic syndrome as presence of any three or more of the following: blood pressure (BP) $\geq 130/85$ mmHg, waist circumference >40 in in men or >35 in in women, triglycerides ≥ 150 mg/dL, HDL <40 mg/dL in men or <50 mg/dL in women, and fasting glucose ≥ 110 mg/dL (Table 55–2). The metabolic syndrome is a clustering of maladaptive characteristics that confers an increased risk of CVD.³ A recent analysis of the National Health and Nutrition Examination Survey (NHANES 1999–2000) revealed that the overall prevalence of the metabolic syndrome is currently estimated at 26.7%, an increase from the NHANES III (1988–1994) survey estimate of 23.1%. Further, an age-dependent increase in prevalence is apparent in both men (10.7%, 33.0%, and 39.7%) and women (18.0%, 30.6%, and 46.1%) for ages 20 to 39, 40 to 59, and ≥ 60 years, respectively.⁷ More recently, a new definition of metabolic syndrome has been proposed by the International Diabetes Federation⁸ (Box 55–1) (Table 55–3).

Insulin resistance appears to play a key role in the pathophysiology of the metabolic syndrome and the associated cardiovascular risk.⁹ These clustered risk factors provide the milieu for impaired glucose tolerance (IGT), impaired fasting glucose (IFG), and overt diabetes mellitus to increase cardiovascular risk.⁹ IFG when associated with mild HTN (SBP 140–149) is independently associated with

METABOLIC SYNDROME NCEP/ATP III GUIDELINES DEFINITION	
Risk Factor	Levels
Blood pressure	$\geq 130/85$ mmHg
Waist circumference	>40 in (men); >35 in (women)
Triglycerides	≥ 150 mg/dL
High-density lipoproteins	<40 mg/dL (men) and <50 mg/dL (women)
Fasting glucose	≥ 110 mg/dL

Note: Meeting any three of the above criteria qualifies for the patient for classification as metabolic syndrome.
Data from the National Cholesterol Program Adult Treatment Panel III, 2001.

Table 55–2. Metabolic Syndrome NCEP/ATP III Guidelines Definition

Box 55–1

Metabolic Syndrome: International Diabetes Federation Definition

Central obesity

Waist circumference^a—ethnicity specific (see Table 55–3)
Plus any two of the following:

Raised triglycerides

>150 mg/dL (1.07 mmol/L)

Specific treatment for this lipid abnormality

Reduced HDL cholesterol

<40 mg/dL (1.03 mmol/L) in men

<50 mg/dL (1.29 mmol/L) in women

Specific treatment for this lipid abnormality

Raised blood pressure

Systolic ≥ 130 mmHg

Diastolic ≥ 85 mmHg

Treatment of previously diagnosed hypertension

Raised fasting plasma glucose^b

Fasting plasma glucose ≥ 100 mg/dL (5.6 mmol/L)

Previously diagnosed type 2 diabetes

If above 5.6 mmol/L or 100 mg/dL, oral glucose tolerance test is strongly recommended, but is not necessary to define presence of syndrome.

From Alberti KG, Zimmet P, Shaw J. *Lancet* 2005;366:1059–62 with permission from Elsevier.

^aIf body mass index is over 30 kg/m², central obesity can be assumed and waist circumference does not need to be measured.

^bIn clinical practice, impaired glucose tolerance is also acceptable, but all reports of prevalence of metabolic syndrome should use only fasting plasma glucose and presence of previously diagnosed diabetes to define hyperglycemia. Prevalences also incorporating 2-hour glucose results can be added as supplementary findings.

increased CVD mortality.¹⁰ Obesity, specifically visceral obesity, has been associated with insulin resistance and premature CVD. A rising body mass index (BMI) is independently associated with a linear rise in systolic BP (SBP), diastolic BP (DBP), and pulse pressure.

PATHOPHYSIOLOGY

The rise in insulin resistance has paralleled the rise in obesity, and the two are strongly linked.¹¹ Obesity, defined in adults as a BMI greater than 30 kg/m², has also been associated with a higher incidence of HTN and DM2.¹² Excess abdominal adiposity is a hallmark of the metabolic syndrome, and imparts a higher risk than subcutaneous adiposity. Visceral adiposity tends to consist of large insulin-resistant adipocytes that have several metabolic abnormalities and are deficient in adiponectin. Insulin-mediated antilipolysis is decreased, and catecholamine-induced lipolysis is increased. Numerous adipocyte-derived cytokines (adipokines) produced by these viscerally located adipocytes mediate inflammation and insulin resistance. These cytokines include increased TNF- α , PAI-1, IL-6, and leptin.³ Visceral adiposity is best measured in the clinical setting using waist circumference rather than weight alone. The parameters currently used are a waist circumference of >40 inches (102 cm) in men and >35 inches (88 cm) in women.

ETHNIC-SPECIFIC VALUES FOR WAIST CIRCUMFERENCE	
Ethnic Group	Waist Circumference (Measure of Central Obesity)
Europids^a	
Men	>94 cm
Women	80 cm
South Asians	
Men	>90 cm
Women	>80 cm
Chinese	
Men	>90 cm
Women	>80 cm
Japanese	
Men	>85 cm
Women	90 cm
Ethnic South and Central Americans	Use South Asian recommendations until more specific data are available
Sub-Saharan Africans	Use European data until more specific data are available
Eastern Mediterranean and Middle East (Arab) populations	Use European data until more specific data are available

From Alberti KG, Zimmet P, Shaw J. *Lancet* 2005;366:1059–62 with permission from Elsevier.

Notes: Data are pragmatic cutoffs, and better data are required to link them to risk. Ethnicity should be the basis for classification, not country of residence.

^aIn the United States, Adult Treatment Panel III values (102 cm male, 88 cm female) are likely to continue to be used for clinical purposes. In future epidemiologic studies of populations of Europid origin (white people of European origin, regardless of where they live in the world), prevalence should be given, with both European and North American cutoffs to allow better comparisons.

Table 55–3. Ethnic-Specific Values for Waist Circumference

Decreased insulin action due to resistance and compensatory hyperinsulinemia may have adverse effects on the insulin signaling cascade.¹³ Clinical consequences of these derangements include hypertension, DM2 and CVD.¹⁴ Correspondingly, studies of patients with both DM2 and HTN show a causal role of insulin resistance and accompanying hyperinsulinemia.^{14,15} Insulin resistance occurs in up to 50% of the 50 million patients with essential HTN in the United States.¹⁶ Untreated patients with essential HTN have higher fasting and postprandial insulin levels than age- and sex-matched normotensive persons regardless of body mass.¹⁷ Normotensive first-degree relatives of patients with HTN also have insulin resistance and dyslipidemia.¹⁸ Genetic predisposition to both disorders tempered by the 21st-century environment (sedentary lifestyle, lack of exercise, poor dietary habits) are the link between HTN and insulin resistance, given that not all hypertensive patients have insulin resistance and hyperinsulinemia and, high insulin levels are not a feature of secondary hypertension.¹⁹

As noted, HTN in DM1 is usually a consequence of diabetic nephropathy. In contrast, HTN in patients with DM2, prediabetes, and metabolic syndrome is a much more complicated interplay of physiologic mechanisms.²⁰ Key players in this scenario include insulin resistance/hyperinsulinemia,⁹ angiotensin II (Ang II), endothelin, and oxidative stress, all of which mediate endothelial and vascular dysfunction.^{9,21} Other contributing factors are increased sympathetic nervous system (SNS) activity,²² sodium retention, and renal dysfunction. Insulin resistance and hyperinsulinemia both play a crucial role in the pathogenesis of hypertension in diabetes mellitus, and obesity itself seems to contribute significantly. Hypertension is associated with hyperinsulinemia/insulin resistance in obese diabetic individuals, nondiabetic obese individuals, and in patients with essential hypertension.

Interestingly, the association among insulin resistance, obesity, and hypertension is absent in Pima Indians, who also have relatively lower muscle sympathetic nerve activity than obese insulin-resistant Caucasian males.²³ This suggests that the SNS may be a link among obesity, hyperinsulinemia, and hypertension in some populations.²²

The mechanisms that are believed to be involved in the pathogenesis of diabetes-related hypertension are summarized in Figure 55–1.

Renin-angiotensin-aldosterone system

Ang II is a powerful vasoconstrictor and has a central role in blood pressure regulation. Studies have shown that Ang II infusion induces insulin resistance while blockade of Ang II results in increased insulin sensitivity.²⁴ Insulin is known to induce vasodilation *in vivo* but this ability of insulin is reduced in insulin-resistant

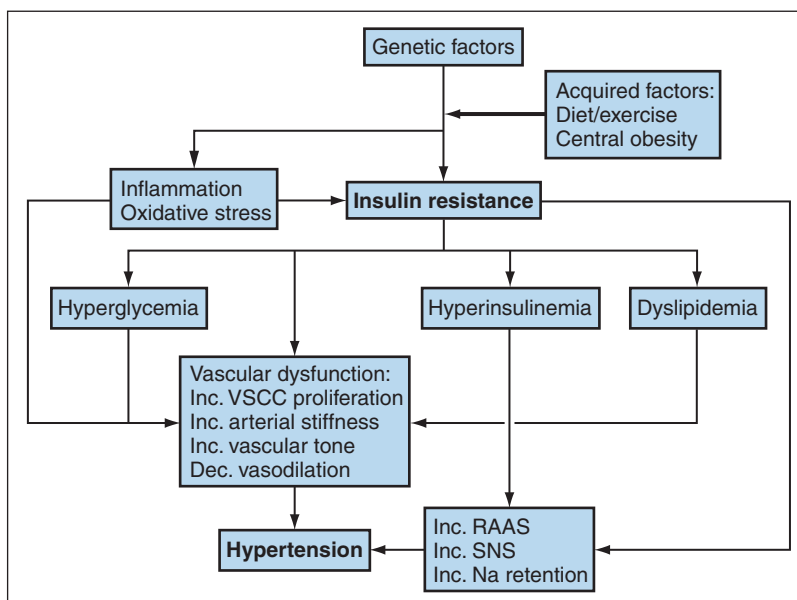

Figure 55–1. Interrelationship of the mechanisms contributing to hypertension in diabetes mellitus. Inc., increased; RAAS, renin-angiotensin-aldosterone system; SNS, sympathetic nervous system.

states and diabetes, potentially because of deranged endothelial synthesis combined with enhanced inactivation of nitric oxide (NO) via Ang II and other mechanisms.¹⁹ Insulin increases the expression and activity of endothelial nitric oxide synthase (eNOS), which results in increased production of NO. NO plays a major role in endothelial vasodilation, and also inhibits the effects of vascular endothelial growth factor (VEGF) in promoting the expression of adhesion molecules such as intercellular adhesion molecule (ICAM) and vascular cellular adhesion molecule (VCAM). This in turn protects endothelial cells from interactions with circulating monocytes that are involved in the atherosclerotic process.

Initially recognized for its role in renal effect on salt and water metabolism, Ang II has been shown to have profound adverse effects on the endothelium.²⁵ For a long time, the most recognized effects of Ang II were mediated via the AT₁R receptor. More recently, Ang II has been shown to exert effects via the AT₁R and AT₂R receptors. Ang II has been shown to influence endothelial cell apoptosis and increase oxidative stress via the type 1 receptor (AT₁R). In contrast, the type 2 receptor (AT₂R) reduces reactive oxygen species (ROS) and increases nitric oxide (NO) production.²⁶ Other effects of Ang II on the endothelial cell have been discovered more recently. Uptake of oxidized LDL (oxLDL) by endothelial cells is mediated by the lectin-like oxLDL receptor-1 (LOX-1).²⁷ Ang II via the AT₁R has been shown to upregulate the effects of LOX-1, thereby enhancing the uptake of oxidized LDL into the endothelial cell, a key step in atherosclerosis. Ang II is a potent regulator of the prothrombotic plasminogen activator inhibitor type 1 (PAI-1). PAI-1 plays a key role in thrombosis, promotes atherosclerosis, and is the major physiologic inhibitor of plasminogen activator. Ang II has been shown to increase PAI-1 messenger RNA and protein in endothelial cells and this effect is mediated by AT₁R via a pathway that involves rho/rho kinase, cyclic adenosine monophosphate (AMP), and ROS.²⁸ Cyclooxygenase-2 (COX-2) activation plays a role in both angiogenesis and atherogenesis via synthesis of prostaglandins and thromboxane A₂, thereby resulting in endothelial cell dysfunction. A different mechanism by which Ang II enhances angiogenesis is via the increased production of vascular endothelial growth factor (VEGF).²⁹ Increased endothelial cell VEGF may potentiate vascular remodeling, increased vascular permeability, and edema. The evidence implicating Ang II in the pathogenesis of HTN in diabetes mellitus is extensive³⁰ (Figure 55–2). Despite all this information, the precise mechanism by which insulin resistance interacting with Ang II results in hypertension still remains unknown and needs further investigation.

Several clinical studies using medications that interrupt the renin-angiotensin-aldosterone system (RAAS) have shown major benefit in decreasing incidence of stroke, diabetes mellitus and end-stage renal disease.³¹ Ang II is synthesized from angiotensin I by angiotensin-converting enzyme. Angiotensin-converting enzyme inhibitors (ACEI) primarily block this conversion, thus preventing it from exerting its potent vasoconstrictor effect. Similarly, blockade of the AT₁R is the primary mechanism of action of

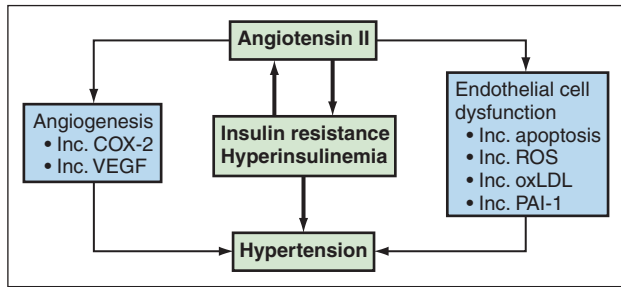

Figure 55–2. Potential pathways through which angiotensin II may contribute to hypertension in diabetes mellitus. COX-2, cyclooxygenase-2; ROS, reactive oxygen species; VEGF, vascular endothelial growth factor.

the angiotensin receptor blockers (ARBs), but they additionally activate multiple AT₁R independent pathways. These pathways include activation of eNOS by stimulation of a PI3-kinase/Akt pathway and activation of peroxisome proliferator-activated receptor.²⁷

Reactive oxygen species

Under normal conditions, oxidant formation is balanced by the rate of oxidant removal.¹⁹ An imbalance between pro-oxidants and antioxidants results in oxidative stress, which has adverse metabolic and clinical consequences. NAD(P)H oxidase is a major source of ROS, which under pathologic conditions play an important role in renal dysfunction and vascular damage. In the vasculature, ROS are derived from endothelial, adventitial, and smooth muscle cells. NAD(P)H oxidase, a multisubunit enzyme, catalyzes the production of oxygen free radicals from reducing oxygen using NAD(P)H as the electron donor.³² Pathologically increased ROS result in endothelial dysfunction, increased contractility, VSMC proliferation, monocyte invasion, lipid peroxidation, inflammation, and deposition of extracellular matrix proteins, all of which may cause hypertension-associated vascular damage.³³ ROS are a strong link between insulin resistance and hypertension.³⁴

Inflammation/Prothrombosis

Chronic inflammation may play a role in insulin resistance and may further aggravate vascular dysfunction, thus predisposing to atherosclerosis and CVD complications.¹⁹ Adipose tissue is a key source of inflammatory cytokines (adipokines) and tumor necrosis factor-alpha (TNF- α) and interleukin-6 (IL-6) are important in this regard.

Cytokines are intercellular signaling polypeptides that regulate the hematopoietic, immune systems and also trigger the inflammatory cascade. Chronic upregulation of IL-6 may predispose to atherosclerosis via a direct effect on the atherosclerotic lesion.³⁵ TNF- α levels correlate with insulin resistance, and this occurs via its ability to serine phosphorylate insulin receptor substrate-1, thus decreasing the activity of the insulin receptor.³⁶ C-reactive protein (CRP) is increased in inflammatory states such as insulin resistance, DM2, and obesity, and is an independent predictor of cardiovascular events.³⁷ Patients with the metabolic syndrome also have increased plasma high-

sensitivity CRP.³⁸ Collectively these increased cytokines contribute to CVD mortality, and HTN may be an additional risk factor in these patients.¹⁹

CLINICAL PRESENTATIONS

Stroke in patients with diabetes mellitus and hypertension

Patients with DM2 have a high incidence of stroke and poor outcomes. Although no clinical studies show a direct correlation between controlling glycemia and modification of stroke event rates, prevention of stroke in these patients is important due the poorer outcomes. Hypertension, heart failure, and cigarette and alcohol use are modifiable risk factors for stroke in patients with and without DM.⁵ In 2002 there were 57 stroke-related deaths in the United States per 100,000 people. Stroke is currently ranked as the third leading cause of death in the United States. There are more than 700,000 strokes annually and more than 4.5 million stroke survivors.³⁹

As the prevalence of DM increases, it has become a well-documented, independent, modifiable stroke risk factor. Indeed, the incidence of stroke among DM patients is up to three times that in the general population.⁴⁰ There is an increase in both short- and long-term mortality in patients with DM following stroke, and admission glucose levels are one predictor of poor outcomes in these patients.⁴¹

Numerous intervention trials have provided compelling support for intensive BP control in patients with DM to prevent stroke. In the UK Prospective Diabetes Study (UKPDS) for combined fatal and nonfatal stroke, achieving a mean BP of 144/82 mmHg resulted in a 44% relative risk reduction compared with the less-aggressive control group that had a mean BP of 154/87 mmHg.⁴² Additional data from the Systolic Hypertension in Europe (Syst-Eur) trial, with nitrendipine-based antihypertensive therapy, showed that the excess risk of stroke associated with DM was abolished by antihypertensive treatment in older patients with DM2 and isolated HTN. In the microalbuminuria, Cardiac and Renal Outcomes in the Heart Outcomes Prevention Evaluation (MICRO-HOPE), 3577 patients with DM treated with ramipril showed a 25% reduction of primary combined endpoints of myocardial infarction, stroke, and CVD death, and a 33% stroke reduction.⁴³

Recent studies have shown the beneficial effects of an ARB/diuretic or an ACEI/diuretic combination in reduction of primary and secondary strokes in high-risk patients, including those with DM.⁴⁴ The recent Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) also showed that treatments using a diuretic and lowering SBP were very important strategies to reduce stroke incidence in patients with DM.⁴⁵ These data support recent guidelines recommending a BP of less than 130/80 mmHg in patients with DM and HTN.⁴⁶ Further, early and aggressive attainment of BP less than 130/80 mmHg in these patients may help mitigate CVD risk and premature mortality.⁴⁷

Renal dysfunction in patients with diabetes mellitus and hypertension

An estimated 35% of persons with DM will develop diabetic nephropathy characterized by proteinuria, decreased glomerular filtration rate, and increased BP, which has become the leading cause of ESRD in the United States. In patients with DM2, the incidence of nephropathy is approximately 20%. Nevertheless, because up to 95% of diabetic patients have DM2, more than half of ESRD cases in DM occur in patients with DM2. The prevalence and incidence of ESRD are approximately twice what they were 10 years ago, and if the trends of the past two decades persist, approximately 175,000 new cases of ESRD will be diagnosed in 2010. This is due in part to the expectation that the incidence of DM2 will double within the next 10 to 15 years, and the fact that patients with DM are living longer and are thus more likely to develop chronic problems, including ESRD. The cost associated with the management of ESRD, in the United States alone, is expected to exceed \$28 billion per year by 2010.⁴⁸

The appearance of clinically detectable, dipstick-positive proteinuria signals the onset of progressive diabetic nephropathy, which is typically followed by deterioration to ESRD over a period of 10 to 15 years. Microalbuminuria, which heralds the onset of nephropathy, is defined as albuminuria detected in urine at levels of 30 to 299 mg/day. Albumin excretion exceeding these parameters is macroalbuminuria or overt proteinuria. Both macro- and micro-albuminuria are major independent risk factors for CVD.⁴⁹

Microalbuminuria predicts the development of CVD and stroke, in addition to progression of diabetic nephropathy. Microalbuminuria has been associated with insulin resistance/hyperinsulinemia, atherogenic dyslipidemia, the absence of a nocturnal drop in SBP and DBP, and salt sensitivity, and has been identified as a part of the cardiometabolic syndrome. For these reasons, it is not surprising that diabetic glomerulosclerosis parallels the process of diabetic atherosclerosis and is a powerful risk factor for CVD and stroke.⁴ Even after adjustment for renal function, microalbuminuria remained a strong risk factor for CVD in a subanalysis of the HOPE trial.⁵⁰ In the HOPE trial, the presence of albuminuria doubled the risk for the composite endpoint of myocardial infarction, stroke, or CVD death, and all-cause mortality. The risk of clinical heart failure was 3.7 times greater in DM2 patients with microalbuminuria compared with those without albuminuria. Furthermore, these risks were significantly reduced with treatment with the ACE inhibitor, ramipril. Medications that interrupt the RAAS, such as ACEIs and ARBs, are increasingly important in reducing the progression of nephropathy in these patients. Chronic kidney disease and the presence of either microalbuminuria or proteinuria dictate lowering BP to a goal of <130/80 mmHg and reducing proteinuria by at least 30% to 50%.⁵¹

Other clinical considerations

Autonomic neuropathy

Autonomic neuropathy is common in diabetic patients, affecting 5% to 10% of long-term diabetic patients and as

many as 35% of those patients with subclinical peripheral neuropathy. Autonomic neuropathy is usually manifested as orthostatic hypertension, sexual dysfunction, and abnormalities of gastrointestinal motility, among other symptoms. Once autonomic neuropathy becomes clinically apparent, it compromises BP regulation.¹⁰ In patients with DM and autonomic dysfunction, excessive venous pooling can cause orthostatic or postural hypotension. Postural hypotension, a decrease in SBP >20 mmHg on standing from a supine position, is usually associated with hypoadrenergic or hyperadrenergic signs and symptoms, such as lightheadedness, dizziness, dimming of vision, nausea, diaphoresis, and syncope. Because of the increased propensity of diabetic patients to manifest increased orthostatic BP changes, measurements should be performed in both the supine and standing positions.⁵¹ Another effective tool is ambulatory BP monitoring, which can be useful in determining the presence of drug resistance, hypotensive symptoms, episodic HTN, or autonomic dysfunction. Autonomic neuropathy and the associated decrease in heart rate variability and increased electrocardiogram QT interval are in part a consequence of a reduced parasympathetic to sympathetic activity in diabetic patients. This abnormality contributes to the greatly increased risk of sudden death in diabetic patients.

Nondipping blood pressure/Pulse pattern

In normotensive and most hypertensive patients, the circadian BP rhythm demonstrates higher BP readings when patients are awake and lower BP readings when they are asleep. This is referred to as “dipping,” and the expected drop is approximately 10% to 15%. “Nondippers” have less than the usual 10% decline at night, a condition more frequent among diabetic patients, as demonstrated by ambulatory BP monitoring. Loss of nocturnal dipping of BP and heart rate are characteristics of HTN associated with DM. This loss of nocturnal dipping in BP and heart rate appears to be due, in part, to dysautonomia that is often present in diabetic patients.²⁷ The nondipping pattern of BP in diabetics is associated with microalbuminuria, proteinuria, and left ventricular hypertrophy, thereby conferring a higher CVD risk morbidity and mortality to patients who have it.⁵² Reduced vascular compliance further contributes to elevations in systolic BP, increases in pulse pressure, and associated CVD risk.

Diabetic cardiomyopathy

Diabetic cardiomyopathy is increasingly being recognized as a specific entity in patients with DM2.⁵³ The development of diabetic cardiomyopathy is most likely multifactorial. Putative mechanisms include metabolic disturbances, such as defective glycolysis and glucose oxidation, myocardial fibrosis, small vessel disease and autonomic dysfunction. Abnormalities of calcium handling that can lead to subsequent diabetic cardiomyopathy have also been demonstrated. Existence of this condition in a diabetic patient may have several therapeutic implications including: improving glycemic control, earlier use of calcium channel blockers (CCBs), ACE inhibitors and ARBs, exer-

cise training, lipid-lowering therapy, and antioxidant and insulin-sensitizing drugs.⁵³ Calcium channel blockers may reverse the intracellular calcium defects and prevent DM-induced myocardial changes. Verapamil significantly improves the depressed rate of contraction and rate of relaxation, lowers peak LV systolic pressure, and elevates LV diastolic pressure.⁵⁴ ACE inhibitors may improve fibrosis in the myocardium and improve endothelial dysfunction.⁵³ Clinically, ACE inhibitors reduce CVD in diabetic patients, particularly diabetic patients with HTN. ARBs and aldosterone antagonists may also have effects similar to ACE inhibitors on myocardial fibrosis in diabetic patients.³⁻⁵

DIAGNOSTIC TECHNIQUES

Diagnosis of HTN in DM requires screening the population with risk factors such as central obesity, dyslipidemia, older age, sleep apnea, and any patient with a family history. Application of proper blood pressure measurement techniques in the office and in the ambulatory setting will lead to better identification of patients and early implementation of treatment. Accurate measurement in the supine and upright positions is recommended in diabetic patients. Both the Seventh Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7) and the American Diabetes Association (ADA) have recommended targeting a blood pressure (BP) of 130/80 mmHg in diabetic patients. Generally this included the use of at least three antihypertensive agents that should encompass a diuretic and an inhibitor of the renin angiotensin system (RAS).³⁻⁵

MANAGEMENT: STRATEGIES TO REDUCE CARDIOVASCULAR RISK

The goal of HTN management in patients with DM is to reduce cardiovascular risk and prevent adverse cardiovascular events. Both pharmacologic and nonpharmacologic approaches to therapy are recommended. The JNC-7 emphasizes the need for the adoption of a healthy lifestyle, including aerobic exercise and a diet that is high in mineral and fiber content and relatively low in fat, refined carbohydrates, and salt content, for the prevention and treatment of HTN in all patients.⁴⁶ Aggressive nonpharmacologic interventions are not only pivotal but indispensable in the therapeutic outcome of all hypertensive populations.

Nonpharmacologic treatment

Diet and weight loss

Several randomized controlled trials have documented the value of modest weight loss in decreasing the risk of HTN and in some cases even obviates the need for antihypertensive medication.⁵¹ The Dietary Approaches to Stop Hypertension (DASH) study, a diet abundant in fruits and vegetables, as well as low-fat dairy products, with or without sodium restriction, substantially reduced BP in hypertensive patients.⁴⁶ Overall, a diet that is high in fiber and potassium and lower in saturated fat, refined

carbohydrates and salt can improve glycemic control, lipid profile, and BP.

Exercise

The Finnish Diabetes Prevention Study showed that overweight subjects with glucose intolerance randomized to intensified lifestyle intervention, consisting of diet and moderate exercise for at least 30 minutes per day, resulted in a marked reduction in the risk of developing DM2 and a significant drop in BP (4 mmHg for SBP and 2 mmHg for diastolic BP compared with control subjects).⁵⁵ A prospective study of 8302 Finnish men and 9139 women showed that regular physical activity was associated with a significantly reduced risk for HTN in men and women, independent of age, education, smoking habits, alcohol intake, and history of DM, BMI, and SBP at baseline.⁵⁶ Overweight and obesity were also associated with an increased risk of HTN, and the protective effect of physical activity was consistent in both overweight and normal-weight subjects. Further, exercise helps to accomplish weight loss. Most studies have shown that more benefit is derived from aerobic than nonaerobic exercise.⁵⁷ Data on effects of the intensity of physical activity on HTN, however, are conflicting. The most recent data show that high physical activity, defined as a combination of vigorous occupational activity more than 30 minutes daily and leisure-time physical activity more than 4 hours a week, is associated with a lower risk of HTN, independent of baseline BMI. Initiation of a graded exercise program is recommended in all hypertensive patients, including diabetics. Older diabetics may need to undergo cardiac assessment prior to initiating vigorous exercise programs. At the minimum, this requires a baseline electrocardiogram and exercise stress testing if there is clinical evidence for possible underlying ischemic heart disease.

Tobacco cessation

Smoking has been independently associated with enhanced risk of microvascular and macrovascular disease in diabetes. The synergistic effect results in an increased

premature CVD mortality. Smoking-cessation strategies should be discussed with patients at each visit.⁵⁸

Pharmacologic treatment

The choice of antihypertensive medications is wide and can be tailored to each specific patient. A key factor is consideration of comorbid conditions such as ischemic heart disease, chronic kidney disease, peripheral vascular disease, and dyslipidemia, as these all impact the choice of antihypertensive medication. On average, the diabetic patient will require at least three medications to reach the target blood pressure of BP <130/80 mmHg. The choice of medications includes medications that interrupt the RAAS (ACEIs and ARBs), thiazide diuretics, calcium channel blockers (CCBs), beta-blockers (BB), alpha-blockers, vasodilators and centrally acting medications such as clonidine. According to JNC-7, diabetes mellitus forms a compelling indication for consideration of specific medications as first-line therapy rather than using the currently recommended thiazide diuretic as first-line therapy (Table 55–4). Therapy should also include a RAS inhibitor. Once therapy is started, close monitoring and titration of medications to achieve goal BP is recommended.⁴⁷

In addition, other interventions and medications that affect overall cardiovascular risk should be considered. These include aspirin (ASA), metformin, thiazolidinediones, sulphonylureas, and insulin to improve glycemic control and HMG-CoA inhibitors (statins) and fibrates to improve the lipid profile. These medications once initiated should be titrated until the targeted endpoint is attained (Figure 55–3).

EVIDENCE-BASED APPROACH: SPECIFIC PHARMACOLOGIC THERAPY

Angiotensin-converting enzyme inhibitors

The RAAS plays a role in almost every step in the progression of atherosclerosis and HTN. Multiple clinical trials have demonstrated the pleiotropic effects of the

ANTIHYPERTENSIVE MEDICATIONS USED IN TREATMENT OF DM-RELATED HYPERTENSION: "COMPELLING INDICATIONS" SPECIFIC TO DM HYPERTENSION		
Diagnosis	Indication	Medication/Study
Type 1 DM	Renal function deterioration	ACEI (CCSG)
Type 2 DM	Cardiovascular events	ACEI (MICRO-HOPE)

ACE inhibitors. In addition to being an effective antihypertensive, the ACE inhibitors have been proven to offer additional benefits in patients with DM. The Heart Outcomes Prevention Evaluation (HOPE) trial studied 9541 patients, 3577 of whom were diabetic.³¹ Ramipril use was associated with a significant 25% risk reduction in myocardial infarction, stroke, or cardiovascular death after a median follow-up period of 4.5 years. Furthermore, the MICRO-HOPE substudy also showed that ramipril treatment was associated with a decreased risk of development of proteinuria in type 2 DM patients with microalbuminuria.⁵⁹ Only 18 diabetics in MICRO-HOPE developed ESRD, but ramipril was associated with a non-significant 30% reduction in this important endpoint, possibly due to the small number of events.

In the Captopril Prevention Project (CAPP), of the 10,985 patients studied, 309 patients in the captopril group and 263 in the conventional therapy group were diabetic. Overall, captopril treatment markedly lowered the risk for fatal and nonfatal myocardial infarction, stroke, and cardiovascular deaths, compared to the conventional therapy group, which consisted of β -blocker or diuretic therapy. The effects of the two regimens in the diabetic subpopulation showed a clear difference in the risk of developing a primary endpoint in favor of a captopril-based regimen.⁶⁰

In addition to lowering BP, ACE inhibitors also decrease the membrane permeability to albumin and decrease intra-glomerular pressure. By reducing microalbuminuria, ACE inhibitors can help prevent the progression to nephropathy. Meta-analyses have suggested that this anti-

proteinuric effect is independent of the changes in BP.⁶¹ In type 1 diabetics, ACE inhibitors have been shown to prevent the progression of diabetic nephropathy to end-stage renal disease (ESRD), while in DM2 there is no clear evidence of this. One complication of therapy is a slight rise in serum creatinine, which is due to volume depletion and is usually reversible.^{5,62} However, renal function should still be carefully monitored since a rise in serum creatinine by more than 30% or a continual rise during the first 2 months of therapy should alarm the physician to the possibility of renal artery stenosis or significant volume depletion. Interestingly, a recent meta-analysis of several long-term trials indicates that ACE inhibitors and ARBs, both of which inhibit the RAAS also reduce the incidence of new-onset diabetes³⁶ (Table 55–5).

Angiotensin receptor blockers

These agents specifically block the angiotensin II, subtype 1 (AT_1R) receptor, and offer effective blockade of the RAAS. ARBs have equivalent antihypertensive efficacy to ACE inhibitors, with fewer side effects, particularly cough and angioedema. This may clinically translate to improved adherence with an ARB compared to an ACE inhibitor. Similar to ACE inhibitors, the ARBs offer additional benefits in diabetic patients. Based on the current evidence and because of their tolerability, ARBs are recommended as first-line therapy for patients with DM, HTN, and significant proteinuria.⁴⁶

The Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) trial with losartan showed a significant 13% reduction in the composite primary endpoint (cardiovascular death, myocardial infarction, or stroke), most of which was due to a significant 25% reduction in stroke versus atenolol.⁶³ The diabetic patients in this study had an even more significant reduction (24%) in the primary endpoint, as well as in cardiovascular mortality (37%) and total mortality (39%), when compared to atenolol.

The Reduction of Endpoints in NIDDM with Angiotensin II Antagonist Losartan (RENAAL) and the Irbesartan Diabetic Nephropathy Trial showed that ARBs reduce proteinuria and the time to creatinine doubling, and slow the progression of renal disease.⁶⁴ The Irbesartan in Microalbuminuria (IRMA)-II trial also showed reduction in progression from microalbuminuria to proteinuria.⁵ The beneficial effects of ARBs on nephropathy were said to be independent of the changes in BP.

In evaluating combination therapy, the Candesartan and Lisinopril Microalbuminuria (CALM) trial showed a numerically greater reduction in both BP and albuminuria when both ARB and ACE inhibitor were used in combination at half-maximal doses than when used alone.⁶⁵ In nondiabetic patients with hypertension and nephrotic syndrome, combination therapy has been shown to be more effective in reducing proteinuria than an ACE inhibitor or ARB alone. Furthermore, this antiproteinuric effect was not dependent on changes in BP or creatinine clearance. Although this appears promising, more data are needed before recommending the combination of these two agents to completely block the RAAS in patients with diabetes. Finally, both ACE inhibitors and ARBs have been

REDUCTION IN RISK OF DEVELOPING NEW-ONSET DIABETES MELLITUS BY ANTIHYPERTENSIVE MEDICATION

Table 55–5. Reduction in Risk of Developing New-Onset Diabetes Mellitus by Antihypertensive Medication

shown to consistently reduce new onset diabetes in hypertensive patients, in part through reduction generation of reactive oxygen species that inhibit insulin signaling.

Thiazide diuretics

Although diuretics have the potential to worsen insulin resistance, perhaps via small reductions in potassium and magnesium, they have consistently demonstrated their ability to reduce the cardiovascular mortality in patients with DM. The ALLHAT, one of the largest antihypertensive trials, concluded that thiazide diuretics comparably reduced combined fatal and nonfatal coronary artery disease (CAD), and all-cause mortality when compared to an ACEI and CCB, and more importantly, prevented heart failure significantly better than any other initial therapy, in both diabetics and nondiabetics.⁴⁵

ALLHAT and other studies have a follow-up period of less than 10 years, and the true impact of new onset

DM on cardiovascular outcomes may not be fully appreciated. In a recent analysis of an observational registry of morbidity and mortality in initially untreated individuals with essential HTN, patients who were treated with diuretics and β -blockers had an increased propensity to develop DM2.⁶⁶ The occurrence of new-onset DM in treated hypertensive patients carried a risk for subsequent CVD events that was not statistically different from those who already had DM and HTN at the onset of the study. However, both groups had a much higher risk than those who remained free of DM. Even though the electrolyte disturbances and the adverse effects on lipid and carbohydrate metabolism are uncommon with low dose thiazide therapy, these recent observations suggest that thiazide diuretics and β -blockers should be initiated cautiously in hypertensive patients with elevated fasting glucose levels, that is, above 100 mg/dL.⁶⁷ Nevertheless, diuretics continue to play an important role in the management of

HTN in patients with DM, especially as an adjunct to ACE inhibitors and ARBs. A recent review of long-term mortality data from the Systolic Hypertension in the Elderly Program (mean 14.3 years) showed that development of DM in patients treated with the diuretic chlorthalidone was not associated with increased cardiovascular or total mortality rates.⁶⁸ Moreover, diuretic treatment in diabetic subjects was strongly associated with lower long-term cardiovascular and total mortality rates. Further research is required to fully define the long-term risk/benefit profiles of commonly used thiazide diuretics in hypertensive patients with impaired fasting glucose levels, especially since hydrochlorothiazide has been more widely accepted in clinical practice than has chlorthalidone. Finally, thiazide diuretics may lose their efficacy in lowering BP when creatinine exceeds 2.0 mg/dL.

Calcium channel blockers

At least 65% of hypertensive patients require two or more drugs to achieve BPs of less than 130/80.⁶⁹ Calcium channel blockers are effective antihypertensive agents but probably should be viewed as adjuncts to ACEIs, ARBs, and diuretics.⁵ They not only lower BP effectively in diabetic patients, but they are intermediate in risk of new-onset diabetes between ACE inhibitors and ARBs (which reduce the risk of incidence DM) and thiazide diuretics or β -blockers (which increase it).⁷⁰ A post-hoc analysis of RENAAL suggested no difference in the primary renal endpoint between dihydropyridine and nondihydropyridine CCBs as second-line agents (after an ARB).⁶⁴ Additionally, the nondihydropyridine calcium antagonists, verapamil and diltiazem, can further reduce proteinuria when added to RAAS blocker therapy.¹⁰ According to data from the Hypertension Optimal Treatment (HOT) study, dihydropyridine CCBs, which are often necessary for adequate BP control, are not contraindicated in patients with proteinuria and may be used as an adjunctive therapy.

The European Trial on Isolated Systolic Hypertension in the Elderly with nitrendipine (vs. placebo) demonstrated that intensive antihypertensive therapy for older patients with DM2 and isolated systolic HTN eliminated the additional risk for CVD events and stroke associated with DM.⁷¹ However, in the ALLHAT study, an initial CCB had a significantly higher incidence of heart failure compared to an initial diuretic but fewer strokes than an ACE inhibitor.⁴⁵

Beta-adrenergic blocking agents

The effectiveness of β -blockers in HTN, CAD, and heart failure management has been proven in multiple clinical trials.⁵¹ Despite their adverse effects on glucose tolerance and the peripheral vasculature, β -blockers play a significant role in the management of HTN in diabetics, especially in those with associated micro- and macro-vascular complications. In the UKPDS, atenolol was comparable to captopril in reducing BP and CVD outcomes⁴⁹; however, when comparing atenolol to other agents in many other trials, atenolol has been consistently and significantly worse than other therapies to which it has been compared.⁷² Beta-blockers have adverse effects on glucose and lipid profiles and have also been implicated in new-

onset DM in obese patients.⁵¹ Beta-blockade may worsen the symptoms of peripheral vascular disease; however, clear evidence that this occurs in practice during controlled studies is lacking. Nonselective β -blockers, such as carvedilol, reduce CVD mortality and microalbuminuria without adversely affecting glucose or lipid profiles, although this may be a BP-lowering effect.⁷³ When used with RAS blockade, carvedilol and atenolol have also both been shown to reduce albuminuria.⁷⁴ In addition, carvedilol slows the progression of nephropathy and improves insulin sensitivity.⁷³ Therefore, these agents play a useful role in antihypertensive therapy of diabetic patients, specifically those with CAD and heart failure.

Alpha antagonists

The selective alpha-1-blockers, such as prazosin and doxazosin, are the only class of antihypertensive agents that may have the combined effect of lowering LDL cholesterol, raising HDL-cholesterol levels, and improving insulin sensitivity,⁷⁵ and they can be useful add-on drugs to reach target BP. Alpha-blockers, however, have relatively may produce orthostatic hypertension, especially in the elderly and those with diabetic neuropathy.¹⁵ Thus, these agents are generally not part of first-line therapy in diabetic patients.⁵

In summary, there is considerable evidence that rigorous control of blood pressure in patients with diabetes reduces cardiovascular events, stroke, and progression of albuminuria and chronic renal disease. It usually requires at least three drugs accomplish goal blood pressure of 130/80 mmHg, and diuretics and RAS inhibitors should be a part of the antihypertensive regimen.

SUMMARY

Insulin resistance, DM, and HTN are closely linked. Genetic predisposition when combined with an enabling milieu (central obesity, inactivity, poor diet) can result in the synergistic occurrence of cardiovascular risk factors seen clinically. The approach to treatment entails consideration of the underlying pathophysiologic mechanisms understanding that insulin resistance is often a progressive state. The presence of peripheral vascular disease, heart failure, coronary artery disease, orthostatic hypotension, dyslipidemia, and diabetic nephropathy all influence the choice of antihypertensive therapy. Reversal of the essential condition with therapy would be ideal, and strategies such as interruption of the RAAS may have this effect. When this is not possible, an approach that targets specific complications, slows progression, or delays onset of target-organ damage should be used.

Quality of life, adverse effects of antihypertensive medications, and other comorbid conditions affect adherence to treatment regimens and the success of therapy. More importantly, the health care team should work closely with each individual patient to prudently, but aggressively, achieve and maintain the goal BP of less than 130/80 mmHg. Use of a statin and aspirin are also an integral part of the comprehensive care of the diabetic patient when aiming to reduce CVD risk, which is the ultimate goal of therapy.

Hypertension in Renal Failure

Branko Braam and Hein A. Koomans

Definition

- Renal hypertension is blood pressure exceeding 140/90 mmHg, due to renal parenchymal disease, and occurring in approximately 40% to 70% of patients with chronic renal failure. Dialysis-associated hypertension is an ambulatory blood pressure or a week-average home blood pressure exceeding 140/90 mmHg in patients with end-stage renal disease (ESRD) on renal replacement therapy.

Key Features

- Structural and functional changes in the diseased kidney lead to (1) inadequate volume control with extracellular fluid volume (ECFV) expansion, (2) inappropriately high renin release, and (3) increased activity of the sympathetic nervous system.
- Furthermore, renal disease is associated with structural and functional changes in the vasculature, leading to reduced vascular compliance, which in turn will cause high systolic pressure load to the heart, low diastolic pressures with potential underperfusion of coronary and cerebral vessels, and high peak pressures in the vasculature leading to further vascular damage.
- Renal disease is associated with a very high prevalence of cardiovascular disease; hypertension further aggravates this risk.
- The “reverse epidemiology” reported for ESRD patients may well be due to the presence of different populations entering dialysis programs: a group with low blood pressure with previous phases of hypertension with cardiac damage and a group with still intact function, for which regular risk applies of high blood pressure.

Therapy

- Treatment of hypertension to levels of 130/80 is pursued by sequential interruption of all deranged axes: (1) normalize ECFV using diuretics or ultrafiltration, (2) inhibit the activity of the renin-angiotensin system using angiotensin-converting enzyme inhibitors or AT1 receptor antagonists, and (3) inhibit the activity of the sympathetic nervous system, primarily using beta receptor antagonists.
- Care should be taken with patients having high pulse pressures, indicating low vascular compliance. Here, blood pressure should be decreased, however, while avoiding excessively low diastolic blood pressure.

lation suffers from reduced glomerular filtration rate (GFR) (<60 mL/min).¹ Worldwide, the number of patients with end-stage renal disease (ESRD) (Stage 5 chronic kidney disease) approximates 0.03%.² CKD is strongly associated with hypertension. The prevalence of hypertension in ESRD approximates 80%.³ Even in early CKD the prevalence of hypertension is increased threefold (Figure 56–1).

The prevalence of hypertension varies somewhat with the underlying disease, with an approximately 40% prevalence in chronic interstitial nephritis, IgA nephropathy, and minimal change disease, and 60% to 70% in diabetic nephropathy, adult-type polycystic kidney disease (ADPKD), and focal segmental glomerulosclerosis (FSGS).⁴ In ESRD, systolic hypertension is more common than combined systolic and diastolic hypertension, and isolated diastolic hypertension is rare.^{5,6}

Control of hypertension in the general population is poor, with only approximately 25% of the recognized hypertensive subjects being adequately controlled. Unfortunately, in patients with progressing CKD or ESRD this control is not better or even worse.^{7–9} This is a serious problem, since it is clear that hypertension is a main factor driving progressive decline of kidney function in CKD, whereas adequate blood pressure control mitigates the rate of nephron loss in many patient groups and settings. Moreover, hypertension is one of the main causes of increased cardiovascular morbidity and mortality, hallmarks of patients with renal failure. Large population studies such as the Hypertension Detection and Follow-up Program (HDFP)¹⁰ and the National Health and Nutrition Examination Survey (NHANES) I¹¹ demonstrated increased cardiovascular mortality in moderate renal failure. A recent meta-analysis of 85 reports covering over half a million patients showed that cardiovascular risk increases when GFR falls below ~75 mL/min.² The risk grows steeply with decreasing GFR and patients starting dialysis have a 5- to 10-fold increased mortality risk. The impact is tremendous in young subjects with ESRD, in whom cardiovascular risk is increased 100-fold.¹²

Hypertension is one risk factor among many others in CKD, such as dyslipidemia, insulin resistance, anemia, hyperhomocysteinemia, hyperphosphatemia, reduced nitric oxide availability, and chronic inflammation.¹³ The presence of these additional factors increases with decreasing GFR³ (Figure 56–2). Against that background, the added cardiovascular risk induced by high blood pressure is huge and, conversely, the impact of adequate

It is increasingly clear that chronic kidney disease (CKD) is extremely prevalent, and likely the most common form of secondary hypertension. Recent data collected in the United States indicates that ~4.7% of the overall popu-

Figure 56-1. Prevalence of high blood pressure by level of GFR, adjusted to age 60 years in NHANES III. GFR was estimated using the abbreviated Modification of Diet in Renal Disease (MDRD) Study equation. Hypertension was defined as JNC Stage 1 (SBP=140 mmHg or DBP=90 mmHg, or taking medications for hypertension) or JNC=Stage 2 (SBP=160 or DBP=100 mmHg). Values are adjusted to age 60 years using a polynomial regression. Ninety-five percent confidence intervals are shown at selected levels of estimated GFR. DBP, diastolic blood pressure; GFR, glomerular filtration rate; JNC, Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure; NHANES III, National Health and Nutrition Examination Survey III; SBP, systolic blood pressure. (Redrawn from National Kidney Foundation. *Am J Kidney Dis* 2002;39(2 Suppl 1):S1-266.)

blood pressure control on patient outcome can be huge. This is important, in part because currently available drugs and dialysis technology make adequate blood pressure control quite feasible. Many studies have shown

that antihypertensive drugs have beneficial effects on cardiovascular morbidity and patient outcome. Also, blood pressure reduction in ESRD by effective volume control during long or daily hemodialysis also improves survival.^{14,15}

There are, however, questions specifically related to renal hypertension. Are blood pressure targets for the general population also applicable to CKD and ESRD patients? Is cardiovascular damage in CKD and ESRD patients typically the result of deficient systolic blood pressure or pulse pressure? Should we rely on predialysis or postdialysis blood pressure measurements? Should we apply 24-hour blood pressure measurements? Is blood pressure control enough, or should we target other properties of the vascular system to monitor and control cardiovascular risk such as pulse wave velocity? Are all drugs equally effective, or do we need a specific approach for this form of hypertension?

In this chapter we will focus on the pathophysiology of renal hypertension, and provide guidelines for management based on the available evidence. For the issue of protection against progression of renal failure, see Chapter 49. A central issue to be discussed in this chapter is the role of volume control, which is pivotal for the correction of renal hypertension.

PATHOPHYSIOLOGY

The mechanism of hypertension in renal failure involves volume overload and vasoconstriction. Volume overload is due to impaired renal sodium excretion, and vasoconstriction may be due to a host of factors related to renal parenchymal changes or renal failure. Volume overload and vasoconstriction are not mutually exclusive—in most patients both factors play a role.

Figure 56-2. Estimated prevalence of selected complications, by category of estimated GFR, among participants aged 20 years in NHANES III, 1988 through 1994. These estimates are not adjusted for age, the mean of which is 33 years higher at an estimated GFR of 15 to 29 mL/min/1.73 m² than that at an estimated GFR 90 mL/min/1.73 m². GFR, glomerular filtration rate; NHANES III, National Health and Nutrition Examination Survey III. (Redrawn from National Kidney Foundation. *Am J Kidney Dis* 2002;39(2 Suppl 1):S1-266.)

Volume overload

Sodium (salt) balance plays a key role in the pathogenesis of renal hypertension. Maintenance of sodium balance (and thus volume balance) depends on excretion by the kidneys, which is impaired in renal failure. This implies that the pressure natriuresis curve is shifted to a higher blood pressure level. The tendency for sodium retention increases with decreasing GFR, and expanded blood and ECFV are found especially in patients with progressed renal failure. Indeed, the well-accepted “intact nephron hypothesis” implies that with declining fluid filtration, sodium balance can only be maintained at the cost of a changed environment, that is, hypervolemia and hypertension drive increased fractional sodium excretion. Many studies have showed direct correlations between blood volume and ECFV with blood pressure in patients with renal failure. However, these results were not consistently reported, perhaps due to variably successful “whole-body autoregulation,” which tends to convert high-volume hypertension into vasoconstriction hypertension.

A strong argument for the role of impaired sodium excretion is the fact that a decreased GFR makes blood pressure more salt-sensitive: the lower the GFR, the more blood pressure tends to rise with an increase in salt intake. However, it is not only the decrease in GFR that makes patients salt-sensitive. When healthy persons are subjected to similar increments in sodium intake per GFR as patients with chronic renal failure, blood pressure does not increase as in patients with renal failure (Figure 56–3).¹⁶ This confirms earlier observations that even extremes of sodium intake have relatively little effect on blood pressure when GFR (and the kidney) is normal. Probably absence of vasoconstrictive hyperactivity makes the difference. Healthy subjects on high sodium intake effectively suppress renin activity and sympathetic activity.

A **B**
Figure 56–3. Mean arterial pressure on low (20 mmol/day) and high (120, 200, and 1128 mmol/day) sodium intake in patients with renal failure (a) and normal subjects (b). Note the consistent increase in mean arterial pressure in patients with renal failure and the absence of change in normal subjects even at extremes of sodium intake. (Redrawn from Koomans HA, Roos JC, et al. *Hypertension* 1985;7(5):714–21.)

However, patients with kidney disease maintain relatively high renin activity and sympathetic activity, that is, for any ECFV, renin activity and sympathetic activity remain elevated (Figure 56–4).^{16,17}

In some forms of renal parenchymal disease, sodium is retained even though GFR is still normal or only mildly impaired. For instance, accurate measurements of ECFV have shown modestly increased values together with modestly increased blood pressure also in early renal disease, such as in ADPKD.¹⁸ In glomerular diseases, such as systemic lupus erythematosus, diabetic or IgA nephropathy sodium retention and hypertension also occur before GFR declines. In these conditions fractional sodium excretion is low, unless volume is retained and blood pressure is high.

The importance of increased intravascular volume rather than increased total ECFV for arterial hypertension becomes particularly clear when one compares patients with chronic renal failure with patients with the nephrotic syndrome: despite the same increase in total ECFV, patients with renal failure display much more increase in blood volume and blood pressure (Figure 56–5).¹⁹ The difference results from the low protein mass in nephrosis, which mitigates the increase in blood volume.

Figure 56–4. Plots of ECV, MSNA, and PRA in patients with chronic renal failure (solid-fill circles) in normovolemic and hypervolemic condition and in healthy volunteers (hollow circles) during use of low- and high-sodium diet. ECV, extracellular volume; MSNA, muscle sympathetic nerve activity; PRA, plasma renin activity. (Adapted from Koomans HA, Roos JC, et al. *Hypertension* 1985;7(5):714–21.)

A **B**
Figure 56-5. Dependence of extracellular fluid volume (per kilogram of lean body mass) on mean arterial pressure (a) and blood volume (b) in patients with nephrotic syndrome (*dashed curve*) and renal failure (*solid curve*). Note the marked increase of blood pressure in patients with renal failure compared with those with nephrotic syndrome. (* $p < 0.05$; ** $p < 0.01$)

Theoretically, the body should correct a sustained hypervolemia and high cardiac output through autoregulation. By increasing peripheral vascular tone and blood pressure, the kidney is forced to restore the elevated blood volume, cardiac output and tissue supply of oxygen and nutrients to normal level. In practice, this concept appears very difficult to prove. Moreover, the gain of this mechanism may decrease when GFR is severely decreased. In fact, patients with ESRD often have a high cardiac output.²⁰ To a lesser extent, this is also the case in normotensive patients.²⁰ Therefore, other factors besides unsuccessful autoregulation may contribute to the persistence of high cardiac output. Anemia, commonly present in patients with ESRD, is associated with sustained high cardiac output to compensate for reduced oxygen delivery to the tissues. The presence of arteriovenous dialysis shunts also increases cardiac output, but tissue perfusion remains normal.

Vasoconstriction

Vasoconstrictive factors that are definitely or probably hyperactive in patients with renal failure are summarized in Box 56-1. Although the origin of these factors is mixed, it is clear the presence of abnormal kidneys plays a key role in their genesis: experimental and clinical data have

shown that bilateral nephrectomy controls hypertension completely, as long as volume is also controlled.

Hyperactivity of renin angiotensin system

Studies from the 1970s showed that in about 20% of cases, hypertension of renal failure could not be corrected by treatment of the hypervolemia. Blood pressure became normal only after bilateral nephrectomy. This was attributed to hyperactivity of the renin angiotensin system (RAS) from the diseased kidneys, and it was concluded that in 80%, renal hypertension is based on volume overload, and in 20% on hyperactivity of the RAS. The advent of angiotensin-converting enzyme (ACE) inhibitors have changed this concept. Nearly all patients with renal hypertension have hyperactivity of the RAS relative to their volume status,²¹ but in some cases the RAS is so hyperactive that blood pressure remains strongly elevated even after volume correction. In these cases blood pressure normalizes only with binephrectomy²² or RAS blockade.²³ Nonetheless, correlation studies using the renin-volume product have suggested that other factors besides volume and the RAS also determine hypertension of CKD.²⁴

The basis for RAS activation in CKD probably resides in patchy areas of underperfusion, leading to the situation that local activation of the RAS dictates sodium and fluid retention in other relatively healthy areas where perfusion is normal. This so-called nephron heterogeneity works as in two-kidney one-clip hypertension. In line with this hypothesis, RAS activation can occur in early-stage CKD when there is relatively much focal vascular damage, such as in nephrosclerosis, or when anatomic changes are prominent, such as in polycystic kidney disease,²⁵ reflux nephropathy²⁶ or (unilateral) hydronephrosis.²⁷ In the latter two situations, uninephrectomy can resolve the hypertension.^{26,27}

Hyperactivity of sympathetic nervous system

It is increasingly clear that, besides RAS activity, sympathetic nervous activity is also high in hypertensive patients with CKD. First, ganglion blockade with debrisoquine

Box 56-1

Hyperactive Vasoconstrictors and Defective Vasodilators in Chronic Renal Failure

1. Whole-body autoregulation
2. Increased activity of the renin angiotensin system
3. Increased activity of the sympathetic nervous system
4. Diminished nitric oxide bio-activity (by increased asymmetric dimethylarginine [ADMA] levels)
5. Increased endothelin
6. Loss of renal vasodilator prostaglandins
7. Hypercalcemia
8. Decreased arterial compliance

was shown to lower blood pressure in hypertensive but not in normotensive patients with CKD.²⁸ Later, direct recordings of sympathetic activity with microneurography demonstrated sympathetic hyperactivity in patients with progressed CKD (Figure 56–6)²⁹ and ESRD.³⁰ On average, sympathetic activity was twice normal, similar as shown in the past for plasma catecholamine concentrations. Binephrectomy normalizes sympathetic activity,³⁰ showing that the kidneys are culprits of the sympathetic hyperactivity.

The afferent signal leading to increased sympathetic output from the CNS probably has a complex basis, involving both ischemia and local chemical factors in the kidney (Figure 56–7).³¹ Unilateral clipping of the renal artery causes sympathetic activation, leading to vasoconstriction, salt retention by the contralateral kidney, and hypertension, effects that can be eliminated by cutting the afferent nerve of the clipped kidney.³² In humans, angioplasty of unilateral renal artery stenosis that successfully lowered blood pressure and RAS activation also resolved the increased sympathetic nerve activity.³³ Therefore, a clear parallel exists with the pathophysiologic basis (and goal) of RAS hyperactivity. Hypertensive (but not untreated normotensive) patients with polycystic kidney disease and normal GFR also have increased sympathetic nervous activity,³⁴ suggesting that renal

Figure 56–7. Sympathetic nervous system activity and renal disease. The diseased kidney sends signals to the brain, resulting in increased sympathetic output that will increase blood pressure. (Redrawn from Koomans HA, Blankestijn PJ, et al. *J Am Soc Nephrol* 2004;15(3):524–37.)

Figure 56–6. Baroreflex response to changes in mean arterial pressure in patients with chronic renal failure before and during long-term treatment with enalapril and in control subjects. Muscle sympathetic-nerve activity and heart rate were plotted against mean arterial pressures that were approximately 4, 8, and 12 mmHg below and 4, 8, and 12 mmHg above the resting levels (solid symbols). Tests were conducted before and during treatment with enalapril in 11 patients and 11 control subjects. Values are means plus or minus standard error.

parenchymal changes possibly associated with local ischemia activate the afferent signal. Besides renal afferent nerve activity, increased concentrations of angiotensin II may also increase sympathetic output through a direct effect on the brain stem. From clinical viewpoint this is important, since drugs that suppress RAS (hyper)activity automatically interfere with sympathetic (hyper)activity (Figure 56–6).²⁹ In fact, this characteristic of RAS blocking drugs may have caused that the role of sympathetic hyperactivity to remain somewhat underappreciated.

Nitric oxide

Studies with stable isotopes have shown decreased arginine-to-citrulline conversion in patients with pre-ESRD.³⁵ Others found evidence for approximately 40% reduction in NO production in hemodialysis patients.³⁶ Diminished NOS activity may be due to decreased renal clearance of the endogenous NOS inhibitor, asymmetric dimethylarginine, of which high concentrations have been found even in early CKD,³⁷ or to decreased availability of NOS substrate L-arginine.³⁸ Patients with CKD also suffer from increased oxidative stress due to multiple reasons,¹³ also reducing bio-availability of nitric oxide. As a consequence, endothelium-dependent vasodilation is diminished in patients with CKD.³⁹ However, it is not clear whether the reduced NO availability also participates in the hypertension, since we do not know whether restoration of normal nitric oxide balance in humans can attenuate renal hypertension. What we do know is that acute experimental inhibition of NOS activity in healthy humans to the level found in pre-ESRD patients or NOS inhibition in chronic studies in experimental animals⁴⁰ causes profound increase in blood pressure.⁴¹ Experimental studies have further revealed that NOS inhibition increase renal and cardiac sensitivity to angiotensin II.⁴⁰

Other pressors

For unknown reasons, plasma endothelin-1, a potent vasoconstrictor, is increased in patients with CKD.⁴² However, the increase is modest, and the relevance for hypertension unclear. Acute blockade of endothelin-A receptor causes a greater blood pressure drop than in healthy controls,⁴³ but long-term studies are lacking. Erythropoietin and calcineurin inhibitors increase plasma endothelin concentrations, which may enhance the hypertensive effects of these substances. Hyperparathyroidism may increase blood pressure by increasing calcium content in smooth muscle cells. However, the effect on hypertension of PTH suppression by means of parathyroidectomy or vitamin D supplementation, if any, is modest.^{44,45}

Depressor systems

The kidney also produces substances with depressor activity, such as prostaglandins, kallikrein, renomedullary lipids, and, as recently discovered, renalase.⁴⁶ These substances are involved in the maintenance of renomedullary perfusion, which from animal studies is known to be essential for normal blood pressure. Whether impaired release of renal depressor substances participates in human renal hypertension is not resolved. However, it is well known that patients with CKD are more sensitive to the hypertensive (and hyperkalemic) action of prostaglandin synthesis inhibitors.

Arterial stiffness

Compliance of large conduit vessels is reduced in patients with ESRD. This has been confirmed by many researchers, both directly as steep pressure–volume relationship of the carotid artery assessed with Doppler techniques,⁴⁷ and indirectly as high pulse wave velocity over the aorta assessed with applanation tonometry.⁴⁸ The effect is an increase in systolic pressure and decrease in diastolic pressure. Indeed, systolic pressure increases more than diastolic pressure in most patients with CKD.⁵ As a result, afterload of the heart increases more than indicated by mean arterial pressure or diastolic pressure. Pathology and high-resolution ultrasonography studies confirm the structural basis involving arteriosclerosis and calcification.⁴⁹ However, there is also a functional component, since hypervolemia and neurohumoral factors such as angiotensin II, sympathetic activity, and endothelin also contribute to decreased arterial compliance.^{50,51}

Besides these functional aspects, some insight has become available on the potential pathways mediating vascular stiffness, in particular on media calcification. On the one hand, dysregulation of calcium phosphate metabolism seems central in calcification, albeit that it is still under dispute whether phosphate levels, calcium-phosphate product or PTH is most important.⁵² Besides, cells with osteoblast-like properties can be identified in the vascular wall in uremia,⁵³ and can be inhibited by bone morphometric protein 7 (BMP7). It is not completely clear whether these cells are vascular smooth muscle cells or bone progenitor cells. These cells can form intracellular phosphate deposits, which induce (intracellular) matrix vesicles, which in turn are involved in osteogenesis.

Interestingly, endogenous inhibitors of vascular calcification have been described, such as matrix Gla protein. MGP knockout mice develop severe media calcification⁵⁴; deficiencies or diminished function of such factors may well contribute to vascular calcification in uremia. Taken together, vascular calcium regulation is a complex phenomenon involving differentiation of cells and seems to be well controlled; dysregulation in CKD is far from understood.

CLINICAL PRESENTATION

Patients with hypertension due to CKD often present with signs of volume excess but this is not necessarily so. Testing for the blood pressure–lowering effect of RAS blockade is helpful to disclose the “volume component” of the hypertension (see “Management” section). In dialysis patients, various other methods are in use to determine whether volume is excessive. There is evidence for reduced tissue compliance in patients with CKD, meaning that hypervolemia can occur in the absence of visible edema.

As mentioned, there is high prevalence of systolic hypertension in patients with CKD, and in particular in ESRD.^{5,6} The prevalence of hypertension is estimated to be approximately 75%.^{55,56} Diurnal blood pressure measurements have shown that the increase in 24-hour systolic pressure load is greater than in diastolic pressure load (Figure 56–8). These studies also showed a prevalence of non-dipping blood pressure profile (see Horl and Horl⁵⁷ for review). Less than 25% of patients with plasma creatinine of more than 600 $\mu\text{mol/L}$ or on dialysis show a normal diurnal blood pressure rhythm.⁵⁸ Absence of nocturnal blood pressure–drop increases the more time has passed since the last dialysis (Figure 56–6), which suggests a role for hypervolemia. Both increased pulse pressure and non-dipping diurnal pressure rhythm predict for development of heart failure and increased cardiovascular mortality,⁵⁹ making this a poor combination.

About one-third of patients with moderate renal failure already have evidence for left ventricular hypertrophy (LVH), and this number increases to ~80% when patients

Figure 56–8. Schematic interdialytic blood pressure pattern. Blood pressure decreases during dialysis, is low during the postdialysis day, with an intact nocturnal dip, and then starts to increase. On Day 2 after dialysis, the nocturnal dip is absent, and blood pressure shows a steep increase just before the next dialysis session.

start hemodialysis.^{60,61} In patients on dialysis, blood pressure correlates with LVH,^{62,63} ventricular dilatation, and *de novo* heart failure,⁶⁰ and worsens the prognosis.⁶⁴

Patients with CKD often present with clinically significant arteriosclerosis, with hypertension being a major risk factor. CT scans showed 92% incidence of coronary artery calcifications and significantly increased carotid artery intima media thickness (IMT) in young adults with childhood-onset CKD.⁶⁵ In the National Institutes of Health hemodialysis study, the prevalence of symptomatic cerebrovascular disease, peripheral artery disease, and coronary heart disease was 19%, 23%, and 40%, respectively.⁶⁶ Incidence of acute coronary syndromes is increased twofold in patients with GFR of less than 60 mL/min,⁶⁷ and 10-fold in patients with ESRD.⁶⁸ Brain-T2MR in predialysis patients has showed high intensity scores pointing to cerebrovascular disease in 75%, with a strong correlation with hypertension.⁶⁹ As many as 85% of patients with CKD and GFR of less than 40 mL/min show asymptomatic lacunar infarcts in association with hypertension.⁷⁰ The incidence of stroke is increased threefold in patients with GFR of less than 60 mL/min,⁶⁷ and 10-fold in patients on dialysis.⁷¹ In dialysis patients, hypertension is a strong independent predictor of both hemorrhagic and ischemic stroke.^{71,72} The prevalence of decreased ankle arm index is increased twofold in subjects with GFR lower than 40 mL/min.⁷³ In a large cohort of male patients presenting with advanced peripheral artery disease (rest pain, ulceration), the prevalence of moderate (GFR 30 to 60 mL/min) to severe (GFR <30 mL/min) CKD was 30% and 8%, respectively,⁷⁴ indicating a ~12-fold increased risk in CKD. Importantly, 90% of these subjects had or were treated for hypertension.

As discussed in Chapter 49, hypertension accelerates the decline of renal function in patients with chronic renal failure, and strict blood pressure control strongly reduces the rate of decline, especially in patients with proteinuria. The presence of cardiovascular disease shortens the time to ESRD,⁶⁸ pointing to a complex relation among hypertension, cardiovascular disease, and progression of CKD. The role of atherosclerotic renovascular disease in this process is unclear. The prevalence of severe renal artery stenosis in ESRD varies between 10% and 40% in adults, depending on measurement techniques. A recent study with CT-angiography in patients starting dialysis showed severe renovascular disease in 41%, the prevalence being extremely high in hypertensive subjects in whom the cause of the CKD was unknown.⁷⁵

DIAGNOSTIC TECHNIQUES

Measurement of blood pressure: How and when?

For patients with chronic renal failure who are not on renal replacement therapy, assessment of blood pressure is not principally different from other hypertensive subjects, and precise instructions can be found in the K-DOQI guidelines⁷⁶ (see also “Management” section). Ambulatory blood pressure measurement (ABPM) is advised in case of suspected white coat hypertension, resistant hypertension, hypotensive symptoms while taking antihypertensive medications, episodic hypertension, or autonomic dysfunction.⁷⁶ Please note that 24-hour ABPM levels are somewhat lower than office measurements,^{77–79} and boundaries are supplied in Table 56–1. It is becoming more and more clear that frequent home blood pressure measurement adequately reflects blood pressure, and leads to better blood pressure control.⁸⁰ In the absence of ABPM systems, frequent home measurements can be used as surrogates, although there is no proof yet of their ability to predict cardiovascular complications.

There is no consensus as to which blood pressure measurement most adequately reflects average pressure load and most accurately predicts the risk for cardiovascular disease in ESRD patients on hemodialysis. As mentioned, ABPM tracings illustrate that average pressure load is probably best assessed by average interdialytic blood pressure; the highest blood pressure and the blood pressure heart frequency product are reached just before the next hemodialysis session (Figure 56–6). Several studies have indicated that predialysis (or “dialysis center”) blood pressure overestimates ambulatory blood pressure. In one study, predialysis systolic blood pressure exceeded the average of ABPM values in the 6 hours before arrival for dialysis by 25/13 mmHg in 40% of the patients.⁸¹ Another report also indicates a strong overestimation of blood pressure by predialysis assessment and failed to show any good (Bland-Altman) agreement between predialysis blood pressure and ambulant blood pressure.⁸² In both dialysis patients⁸² and CKD patients⁸³ excellent agreement between ABPM and home blood pressure measurements has been reported. Taken together, these and other studies indicate that center blood pressure measurements are not likely to reflect interdialytic blood pressure, and either ABPM or home blood pressure measurements are preferred. Which blood pressure to take should, ultimately, be decided on a longitudinal

AMBULATORY BLOOD PRESSURE MEASUREMENT THRESHOLDS IN ADULTS			
	95th Percentile	Normotension	Hypertension
24 hour	132/82	≤130/80	≥135/85
Daytime	138/87	≤135/85	≥140/90
Nighttime	123/74	≤120/70	≥125/75

Table 56–1. Ambulatory Blood Pressure Measurement Thresholds in Adults

association with clinically relevant outcomes. A summary of 11 relevant studies suggests that, whereas predialysis (systolic and diastolic) blood pressure correlates with left ventricular mass, postdialysis (systolic and diastolic) blood pressure correlates with mortality (Table 56–2).⁸⁴ Studies of risk assessment based on ABPM are too scarce to allow a conclusion.

Assessment of pathophysiologic mechanism driving hypertension

Contributions of hypervolemia and vasoconstricting factors to the hypertension can often adequately be estimated with functional assessment of RAS activity using an ACE inhibitor test, by carefully assessing the volume status of the patient (edema, weight gain), and by using pulse rate as a reflection of sympathetic nervous system activity. Using these parameters and following a strict therapeutic approach (see “Management” section), measuring renin activity or sympathetic activity is rarely required or helpful. Only in special circumstances, particularly when blood pressure is low despite suspicion of volume excess, measurement of volume indicators such as brain natriuretic peptide, body composition assessed with bioelectric impedance, and vena cava index may be helpful to discern between hypovolemia or heart failure.

Consequences of hypertension

Left ventricular hypertrophy (or its absence) is easily assessed using electrocardiography; however, the ECG is not very sensitive, particularly in obese subjects.⁸⁵ Nevertheless, LVH indicated by ECG voltage criteria is a strong predictor of cardiovascular morbidity and mortality.⁸⁶ Echocardiography is much more sensitive and yields additional information, such as the type of LVH, potential diastolic dysfunction (which may complicate antihypertensive treatment) and valvular heart disease. It can be argued that informed management of hypertension without echocardiography is hardly possible.

There are currently two methods to assess vascular wall properties under research conditions that may well enter routine clinical use in the next few years: IMT assessment and pulse wave velocity (PWV). Carotid IMT correlates with cardiovascular mortality in hemodialysis patients, independent of blood pressure.⁸⁷ PWV has been shown

to be a strong predictor of cardiovascular morbidity and mortality as well.⁸⁸ Interestingly, we have confirmed elevated PWV in hemodialysis patients and demonstrated that ACE inhibitor treatment and volume depletion additively reduced PWV to levels comparable with healthy controls.⁸⁹ This indicates that arterial wall characteristics are still modifiable.

MANAGEMENT

How to decrease blood pressure

It is important to manage both components of hypertension—hypervolemia and vasoconstriction—and to estimate the contribution of these factors in individuals. In patients with CKD who are not on dialysis, it is practical to start with an RAS blocker, which eliminates the vasoconstriction except structural vascular changes and some of the sympathetic hyperactivity.²⁹ Residual hypertension reveals the hypervolemia component, which can be treated next with diuretics (Figure 56–9). Preferably one should use loop diuretics, of which the dose should be increased to reach the high intratubular concentrations needed to further lower the (already low) fractional tubular sodium reabsorption.⁹⁰ Thiazide diuretics are often insufficient in CKD, but can still be very potent together with loop diuretics, since these shift sodium reabsorption to the thiazide-sensitive tubule segment. In some cases blood pressure remains high despite adequate suppression of the RAS and control of the hypervolemia. Residual vasoconstriction is mostly due to insufficiently suppressed sympathetic activity, to be distinguished from tachycardia. In those patients, addition of the central sympatholytic drug moxonidine on top of RAS blockade can control both sympathetic hyperactivity and blood pressure.⁹¹

In patients with ESRD volume has to be controlled with ultrafiltration. Inadequate blood pressure control occurs more often in patients with large interdialytic weight increase,⁹² pointing to the role of volume excess. Frequent (nocturnal) or long hemodialysis offers an alternative way to control blood pressure.^{93–95} This method diminishes the need for drug therapy, suggesting that systematic and prolonged maintenance of normovolemia with slow

AMI, acute myocardial infarction; CVA, cerebrovascular accident; DBP, diastolic blood pressure; LVH, left ventricular hypertrophy; MAP, mean arterial pressure; PAD, peripheral arterial disease; PP, pulse pressure.

Table 56–2. Blood Pressure in End-Stage Renal Disease and Established Risk for Cardiovascular Disease

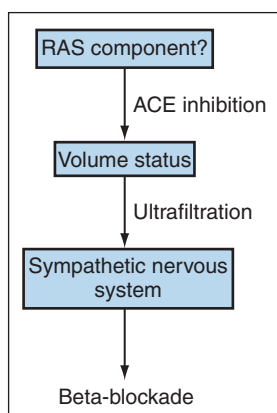

Figure 56-9. Schematic approach to treatment of hypertension in chronic kidney disease and end-stage renal disease. ACE, angiotensin-converting enzyme; RAS, renin angiotensin system.

ultrafiltration eliminates vasoconstrictive factors. The mechanism is unclear. In patients with CKD, it is often difficult to control blood pressure with diuretics alone because these drugs may evoke compensatory reactions of vasoconstriction.

Blood pressure control is important to retard progression of CKD and cardiovascular complications. There is some evidence that RAS blockade offers blood pressure independent protection against progression of CKD and also protects against development and progression of heart failure. Therefore, RAS blockade should be part of the antihypertensive regimen in CKD. Although sympatholytic drugs predictably will have additional value, this is less clear. A recent study showed that patients with CKD treated with RAS blockade showed better control of blood pressure and of renal function decline after addition of moxonidine compared to addition of nifedipine.⁹⁶ The strength of β -blockers in the prevention of coronary syndromes and heart failure is well appreciated in the general population with hypertension, yet their use is restricted to only 40% in patients with CKD and less than 20% in patients on hemodialysis.⁹⁷ This is difficult to understand since the mortality risk after myocardial infarction is extremely high in patients with renal disease. The mortality rate after MI is 14% and 21% in patients with moderate and advanced renal failure, respectively, and 30% with end-stage renal disease.⁹⁸

Several practical problems arise with respect to blood pressure control in ESRD. First, antihypertensive medication is withheld in approximately 60% of patients on the day of dialysis.⁹² Second, dietary sodium restriction, although seemingly trivial, often receives too little attention. This important measure requires careful explanation to the patient.⁹⁹

Since the introduction of specific, high-affinity angiotensin AT1-receptor antagonists (ATRA), the interesting notion

developed that under certain conditions, combined treatment with ATRA and ACE inhibitors may have outcomes exceeding those of either compound alone. Specifically, additional reduction in proteinuria has been shown in diabetic¹⁰⁰ and nondiabetic¹⁰¹ renal disease via RAS “double blockade” compared to ATRA or ACEi alone. Moreover, “double blockade” has been shown to be more effective as compared to single treatment in hypertensive diastolic heart failure¹⁰² and improved cardiac output in another study on heart failure.¹⁰³ It is not clear whether such effects are due to residual Ang II activity or caused by high local activity of the renin angiotensin system,¹⁰⁴ or are due to actions of angiotensin AT2 receptors.¹⁰⁵ With respect to ESRD, little information is available, however, a recent report indicated that double blockade led to further regression of LVH in type 2 diabetic patients who recently started hemodialysis, an effect that was independent of blood pressure.¹⁰⁶ Thus, current data support the use of combined ATRA and ACE inhibitor therapy to minimize proteinuria and to optimize cardiac function in heart failure; however, there is no clear indication for combined treatment to further reduce blood pressure.

What is the blood pressure target?

In CKD, the Kidney Disease Outcomes Quality Initiative recommends the guidelines of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure for patients with chronic renal failure (here defined as an estimated GFR <60 mL/min) and to reach less than 130/80 mmHg as target blood pressure.¹⁰⁷ The European Society of Hypertension Guidelines for Hypertension also recommends a target blood pressure of less than 130/80 mmHg in CKD and less than 125/75 mmHg if concomitant proteinuria of more than 1 g/L exists.¹⁰⁸

In dialysis patients, determination of target blood pressure is more complicated. In contrast to large actuarial studies, several studies in hemodialysis patients have indicated that elevated blood pressure is not associated with increased cardiovascular mortality.^{8,109} Investigators were urged to more precisely analyze this phenomenon; in effect, the absence of a relationship between blood pressure and mortality could be due to increased risk in patients with either low or high blood pressure. Indeed evidence for such a “J”-shaped relationship was derived from the observed increased cardiovascular (and noncardiovascular) mortality in dialysis patients with low predialysis blood pressure; predialysis hypertension was not associated with increased cardiovascular risk, although postdialysis hypertension was.⁸ Others reported a positive association between an increased predialysis mean arterial pressure (MAP) and LVH, and *de novo* cardiac failure and *de novo* ischemic heart disease, but also that a low MAP was associated with increased mortality.⁶⁰ A recent study could not couple this “reverse epidemiology” of low predialysis blood pressure to the malnutrition–inflammation syndrome.¹¹⁰

More recently, serious concerns have emerged about the “J”-shaped relationship between blood pressure and

mortality. One study showed that early mortality (3 to 4 years on dialysis) displayed a “U”-shaped relation with both low and high predialysis systolic and diastolic blood pressure; however, late mortality (>5 years) was associated with high blood pressures only.¹¹¹ Late more than early mortality was due to cardiovascular disease. Another study showed that hypertensive patients entering a dialysis program survived better when their systolic blood pressure was lowered to less than 160 mmHg, unless they also had ischemic heart disease.¹¹² The results of a large number of incident and prevalent cohorts were recently summarized. The incident cohorts seem to indicate that in dialysis populations with relatively little cardiovascular morbidity, hypertension presents itself as a risk factor. Inadequate designs may well have obscured the subgroup of patients with cardiac disease and other comorbidities; other problems with study design, such as erroneous measurements, lack of consideration of medication, inadequate sample size, and the presence of competing risk factors were also identified.¹¹³ The term “reverse epidemiology” can only be justified when relationships are studied with adequate (prospective) designs, and studying relationships at the end of a disease spectrum may be inherently incorrect.⁶²

In the absence of randomized controlled trials, recommendation of target blood pressure remains a matter of opinion. In agreement with recent expert reviews,^{57,113–116} it seems reasonable to divide ESRD hypertension into classic systolic–diastolic and isolated systolic hypertension categories. In case of systolic–diastolic hypertension, it is reasonable to pursue a target of 130/80 mmHg (post-dialysis measurement confirmed by ambulatory or home measurements). These patients will be younger or have a shorter history of renal disease, or have been better protected with antihypertensive medication. In case of preferential systolic hypertension, it is probably better to keep diastolic pressure between 80 to 90 mmHg, and

to accept systolic blood pressure levels between 150 to 160 mmHg, which concurs with the best prognosis in the “U” curve.¹¹² The latter patients will be older, have more LVH,⁸⁴ coronary insufficiency,⁶² and less compliant aorta.¹¹⁴ Further lowering of blood pressure in this group may lead to insufficient coronary perfusion in diastole.

Regarding the group with systolic hypertension, some specific points deserve attention. First, decreased aortic compliance often has a functional component induced by vasoconstrictor hyperactivity that can be eliminated by RAS blockade.⁸⁹ Therefore, we define systolic hypertension as systolic hypertension persisting despite RAS blockade. Second, overhasty blood pressure correction leading to dialysis instability or hypotension may well discourage doctor and patient from reaching optimal blood pressure control and should be avoided. Adaptations of large conduit vessels and smaller resistance vessels take time, as does whole-body autoregulation, and blood pressure correction after volume correction often follows a lag time.¹⁴ Slow and long dialysis is probably the best way to correct blood pressure in these patients. Third, and this cannot be sufficiently stressed, preventing this condition is paramount by starting very strict blood pressure control in the earliest possible stage of CKD.

SUMMARY

Hypertension in CKD and ESRD is a serious threat for cardiovascular complications. Nevertheless, blood pressure is frequently inadequately controlled in these groups. Using overactivity of the RAS and of the sympathetic nervous system and ECFV expansion as pathophysiologic background, blood pressure can and should be well controlled. Few studies have systematically investigated the efficacy of various treatment strategies. Furthermore, prospective studies are needed to further determine optimal blood pressure in the ESRD population.

Chapter
57Hypertension in Racial
and Ethnic Minorities

John M. Flack, Samar A. Nasser, Mark Britton, Anna B. Valina-Toth, Vineeta Ahooja, and Shannon M. O'Connor

Key Findings

- Although the prevalence of hypertension (HTN) differs among ethnic groups, there is little evidence that the relationship of blood pressure (BP) to target-organ injury differs substantively by race or ethnicity
- HTN control rates (<140/90 mmHg) are low among non-Hispanic blacks and non-Hispanic whites, and lowest among Mexican Americans. There is a high prevalence of treated but uncontrolled HTN in Asian Americans (33%), African Americans (35%), and Hispanics (32%) relative to Caucasians (24%). Less intensive antihypertensive pharmacologic treatment likely contributes to the lower BP control rates in African Americans compared to whites.
- There are insufficient data to support the thesis of the existence of unique risk factors for HTN across ethnic groups. However, some risk factors confer quantitatively different risks for HTN in various ethnic groups, in part, because the most pervasive risk factors for HTN—obesity, physical inactivity, dietary excesses/deficiencies—occur variably across racial and ethnic groups. The distribution of these risk factors is not homogenous within racial/ethnic groups as prevalence gradients have been noted across geographic and socioeconomic strata.
- Obesity contributes significantly to HTN risk in all populations and particularly in most racial and ethnic minorities manifesting disproportionate obesity. Obesity also appears to be an important mediator of chronic renal injury. In any population, weight loss and increased physical activity as well as potassium-rich, calcium-rich, and low-sodium diets should favor lower BP levels. An essential component of any HTN treatment regimen or HTN prevention strategy is comprehensive lifestyle modification to the greatest degree possible.
- The use of immutable characteristics to guide therapy for all members of various race/ethnicity groups will occur less frequently as we identify informative hemodynamic, genetic, and vascular markers that vary at the level of the individual.

Hypertension (HTN) is one of the most important and pervasive risk factors for virtually all forms of cardiovascular-renal disease. Although the prevalence of HTN differs among ethnic groups, there is little evidence that the relationship of blood pressure (BP) to target-organ injury differs substantively by race or ethnicity. This *assertion* is important for most non-African American and non-white populations because of the scarcity of longitudinal clinical trial outcomes

data for these groups. Throughout this chapter, non-Hispanic whites will be used as a reference group for racial/ethnic contrasts of epidemiology, BP control, pathogenesis, pressure-related target-organ injury, and treatment outcomes.

EPIDEMIOLOGY

African Americans

The age-adjusted prevalence of HTN in the U.S. population aged 18 years and older is 28.7%. Non-Hispanic blacks have the highest HTN prevalence (33.5%), non-Hispanic whites are intermediate (28.9%), and Mexican Americans have the lowest at 20.7%. The excess prevalence of HTN in non-Hispanic blacks compared to whites is smaller in men (30.9% vs. 27.7%) than in women (35.8% vs. 30.2%). Over the last decade, HTN incidence and prevalence have risen in the major race/ethnicity groups, with the largest increases among women. Interestingly, adults in Spain, Germany, and Finland all have higher age-adjusted HTN prevalence than non-Hispanic blacks, while Nigerians have much lower HTN prevalence rates than U.S. whites.¹ One likely contributor to the lower prevalence of HTN is the much lower prevalence of obesity in Nigerians compared to either whites or African Americans in the United States.

Hispanic Americans

Hispanics are now the largest minority group in the United States. Even though the overall prevalence of HTN among Mexican Americans was similar in the 1982–1984 (Hispanic Health and Nutrition Examination Survey [HHANES]) and the 1988–1991 (NHANES III) timeframe, a slight reduction in population HTN burden (except among men aged 40 to 49 years) is suggested.²

Asian Americans

Asian Americans represent 4% of the U.S. population, although this percentage will increase to 9% by 2050.³ In 2000, Kim and colleagues reported that the age-adjusted prevalence of HTN was 32% in Koreans, a burden that was higher than the prevalence of HTN in the general American population (24%). Hypertension was also more common among men (35%) than women (30%).⁴ In the Multi-Ethnic Study of Atherosclerosis (MESA), the age-adjusted prevalence of HTN in Asian-American (Chinese) was 39%, which was similar to that of Caucasians (38%) and Hispanics (42%), but less than in African Americans (60%).⁵

Native Americans

Hypertension was relatively uncommon in the Native-American population until recently. The prevalence of HTN in Navajo Indians aged 19 years and older rose from 0.1% in 1937 to 4.7% in 1963.⁶ By 1973, 20% of Papago (Tohono Oodham) Indians aged 15 years and older had HTN,⁷ and by 1979 the prevalence of HTN in Navajo Indians aged 19 and older living on reservations was 17%.⁶ However, the mean systolic and diastolic blood pressures in Navajo Indians did not show as great an increase with age as was seen in white and black Americans.

In 1991, 704 Cree and Ojibwa Indians ages 20 to 64 were surveyed in Canada, and only 27% had HTN. The Inter-Tribal Heart Project examined Chippewa and Menominee Indians over the age of 25 years, who were active users of the Indian Health Service clinics, and documented a 31% prevalence of HTN.⁸ This high incidence of HTN among Native Americans was confirmed in the Strong Heart Study (SHS), the largest epidemiologic study of American Indians ever undertaken. The SHS data reported a HTN prevalence of 27% to 56% in both men and women aged 45 to 75 years.⁹

BLOOD PRESSURE AWARENESS, TREATMENT, AND CONTROL

Awareness

Over the past two decades, the number of Americans aware of their HTN has increased. In the NHANES III, HTN awareness was greater among non-Hispanic blacks (74%) and non-Hispanic whites (70%) compared to the Mexican American population (54%). Hispanic women are more aware of their HTN than men.¹⁰

Treatment

In the NHANES III (1999–2000), HTN pharmacologic treatment rates increased by 6.0% ($p=0.007$) between 1988 and 2000. The age-adjusted treatment rate was 63% for non-Hispanic blacks, 60.1% for non-Hispanic whites, and 40.3% for Mexican Americans.¹¹ There are, however, somewhat troubling data that hypertensive African Americans are less intensely treated than hypertensive whites. This occurs despite the fact that HTN is more severe and accompanied by more factors that confer resistance to the BP-lowering effects of pharmacologic treatment than in any other racial/ethnic group. Accordingly, in the Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),¹² African Americans, women, and older participants had lower BP control rates, and were less intensively treated than their comparator groups. The relatively high prevalence of nonbiomedical expectations (i.e., treatment can cure hypertension) in African Americans with HTN¹³ also likely undermines good BP control.

In the Inter-Tribal Heart Project only 58% of hypertensive Indians took antihypertensive medication.⁸ Fewer than 50% of Asian Americans with HTN were pharmacologically treated. Factors that may contribute to the low frequency of antihypertensive medication use and control of BP in the Asian-American population include inadequate

understanding of medications used, economic difficulties, limited health care access, transportation issues, and lack of health insurance.¹⁴

Control

Hypertension control rates (<140/90 mmHg) are highest among non-Hispanic blacks and non-Hispanic whites, and lowest among Mexican Americans (25%, 24%, and 14%, respectively). Non-Hispanic black women have the highest levels of HTN awareness, treatment, and control (79%, 65%, and 29%, respectively). There is a high prevalence of treated but uncontrolled HTN in Asian Americans (33%), African Americans (35%), and Hispanics (32%) relative to Caucasians (24%).⁵ Accordingly, in ALLHAT the largest difference in BP control was found in the black/nonblack group comparison, where blacks were 31% less likely to be controlled (odds ratio=0.69, 95% confidence interval [CI]=0.65–0.73) than nonblacks. Furthermore, between baseline and year 5, the highest control rate was in nonblack men (70.0%), while the lowest control rate was in black women (58.8%).¹² However, less intensive antihypertensive pharmacologic treatment likely contributes to the lower BP control rates in African Americans compared to whites.¹⁵ Approximately 14% of Asian Americans appear to attain BP control with medication alone.¹⁴ According to the Inter-Tribal Heart Project, of Indians who were hypertensive only 28% had blood pressures below recommended levels.⁸

PATHOPHYSIOLOGY

There are insufficient data to support the thesis of the existence of unique risk factors for HTN across ethnic groups. It is, however, accurate to say that some risk factors confer quantitatively different risks for HTN in various ethnic groups, in part, because the most pervasive risk factors for HTN—obesity, physical inactivity, dietary excesses/deficiencies—occur variably across racial/ethnic groups. Nevertheless, the distribution of these risk factors is not homogenous within racial/ethnic groups, as prevalence gradients have been noted across geographic and socioeconomic strata. Accordingly, some pathophysiologic mechanisms are sometimes more or less manifest in racial/ethnic groups. However, these are quantitative rather than qualitative differences. The subsequently discussed pathophysiologic perturbations are unlikely to be solely confined to any race/ethnicity group.

Obesity

Obesity is more common in both African Americans and Hispanics, particularly among women, compared to whites.¹⁶ In African-American women the prevalence of extreme obesity (body mass index [BMI] >40 kg/m²) is almost 1 in 6, a prevalence that is three- to four-fold higher than that of either white or Hispanic women. There are marked ethnic and age-based differences in the rates of weight accumulation. Relative to white women (reference group), the onset of obesity was faster for African-American women and Hispanic women. Hispanic men also develop obesity at earlier ages than white men. After age 28, African-American men develop obesity more rapidly than white men.

Hayashi et al.¹⁷ showed that visceral fat is an independent risk factor for the development of HTN in Japanese Americans. Additionally, high BP correlates well with obesity even in elderly Japanese Americans.¹⁸ Obesity is also strongly associated with HTN in Native-American men and women. The increasing prevalence of obesity is of serious concern, particularly in young Native Americans. In 1992, a high proportion of Navajo adolescents were found to be overweight (33% of girls and 25% of boys).^{19,20} In Native Americans, increasing BMI has been linked to higher systolic blood pressure (SBP) and diastolic blood pressure (DBP) in both boys and girls.¹⁹

Physical inactivity

Physical activity levels tend to decrease with advancing age and are also lower in women than men as well as in persons with lower levels of income and education. African-American women experience greater age-related decreases in the cross-sectional prevalence of physical activity than white women. Independent of social class, the prevalence of “no leisure-time physical activity” was much higher in non-Hispanic black men (24%) and black women (40%) compared to non-Hispanic white men (13%) and white women (23%).^{21,22} Another study found that fewer than half of Asian and Pacific Islander women (42.6%) were sedentary, compared to 36.1% of white non-Hispanic women.²³

MECHANISMS OF HYPERTENSION

Obesity

In all likelihood, obesity contributes significantly to HTN risk in all populations and particularly in most racial/ethnic minorities manifesting disproportionate obesity. Figure 57–1 displays a schematic that depicts how the myriad of metabolic, neurohumoral, and hemodynamic perturbations linked to obesity influence BP levels. There is a multiplicity of obesity-related physiologic effects that contribute to the intermediate BP phenotype, salt sensitivity,^{24,25} as well as resistance to hypertensive drug therapy.^{12,26} Additionally, obesity appears to be a plausible mediator of chronic renal injury.²⁷ Box 57–1 displays the known hemodynamic effects of obesity.

Physical activity

Physical activity lowers BP in hypertensive persons.^{28,29} It is unlikely that the reduction of BP is race/ethnicity-specific. Physical activity improves endothelial function, primarily via the augmented release of nitric oxide (NO), less NO destruction attributable to lower levels of oxidative stress,^{30–32} and greater release from the vascular endothelium. Renal sodium excretion also appears to increase after physical activity. Aerobic exercise reduces inflammation in persons with diabetes via augmentation of the cytoplasmic inhibitor of nuclear factor kappa beta (NF- κ B), leading to decreased

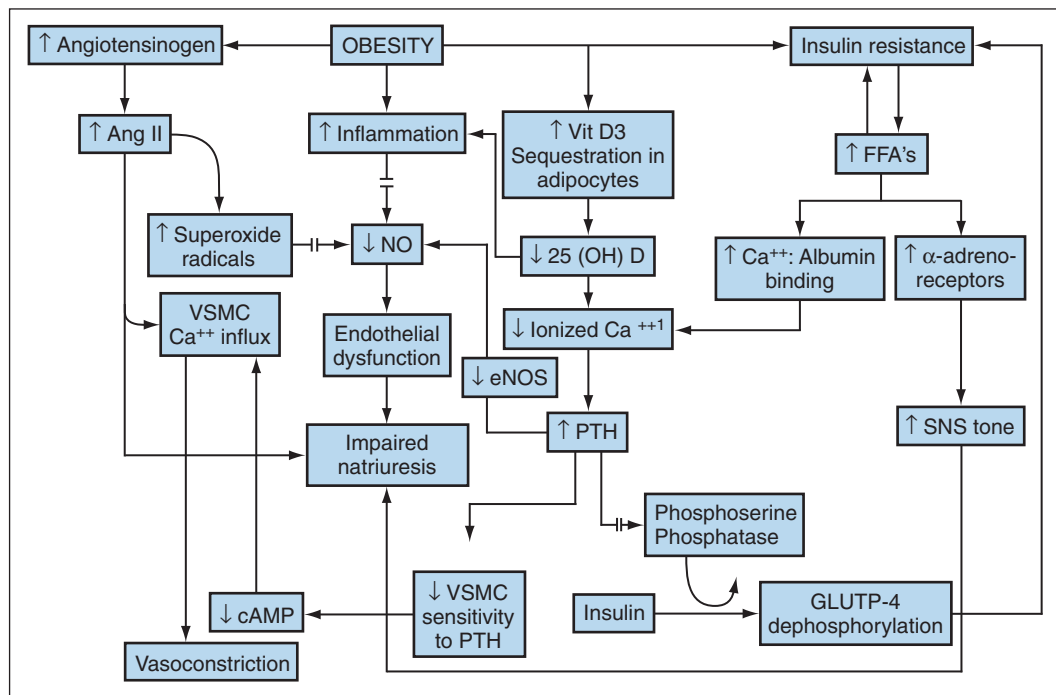

Figure 57–1. This figure provides an integrated schema for how obesity affects the renin-angiotensin system, nitric oxide synthesis, vitamin D, calcium, and PTH metabolism as well as insulin resistance. Persistently high PTH levels antagonize phosphoserine phosphatase, an enzyme that dephosphorylates GLUTP-4, rendering it an ineffective transporter of glucose across the cell membrane.¹ High dietary intake of sodium also promotes calciuria and plausibly contributes to lower circulating ionized calcium levels. Ang II, angiotensin II; FFAs, free fatty acids; Ca⁺⁺, calcium; cAMP, cyclic adenosine 3',5' monophosphate; eNOS, endothelial nitric oxide; GLUTP-4, glucose transporter 4; NO, nitric oxide; PTH, parathyroid hormone; SNS, sympathetic nervous system; VSMC, vascular smooth muscle cell.

 Exaggerated diuresis and ↑ blood pressure after dietary sodium loading to maintain intravascular volume homeostasis

NF- κ B activity and tumor necrosis factor alpha, an inflammatory cytokine.³³

Diet

Long-term dietary patterns plausibly impact long-term trends in BP. Dietary sodium intake raises BP, at least in susceptible people, in the short term. There is also evidence that dietary sodium intake augments vascular angiotensin generation,³⁴ while in salt-sensitive persons, it reduces urinary NO metabolites.³⁵ Sodium also enhances urinary calcium excretion and may therefore contribute to reductions in ionized calcium that can upregulate parathyroid hormone (PTH) secretion (see Figures 57-2 and 57-3).

Dietary potassium intake has been shown to enhance renal natriuresis as well as to augment NO production. Increased dietary potassium intake has been shown to modestly lower BP as well as to augment the nocturnal fall in BP. Recent data documented that dietary potassium intake prevented the sodium-induced increase in circulating asymmetrical dimethyl arginine (ADMA), a known inhibitor of nitric oxide synthesis.³⁶

African Americans consume less dietary calcium than whites, in part because of a much higher prevalence of lactose intolerance leading to lower consumption of calcium-rich dairy products. Lower dietary intake of calcium has been linked to HTN in African Americans. Calcium supplementation modestly lowers BP. It is, however, plausible to speculate that in persons at risk for vitamin D deficiency that low dietary calcium intake would further augment the physiologic signal to raise PTH levels (see Figures 57-2 and 57-3).

Thus, in any population, potassium-rich, calcium-rich, and low-sodium diets should favor lower BP levels. This type of diet would be rich in fresh fruits, vegetables, and dairy products, while simultaneously low in sodium.

Impaired diurnal blood pressure variability

Nocturnal BP levels are independently associated with end-organ damage, over and above the risk associated with daytime values. The attenuation of, or lack of, a nocturnal fall (nondipping) of BP has been associated with serious end-organ damage/dysfunction, such as left ventricular hypertrophy, microalbuminuria, cerebrovascular disease, more rapid loss of kidney function, and increased risk for heart failure.³⁷⁻⁴² Nocturnal decline in BP (daytime–nighttime difference) is approximately 10% to 20%. Obesity has been linked to nondipping of BP, and thus poses a plausible risk for end-organ damage via hemodynamic effects.⁴³ Furthermore, obesity is a risk factor for premature birth, which in turn, is a risk factor for elevated BP, decreased nephron number, and diabetes later in life.^{44,45}

Hypovitaminosis D and secondary hyperparathyroidism

Vitamin D levels are maintained within the physiologic range, largely by conversion of 7-dehydrocholesterol to vitamin D₃ after exposure to ultraviolet light. Figure 57-2 provides an overview of vitamin D metabolism. Dietary sources of vitamin D include fatty fish and fortified milk, although they are less important than exposure to ultraviolet light. In the United States, the prevalence of hypovitaminosis D (<37.5 nmol/L) is significantly more prevalent in African Americans than whites (42.4% vs. 4.2%).⁴⁶ A multiplicity of factors influences the striking excess preva-

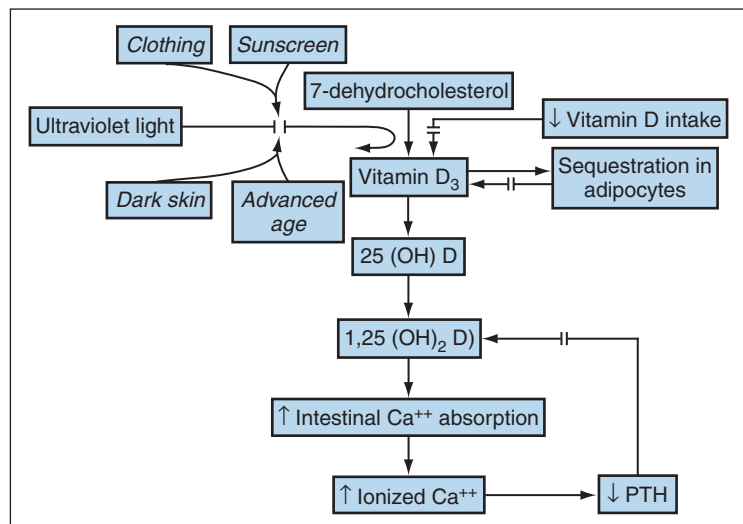

Figure 57-2. A simplified schematic of vitamin D metabolism is presented. Important factors that block the conversion of 7-dehydrocholesterol to vitamin D₃ are prominently displayed. Dark skin is an important factor in the high rates of hypovitaminosis D in African Americans and other dark-skinned populations. (Adapted in part from Yanoff LB, Parikh SJ, Spitalnik A, et al. The prevalence of hypovitaminosis D and secondary hyperparathyroidism in black Americans. *Clin Endocrinol* 2006;64:523; Liel Y, Ulmer E, Shary J, et al. Low circulating vitamin D in obesity. *Calcif Tissue Int* 1988;43:199; and Lips P. Vitamin D physiology. *J Prog Biophys Mol Biol* 2006;92:4.)

lence of hypovitaminosis D in African Americans than whites, including darker skin, higher prevalence of chronic kidney disease, and possibly more pervasive obesity.⁴⁷ However, the inverse relationship between body fat and 25(OH)D levels appears to be significantly more robust in white women compared to African-American women.⁴⁸ Vitamin D production in the skin in response to ultraviolet light is normal in obese persons; however, the significantly enhanced sequestration of vitamin D in adipocytes leads to reduced circulating levels.⁴⁹

It is quite plausible that the physiologic perturbations caused by hypovitaminosis D are initiated by a transient fall in ionized calcium and lead to a reactive rise in PTH that maintains serum calcium levels within the physiologic range. Serum PTH levels begin to rise at 25(OH)D levels that are well above (~75 nmol/L) the deficiency threshold (<37.5 to 50 nmol/L). In a recent study of free-living African Americans living in the Washington, D.C. area, there was a high prevalence of hypovitaminosis D and secondary hyperparathyroidism; among individuals with BMI >35 kg/m², the prevalence of was 35.2% in African Americans and 9.7% in whites.⁴⁷ Intact PTH levels are also negatively correlated with vitamin D levels. Figure 57–3 displays the vascular and target-organ effects of PTH. These data suggest that hypovitaminosis D and secondary hyperparathyroidism are indeed highly prevalent in free-living African Americans, have biological effects that adversely affect vascular function and raise BP, and may be an important determinant in the burden of HTN and thus racial/ethnic disparities in the same. Accordingly, several studies have

shown reductions in BP in humans with elevated BP after supplementation with vitamin D^{50,51} with a significant correlation between reduction in SBP and decline in serum PTH.⁵⁰

Salt sensitivity

Salt sensitivity can be conceptualized as maintenance of intravascular volume homeostasis at the expense of higher blood pressure levels that augment pressure-induced renal natriuresis. Thus, in salt-sensitive persons consuming unrestricted amounts of sodium, steady state in–out volume homeostasis is maintained by raising BP, or, in drug-treated salt-sensitive hypertensives, the fall in BP is attenuated unless sodium intake is decreased. The sodium-linked attenuation of the BP-lowering effect varies by class of antihypertensive agent. Dietary sodium-induced attenuation of BP-lowering responsiveness appears to be greatest for angiotensin-converting enzyme (ACE) inhibitors (and possibly other renin-angiotensin system [RAS] antagonists) than for calcium antagonists^{52,53} or diuretics.⁵² Overall, salt sensitivity has also been linked to antihypertensive treatment resistance, target-organ injury, and nondipping of BP. Figure 57–4 displays a proposed mechanistic explanation for why salt-sensitivity undermines BP lowering in drug-treated hypertensives consuming a sodium-replete diet.

Multiple factors contribute to salt sensitivity including obesity,^{54,55} NO deficient states,^{56,57} psychosocial stressors,⁵⁸ low intake of dietary potassium,^{59,60} advancing age, and reduced renal mass. Salt sensitivity has been documented in virtually every ethnic population that has been tested

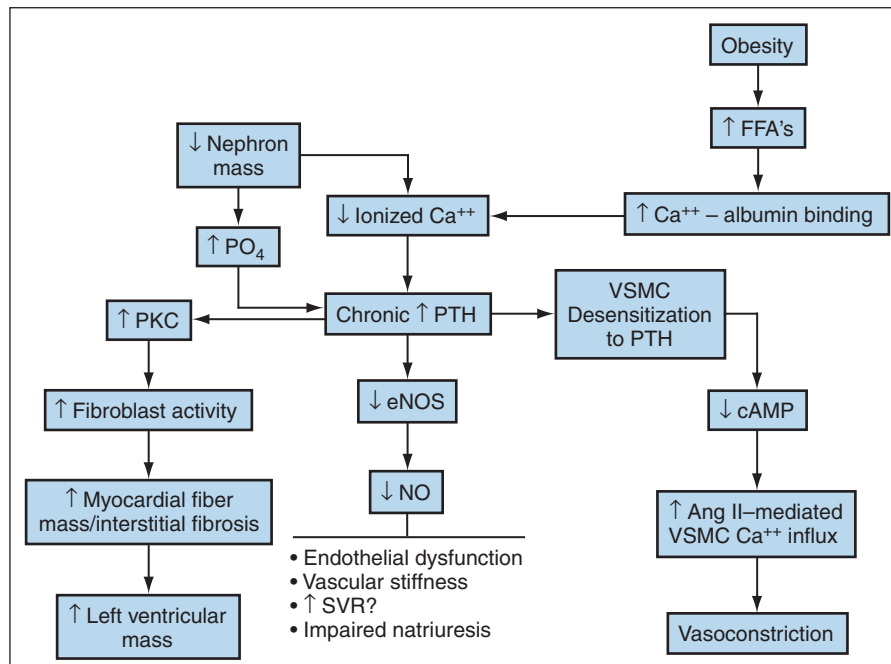

Figure 57–3. This figure displays the vascular and target-organ effects of parathyroid hormone. These effects will raise blood pressure and contribute to vascular injury/dysfunction and target-organ damage. Ang II, angiotensin II; Ca⁺⁺, calcium; cAMP, cyclic adenosine 3',5'-monophosphate; eNOS, endothelial nitric oxide synthase; FFAs, free fatty acids; PO₄, phosphate; NO, nitric oxide; PKC, protein kinase C; PTH, parathyroid hormone; VSMC, vascular smooth muscle cell.

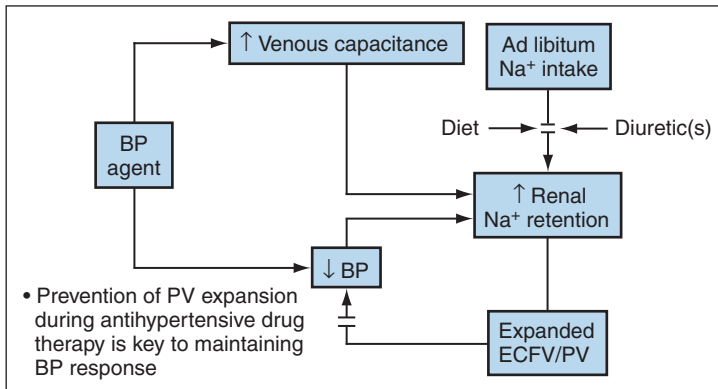

Figure 57–4. This figure displays a proposed mechanism through which antihypertensive drugs that expand venous capacitance (e.g., angiotensin-converting enzyme inhibitors) induce salt sensitivity. These agents expand venous capacitance, and therefore decentralize blood volume. In hypertensive (and obese) patients, venous capacitance vessels are constricted. When BP falls and venous capacitance expands, and blood volume is decentralized, renal sodium excretion increases. Sodium retention continues until the vascular system is “full” again. This expansion of extracellular fluid volume/plasma volume leads to diminution of the fall in BP unless the patient is given a diuretic and/or sodium intake is restricted to levels low enough to prevent plasma volume expansion. BP, blood pressure; ECFV, extracellular fluid volume; PV, plasma volume.

for it. Accordingly, African Americans,^{61–63} whites,^{53,64} Spaniards,^{53,65} Caribbean Hispanics,⁵² Venezuelans,^{66,67} and Japanese^{68,69} manifest salt sensitivity. And, although salt sensitivity has been found in both hypertensives and normotensives, the prevalence is usually higher in the former.^{64,70,71} Moreover, salt sensitivity has often been found to be more prevalent in African Americans than in whites.^{64,70,71}

Vascular function

Endothelium-dependent and endothelium-independent vascular responses have consistently been more abnormal in African Americans compared to whites.^{72,73} There are data suggesting that bioavailable NO, the main determinant of endothelium-dependent vascular function, is lower in African Americans than whites, despite much higher levels of eNOS activity in the former.⁷⁴ It appears that the synthesis of oxygen radicals, mostly via uncoupled eNOS and lesser amounts via NADPH oxidase, raises levels of oxidative stress, accelerates NO destruction, and therefore leads to reduced NO bioavailability in African Americans.⁷⁴

Endothelial dysfunction was linked to obesity in Hispanic women but not men who resided in northern Manhattan.⁷⁵ Impaired endothelial vasodilator function has also been linked to an exaggerated postexercise rise in blood pressure.⁷⁶ There are mixed data in regard to whether peripheral vascular resistance is higher in African Americans than whites.

Stress and hypertension

It has plausibly been speculated that persistent stress beyond the short term contributes to BP elevations.⁷⁷ Mental stress unequivocally raises BP in the short term, at least in part, via activation of the sympathetic nervous system. The

stress and HTN hypothesis may be of particular relevance to populations exposed chronically to persistently high environmental and psychosocial stressors. Although this thesis has not been proven, it is intuitively appealing and is under active investigation. Importantly, acute psychosocial stress (and increased SNS activity) activates NF- κ B, an inflammatory transcription factor, that, in turn activates inflammatory cytokines as well as the hypothalamic-pituitary-adrenal axis.^{78–81} The interrelation of the HPA, SNS, and NF- κ B/inflammatory cytokines is displayed in Figure 57–5. NF- κ B provides an important physiologic pathway through which high levels of stress that are characteristic of Western lifestyles, and especially in African Americans and other racial minorities, might contribute to systemic inflammation, oxidative stress, and vascular/hemodynamic perturbations such as endothelial dysfunction and elevated BP.

PRESSURE-RELATED TARGET-ORGAN INJURY

Albuminuria, chronic kidney disease, left ventricular hypertrophy, stroke, and heart failure predict an attenuated response to antihypertensive treatment.^{15,82} One such example is microalbuminuria, which is associated with cardiovascular risk factors and is considered a marker for “resistance” to antihypertensive treatment.^{15,83,84} Patients with microalbuminuria appear to progress more rapidly along the renal continuum to chronic kidney disease (CKD) (indicated by macroalbuminuria or proteinuria), increased serum creatinine concentration, and decreased GFR. With progressive CKD, single-nephron glomerular pressure increases, eventually leading to glomerulosclerosis.⁸⁵ In patients with early nephropathy, serum creatinine concentration and creatinine clearance is within normal limits, but microalbuminuria—the earliest clinical sign of nephropathy—is already present.⁸⁶ Mattix et al.⁸⁷ examined the distribution of urine albumin and creatinine concentrations measured in spot urine specimens in a nationally representative sample of men and women of various ethnicities. Overall, compared with non-Hispanic whites, non-Hispanic blacks had higher urinary albumin concentrations (21.4 vs. 13.6 μ g/mL, $p < 0.0001$). Mexican Americans did not have significantly different urine albumin concentrations compared with non-Hispanic whites. In this study, non-Hispanic black ethnicity remained independently associated with microalbuminuria even after adjusting for other risk factors, including age, diabetes, systolic and diastolic blood pressure, BMI, and smoking.

An additional detrimental consequence of pressure-related target-organ damage concerns the vascular tree. Arterial stiffness is similar to a double-edged sword, in that it is a cardiovascular disease (CVD) risk factor in itself, as well as a deleterious outcome of various diseases. Hypertension or increased luminal pressure stimulates excessive collagen production.⁸⁸ Furthermore, advanced glycation end-

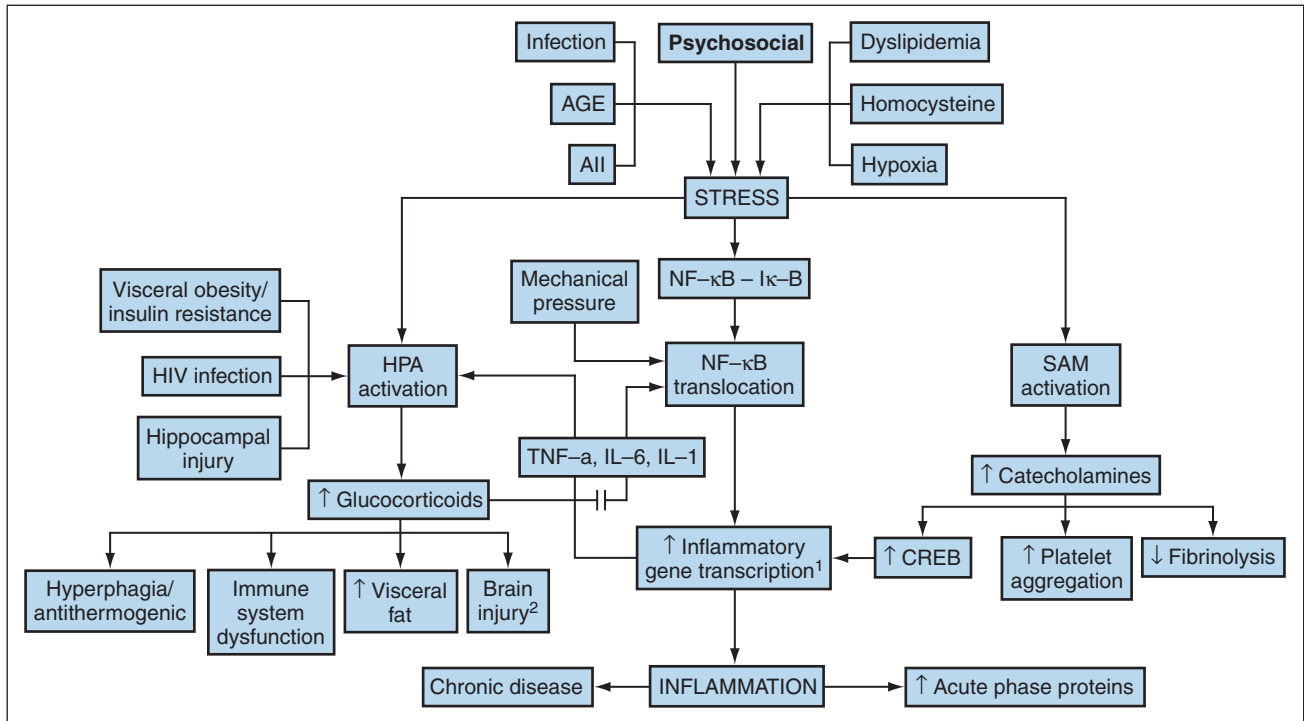

Figure 57-5. This schematic displays how a variety of stressors, including psychosocial stress, can activate NF- κ B, causing separation from its cytoplasmic inhibitor, I κ -B. Once NF- κ B translocates to the nucleus, it can turn on inflammatory cytokines with NF- κ B response elements. This leads to further upregulation of the hypothalamic-pituitary-adrenal axis. Increased glucocorticoids exert a mineralocorticoid effect and promote visceral fat deposition. Activation of the sympathetic nervous system also facilitates upregulation of inflammatory gene transcription. The net result is increased inflammation and oxidative stress. This will lead to decreased nitric oxide bioavailability. Thus, a plausible mechanism exists through which psychosocial stressors might plausibly cause chronic disease including hypertension. AGE, advanced glycation end products; All, angiotensin II; CREB, cyclic AMP response element binding protein; HPA, hypothalamic-pituitary-adrenal axis; I κ -B, inhibitor kappa beta, an inhibitor of NF- κ B; NF- κ B, nuclear factor kappa beta; SAM, sympathetic adrenal medullary. ¹TNF- α , IL-1, IL-2, IL-6, interferon gamma, vascular cell adhesion molecule (VCAM)1, plasminogen activator inhibitor (PAI)-1, cyclooxygenase 2 (COX2), iNOS, and transforming growth factor (TGF) β . ²Hippocampal atrophy and damage to frontal lobe neurons. 3C-reactive protein (CRP), fibrinogen, and cell adhesion molecules. products (AGEs), which result from nonenzymatic protein glycation, form irreversible cross-links between these collagen proteins.⁸⁹ AGE may also affect endothelial cell function by inhibiting the bioavailability of NO.⁹⁰ The ability of the vascular endothelium to release NO in response to pulsatile blood flow during the cardiac cycle correlates inversely to the magnitude of arterial stiffness.

Pressure-induced target-organ damage and mortality are higher among African Americans than among white persons.⁹¹ For example, compared to whites, African Americans have increased risk of many complications, including nonfatal stroke (1.3-fold), fatal stroke (1.8-fold), and end-stage renal disease (4.2-fold).⁹² While African Americans have approximately twice the risk of first-ever stroke and a 1.8 times greater rate of fatal stroke, whites fare better than both Hispanics and African Americans, according to results of the Northern Manhattan Study.⁹³

Asian Americans are believed to have a substantially lower mortality rate of CVD than African Americans. In addition, Asian Americans have a lower mortality rate from

cerebrovascular disease in comparison to African Americans, but it is higher when compared to Caucasians.^{94,95} Fang et al.⁹⁶ demonstrated that Asian Americans with a risk factor such as HTN were more likely to experience a lethal hemorrhagic stroke in comparison to Caucasians.⁹⁶ The prevalence of end-stage renal disease and other hypertension-related diseases are rising in the Asian-American population.⁹⁷ The cerebrovascular disease mortality rate is declining more rapidly in the general U.S. population than among Native Americans.

HYPERTENSION CLINICAL ENDPOINT STUDIES

AASK

Data from the African American Study of Kidney Disease (AASK)⁹⁸ confirmed that initial therapy with ramipril, an ACE inhibitor, slowed the progressive loss of kidney function, and lowered urinary protein excretion more

effectively than amlodipine, a dihydropyridine calcium antagonist, in nondiabetic African Americans with depressed kidney function. There was a difference of less than 2 mmHg in blood pressure between the randomized treatment groups; both groups received the same number (mean 2.75) of antihypertensive drugs. The renoprotective effect of ACE inhibitors was most evident in patients with proteinuria. The AASK study confirmed the superiority of RAS system drugs in African Americans with nondiabetic kidney disease, as had previously been shown in non-African Americans with nondiabetic kidney disease.

ALLHAT

The Antihypertensive and Lipid-lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was a 5-year clinical endpoint trial in high-risk hypertensives that sought to compare the effectiveness of various initial antihypertensive drug therapies for the prevention of CVD and overall mortality. The final study report was on 33,357 high-risk, stage-1 and -2 hypertensives aged 55 years and older with at least one other cardiovascular risk factor.^{99,100} Eligible participants were randomized to chlorthalidone, amlodipine, or lisinopril, and were assigned a target BP of less than 140/90 mmHg. The primary outcome was the composite of fatal coronary heart disease and nonfatal myocardial infarction. In all three treatment arms, BP reductions in whites exceeded those of African Americans.¹⁰⁰ In African Americans relative to whites in the lisinopril group, the deficit in SBP response was -8.2, -6.8, and -4.9 mmHg lower, respectively, at the end of study years 1, 2, and 4. Achieving BP control at less than 140/90 mmHg was also higher in whites than African Americans in all randomized treatment arms. Over the course of the trial, SBP in African Americans was lowered ~1.5 to 2 mmHg more in the chlorthalidone compared to amlodipine treatment group. At baseline, 26% to 28% of BP levels in the randomized treatment groups were less than 140/90 mmHg. At year 4, control rates in the chlorthalidone, amlodipine, and lisinopril treatment arms were 63.4% versus 68.9%, 60.2% versus 68.6%, and 54.2% versus 67.4%, respectively. There were no differences among African-American ALLHAT participants randomized to the chlorthalidone and amlodipine treatment arms in the primary study endpoint or in any of the secondary outcomes. However, in the lisinopril compared to the chlorthalidone groups, African Americans experienced excess stroke (+40%) and combined CVD (+19%). Higher average blood pressure levels in the lisinopril group undoubtedly explained at least part of the excess risk.

INVEST

The International Verapamil sustained release/Trandolapril Study (INVEST) was a prospective, randomized, blinded endpoint study in patients with coronary artery disease and hypertension.¹⁰¹ Study participants were randomized to either verapamil sustained release (SR), a rate-lowering calcium antagonist, or atenolol, a beta-blocker. A post-hoc analysis of 8045 Hispanic participants was made in comparison to 14,531 non-Hispanic participants. Treatment with either a verapamil SR or atenolol resulted in greater BP control in Hispanic compared to non-Hispanic partici-

pants. Hispanics were at significantly lower risk of experiencing a nonfatal myocardial infarction, nonfatal stroke, or death (hazard ratio [HR] 0.87, 95% CI=0.78–0.97) than non-Hispanics. Hispanic ethnicity was associated with a greater risk (HR=1.19, 95% CI=1.04–1.36) of new-onset diabetes. Randomization to the verapamil SR was associated with a decrease (HR=0.85, 95% CI=0.76–0.95) in the risk of new-onset diabetes. In Hispanic participants randomized to atenolol treatment, higher doses of atenolol and hydrochlorothiazide were associated with a higher risk of new-onset diabetes.

LIFE

A post-hoc analysis stratified by race/ethnicity of the Losartan Intervention for Endpoint Reduction (LIFE) trial¹⁰² that enrolled hypertensives with left ventricular hypertrophy demonstrated that African Americans and whites experienced virtually identical levels of BP lowering. Nevertheless, in whites, losartan, an angiotensin receptor blocker, was superior to atenolol, a beta-blocker, in reducing the risk for the primary composite endpoint (cardiovascular death, stroke, myocardial infarction). Conversely, in African Americans atenolol was superior to losartan. There is no plausible explanation for these divergent results.

TREATMENT

Lifestyle modification

An essential component of any HTN treatment regimen or HTN prevention strategy is comprehensive lifestyle modification to the greatest degree possible. Dietary sodium intake to ~2 g/day or less, increased dietary potassium and calcium intake, avoidance of obesity, weight loss if already obese, and regular aerobic exercise (if feasible and appropriate) will lower blood pressure. In addition, these lifestyle changes will reduce antihypertensive medication requirements or allow attainment of lower blood pressure levels at any given dose of antihypertensive medication(s). Dietary practices not only vary among racial/ethnic groups, but vary substantially within these same groups along education, income, and geographic strata. Lifestyle modifications will likely vary more than pharmacologic therapeutic choices across ethnic groups due to different dietary preferences and prevailing cultural influences.

Pharmacologic treatment

There are several published HTN guidelines that provide guidance to practitioners regarding evidence-based therapeutic approaches.^{103–105} Clearly there are differences in response to antihypertensive drugs by race/ethnicity. Nevertheless, as we¹⁰⁶ and Sehgal¹⁰⁷ have emphasized, the largest source of variation in blood pressure response, for example, to ACE inhibitors is within racial groups not between them. Furthermore, clinical trials showing these same differences have also highlighted that when treated with any single drug, the majority of hypertensives of all races/ethnicities tend to remain above the most conservative JNC 7 systolic blood pressure goal (<140 mmHg). Accordingly, drug therapy with multiple antihypertensive agents will be necessary to

control BP. When multiple drugs are used, especially when the regimen contains either a diuretic or a calcium antagonist, racial/ethnic differences in response disappear. Thus, a major recommendation would be to avoid the use of race/ethnicity as the sole, or even major, criterion when selecting antihypertensive drugs. Of course, when a hypertensive patient of any race/ethnicity has an indication for a given antihypertensive drug class, by all means include an agent from that class in the antihypertensive regimen. A good rule of thumb is that when more than two antihypertensive drugs have been prescribed, at least one of them should be a diuretic appropriate to the level of kidney function. And, in some instances, one diuretic will not be enough to combat the expansion of the plasma volume caused by enhanced renal sodium reabsorption from drug-induced expansion of venous capacitance and subsequent fall in blood pressure.

Special considerations

The use of ACE inhibitors has been associated with a several-fold higher risk of angioedema in African Americans than in whites.¹⁰⁸ Nevertheless, until there are more individualized ways to determine who is at risk, it seems prudent to implement heightened vigilance in African Americans regarding angioedema, some of which may present only with cutaneous manifestations.

Most racial/ethnic minorities in the United States have a heightened risk of diabetes mellitus. The overwhelming preponderance of clinical trial data strongly infers that most of the risk reduction attributable to antihypertensive drug therapy is not class-specific. Many hypertensive patients who are racial/ethnic minorities will manifest either impaired fasting glucose or abnormal glucose tolerance. Thiazide diuretics¹⁰⁹ and beta-blockers increase the likelihood of developing diabetes. If diuretics are used, it is highly advisable to block the renin-angiotensin system with either an ACE inhibitor or an ARB to minimize the risk of diuretic-induced hypokalemia and worsening glucose tolerance. Renin-angiotensin system blockade has been shown to attenuate the diuretic-associated risk for diabetes mellitus. Alternatively, anchoring the antihypertensive regimen with a calcium antagonist or perhaps an aldosterone antagonist if kidney function is not depressed, is a reasonable strategy that provides a high likelihood of blood pressure control while avoiding impairment of glucose metabolism. Renin-

angiotensin system blockade has been associated with a 14% to 34% reduction in new-onset diabetes.¹¹⁰ Although the significance of this observation has been questioned, it seems reasonable to consider protection against diabetes as a desirable drug characteristic in diabetes-prone populations.

Treatment status of other cardiovascular risk factors such as dyslipidemia can influence BP responses and the likelihood of HTN control. Statins tend to be used less in African Americans than whites who qualify for treatment. Nevertheless, statins have been repeatedly shown to lower blood pressure.¹¹¹ Although only a small portion of these data were generated in African Americans or other racial/ethnic minorities, it seems inconceivable that the blood pressure-lowering effect would be limited to any racial/ethnic group. Accordingly, we have clear and convincing data in our largely African-American hypertensive patient population that statins lower blood pressure in persons with and without diabetes (unpublished observations). There are multiple plausible mechanisms that may explain how statins lower BP.¹¹¹ Pharmacologic treatment for diabetes mellitus also influences longitudinal BP levels. Specifically, thiazolidinediones lower BP in persons with diabetes.¹¹²

SUMMARY

Despite the fact that prevalence, treatment, and control rates vary among race/ethnicity groups, HTN remains a pervasive clinical and public health problem in virtually all groups. There do not appear to be any known risk factors that are unique solely to one race/ethnicity group, although established risk factors contribute variably to HTN risk because, in part, of their variable prevalence. It must be fully understood that the group characteristics or tendencies described in this chapter, including BP responses to antihypertensive agents, represent shifted, but largely overlapping distributions. The promise of molecular genetics is to develop accurate panels of genetic markers that predict risk of pressure-related complications, therapeutic responses to antihypertensive agents, and the likelihood of adverse drug side effects. Thus, use of immutable characteristics to guide therapy for all members of various race/ethnicity groups will occur increasingly less frequently as we identify informative hemodynamic, genetic, and vascular markers that vary at the level of the individual.

Chapter
58**Hyperadrenergic and Labile Hypertension***Guido Grassi and Giuseppe Mancia***Definition**

- The clinical condition, also called neurogenic, juvenile, labile, or borderline hypertension, is characterized by transient blood pressure elevation (and signs or symptoms of an adrenergic cardiovascular overdrive) that with time may become a stable hypertensive state.

Key Findings

- Frequently found in young subjects (40% of cases).
- Associated with resting tachycardia, palpitations, and generalized swelling.
- Not rarely associated with end-organ damage (cardiac, vascular, and/or renal).
- In some cases a differential diagnosis with pheochromocytoma may be required.

Clinical Implications

- Blood pressure monitoring, lifestyle measures, and correction of risk factors should be the cornerstones of therapeutic intervention, if cardiovascular risk profile is low.
- In the presence of stable blood pressure elevation or concomitant risk factors (smoking, overweight, or obesity), end-organ damage, diabetes or associated clinical conditions, a pharmacologic intervention is required.
- If cardiovascular risk profile is high or very high, pharmacologic treatment is necessary even when blood pressure is in the high-normal range.
- Antihypertensive compounds that actively interfere with the sympathetic nervous system (β -blockers, angiotensin-converting enzyme inhibitors, and angiotensin-II receptor blockers) should be the drugs of first choice.

The concept that sympathetic neural factors favor the development of transient blood pressure elevations that with time may progress to stable hypertensive forms dates back almost four decades.¹ Since then, however, some aspects concerning the definition of this clinical condition have been refined with the introduction of terms such as “juvenile hypertension,” “hyperkinetic hypertension,” and “borderline hypertension.” All these definitions share at least three common features. First, is the fact that the occurrence of this clinical entity is prevalent in the young. Second, the evidence shows that at least in the earlier phases of the disease the abnormal blood pressure elevation can be intermittently detected over days, weeks, or months of

observation. Third, based on clinical findings, this hypertensive state is usually associated with signs or symptoms suggestive of an activation of the sympathetic nervous system (SNS).

PATHOPHYSIOLOGY

The background for the hypothesis that abnormalities in sympathetic cardiovascular control may trigger transient elevations in blood pressure that with time may become stable hypertensive states is based on two main notions. First is the knowledge that the SNS exerts a pivotal role in blood pressure control by regulating cardiac output and peripheral vascular resistance. Second is the evidence that increases in cardiac output and elevation in peripheral vascular resistance represent fundamental hemodynamic features of this clinical condition.

Both notions stimulated studies designed to determine the SNS role in the pathogenesis of hypertension. In the following, I briefly review the evidence on this issue, as well as on the participation of the neuroadrenergic mechanisms at the development and progression of the target-organ damage that is frequently associated with the hypertensive state.

Sympathetic activation in early hypertensive phases: Indirect evidence

The early stages of hypertension are often characterized by a hyperkinetic circulation, that is, by an increase in cardiac output with a concomitant resting tachycardia. These findings, originally reported in the late 1950s,¹⁻² have been confirmed by cross-sectional and longitudinal studies. For example, Brod et al.³ demonstrated that early stages of human hypertension are characterized by an exaggerated hemodynamic response to mental stress that may mimic the so-called “defense reaction” described in experimental animals. Interestingly, in a longitudinal study the abnormal pressor responses to adrenergic stimuli have been associated with the future development of hypertension, a finding that for the first time has allowed researchers to link hyperactivity of the SNS to the occurrence of the high blood-pressure state.⁴ This concept has been further strengthened by the observation, originally reported in 1945 and recently repropounded,^{5,6} that a resting tachycardia (and thus an increase in cardiac sympathetic drive) may represent a marker of the future development of hypertension.

A further step forward in our understanding of the prohypertensive role of the SNS comes from a study by

Julius et al. showing that a consistent fraction (about 30% to 40%) of borderline hypertensive patients are characterized by an elevated cardiac output, a resting tachycardia, and elevated circulating levels of the main adrenergic neurotransmitter (i.e., norepinephrine) (Figure 58–1).⁷ This finding, coupled with the evidence that the abovementioned hemodynamic abnormalities of borderline or juvenile hypertension are reversed by pharmacologic blockade of cardiac beta adrenergic receptors,⁷ has strengthened the hypothesis that adrenergic neural factors are involved in the pathogenesis of the hyperkinetic state. Recently, this hypothesis has been confirmed by the evidence that blood pressure variability, that is, the blood pressure oscillations occurring during the daytime and nighttime periods and closely related to adrenergic drive,⁸ are increased in young hypertensive patients as compared to normotensive ones.⁹

Sympathetic activation in early hypertension: Direct evidence

Interesting additional data on the neurogenic forms of hypertension have emerged through two approaches allowing direct assessment of sympathetic activity, that is, the intravenous tracer infusion of small doses of radiolabeled norepinephrine,¹⁰ and the microneurographic recording of

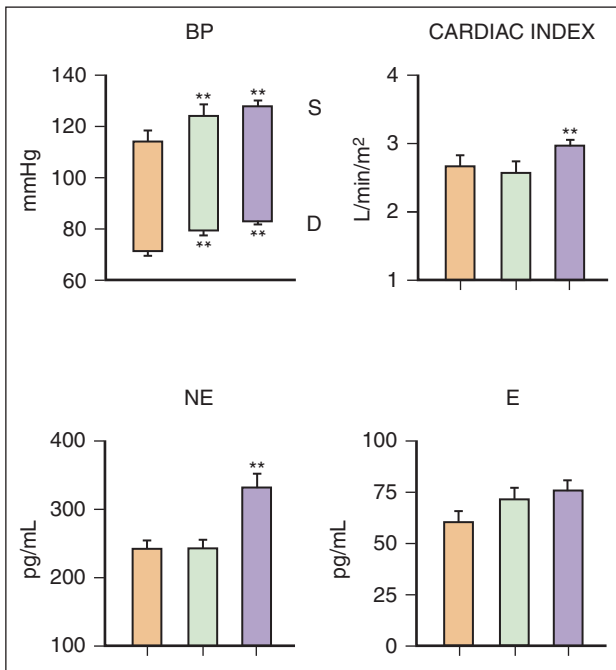

Figure 58–1. Blood pressure (BP), cardiac index, and plasma norepinephrine (NE) and epinephrine (E) values in normotensive subjects (gold bars), and in hypertensive patients without (green bars) and with (purple bars) hyperkinetic circulation. Note that only in the hyperkinetic hypertensive-state cardiac index and plasma norepinephrine are elevated. Asterisks refer to the statistical significance between groups. Values are shown as mean \pm standard error of the mean. (Modified from Julius S, Conway J. Hemodynamic studies in patients with borderline blood pressure elevation. *Circulation* 1968;38:282–88.)

efferent postganglionic sympathetic nerve traffic.¹⁰ By employing the first technique, it has been possible to demonstrate that the increased plasma norepinephrine levels characterizing young hyperadrenergic forms of hypertension depend on an increased norepinephrine release (norepinephrine spillover)¹¹ from adrenergic nerve terminals rather than on a reduced tissue clearance. This approach has also demonstrated that the hyperadrenergic state in labile hypertensive patients is particularly manifest at the level of the kidney and the heart, which are two organs of importance for blood pressure control (Figure 58–2).¹¹

Direct measurement of efferent postganglionic sympathetic nerve traffic to the skeletal muscle district have further confirmed the abovementioned findings, by showing that patients with a borderline elevation in blood pressure display elevated central sympathetic neural outflow.¹² The finding that high blood pressure is characterized by a sympathetic overdrive has been confirmed throughout the years in mild and more severe stages of the disease,¹³ and recently, has been found to characterize white-coat hypertension, that is, the clinical condition characterized by elevated office blood pressure values and by normal 24-hour ambulatory blood pressure profile.^{14,15}

Mechanisms of sympathetic activation

Despite years of investigation, the origin of sympathetic activation in essential hypertension remains largely unknown. Several mechanistic hypotheses have been advanced (Figure 58–3). An attractive hypothesis, for example, is that this activation occurs because of an excessive number of, and/or reactivity to, stressful environmental stimuli that lead, through frequent transient blood pressure elevations, to a permanently hypertensive state. To date, however, this hypothesis has been confirmed only in animal studies, with controversial or circumstantial support in humans.¹⁶

Another attractive hypothesis (not exclusive of the previous one) is that the sympathetic activation originates from an impairment of the baroreflex, that is, of a main restraining mechanism of the sympathetic tone. This is supported by evidence that in congestive heart failure and other diseases, a sympathetic nerve traffic increase is related to reduced modulation of adrenergic tone by the baroreflex.¹⁷ However, in hypertension, baroreflex impairment has been demonstrated for the heart rate, but not for the blood pressure component of the reflex.^{18,19} Furthermore, recent findings by our group have shown that baroreceptor deactivation and stimulation by vasoactive drug-induced changes in blood pressure can affect sympathetic nerve traffic so that it remains unchanged as compared to normotension, at variance from the reduction in the heart rate alterations.¹³

Thus, the available evidence does not support the baroreflex as the origin of the sympathetic activation. These data, however, do not rule out the possibility that reflex cardiovascular regulation may contribute to this phenomenon. First, although unimpaired, the baroreflex is reset toward elevated blood pressure values in hypertension, which means that its influence preserves rather than suppresses the increased sympathetic drive. Second, the sympathoinhibitory influence of cardiac receptors is impaired in essential hypertension,

Figure 58-2. Systemic, renal, and cardiac norepinephrine spillover from adrenergic nerve terminals in young, middle-aged, and elderly normotensive (NBP) and hypertensive (EH) subjects. Only young hypertensive subjects display an increase in total, renal, and cardiac norepinephrine spillover, indicating the occurrence of systemic and regional sympathetic activation. (Modified from Esler M, Lambert G, Jennings G. Regional norepinephrine turnover in human hypertension. *Clin Exp Hypertens A* 1989;11(Suppl 1):75-89.)

although only when accompanied by left ventricular hypertrophy.²⁰ Thus, reflex mechanisms contribute to the sympathetic activation occurring in hypertension, although their effects appear to be late and nonspecific.

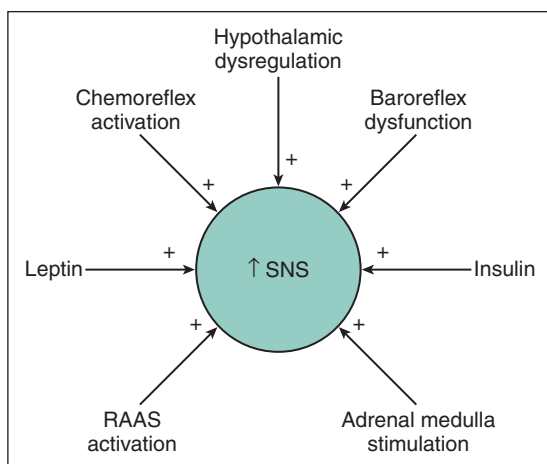

Figure 58-3. Scheme illustrating the possible mechanisms involved in activation of the sympathetic nervous system (↑SNS) in hypertension. RAAS, renin-angiotensin system.

A further hypothesis, which has been advanced in recent years, claims that the sympathetic activation seen in hypertension depends on a metabolic alteration (i.e., hyperinsulinemia and related insulin resistance) accompanying the hypertensive condition. This hypothesis comes from the evidence that in experimental animals and in humans acute infusions of insulin, without altering glycemic levels (the so-called euglycemic clamp infusion technique), markedly stimulate the SNS.^{21,22} This finding is of particular relevance when one takes into account that a large proportion of hypertensive patients (>40%) display elevated insulin levels and an insulin-resistance state. This means that hyperinsulinemia and related insulin resistance may represent one of the mechanisms responsible for the sympathetic activation that characterizes essential hypertension, particularly in its earlier clinical phases. However, this effect is reciprocal, namely, that a state of sympathetic activation may cause insulin resistance as well.^{23,24} A recent study performed in a large number of normotensive and hypertensive subjects, prospectively followed for a 10-year period,²⁵ indicates that sympathetic activation appears to precede the development of the hyperinsulinemic state and blood pressure elevation, a finding which supports the concept that the insulin-resistance state is a consequence rather than a cause of the adrenergic overactivity (Figure 58-4).

Figure 58-4. Values of fasting plasma insulin and plasma norepinephrine (NE) in subjects followed for a 10-year period in which blood pressure (BP) increased less or more than 10% of the baseline values. Note that subjects who will develop hypertension were characterized at baseline by elevated plasma norepinephrine but normal insulin values. Data are shown as mean \pm standard error of the mean. (Modified from Masuo K, Mikami H, Ogihara T, Tuck ML. Sympathetic nerve hyperactivity precedes hyperinsulinemia and blood pressure elevation in a young, nonobese Japanese population. *Am J Hypertens* 1997;10:77–83.)

Cardiac and vascular consequences of sympathetic activation

A number of adverse cardiovascular effects have been reported to take place in experimental and clinical conditions characterized by a blood pressure elevation and an increase in sympathetic cardiovascular influence (Figure 58-5). For example, a direct pro-oscillatory effect of a hyperadrenergic

indirect, these data support the notion that sympathetic neural factors may affect the cardiovascular system by increasing blood pressure variability. Other data, however, support the concept that a sympathetic activation may promote end-organ damage through more direct mechanisms. In the experimental setting this has been shown to occur for left ventricular hypertrophy, which can be promoted by infusion of suppressor doses of adrenergic

Figure 58-5. Scheme illustrating the effects of sympathetic activation on the heart, metabolic and hemorrheologic profile, and vascular and renal function. CO, cardiac output; HR, heart rate; LVH, left ventricular hypertrophy; RAAS, renin-angiotensin system.

state on blood pressure profile and variability has been shown to be involved in the pathophysiology of major cardiovascular events as well as of the end-organ damage associated to high blood pressure. Evidence has been indeed provided that morning blood pressure rise is associated with a frequency of cardiac and cerebral ischemic episodes and with the occurrence of sudden death more closely than blood pressure values observed at other times of the day and night.²⁶ It has also been shown that the frequency of blood pressure peaks over a 24-hour period is significantly associated with the occurrence of left ventricular dysfunction.²⁷ Second, the increase in blood pressure during emotional stress at work or during physical exercise is more closely associated with the degree of left ventricular mass increase than resting or clinic blood pressure.²⁸ Third, the degree of blood pressure reduction during the night is inversely related to left ventricular mass.²⁹

agents (Figure 58–6) and prevented only if a blood pressure reduction is not accompanied by excessive reflex sympathetic stimulation.³⁰ It has also been shown to occur for arteriolar wall hypertrophy or remodeling, a structural vascular abnormality found at an early stage of hypertension.³¹

The involvement of adrenergic neural mechanisms in the hypertension-related vascular alterations is not limited, however, to development of structural changes of the vessel wall. Studies performed in recent years have indeed shown arterial distensibility to be also importantly modulated by sympathetic influences. Removal of adrenergic tone through anesthesia of the brachial plexus or the low spinal cord is accompanied by a marked increase in radial and femoral artery distensibility, respec-

tively (Figure 58–7).³² Femoral artery distensibility also increases in patients with peripheral artery disease who have undergone lumbar sympathectomy.³² This response may originate from abolition of smooth muscle contraction within the arterial wall, because the contracted vascular smooth muscle has an elastic modulus greater than the relaxed one. Such a response leads to the conclusion that sympathetic influences (as well as presumably other influences increasing vascular smooth muscle contraction, such as those elicited by angiotensin II and endothelin) may have a stiffening influence on arterial mechanical properties, particularly in vessels with muscular structure. This stiffening influence, however, may also involve large elastic arteries, because these arteries display smooth muscle tissue and sympathetic efferent innervation.

Figure 58–6. Effects of chronic administration of subpressor doses of norepinephrine (NE) on mean arterial pressure (MAP), myocyte cross-sectional area (CSA), and left ventricular wall thickness (LVWT) in experimental animals. Data are shown as mean \pm SEM. Asterisks refer to the statistical significance with control values (C). (Modified from Sen S, Trazi RC, Khairallah P, Bumpus M. Cardiac hypertrophy in spontaneously hypertensive rats. *Circ Res* 1974;35:775–781.)

Functional modulation of arterial distensibility includes another variable that again is predominantly modulated by autonomic factors and, among them, by sympathetic cardiac drive, that is, heart rate.³³ In experimental animal models, a progressive increase in heart rate by pacing is accompanied by a progressive reduction of carotid artery distensibility.³⁴ This is the case in humans as well because in subjects with an implanted pacemaker, an increase in resting heart rate is accompanied by a reduction in carotid and radial artery distensibility.³⁴

Finally, the importance of sympathetic neural factors in arrhythmogenesis has been repeatedly confirmed, with the evidence that stimulation of cardiac sympathetic outflow reduces the myocardial arrhythmogenic threshold and favors the development of

Figure 58–7. Effects of brachial plexus anesthesia on radial artery distensibility in humans. Note that removal of sympathetic vasoconstrictor influences on radial artery increase the vessel distensibility. B, control; A, after brachial plexus anesthesia; BP, blood pressure. Data are shown as mean \pm SEM. (Modified from Failla M, Grappiolo A, Emanuelli G, et al. Sympathetic tone restrains arterial distensibility of healthy and atherosclerotic subjects. *J Hypertens* 1999;17:1117–23.)

ventricular tachycardia and fibrillation.³⁵ These effects may explain why sympathetic activation and mortality rate are closely and directly related to each other at least in congestive heart failure and in end-stage renal disease.^{36,37} In the case of hypertension, the proarrhythmic effects of the cardiac adrenergic overdrive appear to be potentiated by the presence of left ventricular hypertrophy and myocardial ischemia.

CLINICAL PRESENTATION AND DIAGNOSIS

The elevation in blood pressure values, particularly when as mild as occurs in labile or borderline hypertension, is usually a symptomless condition. In some instances, however, the clinical picture is characterized by manifestations related to a generalized adrenergic activation, such as tachycardia or palpitations at rest, anxiety, and excess sweating. Headache is generally of mild to moderate degree and frequently with a frontal or an occipital location.

The diagnosis is based on the presence of a blood pressure elevation, which is transient in nature and frequently associated with normal blood pressure values. With time, however, the periods characterized by blood pressure elevation become more frequent and a stable form of hypertension may subsequently develop. According to recent guidelines for the management of hypertension, jointly issued by the European Society of Hypertension and the European Society of Cardiology,³⁸ a close monitoring of blood pressure values is recommended in these clinical phases, particularly with the use of home and/or ambulatory blood pressure monitoring in order to avoid the occurrence of a blood pressure elevation due to the white-coat effect.¹⁴

In order to determine the cardiovascular risk profile of the patient, that is, a parameter representing the main indication for the therapeutic intervention (see below),³⁸ along with routine laboratory examinations (blood chemistry tests, urinalysis, electrocardiogram), a number of recommended tests should be performed. These should include ultrasound examination of the heart, with particular focus on evaluation of left ventricular wall thickness, left ventricular end-diastolic diameter, and calculation of left

ventricular mass index; ultrasound investigation of the carotid arteries with the assessment of the intima-media complex thickness and detection of plaques; and finally, evaluation of renal function based on determination of serum creatinine, creatinine clearance and microalbuminuria. In some rare cases (particularly in young subjects without a family history of hypertension), the clinical picture may lead clinicians to suspect an adrenal or extrarenal pheochromocytoma. The differential diagnosis is based on the determination of catecholamines (norepinephrine and epinephrine) as well as of metanepinephrine in several 24-hour urine samples as well as in venous blood. In most patients with pheochromocytoma, the urinary excretion of catecholamines as well as their plasma levels are so high (at least twice the normal values) as to avoid the need for complex further examinations (pharmacologic stress testing MRI examination of adrenal glands, metaiodobenzylguanidine, or computer tomographic scans).³⁹

THERAPEUTIC IMPLICATIONS

Based on the data discussed thus far, sympathoinhibition appears to be a key goal of the therapeutic approach to labile hypertension. Nonpharmacologic lifestyle interventions commonly used in clinical practice and capable of improving both the hemodynamic and the metabolic profile, such as energy-restricted diet or physical training, have been clearly shown to exert sympathoinhibitory effects.⁴⁰⁻⁴² Both these interventions are of particular relevance in the early phases of hypertension, given the evidence that frequently the patients display an overweight or a frank obese state of the central type. Interestingly, this sympathetic deactivation triggered by the two abovementioned nonpharmacologic approaches is usually paralleled by a clear-cut improvement in insulin sensitivity whose alteration represents a common hallmark of obesity.

Sympathetic deactivation should also be one of the goals of pharmacologic interventions based on the use of antihypertensive drugs (Boxes 58-1 and 58-2).⁴² While diuretics appear to be clearly contraindicated due to their inability to counteract the sympathetic overactivity (and to their unfavorable effects on metabolic profile), beta-blockers (particularly those with vasodilating properties) are recommended in order to reduce the adrenergic overdrive to the heart and peripheral circulation. Other preferred antihypertensive drugs in the treatment of the disease appear

Box 58-1

Drugs Acting on Sympathetic Nervous System

- Ganglionic blockers
- Peripheral sympatholytics
- Alpha-1-blockers
- Alpha-beta blockers
- Beta blockers
- Central agents: imidazoline receptor agonists
- Angiotensin-converting enzyme inhibitors
- Angiotensin II-receptor antagonists

Box 58-2

Favorable Effects of Antihypertensive Drug-Induced Sympathoinhibition

- ↓ in heart rate and myocardial oxygen demand
- ↓ in blood pressure variability
- ↑ in insulin sensitivity
- ↑ in trough-to-peak ratio (measure of homogeneity of the antihypertensive effect of a given drug)
- ↑ organ protection and organ damage regression

to be ACE inhibitors and angiotensin II antagonists.⁴² These drugs are (1) effective in ensuring a blood pressure control over a 24-hour period, (2) lipid neutral, (3) capable of improving insulin sensitivity, and (4) exert sympathoinhibitory effects. Also, the new calcium channel blockers, such as cilnidipine and barnidipine, may exert inhibitory effects on adrenergic function,⁴³ unlike “classic” compounds, and the new central sympatholytic agents, such as imidazoline I₁ receptor agonists may trigger favorable metabolic and sympathoinhibitory effects.⁴⁴

SUMMARY

Neurogenic or labile hypertension represents a clinical condition that requires careful examination and follow-up, given the evidence that it may be associated with end-organ damage and cardiovascular complications. The neuroadrenergic nature of the disease underlines the clinical usefulness of drugs capable of counteracting the sympathetic overdrive.

Resistant Hypertension

William J. Elliott

Key Findings

- Resistant hypertension (blood pressure [BP] $\geq 140/90$ mmHg, despite three drugs at near maximal doses for perhaps 3 months) is an important public health problem because of the increased cardiovascular risk associated with uncontrolled hypertension.
- The exact prevalence of resistant hypertension is uncertain.
- At least one cause can be found in 90% to 95% of cases of resistant hypertension.
- The most popular recent causes of resistant hypertension in tertiary hypertension clinics are a suboptimal medication regimen, sleep apnea, and mineralocorticoid excess states (perhaps related to obesity and sleep disorders). In primary care practice, nonadherence to prescribed therapy and white-coat hypertension are probably more common than in specialist clinics.
- After a suitable evaluation, most patients with resistant hypertension achieve goal BP.

Many authors have offered various definitions of “resistant” or “refractory” hypertension; recent definitions are typically more stringent.^{1–3} Since the late 1980s, a consensus definition might be, “Sustained blood pressure (BP) ≥ 140 mmHg systolic or ≥ 90 mmHg diastolic, despite prescription of a specific number (originally two, but now more commonly three) of appropriately selected antihypertensive drugs at near maximal doses.” Some insist that at least one of the drugs should be a diuretic, while others require a specific duration (typically 3 months) for the drugs to be prescribed. Other authorities (typically from tertiary care centers) also suggest that a physician referral is necessary before the hypertension can truly be considered “resistant.”

This definition obviously leaves open many opportunities for discussion. The setting of the measured BP is not specified; therefore individuals with BP that is uncontrolled sometimes (e.g., in the medical office) but controlled in others (e.g., at home) fit the definition. The fact that the medications are prescribed (as opposed to actually consumed) leaves open the possibility that some patients may not be adherent to the instructions about taking the prescribed pills as directed. What constitutes an “appropriately selected antihypertensive drug” is a matter of some debate, and is much less well studied than how medications are best combined to achieve BP goals. A

“near-maximal” dose for one patient may be a modest dose for another, particularly if the weight of the latter patient is twice that of the first.

SCOPE OF THE PROBLEM

Although hypertension has long been recognized as a major remediable risk factor for cardiovascular disease, the most common cause of death in most countries (including the United States), implementation of strategies to control hypertension continues to be suboptimal across the globe. Even in the United States, where public health authorities, pharmaceutical companies, and physicians have been in agreement for decades to reduce the proportion of uncontrolled hypertensives to 50%, current statistics indicate that 69% have BP of $\geq 140/90$ mmHg.³ Although this proportion was lower in 1999–2000 compared to previous years, the proportion in the 18- to 74-year-old age group improved only to 66% from 73%.³ In other countries, uncontrolled hypertension is even more common than in the United States. It is more difficult to achieve the recently recommended lower BP targets for diabetics and those with chronic kidney disease, so larger segments of these high-risk subpopulations remain “uncontrolled.”

How much the specific diagnosis of “resistant hypertension” contributes to population-based surveys of BP control is uncertain. No large national surveys have ascertained the proportion of hypertensives taking at least three medications daily, nor how many of these are uncontrolled. Nonetheless, the epidemiology of uncontrolled hypertension provides some clues to features of those who are more likely to have “resistant hypertension.” The proportion of hypertensive patients with “resistant hypertension” varies from about 3% in worksite-based hypertension control programs that care for relatively healthy people to about 30% in some tertiary hypertension clinics.

EPIDEMIOLOGY OF UNCONTROLLED HYPERTENSION

Perhaps because hypertension prevalence increases with age, older Americans were less likely to have their BP controlled in either 1988–1994 or 1999–2000 (Figure 59–1).^{4,5} Especially relevant to “resistant hypertension” are about 18 million individuals aged 60 years and older in the United States who are treated but uncontrolled (with BP $\geq 140/90$ mmHg). No other subgroup of the population is as large as the treated but uncontrolled people

Figure 59-1. Prevalence (in millions of people) of various subtypes of hypertension in three age ranges in the United States, based on the 1999–2000 National Health and Nutrition Examination Survey,⁵ and the 2000 US Census. The oldest age group (≥ 60 years) had the largest number (10.6 million) of Americans with treated, but uncontrolled hypertension (blue-green bars), which encompasses all patients with resistant hypertension.

over age 60 years. In the national survey of 1999–2002, fully 82.7% of Mexican-American hypertensives were uncontrolled, as opposed to 70.2% of either non-Hispanic white or African-American hypertensives. Treated but uncontrolled hypertension was present in 18.8% of the non-Hispanic whites, 25.8% of African Americans, and 17.6% of Mexican Americans. In 1988–1994, systolic BP elevations accounted for 66% of all BPs above threshold. On epidemiologic grounds, therefore, BP control would be expected to be less common among older minorities with systolic BP elevations.

RISKS OF UNCONTROLLED HYPERTENSION

A recent meta-analysis of 61 epidemiologic studies involving nearly 1 million people concluded that for every 20/10 mmHg of BP elevation, there is a twofold increase in the risk of cardiovascular mortality.⁶ According to one interpretation of all clinical trials in hypertension, it matters more how much BP is lowered than which drug is used to begin the process. Over all clinical trials, a systolic BP difference of 10 mmHg translated to a 33% (95% confidence interval, 29% to 38%) reduction in cardiovascular events. Individuals with uncontrolled hypertension run an excess risk of cardiovascular events, as well as developing target organ damage.⁷

HYPERTENSION CONTROL RATES IN CLINICAL TRIALS

Under the best of circumstances (i.e., clinical trials), well-motivated physicians who treat carefully selected patients using free antihypertensive drugs, can achieve BP control rates in the 65% to 70% range. In all of these studies, a research protocol mandated an increase in the intensity of treatment for patients who did not achieve BP goal. These

data suggest an upper limit for the prevalence of “resistant hypertension” at no more than about 35% of hypertensive patients.

DIAGNOSTIC TECHNIQUES: DIFFERENTIAL DIAGNOSIS

After an appropriate evaluation, one or more reasons for resistant hypertension can be identified in about 90% to 95% of patients (Table 59–1).^{8,9} The relative proportion of each of these diagnoses depends on the population studied. In primary care, nonadherence to prescribed drug therapy accounts for about 50% of patients not achieving BP goal, but in tertiary clinics, this proportion is typically only 5% to 10%. Secondary causes of hypertension display the opposite pattern, being 5 to 10 times more common in tertiary clinics (10%–20% of cases) than in primary care, where one is found in only 2% to 4% of cases.

Nonadherence to prescribed antihypertensive medications

Pharmacy refill data from the general population show that, in treatment of any chronic disease, including hypertension, about 50% of patients stop taking medication 1 year after the first prescription is filled.¹⁰ In primary care, therefore, nonadherence is likely to be the most common cause of resistant hypertension, but this has been difficult to document. Simple, office-based methods to quantify pill consumption are inexact; one such study showed sensitivity of 10% and specificity of 86%.¹¹ Direct questioning of the patient about pill-taking behavior is probably the easiest approach. The best currently available method to document medication adherence is the use of pill containers fitted with electronic monitors that register the time and date of each opening of the bottle (which serves as a surrogate for pill consumption). When these monitors are used, however, many patients suddenly become much more adherent to their prescribed drugs, and improve their BPs.¹²

Two of three recent reports have challenged the long-held belief that nonadherence to prescribed medication is a common cause of resistant hypertension. In the most direct test of this hypothesis in a Swiss tertiary hypertension clinic, after informed consent, both electronic monitoring of pill containers for 4 weeks and ambulatory BP monitoring (ABPM) were performed for 103 patients. Among 49 patients with resistant hypertension, 82% were adherent to their therapy (defined as $\geq 80\%$ of the expected number of container openings), as compared to 85% of treatment-responsive patients ($p=0.33$).¹³ The authors therefore concluded that despite obvious limitations of their study, nonadherence to therapy is not more prevalent among resistant hypertensives. An uncontrolled Swiss study involving only 41 patients with treatment-resistant hypertension showed much-improved BPs after 2 months of electronic monitoring of adherence, and a further improvement when medications were changed, based on these results.¹⁴ Patients with the lowest adherence rates (as determined by electronic monitoring) had the largest improvements in office BPs. These authors

CAUSES OF RESISTANT HYPERTENSION AND ESTIMATED PREVALENCE IN PRIMARY CARE VERSUS TERTIARY REFERRAL CENTERS		
Cause of Resistant Hypertension	Estimated Prevalence in	
	Primary Care (%)	Tertiary Referral Centers (%)
Nonadherence to prescribed medication	~50	10–20
Problems with blood pressure measurement		
Office resistance (“white-coat” hypertension)	~20–30	~10–20
Pseudohypertension or other technical problems	<1	<1
Drug-related problems		
Drug–drug interaction (especially NSAIDs)	~10	<5
Suboptimal antihypertensive drug regimens	~5	~30–50
Medication intolerance consistent with product labeling	<2	<2

Table 59–1. Causes of Resistant Hypertension and Estimated Prevalence in Primary Care versus Tertiary Referral Centers

therefore believe that electronic assessment of adherence is essential in evaluating resistant hypertension.¹¹ Lastly, a systematic review of 30 published studies concluded that there is insufficient evidence to implicate poor adherence (as objectively assessed by electronic monitors) as a cause of poor BP control.¹⁵ However, adherence was significantly better with once daily (vs. twice daily) regimens, and declined as the duration of observation was increased.

The initial diagnostic strategy in primary care for all patients with resistant hypertension therefore involves questioning about pill-taking behaviors. A telephone call to the pharmacy about refill frequency can provide objective evidence of nonadherence. Electronic monitors can be rented for about \$30 to \$40/month, and although typically not reimbursed by insurance, provide the most precise and objective information about short-term (30-day) adherence to prescribed medications.

Problems with blood pressure measurement

In many individuals, BPs measured in the medical office may not be representative of those observed over the entire day. “White-coat hypertension” (office BP >10% higher than the daytime average, as assessed by 24-hour ABPM¹⁶) is found in about 20% to 25% of individuals with elevated office BP readings, whether referred from

primary care offices or tertiary clinics.¹⁷ Although its natural history and need for treatment are debated, most would agree that the “alerting effect” in these patients is seldom abrogated by therapy. In our clinic, the lowest prevalence of controlled hypertension during follow-up (average 1.6 years) was found among patients with nonadherence to prescribed medications (22%), followed by “white-coat hypertension” (25%).⁹ Most physicians are content to diagnose the problem using ABPM, and recognize that, at best, only 75% to 80% of patients with resistant hypertension can be controlled.

“White-coat hypertensive” patients typically have much less target-organ damage than patients with other causes of resistant hypertension. In fact, in the United States, lack of target-organ damage is a prerequisite for ABPM to diagnose white-coat hypertension, its only Medicare-reimbursable indication. In an Italian study, patients with white-coat hypertension were slightly older and had slightly lower BPs at presentation,¹⁸ but these differences are not very helpful with individual patients. In a study of 286 Brazilian patients with resistant hypertension, white-coat hypertension was found in 44% and was associated with a significantly larger nocturnal BP drop.¹⁹ In our clinic, predictors of “white-coat hypertension” at the initial visit included admitting to “nervousness” or “worry” about office BP measurements, much lower BPs measurements

at home with a calibrated device (compared to office BPs), and having a gradual decline in office BPs over 10 sequential readings. None of these, however, was sufficiently sensitive to obviate the need to confirm the diagnosis of white-coat hypertension with ABPM.

As a result, many authors now recommend ABPM routinely for evaluation of the “white-coat effect” as a contributor to resistant hypertension. Although the procedure is instrumental in making the diagnosis, its repeated use over time to monitor the patient’s out-of-office BP is expensive, time consuming, and perhaps better done with home BP monitoring.

In many busy clinical settings, too little attention is paid to proper technique of BP measurement.²⁰ The three most common errors that result in erroneously high readings are using a cuff too small for the large arm, decreasing the cuff pressure more than 2 to 3 mmHg/s, and not having the patient rest comfortably for at least 5 minutes, with the back supported, without recent caffeine intake or smoking, before measuring BP.

A few patients with resistant hypertension have pseudo-hypertension, in which sclerotic arteries resist compression by an external BP cuff, resulting in much higher systolic BP readings than are obtained by intra-arterial measurement. Aortic and other arterial calcifications are often seen in x-rays of such patients. “Osler’s maneuver” (palpation of a hard, nonpulsatile radial arterial when the BP cuff is inflated to obliterate the pulse, typically >200 mmHg) was originally proposed to screen for this condition,²¹ but has since been found to be relatively imprecise. An even less common artifact is “cuff inflation hypertension,” which can occasionally be observed when comparisons are made between traditional auscultatory and oscillometric BP measurements.²²

Medication-related causes

There are three main causes of resistant hypertension that are directly related to medications used to treat it: drug–drug interactions, suboptimal antihypertensive drug regimens, and objective medication intolerance (i.e., when the ability to take a given drug is limited by a known side effect of that drug).

Drug–drug interactions

Antihypertensive drugs with important drug–drug interactions (e.g., propranolol, methyldopa, guanethidine) have generally decreased in prescription volume as other drugs have been introduced that did not have these potential problems. Nonetheless, many commonly used drugs can and do raise BP; some of these are available without a prescription and are therefore not identified by patients as being possible contributors to resistant hypertension.

Among the hypertensive population, nonsteroidal anti-inflammatory drugs (NSAIDs) are probably the most common agents that raise BP via a drug–drug interaction. About 36% of hypertensive Americans (~19 million people) have osteoarthritis, for which an NSAID is a treatment option. In addition, many more people take either an occasional or chronic NSAID for reasons

unrelated to osteoarthritis. Meta-analyses published in the early 1990s indicated that NSAIDs increase BP by about 7–10/3–4 mmHg, with larger effects in hypertensive people, especially those treated with angiotensin-converting enzyme (ACE) inhibitors, beta-blockers, and diuretics. More recent data with NSAIDs selective for the second isoform of cyclooxygenase show similar results. Although acetaminophen is often recommended, many hypertensive patients find exercise (and even walking) without an NSAID difficult, if not impossible. In this setting, physicians tend to use more calcium antagonists and alpha-blockers for hypertension, rather than to prohibit NSAIDs altogether.

Many patients who are treated with cyclosporine, erythropoietin, or corticosteroids experience elevations in BP, but because these drugs are mandatory for their specific clinical condition, alterations are more commonly made to the antihypertensive treatment regimen than to these drugs. Oral contraceptive agents also occasionally raise BP, but because the risk of hypertension is so well known and reasonable alternatives exist, most women who develop hypertension with these agents have the offending agent stopped well before the hypertension becomes “resistant.”

Some patients take drugs, but do not report their use (in addition to NSAIDs, previously discussed). Sympathomimetic drugs, typically found in nasal decongestants and “cold remedies” can raise both BP and pulse rates, especially when taken soon before a BP measurement. Some patients use cocaine and other stimulants, but seldom report this to a physician asked to assist with the BP elevations that these agents can cause. Monoamine oxidase inhibitors, which had been widely used some decades ago for depression, are making a comeback as treatments for dementia and other psychiatric disorders; these can interfere with agents that interfere with the sympathetic nervous system and ameliorate hypertension. Tricyclic antidepressants, which are less commonly used now than selective serotonin reuptake inhibitors, can also potentiate the BP-lowering properties of alpha-agonists (e.g., clonidine).

Suboptimal antihypertensive regimens

The definition of resistant hypertension mandates multi-drug therapy, but the number of possible combinations of even the eight most commonly used drug classes is enormous. All meta-analyses since publication of the Antihypertensive and Lipid-Lowering to prevent Heart Attack Trial (ALLHAT) have indicated that no initial drug prevents coronary heart disease, cardiovascular events, or heart failure better than an initial diuretic. The question of what agent is best to add to the initial diuretic is largely left unanswered. Some combinations of commonly used antihypertensive agents are not very effective in lowering BP (ACE inhibitor plus angiotensin II receptor blocker [ARB], ACE inhibitor plus beta-blocker). In several tertiary clinics, suboptimal antihypertensive medication regimen was the most common of all the causes of resistant hypertension. Management of this problem is discussed in detail below.

Objective medication intolerance

Some patients with resistant hypertension have been previously treated with an antihypertensive agent that unfortunately caused intolerable side effects, resulting in discontinuation of the drug. When the specific side effect has already been reported, has a higher incidence with the drug than with placebo, and is included in the product label, the patient is said to have “objective medication intolerance.” This situation is easier to associate with the drug than a similar one where the specific side effect has not previously been associated with the drug used (discussed below under “subjective medication intolerance”). “Objective medication intolerance” also includes situations during which specific drug therapies are contraindicated, such as a woman with hypertension treated with a diuretic, a calcium antagonist, and an ACE inhibitor, who becomes pregnant, and the ACE inhibitor must be at least temporarily discontinued for the duration of the pregnancy.

Secondary causes of hypertension

While most authors agree that a population of resistant hypertensives is enriched in cases of secondary hypertension, there is controversy about which specific cause is most common. In this context, chronic kidney disease is not usually numbered among the secondary causes of hypertension, as its treatment is similar to primary hypertension (with the exception of using loop diuretics and reducing the doses or frequency of administration of renally excreted drugs). In resistant hypertensives, primary hyperaldosteronism and sleep apnea are being more commonly reported as secondary causes of hypertension than renovascular disease, Cushing’s syndrome, or pheochromocytoma, although some include obesity and insulin resistance as new and emerging secondary causes. Obesity is very important because higher doses of antihypertensive drugs are often required in obese patients to achieve the BP results seen routinely in patients of more

desirable weight; in pediatrics and veterinary medicine, doses are calculated “per kilogram of body weight.” Insulin-induced hypertrophy of vascular smooth muscle could account for resistant hypertension in patients with insulin resistance. Table 59–2 summarizes some of the currently recommended screening tests for the more common causes of secondary hypertension.

Interfering substances

Exogenous substances that are not usually prescription drugs are responsible for a small percentage of resistant hypertension. The BP-lowering effect of many antihypertensive drugs can be reduced, if not obliterated, by a high-sodium diet. This is particularly true among patients with “salt-sensitive hypertension,” which is more common among blacks, the elderly, and those with chronic kidney disease. Recent data from a national survey suggest that dietary patterns (including a significantly higher salt intake) may account for some of the poor BP control in southern U.S. states (the “stroke belt”).²³ Although patients may not be aware of their overconsumption of salt, a 24-hour urine is cheap and effective, but requires some education about proper timing and technique of collection.

The relationship of alcohol intake to hypertension and cardiovascular events is complex. Nonetheless, taking a proper history about alcohol consumption should be part of the initial evaluation of resistant hypertensive patients. Several studies have implicated heavy alcohol consumption with resistant hypertension; three have shown a graded (or dose–response) effect. The current recommendation of several authoritative bodies is to keep alcohol consumption to two or fewer drinks per day for men and one or fewer drinks per day for women.

Illicit substances such as cocaine, amphetamines, and anabolic steroids are typically not reported to the physician, and can raise BP and increase the risk of having resistant hypertension. Recent caffeine intake can also raise BP, as can prolonged high-dose intake. Using tobacco

COMMONLY RECOMMENDED SCREENING TESTS FOR SECONDARY HYPERTENSION		
Diagnosis	Screening Test(s)	Other Tests
Intrinsic renal disease	Serum creatinine (\$15 ^a), AM albumin/creatinine ratio (\$20)	24-hour urine for creatinine clearance, protein, sodium, potassium (\$40)
Mineralocorticoid excess states	24-hour urinary aldosterone during salt loading (\$95), plasma aldosterone/renin ratio (\$125)	Computed tomographic scan of adrenals (\$1700)
Sleep apnea	Berlin Questionnaire (see text)	Formal sleep study (\$900)
Renovascular hypertension	“Clinical prediction rule” (see text); followed by captopril scintigraphy (\$300) if at moderate risk	Doppler ultrasound of renal arteries (\$250), magnetic resonance angiography (\$2900), renal angiogram (\$8000)
Pheochromocytoma	24-hour urine for vanillylmandelic acid (VMA) and metanephrines (\$175)	Plasma metanephrines (\$250), plasma catecholamines (\$250), T ₂ weighted magnetic resonance imaging (\$2750)
Cushing’s Syndrome	8 AM plasma cortisol (\$35)	Dexamethasone suppression test(s) (\$120)
Hypothyroidism	Thyroid stimulating hormone (TSH, \$55)	

^aCosts vary over time and from institution to institution. These are approximate, as cited at Rush University Medical Center, Chicago, in July 2004.

Table 59–2. Commonly Recommended Screening Tests for Secondary Hypertension

or other nicotine-containing products typically causes acute vasodilation and relative hypotension, but the effect is transient and usually followed by higher BPs than before the use. This pattern is occasionally seen on ABPM, and is the reason for prohibiting smoking within 30 minutes of a BP measurement.

Psychological causes

Some patients with resistant hypertension refuse to take specific antihypertensive medications, even though the drug may be useful in lowering BP, because they associate unusual symptoms to the drug. This situation is called “subjective medication intolerance” when these symptoms are not part of the known side-effect profile of the drug. This need not be a sign of psychological problems in the patient, as the first few cases of cough with an ACE inhibitor would have fit this scenario, and cough is now a well-established side-effect of these drugs. Nonetheless, some patients who report rare, unusual, and often incredible stories about their bad experiences with medications must be categorized somewhere, and this is the traditional place for them. The unusual details (“hair hurting, teeth itching”) may be a useful clue in this setting.

Controversy exists about whether patients with resistant hypertension have a higher prevalence of panic disorder, anxiety attacks, or similar psychological diagnosis. Although it has been difficult to assemble a cohort of perfectly matched patients with and without these problems in a resistant hypertension clinic and study them carefully, some patients with resistant hypertension certainly have these problems. The most recent case-control study done in a tertiary clinic showed no difference in the frequency of panic disorder, anxiety, or depression among 136 cases of resistant hypertension, compared to 136 patients with controlled hypertension.²⁴ However, the proportion of patients who had experienced a panic attack (33% vs. 39%) or who fit criteria for current or previous diagnosis of panic disorder (12% vs. 14%) were higher than the authors expected.

MANAGEMENT

Nonadherence to chronic medications

Many simple measures to improve adherence to therapy have been advocated.²⁵ General health education, as well as drug-specific information, improve adherence, perhaps because patients better understand the medication and its intended benefit. Physicians can prescribe the minimum number of easy-to-swallow, once-daily combination pills that can be taken independently of food. Integrating pill taking into a schedule of other routine activities of daily living (e.g., when caring for teeth) regularizes the habit. Involving a significant other (in taking pills and measuring BPs at home) provides social support and a reminder of the importance of adherence. More extreme measures, including hospitalization or nursing home placement for supervised administration of prescribed medications, is seldom necessary.

Problems with blood pressure measurement

All patients should have BPs taken with appropriate technique,²⁰ although incorrect technique is probably not a common cause of resistant hypertension. For hypertensive patients without target organ damage, Medicare reimburses for ABPM to evaluate “white-coat hypertension.” Optimal management of patients with white-coat hypertension is controversial, but all would agree that controlling BP when measured outside the medical office is advisable.

Medication-related causes

Drug–drug interactions

Few patients are currently prescribed the older antihypertensive medications that have serious drug–drug interactions with other medications. Few patients are willing to forego NSAIDs that make it possible to walk and perform other activities of daily living. Few doctors are willing to discontinue important therapies that increase BP (e.g., cyclosporine, erythropoietin); instead higher doses of antihypertensive drugs are typically prescribed. More patients can stop sympathomimetic agents and avoid monoamine oxidase inhibitors, tricyclic antidepressants, and street drugs that raise BP.

Suboptimal drug regimens

The Seventh Report of the Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) has recommended a low dose of a thiazide-like diuretic as first-line therapy for uncomplicated hypertension, based on ALLHAT and other clinical trial data. Very few studies have provided information about what drug class is best as the next agent, so JNC 7 suggests an ACE inhibitor, ARB, beta-blocker, or calcium antagonist (in alphabetical order). A road map for treating resistant hypertension developed in our clinic is shown in Figure 59–2.

Like ALLHAT, the Systolic Hypertension in the Elderly Program, Treatment of Mild Hypertension Study, and the Hypertension Detection and Follow-up Program, we prefer the long-acting thiazide-like diuretic, chlorthalidone, to the much more popular hydrochlorothiazide (HCTZ). It has proven benefits in cardiovascular event reduction in many clinical trials, including the Multiple Risk Factor Intervention Trial. In this important study, the Steering Committee decreed that HCTZ should be replaced by chlorthalidone after 5 years of mean follow-up, because the former was associated with highly significant increases in all-cause and total mortality, when each diuretic-treated group was compared to its referred care group. After the change, the excess mortality disappeared. More recently, an indirect comparison of ALLHAT and the Second Australian Blood Pressure Trial showed that for all cardiovascular events, chlorthalidone was better than lisinopril (in ALLHAT), which is very similar chemically and pharmacologically to enalapril, which was more effective than HCTZ (in ANBP-2). Thus, if one ignores all other potentially substantive differences across these two trials, for cardiovascular risk, chlorthalidone is less than ACE

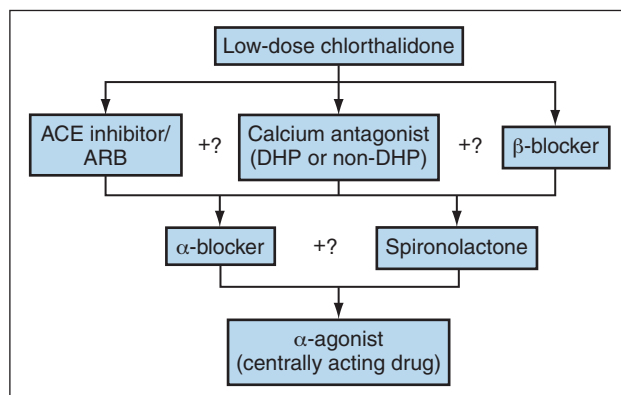

Figure 59–2. Road map for drug therapy of resistant hypertension, based on results at the Rush University Hypertension Center. Note that after chlorthalidone (for patients with estimated glomerular filtration rate of >40–45 mL/min), the second-line drug can be chosen from those on the second line, but the third-line drug should be adjacent to the second line choice. Spironolactone can be added, for most patients, as the fourth-line drug, or introduced later. For patients with an estimated glomerular filtration rate of <40–45 mL/min, twice daily furosemide or another loop diuretic should be used, rather than a thiazide or thiazide-like diuretic. ARB, angiotensin II receptor blocker; DHP, dihydropyridine. (Adapted from Garg JP, Elliott WJ, Folker A, Izhar M, Black HR. *Am J Hypertens* 2005;18:619–26.)

inhibitor, which in turn is less than HCTZ. Unfortunately, chlorthalidone is available in the United States as 15-, 25-, and 50-mg pills, and in only three combination products, which just happen to be the ALLHAT second-step drugs (atenolol, reserpine, and clonidine). Those who practice evidence-based medicine should perhaps become more familiar with these three combination products, all of which are inexpensive and generically available.

Figure 59–2 gives a choice for second-line therapy: ACE inhibitor (or ARB, if cough or other adverse effect prevents use of an ACE inhibitor), calcium antagonist, or beta-blocker. In Figure 59–2, only second-line drugs that are adjacent to each other should be used in combination. This is consistent with ALLHAT, the “Birmingham square,” and several studies of “renin profiling,” all of which suggest that the combination of a beta-blocker + ACE inhibitor (the outside options in Figure 59–2) is less useful in hypertension than it is in systolic heart failure. After two or three drugs from the second-line selections, we and others find a long-acting alpha-blocker to be especially useful in lowering BP, especially when measured in the standing position.^{9,26} Many physicians use clonidine as their usual fifth-line therapy, although its noxious side-effect profile at high doses can reduce adherence, and sudden withdrawal often leads to “rebound” hypertension. Reserpine and alpha-methyldopa have recently been recommended as inexpensive and effective medications that are well tolerated at low doses. Minoxidil, perhaps the most potent vasodilator drug, is particularly useful in men who are already treated with a diuretic (typically furosemide twice daily) and a beta-blocker.

Some authors recommend laboratory testing to more “physiologically” choose any but the initial antihyperten-

sive drug. This may be particularly useful when the patient’s volume status and sodium balance are in question. The finding of a very low level of plasma renin activity despite a thiazide diuretic and an ACE inhibitor, for example, would suggest more (or a stronger) diuretic be added. Another approach, pioneered at the Mayo Clinic, is to perform noninvasive hemodynamic measurements by thoracic bioimpedance for patients with resistant hypertension, and then choose therapy intended to improve the profile. This approach led to significantly better control of hypertension (56% vs. 33%, $p < 0.05$) than therapy directed by a certified hypertension specialist.²⁷ The authors believed their results were due to the bioimpedance measurements being able to detect occult volume expansion, which was followed by higher doses of diuretics.

The drug-related approach to resistant hypertension that is gathering the most attention in the recent medical literature is the use of spironolactone as an add-on drug. This practice is supported by several studies that reported a higher-than-expected prevalence of patients with presumed primary hyperaldosteronism, based on the ratio of plasma aldosterone/renin as a screening test. In addition, Nishizaka and Calhoun and Berecek et al.^{28,29} have shown a good long-term BP-lowering response after adding spironolactone, first in patients with hypertension associated with obesity and the sleep apnea syndrome, and more recently in resistant hypertension (regardless of sleep apnea screening scores). Another study of 25 patients with resistant hypertension showed not only better BPs, but also a reduction in antihypertensive drug use when spironolactone was empirically added to the regimen.³⁰ These promising reports set the stage for a multicenter, randomized clinical trial of spironolactone (or a similar agent) in resistant hypertension.

Recent work from our clinic has indicated that 58% of 141 consecutive patients with physician-referred resistant hypertension had drug-related problems at referral; 94% of these were due to a suboptimal medication regimen.⁹ After a small increase in the number of antihypertensive medications (3.7 ± 0.9 to 4.1 ± 1.0 per day, $p < 0.0001$), 53% achieved their BP target during follow-up. The most common change (60 of 86 patients) that led to BP control involved a diuretic. Changing from a thiazide to a twice-daily loop diuretic (when the estimated glomerular filtration rate [eGFR] was <40–45 mL/min), or from a once daily loop diuretic to chlorthalidone if the eGFR was more than 50 mL/min, were successful in 21 patients. An increase in diuretic dose (often once daily to twice daily furosemide) was successful in 17 patients. Twelve patients had a diuretic added (as it was not part of the regimen on referral), 7 had the diuretic dose decreased, and only 3 had a diuretic discontinued. A summary of the other changes in medications from referral to successful BP control is shown in Figure 59–3. Significant increases in use of alpha-blockers, and calcium antagonists (especially dihydropyridine calcium antagonists) were accompanied by significant decreases in use of nonspecific vasodilators and beta-blockers. The many changes we observed are prioritized and summarized in Figure 59–2.

Figure 59-3. Proportion of patients receiving various pharmacologic classes (*top*) and subclasses (*bottom*) of antihypertensive drug therapy at presentation (*green bars*) and during follow-up (*blue bars*) (average 1.6 years) in a cohort of 141 physician-referred patients with resistant hypertension. During follow-up, the same percentage (53%) of all patients, and of those with a suboptimal medication regimen, achieved goal BP. * significant difference ($p < 0.05$) at presentation versus during follow-up by chi-square test. Objective medication intolerance

Occasionally the problem with a specific medication can be overcome with the same drug supplied by a different delivery system. A good example is the flushing, headache, and tachycardia that commonly result with nifedipine capsules (typically given three to six times/day). These symptoms (but not the pedal edema) typically are much less common with the sustained-release form of the very same drug. A more common management strategy for objective medication intolerance is simply to avoid prescribing the implicated medication.

Secondary causes of hypertension Mineralocorticoid excess states

As noted earlier, based on screening large populations with the plasma aldosterone renin ratio during a period of high-salt intake, several groups across the world have claimed that mineralocorticoid excess states account for 10% to 25% of resistant hypertension. Others note that these patients do not fulfill formal diagnostic criteria for primary hyperaldosteronism, and only very rarely have an adrenal adenoma; most may in fact simply have “low-renin essential hypertension.” Currently, further investigation for primary hyperaldosteronism is warranted if the aldosterone to plasma renin activity ratio is more than

20 ng/dL per ng/mL/hour *and* the plasma aldosterone concentration is greater than 15 ng/dL.³¹ These diagnostic cutpoints will soon require revision, since the direct renin assay has largely replaced the determination of peripheral renin activity in most clinical laboratories. Part of the reason for the increased interest in finding cases of primary hyperaldosteronism is that laparoscopic adrenalectomy is now widely available, at lower cost and probably a reduced risk of major complications, compared to traditional laparotomy. The recent introduction of eplerenone, a selective aldosterone blocker with much less estrogenic activity than spironolactone, may also make medical therapy of idiopathic hyperaldosteronism less troublesome.

Sleep apnea

Since about 1996 there has been an explosion of information about sleep apnea as a potential secondary cause of hypertension, perhaps because of the epidemic of obesity and its related disorders in the United States and much of the industrialized world.^{32–34} The prevalence of previously unrecognized sleep apnea in resistant hypertensive patients has been reported to be as high as 83%.³⁵ In most studies, it is more common in obese (body mass index ~35 kg/m²) men at about age 60 years.^{35,36} Many hypertensive patients with sleep apnea show little or no nocturnal drop in BP

with ABPM, but this is not a very specific finding. The Berlin questionnaire, a very useful tool for screening for sleep apnea in primary care, has 86% sensitivity, 77% specificity, and 89% positive predictive value when evaluated in 744 patients subsequently formally evaluated with polysomnography.³⁷ The most specific screening questions appear to be loud snoring during sleep, daytime sleepiness/drowsiness (especially while driving), and (of greatest predictive value), observed episodes of irregular breathing and/or apneic periods during sleep. For individuals found on screening to be at high risk for sleep apnea, most specialists in sleep medicine routinely recommend a formal sleep study, followed by continuous positive airway pressure (CPAP) during sleep and a weight-loss regimen. This multidisciplinary approach has been shown to lower BP in the short term in refractory hypertensive patients who use the apparatus.³⁸ The stage is now set for a comparative clinical trial of CPAP versus spironolactone in patients with resistant hypertension who score highly on the Berlin Questionnaire.

Renovascular hypertension

The importance of renovascular disease as a common cause of resistant hypertension has been declining recently. Some of this may be due to the fact that renal artery stenosis is now diagnosed fairly often in patients who undergo angiography for other reasons (e.g., coronary or peripheral vascular disease evaluation), but there is uncertainty about the clinical consequences of the discovered stenoses. Similarly, since the publication of three trials comparing medical therapy and renal angioplasty showed few differences in BP control or renal function, enthusiasm for invasive approaches to open the renal arteries has waned.³⁹ In most centers, angiography and angioplasty (now usually with stenting) is reserved for patients who are likely to have fibromuscular dysplasia or atherosclerotic disease for which medical therapy does not control BP or leads to deteriorating renal function.⁴⁰ In the recent Dutch experience, resistant hypertension was found in 41% of patients at high risk for renovascular disease (based on their clinical prediction rule⁴¹), and 20% of these had renal artery stenosis. Initial therapy with enalapril was no more useful than amlodipine in identifying those with renal artery stenosis.⁴²

Rarer causes of secondary hypertension

Because resistant hypertension has a higher prevalence of secondary hypertension than easily controlled hypertension, rare causes of hypertension are to be expected more commonly as well. Unusual aortic pathology and genetic mutations affecting sodium transport figure most prominently in the recent medical literature.

Interfering substances

Lifestyle modifications are the traditional recommended therapy for excessive dietary sodium intake, ethanol consumption, and illicit drug use. Short-term studies show an impressive reduction in BP with each, but longer-term clinical trials and everyday clinical practice are not as optimistic about the ability of many patients to adhere to

these recommendations. For individuals whose 24-hour collection of urine contains more than 120 mEq of sodium, a visit with a nutritionist is recommended for the patient and the person from the same household who buys and prepares food. Reducing alcohol consumption has been followed by improved BP in some studies, but the large randomized clinical trial (performed in U.S. military veterans) comparing advice to reduce alcohol intake and usual care in heavy drinkers did not show a significant reduction in office BP, perhaps because all subjects decreased their reported intake between screening and randomization in the study.

Psychological causes

There are no clinical trial data to support a recommendation to send resistant hypertensive patients with psychological causes for counseling or psychiatric therapy, perhaps because this is a rare cause of resistant hypertension. Another option is to stimulate the peripheral nervous system to counter the perceived symptom; this may be the explanation why transcutaneous nerve stimulation was effective in lowering BP in 12 resistant hypertensive patients in a recent study.⁴³

PROGNOSIS

Several series from tertiary centers that see many resistant hypertensive patients show that, after an appropriate evaluation and modification of drug therapy, the vast majority of patients can achieve goal BP.^{8,9} Whether they have a higher risk of cardiovascular events, even after achieving goal BP, is unclear. However, several clinical trials (including the best example, the Valsartan Anti-hypertensive Long-Term Use Evaluation) have shown, as might be expected, that individuals with initially uncontrolled BP, do suffer more events in the short-term than those who achieve BP goals quite early after treatment is initiated. Insurance company databases show that treated hypertensives do not quite reduce their risk of death to that of similar individuals without hypertension, but those with uncontrolled hypertension fare much worse than those with controlled BP.

SUMMARY

Resistant hypertension (BP \geq 140/90 mmHg, despite three drugs at near maximal doses for perhaps 3 months) is an important public health problem because of the increased cardiovascular risk associated with uncontrolled hypertension. Its exact prevalence is uncertain, but it accounts for perhaps 5% to 20% of referrals to most tertiary hypertension clinics. At least one cause of resistant hypertension can be found in 90% to 95% of cases; the most popular recent causes are a suboptimal medication regimen, sleep apnea, and mineralocorticoid excess states (perhaps related to obesity and sleep disorders). Nonadherence to prescribed therapy and white-coat hypertension are probably more common in primary care practice than in specialist clinics. After a suitable evaluation, most patients with resistant hypertension can and do achieve goal BP.

Chapter
60Perioperative Hypertension:
Preparing the Hypertensive
Patient for Anesthesia for Surgery*Pierre Foëx***Key Findings**

- The presence of hypertensive disease increases the risk of cardiac complications of anesthesia and surgery.
- Hypertensive patients exhibit exaggerated cardiovascular responses to anesthesia and surgery.
- The risk of complications relates to the presence of target-organ damage more than to the level of hypertension.
- Empirical guidelines suggest that hypertension above 180/110 mmHg should be treated before elective surgery, preferably for several weeks. Treatment should also be considered for lower levels of blood pressure associated with target-organ damage.
- Treated hypertensive patients should be maintained on their medication throughout the perioperative period, although ACE inhibitors and angiotensin-receptor antagonists may need to be omitted on the day of surgery.
- Invasive monitoring of blood pressure is recommended for major surgery with active control of hypo- and hypertensive events.

The association between arterial hypertension and adverse cardiac outcome of anesthesia and surgery has been recognized for several decades. However, the level of blood pressure at which initiation or optimization of treatment is required to decrease the short-term risk of adverse events is not firmly established. Over the past decade this issue has become more complicated because the level of blood pressure requiring treatment in order to decrease the long-term risk of arterial hypertension has decreased. Therefore, those involved in the management of hypertensive patients presenting for elective surgery have to decide whether the guideline for reducing the long-term risk of adverse outcome should also be applied to the short-term outcome of patients subjected to the stress of surgery.

If values such as 140/80 mmHg were applied to all surgical patients, it follows that the number of cancellations or deferments would increase dramatically as many patients would present with “white coat” hypertension or exhibit an increase above their usual blood pressure level because they are apprehensive. Even fairly recently only 10% to 14% of treated hypertensive patients achieved the target of less than 140/80 mmHg.^{1,2} As there is no evidence of threshold down to 115/75 mmHg,³ 140/80 mmHg may

come to be regarded as “conservative” within a few years. This would make the question of deferment for treatment even more complicated than it is at present. Cancellations and deferments have significant implications for the patient and for healthcare systems. In order to reach a decision regarding the surgical patient, it is important to take into consideration not only the measured blood pressure but also the presence of target-organ damage and diabetes. However, admission for surgery could for some patients be an ideal opportunity to initiate long-term treatment. Whether this needs to be done before surgery or could be done after surgery is the central issue of this review.

EVOLUTION OF CONCEPTS AND PRACTICE

In 1929, Sprague⁴ published important observations—in a series of 75 hypertensive patients, one-third died during the perioperative period, including 12 who died from cardiovascular complications. The introduction of anti-hypertensive drugs in the 1950s was initially regarded by anesthesiologists as creating a new hazard. It was thought that these drugs, because they interfere with the regulation of the circulation, increased the cardiovascular lability of patients. It became customary to stop antihypertensive medication 2 weeks before elective surgery. As this was not always practical, Dingle,⁵ in 1966, proposed that hypertensive patients should undergo autonomic function testing before surgery. Evidence of impaired autonomic responses would indicate the need to stop the antihypertensive therapy several days before surgery and during the immediate perioperative period.⁵

The recommendation to stop treatment in hypertensive patients was still current in the early 1970s. A dramatic change occurred after Prys-Roberts et al.^{6,7} published a series of observational studies of the interactions of anesthesia and hypertension. The first two studies compared the responses to induction of anesthesia, laryngoscopy and intubation, steady-state anesthesia, and awakening in three groups of patients: untreated hypertensives, treated hypertensives, and normotensive elderly patients. The studies showed that changes in blood pressure were greater in the untreated hypertensive patients than in the treated hypertensives or in elderly normotensives. On the basis of these observations, the authors concluded that treatment of hypertension should be maintained throughout the perioperative period as it would improve cardiovascular stability; this could only be regarded as beneficial.

At the same time the use of beta-blockers was causing great concern. The general consensus was that they should be stopped 2 weeks before surgery. A third observational study by the same group⁸ showed that intravenous beta-blockade with practolol immediately after induction of anesthesia, or prior beta-blockade with oral practolol for 2 days before surgery, was well tolerated, did not reduce cardiac output more than anesthesia alone, and minimized the increase in blood pressure and heart rate seen after laryngoscopy and endotracheal intubation. More importantly beta-blocked patients did not develop ventricular arrhythmias or myocardial ischemia, unlike the non-beta-blocked patients. This could be regarded as a major benefit. The good tolerance of beta-blockade was confirmed by another study involving patients receiving up to 2000 mg of propranolol daily.⁹

Following these studies, the authors came to two conclusions: First, that treatment of hypertension, including beta-blockade, should be maintained; and second, that hypertensive patients should be treated and their blood pressure controlled before elective surgery. Over the next few years, these conclusions were generally adopted. However, almost 35 years later this issue has to be revisited in its current context. In the early 1970s, many hypertensive patients presented with very high blood pressures, well above 200 mmHg systolic and 110 mmHg diastolic. Today blood pressure above 140/80 mmHg is regarded as hypertension. Does it follow that patients with mild or moderate hypertension should be treated before surgery and their blood pressure brought to the currently accepted therapeutic goal to obtain some reduction of the immediate risk? The question becomes increasingly difficult as the seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7) does not make any differentiation between stages 2 and 3 hypertension.¹⁰ Is there evidence that mild or moderate hypertension (stages 1 and 2 of the older classification) justifies postponement, while accepting that for the long term patients need to be treated?

HYPERTENSIVE DISEASE AND PERIOPERATIVE RISK

There is a definite association between arterial hypertension and perioperative adverse outcome. This has been established in a systematic review of observational studies published between 1971 and 2001.¹¹ The studies were concerned with the risk of major adverse event within 30 days of anesthesia and surgery. Studies examining stroke after coronary endarterectomy were excluded because they represent a specific population with a specific risk that relates directly to the operation itself. Eventually 30 studies satisfied the selection criteria. The total number of patients was 13,671, of which 5677 were hypertensive. The studies allowed odds ratios to be calculated and the pooled odds ratio was 1.31 (confidence interval [CI]=1.17–1.56, $p<0.001$). However, the test for heterogeneity between the studies was significant and the source of this variability was sought through a number of sensitivity analyses grouping the data by year of study and by

type of surgery. These analyses yielded little impact on the odds ratio, and heterogeneity among the studies included remains.

With a value of 1.31, the odds ratio is significant but relatively small. However, studies have almost never made any distinction among history of hypertension, treated and well-controlled hypertension, and uncontrolled hypertension. This may mean that some patients could be at high risk while others are a low risk. Patients with a higher blood pressure are likely to be at greater risk of short-term adverse outcome than those with moderately elevated blood pressure.

A number of cardiac risk indices have been developed to facilitate the assessment of surgical patients. These indices emphasized the major contribution of ischemic heart disease, heart failure, renal failure, and in earlier studies arrhythmias, all of which are frequently associated with hypertension. However, the studies did not identify hypertension itself as a significant determinant of adverse cardiac outcome.^{12–16} This is not surprising because very few patients included in the populations examined to derive the risk indices had a blood pressure higher than 180/110 mmHg. Therefore, other cardiac disorders were playing a much greater role and could easily overshadow hypertension as a predictor of adverse outcome. Clearly, the possibility of organ damage must be borne in mind when evaluating hypertensive patients.^{17,18}

ADMISSION BLOOD PRESSURE AND OUTCOME

If it is accepted that hypertension increases the risk of cardiovascular complications of anesthesia, is this the result of the presence of hypertensive heart disease or does it relate closely to the level of blood pressure at the time of admission for surgery? In 1979, Goldman and Caldera¹⁹ examined patients with arterial hypertension who were included in their risk index.¹² No significant differences were found between patients who were hypertensive at the time of surgery and those who were normotensive, treated with diuretics, or hypertensive but relatively well controlled (blood pressure below 160/100 mmHg). The absence of difference may be ascribed to two factors: (1) the study did not have the statistical power to confirm or refute an association between hypertension and outcome, and (2) very few patients had blood pressures that could be classified as stage 3 hypertension. Indeed, only 5 of 196 patients had a diastolic blood pressure higher than 111 mmHg.¹⁹ Other studies^{20,21} also suffered a lack of statistical power. One study showed a clear association between hypertension and perioperative myocardial reinfarction.²² Hypertension has also been shown to play a role in the risk of complications after coronary artery surgery.²³

Two case-control studies^{24,25} have examined the relationship between hypertension and cardiac death within 30 days of surgery with close matching for age, sex, and operation. There was no difference in the admission blood pressure between the patients who died and the survivors.²⁴ This was also true when both elective and emergency

operations were considered, although there was a tendency for survivors to have a higher admission blood pressure.²⁵ While the studies suggest that high admission blood pressure does not correlate with postoperative cardiac death, the limitation of the studies, which also applies to most recent studies of hypertension in surgical patients, is that very few patients had stage 3 hypertension; most had stage 1 or 2 hypertension. Only older studies included many patients with stage 3 hypertension. In such patients cardiovascular lability is greatly increased, and there is a high risk of myocardial ischemia and ventricular arrhythmias if they are untreated.⁷

Today, the absence of a clear association between admission blood pressure and cardiac outcome of anesthesia and surgery may reflect changes in standards of perioperative care of these patients, changes in perioperative drug therapies, changes in standards of monitoring, or improvement in the standard of care of the hypertensive patient in the community leading to fewer patients exhibiting the complications of renal dysfunction, cerebrovascular disease, or other organ damage.

Medical patients with stage 3 hypertension are at a significantly increased risk of target-organ damage that is not always apparent. Unsurprisingly, a recent guideline recommends echocardiography for the detection of left ventricular hypertrophy, and carotid Doppler sonography to detect carotid artery disease,²⁶ as the presence of such target-organ damage increases the risk of perioperative cardiovascular complications.

With the increase in blood pressure there is an increased incidence of electrocardiographic abnormalities.^{27,28} In hypertensive patients, there is evidence of an association between quality of blood pressure control and the occurrence of silent postoperative myocardial ischemia (a marker for postoperative cardiovascular complications).²⁹

Most studies have not considered arterial pressure as a continuous variable, although it is well known that, in the long term, the risk of adverse outcome correlates with the severity of hypertension.³⁰ However, when blood pressure was considered as a continuous variable in surgical patients, it became apparent that the risk of perioperative myocardial ischemia increased with blood pressure: the odds ratio was 1.2 (CI=1.01–1.42) for each 10-mmHg increase in systolic pressure.³¹ This observation indicates that in surgical patients, as in medical patients, the risk of adverse outcome increases with the level of hypertension.

ISOLATED SYSTOLIC HYPERTENSION

Isolated systolic hypertension (ISH), which accounts for the majority of hypertensive patients aged over 60 years, is a relatively new focus of interest. As a consequence of the increase in pulse pressure, ISH increases the cardiovascular risk.³² It makes sense to consider that isolated systolic hypertension is also a risk factor for surgical patients. Studies that have included mostly elderly patients are likely to have included a high proportion of patients with isolated systolic hypertension.^{20–22} As an association between high blood pressure and perioperative adverse outcome was found, these studies can be used to support

the view that isolated systolic hypertension is a risk factor in surgical patients, and certainly where stage 3 is concerned.

More recently, the issue of isolated systolic hypertension has been examined in patients undergoing cardiac surgery in a large (more than 2400 patients) prospective multicenter study.²³ Isolated hypertension was defined as a systolic blood pressure above 140 mmHg with diastolic pressure less than 90 mmHg. Isolated systolic hypertension was associated with a statistically significant increase in the likelihood of perioperative cardiac complications (odds ratio 1.3, CI=1.1–1.6) but not mortality. Based on the findings of the Framingham population,³³ it can be assumed, as the average age of the patients was 65 years in this particular study,²³ that in most patients systolic pressure was considerably higher than the threshold for inclusion (i.e., 140 mmHg). In addition, a detailed study of patients with ISH has shown that, after correcting blood pressure, coronary blood flow was substantially lower than in normotensive patients.³⁴ This further supports the view that isolated systolic hypertension cannot be discounted as a risk factor for anesthesia and surgery.

WHITE-COAT HYPERTENSION

“White-coat hypertension” is particularly relevant to anesthesia and surgery as most patients admitted to hospital or attending an assessment clinic are anxious. As a result, their blood pressure may be repeatedly higher than it would be during ambulatory monitoring. White-coat hypertension seems to have a benign prognosis.³⁵ It is tempting to conclude that there is a low risk of organ damage and that, in the surgical setting, patients whose blood pressure settles to a level consistent with normotension are not at risk of short-term complications. However, this conclusion has not been tested in a scientific study. More importantly, these patients exhibit hyper-reactivity to stress and reduced ability to control rapid increases in sympathetic activity.³⁶ This is potentially hazardous in surgical patients.

There is probably only one study that has examined the influence of labile hypertension on perioperative stability and myocardial ischemia.³⁷ The authors found that patients who were the most likely to develop arterial hypertension after endotracheal intubation often had elevated blood pressure at the time of hospital admission, even though they were normotensive while on the hospital ward. The need to intervene to control hypertensive episodes and myocardial ischemia demonstrates that labile hypertension can be regarded as a risk factor.

ANESTHESIA AND HYPERTENSIVE DISEASE

The risks of anesthesia and surgery relate to several factors: (1) the effect of hypertension on the heart as a target organ; (2) the association between hypertension, coronary artery disease, peripheral vascular disease, and diabetes; (3) the effect of hypertension on the cerebral and renal circulation; (4) the preoperative drugs and their interactions with anesthetic agents; (5) the possibility of

undiagnosed diseases that cause hypertension; and (6) the need for life-saving procedures in patients with uncontrolled hypertension.³⁸ Although preoperative control of blood pressure is generally advocated, no guideline exists as to the level of blood pressure above which deferment of surgery for instituting treatment of hypertension is necessary.

Patients with arterial hypertension exhibit exaggerated hypotension following induction of anesthesia and excessive pressor response to stresses such as laryngoscopy, intubation, surgical incision, and extubation.^{6,7} These changes reflect a large reduction in an otherwise elevated systemic vascular resistance in response to induction of anesthesia. Conversely, large increases in vascular resistance occur following sympathetic overactivity and are responsible for the large increases in blood pressure observed after laryngoscopy, during surgery, and on awakening. Indeed, in untreated hypertensive patients, large increases in norepinephrine and modest increases in epinephrine have been documented following laryngoscopy and intubation.³⁹ The exaggerated vascular responses are responsible for a pattern of blood pressure changes that has been termed “alpine anesthesia.”⁴⁰ Hypertensive patients are also more prone to hypertensive responses (bladder distension, inadequate pain relief) postoperatively. Hypertensive episodes are often associated with arrhythmias and/or myocardial ischemia.⁸ Hypo- and hypertension can cause cerebrovascular accidents. As vascular reactivity is increased in hypertensive patients,⁴¹ the benefit of controlling their blood pressure preoperatively is to reduce this hyperreactivity and to improve their cardiovascular stability. Effective treatment of hypertension also brings cerebral autoregulation to more normal levels.⁴²

Intraoperative hemodynamic abnormalities are associated with peri- and post-operative cardiovascular instability and, in some patients, cardiovascular events such as cardiac death, myocardial infarction, and stroke. In a study of 17,638 day-case patients, Chung et al.⁴³ observed an association between pre-existing arterial hypertension and intraoperative cardiovascular events (hypo- or hypertension, tachycardia). However, probably because most patients were undergoing relatively minor procedures, there were no deaths or perioperative myocardial infarctions. Another large study showed that hypertensive patients were more likely to require interventions for perioperative hypertension than their normotensive counterparts.⁴⁴ Reich et al.⁴⁵ have shown significant correlations among bradycardia, tachycardia, hypotension, hypertension (including pulmonary hypertension), and cardiovascular complications of coronary bypass surgery, confirming previous observations by Slogoff and Keats⁴⁶ regarding the adverse role of tachycardia and hypertension. More recently, Reich et al.⁴⁷ confirmed the association between tachycardia and hypertension and adverse cardiac outcome in patients undergoing prolonged operations.

Unsurprisingly, there is a relationship between the magnitude of changes in blood pressure and their duration and the risk of adverse events. Charlson et al.⁴⁸ found that patients with more than 1 hour of 20-mmHg or greater decreases in mean arterial pressure (MAP) or patients

with less than 1 hour of 20 mmHg or greater decreases and more than 15 minutes of greater than or equal to 20 mmHg increases were at highest risk for postoperative complications. As patients with uncontrolled hypertension are very likely to develop major hemodynamic abnormalities, these studies indirectly suggest that preoperative treatment of hypertension should be beneficial and that more extensive monitoring of the circulation is justified.

MANAGEMENT OF SURGICAL HYPERTENSIVE PATIENT

Ideally, all hypertensive patients should be treated because, in the long term, their prognosis is substantially improved. Hypertension discovered on the occasion of a surgical admission provides a unique opportunity to start anti-hypertensive therapy. However, such a policy, depending on the level of blood pressure at which treatment of hypertension is initiated, can lead to a very large number of cancellations or deferments. Currently, there is little scientific evidence that control of blood pressure has a significant impact on perioperative morbidity, at least in mild to moderate hypertension. Because no large randomized control trial has been undertaken, an empirical approach has developed.

PREOPERATIVE HYPERTENSION: IDEAL VERSUS EMPIRICAL APPROACHES

The difficulty in deciding which patients should be treated before anesthesia and surgery was highlighted in a survey of attitudes of anesthesiologists with respect to clinical scenarios involving hypertension. There was considerable variability as to which patients should have their procedures cancelled⁴⁹; as a result, hypertension is the most common avoidable medical indication for deferring elective surgery.^{50,51} In addition, in a short review published in 2005, Casadei and Abuzeid³⁶ stated, “Thus in the absence of controlled evidence, no firm recommendations can be made to improve patients’ safety.”

An empirical approach based on the severity of the hypertension may be helpful. Patients with severe hypertension (stage 3), defined as a systolic blood pressure of greater than 180 mmHg and/or a diastolic pressure greater than 110 mmHg, should be treated before elective surgery. They are at risk of life-threatening hypertensive crises likely to cause intracranial hemorrhage, ischemic stroke, acute left ventricular failure, ventricular arrhythmias, or renal failure. For patients with moderate hypertension (stage 2), with systolic pressure of 160 to 179 mmHg or diastolic pressure of 100 to 109 mmHg, preoperative treatment should be considered in patients with target-organ involvement. Finally, for those with mild hypertension (stage 1: 140–159/90–99 mmHg), treatment is regarded as optional.⁵²

It can be argued that where blood pressure is consistently elevated to levels of 180 mmHg or greater but there is no target-organ damage, surgery can proceed if there is a strong indication for it. Care should be taken to ensure

perioperative cardiovascular stability with administration of appropriate vasoactive agents. This requires invasive blood pressure monitoring not only during surgery but during the recovery period as well.

There are few substantive guidelines about which patients should be cancelled to allow treatment prior to surgery and for how long should such treatment be initiated before surgery. A recent American College of Cardiology/American Heart Association guideline states that uncontrolled systemic hypertension appears to be a minor clinical predictor of increased perioperative cardiovascular risk.¹⁸ The same guideline proposes that stage 3 hypertension (above 180/110 mmHg) should be controlled before surgery. Control “can be achieved over several days to weeks of preoperative outpatient treatment.” However, “if surgery is more urgent, rapid-acting agents can be administered that allow effective control in a matter of minutes or hours.” Among the agents available, “beta blockers appear to be particularly attractive.”¹⁸ If beta-blockers are used, it makes sense to titrate heart rate to below 60 beats per minute to ensure that beta-blockade is adequate.⁵³ The guideline emphasizes that “continuation of preoperative antihypertensive treatment throughout the perioperative period is critical.”¹⁸ A similar approach has been suggested by others for many years.^{8,54}

In the surgical setting, the issue of white coat hypertension is particularly complex. As many repeat blood pressure measurements as possible must be obtained to inform any clinical decision. Even with this information there is a danger that usually normotensive patients suffering from white-coat hypertension may have their operation deferred and be started on therapy unnecessarily on the occasion of surgery.

Finally, if surgery is to be deferred to allow the blood pressure to be treated, it is unclear for how long treatment should be given before the patient returns. A recent editorial suggests a period of several weeks after therapy has been started.⁵⁵

The major obstacle to the production of agreed guidelines is that no study has, as yet, conclusively shown that treatment of hypertension brings about a significant improvement in outcome in surgical patients. A possible explanation for the lack of clear evidence that treating hypertension prior to anesthesia and surgery is beneficial is that most studies of risk factors have not distinguished between treated and untreated hypertensive patients. Often patients with a history of hypertension have been included, whether or not they were currently hypertensive. No study has tried to divide the patients into subgroups as a function of the severity of their hypertension.

In the absence of strong evidence, patients have to be considered individually. A number of adverse factors (Box 60–1) are taken into consideration for the long-term treatment of hypertension.⁵⁶ It is legitimate to consider that patients with such adverse factors need particularly careful assessment of the risk of anesthesia and surgery and very careful monitoring during the perioperative period. They may need treatment even though their blood pressure does not reach stage 3 hypertension levels.

Box 60–1

Adverse Factors Relevant to Hypertensive Patients

Major Risk Factors

- Smoking
- Dyslipidemia (hypercholesterolemia >6.5 mmol/L)
- Age >60 years
- Male/postmenopausal female
- Family history of cardiovascular events

Evidence of Target-Organ Damage

- Left ventricular hypertrophy
- Clinical ischemic heart disease
- Heart failure
- Stroke/transient ischemic attacks
- Nephropathy
- Peripheral vascular disease
- Retinopathy

From The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Arch Intern Med* 1997;157:2413–46.

In view of the difficulty of defining the level of blood pressure at which patients should be treated before anesthesia and surgery, the question of regional anesthesia as an alternative to general anesthesia arises. Regional anesthesia based on epidural blockade is used extensively mostly because of excellent postoperative pain control. However, in untreated hypertensive patients, extradural blockade was found to be associated with severe hypotension and bradycardia requiring emergency treatment. Such complications were not observed in any of the treated hypertensive patients.⁵⁷ As a result, the need for preoperative treatment of hypertension is the same as that for patients presenting for general anesthesia.

THE PROBLEM WITH ATENOLOL

As many hypertensive patients receive the beta-blocker atenolol, or treatment with atenolol is initiated before surgery, recent findings concerning this particular beta-blocker need to be discussed. In 1997 Palda and Detsky,⁵⁸ in the American College of Physicians guideline for the management of surgical patients with coronary artery disease or risk factors for that condition, stated that these patients should be given atenolol. In the 2002 American College of Cardiology/American Heart Association guideline on the same topic, beta-blockade has been suggested for use in untreated hypertensive patients.¹⁸ Atenolol is often the first beta-blocker that comes to mind. However, a systematic review has shown atenolol to lack protection in the long-term management of arterial hypertension.⁵⁹ This inefficacy has also been demonstrated in the Anglo-Scandinavian Cardiac Outcomes Trial study (ASCOT).⁶⁰ The atenolol-diuretic arm of the study had to be discontinued because of the poor protection offered by this

treatment. However, there is little information on the efficacy of atenolol in the prevention of perioperative cardiac events in hypertensive patients, as opposed to their long-term event rate. In a randomized study of patients with coronary heart disease or risk factors for this condition, Mangano et al.⁶¹ showed that atenolol given for 7 days reduced the risk of myocardial ischemia and improved the long-term prognosis. As early adverse events (i.e., those occurring while patients were in hospital) were not taken into consideration, the benefits of atenolol in the short term can be questioned.

PREOPERATIVE EVALUATION

There is a need to answer the following three questions:

1. Is hypertension primary or secondary? Although secondary hypertension is infrequent, pheochromocytoma, hyperaldosteronism, renal parenchymal hypertension, and renovascular hypertension must be considered because of their anesthetic and perioperative implications. This is of utmost importance because undiagnosed pheochromocytoma is likely to cause life-threatening cardiovascular complications on the occasion of even minor operations.
2. Is the hypertension severe? This requires multiple blood pressure readings to distinguish “white-coat” hypertension from sustained hypertension.
3. Are target organs involved? The presence of coronary or cerebrovascular disease, impairment of renal function, electrocardiographic and radiologic signs of left ventricular hypertrophy, or heart failure puts the patient in a high-risk category. Such patients may require further investigations and/or treatment of the underlying conditions as well as of hypertension.

The frequent use of diuretics in the management of arterial hypertension often results in hypokalemia—unless potassium supplements, ACE inhibitors, or potassium-sparing diuretics are used. Potassium-sparing diuretics may be superior to nonsparing diuretics.⁶² The presence of chronic hypokalemia raises the question of preoperative potassium replacement. This is controversial as rapid normalization of plasma potassium may worsen the transmembrane K⁺ gradient, thereby increasing rather than decreasing the risk of arrhythmias.⁶³ In the absence of arrhythmia and U waves, and with normal T waves, the transmembrane K⁺ gradient is likely to be within acceptable limits (i.e., a 35-fold difference) and potassium supplements may not be needed. If there are electrophysiologic signs of hypokalemia, slow replacement over days rather than hours is indicated.

INTERACTIONS BETWEEN ANTIHYPERTENSIVE MEDICATION AND ANESTHESIA

While it was previously believed that antihypertensive drugs should be stopped before anesthesia and surgery, this is no longer accepted. For most drugs, treatment is

continued throughout the perioperative period and drugs are given the morning of surgery. Because of the possibility of drug interactions, the influence of antihypertensive drugs on the hemodynamic response to anesthesia and surgery has been studied extensively.

Early studies showed that beta-adrenoceptor blockers were well tolerated and promoted hemodynamic stability.⁸ Beta-blockade has been shown to prevent both hypertension and tachycardia in response to laryngoscopy and intubation and to decrease the risk of perioperative myocardial ischemia^{64,65} and adverse cardiac outcome.^{61,66} The evidence for improved outcome, however, is relatively weak as shown in a very recent systematic review of perioperative beta-blockade outside cardiac surgery.⁶⁷ By contrast, beta-blockade clearly reduces the relative risk of death after coronary artery bypass surgery.⁶⁸

In patients with mild or moderate hypertension, chronic treatment with calcium channel blockers, ACE inhibitors, diuretics, and beta-blockers does not cause exaggerated hypotensive responses to induction of anesthesia.⁶⁹ However, ACE inhibitors have been reported to cause hypotension if they are given on the morning of surgery, especially if large doses are used. Some authors recommend omitting the morning dose of ACE inhibitors.⁷⁰ Refractory hypotension may require the administration of terlipressin where conventional drugs have failed to achieve an acceptable blood pressure.⁷¹⁻⁷³ In cardiac surgery, at least, the practice of stopping ACE inhibitors can increase the need for emergency treatment of hypertensive episodes.⁷⁴ It is generally recommended that administration of angiotensin II receptor antagonists be stopped the day before surgery because of the risk of refractory hypotension requiring angiotensin or terlipressin (a peptide similar to vasopressin) to restore an acceptable pressure.^{72,73,75,76}

Studies in patients treated with alpha₂-adrenoceptor agonists have shown a decrease in sympathetic responses to noxious stimuli, decreased catecholamine release, and improved cardiovascular stability.^{77,78} Premedication with alpha₂-adrenoceptor agonists may be useful but is not widely used. Clonidine provides hemodynamic stability and reduces the risk of myocardial ischemia by reducing sympathoadrenal activity.⁷⁹ In addition, clonidine causes anxiolysis and sedation, decreases the need for both inhalation and intravenous anesthetics, and improves the quality of regional anesthesia. However, at least in coronary artery surgery, these benefits may be offset by an increased need for vasoactive and inotropic drugs. The interest for clonidine is likely to increase because its perioperative administration for a short period has been recently shown to decrease the risk of adverse cardiac events.⁸⁰ Dexmedetomidine is more selective for alpha₂-receptors than clonidine. It attenuates both hemodynamic and stress responses to surgery but could cause coronary vasoconstriction.⁸¹ Mivazerol, another alpha₂-adrenoceptor agonist, was shown to minimize the risk of adverse cardiac outcome in patients undergoing vascular surgery.⁸² Because it was not efficacious in other types of surgeries, the development of this agent was discontinued.

PERIOPERATIVE INCIDENTS AND THEIR MANAGEMENT

Cardiovascular instability is the hallmark of untreated or poorly controlled hypertension. In order to make the management of hypertensive patients safer, invasive blood pressure monitoring for major surgeries is clearly indicated. Blood pressure can then be actively managed to prevent departure of the mean arterial pressure of greater than 20% from baseline. Monitoring should continue into the postoperative period until it is clear that the patient is cardiovascularly stable. It is now frequently suggested that in patients in whom there is no contraindication, perioperative beta-blockade is valuable.¹⁸

In hypertensive patients, induction of anesthesia is often associated with large reductions in arterial pressure. This may precipitate myocardial ischemia because the reduction in diastolic pressure reduces the coronary perfusion pressure. Cerebral ischemia can occur because of the reduction in mean arterial pressure in patients with a right shifted cerebral autoregulation. In these circumstances vasopressors may be indicated.

Laryngoscopy and intubation often cause large increases in blood pressure and heart rate. Laryngeal spraying with local anesthetics is generally ineffective in preventing this response which is due to sympathetic activation. Protection can be obtained with beta-blockers,⁸ including labetalol⁸³ and intravenous bolus doses of esmolol.⁸⁴ Glyceryltrinitrate,⁸⁵ sodium nitroprusside,⁸⁶ prostaglandin E₁,⁸⁵ and fentanyl⁸⁷ have all been shown to minimize the increase in blood pressure. Deep anesthesia and the administration of droperidol, vasodilators such as hydralazine, and calcium channel blockers also minimize the rise in blood pressure. As hypertension associated with tachycardia can cause myocardial ischemia, prevention of

the hypertensive response to laryngoscopy, intubation, and extubation is clearly advisable.^{8,88}

Severe perioperative hypertension is a major threat to hypertensive patients, especially increases of blood pressure in excess of about 20% of the preoperative value. Consequences of pressure surges include bleeding from vascular suture lines, cerebrovascular hemorrhage, and myocardial ischemia/infarction. The mortality rate of such events may be as high as 50%.

With adequate blood pressure monitoring, many vasoactive agents can be used safely. The choice of the most appropriate antihypertensive therapy depends upon the clinical scenario (i.e., whether there is tachycardia, myocardial ischemia, cardiac failure, or renal functional impairment) (Table 60–1).

In the face of the most severe hypertensive crises, sodium nitroprusside may be needed; as tachycardia is likely to occur and compromise the coronary circulation, the addition of a beta-blocker may be required. Phentolamine can be given as boluses or continuous infusion. It also causes tachycardia. Nitroglycerine is often advocated. Although it is not a very potent arteriolar dilator, its anti-ischemic properties are useful. Esmolol has gained wide acceptance in the control of hypertension and tachycardia in surgical patients. Because of its short half-life, esmolol has the advantage that undesirable side effects or poor tolerance, if they occur, are only short-lived. A continuous infusion is necessary if prolonged beta-blockade is required.

Other vasodilators for severe hypertension include diazoxide and oral drugs such as prazosin, doxazosin, and terazosin.

Labetalol, a stronger beta- than alpha-blocker, is an effective antihypertensive agent. Its relatively weak peripheral vasodilatation potentiates the hypotensive action of beta-blockade.

DRUGS FOR PERIOPERATIVE MANAGEMENT OF HYPERTENSIVE EMERGENCIES		
Clinical Requirement	Mechanism of Action	Drug of Choice
Extremely severe acute hypertension	NO donor	Sodium nitroprusside
Hypertension plus ischemia	NO donor	Nitroglycerine infusion
Hypertension plus tachycardia and ischemia	Beta blocker	Esmolol, bolus or infusion
	Alpha and beta blocker	Labetalol, bolus or infusion
Hypertension plus heart failure	ACE inhibitor, inodilator, vasodilator	Dobutamine, dopexamine
Hypertension without cardiac complication	Vasodilator	Hydralazine
		Phentolamine
		Nifedipine
		Nicardipine
Hypertension and renal impairment		Fenoldopam
Hypertension caused by pheochromocytoma		Phentolamine
		Labetalol
		Doxazosin, prazosin, terazosin

ACE, angiotensin converting enzyme; NO, nitric oxide.

Table 60–1. Drugs for Perioperative Management of Hypertensive Emergencies

Intravenous hydralazine is an old “stand-by” with a proven track record. Its disadvantage is that it can cause marked tachycardia, as well as flushing, headaches, and dizziness.

Sublingual nifedipine is effective⁸⁹ but the reduction of blood pressure may be excessive and tachycardia may facilitate the development of ischemia. The sublingual route is difficult to control.⁹⁰ Yet 10 mg of sublingual nifedipine has been advocated in the management of postoperative hypertension after carotid endarterectomy.⁹¹ However, because of the variability of its effects, sublingual nifedipine cannot be recommended.

Intravenous fenoldopam, a dopaminergic₁-receptor agonist, has been specifically tested in the management of postoperative hypertension.^{92,93} At variance with other vasodilators, fenoldopam causes a natriuresis rather than sodium retention. There is risk of tachycardia.

Intraoperative and postoperative management has become safer owing to better monitoring, better anesthetic agents, and better recovery facilities. Nevertheless, the availability of very effective drugs to control hypertensive crises should not be taken as indication that proper preoperative preparation is no longer necessary. Devastating elevations in blood pressure can develop over 5 to 10 cardiac cycles: no drug, even injected intravenously immediately, can act quickly enough. It is therefore essential to ensure that patients with severe hypertension are well controlled before anesthesia and surgery. Similarly, those with moderate hypertension and target-organ involvement should be controlled. This approach coupled with the availability of potent hypotensive agents to combat hyper-

tensive crises and effective vasopressors to restore adequate perfusion pressure should make it possible to reduce the risk of cardiovascular complications in surgical hypertensive patients.

SUMMARY

More than 30 years after the first detailed studies of the responses to anesthesia of hypertensive patients, specific evidence-based guidelines for their preoperative management are still lacking. Indeed, in an editorial published in 2004, Spahn and Priebe⁵⁵ state: “Any recommendation to postpone elective surgery for the purpose of blood pressure control must be balanced against the urgency and benefit of the planned operation; must take into account that arterial blood pressure should be corrected slowly, and up to two months may be required to reverse some of the hypertension-induced cardiovascular changes...” This echoes the view expressed earlier by Fleisher⁵³: “Clearly the practice of postponing surgery must be balanced against the urgency of surgery.”

Nevertheless, it is generally agreed that patients with stage 3 hypertension should be treated preoperatively, and those with stage 2 hypertension should be considered for treatment if there is evidence of target-organ damage.

The preoperative evaluation of hypertensive patients presents us with two unique opportunities: (1) to detect the presence of target-organ damage with appropriate investigations, and (2) to initiate long-term treatment where immediate treatment is not regarded as essential before surgery but is necessary for the long-term protection of the patient.⁵³

Chapter
61Hypertension in the Context
of Acute Myocardial Infarction
and Percutaneous Coronary
Interventions*Rumi Jaumdally and Gregory Y. H. Lip***Key Findings**

- Reduction of blood pressure should be gradual to avoid end-organ hypoperfusion.
- Adequate analgesia and an anxiolytic if indicated should be prescribed.
- First-line treatment should include intravenous nitrates or beta blocker with sodium nitroprusside, and/or a calcium antagonist as alternatives, in severe hypertensive emergencies.
- Primary angioplasty is an option if thrombolytic therapy is unacceptable and such service is available.
- In the long-term postcoronary event, beta-blockers and angiotensin-converting enzyme inhibitors are the mainstays of treatment with convincing mortality benefits. In cases with clear contraindications or intolerance to the former, a calcium antagonist, such as verapamil or diltiazem, may be used as an alternative in patients with good left ventricular function.

Clinical Implications

- Thrombolytic therapy and glycoprotein IIb/IIIa inhibitor use may be delayed or contraindicated due to higher risk of cerebral hemorrhage with uncontrolled hypertension.
- Abnormal baseline electrocardiography may cause diagnostic uncertainty and mask ongoing ischemia.
- Left ventricular hypertrophy results in more cardiac complications or sudden cardiac death.
- Secondary causes of severe hypertension should be considered (e.g., aortic dissection, renal artery stenosis, pheochromocytoma).
- Risk of catheter-induced dissection of the aorta or coronary artery is higher in association with uncontrolled hypertension.

Hypertension commonly coexists in patients presenting with acute myocardial infarction (AMI) or undergoing percutaneous coronary interventions (PCIs), often in association with hyperlipidemia and diabetes mellitus. Given the exaggerated coronary event rate in a diabetic cohort, up to 75% of these complications may be attributable to coexisting hypertension.¹ Effective treatment of hypertension leads to substantial reductions in stroke, coronary events, and cardiovascular mortality.^{1,2}

During sleep, blood pressure (BP) in most people is between 10% and 20% lower than the mean daytime value. On arousal and the start of day-to-day activities, there is a surge in BP that may last for 4 to 6 hours. Indeed, cardiovascular events, such as MI, cardiac ischemia, and stroke are more frequent in the morning hours soon after waking compared to other times of day.

For any given level of BP, mortality rates from coronary heart disease vary among different populations and ethnic groups. In the Seven Countries study,³ for example, the absolute risk was much higher in the United States and Northern Europe compared to Japan and Mediterranean populations with similar BP. Indo-Asians appear to have a higher complication rate than white Europeans for equivalent BP elevations.^{4,5} Indo-Asians also tend to experience cardiovascular events at a younger age, but have a lower rate of self-reported hypertension.^{6,7} Afro-Caribbean patients with hypertension are also at greater risk of developing cardiovascular complications compared to white Europeans.⁸

As increased sympathetic nervous system activity has been implicated in the pathophysiology of high BP, a heightened pain exposure response to physical and psychosocial stress can result in high BP levels being recorded in patients undergoing PCI or with an AMI, who are not known to have precedent or antecedent hypertension. Rarely, accelerated or malignant phase hypertension can present with an AMI, as can illicit drug use. For example, MI remains the most frequent, single reported cardiac complication of cocaine use, which itself predisposes to hypertension and left ventricular hypertrophy (LVH).⁹ Systemic causes of arteritis, such as lupus erythematosus and arch aortitis, can also present with a combination of hypertension and AMI.

CLINICAL ASSESSMENT

In addition to a clear and detailed history pertaining to coronary disease, patients should be asked specifically about the initial diagnosis of high BP, the duration of therapy, compliance, and drug type. Other clinical features such as ethnicity, time of presentation, and noninvasive investigations should be noted.

In patients with poorly controlled hypertension, the baseline 12-lead electrocardiogram (ECG) is frequently

abnormal with lateral ST-T segment depression and left bundle branch block, often in association with LVH.¹⁰ As such changes mimic those of cardiac ischemia and infarction, unnecessary delay and confusion may arise in diagnosis, with further problems in recognizing ongoing cardiac ischemia or even re-infarction (Box 61–1).

THERAPEUTIC STRATEGIES

Once the diagnosis of acute coronary occlusion is made, patients with a very high BP present a clinical dilemma. Uncontrolled BP may contribute to a risk of bleeding with thrombolytic therapy for acute MI, or with the multiple antithrombotic drugs (aspirin, clopidogrel, glycoprotein IIb/IIIa inhibitors) used during PCI. Poorly controlled BP may also increase the risk of procedural blood loss during PCI maneuvers.

While use of thrombolytic agents is contraindicated in the presence of very high BP (>180/110 mmHg),¹¹ intravenous drug infusions to achieve adequate BP control may delay and exacerbate myocardial perfusion. Care should be taken to avoid an abrupt reduction of pressure with consequent loss of vasomotor autoregulation.¹² The effects may manifest as cerebral “watershed” infarction, acute tubular necrosis, and even more subendocardial ischemia. The aim, therefore, should be to lower the BP using intravenous drugs infused slowly, with stringent clinical assessment of the patient (Table 61–1).

Nitrates

Nitroglycerine (GTN) infusion probably has the safest profile, and thus is recommended as first-line treatment to lower BP in the acute setting. Nitrates lower the cardiac venous return at low doses with arteriolar (including coronary arteriolar) dilatation, thus improving both heart

Box 61–1

Relevance of Hypertension in Managing Acute Myocardial Infarction and Percutaneous Coronary Interventions

- Exclusion and treatment of secondary hypertension
- Effect of abnormal baseline electrocardiographs on diagnosis
- Synergistic effect of left ventricular hypertrophy on cardiac complications
- Noncoronary cause of ischemia (subendocardial ischemia)
- Concomitant end-organ damage
- Aortic dissection
- Re-evaluation of thrombolytic therapy in favor of percutaneous coronary intervention
- Timely administration of glycoprotein IIb/IIIa inhibitor use
- Coronary dissection and spasm

failure and myocardial perfusion. In those patients with marked coronary spasm presenting with or exacerbating acute infarction, nitrate-induced vasodilatation may also be of particular benefit. A useful regimen of 5 to 10 mcg/minute with increases of 5 to 20 mcg/minute until symptoms are relieved or mean arterial BP is reduced by up to 30% for hypertensive patients has been suggested. Alternatively, sodium nitroprusside results in a reduction of both pre- and after-load in patients with BP in excess of 180/110 mmHg. In the context of AMI and PCI, nitrates have the advantage of prompt resolution (within

DRUGS FOR HYPERTENSIVE EMERGENCIES DURING AMI AND PERCUTANEOUS CORONARY INTERVENTION		
	Indication	Caution
Benzodiazepine	Anxiety Drug abuse	Respiratory depressant
Morphine	Analgesia	Confusion state
ACE inhibitors	Heart failure Diabetes	Aortic valve and renovascular disease Volume depletion
Beta-blocker	AMI Angina	Peripheral and pulmonary disease Heart failure and block Cocaine use
Calcium antagonist (dihydropyridine)	Isolated systolic hypertension in the elderly	Sublingual short-acting nifedipine should not be used
Calcium antagonist (rate limiting, nondihydropyridine)	Angina AMI	Heart failure and block Recent beta-blocker use
Nitrates or sodium nitroprusside	All	Concomitant use of sildenafil Dehydration Right ventricular AMI
AMI, acute myocardial infarction; ACE, anti-tension-converting enzyme.		

Table 61–1. Drugs for Hypertensive Emergencies during AMI and Percutaneous Coronary Intervention

minutes) of BP after intravenous cessation but reflex tachycardia remains an undesirable feature.

Pooled analyses of clinical trials have suggested a modest mortality benefit from nitrate-like preparations used acutely in AMI, with possibly three to four fewer deaths for every 1000 patients treated.¹³ Thus, nitrates should be used if hypotension limits the administration of beta-blockers, which may exert more beneficial effects. Care should be employed if the systolic pressure drops below 90 mmHg in patients with suspected tachycardia or right ventricular wall ischemia or infarction.

Beta-blocker

In the absence of contraindications such as acute heart failure, conduction defects, advanced peripheral artery disease, and pulmonary disease, beta-blockers should be considered as first-line therapy particularly in the first few hours of AMI. Beta-blockers can be administered either orally or by infusion, and intravenous agents such as esmolol and metoprolol have a short half-life, with fast onset and offset of action.

These drugs are effective at lowering BP, and have beneficial cardiac effects by lowering the heart rate, myocardial oxygen demand, wall stress, ventricular arrhythmias, and cardiac output.¹⁴ Furthermore, there is compelling evidence that beta-blockers as acute secondary prevention reduce the risk of all-cause mortality, coronary mortality, recurrent nonfatal MI, and sudden death in these patients.¹⁵

Following fibrinolytic therapy, intravenous metoprolol was associated with a diminished incidence of subsequent nonfatal reinfarction and recurrent ischemia, together with lowered rate of re-infarction or death if given early (<2 hours).¹⁶ Such an effect appears in patients who are not receiving thrombolysis, with early studies suggesting a modestly favorable influence on infarct size and mortality benefit as well.^{17,18} However, caution should be observed in patients with AMI precipitated by cocaine use because of the risk of exacerbating coronary spasm.¹⁹

Randomized trials of beta-blocker therapy in patients undergoing primary PCI have not been performed. However, for those with transient or sustained LV dysfunction, beta-blocker use has been associated with a reduction in composite endpoint of all-cause and cardiovascular mortality, and recurrent nonfatal MIs, whether patients had thrombolysis or PCI for AMI.²⁰ In the context of primary PCI,²¹ beta-blockers can reduce malignant ventricular tachycardia²² and minimize myocyte necrosis, as assayed using periprocedural creatinine kinase release.^{23,24} Pre-treatment may also reduce mortality within the hospital and at a year.²⁵ As potential inhibitor of vascular smooth muscle-cell migration and proliferation,²⁶ some data even suggest that beta-blockers may lower clinical restenosis following PCI.²⁷

Calcium channel antagonists

The calcium antagonists are effective antihypertensive drugs. Short-acting dihydropyridine calcium antagonists (in particular, sublingual nifedipine) can induce reflex tachycardia and dose-related BP fluctuations that may be

detrimental in the setting of an acute MI. Trials in the 1980s of early or late use of nifedipine in patients with AMI have yielded no clear benefit, with the potential for exacerbating ischemia or re-infarction. It appears that there is no role for sublingual or oral nifedipine preparation in treating high BP during AMI. Long-acting dihydropyridine such as amlodipine and nisoldipine have also been studied following PCI. However, randomized controlled trials using the stent procedure showed no reduction in luminal loss following PCI.^{28,29}

Rate-limiting calcium antagonists (verapamil and diltiazem) may be useful in the absence of heart failure or LV dysfunction, especially if beta-blockers are contraindicated and atrial tachyarrhythmias are present. In cases of balloon angioplasty, a meta-analysis of calcium channel blocker use in five trials has shown a reduction in angiographic restenosis.³⁰ In the Verapamil Slow-Release for Prevention of Cardiovascular Events after Angioplasty (VESPA) Trial, the use of verapamil within 30 minutes of PCI and bare metal stent implantation gave broadly similar results.³¹ Thus, the use of rate-limiting calcium antagonist may potentially help in reducing coronary spasm and flow during PCI.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers

Angiotensin-converting enzyme (ACE) inhibitors are potent antihypertensive drugs via their vasodilator, neurohormonal, sympathetic, and renal effects. All the trials investigating oral ACE inhibitor prescription within 24 hours of AMI have shown beneficial results. In a large meta-analysis of more than 100,000 patients randomized following AMI, prescription of ACE inhibitors was linked with a reduction of about 7% in mortality. Patients, who seem to have the highest benefit belong to the 55- to 75-year age group, had anterior territory infarct, and had features of heart failure.³² However, data from the Cooperative New Scandinavian Enalapril Survival Study (CONSENSUS) pointed to an increase in adverse clinical effects in the group treated with intravenous ACE inhibitor. This outcome seems to be related to inducing hypotension in an older cohort within the trial.

Data for the angiotensin receptor blockers (ARBs) also appear encouraging, suggesting that they may be comparable to ACE inhibitors. In the two trials comparing ARBs (losartan and valsartan) with captopril,^{33,34} no difference in mortality was found at follow-up between the two drugs. Thus, ARBs could be considered in patients with AMI who are intolerant of ACE inhibitors, especially in the setting of LV dysfunction.

For patients undergoing PCI electively, oral ACE inhibitors remain the drug of choice. In the longer term, ACE inhibitor treatment is effective in cardiovascular prevention among patients with coronary artery disease, with particular benefits for those with LV dysfunction and diabetes.^{35,36} There are no randomized trials looking at its systemic use in acute primary PCI. Several groups have investigated possible benefits of ACE inhibitors on secondary endpoints following PCI. Although ACE inhibitor therapy before PCI may lead to a reduction

in the requirement for revascularization after coronary stent deployment,³⁷ randomized clinical trials have failed to show any significant reduction in coronary events³⁸ or in-stent restenosis.^{39,40}

SUMMARY

In patients with AMI and those undergoing PCI, underlying secondary causes of hypertension should be excluded. Adequate analgesia and an anxiolytic if indicated should be prescribed.

In the majority of patients with AMI or undergoing PCI, treatment should be aimed at optimizing and restoring blood flow to viable but ischemic myocardial tissue, minimizing drug side effects and reducing mortality. Reduction of BP should be gradual to avoid end-organ hypoperfusion. Recommended strategies could include a regimen leading to a 30% reduction of BP gradually over minutes without inducing a drop to a systolic of less than 90 mmHg. First-line intravenous treatment should include a beta-blocker, failing which intravenous nitrates or sodium nitroprusside can be used. As for initiation of oral therapy within hours of AMI and PCI, beta-blockers and ACE inhibitor remain the drugs of choice. In all cases, contraindications to these drugs should be carefully screened for, with careful monitoring of vital signs during drug administration. Primary angioplasty is an option if thrombolytic therapy is unacceptable and such a service is available. An approach to the patient with AMI and severe hypertension is summarized in Figure 61-1.

In the long-term postcoronary event and or procedure, beta-blockers and ACE inhibitors are the mainstays of treatment with convincing mortality benefit. In cases with clear contraindications or intolerance to the former, ARBs may be used as an alternative. In patients with good LV function, the rate-limiting calcium antagonists are an option.

Chapter
62**Hypertension in Patients with Concomitant Cardiac Disorders***Hung-Fat Tse***Key Findings**

- In a significant proportion of patients, hypertension directly contributes to or is accompanied by a range of concomitant cardiac disorders, including heart failure, atrial fibrillation, and coronary heart disease.
- Numerous clinical trials have demonstrated that adequate blood pressure control, rather than the types of agents used, is essential in preventing those cardiac diseases in hypertensive patients.

Clinical Implications

- The treatment of hypertension in patients with concomitant cardiac diseases often requires multiple pharmacologic agents with additive or synergistic agents for the compelling indications to achieve acceptable blood pressure control and to improve the tolerability of treatment.

The management of hypertensive patients with concomitant cardiac disorders is important and challenging. In most patients, hypertension is accompanied by a range of concomitant cardiac disorders that can contribute to target-organ damage and have a key role in their progression and response to treatment. On the other hand, hypertension also contributes pathophysiologically to the development of these cardiac diseases. Therefore, adequate blood pressure control is particularly essential in those patients, and their blood pressure goals of drug therapy are substantially lower than those patients without cardiovascular diseases (Table 62–1).^{1–4} Unfortunately, recent studies have shown that hypertension remains poorly controlled in a significant proportion of patients.⁵ In the majority of patients with concomitant cardiac diseases, combinations of multiple antihypertensive agents with additive or synergistic are required to improve the efficacy of blood pressure control and tolerability of treatment. Congestive heart failure and atrial fibrillation have been described as two emerging epidemics of cardiovascular disease associated with an ageing population. Coronary heart disease remains the major cause of morbidity and mortality in developing countries. This chapter is intended to provide a comprehensive overview on the management of hypertension in patients with concomitant cardiac disorders, including heart failure, atrial fibrillation, and stable coronary heart disease.

ANATOMY AND PATHOLOGY

An excessive increase in afterload imposed by hypertension leads to cardiac compensation with progressive thickening of the left ventricular wall to cause concentric left ventricular hypertrophy (LVH). However, prolonged pressure overloading due to uncontrolled hypertension can eventually result in progressive deterioration in contractile pumping (systolic) function and the left ventricular cavity becoming dilated. An increase in left ventricular filling pressures due to impairment of left ventricular systolic and/or diastolic function can lead to left atrial enlargement. In patients with hypertension, left atrial enlargement may develop early in the course of disease, and is independent of the presence of LVH and atrial fibrillation.⁶ However, the prevalence of left atrial enlargement increases with the development of LVH, and correlates with the degree of hypertension.⁷ Both left atrial enlargement and LVH play an important role in the development of atrial fibrillation in patients with hypertension.⁶ In addition to coronary microvascular disease, hypertension also contributes to the development of atherosclerotic coronary artery disease.

PATHOPHYSIOLOGY

The pathophysiologic interaction between hypertension and other concomitant cardiac diseases is summarized in Figure 62–1. Even before impairment of systolic function, the stiffness of the left ventricular wall can be increased by the myocardial fibrosis associated with LVH, and myocardial ischemia due to ischemic heart disease. Both of them contribute to the impairment of the filling (diastolic) function of the left ventricle. Ischemic heart disease may also occur because of the combination of hypertensive microvascular disease, concomitant atherosclerotic coronary artery disease in association with other coronary artery risk factors, and increased myocardial oxygen requirements as a consequence of LVH. The combination of decreased oxygen supply in the setting of increased oxygen demand with LVH explains why patients with hypertension have a higher risk of myocardial infarction or other major coronary events, and at higher mortality with acute myocardial infarction.⁸

Furthermore, hypertension is associated with structural changes in the left atrium that can contribute to the development of atrial fibrillation. The structural changes include left atrial enlargement and impairment of left

atrial mechanical function that subsequently lead to alteration of left atrial electrophysiology, and increased atrial ectopic activity that triggers the initiation of atrial fibrillation.⁶ Finally, persistent uncontrolled blood pressure, tachycardia-induced cardiomyopathy associated with atrial fibrillation,⁹ and the development of myocardial infarction can eventually lead to progressive deterioration of left ventricular systolic function that causes heart failure.

CLINICAL PRESENTATIONS

In patients with blood pressure higher than 160/90 mmHg, the lifetime risk of developing congestive heart failure is two times higher than those with blood pressure lower than 140/90mmHg.¹⁰ The risk of coronary artery disease increases with blood pressure, and the risk of a recurrent coronary event in patients with coronary heart disease is also significantly affected by the blood pressure level.¹¹ Effective treatment of hypertension preventing the development of coronary heart disease and heart failure provides further evidences to support a major contribu-

tion of elevated blood pressure to the onset and progression of both conditions.¹²⁻¹⁵ However, there are conflicting data regarding the prevalence of hypertension in patients with heart failure due to the difference in study design and population.¹⁶ These studies have reported that hypertension is a comorbidity in up to 26% to 45% of patients with congestive heart failure. Although hypertension is considered to be the primary etiological factor for heart failure in only 7% of patients, the contribution of hypertension to heart failure is likely to be underappreciated. In patients with hypertension and coronary heart disease who develop heart failure, hypertension is usually regarded as secondary rather than primary cause of heart failure. Furthermore, blood pressure falls as progressive systolic left ventricular dysfunction develops in some patients with hypertension. Impairments of both systolic and diastolic dysfunction of left ventricle associated with hypertension can contribute to symptoms and signs of heart failure. On the other hand, patients with hypertension may also suffer from other primary or concomitant causes for impairment of left ventricular function, such as ischemic and dilated cardiomyopathy, valvular dysfunction, and atrial fibrillation.

Although the relative risk of developing atrial fibrillation in patients with hypertension is lower than other cardiovascular diseases, such as heart failure and myocardial infarction,^{17,18} hypertension remains the most common causes of atrial fibrillation due to its high prevalence in the general population. Indeed, previous cohort studies in United States have demonstrated that hypertension was present in up to half of patients with atrial fibrillation.¹⁷⁻¹⁹ Although in these cases, hypertension was considered as causative for atrial fibrillation in ~15% of patients, the actual incidence remains unclear. One of the major complications of both hypertension and atrial fibrillation is stroke. As compared to general population, atrial fibrillation increases the risk of stroke by three- to six-fold and accounts for at least 15% of strokes.²⁰ The presence of hypertension further increase the risk of stroke associated with atrial fibrillation by an additional two- to three-fold.²¹

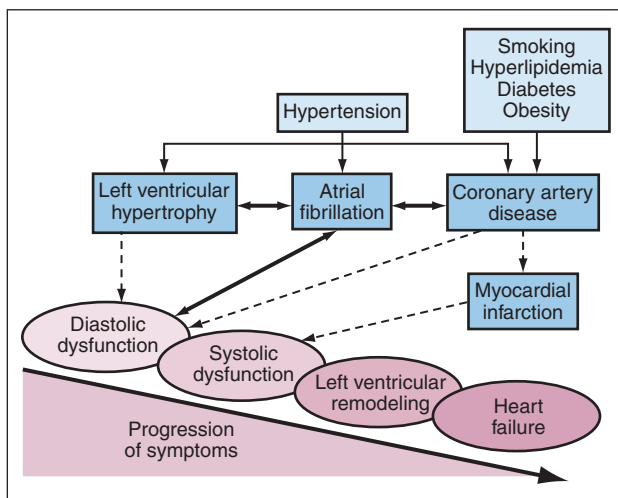

Figure 62-1. Complex pathophysiologic interactions between hypertension and progression to other concomitant cardiac diseases via the development of left ventricular hypertrophy, coronary artery disease, and left ventricular systolic and diastolic dysfunction.

DIAGNOSTIC TECHNIQUES

Rational approaches for treatment in those patients need detailed delineation of the pattern of left ventricular dys-

function and documentation of the arrhythmia in relation to symptoms. The symptoms and signs of heart failure in patients with systolic and diastolic ventricular dysfunction are very similar, and it is difficult to differentiate between them clinically, especially in elderly patients. Furthermore, typical symptoms and signs of heart failure may be absent in patients with early left ventricular systolic dysfunction, even when it is significant. On physical examination, the heart is enlarged and has a prominent left ventricular impulse. A fourth heart sound is frequently observed in hypertensive heart disease, and a third heart sound or gallop rhythm may be present. Electrocardiogram (ECG) may show LVH, evidence of myocardial ischemia or infarction, and the presence of atrial fibrillation. However, as atrial fibrillation can be paroxysmal and frequently asymptomatic in a significant proportion of patients, a 12-lead ECG has limited sensitivity for diagnosis of atrial fibrillation. The use of ECG monitoring with a Holter or loop recorder can improve the detection rate for atrial fibrillation. Measurement of the plasma levels of B-type natriuretic peptide (BNP) may be used to facilitate the initial screening for left ventricular dysfunction in patients with hypertension.^{22,23} Both a BNP level of 35 pg/mL and N-terminal pro-BNP level of 235 pg/mL show a moderately high positive predictive value (82% to 89%) in predicting heart failure in patients with hypertension.²²

Transthoracic echocardiography can be used to evaluate the left atrial size, LVH, and left ventricular function in patients with hypertension. The frequency of LVH detected by echocardiogram is higher than observed with ECG. Doppler assessment of mitral and pulmonary venous flow as well as tissue Doppler are very sensitive methods for detecting changes in left atrial function and left ventricular diastolic function. Analysis of the pulse-wave Doppler signal of the mitral inflow during diastole and the wave-form analysis of pulmonary vein flow are common methods used to detect diastolic dysfunction. Based on the mitral and pulmonary Doppler flow, four stages of diastolic dysfunction have been described. In the first stage, the early mitral inflow (E wave) is less than the late mitral inflow due to atrial contraction (A wave). As a result, there is a reversal of E/A ratio (<1.0) and prolongation of deceleration time (>200 ms) of the E wave. In the second stage, pseudonormalization of the mitral Doppler flow with normal E/A ratio and deceleration time are observed, but the pulmonary venous flow is reversed due to elevated left atrial pressure. In the third stage, a restrictive filling pattern with an increased E/A ratio (>2) and a short deceleration time (<150 ms) occur, which can be normalized by Valsalva maneuver. In the fourth stage, this restrictive pattern can not be normalized by Valsalva maneuver.

However, one of the potential limitations of these Doppler indices is they are preload dependent. Tissue Doppler is a new technique that is used to directly measure the velocity of myocardial displacement at the mitral annulus as the left ventricle expands in diastole. These tissue velocities measured during early filling and after atrial contraction are termed E' and A', respectively. The ratio of E/E' is frequently used as an index diastolic dysfunction. In contrast, this tissue Doppler index is a

minimally load-dependent measurement that can further increase the sensitivity and specificity of diastolic dysfunction detection. Furthermore, impaired left atrium and left ventricular diastolic function and the presence of LVH can predict the development of atrial fibrillation in patients with hypertension.

Diagnosis of coronary artery disease in patients with hypertension is important but can be difficult due to the presence of LVH. As a result, routine exercise stress ECG testing in hypertensive patients is associated with a high false-positive (62%) and -negative rate (53%). Exercise or pharmacologic SPECT thallium or sestamibi tests are more useful noninvasive tests in patients with hypertension. The negative predictive value of these tests is 94% to 98% with an overall accuracy of 70%.²⁴ Although the latest advances in multidetector computed tomography allow visualization of the coronary artery, coronary angiography still remains the gold standard for the diagnosis of coronary artery disease.

MANAGEMENT

Prevention

Adequate blood pressure control through lifestyle modification and antihypertensive therapy can directly prevent heart failure by reducing the left ventricular workload and indirectly via regression of LVH and prevention of ischemic heart diseases. As compared with placebo, previous clinical studies have demonstrated that blood pressure lowering with antihypertensive agents prevents coronary heart disease and heart failure in patients with diastolic or systolic hypertension.¹³⁻¹⁶ Several meta-analyses have been performed to address the differences between regimens based on different drugs in their effects on prevention of heart failure and coronary heart disease.^{25,26} These analyses demonstrate that regimens based on diuretics, angiotensin-converting enzyme (ACE) inhibitors or β -blocker are more effective at preventing heart failure than those regimens based on calcium channel blockers. For prevention of coronary heart diseases, meta-analyses show no clear difference between diuretic, ACE inhibitors, β -blocker, and calcium channel blockers. Treatment regimens based on angiotensin-receptor blockers (ARB) also appear to be useful in reducing heart failure, but not coronary heart disease. Thus these meta-analyses indicate that blood pressure lowering rather than the use of specific agents makes the difference in outcome.

Indeed, current evidence²⁷⁻³² confirms that the level of blood pressure lowering is important in reducing cardiovascular events. In the Heart Outcomes Prevention Evaluation (HOPE) trial, a small reduction in blood pressure with the ACE inhibitor ramipril in high-risk patients significantly reduced the risk of coronary heart disease and heart failure.²⁷ However, there are conflicting data on the specific benefits of various medications over and above the effects of blood pressure lowering. In the Anti-hypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT),²⁸ the incidence of fatal and nonfatal coronary artery disease were similar between

patients treated with a diuretic, ACE inhibitor, or calcium channel blocker based treatment regimen. Further analysis showed that the blood pressure control was better in the diuretic group than the ACE inhibitor group, and the risk for development of heart failure was significantly lower in the diuretic group. In the Valsartan Antihypertensive Long-Term Use Evaluation (VALUE) study, there was no significant difference in the overall risk for fatal and nonfatal heart failure, but the risk of myocardial infarction was increased in patients treated with valsartan.²⁹ However, the risk of heart failure hospitalization was significantly reduced by 36% in patients with controlled blood pressure (systolic <140 mmHg) compared to those without blood pressure control, independent of drug type used.³⁰ In the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) studies, there was no significant difference in the risk of heart failure between treatments with an ARB versus β -blocker.³¹ Finally, in the Anglo-Scandinavian Cardiac Outcomes Trial-Blood Pressure Lowering Arm (ASCOT-BPLA) trial,³² a calcium channel blocker (plus an ACE inhibitor) regimen was compared with a β -blocker (plus a diuretic) regime. Although the former regimen reduced mortality, total coronary events and stroke, there was no difference between the two regimens in the primary endpoint of fatal and nonfatal myocardial infarction. Further analysis suggested that even after adjusting for the blood pressure difference; the calcium channel blocker-based regimen contributed significant effects in decreasing total coronary events and strokes.³³ Based on these findings, newer agents (ACEI inhibitor and calcium channel blocker) appear to be slightly better than older agents (β -blocker and diuretic) in reducing cardiovascular events; however, multiple medications are necessary to achieve blood pressure control and to reduce cardiovascular events.

Optimal blood pressure level

The optimal blood pressure targets in hypertensive patients with concomitant heart failure, atrial fibrillation, and coronary heart disease have not been defined. Despite the importance of hypertension in the development of these concomitant cardiac diseases and their complications, limited data are available on their prevention and treatment in patients with hypertension. Although the optimal blood pressure target in these patients with hypertension remains unclear, aggressive treatment of blood pressure in those patients is recommended.

In the Hypertension Optimal Treatment (HOT) study and INDividual Data ANalysis of Antihypertensive intervention (INDANA) database, there was no evidence of a J-shaped curve to suggest that blood pressure lowering had harmful effects in patients with coronary heart disease.^{34,35} Furthermore, effective treatment of heart failure frequently requires lowering the blood pressure to values below current recommended target in patients with cardiovascular diseases (Table 62–1).

Antihypertensive therapy has been shown to reverse some of the structural changes, such as LVH and left atrial enlargement, that are associated with the development of these concomitant cardiac diseases in hypertension. In

patients with hypertension, blood pressure lowering with antihypertensive agents results in regression of ventricular hypertrophy. However, certain new antihypertensive agents, such as calcium antagonists, ACE inhibitors, and ARBs, may result in more LVH regression, independent of the magnitude of blood pressure reduction.^{25,26} The effect of antihypertensive therapy on regression of left atrial enlargement is less clear. In a comparison study, diuretic therapy appears to be more effective than other classes of agents, including clonidine, atenolol, diltiazem, prazosin, and captopril—in reduction of left atrial size, independent of blood pressure lowering and baseline left ventricular mass.³⁶ Although the clinical implications of these structural changes with antihypertensive treatment on the development of atrial fibrillation remain unclear, appropriate treatment of hypertension, even without atrial fibrillation, results in a significant reduction in mortality and strokes.^{25,26}

Heart failure

In patients with systolic heart failure, ACE inhibitors³⁷ and β -blockers³⁸ are well-established treatment regimens to reduce cardiovascular morbidity and mortality. Current data suggested the use of bisoprolol fumarate, metoprolol succinate, and carvedilol, but not metoprolol tartrate or atenolol in patients with heart failure.³⁹ As shown in Table 62–2, initial treatment of hypertension in patients with systolic heart failure should include ACE inhibitors and β -blockers.^{1–4} Diuretic therapy alone should not be the initial treatment in patients with established heart failure. However, diuretic therapy is an effective adjunct to ACE inhibitors and β -blockers for blood pressure control, and to relieve congestive symptoms of heart failure. In patients with advanced heart failure, antialdosterone therapy with spironolactone reduced heart failure mortality.⁴⁰ ARBs can be used as alternatives to ACE inhibitors in patients intolerant to ACE inhibitor, or in combination with ACE inhibitors.⁴¹ Further analysis suggested the add-on ARB therapy to ACE inhibitors only has beneficial effects in heart failure patients who were not receiving a β -blocker.^{42,43} Long-acting dihydropyridine calcium channel blockers have neutral effect on mortality in patients with heart failure, but they are useful for blood pressure control in those patients who are refractory to other agents.⁴⁴

In contrast to systolic heart failure, very limited data are available on the treatment of diastolic heart failure. Again, aggressive blood pressure reduction with multiple agents to achieve regression of LVH is recommended. Calcium channel blockers may theoretically have several beneficial effects in patients with diastolic heart failure by their blood pressure and heart rate lowering effects and lusitropic properties. Previous studies have suggested that verapamil increases exercise capacity in patients with hypertension and diastolic heart failure.⁴⁵ However, recent studies suggested that candesartan was more effective than verapamil in improving symptoms and exercise capacity in those patients.⁴⁶ Indeed, the CHARM study suggested that treatment with ARBs reduced heart failure hospitalization in patients with heart failure and preserved the ejection fraction.⁴⁷

Atrial fibrillation

Regarding treatment of atrial fibrillation, successful restoration and maintenance of sinus rhythm are conceptually expected to improve quality of life, reduce the incidence of strokes, heart failure and mortality, and avoid the use of life-long anticoagulation. However, recent randomized trials have failed to show any superiority for a rhythm control strategy, primarily pharmacologic rate control plus anticoagulation strategy in terms of quality of life, stroke, or mortality.^{48–51} These studies highlighted the low clinical efficacy of current antiarrhythmic agents to maintain sinus rhythm. This probably contributes to the stroke risk associated with rhythm control, especially in a high-risk hypertensive population. Therefore, in patients with hypertension and atrial fibrillation, unless contraindicated, oral anticoagulant with warfarin should be the mainstay of preventive therapy for stroke, irrespective of whether rate or rhythm control strategy is used. In high-risk patients with atrial fibrillation, including those with hypertension; age more than 65 years; prior history of stroke or transient ischemic attack, heart failure, diabetes, valvular heart diseases, and impaired left ventricular systolic function, oral anticoagulant reduces the risk of ischemic stroke by 68% and lowers mortality by 33%.⁵² However, one of the major drawbacks of warfarin is the potential of increasing risk of hemorrhagic events. Therefore, the risks and benefits of warfarin therapy must be assessed for every individual patient. Compared with warfarin, aspirin is less effective in preventing stroke (22% risk reduction).⁵² In hypertensive patients, aspirin can only be recommended for patients who refuse or cannot safely take warfarin.

In patients who need ventricular rate control, either β -blocker and/or rate-limiting calcium channel blockers (diltiazem or verapamil) are suitable initial choices of therapy in patients with hypertension (Table 62–2). In

patients with impaired left ventricular or LVH, the use of class I and III antiarrhythmic agents is associated with an increase risk of proarrhythmia. In the latest American College of Cardiology (ACC)/American Heart Association (AHA)/European Society of Cardiology (ESC) guidelines for the management of atrial fibrillation, only amiodarone is recommended for rhythm control in patients with hypertension and LVH.⁵²

The effect of specific classes of antihypertensive agents on the prevention of atrial fibrillation remains unclear. Recent studies suggest that blockade of the renin-angiotensin-aldosterone system with ACE inhibitors or ARBs may reduce the recurrence of atrial fibrillation, independent of blood pressure-lowering effect.^{53,54} However, a meta-analysis failed to show a significant reduction in atrial fibrillations with ACE inhibitors or ARBs.⁵⁵ The impact of ACE inhibitors or ARB in patients with atrial fibrillation is currently a focus of several major clinical trials, including the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE) and Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial/Telmisartan Randomized Assessment in ACE Intolerant Subjects with Cardiovascular Disease (ONTARGET/TRANSCEND).

Coronary heart disease

In patients with symptomatic coronary heart disease, the aims of treatment should include control of blood pressure, antiplatelet therapy with aspirin and/or clopidogrel, as well as reduction or cessation of other coronary artery risk factors, such as smoking, obesity, control of diabetes, and hyperlipidemia, relieving symptoms of angina, and preventing myocardial infarction. β -blockers, which reduce blood pressure, angina symptoms, and risk of myocardial infarction, should be considered as the first drug of choice

Table 62–2. Compelling Indications of Various Antihypertensive Drugs from Three Guidelines for Concomitant Cardiac Diseases

in hypertensive patients with symptomatic coronary heart disease (Table 62–2). Furthermore, in patients with coexisting heart failure due to myocardial infarction and/or hypertension, β -blockers (especially carvedilol or metoprolol) may be also used as part of heart failure therapy. In patients with adverse effects or contraindication to β -blockers, persistent angina symptoms or uncontrolled blood pressure, nondihydropyridine calcium channel blockers (diltiazem or verapamil) or long-acting dihydropyridine calcium channel blockers are appropriate alternative or add-on therapy for angina and hypertension. The use of short-acting dihydropyridine calcium channel blockers may increase the risk of adverse cardiac events and should be avoided. Furthermore, in hypertensive patients, aggressive lipid-lowering therapy with statins is effective for primary and secondary prevention of cardiovascular events.^{55,56}

PROGNOSIS

Limited current systematic data are available on the long-term prognosis of hypertensive patients with each of these concomitant cardiac diseases. As discussed above, effective treatment of blood pressure can reduce the risk of heart failure and coronary heart disease, and probably also atrial fibrillation. In hypertensive patients who develop these concomitant cardiac diseases, the long-term risk of cardiovascular morbidity and mortality remains higher.

In patients who develop complications related to hypertension or poorly controlled blood pressure despite treatment, the potential of nonadherence to medications should be considered. Although uncontrolled blood pressure worsens the outcome in those patients, whether aggressive antihypertensive therapy below the current recommended guideline can improve their prognosis merits further investigation.

SUMMARY

With a growing aging population and advances in medical treatments, the number of hypertensive patients with concomitant cardiac diseases will be greatly increased. Despite all the major efforts and guidelines on the treatment of hypertension, a significant proportion of hypertensive patients are either not treated or have suboptimal blood pressure. The treatment of hypertension in patients with concomitant cardiac diseases often will require multiple pharmacologic agents for compelling indications as well as to achieve acceptable blood pressure control. Although different antihypertensive agents may have different advantages in different cardiac diseases, adequate blood pressure control continues to be primary goal of therapy. Future studies are needed to address the optimal blood pressure target and drug treatment regimen in different patient populations with concomitant cardiac diseases.
